mon infections, which other, healthier bodies might be able to handle. Immune-suppressing diseases such as HIV, or autoimmune diseases such as lupus, which attack their own host's cells, make individuals susceptible to diseases that can eventually kill them. No one, in fact, dies from HIV disease (often called AIDS); they die from tuberculosis or malaria or even a common cold because their immune system is unable to produce antibodies to fight off the infection.

Despite the optimism that biomedical advances would be able to rid the world of most diseases, doctors are seeing a resurgence of older diseases and the emergence of new diseases. In this context, protecting biodiversity becomes even more important as people struggle to find ways to cope with both chronic and acute illnesses. In places where biomedical treatments are rarely available, common property resources form essential places for the development of nonbiomedical treatments and medications to minimize the severe symptoms associated with many diseases. The intricate link between disease, health, society, and environment is thus more complex when the invaluable significance of biodiverse ecoregions and their potential to provide short- and long-term mitigations against current and future diseases is considered. This includes biomedical interventions, which continue to also rely on both naturally and synthetically based medications that may help people cope with the day-to-day realities of trying to live healthy lives.

Disequilibrium

DISEQUILIBRIUM, AS USED in ecology, is a term used to describe systems that do not tend toward a stable, homeostatic balance. Whereas an ecological system in equilibrium tends toward stability both in terms of species composition and cycling of abiotic nutrients and energy, a system in disequilibrium exhibits no stable end point, has species composition in flux, and exchanges nutrients, energy, and organisms with surrounding systems.

Disequilibrium systems can be either dynamic or static. With dynamic disequilibrium, disturbances to environments occur too frequently for a stable equilibrium to be reached, and species turnover, the rate at which become locally extinct from a given location and are replaced by new species, is driven by the interaction between frequency of disturbances relative to the mortality and reproductive rates of constituent species. Disequilibrium in ecology thus relies on autecological explanations by examining the response of individual species to various environmental stimuli. In contrast, equilibrium approaches focus on the formation of stable assemblages, and tends to be concerned about the responses of entire communities to environmental stimuli (*synecology*).

Static disequilibrium occurs when species composition in a given area remains stable over short to medium time-scales (hence it is static), but changes when viewed over long time-scales. Disturbance is more prominently featured within disequilibrium ecologies as well. Within equilibrium ecology, disturbance is a viewed as an aberration that interrupts the natural development of stable ecosystems. Disequilibrium ecology views disturbance as a vital and natural component of proper ecosystem functioning, depending on the frequency and spatial scale of disturbances.

DISEQUILIBRIUM APPROACH

The intermediate disturbance hypothesis is an example of a disequilibrium approach to ecology. Following disturbance, rapidly reproducing and dispersing pioneer species (r-species) with short life spans tend to dominate the area of disturbance, and then gradually give way to slower growing, long-lived species characteristic of later successional stages (k-species). The intermediate disturbance hypothesis states that where disturbance is too frequent, species composition becomes skewed toward the pioneer species; whereas if disturbance becomes too infrequent, species composition becomes skewed toward late-successional species. This hypothesis states that the greatest biodiversity occurs with intermediate rates of disturbance, such that viable populations of both r-species and k-species will be maintained. This contrasts with equilibrium approaches, which assert that greatest biodiversity occurs strictly within the stable assemblage of species that develop when disturbance is minimized.

The subject of disequilibrium, especially in contrast to equilibrium, is critical to the philosophy and practice of conservation. Equilibrium approaches to ecology have played a crucial role in the establishment of nature reserves, with a generalized strategy of setting aside large portions of habitat and minimizing disturbance and human involvement. Disequilibrium approaches have been regarded with some suspicion by some conservationists, out of concern that an allowance for disturbance within nature would be used to justify extractive activities and further loss of habitat, despite growing acceptance of disequilibrium ecology's explanatory power. Other ecologists point out that equilibrium approaches can be detrimental to conservation, in that the Balance of Nature ontology suggests that nature will maintain itself, and obscures the necessary role that people must play in actively maintaining biodiversity, especially in the context of global climate change.

Disequilibrium ecology intersects concerns over environmental conservation and social justice as well. Conservation areas designed under equilibrium perspectives emphasize the importance of increased area to promote higher biodiversity, and tend to grow in size as buffers and connective corridors are acquired. With this expansion, land use conflicts often arise. Additionally, the establishment and maintenance of parks in the developing countries often conflicted with the presence of human populations, often indigenous groups or migrants.

MINIMIZING DISTURBANCE

Equilibrium design advocates minimization of disturbance and the exclusion of people from conservation areas, and have resulted in local groups being removed from the landscape. Disequilibrium approaches accept some level of disturbance as being necessary and natural to the maintenance of biodiversity and proper functioning of ecosystems. Some level of human use of landscapes can therefore be tolerated by environments, such as fuel gathering or the collection of nontimber forest products. Some reserves in the developing world have been designed to include people living within the its boundaries. The term *conservation with development* is applied to this application of disequilibrium ecology, allowing a balance of human use with biodiversity conservation.

Disturbances

A DISTURBANCE EVENT perturbs ecosystems, driving ecological patterns and processes outside their normal range of variability. Disturbances may alter species richness, population structure, net primary production, and nutrient flows. These changes may be temporary or long term, depending on both disturbance type and ecosystem characteristics. Determining whether ecological changes fall within normal ecosystem variability requires a judgment call. When is drought severe enough to be a disturbance? When does insect herbivory grade into insect outbreak?

Anthropogenic disturbances are caused by people, and include fire, oil spills, livestock grazing, pollution, logging, and fishing. Natural disturbances are caused by climatic, geologic or biological change. Examples of climatic disturbances are drought, hurricanes, and windstorms. Geologic events include earthquakes, volcanic eruptions, and landslides. Pest or pathogen outbreaks, mass marine mortality, and algal blooms are all biological disturbances. Disturbance impacts also interrelate. A forest suffering from drought is more susceptible to insect outbreak. Oysters in Chesapeake Bay declined due to a combination of storms, overharvest, pollution, and disease. Determining whether a disturbance is anthropogenic or natural is complicated. Evidence that humans have for millennia influenced ecosystems from African savannahs to Amazonian rainforests draws into question any strict divide between human and "natural" drivers of disturbance. The potential for anthropogenic climate change gives disturbances such as glacial movement and hurricanes ambiguous origins.

Ecologists further differentiate endogenous from exogenous disturbances. Endogenous disturbances are caused by internal ecological changes, such as treefalls that open up gaps and alter light, temperature, and moisture regimes. Treefalls immediately impact understory growth, litter decomposition, and ecosystem productivity. They have long-term impacts on microtopography, soil organic matter, and forest structure. Exogenous disturbances are those events that originate outside an ecosystem.

Disturbances are characterized by their intensity, severity, frequency, timing, and geography. Intensity is the energy a disturbance releases per unit time and area. Hurricanes are more intense than mild breezes. Disturbance intensity depends on ecosystem conditions and external forces. For example, fire intensity depends on fuel mass as well as wind speed. Severity is the magnitude of ecological change a disturbance causes. A flood that forever alters a river channel is a severe disturbance.

Frequency is how often a disturbance reoccurs, and is often inversely proportional to intensity. Low-intensity boreal forest fires occur frequently, whereas high-intensity tropical forest fires occur infrequently. Disturbance timing is important. A severe frost during plant budbreak or wildlife birth season will have a greater impact on survival than at other times. Disturbance geography includes its size, shape, and adjacent ecosystems. Whereas a single treefall may impact less than 2.5 acres (about one hectare) of forest, the hurricane of 1938 flattened forests throughout southern New England. The shape of an area impacted depends on site elevation, aspect, and species composition. Proximity and connectivity to an undisturbed area affect species repopulation.

ASSUMPTIONS AND REALITY

Historically, ecologists believed that ecosystems possessed a natural equilibrium, and that variations from this equilibrium reflect an imbalance of nature. This perspective originated with Frederick Clements's theory of ecological succession, which posits that vegetation composition changes through time until reaching a climax community. Ecologists predicted that stable, unchanging conditions were necessary to develop biodiverse ecosystems such as Amazonian rain forests. Disturbances were thought to throw ecosystems off their trajectory toward climax equilibrium and reduce biodiversity potential. Natural resource management incorporated this assumption. U.S. national parks had policies to suppress both natural and anthropogenic fire, which backfired. Fire suppression contributed to fuel buildup and conflagrations such as that in Yellowstone National Park in 1988.

In recent decades, ecologists recognize that disturbances are integral to a healthy ecosystem. Disturbances alter ecosystem structure and rearrange nutrients and energy sources and sinks. Joseph Connell's intermediate disturbance hypothesis proposes that a medium level of disturbances actually increases biodiversity. Coral reefs were once thought to be uniform ecosystems that required a steady environmental state to develop their diversity. Instead, coral reefs are a mosaic of patches that reflect different disturbance events and recovery stages across the landscape.

Analyzing how disturbances impact ecosystem health involves measuring not variations from an equilibrium, but rather ecosystem resistance and resilience. Resistance refers to the relative capacity of a system to return quickly to previous or original conditions after a disturbance. The thick bark of Douglas fir increases its resistance to fire. Debris dams increases a stream's resistance to floods. Resilience is the ability to quickly return to normal conditions after a disturbance. Mountain ash resprouts quickly after fires. The rapid life cycles of stream invertebrates promote population resilience. Postdisturbance recovery may be along a different successional pathway, yet still within normal ecosystem parameters.

Disturbances can push an ecosystem past a threshold to a new state from which it is difficult to return. Once shifts in temperature, nutrients, and consumer species allow algae to dominate coral reefs, corals have a hard time regaining a foothold. Cheatgrass (*Bromus tectorum*) is an exotic that now holds a near monoculture in western U.S. ecosystems because it has outcompeted native vegetation for moisture and altered fire frequency. Native plants are not likely to grow back without significant human intervention.

Ecosystems have disturbance regimes, namely the spatial and temporal scales of disturbance and recovery. Species adapt to disturbance regimes over evolutionary time. Some species even depend on disturbances. Many pines require fire to open up cones and release seeds. Today, resource managers try to manage within disturbance regimes, rather than fighting them. Techniques such as controlled burns mimic natural fire regimes. This approach is part of ecosystem management, which manages for ecosystem health rather than an idealized balance of nature.

Dodo Bird

IN LOUIS CARROLL'S *Alice in Wonderland*, a fictional Dodo bird leads a "caucus race" in which everybody wins a prize. The real Dodo, first discovered on the then-uninhabited island of Mauritius in the 1500s by Dutch and Portuguese sailors, was a loser in the race of survival. Flightless, large, and never exposed to human hunters, the Dodo bird would often haplessly approach European hunters. Because the meat of the Dodo was allegedly distasteful, the Dutch called the bird *Walgvogel,* meaning "bad tasting bird," and the birds were quickly hunted to extinction. The last reliable sighting of the bird was in 1663. A stuffed Dodo bird was sent to Oxford University's Ashmolean museum, but was partially destroyed by a fire in 1755. A discovery in 2005 of Dodo bird bones has added new information about the shape and DNA of the bird.

The Dodo is a symbol of extinction and the uneasy interaction between humanity and the environment. The fact that Mauritius was pristine wilderness, untouched by any human contact, made the animals of Mauritius particularly susceptible to human hunting, and to the nonnative animals that were inevitably introduced by human visitors. The volcanic island of Mauritius is located far off the eastern shore of Madagascar, far from most shipping lanes and—before the 16th century—hundreds of kilometers away from human habitation. There is some evidence that Arab traders could have known about the island, but it was in every sense a separate natural world. This small island, a beautiful emerald in the clear waters of the Indian Ocean, has recently become a tourist paradise and is now home to some two million diverse human inhabitants. Although the Dodo is gone, rare and fragile populations of island birds like the famous pink pigeon maintain a precarious hold in cramped aviaries and on the remotest mountaintops of Mauritius. Although Dodo in Portuguese means "dumb," perhaps the label is best reserved for those who fail to appreciate the lesson of its extinction.

Dogs

DOGS HAVE BEEN human companions at least since the Mesolithic era, some 20,000 years ago. Oddly, whenever they are successfully trained by humans to comply with their specific duties, dogs are rewarded and considered as "intelligent" or "smart" by their masters. Therefore, the term *socialization* used in the case of dogs implicitly refers to the relationships between dogs and humans, and not among dogs.

Nowadays, no one would be too much alarmed to see an adult person having a discussion with a dog, even though we are aware that the animal can not really "understand" the nuance of words. Incidentally, a Canadian professor of psychology, Stanley Coren, has conducted years of research and has published six books about the possible ways of communicating with dogs and understanding the "dog language."

Among their many social uses, dogs can help hunters and shepherds; serve as house guardians; assist the blind; or be used by the police to search for suspects, rescue lost persons, or for security purposes in airports. In Italy and France, the "truffle dogs" are trained in digging up high-value truffles in forests. In the Arctic, Huskies are not only a vital element for transportation, even in 21st century, but are also a true tradition going back thousands of years. Many charity organizations related to dogs have been created. In Canada, the "Fondation MIRA" (and founder Éric St-Pierre) have given a guide dog for free to the blind teenagers in Québec since 1990.

Dogs have contributed to social life in many countries, for instance with dog exhibitions and clubs, one of the first being the Birmingham Dog Show Society founded in 1859. Cities have created bylaws and regulations specially made for dogs. In several parks in New York City, there are special sections for pets, and sometimes separate sections for "big dogs" and "small dogs," to avoid conflicts between animals and owners. On the sidewalks of Paris, dog owners must clean up after their pets; otherwise, a severe regulation imposes a penalty of more than $200.

Dogs are often seen as "man's best friend," but their relationships with people can sometimes be hazardous. In her book titled *Fatal Dog Attacks: The Stories Behind the Statistics* (2002), veterinarian Karen Delise from the National Canine Research Council states that there were "over 540 fatal dog attacks in the United States" from 1965 to 2002. According to the U.S. Department of Health and Human Services, only for 1994, "an estimated 4.7 million dog bites occurred in the United States, and approximately 799,700 persons required medical care."

A DOG IN THE KITCHEN

Dogs are a part of many cultures, but their relationship with humans are set in many different ways and traditions. For instance, in many of France's restaurants, dogs are allowed in kitchens; but in Canada, a restaurant could be closed if an inspector found a pet anywhere in a restaurant. Oddly, one of the world's finest restaurants, founded in 1740 in Paris, is called *Au Chien Qui Fume* ("The smoking dog").

There seem to exist an almost universal taboo against eating dog meat in most cultures, with the exception of China, Mexico, and a few societies in the Pacific Islands. This aversion for the idea of eating dog meat is cultural and probably comes from

Dogs are a part of many cultures, but their relationship with humans are set in many different traditions.

the fact that dogs are seen as puppies, as "a part of the family." In Western countries, most people would accept to eat a common hot dog because they know sausages are in fact made with pork or beef. However, according to Kathleen E. McLaughlin, a correspondent with *The Christian Science Monitor*, the Animals Asia Foundation (AAF), an animal-welfare charity based in Hong Kong, "estimates that up to 8 million dogs are eaten every year in China. Most large restaurants offer a dog dish or two, and nationwide, dog meat is as easy to find in any big restaurant as a hamburger is in the United States."

DOGS IN POPULAR CULTURE

Dogs are present in art and popular culture. Countless popular songs refer to dogs. In 1948, bluesman Lightnin' Hopkins sang "Let Me Play With Your Poodle." Blues singer Big Mama Thornton recorded "Hound Dog" in 1953, which was later sung by Elvis Presley in 1955. Paul McCartney referred to his dog in his song "Martha My Dear" (1968), and included "Three Legs" on his *Ram* album (1971). David Bowie composed a song titled *Diamond Dogs* (1974), looking like a dog on the album's cover. The group Pink Floyd also created a piece titled "Dogs" on the album *Animals* (1977). However, singer Iggy Pop was the canine champion with two provocative songs he wrote: "I Wanna Be Your Dog" (1969) and "Dog Food" (1980).

Director Jacques Godbout made a documentary film about the love for dogs in North America and France, titled *Aimez-vous Les Chiens?* (1975), that linked "De Luxe" dogs with our excessive, consumer's society. The director argues that we treat dogs as we do for ourselves. The film explores hairdressers and restaurants for dogs. But before that odd film essay, dogs became heroes in many Hollywood movies and TV series: the first Rin-Tin-Tin (1916–32) appeared during the silent era, in *The Man From Hell's River* (directed by Irving Cummings, in 1922). From 1943, the MGM also had its own dog star, Lassie. The first of a series of melodramas shot in color, Fred Wilcox's *Lassie Come Home* (1943) told the story of a poor child who tried to find his beloved dog, sold by his parents to an aristocrat. Walt Disney and Ken Petterson issued many versions of *One Hundred and One Dalmatians* (1961).

In cases of anthropomorphism, many dog stars created for younger audiences often have human qualities. As Charles Schultz created Snoopy in his comics strips *Peanuts*, dogs were also very popular in French comic books: in Belgium, Tintin has his dog companion named Milou; in France, Astérix and Obélix have Idéfix, the little white dog. Apart from achieving many exploits, all these imagery dogs heroes could easily talk with their masters.

In ancient Egypt and Greece, artists used to make sculptures of dogs. In their book about the representation of dogs in Western art, Peter Peters Bowron, Robert Rosenblum, William Secord, and Carolyn Rose Rebbert acknowledge that the most important painters have included dogs in some of their works, from Gustave Courbet to Edouard Manet and Salvador Dalí.

An old Arab proverb says "The Dogs Bark But the Caravan Moves On," which can take many different meanings: "No matter what people say, I carry on," or "Those who are against us are worthless," or "The dogs give us the signal so we can go on safely."

Dolphins

DOLPHINS HAVE FIGURED prominently in society for ages. To the Minoans, as far back as 2000 B.C.E., dolphins were symbols of joy and music. Centuries later, the ancient Greeks and Romans featured dolphins in their mythology, art, and literature. The four extreme points of the Australian continent continue as sacred "dolphin dreaming" sites for aboriginal tribes. In fact, all over the world—Australia, Oceania, China, India, Egypt, and Africa—dolphins often appear in stories of human creation and civilization. In contemporary society, dolphins are likewise ubiquitous in popular media and culture. However, the quantity and quality of society's encounters with dolphins today are very different from those of the past. Unfortunately, as greater numbers of people inhabit the world's coastal areas and society intensifies its use of coastal and ocean spaces, dolphins and their habitats are threatened like no time before in history.

Dolphins are aquatic mammals, belonging to the order Cetacea, which is made up of whales, dolphins, and porpoises. Many people are familiar with bottlenose dolphins *(Tursiops truncatus)*, those most often on display at marine parks and aquariums, and the species of dolphin that starred in the *Flipper* television shows and movies. Actually, there are more than 30 different species of dolphins worldwide. Like humans, all dolphins are highly social and most live in groups, sometimes called "fission/fusion" societies, which range from a few members to thousands. With large brains and a substantial cerebral cortex, it is widely accepted in the scientific community that dolphins have considerable cognitive abilities. They communicate with one another using a complex system of whistles, body language, and touching. Dolphin researchers also agree that dolphins have a rich emotional life, including a sense of humor and distinct personalities, as well as a keen sense of self-awareness.

Thus, dolphins apparently share a suite of attributes with people (many of which were once believed unique to humans), such as intelligence, emotions, and self-awareness. However, dolphins also have inner and outer worlds that are completely foreign to humans. Along with physical attributes that make dolphins marvelously suited for their watery environment, dolphins navigate their world primarily through the use of a sophisticated system of echolocation—a system by which dolphins project sonic "clicks" that return echoes to portray a three-dimensional image of the world around them. As sound passes through living tissues, dolphins routinely "see through" each other and every other living organism. It is perhaps a combination of their familiarity and their exotic other-worldliness that has attracted humans and dolphins to one another throughout the ages.

Most people encounter dolphins today by visiting a zoo or aquarium. In the United States, more than 50 million people are estimated to have visited captive dolphin facilities in 2003, where they spent more than $1 billion. Still, the maintenance of dolphins for public display is among the most controversial of issues relating to dolphins in society today. Depending upon the views and values that people attach to aquariums and the dolphins they hold, people might think of aquariums as amusement parks, public education centers, scientific research sites, conservation centers, or simply as prisons. Essentially, these various ways of thinking about dolphins in society fuel the different arguments that either justify or condemn the practice of keeping dolphins in human care.

Such arguments extend also to various interaction opportunities offered at aquariums today (allowing customers to feed or touch dolphins, for example) as well as swim-with-the-dolphins programs, which began in the late 1980s. Commercial swim-with-the-dolphins programs and related activities also take place with free-ranging dolphins in open waters. While many believe that such activities can be beneficial to both humans and dolphins, others strongly oppose any interaction with wild, free-ranging dolphins and suggest that dolphin viewing from a safe distance is the only appropriate form of dolphin interaction in the wild. Other controversial dolphin-society issues include scientific research involving dolphins, the military's use of dolphins, dolphin-assisted therapy, rescue and rehabilitation efforts for stranded dolphins, and human interactions with lone sociable dolphins.

Despite the controversy surrounding many human–dolphin interaction issues, society's affection for dolphins certaintly added steam to the burgeoning environmental protection movement of the 1970s, especially as relates to the plight of whales around the world and the public outcry related to dying dolphins in the eastern tropical Pacific Ocean purse-seine fisheries. Indeed, the Marine Mammal Protection Act of 1972—the primary legal vehicle for regulating dolphins and their habitats in the United States—was enacted largely in response to the urgent call by environmental organizations, humane groups, independent scientists, and others to protect whales and dolphins.

Domestication

DOMESTICATION IS THE taming of animals and the cultivation of plants for human use. Some plants and animals have been domesticated for food; others for their utility as work animals or products such as sources of leather, and others for their aesthetic or entertainment value. The process of domestication began with Paleolithic humans, who domesticated the dog for guarding, hunting, working, and for food. Other animals domesticated early on were pigs, sheep, goats, and cattle. Archeological evidence from grave goods, paleoglyphs, or other evidence shows that even beekeeping had been domesticated before the Bronze Age.

By 2,000 years ago, wild horses, donkeys, cattle, oxen, and camels had been tamed and were being used for human needs. Domestication included not only the taming of wild animals, but development of animal husbandry. The breeding of small wild horses eventually led to the selective breeding of larger horses that could be used to pull chariots, and further advances produced horses large enough to be ridden by heavily armored and armed men.

Animal husbandry meant that animals were selectively bred for even more specialized human uses. Horses were bred as warhorses, as farm draft horses, and as wagon horses. The invention of the horse collar enabled greater "horse power." The breeding of horses or other livestock added immensely to the wealth of nomads, noblemen, and farmers. It also increased the range of foods available for human and animal consumption immensely over what could be gained in hunting and gathering cultures. Christopher Columbus's discovery of the New World opened the way for many new species of plants and animals to be spread around the world, and for many species to be introduced into the Americas. These exchanges were not always wholesome. The introduction of rabbits and the prickly pear cactus to Australia was disastrous. Scholars have debated fiercely about the process of domestication. Some claim that domestication was due to fortuitous mutations in species that made them useful to humans. Others argue that selective breeding is the source of the enormous "favoritism of the species" that human domestication has achieved.

For example, corn (maize) in the New World and wheat in the Old World are two immensely important food stocks for humans. They both came from wild grasses, but were cultivated and dispersed globally in different ways. Wild wheat seeds fall off when the wheat is ripe; however, domesticated wheat heads remain on the wheat stem, allowing them to be harvested more efficiently. The question is whether or not the wheat's current genetic characteristic that causes it to retain the wheat on the wheat stalk is a mutation, or a characteristic what was selectively bred into wheat over the centuries. Some scholars believe that it is both.

Some animals and plants have resisted domestication. For an animal to become domesticated for use by humans, it needs to have a temperament that can be settled and not prone to panic or fear.

Some have argued that in the domestication of dogs, the most ferocious dogs often ended up in the stew pot because they were too dangerous. Those that were friendly got some of the stew. Dogs have been used for work such as herding sheep, pulling traverses and sleds, for war, fighting in sporting matches, and for hunting. The characteristics desired have been selectively bred to produce breeds that are famous for certain skills. The Saint Bernard was bred for rescue in deep mountain snows. Another characteristic needed for domestication is a diet that can be easily met. General diets are more easily provided than are specialized diets. The koala bear and the panda bear have very specialized diets that would, along with other factors, make them difficult to domesticate. Camels can feed on very poor grasses or shrubs, and are to go without water for long periods, making them desirable for transportation in the desert. There is also the question of growth rate and of the ability to breed in captivity. Research is constantly conducted so that humans can better care for domestic and wild animals. A final characteristic of animals is how social they are. If a species of animal such as cattle have a natural herd, pack, or leader established by dominance; it is possible for a human to become the "alpha male" of the group.

By 2,000 years ago, wild horses, donkeys, cattle, oxen, and camels had been tamed for human needs.

The domestication of plants made agriculture possible. Without it, very few humans would survive.

Farming began in the Fertile Crescent about 12,000 years ago, probably with wheat production in ancient Iraq. The dry summers of Mesopotamia and Egypt allowed for the production of cereal grains, vegetables, and fruits. In the Americas, especially Meso-America, the domestication of beans, squash, and maize were revolutionary, and made large civilizations possible. In the Orient, the cultivation of rice was central to the development of civilization. The development of agriculture reduced the areas of the world that were open to hunting and gathering, while the search for plants and animals to domesticate continues. Every species that is tame becomes a plant or animal that is serviceable to humans, but also increases human knowledge and appreciation of nature. For example, the development of aquariums has led to whole industries focused on the entertainment and knowledge of keeping fish. Scholars have sought to understand the domestication process since the beginning of human history with numerous plant and animals, including sea mammals.

Domination of Nature

THE CONCEPT OF the domination of nature can be traced to the 17th-century Scientific Revolution and the subsequent period of the Enlightenment, which was the 18th-century philosophical and social movement that transformed visions of society, science, and nature. Previously, nature and the material world were commonly believed to be a living organism comprised of earth, air, fire, water, and "ether" that formed the stars and planets. Spiritual and religious frameworks that regarded nature as a living being independent of human will provided cultural and moral constraints to the overexploitation of nature.

Seventeenth-century thinkers developed a philosophical commitment to rational science, logical thinking, and mathematical reasoning that allowed nature to be known, managed, mastered, and dominated. According to Francis Bacon (1571–1626), the key conceptual author of the mastery of nature thesis, "nature must be 'bound into service' and made a 'slave', put 'in constraint' and 'molded' by the mechanical arts." Bacon rationalized this mastery using a religious frame of reference, arguing "only let the human race recover that right over nature which belongs to it by divine bequest, and let power be given it; the exercise thereof will be governed by sound reason and true religion." Enlightenment thinkers subsequently developed a mechanical view of nature, viewing reality as a machine comprised of discreet and individual parts whose actions could be known, possessed, and mastered for the benefit of humans. No longer part of nature, humans came to depend on the continued development of science and technology to meet human needs and advance social progress.

The domination of nature thesis has been taken up by various social theorists since the period of the Enlightenment. Max Horkheimer and Theodor Adorno, German philosophers and founding members of the Frankfurt School of Critical Theory, critiqued the real results of the Enlightenment as leading to the disenchantment and alienation of humans from nature, arguing, "on the road to modern science, men renounce any claim to meaning." This alienation is extended to the relationships between humans and even to the self, leading to the objectification and destruction of all human–human and human–nature relationships.

In 1972, philosopher, political scientist, and sociologist William Leiss published the influential work *The Domination of Nature*. His ideas caught the public interest at a time of increased awareness of environmental degradation. In addition, the effects of environmental pollution on human health—during an era of rapid technological changes—began a response to environmental problems. Leiss suggested that theoretical treatments of the domination or mastery of nature can be divided into two categories: those concerning how the "attitude or concept of mastery over nature arose and developed, and those that deal with the practical outcomes of this 'attitude' (what damage has been done in its name, and what we must do to repair it)."

HUMAN ENTITLEMENT

Through the development of an exegesis of the Baconian idea of the domination or mastery of nature, Leiss demonstrates "humanity's entitlement to mastery over nature is a subterranean theme that runs throughout the collective consciousness of the modern era … framed above all by a thoroughly secular natural science." Leiss underscored two important points in his exegesis. First, he argued that any attempt to separate humans from nature as analytical categories is misleading. Second, he explored the process by which the domination of nature came to be identified with scientific and technological progress as a broad social task that developed in response to the formation of human needs. He argued that the human urge for self-preservation spurs ongoing efforts to intensively exploit the earth's resources. But the ongoing creation of new societal wants and needs and the existence of social conflict stimulate the "seemingly endless productive applications of technological innovations" and preclude the setting of limits.

Technology, for Leiss, is the link between the mastery of nature through knowledge and the use of that knowledge to acquire and use more of physical nature in daily life. Leiss demonstrates the contradiction, however, in the growing ability of humanity to produce technological progress and innovation (what he deems *operational powers*), while failing to control the detrimental effects of this technology for both humans and nature. Leiss then proposes a socialist "counter-ideology" of the liberation of nature through the rational use of technology to eliminate wasteful production and environmental destruction. He draws parallels with other historical propositions for social change that involve both living in harmony with nature and using technology to advance the human condition. He also admonishes against using the notion of the liberation of nature as a mere slogan against the continued advances of modern technology. Instead, he argues that "the idea of the mastery of nature must be reinterpreted in such a way that its principal focus is *ethical or moral development* rather than scientific or technological innovation…a task that primarily involves the reconstruction of social institutions."

In 1980, environmental historian and ecofeminist Carolyn Merchant published another important work addressing the historical implications of the Enlightenment's transition toward a science-based view of nature. In *The Death of Nature: Women, Ecology, and the Scientific Revolution,* Merchant argues that when pre-Enlightenment visions of nature as feminine were replaced by a mechanistic worldview as part of the scientific revolution of the 16th and 17th centuries, a hierarchical and patriarchal social order emerged that linked the domination of nature to the domination of women.

Merchant demonstrates the way in which notions of ecology, science, and gender were socially and historically constructed to provide the foundations for the social and economic transition to capitalism, and connects the feminization of nature to the capitalist justification of overexploitation of nature's resources. As a foundational text within eco-feminist thinking, *The Death of Nature* argues for the re-integration of an organic and feminine worldview into modern scientific and technological treatments of nature and society.

The domination of nature thesis underlies many other discussions of the relationship between society and nature in various disciplines, including critical theory, environmental sociology, ecological philosophy, environmental ethics, ecofeminism, social ecology, and ecological Marxism. Most of these fields seek critical ways of understanding how to overturn the domination of nature within contemporary society. They do this by examining the transformation of individual and collective interpretations and implications of this domination and the potential for alternatives. Murray Bookchin, in *The Philosophy of Social Ecology* for example, proposes a theory of social ecology that links the domination of nature to class domination and social hierarchy. But he also argues "at no time can we surrender to the 'inevitability' of domination in certainty that latent liberatory possibilities do not exist." More recently, sociologist Damian Finbar White, in his article, "Hierarchy, Domination, Nature," has followed geographer Henri Lefebvre's distinction between the domination and appropriation of nature and space. He argues "all human societies have been involved in the dynamic appropriation of their natures (that is, in bringing their relations with nature into conscious rational control to survive)," rather than being destined to dominate nature. These notions of the possibility of exiting the domination-of-nature paradigm provide a foundation for contemporary theories of sustainable development, ecofeminism, and bioregionalism, all of which advocate the development of creative ways of sustainable appropriation of nature that allow the survival of all species and the domination of none.

Dominican Republic

THE DOMINICAN REPUBLIC (DR) and Haiti share the island of Hispaniola (also called Quisqueya) in the Caribbean. The island was partitioned formally in 1777 by the Aranjuez Treaty signed between the Spanish and the French colonial powers. The DR is located on the eastern two-thirds of the island and has just over nine million inhabitants, as well as a large undocumented Haitian- and Dominican-born Haitian population (between 300,000 to 1,000,000). Contrary to the experience of many other nations in the Caribbean, and especially neighboring Haiti, the DR was primarily a subsistence agriculture and ranching economy in the late colonial period with some tobacco and cocoa production. Due to the general abandonment of the colony by the Spanish, few settlers could afford to buy or maintain slaves. Relations of production were characterized by generalized impoverishment, low-intensity land use and a relatively small, largely mixed race population. The difference in colonial production with respect to the plantation society across the border has been defining in constructions of race and class on the island. A doctrine of anti-Haitianism was promoted throughout the 20th century and most intensely expressed in the state-supported massacre of 30,000 Haitians in the DR in 1937.

The proliferation of large-scale sugar plantations beginning in the 1870s, the construction of railways, and rising timber exports led to accelerated deforestation by the turn of the century. By 1980, 25 percent of cultivated land was planted with sugar. Most of the hardwood forests—including mahogany—were clear-cut or selectively cleared between 1880 and 1930. The first municipal regulation against logging and river contamination was passed in 1901, but early legislation was not enforced. The first natural reserve was established in 1927 to protect the watershed of the country's second largest river, the Yaque. Following U.S. occupation (1916–24), Rafael Trujillo took over the country for 31 years (1930–61). Trujillo directly appropriated forest and farmland for his or his cronies' private commercial use, while establishing some national parks to protect watersheds. Forest cover in agrarian landscapes was at times considered not under "productive use" and expropriated by the government or local elites.

Almost a decade of political instability followed the assassination of Trujillo, fueling resource extraction by powerful elites and efforts by farmers to resettle areas captured by Trujillo. Joaquin Balaguer, who had served under Trujillo, was elected in 1966 and dominated Dominican politics and environmental policy for the next 30 years. In 1967, in line with Cold War policies throughout the region designed to extend military control to rural areas, the government passed Law 206, placing forests under the protection of the state. Logging was criminalized and the forest service was incorporated into the armed forces. That same year, 12 loggers were killed by the military during a raid on a clandestine logging camp. Militarized campaigns to conserve forests continued, involving forced removals, jail terms, and violence directed toward squatters, subsistence farmers, and charcoal makers. The largest of these evictions took place in 1992, when 70,000 forest farmers were expelled from Los Haitises national park. Following Balaguer's rule, the forest service reverted to civilian administration.

Balaguer's environmental policy yielded a comprehensive natural reserve system reportedly consisting of 74 parks and marine reserves and officially encompassing 32 percent of national territory. Yet, prospects for conservation and effective environmental management of resources are highly uncertain and will depend on trends in foreign investment, the growing tourist industry, export production, and state regulatory effectiveness.

Downing, Andrew Jackson (1815–52)

AN AMERICAN LANDSCAPE designer and author, Andrew Jackson Downing (1815–52) promoted the Gothic Revival style in gardens throughout the United States, writing a number of books and editing *The Horticulturalist*, a magazine published from 1846 until 1852.

Andrew Downing was born on October 30, 1815, at Newburgh, New York. His father was Samuel Downing, a nurseryman. He was named after Andrew Jackson, the American victor at the Battle of New Orleans in January 1815, and later the 7th president of the United States. He left school at the age of 16 and started work in his father's nursery, becoming interested in landscape gardening and architecture. As a result, he started writing about garden landscapes and botany. His first book, *A Treatise on the Theory and Practice of Landscape Gardening, Adapted to North America*, published in Boston, New York, and London in 1841, was widely acclaimed.

This led to work with Alexander Jackson Davis on another book, entitled *Cottage Residences*, which was published in the following year. It included many designs of houses and architectural styles, drawing heavily on an idealistic view of English country housing. In 1845, Downing collaborated with his brother Charles on *Fruits and Fruit Trees of America* (1845), which became recognized as the standard work on the topic. In the following year he started editing and published the journal *The Horticulturalist, and Journal of Rural Art and Rural Taste* which continued until his death. Another book, *The Architecture of Country Houses* (1850), followed, again showing many designs of houses.

Late in 1850, Downing went to Europe, where he saw an exhibition of watercolors by Calvert Vaux, whom he persuaded to move to the United States and work with him as partner in his company. This collaboration on a number of major projects included landscaping some of the gardens of the White House, and also the Smithsonian Institute in Washington, D.C.

Just as business was going well, Andrew Jackson Downing was killed on July 28, 1852, during a fire that followed a boiler exploding on a steamboat. His remains were buried at Cedar Hill Cemetery, in Newburgh. Vaux continued the architectural practice for many years, and in 1858 was one of the men involved in the design of Central park, New York. There is a memorial to him near the Smithsonian.

Drilling (Oil and Gas)

DRILLING IS THE method by which earth is penetrated for the purpose of exploration or production of oil and gas. Exploration wells are intended to gather information about the sedimentary formations that exist beneath the surface, and their structural configuration. Production wells are intended to hit a specific target, or pool, in a place where the production of oil and or gas can be maximized. Drilling is not used exclusively for oil and gas, but is a common method of subsurface exploration and production of groundwater, or even solid mineral resources.

Oil and gas are fluid hydrocarbons that commonly occur in the pore spaces of sedimentary rocks. These hydrocarbons form as the result of organic material, commonly derived from marine plankton, transformed into hydrocarbons. This transformation requires burial, pressure, temperature and time. The pressure and temperature is commonly the result of deep burial beneath successive layers of accumulating sediments. Thicker sediments and deeper burial usually results from longer history of sedimentation and/or higher sedimentation rates in areas that commonly become sedimentary basins. Common sedimentary basins include the Appalachian, Illinois, Michigan, Williston and Gulf Coast basins, to name a few. These basins, and others like them, contain many of the oil and gas fields of the petroleum provinces of the United States.

Once hydrocarbons form, they may migrate from the stratum in which they form (source rock), through or into other strata. The higher the permeability (connected pore space) of a stratum, the more likely hydrocarbons will migrate into or through that stratum. Migration is driven by density. The strata in which hydrocarbons are generated, or through which they migrate, also contain water. Oil and gas are immiscible with water and with each other. Water has a higher density than hydrocarbons, and the hydrocarbons therefore migrate upward relative to water.

An oil or gas pool is formed where the upward-migrating oil and/or gas is trapped by some type of barrier. Barriers are usually impermeable layers that have a geometry that can trap the upward-migrating fluids. There are several possible trap configurations. In an anticline or dome, strata occur in a convex-upward shape, and oil and gas is trapped in a permeable stratum (reservoir rock) that is overlain by an impermeable stratum (cap rock). Oil and gas can be trapped by a fault that superimposes an impermeable stratum against a permeable one. Oil or gas can be trapped by the pinchout or termination of a tilted permeable layer that is underlain and overlain by impermeable strata. Oil or gas can be trapped by the lateral (facies) change within a stratum from permeable to impermeable conditions, and if the stratum is overlain by an impermeable stratum. If a trapping mechanism occurs, and water, oil, and gas are present in a subsurface pool, the gas generally occurs on top (the oil below that) and the water on the bottom. Because the pools have a very specific geometry and location, drill holes must be carefully placed to maximize extraction of the oil and gas.

The environmental effects of drilling can be numerous and varied. Drilling on land requires that an area be cleared of trees and vegetation to allow the transportation and setup of the drill rig. The drilling process itself produces the spillage of drilling mud over the ground surface. Some oil usually leaks out of the hole, but this is usually kept to a minimum. Some of the worst environmental hazards are the result of oil or gas well fires. These are like huge natural torches that are difficult to extinguish. A well fire releases large amounts of carbon dioxide into the atmosphere.

Offshore drilling is usually accomplished from a ship (usually for exploration) or a drilling platform (for production wells). Many consider drilling platforms unsightly. The main environmental concern, however, is seepage or leakage of oil from the drill rig or the producing well.

Despite its adverse effects, drilling is necessary as long as society is dependent on oil and gas as an energy source.

Drinking Water

OF ALL THE uses of water, drinking water is the most fundamental, since the lack of safe and sustained water to drink is life-threatening. Yet, according to the United Nations (UN), as of 2002, nearly 20 percent of the world's population still lacked regular access to clean drinking water. Of these 1.1 billion people, 65 percent were in Asia, 27 percent in Africa, 2 percent in Europe and 6 percent in Latin America and the Caribbean.

In most countries, the state is responsible for the provision of drinking water. Any drinking water supply system consists of three major elements: source (surface water sources such as lakes, rivers, and reservoirs, as well as groundwater sources such as wells), treatment (e.g., adding disinfectants such as chlorine), and distribution to users (including pricing). Drinking water supply systems have had a long history; for instance, the ancient Greeks and Romans were among the first to introduce long-distance water pipelines. However, in recent times, the question of provision of drinking water has become even more critical and complex, particularly with the growth of large cities that are situated at a considerable distance from adequate and reliable sources of water.

How much water people need for drinking varies according to diet, climate and the work they do. The minimum amount of water needed for drinking ranges from about 2 liters in temperate climates to about 5 liters per day for people in hot climates who have to carry out manual work. Pregnant and breastfeeding women need more water. Water for basic needs goes beyond water needed for survival; it includes water for cooking and to maintain a standard of personal and domestic hygiene that is sufficient to maintain health.

Apart from the quantity requirement, drinking water also needs to meet certain minimal quality requirements. Drinking water can be contaminated by a range of chemicals (lead, arsenic, benzene),

For drinking water to be secure and useable, everyone must have safe and easy access to water facilities.

microbes (bacteria, viruses, parasites), and physical hazards (glass chips, metal fragments) that can pose risks to health if present at high levels. Consuming such contaminated water can lead to waterborne diseases like diarrhea, cholera, typhoid and dysentery, and is one of the leading causes of illness and death in the developing world. The World Health Organization has put in place norms on water quality, which form the basis for regulation and standard-setting in many national, regional and local laws. However, standards for drinking water quality continue to be either ill-defined or poorly implemented in many countries.

The question of quality of water is also closely related to the question of sanitation. This is because one of the primary causes of contamination of water is the inadequate or improper disposal of human (and animal) excreta. Meeting adequate levels of sanitation is critical in order to ensure that drinking (and other) water meets certain quality standards.

ACCESS TO WATER

Apart from quantity and quality requirements, in order for drinking water to be secure and useable, everyone must also have safe and easy access to water facilities. For instance, in households using only a remote and unprotected source, health can be jeopardized by water contamination. Further, collecting water from distant sources could also mean that a lot of time is spent on the task, with the result that women and children (who are the ones who bear the burden of collecting water in many cultures) are unable to undertake other productive activities (like going to school).

In addition, there is also the risk of injury while carrying heavy loads. Global coverage figures from 2002 indicate that out of every ten people, roughly five have a connection to a piped water supply at home (in their dwelling, plot, or yard); three make use of some other sort of improved water supply, such as a protected well or public standpipe; and two are unserved, with no choice but to rely on potentially unsafe water from rivers, ponds, unprotected wells, or water vendors.

Drinking water also needs to be affordable. The World Health Organization recommends that no more than 3 to 5 percent of an individual's income should be spent on water. However, the poor often pay far higher amounts for water that is neither safe in terms of quality nor reliable in terms of timing.

FOUR DIMENSIONS OF DRINKING WATER

The four dimensions of drinking water—quantity, quality, accessibility, and affordability—are currently facing high degrees of pressure.

The supply of water in the world has always been finite. Only 3 percent of the world's water is fresh water, most of which is locked in the icecaps of Antarctica and Greenland or in deep underground aquifers, which remain technologically or economically beyond our reach; further, only 0.3 percent of the world's total freshwater reserves is found in the reserves and lakes that constitute the bulk of our usable supply. However, the current shortages in safe and drinking water are also a result of wasteful and unsustainable consumption of water, along with competing (and often more powerful) demands of industry and agriculture. Newer options, such as reusing wastewater, are beginning to be considered.

Similarly, the question of quality has acquired great importance in recent years in the light of growing groundwater pollution as well as contamination of surface water bodies. For instance, in the late 1990s, groundwater in Bangladesh in south Asia was discovered to be contaminated with high levels of arsenic. The deterioration in quality in many places is in large measure due to chemical fertilizers and pesticides used in agriculture as well as dumping of household and industrial waste without treatment. The question of affordability of drinking water has also come to the forefront in recent times (in parts of Africa and Latin America, for instance) due to attempts in many parts of the world to meet costs of public drinking water systems by raising tariffs, and/or privatizing existing water supply systems.

In spite of the high importance of water, it is important to note that a human right to safe and adequate drinking water has still not been fully defined by existing international law or practice, although it is supported by many human rights instruments as well as other international laws, declarations and state practice. To date, the most explicit formulation on the right to water at the international level is the General Comment 15 adopted by the UN Covenant on Economic, Social and Cultural Rights in November 2002. The 145 countries that have ratified the covenant are bound to ensure that everyone has access to safe and secure drinking water, equitably and without discrimination.

Drought

A DROUGHT IS commonly understood as a prolonged and abnormally extreme dry spell in a region's climate in which there is an extended absence of rains. In this vein, meteorologists define drought in terms of the extent and severity of rainfall deficiencies. Agriculturalists define drought in terms of its impact on agricultural production, while hydrologists compare ground water levels, and sociologists define it on social expectations and perceptions. The three main types of drought are: meteorological drought, which is brought about when there is a prolonged period with less than average rainfall; agricultural drought, which is defined as a condition when there is insufficient moisture for the raising of sufficient livestock or crops due either to soil conditions or the agricultural techniques under use, in spite of the fact that there may be adequate precipitation; and hydrological drought, which is brought about when the water reserves available in sources such as aquifers, lakes, and reservoirs falls below the statistical average because of overuse.

Several meteorological processes are responsible for causing drought conditions. Among these are periodic flaring of the sun known as *sunspots*, increases in atmospheric dust, the warming of the planet through increased carbon dioxide (CO_2) and fluorocarbon emissions resulting in the greenhouse effect or global warming, and the effects of the El Niño-southern Oscillation (ENSO). Scientists have argued that in some areas of the world, there is a fairly regular 22-year rain/drought pattern. These scientists believe that this 22-year cycle is linked to sunspot patterns. Sunspots are huge magnetic storms on the sun's surface. They have life spans of only a few days, yet, it is believed that they somehow affect the weather on earth by changing pressure and temperature conditions at the equator, which then results in droughts in certain parts of the world. It is known that sunspot activity reaches a maximum every 11 years. That 11-year pattern is thought to relate to the 22-year weather cycle on earth.

ATMOSPHERIC DUST

Another climatic phenomenon that is believed to result in drought is increased atmospheric dust. Winds at the desert margins spur vast amounts of dust into the air. The fine material is propelled into the atmosphere and transported long distances by the easterly winds as a long dust cloud. Such dust clouds have been observed off the coast of West Africa from satellites and space shuttles, extending far out into the Atlantic Ocean. Some of this dust can be blown all the way across the Atlantic into the Caribbean Islands. The dust layer high up in the atmosphere can hinder cumulus cloud formation because of the warm temperatures emanated by the dust layer as the sun heats it. Because of atmospheric dust, drought conditions might be experienced in regions where rain would usually have fallen.

The massive amounts of greenhouse gases (such as carbon dioxide, methane, nitrous oxide, chlorofluorocarbons, and ozone) that are being spewed into the atmosphere due to recent increased human activity, and intercontinental pollution of the atmosphere with aerosols, can result in more frequent droughts. For example, there has been increased variability of the monsoon weather over the Indian subcontinent in recent decades. This is blamed on polluted "atmospheric brown clouds" traveling from one continent to another, which interact with oceanic warming, resulting in an increased frequency of drought conditions.

Scientists are currently generating large-scale models of the atmosphere called *General Circulation Models* (GCMs), which are composed of mathematical equations and relationships designed to simulate global atmospheric conditions and make projections of the future climate. These models indicate that, as a result of increasing greenhouse gas concentrations, the average global temperature will increase 1.4–5.8 degrees C (2.52–10.44 degrees F) by 2100. With the projected global temperature increase, some scientists think that the global hydrological cycle will also intensify. Thus, the combined impacts of increased temperature, precipitation, and evapotranspiration will be increased snowmelt, runoff, and soil moisture conditions. These models further indicate that rainfall will increase at high latitudes and decrease at low and mid-latitudes where it is normally high. This will result in severe drought conditions in mid-continent regions.

EL NIÑO

One other climatic feature that has been blamed for causing drought conditions, particularly in Africa and Australia, is the El Niño-Southern Oscillation (ENSO) event. ENSO events are major disturbances in the air pressure and surface water temperatures in the Pacific Ocean. El Niño-Southern Oscillation is the result of a cyclic warming and cooling of the surface ocean of the central and eastern Pacific. This region of the ocean is normally colder than its equatorial location would suggest, mainly due to the influence of northeasterly trade winds, a cold ocean current flowing up the coast of Chile, and to the upwelling of cold deep water off the coast of Peru. Periodically, the tropical sun warms these cold waters, causing the surface of the eastern and central Pacific to warm up in an El Niño event. This results in heavy rainfall in South America, but also in severe droughts in the Indian Ocean and the western Pacific, extending as far south as the eastern coast of Australia and as far north as the Horn of Africa. The more intense the El Niño, the more intense and extensive the droughts in Africa and Australia become. The reverse phenomenon, the cooling of the eastern Pacific waters, is known as La Niña. The possible interrelationship between El Niño and global weather patterns, especially the simultaneous droughts in Russia, Africa, Australia, and Central America, was first realized in 1972–73.

On average, ENSO events take place every five years. The largest was recorded in 1982–83, and coincided with the major drought in Ethiopia and the Horn of Africa. The event in 1998, which resulted in massive droughts in southern Africa between 1998 and 2002, is believed to have also affected global weather patterns. In 1998, the southern portion of the United States experienced droughts. There were warm winters in the northeastern United States; at the same time, Alaska and British Columbia experienced unprecedented warm waters. However, it was unclear whether these events were related to the fading 1998 El Niño. Since the late 1950s, there have been several major El Niño events: 1957–58, 1965, 1968–69, 1972–73, 1976–77, 1982–83, 1986–87, 1991–92, 1994–95, and 1998–2001.

The 1982–83 El Niño was the strongest event during the 20th century, causing well over $8 billion dollars in damages worldwide. Australia experienced devastating drought and brush fires. There were massive crop failures in Indonesia and the Philippines followed by starvation. southern and eastern Africa experienced prolonged droughts resulting in disease, malnutrition, and untold deaths of livestock and people. Shortages of fresh water in India and Sri Lanka were commonplace due to drought. Across the Pacific, coral reefs died. Other parts of the world experienced devastating deluges. Tahiti experienced six cyclones. There were massive floods and mud/landslides in the Colorado River basin, Peru, and Ecuador. Downpours in the Gulf States caused extensive death and property damage. The fishingf industry in South America was devastated due to the decrease in nutrients off Peru, which meant fewer anchovy.

In some regions of the world, such as Africa, the American West, and Australia, drought is a recurring feature of the climate, with devastating consequences for human livelihoods. Drought can have social, environmental, and economic consequences. From an economic standpoint, water is crucial to the production of goods and services. In times of drought, national economic growth can be lost, resulting in the slowing of economic development. The quality of crops is often damaged with less food produced, less income for farmers, and increased prices for food. These economic hardships are often followed by high unemployment rates and refugee migrations.

Environmental consequences of drought can include reduced rangeland and forest productivity, reduced water levels, increased fire hazard, increased livestock and wildlife death rates, and damage to wildlife and fish habitat. Although many of the consequences of drought are short term, environmental impacts might have long-term repercussions for the affected area. For example, species of animals can become extinct due to loss of important habitats such as wetlands, lakes, and vegetation. Social impacts include compromised health conditions, conflicts between water users, and reduced quality of life. During droughts, many people in less-developed parts of the world die of starvation and malnutrition. Many others migrate to areas outside the drought-affected location as refugees.

MAJOR DROUGHTS

Several major droughts have been recorded during the 20th century. In 1900, India experienced a major drought in which 250,000 to 3.25 million are estimated to have died due to starvation and disease. The former Soviet Union is said to have lost 250,000 to five million people from starvation during the 1921–22 drought that hit the Ukraine and Volga regions. Another major drought 1932–34 in the Ukraine, Kuban, and North Caucasus regions of the former Soviet Union killed an estimated five to 10 million people. In 1928–30, northwest China lost three million people due to a drought caused famine. Six years later, in 1936, another region of China (Sichuan Province) experienced the worst drought, which killed five million people and displaced over 34 million farmers. Between 1930 and 1937, the United States experienced three waves of drought referred to as the *Dust Bowl*. This series of droughts coincided with the Great Depression with severe consequences, resulting in entire districts of the American Great Plains being depopulated as people were forced to leave.

Millions of people and livestock have perished due to drought on the continent of Africa, particularly in drought-prone areas along the southern rim of the Sahara Desert known as the Sahel and in southern Africa. The 20th century has seen three major famines in northeastern Africa; in 1913–14, 1968–74, and 1982–84. In Australia, recurring drought has meant billions of dollars in losses due to livestock deaths. In 2000–05, a major drought struck large parts of Australia, and for the first time water scarcity began to affect the urban population with heavy restrictions on water usage. Some towns were forced to import water. Other cities along the coast began building desalination plants, and others contemplated using water recycled from sewage.

While drought cannot be reliably predicted, this climatic condition should not always lead to famine and starvation. Certain precautions and infrastructure can be put in place to minimize the impacts of drought, especially in drought-prone areas. Such infrastructure might include the construction of reservoirs for emergency water supplies, putting limits on settlement in drought-prone areas, and education about the dangers of overcropping and overgrazing. The U.S. Agency for International Development (USAID) has established a Famine Early Warning System for much of Africa, a system that collects meteorological and other data to monitor people's access to food and to provide timely notice when a food crisis threatens the region. The International Weather and Climate Monitoring Project at the National Oceanic and Atmospheric Administration (NOAA) of the U.S. Department of Commerce has extended the earlier USAID Famine Early Warning System to other parts of the world, which encompasses all of Africa, Afghanistan, Central America and the Caribbean, the Mekong River Basin, and much of southern Asia. The goal of the program is to provide weather and climate-related information to users within USAID, as well as organizations involved in providing humanitarian assistance.

Drugs

DRUGS ARE CHEMICALS that have a dramatic effect upon a living organism by altering one or more body organs. They can be used to alter or block the processes of diseases. They can also be misused or abused. Drugs are commonly placed into a dozen categories. Those used to treat humans are classified according to the way they affect the human body. They can also be classified by their chemical makeup, the disease they fight, the affect they have on the heart or blood vessels, or their affect on the nervous system. Manufactured drugs have three names: a scientific chemical name, a manufacturer approved generic name, and the brand name of its manufacturer. Since ancient times, drugs have been produced from many different plants, animals, and minerals. Penicillin, an antibiotic, is probably the most famous of the infection fighting drugs. Others antibiotics include the sulfa drugs (sulfonamides).

Vaccines, antiserums, and immunoglobulins are infectious disease-preventing drugs. These drugs work by stimulating the body to create antibodies to fight potential diseases such as measles, smallpox, and polio. When the antibodies combine with the antigens on the bacteria or virus, they render them harmless. Antiserums and immunoglobulins also neutralize the antigens of the infectious disease, such as diphtheria, tetanus, hepatitis, or rabies. The cardiovascular drugs affect the heart or blood vessels by normalizing irregular heartbeats, stimulating the heart beat so that more blood is pumped, and enlarge small blood vessels; or, in the case of hypertensive drugs, treat high blood pressure. Drugs such as analgesics, anesthetics, hallucinogens, stimulants, and depressants affect the nervous system. The analgesic drugs relieve pain, but because some of them contain a narcotic, they are subject to abuse. Narcotics (analgesia plus a sedative) include codeine, heroin, and morphine. Aspirin is a nonnarcotic analgesic.

The general anesthetics are drugs that produce a state of sedation that blocks sensations. Ether halothane and thiopental have been used in surgery. Hallucinogens or psychedelic drugs such as LSD (lysergic acid diethylmide), marijuana, and mescaline produce hallucinations. Hallucinogenic mushrooms and other plants are often grown illegally, and are known to cause drug addiction. The stimulant drugs affect the nervous system. They can reduce fatigue, stimulate the kidneys, or produce other affects. Caffeine, cocaine, and amphetamines are drugs in this category, which are also subject to abuse. Depressants cause the nervous system to become relaxed so that tension and worry are diminished. Tranquilizers (anti-anxiety agents), alcohol, and sedative-hypnotics are depressants. Other depressants include benzodiazepines and barbiturates (Phenobarbital, pentobarbital and secobarbital). Nonbarbiturate sedatives include chloral hydrate and paraldehyde. Recreational drug abuse with these is widespread. Other drugs include diuretics, hormone therapy drugs, vitamins, and immunosuppressive drugs. Drugs used in chemotherapy are the antitumor (antineoplastic) drugs.

Drug abuse has two major forms: recreational and medicinal. The recreational abuse of drugs has created criminal empires. In areas such as Burma or Afghanistan, where opium is produced; South America, where coca leaf is used for the manufacturing of cocaine; and other areas where other drugs producing crops are grown, have been subjected to efforts at eradication including the use of defoliants. The impact on the natural environment has been negative. Steroids have been abused to enhance sports performances. The medicinal abuse of drugs is probably even more widespread than the recreational use. Failure to handle medicines properly has contributed to drug resistance to bacteria strains. It has led to a race to continually produce new drugs against "stronger bugs." Some may consider another form of medicinal drug abuse to be the stimulation of animal growth for increasing meat production, often with negative side effects.

Dryland Farming

DRYLAND FARMING IS rainfed agriculture in arid or semi-arid areas, and growing crops and raising livestock without irrigation in semiarid and dry subhumid areas with minimal rainfall. Because dryland farming systems depend on rain and snow for their necessary moisture, they differ from arid zone systems, where irrigation is necessary, and from humid zone systems, where moisture is adequate or surplus for crops. Due to the limited and seasonal precipitation that shows considerable temporal and spatial variations and high evapotranspiration, agricultural systems in drylands have to adapt to the resulting low soil moisture and the patchiness of the ecosystem created by these conditions. This leads to a high riskiness of agricultural production, which is generally compensated by other diversified forms of income or seasonal migration in different forms of seminomadism.

Croplands cover 25 percent of the world's dryland areas, and the bulk of the world's food (60-70 percent of the world's staple crops) is provided from rainfed agriculture. Nevertheless, agriculture in drylands is considered in general as less favored, since it faces a variety of either biophysical or socioeconomic constraints. In areas of low productivity, yields are generally are less than 50 percent of irrigated systems on comparable land. The vast majority of dryland inhabitants, about 90 percent, live in developing countries. In many cases, they are the poorest of the poor, and display the lowest levels of human well-being.

Increasing degradation due to poor management of soils prone to erosion, steep slopes, saline soils, or low rainfall quantities are some of the limitations for agricultural production, frequently exacerbated by uncertain land tenure systems, growing population numbers, limited infrastructure, and market access and neglect of policy makers in previous decades. Degradation of rangeland is mainly caused by overgrazing, leading to bush encroachment.

Four categories of farming systems can be used to distinguish different development pathways of dryland farming. Traditional subsistence farming, which is based on traditional staple crops as sorghum, maize or manioc, with low opportunity costs for land and labor, have remained almost unchanged in previous decades. Economic growth and trade triggers a movement toward commercial farming in areas of low population density and higher opportunity costs for labor, leading to mechanized, large scale production systems as are observed in cereal production areas in the Argentina, Australia, or United States drylands, and exstensive pastoral livestock systems. Where labor is abundant and land is the constraining factor, intensive cereal systems develop that rely more on the use of high-yielding varieties and fertilizers to increase productivity, for instance in the intensively managed rice-wheat production systems in the Indian Punjab or the intensive rice production systems in Southeast Asia, where intensive livestock production associated with stall feeding is common. Where both land and labor are scarce, dryland farming becomes highly intensified, like the fruit and vegetable areas around the Mediterrenean.

Key factors for improved dryland farming are the increase of plant nutrient and water uptake, increase of organic matter in the systems, and exploring the possibilities for small-scale supplementary irrigation.

Within new economic frameworks, options are proposed to include land management strategies in drylands for the provision of ecosystem services. For instance, agroforestry systems could be created in drylands for carbon sequestration or other markets for the provision of ecosystem services.

Dunes

DUNES ARE PILES of granular material that have been deposited by wind and water into hills or long ridges. Dune formation begins with a process called *saltation*, in which the flow of sand across the desert floor is interrupted by an obstacle that blocks the sand's movement. It then begins to accumulate and eventually to form a hill. The heights of dunes may be shallow, or they may grow up to 500–600 feet (150–180 meters). Most dunes are sand, but white gypsum dunes are found in southern New Mexico's Tularosa Valley at White Sands National Monument. Rarely, dunes may be composed of tephra, shell fragments, or heavy minerals such as magnetite.

Dunes are sculpted by the winds into different kinds of shapes. Transverse linear dunes are formed from moderate winds that push the lighter material to form ripples perpendicular to the direction of the wind. Strong, steady winds form longitudinal (seifs) dunes. The abrasive winds gouge deep troughs in the desert floor. Sand is then deposited in parallel lines on either side of the troughs. If there are slight wind variations, then the tops of the dunes are formed into a wavy appearance. Crescent-shaped barchan dunes are formed into an arc by a constant wind moving faster around the ends of the dune than over its windward top. The horns of the crescent are downwind. In contrast, parabolic crescent dunes have horns that face into the wind. They are held in place by vegetation, so the wind scoops out the center of the dune to form the crescent shape. Star dunes are formed when shifting winds create arms as the sands radiate outward from the stable center of the dune. Whaleback dunes are very large longitudinal dunes.

Dunes occur along ocean shores or on islands. They may also be found on the shores of large lakes, such as the dunes at the southern end of Lake Michigan. Many of the dunes in the sand seas of the Sahara and the Arabian deserts (*Rub' al-Khali* or Empty Quarter) are active, "traveling" dunes. The wind pushes the sand so it moves across the desert to swallow everything that stands in its way, including towns and oases. Dunes that are fixed by vegetation are inactive. Destruction of fixed coastal dunes causes beach erosion and opens areas to flooding during storms. Some dunes give off noises as the sand in the dune shifts from place to place, and are sometimes called *singing dunes*. Great sand dunes occur in Australia, the Atacama Desert, Baja Mexico, and Cape Cod (Massachusetts). The ocean fog supplies the Namibian coastal desert with enough moisture to sustain 100 species in the rainless dunes. Fossilized dunes have been found in a number of places such as the Permo-Trias.

Dust

DUST IS MADE up of very tiny (about 1-10 µm) soil particles (fine silt and clay) and other fine particulate materials carried by wind on local to global scales. Because dust particles are so small, they can remain suspended in air for long periods of time. For this reason, dust may be transported across or between entire continents before being deposited, usually in rainfall. Dust is a form of wind erosion of soil; 40 percent of the soil eroded in the United States is eroded and transported by wind. Long-distance transport of dust can play a role in soil formation and development through the deposition of silt, clay, and soil nutrients and minerals. Scientists suspect that much of the calcium carbonate in the soils of the western United States was deposited by windblown dust. Windblown calcium carbonates and nutrients in dust originating in the Sahara Desert of northern Africa and deposited in the Amazon basin in South America are partly responsible for its fertile soils despite their high leaching rates.

Long-distance wind transport of dust can bury roads and fill drainage ditches; scour and damage fruit and vegetable crops, foliage, cars, and buildings; and choke coral reefs in shallow ocean waters. Viruses, bacteria, fungal spores, pollutants, and toxins transported to new areas in dust can cause illness to plants, humans, and other organisms. When inhaled, dust particles can lead to respiratory illnesses, and naturally occurring soil metals such as arsenic and mercury transmitted in dust can cause metal poisoning. Many fungal pathogens of crop and noncrop plant species are transmitted over long distances by windblown spores.

THE DUST BOWL

One of the most memorable historical images in the North American psyche is the American Dustbowl, which lasted about 10 years during the 1930s. Poor land management that left soil bare, and combined with several consecutive years of drought to make soil extremely vulnerable to wind erosion. Regular dust storms in the U.S. Great Plains blew enormous dust clouds of silt, clay, and organic matter eastward into the Atlantic Ocean. Huge dark clouds of dust shrouded eastern states; it is said that the dust clouds over Washington, D.C., incited Congress to pass new laws to mitigate soil erosion.

Poor land management and overgrazing continue to intensify soil erosion around the world. Billions of tons of dust blow off of arid lands every year, and the dust blows into adjacent states and around the world. Dust storms in the desert southwestern United States are intensifying as recreational motor vehicle use and grazing increase, because these activities kick up dust and kill the natural cyanobacterial biological soil crusts that prevent erosion by binding surface soil particles together. High-altitude dust storms, from places as far apart from each other as Utah and China, deposit dust on snow packs in the Colorado Rockies and cause them to melt faster due to the decreased albedo of darker surfaces.

Faster and earlier snow melt feeds western rivers and reservoirs too quickly, causing them to overflow early in spring and run low late in the summer. This shift in timing has serious economic consequences for industries and communities that rely upon a steady flow of water throughout the summer. Dust from the Taklamakan Desert in China and the Sahara in Africa falls on the Swiss Alps, and Chinese and Mongolian mountain ranges receive dust from the Gobi Desert.

If the use of semi-arid lands intensifies with increased global human populations and agricultural land degradation, the intensity and frequency of dust storms and their far-reaching consequences will likely increase as well. Scientists will continue to study how the deposition of dust from faraway lands interacts with other consequences of global environmental change to affect human and natural communities.

Dust Bowl (U.S.)

THE DUST BOWL describes the regional environmental conditions throughout the central parts of the United States and Canada from 1931 until 1939, where soil erosion was rampant and dust storms swept across the landscape. It came from inappropriate farming techniques and resulted in an exodus of many farming families, who were left homeless during a time of general economic hardship. Many stories emanated from this period, the most famous being John Steinbeck's *The Grapes of Wrath* (1939).

In the period following World War I, there was a sharp increase in the U.S. population. As a result, there was more demand for food, with the result that large amounts of marginal land were developed for wheat, and also for cotton. Much land in what became known as the Great Plains—Oklahoma, Kansas, Nebraska, and South Dakota—was quickly sold, with some returning servicemen and others seeking the opportunity of running their own farms away from the big cities. During the 1920s these communities survived, and a few even thrived. However, the land quickly gave out.

The soil was incapable of nourishing crops for more than a few years. More importantly, the breaking of tough ground, and the destruction of native grasses that had grown in semi-arid areas for over a millennium, saw much of the topsoil carried away by water after rainstorms. Massive soil erosion resulted with the gullying of plowed land, and water full of earth running off the land during rainstorms. Strong winds then made the situation worse. The years 1933 through 1935 were unusually dry, which meant that the water tables of parts of the Plains region were sinking so low that many deep wells slowly ran dry. Thus, these farms quickly turned into desert, with vast dust storms that came to be known as the Dust Bowl. Much livestock died in the dust storms from ingesting the soil, with others unable to scratch a living afterward. From 1934 until 1939, some 500,000 or more farmers and their families were forced to migrate.

One of the states worst affected by the formation of the Dust Bowl was Oklahoma (especially the central and eastern parts of the state) where so many farms failed, it has been estimated that 15 percent of the residents of the state moved west in search of work and new opportunities. These became known as the *Okies* who made up as many as 300,000 of those forced off their land—from a state with a population of 2.3 million at the time. The other areas worst hit were much of southern Piedmont and parts of the upper Tennessee Valley, s some areas in the interior plateau of Kentucky and also in Tennessee, some of the older glacial till in the southern part of Iowa, and also the land covered with loess in Iowa on the east of the Missouri River. The effect on the farmland was that 44 million acres of previously cultivated soil was lost, and another 87 million acres seriously damaged.

From 1934–39, some 500,000 or more farmers and their families were forced to migrate out of the Dust Bowl.

One of the worst days that enlarged the Dust Bowl was on November 11, 1933, when a strong wind stripped the topsoil from tens of thousands of farms throughout South Dakota. Then on May 11–12, 1934, a two-day storm blew away much of the topsoil throughout the Great Plains. A third disastrous day was on April 14, 1935, when blizzards wreaked havoc throughout the United States. It was this storm that led an Associated Press reporter to coin the phrase *Dust Bowl* as the skies darkened with the dust and soil, which was collected up by the wind, was swirled around and deposited hundreds of miles eastward. Other parts of the United States, fearing a similar effect on their communities, started infilling gullies, building check dams, and also embarking on the reforestation of slopes that contained marginal farming land, as well as contour plowing and going back to strip cultivation.

Many of the farmers who left the Dust Bowl at the start of the problems, managed to find work in California and elsewhere. However, as the migration continued, and with increasing unemployment, gangs of men formed vigilante groups to try to keep the Okies and others from trying to take work from them. Some businesses openly exploited the migrants, paying very low wages—barely subsistence levels—and replacing them with further migrants if they complained about the pay or conditions.

The election of Franklin Roosevelt in 1932 saw many policies in the first "100 days" programs to alleviate the early effects of the soil erosion, although it did get steadily worse during his presidency. These involved trying to help many of the migrants, protecting them from the worst abuses of the times. Roosevelt also formed the Soil Conservation Service (later renamed the Natural Resources Conservation Service) to try to ameliorate the worst degradation. There have been many attempts to find a culprit for the Dust Bowl, with some blaming the farmers for bad farming practices. Others view the land speculators who had opened up so much marginal land as the people at fault. A few others believe that politicians should have done more to alleviate the suffering. Certainly in the early 1930s, many felt the problem might only be temporary. But by the late 1930s, federal money was being made available to tap into deep aquifers for more water. Effectively, the rainstorms in 1941 helped end the drought and started to allow the soil to replenish itself. By the end of that year, the United States was at war with Japan and Germany, and many of the ex-farmers and their sons had found employment in the military.

The Grapes of Wrath

The most evocative story about the Dust Bowl is John Steinbeck's *The Grapes of Wrath,* which was published in 1939 by Viking Press. The title comes from the reference to the "Grapes of Wrath" in the *Battle Hymn of the Republic,* and is the story of a family of poor sharecroppers who are driven from their land in Oklahoma.

The father is Tom Joad—the surname coming from the Biblical character "Job," whose faith is tested by God in the Old Testament. When Joad returns home after being paroled from prison for manslaughter, he finds the family farm in disarray and the crops destroyed in the Dust Bowl. Forced to default over outstanding debts, Tom Joad decided to take his family to California in the hope of work. The book covers the search by Tom Joad for a steady job and a house for his family. It also involves him being exploited in an orchard, and becoming a fugitive.

In 1940, Darryl F. Zanuck produced a film of the book through which many people around the world were able to see the effects of the Dust Bowl on small farms. The book has been banned in some counties of America for various reasons, and remains controversial. In 1962, John Steinbeck was awarded the Nobel Prize for Literature for *The Grapes of Wrath.*

Earth Day

THE AMERICAN CELEBRATION of the environment began on April 22, 1970, with activities from coast to coast in dedication of a renewed concern for land, water, and air. Earth Day was initiated, in part, by the moon landings and in particular from emotions stirred by the first photograph of the earth from space. Earth Day was the inspiration of Senator Gaylord Nelson (D–WI) who spent the previous eight years deeply concerned about the state of the physical environment, wanting to take action to rectify the damage. In 1962, Senator Nelson convinced President John F. Kennedy to conduct a national conservation tour to bring the issues of a degrading environment into prominent national view. The president began the tour in September 1963, but his efforts did not bring the results Senator Nelson had hoped for. Nonetheless, President Kennedy's efforts did provide an important start to the program. In September 1969, Senator Nelson announced at a conference that a demonstration aimed at garnering public support for the environment would be held in all areas of the country the following spring. The resulting notoriety from this announcement was extraordinary.

Estimates of participation in Earth Day were set at 20 million, as communities, schools, and a variety of organizations took part in a countrywide outpouring of support for the environment. In New York City, Mayor John Lindsay closed Fifth Avenue from Central Park to 14th Street for two hours in order to provide the celebration a dedicated space. The resulting series of speeches, discussions, musical performances, and Vietnam-demonstration-style "teach-ins" to raise awareness of environmental concerns carried on until midnight. Earth Day was a huge success and it ushered in a new ea in America's stewardship toward its natural endowments that became known as environmentalism.

The era of environmentalism succeeded the conservation movement, which had its greatest prominence from 1850 through 1920. The conservation approach embodied the basic relationship between humans and the natural word, an association that had been articulated in various forms throughout history. However, by 1850, U.S. urbanization brought about a new appreciation for regions of wilderness, dedication to the wise use of natural resources, and the preservation of areas of natural grandeur. The conservation movement recognized and documented human impact on the natural world, suggesting that this influence not be destructive. There emerged a philosophical basis as well for the appreciation of nature. Writers began to

Volunteers from the U.S. Air Force joined local citizens to clean up refuse on Earth Day 2001.

discuss the interface between nature and the American identity in spiritual terms, and to identify a moral connection between the urban dweller and the land. Wilderness and areas of natural beauty were not only idealized, but were also seen as places to preserve for the use of all citizens.

The conservation movement coincided with several large-scale socioeconomic changes that permanently transformed the geography of North America. The industrialization of the American economic system was at its high point of development 1850–1920. This era also marked the emergence of large-scale agriculture and the decline in the small farm. A vast expansion in the surface transportation system occurred during this period, and the emergence and solidification of the urban system took shape. By 1920, North America entered into an era of economic expansion unprecedented in world history. The Soil Conservation Service was founded in 1935 during the New Deal Era under President Franklin D. Roosevelt. In 1937, the Pittman-Robertson Act was enacted to fund fish and wildlife programs. The most ambitious and far reaching single project undertaken in this period was the Tennessee Valley Authority, aimed at taming the wild and unpredictable Tennessee River through the construction of a series of nine dams along its course and a series of electric generating stations. The conservation movement also created the national park system, the national forest system, and the Forest Service. Much of the activity in conservation followed President Theodore Roosevelt's view of conservation as a central focus of national policy.

Earth Day represented a new direction in public concern for the environment. The conservation movement aimed at warding off unwanted misuse of land, air, and water. Earth Day focused widespread attention on a degraded environment and the focus became remedial. Following years of dumping waste materials into Lake Erie, scientists studying the lake proclaimed its literal death in 1970. The Great Lakes were threatened by pollution from the many steel-making plants, taconite processing plants, refineries, paper mills, and sewage systems. Lake Erie was the hardest hit of the Great Lakes as fish life essentially ended and the water became severely fouled.

However, within a decade, the concerted efforts of the United States and Canada brought about what some experts considered a miracle in bringing Lake Erie back to a healthy state and ensuring that regulations were in place to protect the entire Great Lakes freshwater system. The Great Lakes Water Quality Agreements of 1972 and 1978 brought the two countries together in the gargantuan task of cleaning the entire water system. The Clean Water Act, enacted in the 1970s, ensures the continued monitoring of the Great Lakes and other water bodies and the immediate remediation of any environmental dangers.

During the 1970s, legislation to protect the environment appeared, including the Clean Air Act, the Water Quality Improvement Act, the Toxic Substances Control Act, the Occupational Safety and Health Act, the Resource Recovery Act, the Federal Environmental Pesticide Control Act, the Endangered Species Act, the Safe Drinking Water Act, and the Surface Mining Control and Reclamation Act. On January 1, 1970, the National Environmental Policy Act (NEPA) was signed into law. NEPA requires federal agencies to integrate environmental values into their decision-making processes. This federal requirement gave birth to the Environmental Impact Statement (EIS), a key document prepared by federal agencies including the impact on the environment of proposed actions and the listing of reasonable alternatives to those actions. The Environmental Protection Agency (EPA) was authorized under the NEPA. The mission of the EPA is straightforward: to protect human health and the environment. In place since 1970, the EPA works toward the development and maintenance of a clean and healthy environment for the American people. The EPA is headquartered in Washington, D.C., has 10 regional offices, and employs 18,000 people.

AHEAD OF HIS TIME

The founder of Earth Day and its most energetic supporter, Senator Gaylord Nelson is considered to have been far ahead of his time on the environmental front. As governor of Wisconsin in 1961, he created the Outdoor Recreation Acquisition Program. The aim of this program was the state acquisition of one million acres of wetlands, parklands, and open space for common use. While in the U.S. Senate, he authored legislation to protect the Appalachian Trail and the creation of the system of national hiking trails. In addition, he co-sponsored the Wilderness Act, the Alaska Lands Act, and worked on various aspects of consumer protection and protection of national parks. In 1990, Senator Nelson received the Ansel Adams Conservation Award, given to a federal official exhibiting commitment to the cause of conservation and to the American Land Ethic. He was also a recipient of the Only One World Award from the United Nations Environment Program. In 1995, Senator Nelson received the country's highest civilian award, the Presidential Medal of Freedom from President Clinton. The proclamation stated, in part: "As the father of Earth Day, he is the grandfather of all that grew out of that event: The Environmental Protection Agency, the Clean Air Act, and the Safe Drinking Water Act."

Earth First!

EARTH FIRST! IS an anarchical movement relying heavily on the tenets of deep ecology. Earth First!ers embrace a biocentric philosophy whereby the earth and its many natural components receive the highest and utmost protection and consideration in any decision. You cannot become a member of Earth First!, as there is no membership. You cannot pay dues, as Earth First! is neither a club nor a nonprofit organization (like the Sierra Club). To become an Earth First!er one need only to take action in defense of the earth.

The Earth First! movement is said to have been born in a VW microbus in the spring of 1980 and to have been inspired by Rachel Carson's *Silent Spring*, Aldo Leopold's *Land Ethic*, and, most of all, Edward Abbey's *The Monkey Wrench Gang*. Environmental activists Dave Foreman and Mike Roselle, along with Wyoming Wilderness Society representatives Bart Koehler and Howie Wolke and former park ranger Ron Kezar, were upset by the actions of mainstream environmentalists and thus, according to the Earth First! history page at the Sierra Nevada Earth First! website, "envisioned a revolutionary movement to set aside multi-million acre ecological preserves all across the United States."

Anyone is capable of forming his or her own Earth First! collective (group) to work on any environmental or social issue deemed important. The group's self-description on its website notes that:

> while there is broad diversity within Earth First! from animal rights vegans to wilderness hunting guides, from monkeywrenchers to careful followers of Gandhi, from whiskey-drinking backwoods riffraff to thoughtful philosophers, from misanthropes to humanists there is agreement on one thing, the need for action!

Historically, Earth First!ers have worked to bring attention to issues such as logging, mining, grazing, wilderness protection, animal rights, transportation, development, endangered species, and so on. The online *Earth First! Journal* is a migrating literary collective of Earth First! activists. There is also a gathering and celebration of Earth First!ers called the Round River Rendezvous, in which fellow activists camp in a different national forest every July to meet new activists, organize campaigns, and celebrate the movement.

Earth First! is a mentality ascribed to by dedicated individuals who have taken a hard-line stance against anything human-induced that causes environmental and social deterioration, including capitalism, patriarchy, consumerism, corporate-state control, and technology. Often referred to as fringe or far left, the Earth First! movement represents a section of society (globally) whose official slogan is "No compromise in the defense of mother Earth."

In terms of methodology, the worldwide Earth First! stance takes a "decidedly different tack toward environmental issues. We believe in using all the tools in the toolbox, ranging from grassroots organizing and involvement in the legal process to civil disobedience and monkeywrenching."

Criticisms of Earth First! include the claim that the movement is "ecoterrorist." Proponents insist that they support no violent acts, however, and most typical actions include unfurling banners, chaining protesters to logging equipment, sitting in trees, and blocking logging roads, all of which are nonviolent, though often illegal, acts.

An Earth First march in Yellowstone in 1989 reflects their hard-line stance toward environmental and social issues.

Other critics suggest that the ecological and philosophical pillars of the movement may be flawed, including the fundamental concept of bioregionalism, which has been scrutinized for its romantic localism and anti-urbanism, which may actually be environmentally unsustainable. Nevertheless, the critical ecocentric philosophy of Earth First! still makes it a galvanizing movement for a wide range of concerned activists.

Earthquake

AN EARTHQUAKE IS usually caused by the rupture of a geologic fault, or the seam between two large blocks of land that suddenly move in different directions. The two predominant types of faults are thrust faults and strike-slip faults. A strike slip fault is the most common in the United States; it is where two geologic plates move in opposite directions relative to each other, such as the San Andreas in California. A thrust earthquake occurs when one plate moves under another. In 2004, a great earthquake off the Indonesian island of Sumatra was caused by a thrust fault; the rupture along the fault was greater than 93 miles (150 kilometers). The earthquake and the massive tsunami that was generated by the tsunami killed about 200,000 people in the Indian Ocean basin. In the United States and Canada, the Cascadia fault off shore of British Columbia, Washington, Oregon, and California, could potentially generate an earthquake of magnitude 9.0, and could generate a significant tsunami that could endanger people throughout the Pacific Basin. Nations subject to earthquake hazards include, but are not limited to, Indonesia, Iran, India and Pakistan, Turkey, Greece, Italy, China, Japan, Taiwan, Canada, Mexico, and the United States.

Its moment magnitude number, often mistakenly called the *Richter scale* that is now considered obsolete, reports the *magnitude* (M) of earthquakes. The moment magnitude scale is logarithmic, which means that a magnitude 5.0 earthquake (M 5.0) is about 31 times weaker than an M 6.0 quake, and is 1,000 times weaker than an M 7.0 temblor. The primary danger to people posed by earthquakes is from the structural failure of buildings due to ground shaking. A building can collapse partially or totally when the building loses structural integrity. This is more likely to happen when buildings are built on *unconsolidated soils*, such as sand or clay, which tends to amplify the ground motion. People are killed or injured when buildings or other structures

The San Juan Earthquake

A large earthquake struck Argentina on January 16, 1944, and shook some buildings in Buenos Aires, the capital, but caused little damage. In the far west of the country, the city of San Juan, the capital of a province of the same name, along the border with Chile, was devastated. Initially there were no communications with the area, but when news reached Buenos Aires of the damage, and the death of about 6,000 people, the population of one of South America's wealthiest cities decided to raise funds to help the victims and families of the dead.

With Argentina having become incredibly wealthy through its neutrality in World War II—it did enter the war on the Allied side in 1945—the *portenos* (urban residents) of Buenos Aires responded generously and established the San Juan Fund. It was coordinated by Colonel Juan Domingo Perón, the Secretary of Labor in the military government, and an ambitious and aspiring politician.

One of the events that Perón organized was an artistic festival, where actors and actresses, along with the military, would raise money, the highlight of which would be a massive gala performance. Perón took center stage himself in a starched white tunic and peaked cap. It was at this event, on January 22, that Perón was smitten by an actress who was performing that evening, and was wearing a black dress, long gloves and a white feathery hat. Eva Duarte was the illegitimate daughter of a businessman from a country town, and had become an accomplished radio actress. Two years later, by which time Perón was president of Argentina, they were married and his wife became better known as Evita Peron. She died in 1952 from cancer, aged 33, and Perón was ousted as president in 1955, although he was president again from 1973 until his death in the following year.

collapse; the major cause of death in the Loma Prieta (San Francisco) earthquake of 1989 was the collapse of an elevated freeway in Oakland.

A great deal of experience has been amassed on how to build or locate structures to reduce the risk of building collapse in an earthquake. Engineers know how to design buildings that may be damaged in an earthquake, but retain sufficient structural integrity to allow occupants to escape. Modern steel-frame skyscrapers tend to withstand earthquakes remarkably well. The most dangerous types of buildings are unreenforced masonry buildings, and concrete and steel structures that are not built with seismic safety in mind. The 1906 San Francisco and 1925 Santa Barbara earthquakes in California revealed the problems with unreenforced masonry buildings, but the 1933 Long Beach earthquake damaged or destroyed down many masonry buildings, particularly schools. As a result, the California legislature passed the Field Act, which required that public buildings such as schools be built to withstand earthquake forces. In the years that followed, as experience accumulated with other great quakes (1964 Alaska, 1971 San Fernando), improved building codes and practices were adopted that greatly reduced the risk to human life from moderately large earthquakes.

In the United States, various efforts, notably including the National Earthquake Hazard Reduction Program (NERHP), have promoted research, improved building practices, and better public information about the earthquake hazard. Thus, in the United States, the long-term trend has been fewer casualties, but more property damage in earthquake stricken areas. However, seismologists, engineers, and emergency managers have warned that cities like San Francisco, Los Angeles, and Anchorage have not recently experienced "the Big One," an earthquake that would catastrophically damage the region. Continued efforts to improve buildings and to manage risk will make that earthquake, when it occurs, much less likely to kill as many people as it would without these measures. Other nations in the world are not so advanced. For example, in the 1988 earthquake in Armenia, then part of the Soviet Union, poor building practices—in particular, in high-rise concrete and steel buildings that would not have been built under American building codes—catastrophically failed, killing 25,000 people and injuring at least 15,000. Recent earthquakes in Indonesia and along the India-Pakistan border have further illustrated the importance of improved building techniques.

East Timor

THE SMALL COUNTRY 5,794 square miles (15,007 square kilometers) now known as the Democratic Republic of Timor-Leste, or more commonly as East Timor, has been alternately occupied by the Portuguese, the Dutch, and the Japanese. The most repressive occupation, however, occurred in the 20th century when the United States, Canada, Britain, and Australia supported Indonesia's brutal military occupation of East Timor from 1975 to 1999. Estimates of lives lost during this occupation vary from 100,000 to 250,000. Following the 1999 bid for independence, Indonesia retaliated by launching a military backlash and a scorched-earth policy. Around 1,300 Timorese were subsequently killed and 300,000 were forced to seek refuge in West Timor.

Part of the Malay Archipelago, East Timor is a set of islands located in southeastern Asia at the eastern end of the Indonesian archipelago. In addition to the eastern half of Timor, the nation encompasses the Ambeno region in the northwest portion of Timor and the islands of Pulau Atauro and Pulau Jaco. Bordering on the shared waters of the Timor, Banda, and Savu Seas, East Timor has a 438-mile (706-kilometer) coastline. The climate is tropical with distinct rainy and dry seasons, and the country is subject to frequent flooding and landslides and to occasional earthquakes, tsunamis, and tropical cyclones. The terrain is mountainous with elevations ranging from sea level to 9,717 feet (2,963 meters). Natural resources include gold, petroleum, natural gas, manganese, and marble.

The Indonesian occupation left East Timor with an annihilated infrastructure that included massive destruction to irrigation systems, water supplies, schools, and homes. The entire electric grid of the country was wiped out. On September 20, 1999, Australian troops led the International Force for East Timor in restoring peace to the islands. In 2002, East Timor became the first nation to establish independence in the 21st century. The infrastructure is in the process of being restored, and all but 30,000 or so refugees have returned. Current Timorese population estimates range from 800,000 to 1,000,000. Oil and gas resources are being developed, and a petroleum reserve fund has been created.

POOREST COUNTRY IN THE WORLD

At present, however, East Timor is the poorest country in the world, with a per capita income of only $400. Some 42 percent of the population live below the poverty line. An abnormally high fertility rate of 7.8 children per female is partially a response to the high infant mortality rate (45.89 deaths per 1,000 live births) that results from common childhood diseases and a low immunization rate (50 percent for children under two years of age). Approximately 8 percent of the population live in urban areas where one-fifth of adults are unemployed. Low literacy (58.6 percent) and educational (75 percent) rates make it more difficult for young people to obtain employment, and hundreds emigrate each year. Around 80 percent of Timorese depend on subsistence agriculture for survival. The UNDP Human Development Reports rank East Timor 140th of 234 countries on overall quality-of-life issues.

Current environmental problems in East Timor are a result of massive poverty leading to over-extraction

The Quest for Oil

When Alfred Russel Wallace visited Portuguese Timor in 1861, he reported seeing natural oil deposits. In 1901 an Australian chemist, Dr James Frederick Elliott, visited Dili, the capital of East Timor, and also noticed concentrations of oil when he saw crew members of his ship throw matches overboard after lighting their pipes. Some of the matches lit up on hitting the water. As a result, on his return to Australia, he put together a business concern and sent an engineer to Timor to report on whether the quantities there were viable for commercial purposes.

The result was the Australians buying a number of concessions in East Timor, and worried that the Germans might be interested in buying the entire Portuguese possession. After World War I, interest in the Australian oil concessions saw the revival of Australian government interest in buying East Timor if it was offered for sale. The Timor Petroleum Concession Limited was then established to take over what was becoming known as the Staughton Concessions named after Arthur John Staughton, who invested his money in the search for oil.

Oil was found in many places in East Timor, but the various companies that operated the Staughton Concession faced two problems. Much of the oil was of low quality, and the costs of extracting it from extremely remote locations would probably outweigh its sale. There was also a small scandal when a British mining engineer, hired by the Australians, died in Timor of blackwater fever and his widow complained that the Portuguese seized her husband's assets.

During the late 1930s, businessmen connected with Japan became interested in the oil concessions. A Belgian middle-man died in 1940, and the Japanese attack on Malaya and Pearl Harbor in the following year saw the end of plans to find oil in East Timor. During the 1980s oil was found offshore; the Timor Gap Treaty was then signed by Indonesia and Australia, then abandoned when East Timor gained its independence.

and unsustainable harvesting of forests, resulting in widespread deforestation and soil erosion. Coral reefs and fisheries have been threatened and soil eroded by droughts and seasonal rains. The burning of wood in poorly ventilated kitchens leads to a plethora of respiratory diseases. Timorese health is also adversely affected by the fact that 66 percent of the population lack access to improved sanitation, and 48 percent have no access to safe drinking water. There is also great concern that the increased exploitation of petroleum resources may result in further environmental problems, as have been witnessed in poorer oil-exporting nations around the world.

Under the guidance of the Ministry of Development and Agriculture, the Timorese government has expressed its commitment to creating a sustainable environment that will promote economic growth, eradicate poverty, enhance biodiversity, and halt land degradation.

The government is working with Australia and a number of international agencies to establish policies geared toward achieving these goals. However, environmentalism in East Timor is still in its infancy. Due to its status as a fledgling nation, East Timor has not begun participating in international environmental agreements.

Easter Island

EASTER ISLAND, LOCATED in the South Pacific some 2,237 miles west of the Chilean mainland, is a part of the Republic of Chile, and is one of the most isolated inhabited islands in the world. Now officially known as *Rapa Nui*, it is roughly triangular in shape, covers 63 square miles, and has a population of 3,700 (according to the 2002 census).

The first European contact with the island was when the Dutch navigator Jacob Roggeveen landed on Easter Sunday, 1722—hence the name of the island. There was a population of between 2,000 and 3,000, but from oral tradition it was believed that there might have been as many as 15,000 only a century earlier. The massive decline in the population came about as a result of deforestation and overexploitation of the natural resources on the island.

From what the Europeans discovered on that and later visits, the first Polynesian settlers arrived on about 300–400 C.E., possibly with a very small population until the 12th century, when large-scale deforestation started. This appears to have accelerated rapidly by the 17th century, with evidence from archaeological digs showing a significant decline in fish and bird bones as the islanders started to have shortages of hunting tools, and also possibly the birds having no places to nest. This was made worse by the Polynesian rat, which seems to have lived by eating seeds from palm trees on the island.

The most well-known aspects of Easter Island heritage are the Moai, large stone statues that were carved probably between 1100 and 1600, although some were still being carved when the Europeans first came to the island. They caught the attention of much of the world, and Captain Cook described them in his visit in 1774. The carving of the statues, and their movement from the quarry to their final destination further depleted the supply of wood on the island, and hence the massive decline in trees. This all led to soil erosion, and the introduction of the Birdman Cult.

The Birdman Cult of the 16th and 17th centuries saw the introduction of an annual competition whereby a representative of each clan would try to swim to the nearby island of Motu Nui, to find and bring back an egg. The first to return would become the Birdman for that year, having rights over the

Thor Heyerdahl

In 1947 the Norwegian adventurer Thor Heyerdahl (1914–2002) became famous all over the world with his Kon-Tiki expedition, in which he and five colleagues managed to cross the Pacific Ocean. This led to the book *Kon-Tiki* (1950), and Heyerdahl subsequently taking part in a number of other voyages in boats recreating vessels made in the ancient world.

One of Heyerdahl's other interests was in Easter Island, and in particular the existence on the island of the large stone statues known as the *Moai*. This led to Heyerdahl returning to the Pacific in 1955, where he received a large reception from the locals because of his fame. He was asked to pitch his tents on the site attributed to the legendary King Hotu Matua, and began the first archaeological excavations ever undertaken on the island.

At that time the only regular contact with Easter Island was a Chilean warship, which called at the island each year. Heyerdahl's work on the *Moai* fascinated many of the locals and they started to attribute some supernatural powers to him. It was not long before the Norwegian adventurer was able to discover much about the past of the Easter Islanders, and also some customs which could be used to understand their history. Heyerdahl located the quarries where the *Moai* were carved, and bringing European archaeological knowledge to bear, found many other small stone carvings. He was also able to prove, by digging around the *Moai*, that many of them had torsos, and were not solely heads. Some of the Moai had toppled over, and Heyerdahl's colleagues helped put them upright again. The results of his work were published in a bestselling book *Aku-Aku.*

distribution of resources. The last such swim, across shark-infested waters, took place in 1867 and it is believed that the event was a way in which the community was trying to supplement their food supplies. By the mid-19th century the population on Easter Island had risen to about 4,000 but by 1877 had fallen to only 110. This came about from introduced diseases as well as slave-traders operating from Peru. In 1888 the island was annexed by Chile with a treaty drawn up by Policarpo Toro. Many of the locals were forced to live in a shanty town on the outskirts of the capital, Hanga Roa, until the 1960s. Now their heritage is cherished, and the island is visited by many tourists with stopovers by Lan Chile and other trans-Pacific flights stopping at Mataveri International Airport.

There are many tablets found on the island featuring a mysterious script that has not yet been deciphered, and there are some theories advanced by linguists seeking to link the culture on Easter Island with other parts of the world.

Eastern Wilderness Act of 1974

THE EASTERN WILDERNESS Act of 1974 made it possible for lands in eastern states that had recovered from past abuse to be eligible for inclusion in the National Wilderness Preservation System.

Passed in 1964, the Wilderness Act (P.L. 88-577) established a system of wilderness areas called the National Wilderness Preservation Systems. Three federal agencies were given responsibility for managing wilderness lands: the National Park Service, U.S. Forest Service, and U.S. Fish and Wildlife Service (the Bureau of Land Management was later given responsibility for managing wilderness lands after passage of the Forest Land Policy and Management Act in 1976). Provisions of the Act specified criteria for the inclusion of new units in the system. Wilderness lands were to be "…primeval in character and influence… affected primarily by the forces of nature." In addition, 5,000 acres was established as the recommended minimum size for wilderness areas. This meant that the majority of public lands large enough to qualify for inclusion in the National Wilderness Preservation System were located in western states. Between 1964–75, only four of the 95 wilderness areas established in the United States were west of the 100th meridian.

The Eastern Wilderness Act emerged in response to the limited number of wilderness areas created in eastern states after passage of the Wilderness Act. In evaluating the suitability of lands, the U.S. Forest Service had strictly interpreted language found in the Wilderness Act. As a result, areas that had been logged or otherwise altered by human activities were found to be unsuitable for inclusion in the system. The shortage of wilderness areas in the east led to calls for more wilderness lands to be designated near eastern population centers. Among proponents for eastern wilderness lands was U.S. Senator George Aiken from Vermont. A member of the Senate Committee on Agriculture and Forestry, Aiken was an advocate for additions to the wilderness system in Vermont and other eastern states where road construction, housing projects, and other activities were rapidly encroaching on the last undeveloped areas. In 1972, President Richard Nixon acknowledged the unequal distribution of wilderness lands, instructing the Secretaries of Agriculture and the Interior to hasten efforts to identify lands suitable for inclusion in the National Wilderness Preservation System. In the early 1970s Congress began debating the question of wilderness lands in eastern states. One failed proposal called for the creation of a separate eastern wilderness category within the National Wilderness Preservation System.

The Eastern Wilderness Act (P.L. 93-622) served as recognition of the need to protect wilderness lands in populous eastern states threatened by expanding populations and development. Signed into law on January 4, 1975, by President Gerald Ford, the act created 15 new wilderness areas encompassing 207,000 acres in 13 states (Alabama, Arkansas, Florida, Kentucky, New Hampshire, North Carolina, Tennessee, South Carolina, Georgia, Vermont, Virginia, West Virginia, and Wisconsin). Among new wilderness areas were the Sipsey Wilderness (12,000 acres) within Alabama's Bankhead National Forest, the Upper Buffalo Wilderness (10,590 acres) within Arkansas's Ozark National Forest, and Bristol Cliffs Wilderness (6,500 acres) in Vermont's Green Mountain National Forest. Another provision of the law was to direct the Secretary of Agriculture to review and report back within five years concerning the suitability of 17 other units for protection as wilderness. The act also affirmed that wilderness areas were to be managed in accordance with the Wilderness Act of 1964. Unless otherwise indicated, the law addressed only lands located eastward of the 100th meridian.

The Eastern Wilderness Act profoundly impacted land management practices in eastern states. As a result of its passage, wilderness areas are now located in most eastern states and include some small areas such as the Leaf Wilderness (940 acres) in Mississippi's De Soto National Forest. In addition, large wilderness areas have been established in Shenandoah and Great Smoky National Parks.

Ecofeminism

FEMINIST ENVIRONMENTALISTS ARGUE that the domination of women by men reflects and reinforces the domination of the environment by society, and that the two are understood to be linked; patriarchal gender relations in society correspond to androcentric environmental ethics. Ecofeminism posits that the same masculinist habits of thinking and behavior that devalue, oppress, and exploit women also do so to nature; and are mutually reinforcing hegemonic processes pivoting around artificial Western binary oppositions interpreted by religion, science, government, and other androcentric agencies (superiority/inferiority and as domination/subordination that include human/nature, male/female, mind/body, reason/emotion, objective/subjective, and material/spiritual). Furthermore, classism, heterosexism, racism, and speciesism as well as sexism are all presumed to be interrelated. Thus, the liberation of women and of nature from male domination and abuse are causally interconnected. Accordingly, ecofeminism contains political as well as philosophical, theological, sociological, and ecological concerns. At the same time, there are several variants of ecofeminism that in general correspond to different foci for political thought and action within feminism, including liberal, cultural, social, and socialist feminists. However, these variants of ecofeminism have in common feminist challenges and alternatives to tyrannical patriarchal power structures that oppress, exploit, and abuse women and nature in different cultural, environmental, political, and historical contexts.

The French writer Francoise d'Eaubonne founded the *Ecologie–Feminisme* (Ecology–Feminism Center) in Paris in 1972, and coined the term *ecofeminism* in her 1974 book *Le Feminisme ou la Mort* (*Feminism or Death*). Since the mid-1970s, some of the more important pioneers in ecofeminism include Carol J. Adams, Chris J. Cuomo, Mary Daly, Greta Gaard, Susan Griffin, Wangari Maathai, Sallie McFague, Carolyn Merchant, Gloria Orenstein, Val Plumwood, Rosemary Radford Ruether, Ariel Salleh, Vandana Shiva, Charlene Spretnak, Mary Stange, Starhawk, Alice Walker, and Karen J. Warren. The United Nations Decade for Women (1975–1985) and other international initiatives by the UN and other organizations have contributed to the development of ecofeminism as well. Today there are numerous monographs, anthologies, book series, journals, websites, conferences and conference sessions on ecofeminism. However, ecofeminism has been criticized by many, including both feminists and ecofeminists, on various grounds, such as for essentializing the connection between women and nature, idealizing women in non-Western cultures, appropriating indigenous religious rituals, dividing academics and activists, and alienating ecofeminists from feminists and vice versa.

To take a particular example, the Chipko movement in the Himalayan foothills of northern India is one of the earliest political initiatives by women concerned about the environment. Many villages in India have long depended on local forests as a major source of food, fuel, fodder, materials,

Ecofeminism has been criticized by many, including both feminists and ecofeminists, for being divisive.

medicines, and spirituality. However, beginning in the 1970s, women who had been temporarily left behind in the village as men sought employment beyond had to defend their precious forests from outside loggers encouraged by government agencies. The women adopted Gandhian methods of nonviolent resistance by joining hands to encircle and thereby protect trees. The loggers were intimidated and withdrew. The Chipko movement led to the development of government policies on natural resources that were more sensitive to the concerns of local people. It has been recognized in India and internationally for preventing the deforestation of substantial areas of the country.

GREEN BELT MOVEMENT

Another specific case is the national tree planting campaign in Kenya called the Green Belt Movement. It was created by Wangari Maathai in 1977. The National Council of Women of Kenya distributes seeds and seedlings, coordinates, monitors, and assesses local programs. Local women provide free labor in the daily management of the seed collection, quality control, planting, seedling care, and marketing. They plant and maintain small plots of trees adjacent to villages, farms, homes, and schools. In the process, they become skilled foresters, earn extra cash income, elevate their social status, participate in environmental education, and meet the needs of themselves and their families. This grass roots ecofeminist movement has mobilized more than 80,000 women to take charge of their own lives, needs, and habitat through planting more than seven million trees and related activities. Children and men have also become active partners in the programs. Furthermore, planting trees helps to control soil erosion, retain soil water, and prevent desertification. The Green Belt Movement reflects an ethics of caring for other humans and for nature that emulates mothering, partnerships, and friendships as well as a deep concern for future generations. Maathai won international recognition for her environmentalist and peace activism with the award of the Nobel Peace Prize in 2004.

An additional ingredient of some ecofeminism is the women's spirituality movement that sees intimate and vital interconnections among women, nature, and the supernatural. Many consider the earth to be divine as Mother Nature or Gaia, and accordingly, she deserves reverence as well as respect, care, and love. For example, Starhawk has revitalized a variant of nature religion through her neopagan earth goddess worship. She asserts that nonhierarchy is the ethical path to perceive the interconnections and interdependencies of the living Earth. In this context, Starhawk has campaigned as an activist for many feminist, environmental, justice, and peace issues. These range from civil disobedience in anti-nuclear actions protesting the Diablo Canyon power plant and the Livermore Laboratory for research in California, to antiglobalization demonstrations at World Trade Organization meetings in Seattle, Washington, and in Genova, Italy. She has been a major influence on many environmentalists including Earth First! Since 1977 various editions of her book, *The Spirit Dance: A Rebirth of the Religion of the Great Goddess* have collectively sold more than 300,000 copies.

FOCUS ON GENDER

Even though ecofeminism is still in an early stage of development with limited recognition and appreciation, it has focused more attention on gender aspects of human ecology and environmentalism and promises much more in the future, as followers believe the liberation of women will contribute to the liberation of nature as well. Ecofeminism focuses on caring and nurturing human and natural interrelationships. In the process, it integrates and promotes social and environmental justice.

Today, ecofeminism operates at the intersections of the women's, environmental, and peace movements with considerable potential to integrate them and apply their concerns to improve both society and human–environment dynamics as demonstrated by the achievements of the Chipko and Greenbelt Movements. A better future for humanity and the biosphere depends on creating more cooperative, equitable, and healthy partnerships between men and women as well as between society and environment.

Ecological Footprint (EF)

"ECOLOGICAL FOOTPRINT" (EF) refers to a system of measurement developed for estimating human appropriation of ecological resources relative to biologically productive (bioproductive) land area. EFs can show how much land is needed to sustainably support a human population, nation, or a specific component of society, such as a commodity (e.g., soybeans), transportation system (e.g., auto transit), or lifestyle (i.e., a consumption pattern). The utility of footprint analysis (FA) is best understood by considering the ecology of a modern city. Urban inhabitants are concentrated within city bounds but they rely on the importation of resources and exportation of wastes to survive.

Therefore, the land area necessary to produce resources and absorb wastes far exceeds the actual geographic boundaries of the city (or nation)—in wealthy nations ecological flows may be distributed across the planet. FA provides a framework for tracking these resource and waste flows and converting them into a common metric—land area (hectares) per capita—by making use of widely available economic statistics.

The calculation of an EF is based on two key assumptions. First, it is possible to reasonably track most human resource consumption and waste generation, and translate these flows into bioproductive land areas. Second, it is possible to standardize varying land areas by weighting each according to their "potential biomass productivity." The latter refers to production potential that is of economic interest to society, not the diverse assemblage of other organisms necessary for human survival, or biodiversity. Biodiversity is included in national and global analyses but there is much debate over how much land must be set aside. (Estimates range from 8 to 75 percent; in practice, the conservative World Commission on Environment and Development [WCED] estimate of 12 percent of bioproductive land is simply added to the footprint total for the given social unit.) EFs omit resource uses for which conversions into bioproductive land are difficult, such as the impact of local fresh water use, as well as any impact that systematically reduces the ability of ecosystems to regenerate, such as the release of nonassimilable and/or bioaccumulating chemicals (e.g., uranium, polychlorinated biphenyls [PCBs], and mercury).

STANDARDIZATION MEASURES

The novelty of FA is in standardizing resource and waste flows in terms of bioproductive land area, instead of creating arbitrary indices or lumping together ecological and social factors. This requires analysts to distinguish between the quality of land types depending on their level of productivity. For instance, *arable land* is the most productive and is used for staple crops, such as wheat and corn. *Pasture land* is unable to support staple crops and used primarily for grazing. While pasture also produces food for human consumption, the biochemical conversion from plants to meat represents significant energy loss (a factor of 10).

Forest land represents tree farms or forests yielding timber. *Built* or *degraded land* is productive land lost to roads, buildings, and other structures. Built land is considered formerly productive because human settlement patterns indicate that arable land is ruined to accommodate infrastructure. Other types of land included are *productive sea space*, *energy* *land*, and *biodiversity land*. When calculating a footprint, resource and waste flows are first converted into one of the above land areas (in hectares) and then scaled by multiplying by an *equivalence factor* (EQ), also in hectares. EQs express differences in land productivity compared to world average productivity (e.g., in 1999 arable land had an EQ of 2.1 and pasture land 0.5). World average productivity, and consequently the productivity of each above land type, is recomputed each year to account for reductions in resource stocks, such as desertification, fishery collapse, urbanization, and so on.

Taking the example of a typical North American barbecue meal—steak, potatoes, and paper cups and plates—we can see how an EF is calculated. The steak and potatoes require pasture land for grazing, arable land to grow the potatoes, energy for fertilizer, transportation, processing, storage, and cooking, and built land for roads and buildings to transport and store the food. The paper products require forest land for production and have similar energy requirements except that the paper must either be disposed of or recycled, requiring more energy and/or land to store the waste. After each production and waste flow of the meal is converted into the appropriate land type and multiplied by the associated EQ, all of the components are summed. This gives the total EF for the meal, which might then be compared to the world average footprint for a typical meal.

Clearly, EFs can get extremely complicated, especially when doing a *component-based* calculation, as in the latter example. William Rees, who coined the phrase *ecological footprint,* notes the pedagogical utility of component-based analysis. Rees's former student and collaborator, Mathis Wackernagel, emphasizes that the more robust *compound* calculation, which takes the nation-state as its unit of analysis, achieves the central purpose of the tool: "providing a big picture analysis to put the various competing human uses of the biosphere in each other's context." While national EFs may seem even more complicated, economic data for all countries is readily available through the United Nations, and as Wackernagel and Rees note, the inclusion of every possible impact is unnecessary: "there is virtue in accurate simplicity," especially considering the complexity of ecosystem functions. Wackernagel's team has calculated national EFs for most countries back to 1960. This longitudinal analysis reveals that, excluding a conservative set aside for biodiversity, humanity's ecological demand exceeded the earth's regenerative capacity around 1980 (1970 with a biodiversity allocation). By 1999, humanity exceeded earth's capacity by 20 percent. This *overshoot*—a concept William Catton popularized and that served as an inspiration for the development of EFs—is possible because EF calculations acknowledge that populations can indeed grow beyond their carrying capacity, but they will eventually feel the effects of critical resource loss.

Wackernagel and Rees theorized EFs as a direct intervention into debates over sustainability, and particularly as a criticism of traditional economic modeling and the use of monetary equivalents for assessing sustainability (i.e., "pricing" or privatizing nature as a solution). FA implies that traditional economic models do not adequately account for biophysical limits, efficient resource use, ecologically realistic pricing, or intra- and inter-generational equity. By distinguishing human and environmental welfare, EFs provide much-needed conceptual clarity for social researchers. Indeed, the use of EFs within the social sciences is widespread and stimulating vigorous debate over the future of social organization.

Ecological Imperialism

A CORE PREMISE of *ecological imperialism* is that the success of European colonial settlement is due at least as much to nonhuman forces, including plants, animals and pathogens introduced both deliberately and inadvertently, as it is to military, political, economic, and demographic incursions. The term has been developed most fully by Alfred W. Crosby in *Ecological Imperialism: The Biological Expansion of Europe, 900–1900,* an erudite environmental history of the relationships between ecology and European colonialism.

Crosby explores the concept to explain successful European population expansion into particular regions of the world he labels *Neo-Europes*. These areas include temperate zones of North America, South America, New Zealand, and Australia that—while oceans away from Europe—contain comparable climates in which European plants, animals, and diseases could successfully establish. In contrast, European colonial settlements generally failed in regions with tropical climates less suitable for European species and with more virulent diseases.

IMPORT INTO NEO-EUROPES

Along with new technologies, colonists brought to the Neo-Europes what Crosby cals a "grunting, lowing, neighing, crowing, chirping, snarling, buzzing, self-replicating and world-altering avalanche" that collectively supported vast ecological and social transformations. The previously unidentified, yet most important ally, of the Neo-European invaders was their portmanteau biota, "… fellow life forms, their extended family of plants, animals, and microlife…first domesticated or…first adapted to living with humans in the hearthlands of Old World civilization." Successful conquest occurred in those places with ecological similarities to western and northern Europe. "Where the portmanteau biota 'worked,' where enough of its members prospered and propagated to create versions of Europe, however incomplete and distorted, Europeans themselves prospered and propagated."

Weeds, for instance, were of vital importance to the establishment of Neo-Europes. "The exotic plants saved newly bared topsoil from water and wind erosion and from baking in the sun. And the weeds often became essential feed for exotic livestock, as these in turn were for their masters." Domesticated animals "adapted marvelously well to the Neo-Europe" with their ability to "alter environments, even continental environments, …[better than] any machine we have thus far devised." Germs, too, were of immense significance. "It was their germs, not these imperialists themselves, for all their brutality and callousness, that were chiefly responsible for sweeping aside the indigenes and opening the Neo-Europes to demographic takeover," Crosby states. Through years of isolation, indigenous peoples had their own infections (e.g., hepatitis and polio amongst Native Americans; trachoma amongst Australia's aborigines) but they had had no experience of the wide range of Old World ailments such as chicken pox, smallpox, cholera, and influenza, which were to decimate them. Indeed, Crosby suggests that smallpox may have killed up to one-third of the Australian Aboriginal population in the late 1700s. Remarkably, the flow of disease between invaders and invaded was substantially one-way, with relatively few infections and ailments having effect on the Old World.

ASIA AND THE TROPICS

By contrast, Europeans failed to build lasting settlements in Asia and tropical Africa not only for obvious reasons of heat and humidity, but much more importantly on account of their "contact with tropical humans, their servant organisms, and attendant parasites, micro and macro." In West Africa, parasites and disease prohibited European domesticates from thriving. And in Asia, along with the plants and animals that had "existed in and around thousands of villages and cities for thousands of years there had evolved many species of germs, worms, insects, rusts, molds,…attuned to preying on humanity and its servant organisms." While Europe succeeded in exploiting these regions through colonialism, permanent settlements were rarely established. In short, successful conquest occurred in those places with ecological similarities to western and northern Europe. "Europeans and their commensal and parasitic comrades were not good at adapting to truly alien lands and climates, but they were very good at constructing new versions of Europe out of suitable real estate," Crosby states.

Crosby's exposition places the indigenes of Australia, New Zealand and North America into a more complex and controversial relationship than that encapsulated by the notion of "advanced" Europeans achieving some ecological triumph over indigenous peoples. Paul S. Martin's controversial work postulates that Stone Age hunters eliminated entire species of giant animals (such as sabretoothed tigers and giant ground sloths) in a process known as *blitzkrieg*. Crosby draws from this idea to suggest that it "…places the Amerindians, Aborigines, and Maori, on the one hand, and the European invaders, on the other, in a fresh and intellectually provocative relationship: not simply as adversaries, with the indigenes passive and the whites active, but as two waves of invaders of the same species, the first acting as shock troops, clearing the way for the second wave, with its more complicated economies and greater numbers."

EUROPEAN ASCENDANCY

The concept of ecological imperialism has been extended both temporally and spatially to further explain European ascendancy and its ecological impacts. In the preface to the second edition of *Ecological Imperialism*, Crosby makes the point that more than simply establishing different patterns of social and environmental practice, ecological imperialism provided colonial powers such as Britain, the United States, Germany, and Japan with the ecological assets that allowed them make a "quantum jump" in productivity, which consequently facilitated scientific, industrial and agricultural revolutions. With resources provided by their colonies, imperialist powers were able to start and fuel enduring industrial revolution. More controversially, in *Guns, Germs, and Steel* (1997), Jared Diamond argues that the dominant position of Europe on the stage of colonialism was due to ecological and physical characteristics of Europe and Asia; for example, that the suite of successful European domesticated animals was due to the east-west orientation of Eurasia and the lack of physical barriers to the movement of technology and species.

Other uses of the term *ecological imperialism* include many accretions that link colonialism to ecological change conceptually. Johnston's interpretation emphasizes the importance of the colonists' introduction and imposition of particular forms of agricultural production and surplus distribution arrangements together with associated environmental management practices. Elsewhere, critics of international development have used the term to refer to either the disastrous impacts of current policies on or the remaining control of post-colonial ecologies.

Criticisms of Crosby's ideas have been relatively few; however, Cronon views his uncritical adoption of Martin's "blitzkrieg' theory and the lack of more explicit linkages to cultural determinants of European expansion as potential faults. Others, looking more closely at the ecology of species exchange across the Atlantic, found no inherent advantage to European species and a much more complex web of species exchange than described by Crosby. In the period from 1500–1900, plant transfers may have been more evenly balanced than Crosby suggests that "acquisition of Amerindian crop plants had a dramatic impact on 'Old World' economies and social histories." However, these criticisms remain minor corrections to Crosby's central and still compelling argument.

Ecological Modernization

ECOLOGICAL MODERNIZATION IS a diverse body of literature that has emerged from environmental sociology. It focuses on the institutional response of industrialized countries to environmental challenges. Arthur Mol understands ecological modernization to be the third wave of environmental concern and reform, following from nature conservation and limits to growth approaches. F. H. Buttel sees ecological modernization as "a new, and in many ways improved, synonym for sustainable development" and recognizes the appeal of optimism within ecological modernization, something that he contrasts with the pessimistic connotations of other approaches for "thinking about the problems of metropolitan transformative industry in the North."

According to Michael Carolan, the ecological modernization approach is said to have attained "near paradigmatic status within socioenvironmental circles," and Renato Orsato and Stewart Clegg view it as the "dominant approach in today's environmental policy, practice and theorization." Joseph Murphy's introduction to a theme issue about ecological modernization in the journal *Geoforum* said of geographers and other social scientists, "most of those working on the relationship between environment and society and focussing on the state, production and consumption are likely to be aware of it." This familiarity is also acknowledged by Buttel, who noted that "Ecological modernization was unknown to virtually all North American environmental scientists half a dozen years ago" but within a short span of time has "come to be regarded on a virtual par with some of the most longstanding and influential ideas and perspectives in environmental sociology."

DEBATE OVER ORIGIN

The origins of ecological modernization are debated. Some authors say that it is an idea that originated in the corporate sector in the United States in the 1980s, spread to Europe following the 1987 publication of *Our Common Future* (also known as the Brundtland report), and had a significant impact on national environmental planning in countries such as the Netherlands. Other authors claim that the German sociologist Joseph Huber should be credited as its founder and that the theory was first developed in a small number of western European countries, notably Germany, the Netherlands, and the United Kingdom.

The theory emerged as a critique of both neo-Malthusian approaches and neo-Marxism (which was popularly represented in debates with ecological modernists through the "treadmill of production" thesis). The ecological modernization approach does not reject industrial production and consumption processes, but accepts their inevitability and instead considers it desirable to focus on the changing character of these processes using ecological criteria as a measure of quality.

Ecological modernization is a perpetuation of the modernist values of rational thinking and the application of knowledge to problem solving. It recognizes that modern states can, if they are willing, incorporate environmental concerns into their regular activities. That is, the environment can be institutionalized and accorded similar treatment to social and economic issues. Since the mid-1990s, this approach has been increasingly challenged by multilateral trade agreements that make it more difficult for states to regulate environmental issues within their boundaries. The formation of trade blocs has also meant that the focus of ecological modernization research is no longer on national economies, but increasingly considers how environmental regulation may contribute to trade advantages for a country. The global nature of some important environmental issues and their policy responses, for example the issue of climate change, has also enabled ecological modernization to develop more of an international perspective in recent years.

THREE FACES

Peter Christoff noted that the increasing popularity of the term *ecological modernization* "derives in part from the suggestive power of its combined appeal to notions of development and modernity and to ecological critique." According to Christoff, ecological modernization has been used in three main ways: as a technical adjustment, as a policy discourse, and as a belief system.

The technical adjustment approach is often restricted to those sectors of the economy where such a change is profitable. Importantly, unless the economic gains from technical improvements in pollution control or energy use, for example, are reinvested in ecological modernization processes, then what has been created is greater capacity to have an impact upon the planet. In this version of ecological modernization, one of the ways environmental improvement (and hence economic gain in most cases) is achieved is through the adoption of a systems approach to resources, energy, and waste. It has similarities with the industrial ecology approach to improving environmental outcomes of production and consumption processes. Arthur Mol and David Sonnenfeld identify the early writings of authors such as Joseph Huber as being "characterised by a heavy emphasis on the role of technological innovations in environmental reform, especially in the sphere of industrial production." They indicate that from the late 1980s to the mid-1990s, the influence of technological innovation declined relative to institutional dynamics and cultural dynamics in the ecological modernization literature.

The policy discourse version of ecological modernization is most clearly represented in the writings of Albert Weale and Maarten Hajer. Similar to the corporate perspective, the key ideas of this version of ecological modernization are that economic growth and environmental responsibility are not irreconcilable, and in fact they make good economic sense for three reasons. First, improved environmental technology can generate economic savings that benefit a corporation financially, but also an urban area, state, country, or the world. Second, governments that enforce more stringent environmental regulations and encourage technological development to meet these regulations become the leaders in a sector and are able to establish valuable new industries that can earn export income. Third, there is a public relations benefit as these countries are able to project themselves as being environmentally responsible global citizens. Again, the change in policy is incremental and does not require the overthrow of existing political and economic structures.

A more radical approach is the concept of ecological modernization as a belief system. In this approach, rather than being a policy discourse to maintain existing economic relationships but to make them "greener," ecological modernization is a challenge to the market-based emphasis on efficiency. Carolan is particularly critical of the emphasis on efficiency and argues that it does not necessarily lead to sustainability. The idea of environmental modernization as a belief system is what Christoff identifies as being *strong* ecological modernization. In contrast, the *weak* version of ecological modernization Christoff identifies perpetuates existing relationships and narrow, technological-oriented thinking. This distinction is also employed by George Gonzalez to highlight the perceived limitations of the approach to climate change by the World Business Council for Sustainable Development and the International Chamber of Commerce. In this example, "these groups propose to reform the operation of capitalism through the development and deployment of technology rather than by promoting environmentally sensitive land management planning techniques." From an ecological perspective, the strong approach will likely generate the greatest ecological benefits. From cultural and economic perspectives, the implementation of a strong version of ecological modernization is fraught with challenges because it does require genuine, meaningful, and lasting change.

OTHER PERSPECTIVES

It is debatable whether the strong version of ecological modernization is really ecological modernization at all. This debate centers on who gets to define the terminology and the parameters of an idea. Depending on who is doing the labeling, the strong version of ecological modernization either refers to broad changes to institutional structures in society, democratic decision making, and an open approach to the environment and economy relationship based on what David Gibbs calls "multiple possibilities with ecological modernisation providing orientation" or it appears to include elements of neo-Marxist, neo-Malthusian and limits-to-growth thinking. While some authors see it as a strand of ecological modernization theory, it could also be interpreted as a conflicting theory or theories. This is apparent in debates between Michael Carolan on the one hand and Arthur Mol and Gert Spaargaren on the other. Ecological modernization is essentially an incremental and reformist approach, and the strong version of ecological modernization calls for more fundamental changes.

A notable attempt at bridging these divides is found in the work of Orsato and Clegg in their notions of *radical reformism* and "*critical Ecological Modernization.* These authors argue that in order to make ecological modernization a progressive force for moving toward sustainability, it is necessary that radical technological changes be made. This is often not possible unless incremental institutional changes are made, an approach that contrasts with the strong version of ecological modernization that calls for radical institutional change. According to these authors, "radical technological innovations and incremental institutional reform, together, constitute the concept of *radical reformism,* which may have important implications for the development of ecological modernization theory and its normative application."

Environmental improvement is achieved partly through a systems approach to resources, energy, and waste.

FUTURE TRENDS

Traditionally, the challenges to the ecological modernization approach have mainly come from neo-Marxists ("treadmill of production" literature) and from authors concerned about limits to growth. These approaches are predominantly concerned with physical conditions. The recent work of Mol and Spaargaren attempts to move beyond these debates by incorporating ideas from what John Urry describes as a *sociology of flows* into the ecological modernization literature. This would enable the literature to develop a more multinational approach as it questions the ability of states to regulate flows of money, capital, people, and material substances, but there is a tension about the issue of control and how much planned change can effectively be implemented in the contemporary world. This tension between the modernism inherent in ecological modernization (which is similar to neo-Marxist and deindustrialization approaches in this regard) and the recognition, and sometimes celebration, of chaos in postmodern approaches is likely to be one of the important debates within the ecological modernization literature in the near future.

The usefulness of ecological modernization is still being debated. As Gibbs noted, while it may offer some hope for better environmental outcomes, the concept "can equally serve as a cover for *business-as-usual* with a slight green tinge." This partly depends on what one perceives as being useful, and whether the perceived limitations of various strands of ecological modernization can be overcome or if they are inherent and intractable. Various options for strengthening the body of literature to overcome perceived shortcomings include bringing in notions of strategic capacities, structural frameworks, and the role of actors and notions of embedded autonomy, civil society, and state–society synergy theories derived from the Weberian tradition. Ecological modernization is likely to be developed into the future as academics and policymakers continue to articulate nature–society–economy relationships in ways that are at least more environmentally benign than previous versions of these relations.

Ecology

ECOLOGY IS THE study of the patterns and processes governing the abundance and distribution of organisms and their relationships to their environment. The environment includes abiotic factors—such as the soils, geology, sunlight, climate, and other physical and chemical factors—as well as biotic factors, such as other organisms within the same or neighboring habitats. The term *ecology* derives from *oekologie*, first coined in 1866 by the biologist Ernst Haeckel, joining the Greek *oikos*, or household, and *logos*, or study. The field of ecology combines diverse scientific traditions from natural history, experimentation, field study and mathematical modeling to advance our understanding of the processes and patterns maintaining and altering biodiversity. As a *positive* science, ecology does not make *a priori* value judgments; nevertheless, it is strongly associated with the normative goals of modern environmentalism that ascribe a fundamental intrinsic and utilitarian value to nature. As such, ecological research and study is a key component of conservation biology, concerned with understanding and protecting biological diversity at multiple scales.

Ecology is a broad field that encompasses several thematic, areal, hierarchical, systematic, and methodological foci and traditions. For instance, distinct thematic/areal traditions are reflected in tropical ecology, desert ecology, freshwater ecology, marine ecology, and so on. Distinct hierarchical scales of biodiversity correspond to behavioral ecology (individual adaptations), autecology (populations of one species), synecology (communities of multiple species), and landscape ecology (structure, composition and function of landscapes). Disciplinary and methodological approaches define chemical ecology, genetic ecology, mathematical/theoretical ecology, statistical ecology, spatial ecology, and evolutionary ecology. These distinct traditions are not mutually exclusive, but often overlap in significant ways and have evolved over time.

HISTORY OF ECOLOGICAL THOUGHT

The history of ecological thought, like that of the field of conservation biology, traces back several centuries. The earliest formal practice of ecological research on the relationship between organisms and their environment dates to the botanist Alexander von Humboldt, who in the early 19th century, described the relationship between plant distributions and regional climates. His work was followed by the publication of Charles Darwin's *The Origin of Species* in the mid 1800s, postulating an evolutionary, *mechanistic* perspective for ecology that departed from its earlier, descriptive focus. As developments in ecology continued over the next several decades, advances were made in the understanding of global bio-geochemical cycles (e.g., the nitrogen cycle); and the term *biosphere* came to be coined in 1875 by geologist Eduard Suess, to refer to that global sphere where the biota interacts with the lithosphere, atmosphere and hydrosphere. Such dynamic interactions were the focus of ecologists such as Henry Cowles and Frederic Clements toward the dawn of the 20th century, who established a tradition known as "dynamic ecology." In the coastal dunes of the Great Lakes and the western prairies of the United States, respectively, Cowles and Clement examined the process of *ecological succession*, the sequence of ecological changes following a disturbance. Succession is the process by which an ecological community progresses over time from an initial, simple state to a latter, complex state as the system approached a stable equilibrium (sometimes called homeostasis). The change in the overall ecological community over time reflects, among other things, the loss and gain of individual species. A disturbance; such as wind damage, opening up of a forest gap by treefall, plowing of a field, creation of a patch by waves in an inter-tidal zone, or a rainfall event that creates an ephemeral pool, creates new localized habitats for different species to colonize and exploit. According to *successional theory*, early colonizers or invaders tend to be those that are best adapted to reproduce rapidly and quickly colonize the new habitat, and typically have high reproductive rates and small life spans. Such species are often referred to as r–strategists. During later stages in the successional sequence, r–strategists are gradually replaced by species that are slower to exploit the initial post-disturbance conditions, but are better adapted to continuing a viable population in the long term at or near the system's carrying capacity. Such slow-growing species are often referred to as K–strategists. According to strict Clementsian interpretation, most successional patches (*seres*) in a given locality will tend eventually toward a particular assemblage of "climax" species (i.e., a "monoclimax") at the conclusion of the successional sequence, even when those *seres* reflect different stages in the successional series. The role of humans in ecological processes was viewed in a negative light, as interfering with the processes of natural succession.

The ecologist Arthur Tansley often acknowledged the significance of the work of Cowles and Clements, and yet, disagreed with the Clementsian notion of a monoclimax. He argued instead that environmental gradients and varying disturbance regimes within a climatic zone meant that later successional stages would support not a single but multiple climax communities. He took further issue with the uniformly negative portrayal of human agency in ecological dynamics, suggesting instead that human–nature interactions gave rise to anthropogenic climax communities (such as agro–ecosystems). In 1935, Tansley introduced the term *ecosystem* to refer to the interacting system formed by biota with its environment. His models were strongly influenced by emerging ideas about systems and fields in physics at that time, and suggested that organisms could best be studied as interacting components of (bio)physical systems. This method of ecological study, one that focuses on calibrating and understanding the behavior of the system's component to understand system behavior, is sometimes referred to as a *tactical* approach. The ecosystem concept was subsequently adopted and elaborated by Eugene Odum, often referred to as the father of modern ecology.

In 1953, Eugene Odum and his brother, Howard Odum, jointly authored the first definitive textbook on modern ecology, established ecology as a bona fide academic discipline and educated the first generations of ecosystem ecologists in North America. Eugene Odum was also an early developer of the *strategic* ecosystem approach to studying ecological communities, maintaining that in order to understand system functioning, it is most expedient to focus on the essence or key aspects of the system's overall behavior rather than its components in all their detail. Odum applied the strategic ecosystem approach to ecological communities in their successional paths, theorizing that older, more advanced communities should contribute to overall ecosystem stability, or homeostasis, securing protection against environmental disturbances.

THE RISE OF THE ECOSYSTEM CONCEPT

Other developments preceded and paralleled the rise of the ecosystem concept in ecology. Charles Elton expanded on the ecological form (structure) and function that exists at any given time in a successional sequence, rather than the process of change over time. In 1927, Elton proposed a set of principles in his text *Animal Ecology* that aimed to explain an organization of ecological communities focused upon the food chain and laid the foundation for present thinking on trophic interactions. Elton's food chain consisted of the photosynthetic conversion of solar energy as the first link with herbivores and predators making up the remaining two or three links, and ascribed distinct roles to plant and animal species as producers, consumers, decomposers, etc. Elton also proposed the pyramidal structure of the food chain in considering how the size and populations of a species (as food or consumer) relate to its position in the pyramid (e.g., smaller populations of slowly reproducing, large predators such as whales depend upon larger numbers of rapidly reproducing, tiny zooplankton). Finally, Elton proposed the idea of the ecological niche as the function of a species in a community, maintaining that no two species in a community could occupy the exact same niche because of competitive exclusion.

Elton, Tansley, the Odums and other ecologists influenced by developments in physics turned to the second law of thermodynamics to focus on the flow of materials (e.g., food/nutrients and water) and energy through ecosystems, and further unified the consideration of biotic and abiotic components in ecology. There were attempts to merge lessons from trophic structure and ecosystem function. For instance, Raymond Lindeman and others studied the productivity of each trophic level and the efficiency of the transfer of energy from one level to the next in order to understand the functioning of entire ecosystems. Ecosystem function began to be quantified and measured in energy units. For instance, the net primary productivity (NPP) of diverse natural and human–modified ecosystems is calculated and compared to assess aspects of ecosystem function, such as carbon sequestration (the rate at that carbon dioxide is photosynthetically removed from the atmosphere).

Several systems ecologists now include humans as part of an expanded ecosystem, the ecological–economic system. The Odums's unified theory of ecosystems as applied to ecological succession also postulated, similar to Clements, a stable, homeostatic system that expended less energy on production (therefore maintaining steady biomass) and more on ensuring stability in the face of environmental fluctuations. Unlike Clements, the new homeostasis entailed a dynamic and open ecosystem that could theoretically allow periodic flows of organisms, materials and energy across its boundaries. The Odums and subsequent ecosystem ecologists became the foremost proponents of ecosystem-focused science in the 1960s and 1970s, engaging in large-scale research projects in diverse biomes such as grasslands, deciduous forests, tropical forests, etc. to advance theoretical understanding. From a policy perspective, many ecosystem ecologists advanced the preservation of nature untouched, as far as possible, by the human hand.

COMMUNICATION AND POPULATION

Although systems ecology provides a holistic framework for the consideration of ecosystems, community and population ecology continue to be important approaches to understanding species diversity, distribution and turnover. Proponents of population ecology such as Robert MacArthur argued that *unified ecosystem theory* failed to generate testable hypotheses, producing instead abstractions that were not very useful for disciplinary advancement. Autecology and synecology play critical roles in the field of conservation biology, which is concerned with the conservation of species and other higher levels of biotic diversity. Population ecology (autecology) focuses on demographic patterns and changes, geographic distribution of species abundances and the processes that influence such patterns.

Among such processes are competition, predation, dispersal and extinctions. MacArthur and his research colleague Edward O. Wilson conducted studies of species diversity on islands in the Caribbean and the results of their work formed the basis for their theory of island biogeography published in 1967. According to *island biogeography theory*, the equilibrium number of species on an island is a function of the island's size and its distance from the mainland. An island's size has a well-established relationship to the numbers of species it can support: species are more likely to undergo extinctions on smaller islands; larger islands therefore typically retain higher numbers of species. An island's distance from the mainland influences the rate of immigration of species from the mainland. With increasing island size or decreasing distance from the mainland—or both—the rate of species increase drops off after some point, and species richness reaches an equilibrium. The theory of island biogeography is explicitly linked to the *metapopulation* concept in ecology in drawing attention not only to populations in individual patches, but also toward how those patches and their populations are connected in space and time to form a metapopulation. *Island biogeography theory* has been applied extensively in the field of conservation biology and reserve design (wherein reserves may be viewed as islands supporting species richness) and has inspired much debate about the relative biodiversity merits of single large or several small (SLOSS) reserves.

Photosynthetic conversion of solar energy was the first link in Elton's food chain; herbivores and predators rose next.

Population ecology examines the geographic range of populations (individuals of a species within a local area) as influenced by that of suitable habitat, and focuses on population dispersion (e.g., clumped, evenly spaced or random spacing of individuals), dispersal and mortality as functions of spatial variation in habitat quality and quantity, as well as of biotic interactions. The structure of a population includes the density and spatial distribution of its individuals, proportions in various age classes, and the change in each of those variables over time.

The Poisson distribution is often used to analyze spatial patterns in population data and reveal the density of populations in a given area. Local populations may interact with one another, forming metapopulations residing in a network of source and sink populations. Certain habitats may be resource rich, enabling higher reproduction rates than can be maintained in the area, forming a source population that may emigrate to lower-quality habitats that house sink populations. Processes of emigration and immigration are captured mathematically in dispersal models. Population models differ based on whether they assume seasonal or continuous reproduction, and whether or not generations may overlap. According to many equilibrium models, population increase may be regulated by factors that are density-dependent (e.g., food availability, predation, disease) or density-independent (e.g., temperature, rainfall). Prevailing theories diverge from equilibrium assumptions, focusing instead on demographic stochasticity (random variation in birth and death rates) and environmental stochasticity (random environmental variability). Developments in *metapopulation theory* afford some room for the integration of equilibrium-based population dynamics models with demographic and environmental stochasticity.

GENETIC STRUCTURE: DNA

The genetic structure of a population is studied using modern techniques of DNA analysis. Small populations are particularly vulnerable to the loss of genetic variation through inbreeding and genetic drift—often referred to as a *population bottleneck*—such as that experienced by the small, genetically uniform populations of cheetahs in Africa. Concepts such as effective population size and minimum viable population size derive from population ecology and are of particular interest in conservation biology; they relate to how large a population has to be to avoid the loss of genetic diversity and survive for a specified time.

Species interactions in ecology are generally of four kinds: competitive, predator-prey (or consumer-resource), detritivore-detritus, and mutualism interactions. Competitive relations in particular have long been a strong focus in evolutionary ecological theory. Competition can occur over resources such as space, nutrients and water, and through physical or chemical means. Charles Darwin's theory of natural selection focuses on intra-specific competition, wherein those organisms with traits that result in a competitive (and therefore reproductive) advantage are those that are selected for and prevail. Intra-specific competition is thus related to population regulation and evolutionary change. At the inter-specific level, species that are the best performers in an intense competition for limited resources tend to survive, while those that are poor competitors adapt or perish. Such competition may therefore affect community structure and composition. Experiments by Tansley and others mustered support for the importance of inter-specific competition in determining the presence of absence of a species, although the results were mediated by environmental conditions. Garrett Hardin's principle of competitive exclusion predicts that two competing species cannot coexist on a single limiting resource. The ornithologist David Lack observed, however, that several species with similar ecological needs did, in fact coexist in natural settings, and hypothesized that species may evolve to co-exist within the same habitat by diverging in their ecological needs and thereby reducing competition. Coexistence among competitors is also enabled by disturbance regimes that effectively maintain fluctuating environmental conditions (i.e., a nonequilibrium system) and prevent competitive exclusion.

Coevolution is said to occur when two species not only coexist, but evolve in a reciprocal manner in response to each other's characteristics, such as yucca plants and their insect pollinators. However, *coevolution* is usually investigated amongst local populations of interacting species. Local variation in environmental conditions means that species may interact in different ways in different populations, and therefore a coevolutionary response may be specific to two particular populations of the interacting species, rather than the two species in general across their entire ranges. The choice of spatial scale, therefore, is critical to the study of coevolutionary interactions.

Predator-prey relationships in population ecology are perhaps best summarized in the work of

Alfred Lotka, Vito Volterra, Georgii Gause and others, who tried to describe though experimentation and mathematical equations how populations of interacting species—such as a predator and a prey—reached a stable equilibrium. Predators may drive prey populations extinct, or in the presence of spatially distributed prey refuges and/or additional (source) populations of predators, result in alternative outcomes. Predator-prey relations are often considered density-dependent: increases in prey density can positively affect predator populations by improving their growth and/or immigration rates; however, the greatest number of predators is supported at an intermediate prey density, at which the prey population reaches its maximum recruitment rate. Similar mathematical formulations have been derived for other types of interactions, such as parasitoid-host interactions.

THE ROLE OF SPATIAL PATTERN

The role of spatial pattern is critical in population and *metapopulation* dynamics. The patchiness of resources, habitats and populations of predator, prey, parasite and/or host populations strongly structures processes of interaction within a local patch and across its surrounding regional context or landscape. The field of landscape ecology is distinctive for its explicit focus on spatial pattern and its implications for ecological processes. In other words, landscape ecology deals with how the structure and composition of the landscape drives the ecological patterns and processes at various hierarchical scales (e.g., organisms, populations, species, communities and ecosystems). Strongly influenced by applied fields such as forestry, landscape architecture and agriculture, landscape ecology has straddled the divide between basic and applied ecological research since its consolidation in the early 1980s. In its initial phases, landscape ecology focused on developing techniques for the quantification and scaling of spatial pattern. These efforts produced a vast array of metrics to describe the spatial arrangement of habitat patches, such as fragmentation, fractal dimension, connectivity, and contagion, as well as techniques to determine the appropriate scale at which pattern-process relationships of interest could be analyzed and correlated. With the maturation of the discipline came a more concerted effort to conduct pattern-process experiments at the landscape scale, and develop insights bridging with other long-standing ecological traditions and theories.

Because ecological questions are posed and analyzed within a broad scale, landscape ecology offers an interesting opportunity to synthesize insights from multiple ecological traditions, including theoretical and behavioral ecology, community and metapopulations, genetics and evolutionary ecology and ecosystems research. In addition, landscape ecology affords a ready interface for collaboration with other (non-ecological) disciplines and applied traditions, particularly; geography, environmental science, regional and land-use planning, photogrammetry, remote sensing and geographic information science, restoration ecology, conservation biology and wildlife management, watershed management, forestry and landscape architecture, and global environmental change—including climate change as well as land use/cover change.

LANDSCAPE HETEROGENEITY

The basic components of landscape heterogeneity include the patch, boundary/edge/ecotone and mosaic, while relevant processes may be those that define or affect disturbance, fragmentation, and connectivity. Patches are landscape units that may be considered relatively homogenous for purposes of study and analysis, and can change in area, shape, and quality over time. Boundaries or edges refer to the area of transition between two dissimilar environments (or between a patch and its surroundings, sometimes referred to as the matrix). An ecotone is typically an edge area as well, but is used to denote the varying gradient of environmental conditions in the transitional zone.

Ecotones can be sharp or gradual. The numbers of different types of patches, their relative size, shape and abundance, and their spatial arrangement (e.g., average distance between patches) together define the structure and composition of the landscape; a landscape mosaic in particular refers to a collection of patches. Landscape function refers to the interaction of landscape components and the flow of organisms, materials, and energy through the landscape.

The issue of hierarchy, scale (extent, map scale, spatial resolution or minimum mapping unit, and temporal scale), and scalar dynamics comprise important concerns in landscape ecology. Different sets of ecological criteria matter at distinct hierarchical scales. Kotliar and Wiens demonstrated, for example, that insects used different sets of criteria to select a leaf vs. a tree or patch. Studies have found that relationships between spatial pattern and process at one scale of analysis are typically not generalizable to other scales (e.g., the ecological fallacy). Landscape-scale simulation modeling experiments and percolation theory suggest critical thresholds at which particular ecological processes, such as colonization by an invasive species, or a disturbance such as fire, will spread across the landscape. Theories from population ecology, such as *island biogeography theory* or mathematical models of *metapopulation theory* have long focused on spatial heterogeneity in patchy environments, and are particularly relevant for landscape ecology. Perhaps the most interesting examples of theoretical development in landscape ecology derived from its engagement with social science theories of land use and landscape change.

Competition of the species in an ecological area can occur over resources such as space, nutrients, and water.

For instance, research in the Human Dimensions of Global Environmental Change has conducted landscape ecological studies integrating geographic, sociological and anthropological theories of human decision-making strategies, explaining and predicting deforestation and other land use transformations in tropical forests and other environments. It is precisely owing to its analytical focus on spatial heterogeneity and disturbance, and its broad synthetic scope including human roles in ecological systems that landscape ecology has particular relevance for conservation biology and land use planning. Insights into how disturbance maintains or alters landscape structure and function, biodiversity and ecosystem stability and resilience are relevant for conservation planning and reserve design. It is far more ecologically and economically feasible to manage disturbance regimes rather than restore landscapes or ecosystems after dramatic degradation.

Most ecological studies employ theoretical, mechanistic or empirical/statistical models in order to explicate the pattern-process relationships of interest in a given region or ecosystem. Models can range from simple abstractions that capture only essential elements of systems, to complex models with detailed specifications and multiple parameters that aim to accurately replicate and predict system interactions. Mechanistic models are built on a causal or process-based understanding of a system, particularly useful for scenario testing and impact assessments, but prone to problems of calibration and validation as well as to oversimplifying reality. Statistical models, on the other hand, are based on empirical data, but may capture only correlations rather than causal relationships. Most landscape ecological models today are spatially explicit, meaning that they use spatially referenced datasets, such as those derived from satellite imagery and/or maps and geographic information systems. Aside from the relative strengths and weaknesses of the modeling approach itself, models are also limited by the quality of the data. For instance, seasonal changes in highly local land uses in a tropical forest–agriculture mosaic may be difficult to derive in sufficient detail from satellite imagery, since it is often difficult to obtain cloud-free scenes in such areas. More frequent imagery, such as that provided by the Moderate Resolution Imaging SpectroRadiometer (MODIS) or the Advanced Very High Resolution Radiometer (AVHRR), may not offer data at a fine enough pixel resolution for detecting activity. Other limitations may include insufficient or inappropriate thematic resolution, spatial resolution, accuracy and uncertainty, and mismatch between social and ecological spatial variables.

The traditions in ecology constitute complementary and sometimes contradictory approaches to understanding the patterns of distribution of biological diversity and the processes that explain that distribution. They contribute to fundamental ecological concepts regarding ecosystems; the structure, composition and functioning of ecological systems; the biotic and abiotic determinants of change, stability, resilience and productivity; concepts of equilibria versus nonequilibria; and the effects of spatial heterogeneity on ecological processes. These and other insights from ecology are brought to bear upon the contemporary problem of global biodiversity loss, altered biogeochemical cycles and transforming climate regimes—all aspects of global environmental change.

ECOLOGY MOVEMENTS

Ecology's general identification with the study and valuation of nature, moreover, makes it a common if sometimes unwilling ally in the modern environmental movement since the 1960s. The social movement, as distinct from the scientific ecological tradition, has been influenced by conservation ideas and philosophies dating back at least two centuries, and is fueled by a publicly perceived global crisis of environmental contamination and species extinctions. The publication of Rachel Carson's *Silent Spring* in the 1960s inaugurated the environmental movement in the West. The focus on pesticides, and other environmental contamination in the 1960s was succeeded in the 1970s, 1980s, and 1990s by concerns about the threat of nuclear disasters, acid rain, ozone depletion and its effects on human and ecological health, rising rates and extents of tropical deforestation and biodiversity loss, and climate change (including global warming). While ecology has engaged with the environmental movement through these crises, albeit in ways that lacked a unified approach or a consistent and clear set of recommendations, a strong dissonance between the scientific ecology and environmentalists revolved around the Gaia hypothesis. Certain elements of the environmental movement draw on the concept of *Gaia* proposed by the atmospheric scientist James Lovelock in the 1960s. According to this hypothesis, the biosphere is a system that self-regulates through feedback relationships and functions as a single organism. While ecologists overwhelmingly acknowledge the interactions between biotic and abiotic components of the biosphere, as well the ability of biota to alter its physical environment, they debate the concept of homeostasis implied in the Gaia hypothesis and criticize the hypothesis itself for being overly teleological.

Ecomanagerialism

COINED BY VIRGINIA Tech political science professor Timothy Luke, *eco-managerialism* refers to a particular type of environmental management carried out by "professional-technical workers" who are trained in environmental science and policy schools at Western universities, which emphasize "sound scientific and technical" solutions to environmental crises. Specifically, Luke argues that specially trained environmental *experts* define their managerial goals in relation ecosystem "goods" and "services," which necessitate a treatment of the physical environment primarily in terms of natural *resources*. This means that environmental managers, though charged with the protection and conservation of the physical environment, also protect the dominant economic and political interests that surround those resources.

This notion of ecomanagerialism favors a capitalistic and technocratic approach to environmental management, where efficiency and economic development are the primary motivations for environmental policy and management, rather than other potential solutions to environmental concerns, such as behavioral changes, economic restrictions, or alternative technologies. In essence, Luke's idea of ecomanagerialism attempts to acknowledge and understand how modern resource management has cast nature primarily as an economic and political "asset" that can only properly be managed by technical environmental experts. The physical environment, under a regime of ecomanagerialism, is valued far less for its preexisting ecological processes, than its function in the modern capitalist economy. Furthermore, the material and discursive practices of ecomanagerialism constitute a form of power that Luke refers to as "geopower," where only eco-managers are employed for resource management and to solve impending ecological crises. This requires that the goals of environmental management employed by eco-managers are defined in terms of modernization, where the average citizen is made to think that he or she cannot fully understand the complexities of the natural environment.

The basis of ecomanagerialism lies in the discursive transformation of ecological processes and systems into economic commodities or natural resources. Luke claims that this occurs in the modern research university. Here, students learn to manage, manipulate, and control nature as "a sanding reserve, a resource supply center, a waste reception site." This is essential for making nature and the physical environmental legible and comprehendible to various policy-makers and engineers, but also makes the physical world politically relevant (in so far as it has economic and social services). Drawing on Foucault's notions of discourse, power, and knowledge, Luke claims that these eco-managers, produced by schools such as Berkeley's Department of Environmental Science, Policy, and Management and the Yale School of Forestry and Environmental Studies, use nature to "legitimize many political projects" aimed at facilitating or sustaining capital accumulation. This is done through the exercise of disciplinary forms of geo-power in the modern capitalist economy held by a new class of experts, specialist, engineers, and planners. Similarly, this practice often disguises the role of the capitalist economy in creating the very environmental problems ecomangers are required to solve.

Luke identifies three primary forms of eco-managerialism, including resource managerialism (where ecosystem services are protected and supplied for economic production), risk managerialism (which calculates and oversees the amount of destruction on natural systems to sustain a minimum level of economic and social health), and recreationist managerialism (which manages the natural environment for recreational consumption as a resource, such as public parks). Luke's critique of ecomanagerialism lies in its assertion that only "positivistic technical knowledges" can be used as a means to address environmental concerns. This often excludes socially and politically based solutions to environmental concerns, which might not necessarily accelerate and facilitate capitalist accumulation. These practices not only obscure the complex and uneven power relations inherent in environmental management, but also the way in which eco-mangers inevitably reproduce themselves by reproducing the environmental crisis they are expected to solve. Ecomanagerialism is a self reproducing and expanding form of modern environmental management.

Economics

ECONOMICS IS THE exchange of resources. More particularly, it has historically been the social science that deals with the production, distribution, and consumption of goods and services. Some economic theorists also add that economics deals with the theory and practice of economic management.

Historically, economics has posited that economic activity occurs when humans engage in a transaction that involves the exchange of goods and/or services between parties. This interpretation of economic activity was adequate when the human population was low and its economic activity had only a limited impact on nature. However, modernization and technology has led people to engage in economic activity in greater numbers that has led to the destruction of vast areas in nature.

Since the 1970s, economic theories have arisen that emphasize that the nature of economic costs comes with direct and indirect consequences. Therefore, to preserve the biological diversity of the earth, and to promote economic equity alternatives, economic theories and approaches have been developed, which seek to make biodiversity central to economic activity.

For all humans, the exchange of scarce resources, both renewable and nonrenewable, is necessary for the development and maintenance of life. *Nonrenewable* resources include minerals and petroleum, which cannot be reproduced once consumed. However, where there may be no other resources, substitutes may be used if costs of extraction and processing are acceptable to consumers in the market; for example, diamonds and oil can be synthesized. However, the key issue will always be at what price.

Renewable resources are those resources that are harvested after being planted, cultivated, raised, or otherwise produced in a manner that allows for more of them to be produced from the same source. The very idea of husbandry is rooted in the idea of renewable resources. Successful farmers do not consume their seed corn or their breeding stock except in extreme emergencies. The range of human needs combined with human wants results in an economy of goods and services, which requires huge volumes of these natural resources that are is grown, caught on land or in waters, or mined.

Mined resources include minerals, inorganic building materials, soils, petroleum, and other resources that are used in building the foundation of modern industrial society. These types of resources have been produced by the geochemical processes at work in the earth's crust, and include sedimentary rocks, metamorphic rocks, and igneous rocks. They are considered *nonrenewable* resources because the geological conditions in which they were formed cannot be repeated by nature.

Granite, for example, is a hard, igneous rock that is found in abundant supply. It has been used in the past for cobblestone streets or in the building of large structures. Other types of mined, igneous rock include those rich in feldspar or other minerals.

Metamorphic rock can also be found in abundance. Large supplies of marble are used in sculpting or in buildings such as the United States Supreme Court. Marble for that structure was shipped from Alabama, Georgia, Vermont, Italy, and other places. In addition, marble can be ground to a fine powder and used in white paint or in hundreds of other products. There is a threat that due to the growing consumption of these mineral resources, its supply could one day be exhausted.

VALUES AND ECONOMIC TYPES

Economics is concerned with values. Some things have *intrinsic value*; they are valuable regardless of whether or not they have any use. *Instrumental value* is value derived from the utility of something. Diamonds are not of great intrinsic value. They are, however, of great instrumental value for romance and industry.

Generally speaking, there have been three types of economies: *barter economies, command economies,* and *market economies*. All three have been mechanisms for the exchange of goods and services. *Barter economies* were the first types of economies and still abound. They may exist in the industrial world when people trade goods or services in any number of ways. Or they may exist in the Third World, for example, when people gather honey in a forest in India to trade for meat hunted in the same forest. *Command economies* are economies in which the government directs the manufacture and/or the distribution of goods and services.

Modern wartime economies have usually been command economies. In modern times, socialist and Communist economies have been economies that have sought to establish economic justice by their power to control the production, distribution, and consumption of goods and services, and by means of "equitable" distribution of what is produced. However, all too often, socialist and Communist economies have been unsuccessful in producing goods and services as well as achieving their moral principle of equality of distribution. This moral failure has often been due to directing the production of luxuries to political forces.

Capitalism is a form of *market economy* that concentrates the means of production in the hands of a great many producers. Many scholars believe that capitalistic societies have been much more successful at creating vast quantities of goods and services than socialist or Communist societies. Those scholars believe that experience has shown in the last several centuries that people in pursuit of their own self-interest are producers of more goods and services in greater varieties and quantities than they are as producers for a system that distributes goods and services on the basis of inherent worth rather than productive success. Capitalism allows individuals to pursue their own economic self-interest. It therefore also promotes conditions of economic freedom to allow the trading of goods and services in market places without government intervention.

Socialism, Communism, and capitalism have had their political expressions as ideologies; that is, as systems of politico-economic thought. In the ideological partisanship that has been fought out in a variety of ways, partisans have often championed socialism, Communism, or capitalism in ways that have conveniently ignored real problems with these systems.

It is interesting to note that all three economic ideologies arose in the early days of the Industrial Revolution, when inhumane exploitation of the working class took place. These workers were often economic refugees from the countryside. The poor were compelled by economic necessity to toil in factories at poor wages. On the other hand, liberal exponents of the free market system were focused on those who defended economic privileges, government-authorized monopolies, or the restrictions of command economics. While addressing the human problem of economics, they ignored the nature side of economics.

NATURAL RESOURCES

The economic resources used to produce goods and services require natural resources. As a consequence, nature—and quite often humans—have been negatively impacted by ruthless exploitation of natural resources. For example, the clear-cutting of timber may have been the cheapest way to cut the most timber, but dire consequences have resulted from this method. Clear-cutting destroys the watershed so that during heavy rains, floods result, and the silting in streams kills fish and destroys habitat. Nature, and not the timber industry, pays the severe price of clear-cutting.

For centuries, individualistic market economies were able to externalize their costs of pollution and human capital costs. The same was usually true of socialist and communist societies, which were industrial societies. The pollution in the old Soviet Union was probably as bad if not worse than that in capitalist societies. Ultimately, the success of industrialization to extract ever greater resources, and its ability to manufacture huge quantities of goods, had a tremendous impact on nature. People took notice when they realized that streams in which they had once swam or fished in years before were too polluted to drink from—even if the water was boiled.

To combat the short-sighted exploitation of the environment, nature-oriented economic ideas and studies were advanced. Oddly enough, it was not concern for nature that was the first motivation.

Rather, it was the desire to rationalize markets with monopolistic control. For example, John D. Rockefeller was able to capture control of most of the oil production in the United States through his Standard Oil Company. The early days of the oil industry was centered in western Pennsylvania, Ohio, and West Virginia. The booms created many producers who pumped the oil as quickly as they could. Regard for the environment was little, if any. At times so much oil was brought to market that prices bottomed out. Excess oil was then dumped into creeks.

This form of unbridled capitalism—which was wide open to people with little or no capital—was in the end destructive. So also were the corporations mining, logging, or extracting resources without concern for the future destructive consequences. The only principle of concern was that profits were high and costs low.

Conservation was championed by President Theodore Roosevelt, a naturalist as well as an antimonopolist who supported enforcement of the Sherman Anti-Trust Act. He was began serious governmental regulation of the exploitation of nature.

THE PRICE OF NATURE

Concern for the environment has merged in recent decades with a concern for a fair distribution of economic production, to create several approaches to economics that involves the putting a price on all aspects of human engagement with nature. Biological conservation inevitably involved the making of economic decisions. In reality, all economic activity is human activity, and because it involves the exchange of values, it is also an ethical activity. This means that biological conservation seeks an ethical use of resources in such a way that resources are used responsibly and also shared equitably.

This view is concerned with preserving the biodiversity of the earth. For some, all living things have intrinsic worth. However, conservation biology is concerned more with instrumental values, especially as these can be converted into economic values. The issues concern the cost-benefit ratio of maintaining biodiversity.

Cost-benefit ratios are utilitarian in character. They seek to establish the pain, damage, destruction, or financial cost of doing something versus the pleasure or benefits derived, such as building a dam or clearing a section of tropical rainforest to farm or raise cattle. Costs involve more than the financial or resource outlays needed to dig a mine or build a refinery. Costs may be in fact much greater, because species of animals or plants are driven to extinction or reduced in number. The pollution that creates beautiful sunsets is also causing damage to the environment through acid rain to and to human health by damaging lungs.

Benefits are the goods that are derived from human actions. Goods may be tangible, such as cut logs, mined ores, or crops. Or it may be the intrinsic benefit of an unspoiled vista of nature or the peaceful silence of a place far from traffic and other human noise.

In calculating the economic values of human extractions from nature, it is important to recognize that at least one and perhaps as much as 3 billion people derive goods from the biota (the animals and plants of a region). For example, firewood is needed for heating and cooking by people who have no other resource. They may in many locations use deadfall or other combustible materials without any significant impact on the environment. However, in arid locations, their scavenging may be as destructive of the environment as the goats they herd.

Resource economics is a field of study that uses the concepts of natural resources and human resources. The field of resource economics includes the study of agricultural production, bioeconomics, community economic development, environmental economics, environmental policy studies, and resource utilization.

Environmental economics is a subfield of modern economics. It focuses on issues involving the environment, and uses the methods of neoclassical economics. It is usually distinguished from *ecological* or *green economics*. Much of its focus is on environmental policies—local, national, and global. Studies it develops are economic arguments or explanations that include the cost-benefit ratio of projects on the environment. It seeks to propose alternative environmental polices that prevent pollution as an external cost and to minimize the environmental impact of economic activities.

The concept of external cost is central to environmental economic theory because its proponents argue that the cost of goods and services cannot be determined merely by their price. Rather, the impact on the environment both in the short and long term must be included.

Ecological economics argues that economics is a subfield of ecology. This is a reversal of classic economic theory, which if it considered the environment at all would have considered ecology a minor topic of concern.

The field is also concerned with the *Tragedy of the Commons*. This concept is a model for showing how free access to common resources by individuals pursuing their self-interests will be destructive as each tries to maximize their gain, and are therefore inadequate. The claim that markets are efficient is not fully justified. Inefficiencies in the marketplace may result in market failures, requiring intervention by government to engage in the authoritative allocation of goods and services.

This idea clashes with ideas of economic liberty and property rights and with much of the historic legal doctrines of the common and civil law system. However, the right of an individual or company to pollute upstream waters has been restricted if not outright denied by the United States River Keepers Law of the 1880s. This law allows downstream users of water to seek remedies for torts caused by upstream pollution, even if the government will not or does not act.

Approaches to environmental economics are numerous. It has been a major influence in the development of natural capitalism, the basis of which is that the world and its resources are a form of capital just like the physical capital of houses, automobiles, or other values currently counted as capital in mainstream economics.

Natural capitalism is also concerned with globalization. It opposes permitting developers to use Third World resources without regard to their environmental impact. It seeks to stop profits gained by the sale of goods and services in economies that are restricting economic activity or redirecting it into more expensive technologies in order to protect the environment. Because of its critique of globalization, its participants have been associated with antiglobalization movements.

Ecological economics is either an approach to economics or a branch of economics. It incorporates the interdependence of human economies and natural ecosystems. It considers neoclassical economics as prejudiced and ineffective in meeting the challenges faced by both nature and humans. To achieve its objective of responsible economic activity, it must achieve a global common welfare with sustainable economic development. It promotes preserving biodiversity and opposes mere energy economics on the grounds that creating greater energy supplies without regard to environmental or human costs is destructive.

Green economics places the economy within the natural world as a subordinate part. It views economic transactions to include the whole of nature, rather than just the parties directly involved in the transaction. Its comprehensive approach to economics has used insights from a number of other new disciplines, including postmodernism, critical theory, ecology, and animal rights. It also uses insights from environmental economics and ecological economics. It is often associated with antiglobalization and localization theories.

In the struggle for survival, the only species with the power of exercising dominion over the earth is the human species. The power of free choice can make human economic decisions destructive or they can be exercises in stewardship.

Ecosystem

COINED IN 1935, the term *ecosystem* did not appear in titles of scientific papers until the 1940s, and was not listed in the indexing system of Biological Abstracts until 1957. Use of the term in the scientific literature did not attain wide prominence until the 1970s. The term *ecosystem* originated with English ecologist Arthur Tansley (1871–1955) in the paper: "The Use and Abuse of Vegetational Concepts and Terms," published in *Ecology* in 1935. Tansley's basic notion was that of a system that combined living organisms, the *biome*, with the physical environment. What was novel about the term to ecologists was the incorporation of the physical environment as part of the unit of study. Ecology had so far been confined to departments of biology in the academy, and was focused on community, population, and organism studies rather than the relationship between organisms and the physical environment. Thus, the key concept conveyed by the word *ecosystem* is the inclusion of the physical-chemical environment as a fundamental part of the ecological unit.

Inclusion of the physical environment by the term *ecosystem* is probably the primary aspect of the concept that nearly all ecologists agreed on, and it is still this basic concept that lies at the root of the term's definition (at least in its scientific usage). Part of what makes any discussion of the ecosystem concept problematic is that it is highly abstract. For example, *ecosystem* has often been used interchangeably with the allied concept of *community* (ideally conceived as only including the biological organisms in a particular location and their relationship with one another). As Golley states, for much of its history ecosystem studies have been "an exciting but ill-defined and poorly integrated body of science." The ecosystem concept as proposed by Tansley has been described as the machine model applied to nature. Tansley's focus was on developing the study of ecosystems along the traditional reductionist natural science model, with mathematical and experimental rigor. Tansley wanted the concept to have legitimacy as a fundamental part of natural science. However, the term soon became entangled with the holism or super-organism conception of biological communities in American and German ecological thought in the early 20th century.

EMBELLISHMENT OF THE CONCEPT

Ecologists such as Frederick Clements (1874–1945) and John Phillips conceived of ecological communities as super-organisms following a set path of development and maturation. Clements's notion of a predetermined development of ecological systems (succession) that resulted in an endpoint called a climax was compared to the growth and maturation of an organism. Although amended by ecologist Robert Whittaker in 1953, the original Clemensian notion of unspoiled nature as balanced and perfect has remained ascendant in the popular consciousness. This aspect of the concept, which was to play prominently in the development of environmentalism, suggested the notion of ecosystems striving to reach an inherent perfection that was disturbed, or thrown off course, by humans. It was a fusion of a teleological notion applied to nature with that of a supposedly scientific concept. This view had much to do with the background assumptions that led to many of the world's environmental laws and particularly protectionist laws that sought to put large areas of the planet's surface off limits to human influence.

Tansley was opposed to this embellishment of his original concept, viewing such super-organism or holism conceptions as philosophical and even theological speculation, not science. Tansley wanted the ecosystem concept to be taken seriously as a legitimate science and the study of ecosystems to be approached with standard scientific experiment and

This fusion of the holism, or super-organism concept of nature with ecosystem, has continued to the present day.

analysis, not conjectures about "emergent properties." The super-organism conception of ecosystems came out of larger cultural currents in the late 19th century. For example, concern with the disappearance of the rural, organic, peasant community because of the rapid industrialization and urbanization of Europe, as expressed by writers within the German Romantic tradition, influenced ecological thinking in the early 20th century. In her book *Ecology in the Twentieth Century*, Anna Bramwell traces this influence on ecological thought, including an analysis of how ecological holism influenced National Socialism in Germany in the 1930s where concern with the organic ties between the German people and their homeland, as expressed by the motto "blood and soil," fueled an emphasis on ecological research within the Third Reich.

This fusion of the holism, or super-organism concept of nature with ecosystem has continued to the present day, particularly among environmentalists. In this sense, ecosystem has taken the place of Mother Nature as a moniker for the totality of nature—nature as it's supposed to be; taking on precisely the moral and theological overtones that Tansley objected to. This aspect of the ecosystem concept has resulted in perhaps its most important sociological influence with respect to its dominance in popular culture, outside its original scientific venue. Since the term's inception it has carried a double valance, one being a more scientific or systems notion of the term, the other more philosophical and normative. Yet both senses of the concept often become conflated, even among ecologists.

The legacy of the ecosystem concept as envisioned by Tansley was carried forward and implemented in scientific studies by pioneering ecosystem ecologists such as Raymond Lindeman (1915–42; considered to have conducted the first ecosystem study at Cedar Bog Lake in Minnesota), Hebert Borman, Gene Likens, and Eugene and Howard Odum. Ecosystem studies became highly influenced by computer modeling, thermodynamics, and cybernetics. The dominant approach was to model the flow of energy and nutrients through a system that had semi-definite boundaries such as a lake or watershed. The diversity of organisms in these systems was simplified by the representation of trophic levels, where energy and material flow was studied with input-output models.

One of the early sources of funding for such studies was the U.S. Atomic Energy Commission (AEC). In the 1950s the AEC commissioned research on the fate of radio nucleotides in the environment as a result of atomic bomb testing and production. These studies and the funding provided a welcome boon to the fledgling field of ecosystem ecology. Early and ongoing ecosystem studies at AEC sites like the Hanford Nuclear Reservation in Washington State, and Oak Ridge National Laboratory in Tennessee, have produced an impressive body of work in ecosystem ecology. In the 1960s, the International Biological Program (IBP) funded many large-scale ecosystem studies, ushering in the heyday of computer modeling and cybernetic theory, an endeavor that did not live up to its initial expectations.

Perhaps the most well known ecosystem ecologists of the 1960s and 1970s were the Odum brothers. Howard Odum was known for his energy models of ecosystems, including his classic study of Silver Springs in Florida, and Eugene Odum, who was probably the greatest single influence on ecologists in the second half of the 20th century, author of *Fundamentals of Ecology*, which became the standard college textbook on ecological science from the 1950s through the 1970s. Howard Odum focused almost exclusively on the machine metaphor of the ecosystem, looking at energy flow and trophic level relationships of whole systems and incorporating mathematical description and computer modeling of ecosystems extensively. Eugene Odum, on the other hand, while still clearly within the natural science model of the ecosystem concept promoted by Tansley, also incorporated Clemensian conceptions that stressed determinate succession and climax states.

The ecosystem concept was also important to natural resource scientists who saw a way to make more efficient use of natural systems for the management of forestry, fisheries, and wildlife. Environmental scientists also saw utility in the concept, such as the use of wetlands for wastewater treatment. However, in a good example of institutional lag, it was the 1990s before many natural resource management agencies explicitly took on the task of managing natural resources within an ecosystem paradigm. In the early 1990s, the term *ecosystem management* was coined in an attempt to market this new emphasis in federal resource management agencies such as the U.S. Forest Service.

CONTROVERSIAL CONCEPT

The ecosystem concept has never been without controversy; not only was it poorly defined, it often took on more of the character of doctrine than science. Golley relates that ecosystem terms were often presented as pronouncements of authority, rather than scientific hypotheses to be tested, and the culture of ecosystem science tolerated little dissent. Those outside the discipline were not impressed. As Golley states, “Ecologists were not questioning the cultural paradigms, they were working within them.” By the 1980s, as the term *ecosystem* was becoming a household word in the popular culture through the spread of the environmental movement, professional ecologists were beginning to have serious doubts about the concept, and some were starting to question its relevance. A reformulation of the concept was in the making. Although controversy and debate has surrounded the concept since its inception, the reevaluation that began in the 1980s eventually took on the moniker of the new ecology.

One of the changes advocated in the reformulation of the concept was an emphasis on process and scale. Works such as *A Hierarchical Concept of Ecosystems* (1986) argued that an ecosystem is not a place or set of components somewhere between the size of a community and the biosphere, but rather denoted a set of relationships or processes that take place at multiple spatial and temporal scales, from the gut of a termite to the biosphere itself. As described by ecologists Timothy Allen and Thomas Hoekstra, ecosystems are “intangible” and consist of “pathways and processes and fluxes” that are “transformations of matter and energy” and more easily conceived as “temporally rather than spatially ordered.” Rather than something existing in nature, ecosystem is a more or less useful model of ecological phenomena that reveals some things and hides others.

Other changes that were taking place as part of the new ecology included the rise of new theories of community assembly, and rising evidence that many principles of ecosystem science lacked scientific rigor and had little empirical grounding. For example, the widely cited stability-complexity hypothesis held that complex ecosystems were more stable than simple ecosystems, even though this assertion had little empirical support. An increasing number of studies demonstrated that simple ecosystems could be very stable and complex ones highly unstable. Along with developments in systems and information theory, chaos theory, and the highly nonlinear behavior of ecosystems, led to the conclusion by many ecosystem scientists that there could be no laws in ecology. Rather than paladins of unspoiled nature and balanced perfection, ecosystem behavior was more often nonlinear, unstable, and in constant flux, with disturbance and nonequilibrium states more common than not. Ecosystems were increasingly seen as products not of nature’s design, but chance, largely dependent on the particular history of a site.

The Clemensian notion of ecological communities that had become a part of ecosystem thinking from the term's inception, along with associated ideas about equilibrium, holism, and determinate community composition, was being replaced in the 1980s and 1990s with the idea that chance and local context directed community structure. In the early 20th century, Henry Gleason (1882–1975), a contemporary of Frederick Clements, had proposed a conception of the ecological community as a random assemblage of organisms that were found together in the same place purely by chance, due to having similar requirements for climate or soil. Gleason's basic view of community structure has now largely replaced Clements's. This Gleasonian view has been formalized in a new ecological theory known as *neutral theory.* Credited largely to ecologist Stephen Hubbell, neutral theory in essence states that what organisms will be found in a particular place is simply a function of the abundance of their propagules. From the Clemensian superorganism ecosystem, science has moved closer to the view that ecosystem denotes processes that are in flux, random assemblages of components, and future development not dependent on general ecological laws, but rather the largely unpredictable idiosyncrasies of a particular site.

A PARADIGM SHIFT IN ECOLOGY

Daniel Botkin popularized what has been called the paradigm shift in ecology in the book *Discordant Harmonies: A New Ecology for the Twenty-first Century*. Ecosystems are indeterminate, unpredictable, nonlinear, and constantly in flux; there are no laws in ecology because ecosystem behavior is highly dependent on context, a condition that some have termed *all ecology is local.* Even long-term studies of a particular place have shown that generalizations are risky and that ecosystems follow indeterminate paths of change that cannot be predicted, even with many years of monitoring data. A response to the recognition of the idiosyncratic nature of ecological systems is the promotion of adaptive management among natural resource scientists. Adaptive management recognizes the failure of trying to implement broad stratagems of ecosystem use from general theory, and instead advocates a "learn as you go" philosophy, where management endeavors are carefully monitored, as well as the response of the ecological unit, so that learning can take place over time about the particularities of a given locality.

Another change occurring in parallel with the developing new paradigm in ecology was increasing interest by social scientists, particularly natural resource sociologists, in incorporating humans and the works of human culture as legitimate parts of ecosystems. Some have used the term *human ecosystem,* or *socio-biological system,* to indicate this new focus. This move to reconceptualize ecosystems as including humans and their culture is being further reinforced by environmental historians who are increasingly producing findings of the tremendous impact pre-modern humans have had on ecosystems that were once considered pristine, such as the Amazon rainforest and pre-Columbian North America.

In tandem with the new ecology, which is showing that ecosystems are not supposed to be any particular way, the latest research in environmental history is revealing an ancient dynamic interrelationship between humans and the landscapes and seascapes they inhabit. This relationship has resulted in ecosystems that are not in, or out of, some preordained configuration or balance, but simply reflect the arbitrary history of events that occurred in a particular place on the planet, whether human-caused or not.

These new developments in ecosystem science, natural resource sociology, and environmental history are revolutionizing how we understand our place in nature. This new ecosystem paradigm has implications for social policy regarding the management of natural resources and the environment. As presented in such venues as the book *Defending Illusions: Federal Protection of Ecosystems*, by Allen Fitzsimmons (1999), and at environmental law conferences, such as one held at Duke University in 1996, the conclusion is that many environmental laws that have the implicit goal of protecting some perfection in nature no longer conform to ecological science and the epistemology of the ecological or human sciences. Ecosystems are socially constructed. The ecosystem concept has its uses and insights; what it denotes and connotes will change through time, not only because of new discoveries in ecological science, but more importantly because of the different ways humans of the future will value and perceive nature. What is relevant to humans now may not be in the future; the stories we tell about nature, and ecosystems, will change.

Ecotage

ECOTAGE INVOLVES ECOLOGICALLY motivated acts of sabotage, such as tree spiking, uprooting genetically modified crops, disrupting power lines, liberation of caged animals, and destruction of equipment or data from controversial research. These illegal acts are also known as *ecodefense* or *monkeywrenching*. Two of the main goals of ecoteurs are to cause economic harm to corporations and to dissuade the public from wasteful or ecologically disruptive practices, like driving sport utility vehicles (SUVs) or permitting suburban sprawl in wetlands.

While ecoteurs have a range of different moral philosophies, they most often do not support causing death or injury to humans from their actions. Spiking trees with metal or ceramic nails can harm loggers, but the likelihood is small given that trees should be cut within twelve inches of the ground and spikes are placed higher. Even the most radical environmentalists usually go to great lengths to assure humans are absent from their material targets before sabotage is carried out.

ECOTERRORISM

State officials tend to classify ecotage as *ecoterrorism*, which reinforces the use of harsher penalties if saboteurs are caught. In the United States, there are various governmental agencies, including the FBI, cooperating on the investigation of radical environmentalism, which since 2001 has been considered the largest national terrorist threat. Significant resources have been invested into halting incidences of ecotage. However, the autonomous structure of ecotage cells that maintain their anonymity within loose, nonhierarchical networks defies surveillance and infiltration.

The name *ecotage* seems to have originated from the 1972 book by Sam Love and David Obst. The concept became popular as a result of Edward Abbey's 1975 novel, *The Monkey Wrench Gang*. There are a few manuals published on ecotage tactics, such as Dave Foreman's 1985 "Ecodefense: A Field Guide to Monkeywrenching." Foreman was one of the cofounders of Earth First!, a radical environmental movement known for direct action, that emerged in the 1980s. The northwest United States has been a hotspot for environmental groups, such as Earth First!, particularly in areas of old growth forest.

A number of mainstream environmental organizations have direct action trainings where members learn to climb buildings or other structures and hang banners that draw attention to ecological damage or injustice. A well-known group implementing more extreme acts of environmental sabotage is the Earth Liberation Front (ELF). ELF has created more than $100 million of damage in the United States since 1997. Although the origins of ELF are under debate, some believe that they are a radical offshoot from Earth First!. ELF has taken responsibility for arson in private logging company and U.S. Forest Service offices. In 1998, fires were set in buildings located on Vail Mountain in Colorado in a combined ELF and Animal Liberation Front (ALF) action. The mountain provides a unique habitat for lynx, and Vail was targeted to disrupt it through construction of large-scale commercial recreation facilities that required infrastructural development in fragile ecosystems.

ALF is an older organization than ELF. ALF started in the United Kingdom, but cells later developed in the United States. Well-known U.S. actions include arson in slaughterhouses and university facilities conducting animal research. In addition to "rescues," where animals are released from cages on commercial farms or in research institutes, U.S. animal rights activists have also disrupted hunts of mountain lions, bison, and other game since the 1980s. Activists in the United Kingdom pioneered strategies to disrupt hunts in the early 1960s.

Another well-known group of ecoteurs is the Sea Shepherd Conservation Society. These international activists often interfere with marine harvest at the point of extraction. Society members cut illegal longlines and harass unlicensed fishing vessels. Some larger actions attributed to this group are the sinking of two whaling vessels and the destruction of a whale processing station in Iceland.

There have been an increasing number of prominent international cases of ecotage in recent years involving resistance to genetically modified crops. Actions include uprooting of genetically engineered potatoes at the Crop and Food Research Center in New Zealand. Canadian targets have been related to research on biotech forests. In the United Kingdom, where there is a long tradition of ecotage, consistent destruction of research sites since 1997 has made ongoing study of genetic modification difficult.

Ecotone

AN ECOTONE IS the highly dynamic boundary between two disparate ecosystems: vegetation types and biomes. Ecotones can be very narrow and sharply defined, such as a terrestrial-aquatic boundary, or they can represent a broad transition between differing biomes, such as a gradual conversion between grassland and forest. Often, the flora and fauna found on either side of an ecotone will not be similar to one another, and species favoring one side of the ecotone will not fare as well on the other. Because of the variability in vegetation cover and abiotic factors characterized by ecotones, biodiversity across an ecotone tends to be higher than in relatively homogeneous habitats on either side of the ecotone. Ecotones can be formed by natural processes, such as floods, fires, and volcanic activity, but increasingly, human land use activities have created ecotones. Examples of anthropogenic ecotones are agricultural-pastoral boundaries, urban-rural spaces, and parks or protected land adjacent to lands used to meet human resource needs.

Ecotones typically favor certain types of vegetation and fauna over others. Species requiring a high degree of stability and habitat continuity will not be successful in or near an ecotone; species adapted to disturbances or boundaries can better exploit the resources found in these niches. Abiotic factors such as erosion, sediment deposition, snow accumulation, nutrient availability, salinity, and temperature are all affected by ecotones and tend to differ from one side of the boundary to another. Ecotones also can create microclimates, which further favors certain species over others. For example, a meadow surrounded by forest will be characterized by greater temperature extremes and more rapid changes in temperature than the surrounding forest. Additionally, direct sunlight reaching the ground will cause faster evaporation, and potentially dry meadow soils faster than those in the forest.

One concern that land managers express over ecotones is that they favor the success of invasive species. Human land uses such as road building or agricultural activities create ecotones with wholly different competition and predation regimes. Areas of undisturbed natural habitat are typically more resistant to invasive species, but patches where parts of previous ecosystems have been removed prove particularly prone to colonization by invasives, such as fire ants, kudzu, tumbleweed, or buffelgrass.

In areas characterized by naturally occurring habitat variability or "patchiness," land managers can use certain techniques such as prescribed burns, tree harvesting, or grazing by animals to create desired ecotones. The mosaic of desert, grassland, riparian areas, and forests in the western United States are typical of this highly fragmented, ecotone-rich land cover. Because ecotones are a naturally occurring part of ecosystems, it is necessary to ensure the continued existence of threatened species. The maintenance of ecotones can be one aspect of human management in protected areas.

Ecotones are typically far from stable, and undergo spatial and temporal changes. Sea level changes impact the placement of the marine-terrestrial ecotone. Forest succession at an abandoned beaver pond represents a changing ecotone. Tree lines migrate up and down mountainsides as a result of changes in temperature and precipitation. Recent concern has focused on ecotone dynamics as a result of anthropogenic effects, including climate change. Ecotones are necessary for a certain amount of ecosystem function, which humans rely on. For example, sea level rise may obliterate many productive salt marshes, coral reefs, and estuaries, which provide nursery areas for countless species of marine, freshwater, and anadromous species, leading to a decline in productivity of fisheries and other human uses.

Ecotourism

TOURISM IS OFTEN described as the world's largest industry and, while a small component of the overall industry, ecotourism is believed to be one of the fastest growing sub-sectors. Definitions of *ecotourism* are many, and have proliferated since the term was popularized in the 1980s. One consequence of multiple definitions is the associated difficulty in measuring the size of the ecotourism market; estimates range from 2 to 25 percent of all leisure travel. A second consequence is that ecotourism has been so broadly interpreted that its value as a tourism category has been questioned. Ecotourism options range from overnight stays in remote huts made of local materials and without modern amenities to luxury stays in exclusive eco-spas costing thousands of dollars per night. Activities can include bus tours of natural areas, passive bird watching or whale watching on guided tours, or active trekking and bush camping, sometimes without a guide. Regardless of definition, amenities, or activities, however, the popularity of ecotourism is reflected in a variety of ways; for example, the United Nations declared 2002 the Year of Ecotourism and *The New York Times* tagged ecotourism as the "buzzword of the year" for 2006.

KEY CHARACTERISTICS

While there is no universally accepted definition of ecotourism, several key characteristics appear are evident, although with varying emphasis and importance attached to them. First, ecotourism occurs "in nature," and tourists travel purposefully to areas where they can enjoy, see, and interact with nature. Second, ecotourism (and associated infrastructure) should be "low impact," with minimal disturbance to the environment. This has implications for tour operator, service provider, and tourist behavior. Third, some portion of the profits generated from ecotourism should fund conservation efforts. Increasingly, a small but growing number of ecotourists directly donate their time and labor to work for conservation, an activity labeled volunteer ecotourism. Fourth, ecotourism should educate both tourists and local people about nature (and its value). Fifth, ecotourism should provide economic opportunities for local communities, with the idea that these will translate into incentives to preserve nature. Finally, ecotourism development should be undertaken with respect for local cultures, and ideally with local participation in planning and management.

Generally, over time, ecotourism definitions have been expanded from an early focus on the purpose of ecotourism (to visit nature, provide educational opportunities and fund conservation) to incorporate principles of ecotourism (responsibilities for minimizing impacts, supporting local economic development and respecting local cultures). This evolution reflects a shift from descriptive definitions of ecotourism to more normative ones, and the normative emphasis reflects ecotourism's inclusion in the broader category of alternative tourism. Alternative tourism was popularized in the 1980s and 1990s, partly in response to the increasing evidence of the negative impacts of mass tourism on economies, cultures, and environments. Its concern is with the well being of host communities rather than that of the tourism industry. In all of these six characteristics, ecotourism is situated in contrast to traditional, mass tourism, and as such is proposed as a morally superior alternative, one that allows tourists and the tourism industry to alleviate rather than contribute to local environmental and economic problems.

RECONCILING WITH CONSERVATION

Ecotourism is a popularly promoted means of reconciling wildlife conservation with economic development, particularly in developing countries. Some developing countries are renowned ecotourism hotspots and cited as ecotourism success stories. For example, both Costa Rica and Belize rely on tourism as their largest foreign exchange earner, have protected large portions of their land (and waters) in national systems of protected areas, and cater to the ecotourist niche. Wildlife conservation organizations and park protection agencies initiated much of the discussion of the ecotourism concept. The World Conservation Union, World Wide Fund for Nature, and Conservation International, for example, all promote ecotourism as one means of achieving conservation and development. Ecotourism is often paired with community-based conservation, with community members working as tourist guides and park rangers, or investing in the provision of tourist goods and services. Proponents argue that ecotourism that provides local employment and small business development creates higher economic multipliers, and that a community approach to decision making helps to ensure traditional lifestyles and community values are respected. In the most optimistic scenarios, communities are "empowered" through ecotourism, develop a sense of "pride" in their natural resources, and even experience a resurgence in cultural traditions of interest to the discerning ecotourist. Ecotourism in this vision represents the ultimate realization of mainstream sustainable development.

SHORTCOMINGS AND RESPONSES

While ecotourism in theory aspires to meet both conservation and development goals, the ability of ecotourism in practice to deliver on these goals is increasingly questioned. There are examples of ecotourism projects that meet one or several of the criteria listed above, but overall the literature on ecotourism is dominated by impact studies of particular cases that, in general, have shown ecotourism in practice to be disappointing. Further, ecotourism often suffers the shortcomings associated with tourism in general.

First, economically, conservation revenues from ecotourism have been disappointing, with leakage (money leaving the community) remaining high in some areas, due to the presence of foreign investors, extra-local tour operators, and/or state policy that favors foreign investors. At a more theoretical level, the global push for ecotourism development reflects and reinforces an environmental-economic paradigm that commodifies nature and requires economic justification for all nature conservation.

Second, politically, local support for conservation activities through ecotourism can be lacking in spite of monetary gains, particularly if local people are treated as passive recipients of such gains rather than actively involved in ecotourism planning and management.

Third, socially and culturally, ecotourism has experienced many of the problems associated with traditional tourism, e.g., increased incidents of crime and drug use, commodification of cultural practices for tourist consumption, and erosion of local social and cultural norms. Ecotoursim has the additional impact of imposing Western visions of nature on local environments and people. These visions often focus on aesthetic nature and demand an “Edenic” experience for ecotourists. Local people associated with such nature are also required to meet tourist expectations of exotic and/or simple and, as a result, their own development aspirations can be curtailed rather than advanced by ecotourism. As a result, ecotourism has been labeled *green imperialism*, a new way for the developed north to dictate how resources are used in the south. Fourth, the aspirations of ecotourists as “alternative consumers” are often questionable, with ecotourists characterized as self-indulgent consumers of people and places, attempting to build their cultural capital. In this way, ecotourism has been called *green greed* and ecotourists *ego-tourists*.

Fifth, the popularity of ecotourism has been associated with *green-washing*, or the repackaging of traditional holidays as ecotours with minimal changes to actual activities. With ecotourism and ecotourist labels applied broadly (and some would argue indiscriminately), it has become increasingly difficult to distinguish either from traditional tourism and tourists. Finally, the sheer popularity of ecotourism and the high tourist numbers at particular sites, what some have labeled *mass ecotourism*, belies its ability to be low impact or alternative. These shortcomings can combine to translate into a failure to protect natural environments, or worse to directly damage those environments ecotourism seeks to protect.

As awareness of the shortcomings of ecotourism in practice has grown, academics and practitioners have adopted several responses. The first response focuses on “getting ecotourism right.” In this view, the original theory of ecotourism holds true and the challenge is to improve the practice. “Best practice” frameworks against which ecotourism projects can be assessed have emerged. Conservation organizations have produced ecotourist codes of conducts or developed eco-labeling schemes to distinguish ecotourism operators from the green-wash. The second response involves distinguishing between different forms of ecotourism.

For example, ecotourism (and ecotourists) can be situated on a spectrum from “hard” to “soft,” with activities at the hard end representing the ideal ecotourism described in the literature and those at the soft end resembling mass tourism. Some authors have argued that soft ecotourism, where tourists become temporary ecotourists for short periods of time as part of traditional holidays (e.g., by taking a day trip to a national park), might in fact be environmentally preferable to hard ecotourism. While the potentially high number of soft ecotourists might seem antithetical to the ecotourism concept, their impacts can be concentrated at a few well-serviced

Wildlife conservation organizations and park protection agencies initiated much of the ecotourism concept.

sites rather than dispersed in fragile ecosystems. Additionally, mass tourism providers may be better situated to implement sustainability overall (e.g., by investing in energy saving technologies or recycling), due to economies of scale. A second attempt to distinguish between forms of ecotourism is to place them on a spectrum of commodification, with least commodified forms being most desirable and closer to the ecotourism ideal; volunteer ecotourism may be one example of decommodified ecotourism. The types of distinctions made between hard and soft ecotourism, or least commodified and most commodified, allow for a more accurate assessment of the actual size of the ecotourism industry, and movement away from an overly broad label that covers too much to be meaningful while retaining a focus on the desired characteristics of ecotourism. The third response has been to more critically assess the ecotourism concept from a variety of theoretical perspectives. Advocates of this response argue that without a more sophisticated theoretical understanding of ecotourism, case study research will keep rediscovering the disappointments of ecotourism in practice. For example, understanding the political economy of ecotourism can help explain why local people receive few ecotourism benefits, and this understanding can be used to strategize ways to overcome this reality and capitalize on ecotourism opportunities. Political ecology can assist in positioning ecotourism as a phenomenon both reflecting and reinforcing human–environment relations, and can help explain why ecotourism remains so popularly promoted in spite of the disappointments of ecotourism in practice.

The final response that stands in contrast to all of the others is to abandon the term *ecotourism* altogether. In this view, ecotourism has become too ambiguous to be meaningful, and yet the label carries unchallenged assumptions that can lull tourists into a false sense of complacency. Instead of assessing the extent to which various examples of tourism meet the criteria of ecotourism, the aim should be to make all tourism (more) environmentally, economically, socially, and culturally sustainable. While there is appeal in this approach, the contemporary popularity of ecotourism suggests that both tourists and the tourism industry are invested in this market niche and that the ecotourism label is a powerful and desirable one. It is more likely that a combination of the first three approaches will continue to be pursued. Whether or not this will result in improved performance of ecotourism in practice, and more examples of ecotourism success stories, remains to be seen.

Ecuador

ECUADOR, A NATION on the west coast of South America, straddles the Amazonian lowlands, the Andes, a humid coastal plain, and the Galapagos Islands. The population of about 12 million (2001 census) is well along in its demographic transition, with low and declining death rates and declining birth rates. Approximately 1.5 million migrants overseas (especially New York and Spain) provide an important support for the country's economy through their remittances. Almost all of the population identifies as Mestizo, with small but important indigenous and Afro–Latin American minorities. Almost half the population lives in or near the three main cities, Quito (the capital), Guayaquil (the largest city and main port), and Cuenca (most important city in the southern highlands).

Agriculture has been practiced in the highlands for thousands of years, resulting in the deforestation of this part of the country. Traditional agriculture deploys a wide range of crop species and varieties, and sophisticated systems of irrigation and crop rotation on sloping land. Commercial agriculture provides important exports, including bananas. Recently, flower cultivation has been a heavy user of scarce water supplies in the highlands, while shrimp farms on the coast have done away with much of the country's mangrove habitat. Much of the highlands have been reforested with exotic species (especially Eucalyptus and Monterey Pine) for local use. High altitude environments (*páramos*) are managed by burning and are used for grazing sheep and cattle.

The country has several active volcanoes that present a significant hazard. Much of the Quito urbanized area is at risk from lava flows from the Cotopaxi volcano. Earthquakes are also a hazard; several cities have been destroyed in the last few centuries. A nationwide monitoring program is in place, managed by the Polytechnic University in Quito, to provide early warnings.

Water resources are especially critical for the country's future. A sophisticated water system has been installed for Quito relying on high altitude reservoirs (and associated ecological services from local communities), but other cities and towns often make do with unsafe and unreliable water supplies.

The first national park was created in the Galápagos Islands in 1936. The system of parks and preserves now covers almost 20 percent of the national territory, and is managed by the Ministry of Environment. Tourism, including ecotourism, provides growing support for the country's economy,

Petroleum exploitation in the Amazon basin began with the drilling of the first productive well in 1967. In subsequent decades, oil became the country's major export. The construction of roads led to an influx of colonists, especially in the northeast, which in turn led to deforestation and pressure on indigenous communities. There have been oil spills and contamination of local waterways associated with oil production, and continuing struggles with local indigenous communities over impacts on their land and livelihoods.

Eden, Garden of

THE GARDEN OF Eden appears in the writings of the Abrahamic religions, Judaism, Christianity, and Islam. In the biblical creation story of Genesis, it is a beautiful garden of trees planted by God in the land of Eden and watered by a river. God intends that the first man and woman, Adam and Eve, live there in contentment and innocence. God takes all the animals that he has created there so that Adam can name them. At the center of the garden are two fruit trees; the Tree of Life and the Tree of Knowledge. Adam and Eve, encouraged by a serpent, ignore God's prohibition not to eat from the Tree of Knowledge. They thereby gain an awareness of good and evil but lose their innocence. God drives the couple from the Garden, placing an angel at the entrance to prevent their access to the Tree of Life and immortality. God further condemns Adam, and thus all humans, to secure food by hard labor in the fields, making the ground cursed and choked with weeds rather than naturally abundant as in the Garden.

Elsewhere in the Bible, the Garden of Eden is represented as the "garden of God," a paradise of lush growth and majestic trees, a place of comfort and contentment for humans, and the utter opposite of deserts and wastelands. The prophet Isaiah assures Israelites in Babylonian captivity that one day God will convert their harsh environment into a new Eden. It is thus a symbol of the renewal of both land and society, and an image of promise.

In the rabbinical tradition, the Garden of Eden was the embodiment of perfection, the ultimate reward for righteous souls after death. The Garden of Eden is also mentioned in the Qur'an and is associated with paradise.

The Garden of Eden has also been described as a mythological creation story, a future celestial paradise that awaits the virtuous or a real place on earth that was destroyed by the Flood. Some have sought the location of a real Garden, still in existence long after its primeval role in Creation but lost to the knowledge of humans. Medieval legend tells of St Brendan making a seven-year Atlantic voyage in search of it. Some European voyages of discovery in the early modern period were partially inspired by the search for an earthly, utopian paradise. The American tropics were particularly seen as edenic lands. Columbus thought that the great Orinoco river might be one of the four rivers of Eden. In more recent times, satellite imagery has been used to suggest that the dried-up Wadi Batin and the Karun River, combined with the nearby Tigris and Euphrates, make up the four rivers, placing the Garden under the waters of the Persian Gulf.

Any geographical location for Eden is hypothetical, but the garden has also been a compelling symbol of a once-effortless relationship between humans and the divine, and of harmony between society and the environment. Medieval scholars claimed that Adam's control of the garden and the obedience of animals in Eden gave humans complete authority over all plant and animal life, which was clearly put on earth to serve them. Around this same time, the Garden of Eden was also seen as a model for botanical gardens. Some tried to recreate the garden, which they believed had been swept away by the Flood, by gathering all the plant species from the known world for study. Botanical gardens today continue assembling the plants of the world, although their aim is species conservation, not spiritual inspiration.

The nostalgic longing to recover a lost paradise, an ancient golden age when humans lived in harmony within an abundant nature, is common in many cultural traditions around the world. Some anthropologists suggest that the Garden of Eden story represents a cultural memory of simpler times when humans lived freely as hunters and gatherers rather than toiling at agriculture in fixed locations. Environmental historian Carolyn Merchant argues that the "recovery narrative" implicit in the story of the Garden of Eden was used as a powerful justification in American history to convert the "wilderness" into a garden and, within the early national parks movement, to forcibly evict indigenous peoples from areas designated as pristine.

The concept of "the last Eden" is still applied to a number of relatively "unspoiled" and inaccessible places on earth, which harbor a diversity of rare plant and wildlife, such as the rainforests of the Amazon, the Congo Basin, or Borneo. The aim of restoring or preserving such parts of the world in a "wild" Edenic state can cause conflict over the rights and aspirations of indigenous peoples, environmentalists, tourism developers, and industrialists.

Edge Effect

AN EDGE EFFECT refers to the effect of a prevailing boundary between contrasting spatial environments within an ecosystem or landscape. Landscapes are comprised of heterogeneous mosaics of habitat patches of varying size, shape and quality; these characteristics change over space and time. The edges or boundaries between habitat patches have implications for ecological processes between patches (e.g., animal movement) as well as within them (e.g., light penetration from patch edge to interior affecting within patch resource availability). The spatial configuration of patches—or landscape spatial pattern—includes the degree of fragmentation of or connectivity among habitat patches within the landscape, thereby influencing ecosystem and landscape-level processes such as seasonal animal migration, effective range and dispersal, as well as the ecological impacts of natural or anthropogenic disturbance.

Edge regions among contrasting environments within a landscape are often referred to as *ecotones*. An example of a commonly considered edge is that between a forest patch and an adjacent non-forest land cover, such as pasture. Such an edge would define a sharp *ecotone*, and the forest patch would be characterized by a gradient of environmental conditions from its edge to its interior, with varying degrees of available light, ambient air temperature, wind exposure and soil moisture conditions. Close to the forest/nonforest edge, penetration of light and wind into the forest patch creates microhabitats that favor particular light/gap-loving, opportunistic plant and animal species. Increased "understory" growth closer to forest edges because of an increase in the dominance of light-loving plants, combined with lower soil moisture conditions may increase the risk of forest fires at edge locations, further creating new edge areas.

Widespread fragmentation of eastern and Midwestern forests in the United States has increased the abundance of the pasture-loving, brown-headed cowbird, which increasingly parasitizes the nests of interior-dwelling forest birds, driving a widespread reduction in their populations. Predation on bay scallops by fish and invertebrate species is much greater in patchy seagrass areas than in large homogenous expanses of seagrass.

The ratio of forest patch edge to its interior area is one commonly used metric in the field of landscape ecology, and characterizes the degree of forest fragmentation and edge habitat in a landscape. While much of landscape ecological research has focused on the quantification of landscape pattern, including edge-interior ratios and fragmentation and connectivity indices, increasingly studies are examining the ways in which such patterns influence ecological processes, and edge effects comprise a significant area of focus. It is estimated that the forested area of the Amazon Basin that was subject to edge effects in 1988 by virtue of being located within 1 kilometer of a deforested site (341,000 square kilometers) exceeded the extent of actual deforestation (approximately 230,000 square kilometers). Several anthropogenic environmental changes, particularly changes in land use and cover, thus have both direct and indirect consequences for ecological systems.

Education

EDUCATION IS VALUED around the world as a means of promoting individual advancement and well-being, and for its potential to encourage economic growth and employment, empower women and minority groups, and reduce infant and child mortality rates. Universal access to education has been an international policy goal since the creation of the Universal Declaration of Human Rights in 1948, and since the 1960s it has also been increasingly linked to environmental management and international development efforts. This has been especially true since the United Nations Conference on Environment and Development (also known as the Earth Summit) was held in Rio de Janeiro in June 1992. One of the important documents to come out of the conference was *Agenda 21*, a key set of plans and international agreements aimed at achieving global sustainable development in the 21st century. Education has a central role in the plans outlined by *Agenda 21*:

> Education, including formal education, public awareness and training should be recognized as a process by which human beings and societies can reach their fullest potential. Education is critical for promoting sustainable development and improving the capacity of the people to address environment and development issues. While basic education provides the underpinning for any environmental and development education, the latter needs to be incorporated as an essential part of learning.

While many people agree with the spirit of the ideas outlined in *Agenda 21*, there is active debate about how best to implement them in practice. Educators, policymakers and activists around the world question what the content and aims of such educational programs should be, as well as what their benefits and costs might be for individual nations and communities. Governments, international organizations, and conservation and community groups promote environmental learning under a number of different labels, and employ a variety of different topics of study and teaching methods. These programs may be formal or informal, may be found in many different settings, and may address a number of different audiences.

Formally organized programs usually take place in schools, classrooms, museums, or protected nature areas (including national parks and privately-owned conservation areas), while less formal community development and popular education projects or public awareness campaigns occur in other ways, such as through public meetings or the use of mass media. Public awareness campaigns, for instance, employ mass media such as newspapers, television and radio to spread environmental messages to the general public. Programs may do a variety of things; including promoting awareness of environmental concerns such as pollution or deforestation, encouraging environmentally sustainable behaviors such as recycling, reforestation, or the increased use of public transportation, or working to promote or protect specific kinds of knowledge about—and interactions with—local environments (for example, encouraging the use of local or traditional agricultural and harvesting practices).

UNDERSTANDING ENVIRONMENTAL EDUCATION

The contemporary environmental education movement began in the 1960s and 1970s—an era of history characterized by growing concern over the state of the natural world and also increasing interest in ecosystem and species preservation from the international scientific community. Environmental education in this period relied heavily on a style of public education and awareness-building that emphasized learning in the natural sciences, and especially in biology, botany, and ecology. Topics of particular interest included the scientific study of food and agriculture; tropical forests; biological diversity; desertification and drought; fresh water; oceans and coasts; energy; atmosphere and climate; solid waste and sewage management; and hazardous substances; as well as related concerns such as population growth, global security, and development.

The idea of promoting knowledge about the environment was also taken up by international conservation and development movements around this same time. Organizations such as the International Conservation Union (IUCN) and the United Nations Educational, Scientific and Cultural Organization (UNESCO), for example, had begun creating curriculum materials for all levels of formal education as early as the mid–1960s. International support for environmental education continued to grow throughout the 1970s and 1980s, and it was a major topic of discussion at a succession of important international meetings. The United Nations Environment Program (UNEP) and UNESCO co-founded the International Environmental Education Program, for instance, and formally launched it at an International Workshop on Environmental Education in Belgrade in 1975. This important conference produced the first inter-governmental statement on environmental education, *The Belgrade Charter—A Global Framework for Environmental Education*. A followup conference, the First Intergovernmental Conference on Environmental Education, was hosted by UNESCO in Tbilisi, Georgia, USSR in 1977. The final report of this conference, known as the *Tbilisi Declaration*, contained recommendations for the implementation of environmental education in formal and informal education, as well as a framework for international co-operation that is still in use today. The next major international initiative came in 1980, with the publication of the *World Conservation Strategy* by IUCN, UNEP and the World Wildlife Fund. Further statements have followed, including the 1987 publication of *Our Common Future* (a reformulation of the *World Conservation Strategy*, often known as the Brundtland Report), as well as the publication of *Agenda 21* in 1992.

Although the term *environmental education* has dominated policy language and practitioner vocabulary for the last several decades, its meaning changed significantly between the publication of *The Belgrade Charter* and *Agenda 21*. The text of *The Belgrade Charter* focuses on description of the unprecedented economic growth and technological progress of the 1970s, and how this is linked to severe environmental consequences. It identifies the goal of environmental education as: “To develop a world population that is aware of, and concerned about, the environment and its associated problems, and which has the knowledge, skills, attitudes, motivations and commitment to work individually and collectively toward solutions of current problems and the prevention of new ones.”

The document also calls for the use of environmental education to develop “a new global ethic… which espouses attitudes and behavior for individuals and societies that are consonant with humanity’s place within the biosphere.” Environmental education, in this view, is intended to raise public awareness of the damaging effects of human activity on the natural world, and to encourage individuals and nations to adopt more environmentally friendly behaviors and lifestyles.

Education is critical for promoting sustainable development and to address environmental issues.

While the language of *The Belgrade Charter* emphasizes the need to protect the natural world from human activities, *Agenda 21*, on the other hand, suggests that a balance must be found between addressing the needs of the environment and those of humankind. It specifically describes the interconnections between environmental management, and economic and social development, and therefore moves away from blaming environmental problems solely on human mismanagement. Environmental education—in this view—is not just about raising awareness of environmental problems like pollution or deforestation, but is an integral part of more complex and integrated relationships: "To be effective, environment and development education should deal with the dynamics of both the physical/biological and socio-economic environment and human (which may include spiritual) development."

This changing understanding of the links between environmental management, education, and society had already begun in the late 1980s alongside criticism of the idea of *development*. The introduction and growing popularity of the concept of "sustainable development" led many educationalists to rethink the terms they used to describe their work. Some of these new terms included: *education for sustainable development, education for sustainability,* and *education for a sustainable future*. Narrow definitions of environmental education, which saw it as roughly equivalent to science education or nature study, were also expanded by some educators to encompass related ideas such as peace education, population education, and human rights education.

Some educators and theorists also added various qualifiers to the term in order to signal the expanded scope of their work, resulting in new concepts such as *socially–critically environmental education or grassroots environmental education*. Advocates of these alternate approaches argued that early understandings of environmental education—such as those found in *The Belgrade Charter*—focused too heavily on the protection of natural environments and did not sufficiently take into account the needs and rights of human populations. International discussions about the relationships between environmental management and education since that time have centered on the different opportunities and limitations of these various approaches to education about the environment, as well as their potential to encourage environmentally friendly behaviors and social change.

Debates about education and the environment in the contemporary world, therefore, are closely related to wider discussions about how best to go about managing both the environment and the development process. In the simplest terms, these debates can be divided between perspectives that emphasize the teaching of science and those that seek to actively link environmental and social issues. Some styles of environmental education, for instance, promote awareness of environmental problems and the scientific or technical solutions for them (for example, the creation of strictly protected nature areas). Advocates of such science—oriented styles of education argue that when students are taught about these issues they will learn to love—and therefore be inspired to protect—the natural world from destruction. Other educators, however, argue that environmental concerns cannot be understood in isolation, but should be linked to the economic and social factors that influence human activity. This second kind of perspective on education reflects the increasing popularity of the idea of sustainable development, and encourages critical thinking about issues such as human rights, peace, poverty, and gender inequality, and the ways that these issues relate to both the successes and failures of environmental management.

IMPLEMENTATION

The style of educational programming promoted in a particular place, however, is often as much the result of national or local conditions and worldviews as it is of academic or policy debates. This is not just because of differences in perspectives on education and the environment in different locations, but is also related to the kinds of actors involved in the process. Nongovernmental organizations (NGOs), and especially international conservation groups, have been some of the most active promoters of environmental education since the 1970s. The World Wildlife Fund, for instance, is one of many international conservation NGOs with established educational programs and projects used by teachers and students around the world. National parks and protected areas in many nations also routinely include environmental education programs as part of their work in conservation, research, and tourism. Since 1992, and in accordance with the recommendations of *Agenda 21*, many national governments have been working to create national environmental education plans and strategies that address the inclusion of environmental topics in state school systems, higher education, government, and business. At the local level, schools and community groups often take an active role in promoting environmental topics, either through activities in the classroom or outside the school walls (for example, visits to protected areas or participation in neighborhood clean-up campaigns).

SPECIAL INTERESTS

Decisions about what are the most appropriate form and content of educational programs in a particular place are rooted in the interests and understandings of the specific organizations or individuals promoting them. Conservation NGOs or organizations that own large protected areas, for instance, are likely to employ programs that support their views on environmental protection, research, and advocacy. Sustainable development NGOs or advocacy groups, on the other hand, may choose to place a stronger emphasis on the social links between environmental management and society, or even more specifically on the interconnections between environmental management and the livelihoods of women, indigenous groups, or ethnic minorities. Schools or other formal education institutions are likely to promote learning when and where it fits most easily into existing teaching demands—whether that be within science or social science curricula.

The different needs and interests of these many actors can be a source of both conflict and collaboration. In Costa Rica, for instance, the state has taken a very active role in the promotion of environmental learning in the national education system since the late 1980s. The current national curriculum covers issues in ecology and biology, as well as making broader linkages to topics such as public health, poverty, and Costa Rican society. Support for these efforts has arisen from businesses, research and conservation groups, educational organizations, and individual citizens, many of whom have received significant financial benefits from the successful promotion of the nation as a premiere international ecotourism destination. In the United States, on the other hand, conflicts between powerful business interests, governments, conservation NGOs, and community groups, have meant that environmental education remains marginal to mainstream education systems and has instead been largely promoted by environmental NGOs and private conservation interests. Such different realities of environmental education practices illustrate that decisions about the content of programs or styles of teaching, as well as opportunities for collaboration and conflict, depend on complicated economic, political, and social factors in every location.

Indeed, decisions about the implementation of environmental education, as well as its actual effectiveness in practice, often occur under serious economic and political pressures. National and international policymakers work to maximize investment in both basic and higher education in order to reduce poverty and to promote economic and social development, but these processes involve a wide array of individuals and organizations and are therefore far from simple. International financial organizations, such as the World Bank, have considerable influence on the national education policies of many developing countries, and have tended to provide more funding for science, technical and vocational subjects than for the arts and social sciences.

National education actors, such as education ministers and legislators, must therefore address international demands for education provision while also providing socially and culturally appropriate education that meets the expectations of educators, parents, and employers. At the local level, educators may be under significant pressure to meet state curriculum guidelines in order to prepare students for exams and to gain recognized qualifications, but must also remain sensitive to local economic and social conditions, and especially to local perspectives on the environment. Educators may also face pressure from local employers or other community members to provide students with knowledge and training that will lead to future employment.

Naturally, these relationships between educational actors do not just involve the imposition of pressure from the top downward. Each nation's influence within international organizations also provides policymakers with opportunities to participate in negotiations of international educational policy and aid decisions. To take the example of Costa Rica again, national leaders and policymakers have a significant voice in international discussions of environmental management, education, and development, and have frequently been applauded for progressive legislation and programs. At the community level, too, students, adults and local organizations have the power to make their own decisions about participation in environmental education programs, as well as about the creation of locally appropriate projects for young people or the general public.

The economic, political, and social circumstances of individual nations and communities, in fact, can have a huge influence on how people think about—and advocate—particular kinds of environmental knowledge and education. This is true both in terms of the specific topics chosen (such as reforestation, pollution reduction, water or waste management, or the participation and empowerment of vulnerable groups in environmental decision making) and the methods of teaching used (formal programs in schools, informal workshops provided by community organizations, or the use of mass media for public awareness campaigns). Education about the environment in every location and at every level—local, national, or international—is a dynamic process that involves many diverse actors, interests, and understandings of the links between the human and natural worlds.

Efficiency

EFFICIENCY IS THE ratio of outputs to inputs in a system, whether that is benefits to costs, results to effort, or action to energy. Economic efficiency is satisfied when an activity's benefits exceed its costs; or, stated otherwise, the ratio of benefits divided by costs is greater than one. Energy efficiency is measured in a similar way by the ratio of work divided by effort. In practice, this tends to be a measure of work accomplished relative to the energy required to produce the work. Dividing benefits/work by costs/effort allows comparison across options.

The range of costs and benefits associated with an option might be limited to effects with well-recognized dollar values, and only those costs and benefits accruing directly to those involved in the decision-making process, such as an individual business. Alternatively, efficiency assessments might include consideration of costs and benefits experienced by the larger community, and costs and benefits that do not have market-determined values. Such social efficiency measures are commonly used for assessing environmental policy options.

Assessing social efficiency gains can be conducted a number of ways. Comparing benefit-to-cost ratios across options and choosing the greatest does not consider the distribution of costs and benefits. Comparing only net social benefit assumes that if those experiencing increased net benefits (benefits minus costs) could more than compensate those experiencing decreased net benefits, the option increases social efficiency. In practice, it is rare that any such transfer compensation occurs. This measure, *Kaldor-Hicks efficiency*, is the efficiency typically employed for cost-benefit analysis. An alternate, more equity-demanding efficiency measure considers that an efficiency gain only occurs if no one experiences decreased net benefits. This is known as Pareto efficiency. Other comparisons of options give greater consideration to equity, although they experience rare usage in policy settings. Distributive efficiency involves identifying the allocation of resources or costs and benefits that provides the greatest net social welfare. Another method entails maximizing the product of individual net benefit gains, thereby identifying the most equitable distribution of gains, inspired by the Nash Bargaining Solution in game theory. The *maximin* principle advocates maximizing the least individual net welfare or net welfare gain, inspired by John Rawls's theory of justice.

EFFICIENCY MEASURES

Efficiency measures are typically employed to prevent or minimize waste and seek to identify options that do not expend unnecessary energy, while economic efficiency measures are used to avoid wasted expenditures. Demand for water usage in areas such as agricultural irrigation and watering lawns can often be equally well met with less water when using more water-efficient technologies. In agriculture, achieving the same production with less water, all else being equal, demonstrates more water-efficient methods. Demand for gasoline is not based on a demand for gasoline itself, but for the transportation it allows. Transportation efficiency, the energy needed to transport a given object a given distance, provides a good case study for consideration of how different perspectives on efficiency—in which benefits and costs are most important—can lead to different policy recommendations.

Fuel efficiency is often targeted as a goal for addressing environmental concerns such as air pollution and climate change. Fuel efficiency for automobiles typically refers to the mileage per gallon (mpg) of gasoline. In 1975, in the wake of high oil prices due to the 1973 Arab oil embargo, the Energy Policy and Conservation Act set fuel efficiency standards that automakers were required to meet on average across their entire fleet. These are known as Corporate Average Fuel Economy (CAFE) standards.

Fuel efficiency improvements equate to reduced gasoline demand and reduced air pollution, such as carbon dioxide and particulate matter. If people drive the same amount with vehicles achieving greater fuel efficiency, less gasoline is consumed. The extent of gasoline demand reductions depends on the price responsiveness of drivers to the cost of driving, or in economic terms, the price elasticity of demand for driving. The more responsive, or elastic, demand for driving, the less there will be a reduction in gasoline consumption. Elastic demand for driving will equate to increased driving with reduced driving costs. This response reflects the joint influence of supply costs and consumer demand on gasoline consumption and the associated pollution and traffic concerns. Many urban planners seek to increase use of public transportation by making it less costly, more convenient, or making driving more expensive as through tolls and parking fees. Public transportation is more energy efficient than individual driving because more people can be moved with the same amount of energy. Therefore, while fuel efficiency in cars does save costs and reduces air pollution, a more fundamental goal of energy efficiency, minimizing the energy required for transporting people, is likely to have greater net energy conservation benefits.

From an economic standpoint, transportation considerations of energy efficiency are closely tied to economic efficiency. Once a vehicle is built, if it has greater fuel efficiency than an earlier model, it will be less costly to drive and therefore be more economically efficient. However, more fuel efficiency in vehicles, all else being equal, typically requires more advanced engine and energy management technologies that are more expensive. Therefore, an individual's private considerations of economic efficiency might change when considering the total costs, if the individual does not personally see much benefit from reduced pollution and societal gasoline consumption. Total private cash costs of transportation with a more fuel efficient vehicle might be greater or less than those with a less fuel efficient vehicle, depending on the price of the vehicle and the price of gasoline. Even if total private cash costs are greater with a more fuel efficient vehicle, net benefits to society might be increased, due to health and environmental benefits from reduced pollution and gasoline demand. The case of transportation efficiency reveals the varying conclusions depending on the type of efficiency considered, the time frame for costs and benefits, and the size of the group considered. Fuel efficiency and transportation efficiency maximizing can lead to different conclusions because of different consideration of and consequences for resource depletion, pollution, and congestion.

Because most market-based decisions are made by individuals, only individual economic efficiency considerations are typically included. Achieving more socially efficient outcomes can require incentives for individuals to change their economic decisions. These incentives can come from private or governmental organizations. In some cases, where the more socially efficient outcome is deemed of great importance, direct government intervention might be necessary. An example would be regulations to keep lead out of drinking water so as to avoid birth defects, even though the added cost might reduce an individual company's economic efficiency.

Egypt

AS ONE OF the oldest civilizations in the world, the Arab Republic of Egypt has a long and rich history. Throughout much of that history, Egypt's prosperity depended on its ability to benefit from the annual flooding of the Nile River as it deposited fertile soil from other countries onto the Egyptian shore. Egypt's system of levees designed to control the Nile has been traced as far back as 3,000 B.C.E. In the capital city of Cairo, the Nile broadens to meet the Mediterranean Sea. Egypt's importance to the global transportation sector was renewed in 1869 with the completion of the Suez Canal, linking the Indian Ocean with the Mediterranean Sea. The importance of the canal led Britain to seize control of Egypt in 1882, but independence was regained after World War II.

After a long history of colonization, by the 1950s, Egypt had become one of the poorest nations in the world. The completion of the Aswan High Dam in 1971, the largest rock fill dam in the world with the capacity to store three years of Nile water flow, was thought to be an engineered solution to the country's underdevelopment. While the dam allowed increased intensification of agricultural production, and paired well with a massive influx of development assistance and foreign expertise, most of these technical experiments and interventions did little to reduce real poverty and in many cases dismantled local and regional agro-ecological traditions. Although the dam also provided electricity for some 20,000 rural residents, moreover, many critics believe that the environmental impact of the dam was too great a price to pay, particularly since the rich silt from the Nile is no longer available to increase soil fertility and a large amount of water is lost to evaporation.

The tourist industry, which engages 10 percent of the work force, is essential to Egypt's economy, producing around $6 billion a year in government revenue. The industry received a major blow on April 25, 2006, when bombs ripped through popular resort towns on a national holiday. Officials have estimated that 125 people were killed in Egypt by religious terrorists over an 18-month period. With a per capita income of $4,400, Egypt is ranked 141 of 232 countries in world income. One-fifth of the Egyptian population lives in poverty, and 10 percent of Egyptians are unemployed. While 68.3 percent of males over the age of 15 can read and write, only 46.9 percent of adult females can do so. The United Nations Development Program (UNDP) Human Development Reports rank Egypt 119 of 232 countries on overall quality of life issues.

With a 2,450 kilometer coastline bordering the Mediterranean and Red Seas, Egypt encompasses 6,000 square miles of inland water sources. The 995,450 square kilometer of land area includes the Asian Sinai Peninsula. Egypt shares land borders with the historically contested Gaza Strip, Israel, Libya, and the Sudan. Egypt is made up an extensive desert plateau interspersed with the Nile valley and delta. Elevations vary from 133 meters at the Qattara Depression to 2,629 meters at Mount Catherine. The desert climate produces hot, dry summers and moderate winters, along with periodic droughts, flash floods, and landslides. Earthquakes are common. In the spring, Egypt experiences the khamsin, a driving windstorm, and dust and sand storms are frequent. Natural resources include petroleum, natural gas, iron ore, phosphates, manganese, limestone, gypsum, talc, asbestos, lead, and zinc.

As the population of Egypt has increased currently to 77,500,000, partially through an influx of refugees, fertile agricultural lands have been lost to urbanization and windblown sands. Over 95 percent of the population is concentrated in less than five percent of land area around the Nile, vastly straining resources. Carbon dioxide (CO_2) emissions per capita metric tons rose from 1.0 in 1980 to 2.1 in 2002. Egypt produces 0.6 percent of the world's total of CO_2 emissions, and the country has one of the highest levels of air pollution in the Middle East and North Africa. Soil salination is occurring in the areas below the Aswan High Dam, and wide areas of Egypt are being subjected to desertification.

Oil pollution has damaged coral reefs, beaches, and marine ecosystems. Water has become increasingly polluted from agricultural runoff, raw sewage, and industrial effluents. In areas outside the Nile Valley, fresh water resources are limited. While 98 percent of Egyptians have access to safe drinking water, only 68 percent have access to improved sanitation. In 2006, scientists at Yale University ranked Egypt 85 of 132 countries on environmental performance, below the relevant income and geographic groups. Low scores were received in the areas of air quality, production of natural resources, and biodiversity and habitat. Although only 0.1 percent of Egypt's land area is forested, the government has protected nearly 10 percent of the land. Of 98 endemic mammal species, 13 are endangered, as are seven of 123 bird species.

In 1977, the government initiated the Sekem project, a network of 150 biodynamic farms established to promote sustainable development. In 1996, the Egyptian government introduced a plan to reclaim

The Curse of the Pharaohs

Following the discovery and the opening of the tomb of Tutankhamun in the Valley of the Kings in November 1922, there were a number of rumors about a possible "Curse of the Pharaohs." Some have claimed this was more than a psychological "curse," but was actually the result of poisons or hidden mosquitoes.

The idea of the curse of the Pharaohs received much attention when, in March 1923, a British novelist Marie Corelli wrote that there would be terrible consequences for the people involved in opening the tomb of the dead boy pharaoh. The goddess Wadjet, represented by a cobra, was a protector of the pharaohs. When it became known that on the day Howard Carter opened the tomb, his pet canary was eaten by a cobra, the theories of Corelli received greater attention. A few weeks after Corelli's prediction, Lord Carnarvon, who had financed the work of Howard Carter, died of pneumonia in Cairo, leading to much speculation about the curse. It was also claimed that all the street lights in Cairo went out when Lord Carnarvon died, although some have suggested that this was a regular occurrence given the poor power supply; and also Lord Carnarvon's dog, Susie, apparently died in England at the very moment her master died.

Many writers have speculated over the curse of the Pharaohs, including Arthur Conan Doyle, the author who created the fictional character Sherlock Holmes. However, detailed medical studies, some published in the *British Medical Journal* and other learned publications, have suggested that there is no evidence to link reports of a large number of early deaths to the opening of the tomb—indeed, many of the people involved in the opening of the tomb, and those who visited soon afterward, including members of the Belgian Royal Family, lived long and active lives. The death of Lord Carnarvon could largely be put down to poor health from a car accident twenty years earlier, and the rest of the events mere coincidence.

Osman Ahmed Osman

Born at Ismailia, Egypt, Osman Ahmed Osman attended Cairo University, and his first building project was the construction of a single garage for his neighbors. Three years later, he and his brother Mohammed formed Osman Company, which by 1950 employed 2000 men. His early projects included work on the enlarging of the harbor of Port Said at the northern end of the Suez Canal, and also a new international airport for Cairo.

He submitted an estimate for work for the $1.5 billion Aswan Dam because, he later said, he "wanted to be part of the great project, to have his place in history." To make sure his costings were correct, Osman set up two teams of estimators, each unaware of the other, while he and a few of his associates formed a third team. The three estimates only varied by 2 percent, and not only was Osman able to submit a very low estimate—so low that the Supreme Court thought he had made a mistake—he was able to realize a profit of 500,000 Egyptian pounds.

At one stage during the building of the dam, when Soviet trucks donated by Nikita Khrushchev were found incapable of moving soil fast enough, Osman had to buy British trucks, which were hidden when the Soviet leader visited the project. At the completion of the Aswan Dam project, the Egyptian President Nasser nationalized the company but allowed Osman to control projects outside Egypt. The company was renamed Arab Contractors.

Osman was appointed Minister of Reconstruction in November 1973 after Egypt's defeat in the Yom Kippur War, and was appointed deputy prime minister in 1981. He later published his memoirs, *Pages from My Experience.*

millions of hectares from the Western Desert. Like the Aswan High Dam project, the land reclamation project was criticized as an environmental disaster. In 1994, Law 4 was passed to restructure the environmental ministry, creating the Egyptian Environmental Affairs Agency and charging it with planning, policy development, coordination, and enforcement of environmental laws and regulations. The Cairo Air Improvement Project was also implemented to deal with the growing problem of air pollution, and the Environmental Protection Fund promoted projects dealing with solid waste management.

In 1999, Egypt joined nine other riparian nations in the Nile Basin Initiative designed to promote sustainable resource development and transboundary cooperation along the Nile. Egypt also participates in the following international agreements on the environment: Biodiversity, Climate Change, Climate Change–Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, Tropical Timber 94, and Wetlands.

Ehrlich, Paul R. (1932–)

PAUL R. EHRLICH, the Bing Professor of Population Studies at the Department of Biological Sciences at Stanford University, is an entomologist and author on human overpopulation. He is well-known around the world for his book *The Population Bomb* (1968).

Ehrlich was born on May 29, 1932, in Philadelphia, Pennsylvania. He earned his B.A. in zoology at the University of Pennsylvania, and his M.A. from the University of Kansas. In 1957, he completed his Ph.D. at the University of Miami, and then worked at the Department of Entomology at the University of Kansas. Two years later, Dr. Ehrlich joined the faculty at Stanford University and became a professor of biology in 1966, and Bing Professor eleven years later. His academic interests were initially in the field of entomology, but he has also become interested in the field of population growth. His first book, published in 1960, was *How to Know the Butterflies*. It was followed three years later by *Process of Evolution*.

In 1968, *The Population Bomb* was published. It expanded on ideas raised in an article he wrote for *New Scientist* magazine in December 1967. In the book, Ehrlich predicted that the world might face major famines between 1970 and 1985 owing to a massive growth in population and the inability of food supplies to keep up with this. Some scholars saw Ehrlich in the mold of early 19th-century economist Thomas Malthus, who had also predicted that the population was increasing at a rate that was outpacing the ability to produce more crops. Ehrlich said that he was more influenced by William Vogt's *Road to Survival* (1948), which he had read while at high school.

There has been extensive criticism of Ehrlich's ideas, since the widespread famines he predicted did not occur, and because other scarcity-reducing innovations have occurred over the recent period of population growth, including the Green Revolution, in which agronomists developed ways of increasing food production. His supporters argue, however, that his book reinvigorated debate on the issue of overpopulation.

In 1968, Paul Ehrlich and others formed the Zero Population Growth group. He issued a revised version of his *The Population Bomb* in 1971, and has since written many more books, including *The End of Affluence* (with A.H. Ehrlich, 1974), *The Race Bomb* (with S. Feldman, 1977); *Machinery of Nature* (1986); and *The Birder's Handbook* (with D. Dobkin and D. Wheye, 1988).

His most recent major works were *One with Nineveh: Politics, Consumption and the Human Future* (with A.H. Ehrlich, 2004); and *On the Wings of Checkerspots: A Model System for Population Biology* (co-edited with Ilkka Hanski, 2004). He has also published over five hundred articles.

AWARD-WINNING EFFORTS

Ehrlich's work has earned him the Crafoord Prize in 1990, along with biologist E.O. Wilson. The prize was established in 1980 in Sweden and awarded by the Royal Swedish Academy of Sciences, to support those areas of science not covered by the Nobel Prizes. Ehrlich has also won many other awards, including the Volvo Environmental Prize in 1993; the United Nations Sasakawa Environment Prize in 1994; the Heinz Award for the Environment in 1995; the Tyler Prize for Environmental Achievement and the Dr. A.H. Heineken Prize for Environmental Sciences in 1998; the Blue Planet Prize in 1999; the Eminent Ecologist Award of the Ecological Society of America; and the Distinguished Scientist Award of the American Institute of Biological Sciences in 2001.

El Salvador

POLITICALLY UNSTABLE THROUGHOUT the 1980s, peace was achieved in El Salvador in 1992. The agreement between the existing government and leftists rebels paved the way for much-needed reform in El Salvador. Bordering on the northern Pacific Ocean, El Salvador has a coastline of 190 miles (307 kilometers) and is the only country in Central America that does not have a Caribbean coastline. Along the Pacific coast, the climate is tropical. The rainy season, which lasts from May to October, is followed by a six-month dry season. In the uplands, the climate is temperate. El Salvador's terrain is mountainous with a narrow coastal belt and central plateau.

Due to the presence of volcanic activity, El Salvador is sometimes called the Land of Volcanoes. The country is also subject to frequent, potentially destructive earthquakes and hurricanes that damage the environment and threaten human life and property. Nearly a third (31.85 percent) of El Salvador's land is arable. Although 59 percent of Salvadorans live in densely populated urban areas, there are only 30 passenger cars per 1,000 people. Other natural resources include hydropower, geothermal power, and petroleum.

Though it is the smallest country in Central America, El Salvador is the third richest. With a per capita income of $5,100, El Salvador ranks 131st of 232 countries in terms of income. Family income is unequally divided, however; among the population of 6,704,932, the wealthiest 10 percent of the population hold 39.3 of national resources. The misdistribution of resources and the large population of landless peasants form the roots of historical unrest in the country, with implications for the nation's future.

Major environmental issues in include deforestation, soil erosion, and water pollution. Soils are also highly contaminated from improper disposal of toxic wastes by chemical and fertilizer industries. In addition, El Salvador faces a rising threat to the human environment with an HIV/AIDS rate of 0.7 percent. It is estimated that some 29,000 are living with this disease, which has been responsible for 2,200 deaths. A 2006 study by scientists at Yale University ranked El Salvador 73rd of 132 countries on environmental performance. This ranking placed the country below the relevant income group average (67.2) and significantly below the geographic group average (72.3). The lowest scores were received in the areas of biodiversity and habitat protection and air quality. The Salvadoran government

Land of Volcanoes

El Salvador has been described by some writers as a "land of volcanoes," and although it is the smallest mainland nation in the western hemisphere, only about the size of Massachusetts, it has 25 significant volcanoes, four of which are active. It is partly from these volcanoes that El Salvador has some of the most fertile soil in Central America, being ideal for growing coffee, the largest crop in the country.

The largest volcano in El Salvador, Santa Ana, is 7,800 feet (2,377 meters). A major tourist attraction, the eastern slope has the Lago de Coatepeque, a 4 mile (6 kilometer) wide and 392 foot (120 meters) deep volcanic lake, around which are located a number of expensive holiday houses belonging to wealthy people from San Salvador, the nation's capital.

The newest volcano, and the most famous, is Izalco, in the west, located on the same fault line that affects California. Much of the volcano of Izalco was created on February 23, 1770, when there was a minor eruption followed by other eruptions. This quickly led to the formation of a mountain of 6,000 feet (1,829 meters). At Lake Ilopango, an eruption near there in 1879–80 was attributed to the fury of a goddess who lived in the lake.

Each year since 1922, on September 1, there has been a festival to commemorate the eruption of a volcano on that day. In addition to the volcanoes, El Salvador is regularly affected by earthquakes, with some happening in 1575, 1594, 1671, 1719, 1798, 1806, 1815, 1839, 1854, 1873, 1917, and on May 3, 1965.

has protected 0.4 percent of the land, and particular attention has been paid to the Los Cóbanos Reef and the wetlands of Guija Lake, Olomega Lake, Cerrón Grande, and El Jocotal. None of the 141 bird species endemic to El Salvador are threatened, and only two of the 135 endemic mammal species are endangered.

The Ministry of the Environment and Natural Resources is actively involved in educating Salvadorans in environmentalism. Through the Environmental Law of 1998, the ministry has the responsibility for conservation and protection of flora and fauna, improving air quality, promoting access to clean water and improved sanitation, and integrating the management of water resources and waste management. Under the Joint Declaration Central America–USA (CONCAUSA), the United States provides El Salvador with assistance in environmental planning and policy implementation with the goals of protecting natural resources, conserving biodiversity, encouraging energy development, and reducing pollution levels.

El Salvador has demonstrated commitment to the global environment by participating in the following international agreements: Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Ozone Layer Protection, and Wetlands. The Law of the Sea agreement was signed but has never been ratified.

Electrical Utilities

ELECTRICAL UTILITIES ARE organizations that are responsible for generating and marketing electricity to the public and government sectors. Because of the strategic importance of electricity to society and the economy and the fact that many geographically remote areas would not be profitable to supply, many electrical utilities are publicly owned. State-owned agencies have in some countries superceded private sector projects that were the first to be constructed, although in some cases the two sectors may share the burden of providing power. In some places, comparatively small, not-for-profit utilities can also exist to supplement the larger power grid and help in protecting the interests of rural households and communities. However, over the last few decades, many governments have been experimenting with different forms of privatization and deregulation, which in many cases have led to higher prices for consumers and high levels of profit for shareholders. In some cases, such as California, manipulation of the energy markets has led to massive levels of profit achieved through price gouging.

THREE FUNCTIONS

Electrical utilities deal with all or some of the three functions of the industry: generating electrical power, distribution of the power, and the collection of fees. In some cases, there may be brokers who buy and sell power but are not responsible for producing or distributing it. State-owned utilities customarily perform all of these activities, but may disaggregate for privatization or corporatization. Clearly, some parts of the process offer more opportunities for profit-making and are more popular than others with potential shareholders. In any case, the privatized corporation is likely to be regulated by a designated public office, and legislation will generally have to ensure that its future behavior is appropriate. Regulatory areas of concern include the maintenance of the distribution system, the safety of the generating plant and its environmental impact, the secure provision of services, and the degree to which prices are permitted to vary.

Since a great deal of electricity generation is based on hydrocarbons, which may be sourced internationally and on an open market, it is inevitable that the price will vary. However, electric power is essential for safety and health institutions, whose abilities to pay are generally not flexible enough to accommodate significant price fluctuations. Consequently, these institutions benefit from regulations that cap prices and provide guarantees in terms of safety and security of delivery.

Despite some inefficiencies involved in distributing power over long distances, this option is still quite feasible in many cases. The development of hydroelectric power in Laos, for example, has been affected through both World Bank funding and extensive investment from Thailand, which is expected to produce a demand for power that is unlikely to occur domestically for many years. Cross-border provision of electricity poses a number of questions about taxation, responsibility for environmental impacts, and equity issues concerning the desirability of transferring valuable domestic resources overseas. These questions are customarily dealt with by using market or semi-market based transactions with negotiations involving government agencies and representatives.

Providing an appropriately fair and transparent regulatory regime is important in encouraging private-sector investment in renewable energy generation and the accompanying utilities. Incentives may also be necessary for this investment in cases where initial production is unlikely to be strongly profitable, at least not in the short term. The exact extent to which regulation is required remains uncertain: some countries, such as those that are part of the European Union, maintain heavy frameworks that are more rigorous than in many other countries. Harmonizing regulations across borders where institutional differences are influential remains a very complex task.

Electricity

ELECTRICITY IS A term for energy that can be present or flow as an electric charge. It is visible in lightening flashes. Electric eels, electric catfish, and electric rays use electricity for hunting or defense. Electricity occurs at the subatomic level in the form of electrons that orbit the nuclei of atoms. Electrons form force fields to hold atoms together as solids.

Electricity can be static or conducting. Static electricity occurs when there is an imbalance between materials that are positively and negatively charged with electrons. Electric currents are a flow of electric charges through a conducting material, such as copper, and can be harnessed for useful purposes. The production of conducted electricity, its use in electronics, and in electric power motors is one of the great developments of the 20th century, and has created enormous changes in human life.

The environmental impact of electricity has been enormous. The invention of the electric light bulb almost destroyed the Standard Oil Company created by John D. Rockefeller. The advent of kerosene oil for lamps probably saved whales from extinction because it ended much of the demand for whale oil used for decades to light lamps.

To supply electricity, electrical generating plants had to be built. The power to turn an electrical dynamo came from water power. Great numbers

Conducted electricity is one of the great developments of the 20th century, creating great changes in human life.

of the dams built in the United States and around the world since 1900 have been for the purpose of generating *hydroelectricity*. The whole Tennessee Valley Authority system was designed not only for flood control, but also for the generation of electricity. Other famous dams such as Hoover Dam and the Boulder Dam were built for supplying water for irrigation, but also for electrical generation. The dams have had an enormous environmental impact on industrial, urban, and suburban growth.

Other energy sources that supply electrical power can also be created by the heating of water that creates steam for turning the turbines of electrical dynamos. Coal, gas, oil, and atomic power are the principal fuels. These fuels all have ecological consequences. Coal mining's environmental impact is considerable, because the vast quantity of coal needed for electrical generators is often the cheaper kind that is produced by strip mining. The cleanest option is likely natural gas, but it too has a negative impact as the methane in natural gas is converted into carbon dioxide, which contributes to global warming and the buildup of greenhouse gases. Nuclear power is at the same time the cleanest and the dirtiest of the fuels used for powering electrical power plants. The immediate impact of nuclear fuel is insignificant unless a disaster such as Chernobyl occurs. Spent nuclear fuel can be recycled in some cases; however, it is often recycled into weapons-grade nuclear material. If it is to be disposed of as waste, there are enormous difficulties in finding a place that will be safe for thousands of years from leaks that could poison the environment over vast areas for centuries.

Electrical transmission lines crisscross the more developed areas of the world, marring the natural beauty; however, they have also brought electricity to rural homes and a better way of life by enabling contact with population centers via radio, television, and Internet connections. Electric cars were popular from the 1880s until the 1920s, when the low cost of gasoline and the greater range of gasoline engines pushed consumers into buying gasoline-operated automobiles. However, since the 1970s, the development of electric-powered vehicles from personal golf carts to larger cars has proceeded steadily to replace gasoline engines.

Elephants

THERE ARE TWO main species of the elephant (*Elephas maximus*), which are commonly known as the African elephant and the Indian elephant. The African elephant is the largest living land creature and can weight up to eight tons and measure several meters in height. The Indian elephant is slightly smaller. Elephants are well known for their trunks and for their tusks, which are made of the highly prized substance ivory, making elephants a major target of poachers. The number of elephants in the wild has declined considerably as a result of encroachment onto their natural habitat and through poaching. There are estimated to be somewhere between 300,000–600,000 African elephants remaining in 37 different countries, and between 35,000–50,000 Asian elephants in 13 countries. Hundreds are known to die each year as the result of human action, either directly or indirectly. Some elephants aggressively respond to such human action, and may even suffer from post-traumatic stress disorder. The area of ground that they have been able to inhabit has declined considerably, as many parts of the world have undergone climate change. Elephants were, for example, prevalent throughout much of China, but are now limited to the narrow strip of the Xishuangbanna on the borders of Laos and Burma (Myanmar), where less than 300 wild animals remain.

Elephants are related to a wide range of other mammalian creatures, including extinct tusked creatures, and those that have survived, such as the dugong. They live customarily in social groups of up to 100 or more, and recognize all members of the tribe. Family relationships are very strong. Large and powerful animals, elephants have an important role to play in shaping and preserving the environment in which they live. The roadways they create by regular movement through the forest enable light and smaller animals to reach areas that might otherwise be inaccessible. These roadways also act as

Elephants of War

As well as beasts of burden, elephants were used in warfare by many peoples, with varying degrees of success. Hannibal's use of elephants was probably the most famous, but he was only one of many commander to use them in battle.

The soldiers of Alexander the Great encountered war elephants for the first time at the battle of Gaugamela in 331 B.C.E. when a small number of Indian elephants were deployed by the Persians. The only reference to them being at the battle identifies them as Indian elephants. However, it was not long before Alexander the Great's army faced some 200 elephants from the army of Porus, King of India, at the battle of Hydaspes in 326.

The Macedonians used elephants in their armies during the Diadochi Wars, with Ptolemy having 73 and his opponent Antiochus having 102 at the battle of Raphia in 217. However, it was their use by the Carthaginians that captured the imagination of Roman writers. With the Carthaginian Empire based in North Africa, small North African elephants were trained for battle, along with some Indian ones. In 219–218, Hannibal took 34 elephants with him from Spain in his invasion of Italy. Only seven of the elephants survived the journey, causing great shock among the Roman soldiers. One lived on in Italy for a few years, with some coins of the period showing it as an Indian elephant. When the Romans attacked North Africa, Hannibal deployed large numbers of elephants at the Battle of Zama in 202 B.C.E. However, the Romans were prepared for this, and making loud noises, they drove the elephants back onto the advancing Carthaginian armies, contributing to the Carthaginian defeat.

By this time elephants were being used by armies in India, China, and in southeast Asia. The Khmer empire of Angkor and their opponents, the Chams of central Vietnam, both used war elephants in their battles, as did the Thais who captured and destroyed the city of Angkor in 1432.

conduits for seeds, some of which are fertilized by elephant dung, as well as being possible firebreaks or drainage channels. Loss of elephants, therefore, can affect a wide range of flora and fauna. However, many African villagers consider elephants to be large pests, since the passing of a herd through a village can cause its destruction. Elephants don't migrate very often, but may be forced to search for safe habitat and food. Elephants have been domesticated for approximately 4,000 years and have been used as beasts of burden, as a means of lifting heavy objects, and in warfare. Elephants are not aggressive, but permit troops to mount them, to shoot arrows, or wield melee weapons. Elephants continue to be taken from the wild for their labor in the contemporary world. Some, as in Thailand, are kept to perform for tourists and are often abused.

El Niño–Southern Oscillation (ENSO)

THE EL NIÑO–SOUTHERN Oscillation (ENSO) is a phenomenon that occurs in the tropical Pacific Ocean approximately every two to five years and typically lasts nine to 12 months. ENSOs, and the opposite condition, called La Niña, represent severe disruptions of the normal weather patterns over the Pacific and have significant impacts on weather around the world. These events typically start around August, reach their peak intensity in December through April, and dissipate in the spring and early summer. However, particularly strong events can persist for up to four years.

ANATOMY OF THE PHENOMENON

Under normal conditions, the northeast trade winds push surface waters westward across the tropical Pacific ocean. These waters warm as they absorb solar energy and pile up in the western Pacific near Australia and Indonesia. Here, the warm water contributes to low air pressure, and the resulting convection, along with evaporation from the warm ocean, creates plenty of rainfall. At the same time, the eastern Pacific (off the coast of South America) normally has cool surface temperatures, due to cold surface currents flowing toward the equator from higher latitudes. In addition, cold water is brought up to the surface to replace the water that has moved westward, in a process known as upwelling. Because the ocean surface tends to be cold in the eastern Pacific, the air pressure tends to be high and there is little rainfall. However, the upwelling brings nutrients to the upper layer of the ocean, so even though the land is dry the ocean is extremely productive and fisheries thrive.

When an ENSO occurs, this normal condition is altered. In the ocean, warmer-than-normal surface waters move eastward along the equator, and sea surface temperatures become unusually warm in the eastern tropical Pacific Ocean (along the equator between the International Date Line and South America). Off the coast of Peru, fisherman historically observed unusual warm currents around Christmastime and referred to them as *El Niños*, referring to the Christ Child. The name was later extended to refer to the entire warming event.

The warm waters in the eastern Pacific cause lower than normal air pressure in that region, while the unusually cool surface waters in the western Pacific create high pressure. This is the Southern Oscillation part of the phenomenon, and can be thought of as a seesaw-like shift in the air pressure pattern across the tropical Pacific. Because the pressure pattern is reversed across the tropics during the ENSO event, the trade winds slow down or even reverse. The oceanic and atmospheric parts of the phenomenon reinforce each other: weaker trade winds allow more warm water to accumulate in the eastern ocean, while warm water in the east contributes to a weakening of the trades.

The reverse of the El Niño pattern is referred to as a La Niña and is characterized by unusually cold sea surface temperatures along the equator, lower-than-normal pressure in the western Pacific (near Indonesia and Australia), higher pressure in the central and eastern Pacific (near South America), and stronger-than-normal trade winds. La Niñas frequently occur immediately after El Niño events. Although the names El Niño and La Niña are common, it is increasingly preferred among atmospheric scientists to refer to these events as the "warm phase ENSO" and "cold phase ENSO," respectively.

HUMAN IMPACT

ENSO events have been occurring for at least 5,000 years based on paleoclimatic and archaeological evidence and have had significant impacts on human societies around the world. The most obvious impacts are seen around the Pacific Basin, where ENSO events bring heavy rainfall, flooding, and mudslides to the normally dry west coast of South America. During the 1982–83 event, one of the largest El Niños on record, approximately 600 people were killed in Ecuador in Peru. At the same time, the cold upwelling off the coast of South America was cut off, and fisheries declined. The economically important Peruvian anchovy industry was decimated during the 1982–83 event and has yet to fully recover. In the western Pacific, El Niño brings lower-than-normal rainfall and drought to Indonesia and northern Australia. During the 1997–98 event, another extremely strong El Niño, forest fires in drought-stricken Indonesia resulted in billions of dollars in damage and serious air pollution that was responsible for at least one deadly airline crash.

ENSO events have significant weather impacts outside of the Pacific Basin as well. When the warm ocean water shifts eastward, the main area of low surface pressure and convective storminess shifts eastward as well. This shift in pressure patterns results in altered patterns in the upper-level winds, which flow west-to-east at the top of the troposphere. Because the upper-level winds play a major role in determining where storms will form and move, they link the tropical Pacific to the rest of the world.

In the United States, ENSO events are associated with unusually wet and mild spring conditions across the southern half of the country, along with drier and warmer conditions across the northern half. ENSO events frequently produce stronger-than-normal upper-level winds across the southern United States and out into the tropical Atlantic Ocean. These upper-level winds disrupt the formation of hurricanes in the Atlantic Basin, and so El Niño years tend to have a reduced chance of hurricanes in the Gulf of Mexico and the Atlantic Coast. However, the strong jet stream over the southern United States gives this region a greater likelihood of severe weather, including tornadoes. Also, El Niño contributes to increased hurricane frequency in the eastern Pacific.

La Niña events tend to have the opposite effect on the United States. During a La Niña, the jet stream is shifted northward. As a result, the northwest coast and the Midwest often experience wetter-than-normal winter and spring weather, while the southern half of the country is warmer and drier than usual. Severe weather and tornado outbreaks are less likely than usual in the southern states. However, La Niñas produce upper-level patterns that are favorable for hurricane formation in the Atlantic and these storms become more likely to make landfall on the Gulf and Atlantic coasts.

Globally, El Niño events have been linked to increased precipitation in eastern equatorial Africa and parts of the Indian Ocean, while Brazil, India, southeastern Africa, and Madagascar generally experience drought. The opposite patterns tend to occur during La Niña events.

ONGOING STUDY OF ENSO

Although ENSO events have been occurring for thousands of years, a full understanding of the phenomenon had to wait until the latter part of the 20th century, when a sufficient amount of observational data in the tropical Pacific became available. The earliest piece of the puzzle was provided by Gilbert Walker, who first identified the Southern Oscillation while seeking an explanation for the occasional failure of the monsoon in India (which resulted in devastating famine when the rains did not arrive). In the 1950s, Jacob Bjerknes made the connection between the Southern Oscillation and the sea surface warming in El Niño episodes. Bjerknes hypothesized the complex ocean–atmosphere linkages known as ENSO in 1969. His hypothesis was able to be tested during the strong ENSO of 1977–78, and again during the event of 1982–83. Subsequent events have provided opportunities to refine our understanding of the process and impacts of this major source of variability in the global climate. One of the major questions still remaining is what impact global warming will have on the intensity and frequency of ENSO events. Thus far, there is insufficient evidence to determine whether or not any relationship exists.

Enclosure

THE CONCEPT OF *enclosure* refers to the conversion of communal or commonly held public lands into private ownership. It is used most often to refer to the vast changes in land tenure in the English landscape between the 15th and 19th centuries, when over 6.8 million acres—21 percent of the English land area—were "enclosed." Enclosure involved the reorganization of both public and private open field and meadow land properties, and also the reclamation of unused commons, moors, heaths, and other lands designated as wastes. Open fields and scattered cultivation plots were considered to be inefficient, and communal management strategies were thought to inhibit innovation. Other motivations for field enclosure included securing the right of way for roads and additional building lands for townships, establishing mineral rights, and stemming soil fertility decline due to overuse of common open fields. Finally, larger farm units made for easier administration and collection of rents.

Enclosure in England was both a public and a private process. Acts of Parliament to enclose public lands were initiated in 1604, but were mainly legislated between 1760 and 1830. Parliamentary acts dominated after 1750, with more than 5,000 acts of enclosure in the subsequent century. "General enclosures acts" were implemented upon petition from a landlord or following a formal agreement signed by parties including, for example, a landowner and communal land users. In cases of division of public or common lands held by a township, commissioners were employed to assess the claims of the various users and assign rents. As a private process, individual users of manor properties negotiated to establish leaseholds, often allowing the manor owner to charge increased rents.

TRANSFORMATION OF AGRICULTURE

Despite popular protest and a series of rebellions by the traditional users of the common lands, the completion of the enclosure acts in England affected more than just changes in land tenure. It resulted in the transformation of traditional models of agriculture based on open fields and communal grazing areas without fixed boundaries into small, private holdings separated by physical barriers including ditches, fences, and hedges.

The social and economic results of English parliamentary enclosure included the dispossession of small farmers and landless laborers, contributing to what Karl Marx and others have referred to as the creation of the English working class, which played a major part in driving the Industrial Revolution. The loss of open fields led to a decline in access to grazing for small husbandry and reduced access to nonwage sources of subsistence including the gathering of fuel wood, fruits, herbs, and other wild resources and reduced ability to glean the remains of harvest from common fields. According to one estimate, enclosure negatively affected not only those entirely dependent on the open field structure for economic survival, but up to 60 percent of families already working for a wage by the end of the 17th century.

The concept of enclosure has been used in critiques of contemporary land and natural resource conservation policy in reference to the creation of conservation areas through the exclusion of traditional users. The theory of the Tragedy of the Commons and the assertion that rural productivity and the environment are threatened by the absence of property rights, suggest that erecting formal property boundaries to eliminate open-access to forests, rangelands, and other resources will improve both conservation and economic outcomes.

Conservation and development initiatives based on these ideas have produced "conservation refugees" in what has been referred to as *greenlining* or *ecological expropriation* as the rights to traditional subsistence areas are restructured to limit use by certain populations. The estimated displacement of local peoples by nature reserves and national protected areas in Africa, for example, numbers in the millions. The lack of political leverage by the affected populations to contest the enclosure of their traditional lands has contributed to an increase in poverty with little documented improvement in conservation outcomes, in addition to the added costs of resettlement and park monitoring. In addition, common property research has shown that many common land use areas are managed by a well-developed system of community rules and regulations.

Endangered Species

DEPENDING ON THE status of their populations in the wild, animals and plants may be designated as rare, threatened, and under extreme conditions, endangered. The 1800s in the United States were a period when a number of large, highly visible mammals, such as the plains bison *Bison bison* and the eastern subspecies of the elk *Cervus elaphus canadensis* were being hunted. The disappearance of such important prey increased the threat to the wolf and mountain lion, both predators dependant on ungulates (hoofed mammals) for food. In 1966, the United States Congress passed the Endangered Species Preservation Act, which provided limited means of protection to native animals. The Endangered Species Conservation Act of 1969 took a wider view and provided protection to species facing extinction globally.

Finally, The Endangered Species Act (ESA) signed by President Richard Nixon into law in 1973, defined the term *endangered species* "as any species that is in danger of extinction throughout all or a significant portion of its range other than a species of the Class Insecta determined by the Secretary (of the Interior) to constitute a pest whose protection under the provisions of this Act would present an overwhelming and overriding risk to man." Section 4 of the ESA lists the various factors that help determine endangered status for a particular plant or animal. It requires the development and implementation of species recovery plans, as well as the designation of critical habitat for listed species. The ESA went even further, bringing together the provisions of Acts passed in the 1960s, resulting in the application of the same laws to U.S. and non-U.S. species. All classes of invertebrates became eligible for protection and all federal agencies were required to start conservation programs for endangered species.

The U.S. Fish and Wildlife Service (USFWS) and the National Oceanic and Atmospheric Administration's National Marine Fisheries Service (NMFS) share responsibility for administering the ESA. The USFWS generally manages land and freshwater species while the NMFS manages marine and anadromous species (fish born in fresh water that migrate to the ocean and return to spawn in fresh water). Of the 1,869 species currently listed under the ESA, 1,300 are found partly or completely within United States territory. At present, NMFS has management responsibility for 62 species, including the endangered blue whale *Balaenoptera musculus* and the marine leatherback turtle *Dermochelys coriacea*. The NMFS protects marine species from accidental capture in fisheries, habitat destruction, pollution, overharvest, and harmful contact with vessels by implementing time and area closures, modifications to fishing equipment, safe sea turtle handling practices, minimizing the effects of intense underwater sound, and minimizing strikes from ships by providing information on whale locations to ships at sea.

ENDANGERMENT BY DEVELOPMENT

In historical terms, as nations developed, increasing numbers of species have become endangered. Only the nature of the threat has changed, from excessive harvest of species to habitat change and destruction largely due to expanding agriculture and urbanization. The ESA is one of the most comprehensive wildlife statues implemented anywhere; its provisions spark direct conflict with industrial and commercial interests. Its impact is such that in the United States, the National Mining Association, an organization of the mining industry that employed over 250,000 workers in 2004, accused the USFWS of using the ESA to delay or stop mining projects altogether and called on the U.S. Congress to step in and "reform" the ESA.

The loss of biodiversity is a global concern. There are indications that current species extinction rates are 1,000 to 10,000 times the natural or "background" rate, higher than at any time for the past 65 million years. Populations of many species have collapsed to very low levels. Captive breeding programs are being run for endangered species such as the Himalayan musk deer *Moschus chrysogaster* spp. in China and India, and the USFWS's breeding program for the Black-footed ferret *Mustela nigripes* in Colorado and Utah. Other endangered animals are strictly protected in wildlife reserves, such as elephants, tigers, and the wild buffalo *Bubalus bubalis*.

THE RED LIST

In 1963, international concern at the loss of species and habitats led to the idea of a global list of threatened species. This compilation of species of special interest has come to be known as the International Union for the Conservation of Nature and Natural Resources (IUCN) Red List of Threatened Species, or the Red List for short. Also known as the World Conservation Union, the IUCN was founded in 1948. IUCN's Species Survival Commission (SSC) made up of about 7,000 volunteer scientists and species experts, is one of the six commissions that guide the work of the IUCN. The SSC's members are constituted into Specialist Groups, such as the African Elephant Specialist Group, that provide the scientific information necessary to assess the status of an animal or plant species. This evaluation determines whether a species is listed in the Red List, and if so, at what level of threat.

The Red List is the world's comprehensive and authoritative inventory of the best-known conservation status of plants and animals. It provides an index of the threat status of two groups that have been completely assessed—birds and amphibians. The Red List is also considered an indicator of the results of wildlife conservation programs. It assists in monitoring global trends of biodiversity and helps focus public attention on species that require immediate protection.

Species in the Red List of 2004 are assigned to one of nine categories of conservation status—Extinct; Extinct in the Wild (such as the Hawaiian Crow *Corvus hawaiiensis*, last seen in the wild in 2002); Critically Endangered (882 species); Endangered (1,779 species); Vulnerable (2,337 species); Near Threatened; Least Concern; Data Deficient; and Not Evaluated. The categories Critically Endangered, Endangered, and Vulnerable are for species at risk of extinction. The updated 2006 Red List contains 16,119 animals and plants facing the risk of extinction. Between 1996 and 2004, the number of species at risk of extinction in most groups of animals and plants has increased, indicating that man-made causes of environmental change continue to outpace conservation efforts. Particularly, the dramatic jump in threatened amphibians points both to better knowledge of their conservation status, and an increase in threats to wetlands. The degree of threat and risk of extinction is calculated in an intensive data-driven process depending on five biological criteria: rate of species decline, population size, area of geographic distribution, extent to which population and distribution are fragmented. The small size of many islands makes their animals and plants particularly prone to extinction, as in Hawaii where half of the approximately 100 land bird species were lost as a result of the activities of the native Polynesian islanders.

The causes of species endangerment are numerous. Human populations in species-rich developing countries continue to increase, with about 40 percent of the people living in abject poverty and depending on forests for firewood, timber, bamboo, and for cattle fodder. Dry and moist forests are being logged, then overgrazed, and finally com-

The Red List of Threatened Species lists the African Cheetah as "threatened indirectly by loss of prey base through human hunting activities and directly because it is considered to be a threat to livestock."

pletely denuded contributing to the loss of precious topsoil. The draining of wetlands, water diversion and pollution, the introduction of exotics, hunting, and unsustainable use of resources are other common factors. More recently, human migration and displacement, armed conflict, and global warming have emerged as direct and indirect factors contributing to species endangerment.

Endangered Species Act (1973)

WIDELY REGARDED AS the strongest and most significant piece of environmental legislation in the world, the Endangered Species Act (ESA) makes the protection of rare or imperiled species of plants and animals the highest priority of the U.S. federal government, at least in theory. Its core features are: a list of protected plants and animals; designation of "critical habitat" for listed species; mandatory compliance of all federal agencies and actions with the terms and objectives of the ESA; and the right of the public, through the National Environmental Policy Act, to petition for listing and to sue for compliance. Although the ESA's overall efficacy is disputed and political wrangling about it is intense, it nevertheless enjoys widespread support among the general public.

The 1973 Act replaced two earlier and weaker laws passed in response to surging environmental sentiment following publication of Rachel Carson's 1962 book, *Silent Spring*. The Endangered Species Preservation Act (1966) aimed to save the whooping crane and other charismatic birds such as the bald eagle by authorizing the Secretary of Interior to create a list of endangered domestic fish and wildlife and to spend a limited amount of money to buy habitat for their protection. The Endangered Species Conservation Act (1969) expanded the Secretary's authority to cover foreign species and banned imports of products made from listed species, in hopes of protecting the world's whales. A subsequent dispute with the Pentagon over listing the sperm whale—whose oil was used in submarines—helped motivate the stronger law and foreshadowed the legal–bureaucratic dramas yet to come.

Congress passed the new law almost unanimously. It extended protection to plants and invertebrates as well as fish and wildlife; required the designation of critical habitat for all listed species; forbid federal agencies from authorizing, funding or carrying out any action that might jeopardize the continued existence of listed species or that "destroys or adversely modifies" critical habitat; and forbid any party from "taking" a listed animal species without a permit. It defined *take* as "to harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or to attempt to engage in any such conduct." Penalties can rise to $50,000 and a year in prison, although prosecutions for "take" are virtually unheard of. Enforcement authority resides in the U.S. Fish and Wildlife Service for land and freshwater species (the vast majority of the total); the Department of Commerce's National Marine Fisheries Service (now known as NOAA Fisheries) is responsible for marine and anadromous species.

Ever since its passage, the ESA has been prone to unintended consequences, political firestorms, and scientific uncertainty. That private landowners might intentionally kill a species or destroy its habitat just before listing (or "shoot, shovel, and shut up" after listing, as the saying goes) prompted amendments and administrative reforms through the 1980s and 1990s in search of mechanisms to indemnify landowners who conserve or create habitat. From the snail darter (which nearly killed a Tennessee Valley Authority dam halfway through construction) to the spotted owl (celebrated or blamed—rather misleadingly—for decimating the timber industry in the Pacific Northwest), the nation's highest courts have consistently upheld the ESA's constitutionality and its priority over political and economic expedience. Yet in several cases Congress has then exempted projects, suspended listings, or enfeebled enforcement.

The ambiguity and ambivalence can be traced directly to the act itself, which walks a thin, tortured line between the simple ideal of preventing extinctions and the complex political economy of on-the-ground preservation. The law stipulates, for example, that critical habitat be determined "solely on the basis of the best scientific and commercial data available," yet it also directs the Secretary of Interior to consider "the economic impact, and any other relevant impact, of specifying any particular area as critical habitat." It then gives the Secretary discretion to exclude "any area from critical habitat if he determines that the benefits of such exclusion outweigh the benefits" of inclusion, *unless* he determines that exclusion will result in outright extinction. As more and more species have been listed over time—from fewer than 300 in 1980 to more than 1,300 in 2006 (excluding foreign species)—the limitations of scientific knowledge have become ever more acute, resulting in ever wider discretion. Only 475 listed species have had critical habitat designated in their behalf, even though habitat loss and modification dominate the causes of endangerment (for the U.S. excluding Hawaii and Puerto Rico, the top four are urbanization, agriculture, reservoirs and related water installations, and tourism and recreation development).

End-of-Pipe Regulatory Approach

THE END-OF-PIPE REGULATORY approach focuses primarily on the costs and issues relating to the point of origin of substances that cause environmental problems. The substances emerge from the end of a pipe, linking an industrial process with the external environment. Consequently, the burden of responsibility for any costs arising from this interaction is to be borne by the individual or organization that owns the pipe. Regulations have been created to try to ensure that pipe owners, therefore, meet any costs that accrue. This approach has been effective in minimizing environmental problems, since it has been clear whose responsibility any emission would be, and what penalties would apply in the event of noncompliance with regulations. Nevertheless, a number of dissenting voices have been raised against the approach and, while most of these can be discounted as the special pleading of industrial interests unwilling to accept responsibility for their own actions, some more cogent arguments have also been raised. It has also been argued that the approach has been too often inflexible and has failed to reduce a great deal of the toxic spillage that continues to occur.

In 2003, the U.S. Environmental Protection Agency (EPA) concluded that the rising number of regulations needed to monitor and control all of the possible forms of substance emission represented an inefficient and expensive approach to the problem. Further, the approach fails appropriately to take account of the various upstream economic or industrial activities that may have more influential impacts on the natural environment than those taking place at the dripping of the pipe-end. Regulating upstream activities may be undertaken as a separate stage of activity in which the responsible party may be monitored and, if necessary, penalized or else causing a single organization to be considered responsible for the whole process from production to delivery of industrial products and all stages along the way. The EPA has accepted the need for a more sophisticated approach to environmental pollution and the reduction or simplification of the existing regulatory regime to face current and future challenges.

The end-of-the-pipe approach also assumes that what happens at the end of the pipe is somehow inevitable and necessary. On the contrary, some environmentalists argue that the impact of the results of end-of-pipe activity depend upon such factors as the structure and extent of demand, which may itself be subject to well-judged intervention. For example, driving an automobile results in the burning of hydrocarbon fuels that have a detrimental effect on the environment. Therefore, in many countries, motorists are taxed on fuel purchases. Much of the contemporary understanding of how the negative impact of this activity should be managed is based on this approach. However, it is possible that alternative energy sources or changes in lifestyle and urban planning might significantly reduce the need for burning so much hydrocarbon fuel. Fixation on an end-of-pipe approach, therefore, can blind innovators to problems throughout the line when resolving environmental issues.

Energetics

ENERGY, SUCH AS lightening or sunlight, flows from one place to another. Energetics scientifically studies the way energy flows when it is being transformed from one form of energy into another form.

Energetics is a very broad scientific discipline that encompasses many disciplines, such as biological energetics, biochemistry, chemistry, ecological energetics, and thermodynamics. The boundary between these disciplines and other branches of energetics is a matter of considerable debate. The general aim of the discipline of energetics is to discover principles that can describe the useful and nonuseful tendencies of energy flows under transformation. The principles are statements that describe the way in which the phenomena observed as energy flows occur whenever they are observed in the same set of conditions. The ultimate goal of science in this and other areas is to identify and understand uniformities of nature than can be stated as laws of nature, or scientific principles. For example, the discipline of thermodynamics has developed principles that are usually referred to as the Laws of Thermodynamics. These descriptive statements of uniformities of nature can be called Laws of Energetics, as well.

Among the basic principles of energetics, the first is that if two systems are in a thermal equilibrium, and if the first of the two systems is also in equilibrium with a third system, then the second of the first two systems is also in equilibrium with the third system. A second principle says that the Second Law of Thermodynamics applies to a system so that over time, entropy increases so that energy is lost for further useful application. A third principle says that as energy increases in a system from an outside source, some of it is expended as work. A fourth principle states that as a system loses heat, all processes decline and eventually stop completely as the system approaches absolute zero.

The study of energetics in ecology systems is a quantitative discipline that is concerned with the flow of energy through environmental systems. Its goal is to discover the mechanism that allows energy to flow through ecological networks. The networks are composed of levels of energy-using or trophic relationships. A systemic approach seeks to discover the ecosystem energy interconnections.

Biological energetics studies the work done by organisms, everything from metabolism to reproduction to defensive actions. It measures work in either units of kilojoules (kJ) or units of kilocalories (kcal). The units measure how work is converted to heat or how heat can be used in work in the three biologically important forms of energy: chemical, electrical, and radiant energy, all of which may exist as potential or kinetic energy.

Organisms, fish, mammals, and all other life forms need to constantly acquire sources of energy such as food, and require the expenditure of energy to exist and to perform the functions of life. The energy facts of life are that the First and Second Laws of Thermodynamics apply to all living organisms. There is a real sense that death is a successful operation of the Second Law of Thermodynamics in the life of an organism. Energetics studies the way in which energy is transformed from potential to kinetic energy by the mechanisms of an organism.

The discipline of energetics has an ancient lineage. The ancient Greek philosopher-scientists were the first to study the subject. Energetics was advanced by the German philosopher Gottfried Wilhelm Leibniz (1646–1716). It was given modern expression in the work of William John Macquorn Rankine (1820–72), a Scottish engineer and physicist. Rankine was, with Lord Kelvin (William Thomson) and Rudolf Clausius, an important contributor to the development of thermodynamics in the 19th century. His paper "Outlines of the Science of Energetics," published in the *Proceedings of the Philosophical Society of Glasgow* in 1855, is often cited as the beginning of the formal discipline of energetics.

The application of energetics to human–ecological problems in recent years has allowed new views onto old problems. Human ecologists have, for example, compared energy flows through differing agricultural systems, examining their relative efficiency, as in Bayliss-Smith's comparative work, which reveals the remarkable efficiency of traditional agrarian practices relative to modern farming. Energetics has also been used to make more spurious and functionalist claims, however, using energy efficiencies as an explanation for cultural practices. Overall, the potential for energy-based analysis in modern environmentalism is arguably yet unrealized.

Energy

ENERGY HAS DIFFERENT meanings in different contexts. In layperson's terms energy can be defined as the measure of potential to bring changes in a system. In physics parlance, energy refers to capacity of doing work. Energy can occur in various forms: kinetic, potential, electromagnetic, sound, and so on. Energy of a moving car is kinetic energy, whereas the energy of water stored in a dam is potential energy. Energy can be converted from one form to another. For example, when water falls from a dam, the potential energy of water gets converted into kinetic energy, which drives turbines to produce electrical energy. When a car crashes into a wall, the kinetic energy of the car is converted into heat and sound energy. When such a conversion occurs, some of the useful energy is lost. As a result, not all energy can be converted to useful work. However, energy can neither be created nor destroyed (First Law of Thermodynamics). In SI units, energy is measured in Joule (J), which is equivalent to the work done when one Newton force is applied to move an object by 1 meter. Maintaining vital cellular activities that are necessary for survival requires a minimum of 4,000 kJ/day; whereas 20,000 kJ/day are required for activities such as bicycle riding, jogging, or construction work.

Energy sources have been broadly categorized as renewable and nonrenewable. Renewable energy refers to the energy that can not be depleted either due to its short-time frame of regeneration (e.g., biomass, ethanol from corn) or a source itself is inexhaustible for a considerable period of time running into millions of years. Traditionally, energy from sources such as solar, wind, geothermal, and biomass are considered to be renewable. Nonrenewable energy, on the other hand, can be depleted faster than it is regenerated, which usually occurs over a geologic time frame, that is, millions of years. Examples of nonrenewable energy sources are coal, oil, and natural gas.

Energy is very critical for industry, economy, and ecosystems since without energy, none of these can function and would not have existed today. The primary energy driving the earth system is solar energy, with tidal (lunar) and crustal energies being the next two most prominent sources. One example is the hydrological cycle. Solar energy heats up the oceans evaporating water into the atmosphere. Water vapors rise up due to lower density and eventually cool down to form clouds. Precipitation in the form of ice, snow and rain occurs from the clouds, which feed rivers, lakes, and groundwater, providing much-needed fresh water for humans and other living organisms. In ecosystems, primary producers (plants, green algae, diatoms, etc.) capture solar energy through photosynthesis and store it in carbohydrates, ATP, and acetate in the form of chemical energy. This stored chemical energy meets the energy demand of all other species higher up in the food chain or at higher trophic levels, including detritus. In addition, producers also release oxygen, an important component of cellular respiration that provides energy for all life functions of living organisms including movement, growth, and reproduction. Detritus plays an important role in an ecosystem by breaking down the dead plants and animals and releasing nutrients back into the ecosystems. In doing so, detritus derives energy from dead plants and animals. These nutrients, in turn, support the growth of primary producers. Industry derives materials and energy from the ecosystems that fuel growth and economic development. Fuels such as coal, oil, and natural gases, which are predominantly used by economy, are derived from energy stored in dead plants and animals through a series of transformations over a period of millions of years. Many of valuable materials we derive from ecosystems such as medicines, timber, foods, and biofuels are all products of biochemical pathways involving solar energy.

However, energy can also be destructive. Violent meteorological processes such as lightening, tornadoes, snow avalanches, and geological processes such as earthquakes, tsunamis, volcanoes are all manifestations of highly concentrated forms of energy derived either from sunlight or from the energy stored in the mantle of the earth.

HISTORY OF ENERGY USE

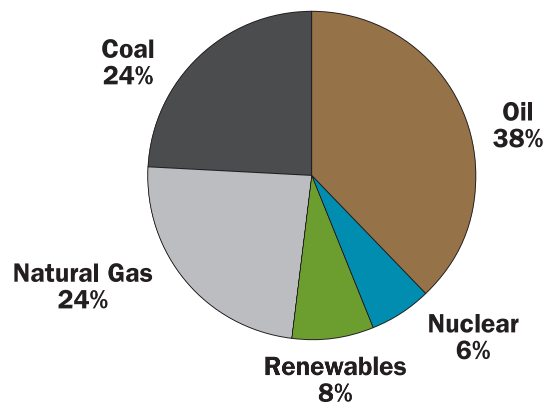
Other than sunlight, fire from biomass is probably the earliest reported use of energy by humans. In preindustrial societies, wood, straw, and charcoal were used to meet energy needs such as home heating, cooking, and ore smelting. Many such sources have been severely depleted due to their use in a nonrenewable manner. Energy required for labor was derived from the muscular power of humans and animals. For example, people used to plow agricultural fields with the help of animals. Seeding, planting and harvesting of crops used to be done manually by hand. Activities such as grain milling and transportation involved the use of cattle such as water buffaloes.

More sophisticated types of energy devices such as waterwheels and windmills were introduced only toward the end of the preindustrial period. In the early eighteenth century, the renowned scientist Lavoisier designed a 1,700 degree C solar furnace that concentrated solar energy and converted it to heat.

With advent of the industrial revolution, the demand, use, and diversification of energy substantially increased. For example, per capita annual combustion of fuels was 500 kg of wood equivalent by 1850s, which is very nominal compared to the current energy consumption. Taking into account the differences in energy efficiencies, annual per capita consumption of energy in 1995 was 20 times higher than in the 1850s. From early 1990s, electricity production from fossil fuels began. In 1990, less than 1 percent of fossil fuels were devoted to electricity production, which rose to 25 percent by 1990. Hydroelectricity came into existence in mid-1890s, and its global production has been increasing ever since. However, hydroelectricity production has almost leveled off in the United States since the 1970s, as virtually all viable sources of hydroelectricity have been utilized.

In 1956, the dream of the harnessing nuclear energy through controlled atomic fission was realized when the first commercial fission reactor came into operation. Initially nuclear energy was heralded as the energy of the future and a viable substitute for fossil fuels. In a flurry of activities, several nuclear power plants were built in the 1960s and 1970s, mostly in the developed countries. However, due to high construction costs, stringent safety requirements, containment of nuclear waste and disposal, and possibility of nuclear disasters (Three Mile Island Accident), and low crude oil prices, nuclear power plants became a less-preferred option. Very few nuclear plants were commissioned after 1980, and the much-hyped nuclear energy solution failed to live up to its earlier prediction.

In last 20 years, alternative sources of energy such as solar, wind, and biomass have received more attention. In terms of electricity production, wind energy is emerging as an attractive option. Production of biofuels such as ethanol and biodiesel is gradually increasing, which find their applications in automobiles as substitutes for gasoline and diesel. Brazil leads the world in biofuel production. Brazil produced 14 million m^3 of ethanol from sugarcane in 2002. In the renewable energy category, hydroelectricity still predominates. In 1997, the share of hydropower in the renewable sector was 55 percent, followed by biofuels (38 percent) and geothermal (5 percent), whereas solar and wind energy accounted for only 2 percent of renewable energy produced in the United States. Nonrenewable energy including oil, gas, and coal had the largest share (86 percent) of the total marketed energy worldwide in 2003. The total primary energy consumed worldwide in 2005 was 9800.8 million tons oil equivalent (toe).



World marketed energy use by fuel types in 2003 (totals do not equal 100 percent due to rounding errors).

PLANETARY ENERGY FLOWS

The earth receives 3.93×10^{24} J/yr of solar insolation. The oceans capture 5.2×10^{19} J/yr of tidal energy resulting from gravitational forces of attraction of the sun and moon acting on the earth. The earth's crust draws 4.74×10^{20} J/yr of the heat energy from the mantle. In addition, it derives the heat energy from the radioactive decay of radioactive elements present in the interior part of the earth that equals 1.98×10^{20} J/yr, making the total crustal heat energy 6.72×10^{20} J/yr. Solar insolation and tidal energy contribute 6.49×10^{20} J/yr of heat by passing some of the energy as compression and chemical potentials. Thus, the total heat outflow in the earth system is 13.21×10^{20} J/yr. An ecosystem captures only 1% of solar energy falling on it. When energy is transferred from autotrophs to consumers at higher trophic levels, energy gets lost. Only 10 percent of the energy entering a given trophic level gets transferred to the next trophic level.

FOSSIL FUELS

Fossils fuels comprising petroleum, natural gas, and coal are primary energy sources. All fossil fuels are products of a series of biological, chemical, and physical transformations of plant and animal remains over geological time frames. It is estimated that total reserves of fossil fuels in the earth was about 317,700 × 10^{18} J in 1999.

Coal: Coal, which led to the growth of fossil-fueled civilization, is a solid black or brown mass obtained from the arrested decay of the metamorphosed remains of plants that were buried in marshes and bogs millions of years ago. First plant debris got converted to peat through bacterial and chemical transformation. Thereafter, a series of actions involving heat and pressure converted peat into various types of coal. Coals are not identical because of differences in original vegetation, the extent of transformation, the magnitude and duration of pressures, and temperatures. Coal primarily consists of carbon and small amounts of sulfur, nitrogen, and ash. Good-quality coals—*anthracite and bituminous* coal—were obtained from the wood of large, scaly barked trees that grew in large coastal swamps about 2 million years ago. The low-quality coals—*lignites*—are the youngest, and soft with a brown tinge. Due to appreciable amounts of moisture, sulfur, and ash, they have low heat content and emit substantial amounts of oxides of sulfur and nitrogen. Coal is extracted either by surface mining or underground mining.

Petroleum: Petroleum, also known as *rock oil*, is a liquid present in the upper earth crust. Like coal, petroleum is derived from biological, chemical and physical transformations of plant and animal debris over millions of years. Petroleum is a complex mixture of hydrocarbons with a varying molecular weight and physical and chemical attributes. Petroleum, being a hydrocarbon, primarily consists of carbon and hydrogen with small amounts of nitrogen and sulfur and a few metals. Petroleum is processed and refined to produce gasoline, diesel, jet fuel, methyl tertiary butyl ether (MTBE), tar, and other products.

Natural Gas: Natural gas occurs in the underground reservoirs of porous rocks. It also occurs as a mixture with petroleum and is recovered by petroleum refineries. Natural gas consists of methane as a major component (70–90 percent by volume) with smaller amounts of ethane, propane, butane and other paraffins. In addition, natural gas consists of inert gases such as nitrogen and carbon dioxide along with hydrogen sulfide. Natural gas is distributed to consumers (industrial, commercial, residential) via pipelines. Natural gas is also liquefied and transported by special tankers.

BIOMASS ENERGY

Biomass refers to plant-based organic products such as wood, corn, soybean, crop residues, and organic wastes. Biomass can be burned directly to produce heat and electricity or converted to liquid fuels and gas through pyrolysis, fermentation, and anaerobic digestion. Biomass is an important part of the renewable energy supply in developing countries and is used primarily for heating and cooking. It is gaining importance in developed countries for electricity production and automobile transport. Biomass has chemical energy stored in carbohydrates and other complex organic compounds that can be harnessed for different uses. Biomass as an energy raw material is attractive due to its wide distribution, availability, and renewability, which make it possible to develop decentralized energy production and distribution systems. However, its low energy content, the need for drying, transportation, and competition for land with other uses such as food, wood, and shelter undermine its advantages.

Biomass, including wood, switchgrass, and bagasse has been used to generate process heat, steam, and electricity either through direct burning or gasification. The biomass gasifiers yield gaseous products whose composition varies depending on the nature of feedstock and reactor conditions. Short-rotation woody crops such as sycamore, poplar, and eucalyptus have been studied for use in electricity production through co-firing or gasification. Biomass can also be converted to gaseous products and coke through pyrolysis that can be used for space and water heating, cooking, and process heat. Ethanol is derived from sugarcane and corn by fermentation, and has been used as a transportation fuel. In the United States, the total ethanol production from corn topped 4 billion gallons in 2005. Recent studies suggest that ethanol can also be produced from cellulosic feedstock, expanding the possibility of ethanol production. It is estimated that the global potential for ethanol production from crop residues and wasted crops could be 442 GL/year. Biodiesel has been synthesized from a variety of oilseed plants, including soybean, jatropha, rapeseed, and sunflower through transesterification.

Biomass such as municipal wastes and cattle manure is used to produce methane through anaerobic digestion. Methane digesters are more popular in developing countries. Thousands of homes have benefited from installations of methane digesters. These digesters mainly rely on cattle manure for energy feedstock. A typical digester consists of a digester chamber, where an anaerobic reaction occurs; a metal dome with a pipe to collect biogas (methane); an inlet to feed the digester with manure; and an outlet connected to overflow tank that collects digested slurry. The digested slurry is applied to farmlands to improve soil fertility and increase productivity. Biogas is mainly used for cooking and lighting. Since biomass burns more cleanly than fuel wood, it has reduced indoor air pollution and respiratory diseases, particularly for women, since women normally prepare meals for their families in developing countries.

SOLAR ENERGY

Due to widespread availability of solar power, people have been harnessing solar energy in many ways since time immemorial. An example is the passive energy system utilized by the homes of the Anazasi Indian Tribes in the southwest United States. The solar energy technologies can be broadly categorized into four groups: passive heating, active heating, solar-thermal electric, and solar photovoltaic.

Passive solar technology relies on design and placement of windows and walls to optimize heat collection, and retention in buildings. The characteristics of building materials such as cement, clay, stones are also taken into consideration. The term *passive* implies the absence of moving parts and controls. Active solar technology, on the other hand, is designed to capture greater amount of available solar energy by utilizing collectors and a circulating coolant that transfers heat from the collector to the point of use. The term *active* implies that it has moving parts and controls. A solar water heater is one example of active technology. There are several types of collectors that have been used: flat-plate collectors, focusing collectors, evacuated tube collectors, and parabolic dish solar collectors. Of these, flat-plate collectors are most widely used, mostly in homes.

The principle of a solar-thermal electric system is same as that of active solar heating. The only difference is that the heat captured from the coolant is used to heat a primer fluid that can be pressurized water or compressed air that drives a turbo generator unit to produce electricity. Focusing or parabolic dish solar collectors are used for such an application.

A solar photovoltaic system is based on the principle of the photoelectric effect. A photovoltaic system converts solar energy to electrical energy when solar rays fall on the p-n photvoltaic device, causing the release and migration of electrons from an n-type semiconductor to a p-type semiconductor. Silicon dioxide, cadmium telluride, and copper indium diselenide are the commonly used semiconductors in photovoltaic cells. Features such as simplicity, low maintenance requirements, absence of moving parts, and scalability make it attractive. Nonetheless, the main concerns of photovoltaic have been the cost and efficiency. Efficiency of solar-electricity conversion has improved from a few percent to 20 percent, and costs have decreased from $250/W to $2.5/W or less. These numbers are still not good enough for large-scale commercial production and adoption, especially considering low costs of fossil fuels.

WIND ENERGY

Wind power technology utilizes the energy of the sufficiently strong winds to drive turbines and produce electricity. The differential heating of the earth's land and sea surfaces produces winds by creating a pressure gradient. Air moves from the area of high pressure to low pressure, creating a wind. Wind electricity production is basically the extension of traditional windmills. Wind power plants are usually installed in the areas that experience regular and reasonably strong winds with speeds greater than 5.5 m/s. Theoretically, it is possible for the earth's winds to provide 5,800 quadrillion BTUs of energy per year, which is 15 times more than the present world energy demand.

The worldwide wind-electric capacity has been increasing steadily. The world wind power capacity was 58,982 megawatts (MW) in 2005, which was less than 1 percent of the worldwide electricity supply. In 2005, Germany was leading wind power production with 18,428 MW capacity, followed by Spain, The United States, India, and Denmark. Although wind energy is relatively economical among renewable energy alternatives, concerns about aesthetics and noise pollution, failures of some product lines, remoteness of suitable sites from highly populated areas requiring high voltage transmission systems, and daily and seasonal variation in wind speed are obstructing its rapid expansion.

GEOTHERMAL ENERGY

Geothermal energy is the energy extracted from the porous and permeable hot rocks with or without fluid present in the earth's crust, a few miles below the surface. The upward conduction and convection of the heat from the mantle, and the heat energy produced by radioactive disintegration of radioactive elements heat up the rocks. Occasionally, magma also intrudes the earth crust, transferring heat to the rocks. At places where subterranean faults and cracks are present, rainwater and snowmelt seep underground and come in contact with the hot rocks, where the water is heated and returns back to the surface in the form of hot springs, geysers, and mud spots. If the heated water cannot rise to the surface due to the presence of impermeable rock above, it fills the pores and cracks of the hot rocks below, creating geothermal reservoirs. The temperatures of water in geothermal reservoirs are far greater than those of hot springs, reaching more than 350 degrees C. The hot water can exist as a supercritical liquid or saturated steam, and can be extracted by drilling and used for electricity generation or space heating. The hot water either rises to the surface naturally or has to be pumped up. Generally, shallower geothermal reservoirs with lower temperatures (41-149 degrees C) are used for heating in spas, greenhouses, industry, and homes.

The majority of geothermal power plants under operation today are flashed steam plants. When the hot water is suddenly released from the reservoir pressure, it boils and produces steam, which drives the turbines and generates electricity. To maintain the reservoir pressure and recharge the reservoir, cold water is recycled back to the reservoir. Since the installation of the first geothermal system at Larderello, Italy in 1904, its use has increased worldwide, with the current production capacity standing at 8,000 MW.

NUCLEAR ENERGY

Nuclear power has a share of 17 percent of the world's electricity supply and contributes about 7 percent of the world's energy supply. Nuclear energy is primarily derived from the atomic fission of heavy isotopes such as ^{235}U and ^{239}Pu. When fission of heavy isotopes occurs upon neutron bombardment, it is accompanied by the release of more neutrons and a net mass loss. This lost mass manifests itself in the form of energy according to the famous equation, $E = MC^2$. When a fission reaction occurs uncontrollably in a critical mass, a massive amount of energy is released, which is the basis of atomic bombs used in the World War II. However, if the fission reaction is controlled and kept in a steady state by using control rods such as cadmium that capture neutrons, thus preventing them from causing more fission reactions, heat energy can be generated in a sustained manner. This heat energy is used to produce steam that drives turbines to produce electricity. The first constructive application of nuclear energy was the nuclear driven submarine that used a small boiling water reactor.

There are different types of nuclear reactors used for producing electricity. They are: light-water reactors (LWR), pressurized-water reactors (PWR), boiling water reactors (BWR), large tube type reactors (RBMK), heavy-water cooled reactors (also known as CANDU), gas-cooled reactors (GCR), and liquid metal reactors (LMR).

An important component of nuclear energy is the fuel itself. The fuel, mainly uranium, is extracted from earth as uranium-bearing ore by surface mining. Uranium is separated from its ore in a chemical leaching facility as U_3O_8. This is followed by its conversion to gaseous uranium, UF_6, which facilitates its enrichment via gaseous diffusion or centrifuge-based process. The enriched UF_6 is converted into UO_2 and fabricated into rods for use in nuclear reactors. The enriched uranium contains 3% or more of ^{235}U. When the fuel rods no longer become usable, they have to be removed and stored as spent fuels to avoid radioactive contamination in the surrounding environment. The long-lasting containment of the spent fuel is one of the concerns afflicting the nuclear power technology.

HYDROPOWER

Hydropower is the largest renewable energy used in the world and contributes 20 percent of the worldwide electricity production. Hydropower comes from moving or falling water that drives turbines and generates electricity. In the process the potential energy of water is converted into electric energy. This has been possible due to the hydrologic cycle, which is driven by the solar energy. The amount of power that can be extracted from water is a function of the head (difference in height between the water's outflow and the turbine), volumetric flow rate of water, and efficiency of the turbine.

Energy stored in water is tapped in three different ways: creating a reservoir by dam construction, diversion hydropower in which a part of the river is diverted through a canal and made to fall from a suitable location that provides adequate head, and pumped storage, wherein power in off-peak hours is used to pump the water from the source to the reservoir located at the higher elevation and its energy is subsequently tapped during the peak hours. Hydropower installations are economical and known for robustness and durability. Some hydropower plants are operating even after 100 years. Canada is the largest producer of hydropower, which meets 70 percent of the total electricity demand. Virtually all of Norway's electricity comes from hydropower. Iceland meets 83 percent of its electricity demand from hydropower. Overall, it is estimated that it is economically feasible to harness more than 7,300 TWh/yr of hydropower worldwide.

Fossil fuel use has dramatically increased, leading to an unprecedented rise in carbon dioxide levels.

TIDAL ENERGY

Since ocean tides embody vast amounts of energy, they have become a part of an effort to harness earth's renewable energy dating back to medieval periods. Tidal waves offer possibilities of harnessing energy in two ways: kinetic energy that results from the currents between the high (surging) and low (ebbing) tides, and potential energy due to the head between high and low tides. However, all tidal energy installations at present exploit the potential energy of tides, even though harnessing kinetic energy also looks feasible. High and low tides are due to the earth's rotation and gravitational force of attraction between the moon and earth, and the sun and earth.

To capture the potential energy, barrages consisting of sluices and turbines are built to trap the ocean water in the basin during the high tides. During the low tides, the head is created between the water levels inside and outside the barrage. Due to this head, water flows back to the ocean when sluices are opened, thereby driving turbines and generating electricity. This mode of operation is called ebb generation. Alternatively, tidal energy can be captured through a flood generation method. A barrage is built to hold back the incoming high tides that create a head difference across the barrage. As water flows into the basin, turbines rotate producing electricity. This is a less efficient mode of operation A tidal power plant cannot provide continuous electricity, because high and low tides occur only twice a day. Typically, a conventional tidal plant generates electricity for 6–10 hours a day irrespective of a mode of operation. Today the worldwide tidal power capacity stands at about 11,000 MW.

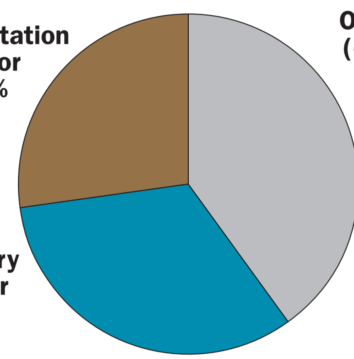
ENERGY USE

Energy finds its use in every facet of human and ecosystem activity, such as transportation, industry, and commercial and residential buildings.

Transportation is an important component of our daily life and, on average, a person spends 10-15 percent of their income for transportation. Energy consumption in the transportation sector accounts for one-fourth of the total national energy use in the developed countries. Most of this energy goes into driving personal vehicles and heavy trucks. Automobiles require 5,874 Btu of energy per mile per vehicle. Sport utility vehicles and light trucks consume even more energy per mile (7,247 Btu/mile). Air transportation consumes about 10,481 Btu/passenger-mile. Almost all personal vehicles and other means of transport are fueled by petroleum although renewable energy is finding its way in. For example, natural gas constitutes 2.5 percent of energy consumption in the transportation sector whereas the electricity accounts for 1.2 percent in the United States.

Industry accounts for the largest energy use in the world. In the United States, the industry sector consumes about 35 percent of the total national energy output. Worldwide it accounted for 33 percent of the total energy consumption in 2003. The most energy-intensive industries are paper, chemicals, primary metals, and petroleum. Fossil fuels are used in the petroleum and petrochemical industries not only as fuels, but also as feedstock. Since the majority of energy used in industry comes from fossil fuels, carbon dioxide emissions from the industries is significant. Industry contributes about 20 percent of the total air pollution.

The reason why commercial and residential buildings consume a substantial amount of energy is that energy is required not only for their construction but also for operation and maintenance. Production of building materials are highly energy intensive. To produce 1 ton of aluminum requires 150-220 GJ of energy, whereas 1 ton of steel needs 25-45 GJ. However, other building materials such as brick, concrete, and wood consume far less energy. In residential buildings, space and water heating alone accounts for 80 percent (worldwide average) of the total energy use in buildings. Refrigeration and lighting accounts only 9 percent of energy consumption in buildings.



Shares of world-wide energy consumption by sectors in 2003 include transportation, industry and other uses.

ENVIRONMENTAL IMPACTS

Whether energy is renewable or nonrenewable, impacts of energy on the environment at all stages, from the cradle to grave, is inevitable. Even seemingly benign technologies such as solar and wind have indirect impacts on the environment. Manufacture of components used in wind turbines and blades require fossil fuels, which emit greenhouse gases and other air pollutants. Wind power plants have been criticized for their impacts on natural aesthetics and threat to certain bird species. Solar cells and batteries use toxic chemicals that need to be disposed off carefully or recycled. Production of biofuels requires agrochemicals, fossil fuels, and capital equipment that emit harmful pollutants into the environment directly or indirectly. Agrochemicals such as pesticides and fertilizers impact surface water bodies (eutrophication, aquatic toxicity) whereas fossil fuel use emits greenhouse gases and other air pollutants including PM10, volatile organic compounds, sulfur dioxide, carbon monoxide, etc. Large-scale hydropower developments alter river and riverside habitats, disrupt sediment flow and natural fish migration, submerge large lands, and displace local communities.

The magnitude of environmental impacts can become severe with nonrenewable energy. For example, underground mining in the Appalachian regions of the United States has severely contaminated local water supplies, rivers and streams mainly from acid mine drainage. Surface mining of coal left thousands of hectares in Appalachia and midwest denuded that they could not be restored or reclaimed for other uses. Also, acid drainage and spoils banks were more severe.

Moreover, when coal is finally combusted in power plants or other industry, it releases carbon dioxide (CO_2), nitrogen oxides, sulfur oxides, and other air pollutants. Sulfur and nitrogen oxides are formed from sulfur and nitrogen present in the coal as impurities. Acid rain caused by sulfur-containing coal burning especially from power plants has been documented, which has had serious impacts on some lakes and streams of northeastern United States and Canada. In addition, coal combustion can cause serious health problems, such as respiratory diseases and irritations. The deadly smog that killed thousands of people in London in 1952 was associated with coal combustion. Coal power plants are also blamed for mercury emissions.

Use of coal and other fossil fuels in electricity production (diesel, gasoline, natural gas, transportation and industry) has dramatically increased since the last century, leading to an unprecedented rise in carbon dioxide levels. Carbon dioxide is believed to be a major culprit behind global climate change. It is estimated that 22 gigatons (Gt) of CO_2 are released into the atmosphere every year from combustion of fossil fuels. Consequences of climate change can be serious, such as polar ice melting causing a rise in sea levels and subsequent submerging of coastal cities, extreme weather patterns such as extended drought, heavy rainfalls, and hurricanes, loss of species, and emergence of new tropical diseases.

Nuclear energy also has its share of environmental impacts and critical health and safety issues. Since the fuel, uranium, used in the nuclear reactor has to be mined, it presents similar environmental problems as other mining activities, which include destruction of the local habitats and contamination of water bodies. Workers working in uranium milling can be exposed to harmful radiation. In addition to the safety issues that arose in the context of the Chernobyl and Three Mile Island accidents, the long-term disposal of spent nuclear fuels is another unresolved problem. These spent fuels continue to emit harmful radioactive rays even for thousands of years due to long half-lives of radioactive isotopes. The spent fuels have to be isolated and stored in a safe and remote place, which creates unique technological and institutional problems.

THE FUTURE

What kind of energy mix we will have in the future is largely determined by the availability of fossil fuels and their cost, as well as the energy needs and corresponding energy policies of individual countries and their collective global strategies. Costs of renewable energy technologies such as solar and wind have come down significantly over the decades. However, renewable technologies, except hydropower, are still expensive and cannot survive without subsidies and incentives. Further decrease in costs is possible, but will not occur immediately. As long as costs of fossil fuels remain low, expansion of renewable energy technologies is likely to occur at a slow pace, and the current energy mix may remain unaltered for the near future. Intermittent or variable energy production and diffuse nature of renewables make them unsuitable for distribution over large areas. The proximity of renewable resources to the major population centers may improve their appeal since they require little investments in transmission and distribution networks. Renewables are an attractive option for decentralized energy production.

Energy Crisis (1973)

THE ENERGY CRISIS refers to the social and political-economic disruptions resulting from an abrupt change in the price and availability of world oil supplies in 1973. The crisis was triggered when Arab members of the Organization of Petroleum Exporting Countries (OPEC) declared an embargo on oil exports to Western nations supporting Israel in the Yom Kippur War. During the same period, OPEC countries (at the time responsible for more than half of world oil production) began to regulate the price and volume of their deliveries. As a result, the price of crude oil quadrupled, from around $2 per barrel in October of 1973 to nearly $10 per barrel in June of 1974.

OPEC's actions had immediate effects. By exercising control over a commodity critical to the global economy, Middle Eastern oil-exporting countries enhanced their geopolitical power in relation to industrialized nations. The dramatic rise in oil prices also led to a rapid accumulation of wealth in exporting countries such as Saudi Arabia. Meanwhile, for industrialized countries that had become increasingly reliant on cheap imported oil to fuel post–World War II economic expansion, supply disruptions and higher energy prices contributed to a period of inflation and economic recession. In the United States, lengthy lines at gasoline stations became symbolic of the 1973–74 "oil shocks."

The environmental implications of the energy crisis have been complex. Recognizing the precarious nature of their dependence on foreign energy sources, oil-importing developed countries made attempts (with uneven success) to reduce demand through conservation and investment in alternative energies. Thus, Japan stepped up its development of energy-efficient vehicles, and France invested heavily in nuclear power. However, industrialized countries also acted to secure non-OPEC energy supplies through more intensive exploitation of oil fields under their control and increased exploration. For example, the United States developed Prudhoe Bay reserves in Alaska; the United Kingdom and Norway intensified development of North Sea offshore deposits; and production increased in Mexico and the Amazon in the decades following 1973. This spatial expansion of oil production contributed to a decline in OPEC's power and to a return to relatively low oil prices in the late 1980s, thereby helping to guarantee the world's continued dependence on fossil fuels. It also served to integrate these peripheral regions into the global economy and subject their ecologies to the often-devastating impacts of oil extraction and distribution, for example, the *Exxon Valdez* spill in Alaska and the pollution, deforestation, and social dislocation resulting from post-1973 oil development in the Ecuadorian Amazon.

IMPACT OF OIL WEALTH

The wealth generated in oil-producing countries by the 1973–74 price hikes also had environmental consequences, although more indirectly. Many of these "petrodollars" were circulated through international financial institutions and then lent to developing countries seeking finance capital. With the debt crisis of the 1980s and ensuing structural adjustment policies, many developing countries intensified the exploitation of their natural resources—often by liberalizing their extractive and agricultural sectors—in an attempt secure the foreign exchange necessary to pay off their debts. Thus, the social and environmental impacts of the recent increase in nature-based production in the developing world are, in part, legacies of the 1973 energy crisis.

Enron

ENRON IS THE name of the company that caused a major corporate accounting scandal and related financial irregularities in 2001 that disrupted financial markets. In 1985, Houston Natural Gas merged with InterNorth, a natural gas company based in Omaha, Nebraska. The new company was renamed Enron, and in 1986, Kenneth Lay becomes chief executive. At the same time, Lay found another avenue for greater wealth: deregulation of the natural gas industry. He used his connections and had Enron make political donations in order to influence Congress to make natural gas an unregulated, tradable commodity. In 1989, as the natural gas was deregulated, Lay created the Gas Bank. This initiative was to form a bridge between producer and consumer, ensuring consumers long-term supplies at set rates while stockpiling reserves of natural gas bought from producers.

In 1990, Lay hired former business consultant Jeffrey Skilling to look after the companies' energy trading operation. Andrew Fastow, who later became the mentor of the firm's dubious accounting practices, was one of the first hires. The same year, Lay was given $1.5 million in cash compensation, along with millions of shares of Enron stock. Enron's chief financial officer (CFO), Andrew Fastow, found a new use for the Gas Bank: he created Cactus, the first of what would eventually amount to 3,500 dummy companies created by Enron. Enron would make phony deals with the Gas Bank and assume, as supposedly separate and independent companies, any debts the Gas Bank incurred. By keeping Cactus off the books, Enron's actual indebtedness would be hidden. Thanks to Cactus and other dummy companies created by Fastow, none of Enron's earning's reports would be accurate, but to unsuspecting observers Enron seemed to do very well.

Enron's corporate culture changed radically during the mid–1990s. Bonuses and salaries became dependent on the closing of deals, and employees starting battling each other for the rights of each deal made. In May 1995, James Alexander, an executive in Enron's Global Power & Pipelines division, warned Lay of suspicious accounting of the division's finances. Lay did not act on the warning. In 1997, Skilling was promoted to president and chief operating officer. Fastow created a series of companies—codenamed Chewco and Jedi—designed to keep debt away from Enron's books while inflating the firm's profits. That year, *Fortune* magazine named Enron the most innovative company in the United States. In 1999, Fastow set up the first of the secret partnerships, which generated huge bonuses for him and his associates, while hiding Enron's many poorly performing assets and investments. At the same time, Enron launched its broadband services unit and Enron Online, the company's website for trading commodities, which soon became the largest business site in the world. About 90 percent of its income would eventually come from trades over Enron Online.

By August 2000, Enron shares reached a peak of $90. That year, California learned what Enron had wanted from a deregulated marketplace. For years afterward, Enron employees would insist that the catastrophe was California's fault and that Enron had done nothing wrong. Government investigators discovered that Enron's dummy companies had traded natural gas and electricity among themselves, with each trade increasing in price, until the commodities were sold to California for several times their actual market value.

In August 2001, an Enron employee, Sherron Watkins, met Lay to alert him to her concerns about dodgy finance and accounting practices at the firm. Later, on October 16, Enron shocked the markets by announcing a $638 million loss for the previous three months, and write-offs worth $1.2 billion; three days later the U.S. stock market watchdog launched an inquiry into Enron's finances. A week later, CFO Andrew Fastow was replaced. On November 2001, rival firm Dynegy made an offer to buy Enron. Shortly thereafter, Enron announced even further losses and previously undisclosed debt. As Enron's share price fell below $1, Dynegy broke off the takeover talks. On November 8, 2001, Enron filed a Form S-K with the SEC, announcing that its failure to account properly for transactions with partnerships known as KLM Cayman, L.P. and Chewco Investments, L.P. required the company to adjust its financial statements for 1997–2001. The Securities and Exchanges Commission added accountancy firm Arthur Andersen, the auditor for Enron, to its investigation. In December 2001, Enron filed for bankruptcy protection, the largest bankruptcy in the United States history at that time. Thousands of employees were laid off.

In January 2002, Lay resigned. Arthur Andersen declared that its employees destroyed a "significant but undetermined" number of Enron documents. The transnational company was later fined for its actions. In October 2002, Fastow was arrested on the charges of fraud, money laundering, and other accusations. Enron defendants faced over 30 felony charges, including alleged violations of the Securities and Exchange Act of 1934. The charges stated that Enron knew and did not disclose actual earnings and hedges to the public. In May 2006, Lay and Skilling were found guilty of conspiracy, fraud, and other charges. The collapse of Enron raised new questions about the adequacy of U.S. corporate governance rules. The secret partnerships and deceitful accounting hurt Enron's shareholders, customers, and employees and tarnished the reputation of senior managers. The failure of Enron caused damage in the world of accounting that stretched far beyond Arthur Andersen. The Sarbanes-Oxley Act, a measure that attempted to improve the audit process for public companies in the United States, passed largely as a result of the Enron failure.

Environmental Accounting

THE FIRST ENVIRONMENTAL accounts were constructed by Norway in the 1970s and were slowly adopted by other nations. At the firm level, companies are becoming progressively more aware of the environmental and social liabilities pertaining to their operations and products, with associated financial effects. Uncertainties in measuring these financial effects can be addressed by using environmental evaluation and accounting techniques. Environmental accounting can support national income accounting, financial accounting, or internal business managerial accounting. It is an effective tool for a company's greener management practice. Moreover, the term *environmental cost* has at least two major dimensions: it can refer solely to costs that directly impact a company's bottom line, or it can also encompass the costs to individuals, society, and the environment for which a company is not accountable. Government involvement is a critical factor for corporate accountability for the environment. Corporate environmental accounting is also a strategic management tool for the improvement of corporate policies and decision-making practices.

The principal goal of environmental accounting is the identification of decisions that will enhance profitability and lead to environmental improvements. There are several major problems that occur when identifying and measuring environmental costs. For example, while it is feasible to value a forest in terms of its possible source as wood, no calculation can be made for that tree as part of a rainforest in which it is home for a rich ecosystem. Environmental costs are one of the many different types of costs businesses incur as they provide goods and services to their customers. Some critics argue that modern environmental accounting models have been developed based on procedural liberal frameworks that limit the proposals for reforms, namely concerning the role of the companies and their impact on nature.

SMART BUSINESS DECISIONS

Many environmental costs can be considerably reduced or eliminated as a result of business decisions. Environmental costs (such as wasted raw materials) may provide no added value to a process, system, or product. Uncovering and recognizing environmental costs associated with a product, process, system, or facility is important for good management decisions, and requires paying attention to current, future, and potential environmental costs. How a company defines an environmental cost depends on how it intends to use the information (for example, in cost allocation, capital budgeting, and process/product design). Moreover, it may not always be clear whether a cost is "environmental" or not: some costs fall into a gray zone or may be classified as partly environmental and partly not.

Whether or not a cost is "environmental" is not critical: the goal is to ensure that relevant costs receive appropriate attention. Costs incurred to comply with environmental laws are environmental costs. Costs of environmental remediation, pollution control equipment, and noncompliance penalties are all environmental costs. Other costs incurred for environmental safety are likewise clearly environmental costs, even if sometimes they are not explicitly required by regulations or go beyond regulatory compliance levels.

Environmental accounting can be applied at different scales of use and different scopes of coverage. Companies will likely want to assemble cross-functional teams to implement environmental accounting. Because environmental accounting is not solely an accounting issue, and the information needed is split up among all of these teams, open communication is necessary between teams. This can require, for example, pulling some environmental costs out of overhead and allocating those environmental costs to appropriate accounts. By allocating environmental costs to the products or processes that generate them, a company can motivate affected managers and employees to find pollution prevention alternatives that lower those costs and enhance the benefits. Proposals to integrate environmental costs and benefits into national accounts can also only be evaluated by considering them in the context of their likely policy use.

ECONOMIC IMPLICATIONS

Effective environmental management is based not only on an understanding of the volume of pollution and material use, but also on an understanding of the economic implications. Even if the value of the environment is immeasurable, a figure can be placed on the cost of environmental destruction. Therefore, it is possible to use accounting to help the environment. For example, the full cost of transportation systems should be assessed; not just the cost of building roads, but how trucks and cars impose a burden on the country's environmental health (such as air pollution, loss of arable land, and runoff). Also, there should be an examination of how subsidies damage the environment. For example, with a shortage of water, should a country continue to grow agricultural products using water-intensive agriculture? Most often, the corporate goals of companies are fundamentally in conflict with sustainability. The value of an information framework, combined with an understanding of accounting's role in corporate decision-making, highlights a set of considerations that guide the search for environmental accounting priorities.

Environmental Determinism

THE AVERAGE SWEDE will live 80 years while the average person in Malawi will live half as long. Why do Scandinavians live longer than residents of Malawi by a factor of two? A proximal reason is that European countries have more productive economies, higher incomes and better healthcare, which all contribute to increased longevity.

The more complex task is to explain why some countries are rich and others poor in the first place. Recently, scholars have reprised a "geography is destiny" argument that concludes that the natural environment ultimately determine a region's eventual level of economic prosperity. This essay explores the 19th century origins of environmental determinism as an explanation for 21st century socio-economic disparities.

Environmental determinism attributes economic inequalities to natural laws, and the uneven distribution of land and temperate climates. The notion that some countries have natural advantages over others is ascribed to German geographer Friedrich Ratzel, who was influenced by the concept of *social Darwinism*. British philosopher Herbert Spencer promoted social Darwinism as an altered interpretation of the theory of evolution, which Charles Darwin outlined in his 1859 book *Origin of the Species* (Livingstone 1992). Hence, this essay first explores Darwin's theory of evolution as the inspiration for social Darwinism, which in turn will be explained as the theoretical precursor to environmental determinism.

SOCIAL DARWINISM AS PRECURSOR

Darwin argued that species evolve over generations through the natural selection of physical traits and competition between species for scarce resources. Organisms undergo spontaneous genetic mutations that might, for example, enhance their ability to compete for food. Better nutrition will improve the chances an organism has to reproduce and transmit the improved trait to future generations. A mutation that hinders the animal's ability to compete will likely not be "naturally selected" for future generations because the animal will not survive long enough to reproduce.

Darwin's emphasis on biological competition inspired Herbert Spencer to promote "social Darwinism" as a socio-political counterpart to British economic philosophy. In 1776, Adam Smith outlined the philosophical foundation for Britain's unrivalled 19th century economic prosperity. He argued in *Wealth of Nations* that capitalism worked best when guided by the "invisible hand" of a marketplace comprised of individual buyers and sellers acting out of "enlightened self-interest." The state should stay out of the marketplace so that it does not disrupt the natural competition between individuals needed for a healthy market. Seen in this light, social Darwinism appears to be a natural theoretical extension of Smith's "invisible hand" and Darwin's "natural selection."

British economist David Ricardo extended the notion of competition between individuals to explain trade relations between nation-states. Writing in 1817, Ricardo articulated a theory of comparative advantage that justified why countries should eliminate governmental barriers to trade. Countries should instead engage in free trade, even if one trading partner is more productive and technologically advanced than the other. Thus both Adam Smith and David Ricardo promoted *laissez-faire* or "leave us alone" capitalism that emphasizes free markets devoid of government interference.

Herbert Spencer wanted to develop a political theory to complement *laissez-faire* economic theories. Spencer borrowed from Darwin's theory of evolution, based as it was on biological competition, to argue that society was a competition between individuals for scarce resources such as income and political power. As in any competition, there is going to be winners and losers. Society should accept social inequality as a natural outcome of a process he was the first to describe as "the survival of the fittest."

By framing social inequality as a natural process, Spencer could use the scientific trappings of Darwinism to argue against government intervention to help society. The implication is that people succeed or fail entirely because of their own hard work or personal failings. Congenital infirmity, gender, or class origins can be conveniently overlooked as factors contributing to one's social status. This rhetoric ultimately served to maintain the status quo conditions of social inequality expressed through class, gender and racial divisions. The rhetoric of "naturalized" competition between individuals was extended to explain success and failure in the business world. Industrialist John D. Rockefeller cited "survival of the fittest" to explain the economic success of Standard Oil during the Gilded Age of late 19th century America.

IMPORTANCE OF GEOGRAPHY

Environmental Determinism can be simply defined as the territorial manifestation of social Darwinism. Herbert Spencer made the biological analogy that society is a living organism governed by natural laws. Friedrich Ratzel went one step further to argue in his 1897 book *Political Geography* that nation-states were analogous to living organisms. Like any organism, a healthy nation-state could expect its population to grow as long as it had access to adequate natural resources and room to expand. When territorial or resource limits are reached, Ratzel argued that a country must expand its *lebensraum,* or "living space," to survive. The finite supply of land means that countries must compete with each other for territorial supremacy. As with any competition, there will inevitably be winners and losers, with "higher forms of civilization [expanding] at the expense of the other."

Ratzel echoes Spencer to imply that when one country expands at the expense of another, it is nothing more than a spatial expression of "survival of the fittest." Territorial realignments resulting from interstate rivalries and wars are "environmentally determined" by natural laws akin to natural selection.

Environmental determinism is geopolitically significant because it allowed Europeans to justify colonial and imperial land grabs as merely being the outcome of objective natural laws. This excused them from viewing colonialism and imperialism through the moral lens of Judeo-Christian values. Instead, they could see their actions through the amoral lens of the marketplace, where natural or environment laws determine social and regional inequalities. From this perspective, the question of why some countries are rich while others are very poor is beside the point because inequalities result from natural laws.

Environmental Impact Statements (EIS)

ENVIRONMENTAL IMPACT STATEMENTS (EIS) are written, multidisciplinary scientific-technical reports whose goal is to predict and evaluate the environmental effects of a proposed project. EIS allows to compare the state of the environment *with and without* the project in order evaluate the changes that would happen in a certain location if the project was carried out. In such studies often the term *environment* is used to refer to *both* the physical-natural system and the social-economic-cultural one.

EIS are decision-making tools to be used by resource managers, land planners and many other elected officials and appointed staff whose mission is to take care of the environment and their elector's quality of life as well as lead the sustainable development process of nations worldwide.

Since the appearance of the Green Revolution in the 1970s, the ecologist movements and the concepts of conservation and sustainable development as key issues in most parts of the western world, EIS have become one of the most efficient and necessary tools to achieve sustainable development goals, as established by the United Nations Conference on Environment and Development (Earth Summit), held in Rio de Janeiro in 1992.

APPLYING AN EIS

EIS come into the scene whenever a new project appears, either if this project has a large scale, for instance the construction of hydroelectric plants or mining projects, or if it has a more punctual scale (construction of buildings, landfills, pulp mill, petrochemical or any other type of industrial plants). When the investor (whether a private company, the State or a single individual) decides to go on a project, in most countries legal framework requires that he first prepares and then presents an EIS to the government planning office as a way of controlling what kind of impacts are going to occur on the environment.

An EIS document's common structure is composed of the following items: an executive summary, project description and alternatives, legal framework, environmental diagnosis or baseline, environmental impacts, mitigation measures, environmental management plan (emp), closure plan, organizations consulted and bibliography, and conclusions and recommendations.

The executive summary provides a summary of the main results of the study, that is, the major impacts the project would provoke as it is proposed, the mitigation measures proposed by the group that elaborated the EIS, the cost of such measures, and the improvements their implementation would provoke in the environment.

The project description includes all the data relevant to the construction and operation activities, with all investments costs, the workforce involved and the facilities description. The project alternatives are critical: they show the different locations considered for the project, the different technologies evaluated, the different transportation routes considered and the best one selected.

The legal framework must include regulations at all jurisdictional levels related to the impacts the project could provoke. For instance, in a petrochemical plant the EIS must consider the hazardous wastes local regulations and soil and quality regulations.

The environmental baseline must include both the up-to-date description of the socio-economic (economy, employment, education, health, transport, infrastructure, services, housing, poverty) and physical-natural (natural resources, biology, fauna, flora, geology, hydrogeology, air, soil and water quality) aspects of the place where the project will be developed. The idea is having the best description of the area involved in a zero moment, before the project is carried out, so as to evaluate how would the project change such area.

The environmental impacts section must provide a detailed prediction of both positive and negative impacts the project will cause, often being showed in a matrix (the most known models are Leopold's and Batelle's ones). Then, mitigation or remediation measures are proposed to diminish the negative impacts. Also measures to encourage positive aspects should be proposed. The EMP includes those measures and also monitoring plans so that the authority can keep a control during the whole lifetime of the project. The closure plan is performed in order to assure that once the project has finished, for instance a mining one, all the facilities used for it will not be abandoned but instead will receive the necessary treatment to avoid pollution of the environment's resources.

EIS are not reports done on the desk and then delivered. They often require considerable fieldwork for technicians, public consultation with local residents of the area affected to know their points of view and concerns—a process that can last months or years, all depending on the scale of the project and the public disputes that arise. That is because EIS are often very controversial as the conclusion and evaluation of impacts are not "objective," but rather have a bias toward the interest of one of the parts.

These kinds of studies receive different names worldwide, but they all refer to the same thing and have similar goals. For instance, the United States version is the Environmental Impact Statement (EIS), while in England, they are called Environmental Impact Assessment (EIA). Moreover, even within the United States there are different names for it; for instance in California, they name it Environmental Impact Report (EIR).

EIS are a legal requirement in many countries before any project is carried out. For instance, in the United States and according to the National Environmental Policy Act (NEPA), whenever the Federal government or any private company takes a "major Federal action significantly affecting the quality of the human environment," it must first consider the environmental impact in an EIS document. Although EIS are mostly performed by consultation companies, they are also conducted by universities and public research centers, which makes such studies more reliable and accountable for the public as the profit is not the sole engine of their motivation.

Environmental Organizations

THE MANCHESTER ASSOCIATION for the Prevention of Smoke may be the earliest environmental organization on record. Yet the group's establishment in 1843 precedes the modern application of the term *environmental* by much more than a century. Despite the lack of such an overarching category during that formative time, the United Kingdom would lay claim to a number of other local and national environmental groups in the subsequent decades of the 19th century, including the Commons, Open Spaces and Footpaths Preservation Society (1865) as well as the short-lived colonial Natal Game Protection Association (1883). The only other country to substantially contribute to this new phenomenon during this time period was the United States. There were some tentative initial steps, including an unsuccessful first attempt at establishing an Audubon Society (1886–89), as well as the 1887 establishment of the Boone and Crockett Club by Theodore Roosevelt and his patrician colleagues (more of a club than an environmental group). The "archetypal" environmental group would appear nearly a decade before the century ran out: the Sierra Club.

In 1890, conservationist John Muir celebrated the designation of Yosemite as the first national park. During the campaign, the idea of establishing a promotional organization had been considered, but the idea would not reach fruition until 1892. That year, with Muir at its helm, the Sierra Club was established with the tripartite mission of fostering enjoyment of the outdoors, providing information about the Pacific Coast's mountain regions, and advocating for their protection. Over the course of the 20th century, the Sierra Club would come to be mostly associated with the latter conservation mission—albeit with a far greater geographic encompassment than the mountain ranges of California.

Since those early initiatives, the number of environmental organizations has expanded dramatically, particularly during and after the birth of the new environmentalism in the 1960s. One assessment found approximately 10,000 environmental organizations in 1990 in the United States alone. Extrapolating how many environmental organizations work at an international level is also daunting, and it is worthy of note that whereas approximately 1,400 nongovernmental organizations (NGOs) were accredited to attend the 1992 Earth Summit in Rio de Janeiro, 20 years later over 3,200 organizations attended the 2002 World Summit on Sustainable Development in Johannesburg, South Africa. However, these NGOs were not necessarily environmental organizations.

A WIDE VARIETY

Environmental organizations range from small neighborhood groups with a handful of members and no budget, to international bureaucracies with membership in the millions and budgets in the tens of millions of dollars. One of the few well-known examples of a smaller environmental organization is the Love Canal Homeowners Association, created in 1978 by Lois Gibbs in response to health problems arising from a toxic waste dump that had been converted into a housing and school development in Niagara Falls, New York. The group's efforts would lead to a federal home buyout of the area, as well as passage of one of the most significant U.S. environmental laws since the early 1970s. In regard to the larger environmental organizations, perhaps most emblematic were the members of the Group of Ten, a now defunct coalition of large and relatively well-funded national environmental organizations—most of them based in Washington, D.C.—that ranged from the National Parks and Conservation Association and the Wilderness Society to the Natural Resources Defense Council and the Environmental Defense Fund (now Environmental Defense).

Despite their tremendous diversity on so many fronts, environmental groups are typically separated into one of two camps in terms of their general focus. On the one hand are the "brown" organizations that focus primarily on human health issues; on the other are the "green" organizations that focus on issues relating to biodiversity conservation.

Many chafe at this distinction, and countless organizations explicitly emphasize the critical and inextricable ties between humanity and biodiversity. Nonetheless, the strategic focus of most groups can still be tied to one or the other of these two categories.

FROM RADICAL TO MAINSTREAM

Environmental organizations' missions, goals, and strategies range from radical to mainstream. From a vantage point based on these polar opposites, social theorists have identified two divergent strategic approaches adopted by agenda-driven organizations emanating out of civil society. On the one hand, organizations can adopt a "fundamentalist, expressive" approach that directly protests the practices and ideology of the dominant authority—whether that authority consists of a particular government or, more broadly, generally held beliefs and values embedded throughout society. On the other hand, they can take a "pragmatic, instrumental" approach that attempts to change authoritative societal structures (including those widely held beliefs and values) from within the system.

But environmental groups use a wide variety of tactics that span the reality lying between these two nonexclusive strategies: Identifying, framing, advocating, and lobbying on particular environmental issues; building constituencies over environmental issues; mobilizing public opinion through the use of media and grassroots channels; influencing planning by government agencies and citizen groups; engaging in innovative problem solving; gathering information and consulting on scientific issues; conducting independent monitoring and reporting on environmental conditions and initiatives; seeking legal recourse for environmental protection through the judicial system; implementing new policies; organizing boycotts, public protests, and demonstrations, and conducting civil disobedience; and building coalitions with other environmental groups and with other sectors of civil society.

These tactics have been applied in domestic and international arenas. In the latter arena, environmental organizations have added a number of additional tactics that include: lobbying governments to enter into environmental conventions, monitoring the enforcement of conventions, democratizing international negotiations over environmental issues, directly protecting valuable habitats, and educating domestic public audiences on the need for international environmental protection.

Although such international approaches are often traced to the 1972 Stockholm Conference on the Human Environment, environmental organizations have been working at an international level since at least the dawn of the 20th century. Many of them have been explicitly created for just such purposes. Two early examples are the North American Fish and Game Protective Association, which held its first meeting in 1900 in Montreal, and the 1903 establishment of the Society for the Preservation of the Wild Fauna of the Empire in the United Kingdom (now Flora & Fauna International). In the United States, environmental organizations became more active in international issues during the 1970s when they started building alliances with groups from other countries, particularly as the links between international economic and political forces were becoming more obvious in light of environmental problems such as ozone depletion, climate change, and tropical deforestation. Two of the largest U.S. environmental organizations focusing on international work are Conservation International and the World Wildlife Fund.

FROM A DUBIOUS HISTORY

In reviewing the historical development of environmental organizations over the last few decades, the noted biologist Edward O. Wilson recalled that the role of environmental organizations "was basically that of evangelists and beggars" when he joined the global conservation movement in the early 1970s. By the 1990s, however, "the major global NGOs had grown strong enough to initiate direct action on their own toward the salvaging of forests and other threatened natural environments." With large memberships, articulate voices, and political acumen, environmental groups have attained an anticipated and well-respected voice in domestic and international debates over environmental policy. Environmental groups have created a "world civic politics" within which they act as the principal intermediary "agents of change" for individuals and governments.

GROWTH AND EFFECT

This literature remains rife with debate over exactly how effective environmental organizations have been in changing the course of international environmental affairs. Yet the debate is largely over degree, and only a few observers from the realist camp of international relations would contend that environmental organizations have had a negligible effect. This is particularly the case in light of the growing number of environmental transnational advocacy networks (TANs) that address: broad global issues such as ozone depletion or climate change; project-specific environmental controversies, many of them associated with World Bank financing for large development projects such as dams; and environmental issues across transborder regions, such as ongoing deforestation in the nine-country Amazon Basin or the loss of large carnivores in the Yellowstone to Yukon region of Canada and the United States. Although some researchers have argued that participation of environmental organizations in such networks represent little more than extensions of domestic policy concerns, rather than a fundamental concern over international environmental protection per se, the number and size of these networks have blossomed in the past two decades.

At the same time that many credit environmental organizations for achieving environmental protection, there are many barriers that limit their effectiveness. Principal among these are a perpetual dearth of financial resources and a recurrent unwillingness to coordinate their efforts amongst each other (despite the existence of TANs).

Wavering public support for environmental organizations also remains a challenge; at least in the United States, membership in environmental organizations has fluctuated largely in response to broad governmental policies on the environment. For example, membership declined during the pro-environment years of the Carter administration, but grew substantially during the Reagan administration, which was widely seen as hostile to environmental policies.

In addition to these barriers, critics of environmental organizations have arisen on the political left and right. For different reasons, both ends of the political spectrum have expressed concern over the cooptation of environmental groups by either governments or corporate actors. And as with organizations rooted in other social movements, many environmental organizations have followed a classic pattern in which they originally coalesce as volunteer-driven assemblages of like-minded people, but over time inevitably transform into bureaucratic and professionally staffed interest groups. Given the rapid growth in this professionalization of the environmental movement, it is not surprising that some have criticized the large annual salaries that have been granted to many of the leaders of large environmental organizations. In addition, many environmental organizations spend large portions of their budgets on fundraising and either own or rent expensive office spaces—the costs of which, critics argue, do not justify their benefits.

TANs have addressed many international issues, such as the loss of large carnivores in transborder regions.

LACK OF DIVERSITY

Lack of racial and gender diversity has also been seen as a problematic characteristic of most environmental organizations. It was not until 2005 that the first African American was hired as an executive director of a large U.S.-based environmental organization (the National Wildlife Foundation, est. 1936). This stereotype is somewhat belied by the growing number of groups under the aegis of the environmental justice movement, one count holding their number in the United States at over 7,000. Because of their roots in both the civil rights and environmental movements, these smaller organizations have arguably been more effective than the larger organizations in protecting urban and poverty-stricken populations from environmental threats. Yet despite the stated willingness of the larger U.S. environmental organizations to adopt an environmental justice agenda, critics still see a wide divide between these newer groups and the old guard.

No small number of friends and foe alike have denounced the practice of shrill doom and gloom mass mailings from environmental organizations—mailings that not only consume resources, but that allegedly rely on incomplete, exaggerated, and/or inaccurate information in an attempt to scare potential donors into writing checks. The focus on recruiting new members through mass mailings has also been associated with a decline in the social capita that only comes with engaged participation in environmental activities. As social critic Robert Putnam has put it, this type of approach provides "neither connectedness among members nor direct engagement in civic give-and-take, and they certainly do not represent 'participatory democracy.'" Citizenship by proxy is an oxymoron."

Although Putnam is careful to note that such practices are not necessarily immoral, other critics have expressed strong reservations about the growing influence of environmental organizations as a potentially antidemocratic form of institutional exclusivity. At the other end of the political spectrum, a number of critics more friendly to an environmental agenda believe that such antidemocratic tendencies are manifested in the lackluster performance of environmental organizations in drawing attention to electoral politics—or to be more exact, in getting out the vote for the environment. With a few exceptions such as the Sierra Club and the League of Conservation Voters, the critics argue, most large U.S. environmental organizations have been overtly apolitical largely in order to maintain a noncontroversial reputation for purposes of fundraising appeal. Accordingly, some recent research has indicated that environmental legislation is more associated with grassroots protests than with the activities of environmental groups per se. Overall, a common refrain in the United States holds that the larger environmental organizations have lost touch with the grassroots—and that this loss of connection to a wider audience has dramatic consequences, including the purported death of environmentalism.

INTERNATIONAL CONCERNS

Many of these domestic concerns are reflected internationally, but with the added complexities of defining sovereign control over natural resources, and the role of foreign environmental organizations in exerting undue influence over domestic policy-making. Most notably, Western environmental organizations working in Africa have been accused of participating in the continent's history of paternalistic European treatment of wildlife resources. Whereas the early colonial power structures simply marked off territory as game reserves and banned native peoples from subsistence hunting, but not wealthy Caucasians from trophy hunting, critics accuse contemporary environmental organizations of attempting to impose conservationist policies without full local input in how those policies are determined and implemented.

Similar claims have been made in regard to how international environmental organizations operate in Asia and Latin America, and Western green aid to eastern Europe has also had reportedly mixed effects. In Russia, for example, the number and visibility of environmental groups have been much strengthened through foreign aid since the demise of the Soviet Union, but apparently it has not been met with a concomitant rise in either public interest in environmental issues or, most importantly, in the actual protection of the environment.

The wide range of interests, capabilities, and perspectives between different environmental organizations makes it difficult to generalize about the phenomenon. At the most critical end of the spectrum, environmental organizations serve as mere institutional flourish draped over the power and influence of power-hungry individuals. This is an extreme point of view, but environmental organizations are nonetheless human institutions. From the other end of the spectrum, the critics can be reasonably accused of neglecting the broad practical implications of institutional persistence and legitimacy that has been achieved through the growth and maturity of environmental organizations worldwide. The rise of environmental groups over the course of the 20th century has mirrored and led the growing importance of civil society in domestic and world affairs—and so while numerous NGOs can be found in other issue arenas such as human rights and labor, their rise to influence has perhaps been most notable in the environmental sector.

Environmental Protection Agency

THE U.S. ENVIRONMENTAL Protection Agency (EPA) was established under President Nixon's Reorganization Act 3 of 1970. The creation of the EPA was part of a sweeping transformation of American environmental regulation that is often credited to the social movements that evolved around growing public and scientific awareness of environmental crises. The publication of *Silent Spring*, the burning of the Cuyahoga River in Ohio, and the Santa Barbara oil spill are often cited as significant events, which crystallized mainstream opinion around the need for a strong federal regulatory hand in ensuring environmental quality.

Strong federal environmental roles were minted in landmark laws such as the National Environmental Policy Act (1969), the Clean Air Act (1970), the Clean Water Act (1972), and the Endangered Species Act (1973). The EPA was created as an independent agency to administer many of these laws: few believed that the Department of Commerce, for example, could fairly and firmly regulate polluting industries that it was simultaneously promoting and protecting through trade policy.

Another narrative concerning the federalization of environmental regulation puts less stress on the achievements of environmental social movements, pointing to the fact that these movements were still nascent—and drowned out by antiwar and other social movements—at the time of these laws' passage and the EPA's founding. Regulated energy industries, which faced a welter of individual state-level regulations, also called for federal environmental regulation. These industries felt that the best long-term strategy would be to use their established influence with politicians, like Senator Edwin Muskie, to proactively shape the environmental debate and the ultimate form of federal environmental regulation. This would give regulated industries a single target, rather than 50 different targets, when attempting to influence environmental regulation. It has also been suggested that the founding of the EPA was the result of competition between President Nixon and Democrat senators with their eyes on the 1972 presidential election, over who would be perceived as "more environmentalist." Because no political benchmarks concerning environmentalism existed, Nixon and his competitors continued to try and out-do each other.

MAJOR TASKS

The EPA is charged with executing many of the major environmental laws and programs including (but not limited to) the Clean Air Act, the Clean Water Act, the Ocean Dumping Act, the Comprehensive Environmental Response Compensation and Liability Act (CERCLA—also known as "Superfund"), the Resource Conservation and Recovery Act, the Toxic Substances Control Act, the Federal Insecticide, Fungicide and Rodenticide Act, the Safe Drinking Water Act, the Emergency Preparedness and Community Right-to-Know Act, and the Solid Waste Disposal Act. Although executing many of these laws entails regulatory duties and the ability to ensure compliance and pursue enforcement, the EPA has also developed broad nonregulatory programs in education, information provision, and the delivery of federal money to state, tribal, and local environmental programs. As the political enthusiasm for environmental enforcement has waned with the growth of the Wise Use and Sagebrush Rebellion movements, the EPA's regulatory and enforcement activities have been deemphasized at the expense of such grants and voluntary programs. The administration of the Toxic Release Inventory, which provides information to the public on sources of toxins in their locales, and the $15 million in grants given each year to develop state-level wetland protection programs, are popular examples of nonregulatory EPA programs.

The EPA was pieced together largely through the transfer of staff and existing programs from other areas of the executive branch, such as the Departments of Health, Education, and Welfare (which had regulated air pollution, water hygiene and solid waste), and the Food and Drug Administration (which had regulated pesticides). From the beginning, the EPA was divided organizationally into six areas: air, water, toxics, solid waste, research and development, and enforcement. The current organizational structure still reflects indecision as to whether to organize by medium (air and water) or by regulated substance (solid waste and toxins).

Each of the 12 headquarters offices and 10 regions are headed by a politically appointed assistant administrator, with one politically appointed deputy and one career deputy. The EPA is thus rather thickly invested with political appointees relative to its size. This is perhaps because many of the environmental laws it executes are potentially quite powerful and disruptive to the economy and industry. The deep penetration of political appointees ensures that agency actions are considered in the light of (and often constrained by) political policy considerations. The fact that policy decisions are made at the headquarters level under relatively close political supervision has produced an enduring tension between the regions (often staffed by career environmental scientists) and headquarters (where staff are largely lawyers and policy specialists).

The influence of political decisions was evident in the notorious incident in which President Reagan's appointed EPA administrator, Anne Burford, was charged with contempt of Congress. She and many other EPA appointees resigned after refusing to provide a congressional investigation with documentation relevant to potential conflicts of interest in administration of the Superfund toxic cleanup program. Although the respected first administrator, William Ruckleshaus, was brought back to the post in an attempt to restore the reputation of the agency, the Burford legacy has persisted as a deep cynicism among environmentalists concerning the political nature of EPA regulatory activities. Staff members, often sympathetic to environmental causes, have occasionally leaked sensitive documents to journalists or environmental nonprofits, and the regional staff has an often-contentious relationship with the headquarters management in Washington. In both Democrat and Republican administrations, it has been common for the EPA to use its regulatory and enforcement powers only lightly or selectively, often waiting until a lawsuit from an environmental advocacy organization forces it into more direct compliance with its regulatory mandates.

The EPA is a standalone federal agency, unaffiliated with any department, and this isolated institutional position has been both a strength and a challenge. On the one hand, it is beholden to no constituency in the way that the Department of Commerce must both serve and regulate industry, or that the Department of the Interior must both serve and regulate resource extraction. However, within the hierarchy of the executive branch, the EPA's lack of affiliation and lack of powerful civil-society constituents puts it at a disadvantage in budget and allocation decisions.

The EPA is a popular target for cuts and lacks private-sector interests who will argue for Congressional augmentation of a spare White House proposed budget. However, as its regulatory duties have been muted in recent administrations, its role as a distributor of federal money to state environmental programs has grown, and the EPA has used its alliances outside the federal government to aid its political position within the executive branch. Nonetheless, the institutional culture of the EPA is one of caution, consultation, and networking: rapid unilateral or aggressive action is the exception. This is arguably inimical to the goal of achieving the dramatic environmental improvements sought in the laws the agency executes.

Environmental Racism

ENVIRONMENTAL RACISM IS intentional or unintentional racial discrimination in environmental decision-making, systematic exclusion of people of color from the mainstream environmental movement, negligent enforcement of environmental protections, laws and regulations along racial lines, and disproportionate distribution of environmental burdens on racial and ethnic minorities where they live, work, and play.

Environmental racism has been endemic throughout U.S. history as a parallel story deeply rooted in the ideological constructions of race, nature, and society. Environmental racism can be traced to colonial dispossession of Native American homelands to their expulsion from national parks and wilderness areas for the benefit of 19th century white, middle-class tourists and environmentalists, such as John Muir. For the African-American community, slavery's expropriation of environmental knowledge, reconstruction-era land loss, and consequent rural exodus to segregated urban centers, forcibly reconfiguring the community's relationship to the natural world. In the 20th century, racial and ethnic minorities have faced increasing environmental hazards as they represent large percentages of the urban working class exposed to the toxic threats of industrial society in the workplace to neighborhoods yet excluded from the mainstream environmental movement.

Within these larger trends in American history, key moments further refined the meaning of environmental racism as part of the contemporary movement for environmental justice. In the 1960s and 1970s, the United Farm Workers' Union (UFW), led by César Chávez, mobilized the first labor movement to address an environmental injustice—the hazards of pesticide exposure of Latinos and Filipinos in the fields of California. By the early 1970s and early 1980s, waste-facility siting controversies rose to national attention as the Love Canal incident transformed the question industrial contamination and toxics into a political issue. But in 1982, popular protest and mobilization against the planned hazardous waste dump for 40 thousand cubic yards of polychlorinated biphenyls (PCB)-contaminated soil in Warren County, a predominantly African-American community in North Carolina, is widely viewed the transformative event in the environmental justice movement.

During the Warren County struggle over the planned waste dump, church activists and the nationally recognized civil rights leader Reverend Dr. Benjamin F. Chavis, Jr. drew widespread attention to the unequal burden of African Americans to hazardous waste storage sites and the community's marginalization in environmental decision-making. As a direct result of grassroots mobilization in Warren County, Dr. Chavis commissioned the United Church of Christ Commission on Racial Justice (UCCCRJ) to examine race and location of toxic waste sites. The groundbreaking report *Toxic Waste and Race in the United States* (UCCCRJ 1987) was the first national study to document the strong correlation between race and hazardous landfill locations at a national level. Moreover, Dr. Chavis first articulated the term *environmental racism* for a national audience during the presentation of the UCCCRJ report at the National Press Club in Washington D. C.

EXPANDING THE SCOPE

Since the first use of the term *environmental racism* by Chavis, activists and scholars have expanded the meaning and scope of the term. Initially, "environmental racism" only addressed explicit racist acts in hazardous wastes storage unit locations and the consequent distributive inequities of environmental burdens and toxic exposures. Over the past decade, the grassroots environmental justice movement and academic community, to a lesser degree, have expanded the application of "environmental racism" to include institutional discrimination in decision-making process and procedure of environmental policy making. In 1991, grassroots activists led the First National People of Color Environmental Leadership Summit. The Summit resulted in the acceptance of 17 Principles of Environmental Justice that expanded claims of communities of color to participate as equal partners in environmental planning, policy implementation, and enforcement. Moreover, the Summit broadened the scope of environmental justice to include concerns from all vulnerable groups—such as women, children, and the poor.

Social science has explored environmental racism in research since the early 1990s, marked by the seminal publication of Robert Bullard's *Dumping in Dixie* (1990). Drawing from strong quantitative and geospatial approaches, social scientists have attempted to "prove" statistically racial discrimination. However, critics have strongly underscored the "racial pitfalls" of highly empiricist approaches that assume racism and discrimination are discrete, overt acts or social artifacts that can be measured through quantitative analysis. Critics argue that this position belies any attempt to examine racism as an ideology operating in a particular political economic system. Recent academic study and mobilization against environmental racism has begun to address how environmental racism operates at the global scale, paying particular attention to toxic trading, global electronics industry, and climate change.

Environmental Refugees

Since this term first appeared in the mid–1970s, discussions have focused around three broad concerns that are raised by the phenomenon. These are: what are environmental refugees, what are the causes of their plight, and how might these causes be removed, or reduced in impact?

First, in terms of definitions, it is important to recognize that the term *environmental refugee* (or *ecological refugee*) is not a legal designation. The 1951 International Convention on the Status of Refugees defines *refugees* in strictly political terms. According to that Convention, a *refugee* is an individual who has fled his or her country because they fear persecution on the grounds of their race, religion, nationality, political beliefs, or membership in a social group. Such a definition is one that highlights the erosion of civil and political rights of the individual; it pays no heed to their economic or environmental rights, nor to the circumstances that might lead to a deterioration of those rights.

Since the integrity of a region's environment or the viability of the local economy are as important in any individual's ability to maintain their quality of life, however, many critics have come to argue that the definition of *refugees* should be expanded to include *environmental refugees*—defined as individuals who are obliged to flee their homelands because deterioration in their local environment has made it dangerous, unhealthy, or impossible for them to continue to support themselves and their family in that region.

Critics of the term have pointed to many problems with such a definition. Are only natural calamities to be considered (such as volcanic eruptions) or are human-induced environmental disasters to be included (such as the Chernobyl nuclear power plant disaster in Ukraine)? Is the time scale of the event relevant to claims of refugee status—for example, is the slow salinization of soils any less relevant than the effects of a massive tsunami? Is permanent displacement required or are temporary movements of concern as well? Some scholars even debate whether the term *environmental migrant* might not be a more useful term to use as the term *environmental refugee* is so imprecise, and devoid of rights under international treaty.

Political opposition and the fear of being inundated with an ever-expanding number of migrants makes it highly unlikely that the 1951 Convention can ever be amended to include the category of "environmental refugees." However, this lack of legal meaning need not detract from the general usefulness of the concept as it places their plight firmly on the agendas of policymakers and researchers.

At an international level, the interconnectedness of the global environment means that the plight of environmental refugees is ultimately part of everyone's concern, and—as a corollary—whatever action occurs to protect the global environment will also help ease their situation. Therefore, treaties to mitigate the consequences of global warming not only alleviate the toll on the earth's entire ecosystem, but also enable local environments to support individual populations. Through such agreements, the predicted flooding of the Maldives and several small Polynesian island states by the middle of this century may yet be abated, and one of the most dramatic examples of future environmental refugee flows could be prevented.

The recent advances in human security and disaster research have been very useful to this discussion as they have clearly shown why environmental deterioration produces environmental refuges in certain circumstances but not in others. This growing body of work has shown how poverty is often the root cause of such movements. Richer communities are able to withstand repeated floods or crop losses; economically deprived or more "vulnerable" communities simply cannot and must seek alternatives elsewhere. Therefore, according to this approach, the root causes of many environmental refugee movements lie not only in the deterioration of the environment, but in the social and economic structures of the region's society and, in particular, in those institutions that create or sustain local poverty.

It follows from this research that any broad strategy to combat the plight of environmental refugees needs to focus on local economic development, and on the creation of community resilience, as much as it does on the more immediate consequences of environmental change.

Environmental Services

ENVIRONMENTAL SERVICES HAS become a central concept in environmental management. Environmental services are functions of ecosystems that are valuable to society. They include carbon storage by vegetation, water, and soil; water filtration and flood control by wetlands and upstream slopes; the provision of wildlife habitats, genetic diversity, scenic beauty, and recreational opportunities by forests and other ecosystems; and the production of useful materials. *Ecosystem services* is also used to describe these environmental services.

For many private, government, and international environmental agencies, conservation of environmental services is replacing protection of endangered species and wilderness as a policy focus. Ecosystem services is the central organizing idea in the 2005 Millennium Ecosystem Assessment. As a representation of scientific and policy consensus about the biosphere, the assessment is the successor to the influential 1987 Brandt Commission Report, *Our Common Future*.

The assessment warns that humans are overusing or undermining ecosystem services so much that we are "living on borrowed time," and defines four categories of ecosystem services: Provisioning services, such as food, water, timber, and fiber; regulating services that affect climate, floods, disease, wastes, and water quality; cultural services that provide recreational, aesthetic, and spiritual benefits; and supporting services, such as soil formation, photosynthesis, and nutrient cycling.

The idea of environmental services promotes recognition of the myriad ways in which individuals, communities, and economies depend upon the "life-support functions" of ecosystems, both nearby and distant. It draws attention to the fact that most of these services remain external to economic calculations: they are provided at no monetary cost to those who depend upon them or profit from them. The measuring and mapping of ecosystem functions can help to clarify what will be lost or gained as a result of different land use decisions and conservation regulations. Environmental and ecological economists estimate the economic values of ecosystem functions so as to provide a more informed and rational basis for these social choices.

MARKETING OF SERVICES

Some carry this idea further, arguing that the world's natural environment can best be safeguarded by the privatization, monetary pricing, and market exchange of environmental services. The premise of this "conservation by commercialization" strategy is that it will foster more efficient resource use and the greatest conservation gains for the least cost. Environmental services markets are already established in industrialized countries. New, global green markets are being designed to link local ecosystem service providers with government agencies, nongovernment organizations, and private investors worldwide.

The such largest markets involve carbon emissions reduction credits. They permit the buyer, such as a power company, to continue emitting CO_2 or other greenhouse gasses into the atmosphere in excess of the amount allowed by law or promised by the company. The funds paid by the buyer of these credits, also called *offsets*, are meant to finance activities to reduce emissions by another firm or create new carbon sinks in another community or country. For example, they might fund a tree plantation in the tropics or pay landowners not to cut existing forests. Markets in offsets for damage to biodiversity and other ecosystem services are also being developed.

These markets are highly controversial. Their advocates of say they offer "triple-win" solutions for buyers, for sellers (such as the owners or stewards of forests), and for nature, with no significant sacrifices by anybody. Others maintain that, while the concept of ecosystem services is a useful aid to decision making, market prices cannot encompass the full values of nature or the different benefits of ecosystems to people who depend on them for survival and people who admire them from a distance. Even strong advocates of environmental services markets debate whether they can simultaneously foster conservation and "reward the poor," which is the stated goal of many international environmental services projects. Some critics contend that putting a monetary price on ecosystem services lays the groundwork for expropriating them from poorer people and weaker countries, enabling the world's wealthy to "own" and determine the fate of the planet's ecosystems.

In any case, the environmental services concept—particularly when linked to the idea that ecosystem functions should be commodified—is not epistemologically innocent. Environmental services trading requires new ways of representing nature, new methods of measuring nature's values, and new institutions to standardize and reproduce those representations and methods.

The increasing prominence of environmental services markets in the policies of governments and international agencies makes them an important frontier in the re-regulation of socionature. A critical question is: in whose interests will this re-regulation it be carried out?

Environmentalism

ENVIRONMENTALISM IS A social and political movement emerging in the mid-20th century in various Western countries like Germany, Sweden, and the United States. Environmentalism is not just a mere concept for the defense of the environment; rather, environmentalism argues that the protection of nature is more important than economic matters, industry, corporations, governments, and private interests. In other words, creating new jobs for a future nuclear power plant would be meaningless for environmentalists if it also brought pollution, hazardous waste, and industrial risks to a region. Therefore, environmentalism implies bringing environmental concern into a political sphere.

Environmentalism promotes environmental consciousness and cries for a social change on varied issues such as deforestation, desertification, global warming, greenhouse gases, nuclear hazards, and genetically modified organisms.

Some observers see environmentalism as a democratic mode of civic participation—*civic environmentalism*—while other scholars perceive it as an ideology with a coherent worldview, or even as a kind of religion, as argues environmental historian Thomas Dunlap in his 2005 book *Faith in Nature: Environmentalism as Religious Quest*.

Because it carries more values than just the respect of the protection of natural resources and land management, environmentalism is often linked with other ideologies or political movements not necessarily related with the environment, such as antiglobalization, anticapitalism, counterculture, and even anti-Americanism. As a consequence, corporations and their lobbyists who seek to legitimize industrialization are often the targets of environmentalists and social activists. On the other side, most groups that promote environmentalism usually emerge from civil society.

The main ideas of environmentalism—respect for nature, protection of wildlife, and green energy production—have historic roots that have been passed through the generations as many environmentalists advocate for the preservation of natural resources, even beyond their own life spans, for the benefit of future generations. Specifically, advocacy groups like the Sierra Club (founded in 1892 by John Muir), the World Wildlife Fund, Friends of the Earth, and Greenpeace are now global organizations using and adapting some of the strategies of public funding and advertising in order to bring their messages to a large public audience. These organizations use the media in various ways in attempt to influence public opinion on debated issues such as the defense of wildlife, global warming, and air and water quality.

In many cases, environmentalist movements are the result of a strong reaction to major events that are seen as a threat to health, wildlife, landscapes, or security. For example, when U.S. biologist Rachel Carson (1907–64) published her book *Silent Spring* in 1962, it created a whole movement against the use of DDT, a now illegal toxic insecticide that was ini-

Many environmentalists advocate for the preservation of natural resources for the benefit of future generations.

tially used to control mosquito populations in battle against malaria. Typically, average citizens are converted to environmental activists when they believe that their governments do not act in order to protect their land against pollution, or when they feel there is no one else who would care as much as they do about the future of nature. For instance, a large international network of environmental groups such as Friends of the Earth was founded in 1969 in the United States by David Brower to promote a fair use of nature. Similarly, Greenpeace was a pacifist organization created in 1971 to oppose the United States nuclear testing in the Pacific region.

IMPORTANT DISTINCTIONS

Environmentalism should not be confused with all environmental movements, since there are many degrees and perspectives. Other ecological movements, such as deep ecology and ecological radicalism, take a more radical perspective on the environment stating that the preservation of nonhuman nature is even more important than the interests of human beings, and therefore nature and wildlife must be protected and defended as such against abusive human activity. Because environmentalism carries a will to advocate a form of social change, it is not a synonym for environmental education, and it should also not be confused with sustainable development, which promotes industrialization in harmony with the environment.

Sociologist Steven Yearley, a leading expert on environmental issues, has explained that environmentalism can be interpreted either as a social construction or as a characteristic of anxiety over environmental risks in contemporary Western societies. Yearley also sees these networks of environmental groups and nongovernmental organizations (NGOs) as competitive with each other in their common quest for legitimate causes, new members, funding, and media exposure.

Because environmentalism opposes itself to official discourses from corporations and governments, the counter-discourses get a high level of credibility from their members, even about debated issues such as global warming. Most citizens are not scientists; therefore, their opinions do not rely on their own observations, measures, and evaluation of scientific data, but rather on their beliefs and sometimes the contradictory testimony of scientific experts. In that sense, environmentalism can be similar to an ideology that is in conflict with other ideologies in the public sphere.

Countless films related to environmentalism and similar issues have been produced. In recent decades, some documentary films have brought the ideas of environmentalism to a wide audience such as former U.S. Vice President Al Gore's 2006 film *An Inconvenient Truth*, which focused global warming. Also well known is Peter Watkins's 1987 film *The Journey*, which shows not only how the environmentalist movements work, but how many activists are perceived and often rejected by some members of the media in Canada, Scotland, Norway, Japan, Australia, and the United States.

Environmentality

ENVIRONMENTALITY IS A neologism (or newly invented word) devised to describe a novel set of political processes in and through which the environment is being governed and controlled. The types of political practice discerned within work on environmentality were first described in the pioneering work of Michel Foucault. In a series of lectures, partly given at the Collège de France between 1978–79 and later in the United States, Foucault outlined a history of the changing objectives and technologies associated with state power (or to use Foucault's term, *governmentality*).

GOVERNANCE OF EACH AND OF ALL

Within these lectures, Foucault revealed that the practices of governments were not universal or unchanging, but were marked by a shifting set of rationalities concerning what the purpose of states actually was. According to James Faubion, Foucault's account of governmentality was an attempt to explore the links between the government of the self and the government of a national population, or to put it another way, the governance *of each and of all*. At the heart of Foucault's history of state power was a desire to show how the reason, rationality, or *mentality* of government had shifted in the modern era from being one devoted to securing the sovereign power of a government over its territory, to one committed to establishing the *right disposition of things* in order to assure continued wealth, power, and prosperity. According to Foucault, securing the right disposition of things is most effectively achieved by governing the conduct of the individual while anticipating the needs and likely productivity of the whole of society. The key to both of these goals was an effective knowledge of the society to be governed and the deployment of disciplinary tactics to guide the activities of the population at an individual level. It was in this context that Foucault equated the practices of the modern state with "the head of a family over his household and his goods." Consequently, just as the head of a household knows and controls her/his family, the state knows and controls its population through the complex webs of surveillance and disciplinary tactics it deploys.

The notion of environmentality embodies an attempt to understand how this new mode of modern government applies to the political control and management of the environment. The word *environmentality* was first used by Timothy Luke and reflects a hybridized summation of Éric Darier's notion of *environmental governmentality*. While a concern with the governmentalization of the environment is implicit within Foucault's own account of governmentality (particularly in his discussion of the *ensemble of objects* that make up a territory), he does not outline the significance of his theory for studies of the environment directly. It is in this context that writers such as Luke, Darier, Michael Goldman, Paul Rutherford, James Scott, and Arun Agrawal have worked assiduously to reveal the different ways in which the environment has been governmentalized. According to Darier, studies of environmentality should focus primarily on political interventions within the environmental field, which have occurred since the early 1970s. Darier chooses to focus on this historical period because it is only at this point that we see—through the establishment of environmental ministries, policies, and acts of legislation—the emergence of the environment as a distinct arena for government intervention. Darier asserts that the object of environmentality is not to develop a history of how the environment has been governmentalized, but rather to study how the notion of the environment inserts itself into the longer history of the practices associated with governmentality.

Through a detailed study of Canada's 1990 *Green Plan,* Darier argues that the governmentalization of the environment is achieved through the collation of knowledge about the national environment and the establishment of new systems of environmental citizenship and education, which govern the conduct of individuals' environmental conduct.

The work of Michael Goldman and Timothy Luke has extended the application of environmentality from a study of national environmental governance to consider the government of the environment at a global level. Through studies of the transnational activities of the World Bank and the government of the United States, respectively, Goldman and Luke show how a sensitivity toward the practices of environmentality reveals the increasing up-scaling of environmental power from a national to a global level. According to Luke, the global and interconnected nature of contemporary environmental threats means that in order to secure the right disposition of things within a given territory, a state must also work to protect the functioning of transnational ecological systems. It is in this context that Luke interprets the policies of sustainable development currently being pursued by the United Nations and the environmental policies of Clinton-Gore administration in the United States as attempts to secure national forms of socioeconomic productivity through the governmentalization of the total setting of the global environment.

Most prominently, Arun Agrawal's research has revealed the way decentralized institutions of forest governance, specifically in India, have led to a system of management that transforms local people, as subjects, to become concerned about forest protection. This work has most clearly and empirically demonstrated that changes in governance can lead to a actual changes in the identities of people, as political subjects, as they encounter and relate to state institutions. Whether it is used to analyze the ways in which social conduct toward the environment is being changed or how the global environment is being governed, it is clear that theories of environmentality are having a profound affect on contemporary understandings of the links between state power and the environment.

Epidemic

IN EPIDEMIOLOGY, AN epidemic is defined as a disease that appears as new cases in a given human population, during a given period of time, at a rate that substantially exceeds "normal," based on recent experience. However, the definition of *epidemic* can be subjective depending on what is "normal." For example, a few cases for a very rare disease like rabies may be classified as an epidemic, while cases of a common disease, as the common cold, would not.

Epidemics can be categorized based on the size or the intensity of appearance of cases of a new disease. For example, an epidemic may be restricted to one locale (an outbreak), more general (an epidemic) or even global (*pandemic*). Also, when diseases occur at a constant but relatively high rate in the population, it is termed as *endemic*. An example of an endemic disease is malaria in some parts of Africa (for example, Liberia) in which a large portion of the population is expected to get malaria at some point in their lifetimes.

Epidemics can also be classified by their pattern of transmission. The disease can be transmitted by a vector, from person to person, or from a common source such as contaminated water.

Some of the famous examples of epidemics include the bubonic plague epidemic of Medieval Europe known as the Black Death, the Great Influenza Pandemic concurring with the end of World War I, and the current AIDS epidemic, which some also consider to be of pandemic proportions.

The Bubonic Plague, or Black Death, was a devastating pandemic, which first struck in China. This plague traveled to Europe by rat-infested Italian ships trading goods across the Mediterranean Sea. The plague reached England by the late 14th century and within 4 years (1347–51) it had killed over a million people, one-third of Europe's entire population. Including Middle Eastern lands, India, and China, the Black Death killed at least 75 million people, taking the form of the most dangerous pandemic ever to be known in the history of epidemics. In addition to its massive effect on mortality, the Black Death irrevocably changed Europe's social, economic and cultural structure. The deaths changed the size of the civilization, which further led to changes in trade, the church, art, and music. The disease was completely eradicated in Europe only at the beginning of the 19th century, but survives in other parts of the world (Central and Oriental Africa, Madagascar, and Asia).

GREAT INFLUENZA PANDEMIC

The Great Influenza Pandemic during the World War I killed more people than the war itself, somewhere between 30 and 40 million people. The origin of this influenza is not precisely known. It is thought to have originated in China and the war is believed to have accentuated its spread to take the form of a catastrophic pandemic. The pandemic affected everyone. With one-quarter of the United States and one-fifth of the world infected with the influenza, it was impossible to escape from the illness. The influenza virus had a profound virulence, with a global mortality rate at 2.5 to 5 percent compared to the previous influenza epidemics, which were less than 0.1 percent. The age specific death rate for the age group 15 to 34 years due to influenza and pneumonia were 20 times higher in 1918 than in previous years. The Great Influenza Pandemic was the most calamitous infectious disease pandemic in U.S. history, which killed around 28 percent of the U.S. population. The effect was so severe that the life expectancy in the United States was decreased by 10 years. Like many other pandemics, this influenza pandemic also had profound influence on socioeconomic status of the people. According to John Barry, author of *The Great Influenza: The Epic Story of the Deadliest Plague in History*, even though it killed at least 40 million people in less than a year, the 1918 influenza pandemic's most alarming consequences may have been that it nearly extinguished the basic humanitarian impulses that bind civil society together.

AIDS

At the beginning of the 21st century, Human Immunodeficiency Virus (HIV), which causes the Acquired Immune deficiency Syndrome (AIDS), has killed more than 25 million people since it was first detected in 1981. Nearly twice that many, 40 million, are living with the virus. Without some major breakthroughs, most of these people are expected to die during the next 10 years or so. Despite recent, improved access to anti-retroviral treatment and care in many regions of the world, the AIDS epidemic claimed between 2.8 and 3.6 million lives in 2005, of which more than half a million were children. Interestingly, over 90 percent of people infected with the HIV live in the developing world. The Joint United Nations Program on HIV/AIDS (UNAIDS, 1999) expects that this "proportion will continue to rise in countries where poverty, poor health systems, and limited resources for prevention and care fuel the spread of the virus." Sub-Saharan Africa remains by far the worst-affected region, with 23.8 million to 28.9 million people living with HIV at the end of 2005. Just under two thirds (64 percent) of all people living with HIV are in sub-Saharan Africa. South and southeast Asia is the second most affected region with 15 percent. If the current trends of HIV infection and mortality due to AIDS continue to hold, the HIV/AIDS epidemic will develop into a devastating pandemic. It will then dictate the size, growth, and age-sex structures of entire populations around the world.

Epidemiology

EPIDEMIOLOGY IS A population's health science. It utilizes a population approach for the study of the distribution (person, place, and time) and determinants (biological, social) of health and disease in defined populations of varying characteristics, and how to use the information for the prevention and control of various health problems.

The term *epidemiology* is of Greek origin and can be roughly translated as the study among or upon people. The origins of epidemiology can be traced back to the era of Hippocrates, when the idea that environmental factors (seasons, winds, hot, cold) can influence disease occurrence was in circulation. However, epidemiology's development into a full-fledged discipline excelled in the 19th century with the work of John Snow, on which identified the relation between drinking water supplied from a certain company and the risk of death from cholera. Although epidemiology originated from the study of communicable diseases, it eventually developed a more comprehensive scientific approach to studying various health-related states including noncommunicable diseases, disability, accidents, quality of life, and others.

An epidemiologist is a scientist who uses epidemiological methodology to investigate various phenomena related to the health of the population. An epidemiologist should also have some knowledge of other public health disciplines, statistics, and social and medical sciences. An epidemiologist's range of functions includes practical applications, such as outbreak investigation and field epidemiology, in addition to applications such as formulating and testing epidemiological hypothesis and developing study designs. However, in all efforts, the epidemiologist aims to use epidemiological thinking and methods to contribute to disease prevention and health promotion.

Traditionally, epidemiology has been classified by type of discipline or disease and physiology. Examples of epidemiology discipline classifications include: environmental, social, pharmacoepidemiology, nutritional, genetic, molecular, and clinical and surveillance. Examples of disease and physiology–based classification include: reproductive epidemiology, epidemiology of aging, cancer epidemiology, and injury epidemiology.

Epidemiology attempts to answer various questions regarding the distribution of diseases and the determinants of health, such as: How many people developed the disease? What is the disease burden in a certain population? Why a specific group of the population developed the disease while the others did not? What are the factors associated with disease? What are the different stages of disease? What is the prognosis? Is there a causal relation between a certain factor (exposure) and the disease? Are the interventions used to prevent or control the disease effective? What are the public policies that should be formulated and the regulations to be applied to safeguard the health of the population?

ANSWERING THE QUESTIONS

In its attempt to provide scientifically sound answers to theses questions, epidemiology adopts two main approaches. Descriptive epidemiology focuses on studying the occurrence of disease, disability or any other health-related phenomenon. It observes and describes the relation of the disease with the basic population characteristics such as age and sex. The person, place, and time triad is the cornerstone of descriptive epidemiology. It does not aim to tests hypotheses, for example to prove or disprove a causal relation. In contrast, analytical epidemiology usually studies causal relations, tests hypotheses, and measures the association between exposures and outcomes.

Measuring and comparing the occurrence of diseases and death is achieved by using various measurements of morbidity and mortality. *Prevalence* refers the total number of persons with the disease or health related event during a defined period or point in time, and the *prevalence rate* is calculated by dividing this total number of cases or persons with the disease by the population at risk of having this event. *Incidence* refers to the new events or cases in a defined period only and the incidence rate is calculated by dividing the new cases by the population at risk at the same period, and can be expressed as person-time. Comparing the occurrence of disease among groups of people with different exposure status (exposed vs. unexposed) is useful to show the effect and to calculate the risk of being exposed to a certain factor (exposure) on a health outcome (disease). Both absolute (risk difference) and relative (risk ratio) comparisons of risk are available. Various measures can be used to assess mortality such as the crude mortality rate, which is calculated by dividing the number of deaths in a defined period by the average total population in the same period. Other measures of mortality include age-specific and age-adjusted mortality rates, which allow comparison of rates among populations with different age structures.

EPIDEMIOLOGICAL STUDY DESIGNS

Answering these different epidemiological questions requires the use of suitable epidemiological study designs, which are classified into observational and experimental studies. Experimental studies involve an intervention introduced or eliminated by the researcher/epidemiologist, while the observational studies are based on observation and measurement only. Examples of observational studies include ecological, cross-sectional, case-control, and cohort studies. A cross-sectional study can be used, for example, to determine the prevalence of diabetes mellitus in a certain population. Experimental studies include the randomized controlled trial, which is considered the gold standard of epidemiological designs, field trials, and community trials. An example of experimental study application is the use of a randomized controlled trial to study the effect of a new oral hypoglycemic drug on controlling blood glucose in persons with diabetes mellitus. Epidemiological studies vary in their characteristics such as the capacity to study causal relations, the cost of conducting a study, the duration, the required sample size, and other characteristics. These characteristics affect the choice of a certain epidemiological study over the other.

Epidemiological study errors that can affect the accuracy of collected information include random error, systematic error (bias) and confounding. Minimizing the effects of those errors is an important component of epidemiological study design and analysis.

SURVEILLANCE

Another important aspect of epidemiology is surveillance, which involves a continuous systematic process that involves data collection, analysis, interpretation and dissemination of results. Data collected include information on diseases, risk factors, complications, and health practices. Surveillance objectives include detecting epidemics, monitoring disease trends, identifying risk factors and the emergence of new diseases and microbes.

Outbreaks are usually marked by an unexpected rise in the incidence of a certain disease above the base-line level. Outbreak investigation classically originated from communicable diseases outbreaks such as typhoid. In the modern age, different types of outbreaks have been identified including outbreaks due to environmental factors such as contamination with chemicals. An example of an environmental pollution epidemic is the Minamata Bay-Japan case, where methylmercury accumulated in fish due to the release of chemicals containing mercury from a nearby factory. This caused severe poisoning among fishermen and their families who consumed fish as a main food item. Epidemiology played a crucial role in identifying the cause of and in controlling such epidemics.

Equatorial Guinea

THE NATION OF Equatorial Guinea is located in west central Africa. The total land area is 10,811 square miles (28,000 square kilometers) and includes the mainland region as well as the islands of Bioko, Annobon, and others. In 2006, the estimated population of the country was 540,000, and it was one of the last African countries to gain independence (in 1968, from Spain). Continental Equatorial Guinea rises from a wide coastal plain to the hilly terrains of the interior. The Mbini River Basin covers much of this region, which is home to about 80 percent of the population. The islands are volcanic and present altitudes above 9,840 feet (3,000 meters) in Annobon. The climate is hot with abundant rainfall throughout the year. About two-thirds of the continental portion is covered by tropical rain forest.

Since 1995, Equatorial Guinea has become one of the largest oil producers and exporters of Sub-Saharan Africa. Oil fields were discovered in the islands in the early 1990s and large-scale production began in 1995. In 2004, the country was producing nearly 400,000 barrels/day (the third-highest rate among African nations, after Nigeria and Angola), with estimated reserves of 1.3 billion barrels. Because of oil operations, the country ranks third in Africa (after Angola and South Africa) in U.S. investments. The contribution of oil to Equatorial Guinea's Gross National Product (GNP) rose from 7 percent in 1992 to 83 percent in 2000. Booming oil prices in 2004, 2005, and 2006 induced sharp increases in the country's GNP, which attained double digits during these years. However, oil revenues have not been directed to development, and there are serious accusations of misappropriation of oil money by the government. Meanwhile, Equatorial Guinea remains one of the poorest countries in Africa, with much of the population subsisting on $1 a day or less and health indicators among the worst of the region (life expectancy is around 50 years and the infant mortality rate is 111 per 1,000). Malaria has taken a heavy toll, especially among the young, and waterborne diseases are also widespread, as only 45 percent of the population have access to potable water in urban areas (42 percent in rural areas).

Deforestation has become widespread during the last decades. Originally, the tropical rain forest covered about 96 percent of the country. By the year 2000, this area had been reduced to 62 percent. Before the oil boom of the 1990s, timber (okume and ebony) was the main commodity produced in the country. About 3.2 million acres (1.3 million hectares) are susceptible to timber production. In 1993, about 1.4 million acres (600,000 hectares) had been authorized for exploitation, but the devaluation of the currency in 1994 prompted an increase in the number of concessions (mostly to Chinese and Russian investors) to the point that by the end of the 1990s, all productive forests had been organized in some 80 lots and were regularly exploited. One large Chinese company controls virtually half of the timber produced in Equatorial Guinea. In 2003, about 16 percent of the land was protected, although there are concerns about the growing illegal traffic of plants and animals. In the late 1988 there were accusations that the waters surrounding the island of Annobon were used to dump toxic and nuclear wastes produced in Western countries.

Equilibrium

EQUILIBRIUM IS A term from general systems theory that has been a central concept in ecology for several decades. In general systems theory, equilibrium is a steady state (homeostasis) that the system achieves due to negative feedback, causing changes in the system to quickly return to the initial state. In terms of ecology, equilibrium occurs when a biotic community maintains a constant species composition and abiotic nutrients and energy are cycled through food webs such that the amount of energy and nutrients entering the biotic community are balanced by output of these abiotic components. Equilibirium is considered to be reached in late stages of ecosystem development when high biodiversity across all trophic levels and a high degree of niche specialization result in all available environmental resources being cycled through the foodwebs, such that no excess nutrients are available for new species to become established. Equilibrium is closely tied to the hypothesis that high biodiversity conveys ecosystem stability, and has been a fundamental concept behind modern conservation design.

A FUNCTION OF HIGH BIODIVERSITY

Equilibrium occurs as a function of high biodiversity across all trophic levels due to intertrophic and intratrophic competition. Within a trophic level, interference competition between individuals of different species for the same resources causes these species to sort into specialized niches through competitive exclusion. With high biodiversity within a trophic level, species become competitively specialized into very narrow niches with each species having a higher efficiency in resource utilization within that niche, such that all of the resources in question are consumed at that trophic level. Across trophic levels, greater specialization among predators for their prey assures that predator populations are controlled by the individual numbers of their prey species; the predator population fluctuated with that of its prey, and neither becomes extinct. Populations of species are thus controlled from the lowest trophic levels, and species composition is maintained, as no single species is able to consume another into extinction without becoming extinct itself. This encourages greater specialization, thus ensuring available environmental resources are cycled, and maintaining a constant species composition in the ecosystem, which is in a state of equilibrium. The stability of these ecosystems also require sufficient time to pass for competition to sort species into their various niches, in which disturbances do not occur that upset the balance of species.

The equilibrium theory of island biogeography proposes that ecosystems are maintained in a state of dynamic equilibrium. For a given ecosystem, the overall number of species will remain relatively constant over time, although species turnover (the replacement of locally extinct species with new immigrants) occurs. As a study of island environments, the theory asserts that immigration rates into an island are inversely proportional to distance from the nearest continent, extinction rates are inversely proportional to area of the island, and that the equilibrium number of species occurs at the point the two curves are equal. Although originally formulated for predicting biodiversity on oceanic islands, the theory has been widely applied in conservation ecology, with isolated mountaintops and habitat patches within a heterogeneous landscape viewed as functional islands.

Within conservation ecology, the implications of equilibrium have far reaching implications for

In the Equilibrium Theory of Island Biogeography, ecosystems are maintained in a state of dynamic equilibrium.

human–environment interaction. An equilibrium view of nature is one in which species are free to interact and coevolve into stable assemblages over long periods of time. To do so, these systems must be free of disturbance. With disturbance seen as an aberration to these systems, humanity is viewed as having no place in these environments. This scientific view of the environment is rooted in Western ideals regarding the separateness of humanity and nature. Furthermore, these equilibrium perspectives suggest that reserves must have sufficiently large area to prevent extinctions and maintain viable populations of species.

Ecological equilibrium as a model for ecosystem and biodiversity management has been criticized in recent years. First, disturbance has been observed to be a natural and frequent occurrence in ecosystems, such that several terrestrial ecosystems have been identified as functioning within a particular disturbance regime.

Fire ecology is an example of one of these disturbance regimes, whereby midlatitude grasslands and Mediterranean ecosystems, among others, have been identified as being adapted to relatively frequent burnings, such that periodic burning is necessary for proper ecosystem function. Disturbances are seen to occur frequent enough that ecosystems are now often viewed as being in a constant state of flux in terms of species composition and nutrient cycling. Equilibrium is viewed more as an unstable property that an ecosystem may possess at any given moment, rather than as a teleological endpoint that the system naturally gravitates toward. Ecosystems are more frequently described as being in disequilibrium, or nonequilibrium, within the ecological literature.

Second, equilibrium models have been criticized from within conservation ecology itself on philosophical and political grounds. Although equilibrium models provide a politically defensible approach to conservation (an ecosystem's integrity can only be maintained by being set aside and left undisturbed by people), and there is a tendency to maintain these equilibrium discourses as a result, conservationists criticize equilibrium approaches for encouraging a natural ontology in which nature will return to its natural balance if left alone, and obscures the need for increased human intervention into ecosystems to preserve biodiversity.

Finally, the equilibrium perspective has been used to justify the removal of people from landscapes targeted for conservation reserves. Social and environmental justice concerns have been raised over ecological equilibrium as a result.

Equity

EQUITY REFERS TO the distribution of wealth or power and is closely related to notions of justice, fairness, and equality. The concept permeates several disciplines of social thought, including prominent roles in economics, geography, and political philosophy. Equity concerns have become inextricably bound to environmental quality. This intrinsic relationship between equity and the environment takes many forms across space and at different scales, yielding the paired concept of environmental equity.

Empirical trends in world economic development, such as uneven resource exploitation and disparate vulnerability to environmental harms, underscore the prevalence of environmental inequities among nations, economic classes, and cultural groups. These inequities have coalesced into at least three interrelated topics pursued by environmental equity activists and scholars: environmental justice, natural resource access, and intergenerational equity.

Environmental justice exposes inequalities in the incidence of environmental harms across differences in race, gender, economic class, or national economic development. The disposal of toxic and hazardous waste near areas inhabited by racial minorities in the United States sparked an environmental justice movement that has become embedded in local, national, and international environmental politics. Global climate change provides a vivid and complex example of the environmental equity and justice notions that shape contemporary policy debates. In the early 1990s, global climate change emerged onto the international environmental agenda, spawning proposals to curb anthropogenic greenhouse gas emissions.

Such policy responses could impose an inequitable burden on developing countries by restricting their ability to exploit the same sources of energy used by richer nations to develop economically. In 1997, the Kyoto Protocol amendment to the United Nations Framework Convention on Climate Change attempted to accommodate such environmental equity concerns by acknowledging that developed countries, such as the United States and Japan, bear the primary responsibility for current and historical emissions of greenhouse gases. The Kyoto Protocol took force in 2005 without United States approval, and it stipulates a "common yet differentiated responsibility" that excludes some developing countries from emission reduction requirements.

Equity also exists centrally in natural resource access issues. For example, the richest 20 percent of society consumes 17 times more energy resources than the poorest 20 percent, and this pattern applies to many other natural resource and environmental harms. The disparities in resource access and consumption can be gleaned by evaluating the eco-footprint of citizens from different countries. Eco-footprint analysis portrays the amount of land and water needed to accommodate per capita consumption of resources and the disposal of associated waste. While the United States, Canada, and countries of western Europe have an ecofootprint of 12.35 to 24.7 acres per person (5–10 hectares), China's per capita ecofootprint lies between 2.47 and 4.94 acres (1–2 hectares). An important corollary to uneven resource exploitation stems from inequalities in the generation and disposal of environmental waste, such as toxic and hazardous materials. The disproportionate burden of that waste on poorer segments of society underscores the primary concerns of the environmental justice movement. European colonial history adds an important dimension to resource access issues due to the well-documented record of exporting natural resources from resource rich colonies in Africa, South America, and south Asia to the former ruling nation states, such as France, Spain, and Great Britain. This colonial legacy influences contemporary resource access debates, especially as the nation states forged from former colonial territory confront resource exploitation limits imposed by international environmental agreements and economic development funding arrangements. The resource development paths once available to many contemporary economic powers have proven untenable for developing countries required to pursue more efficient technologies.

COLONIAL INFLUENCE

The persistence of colonial influence in natural resource access and economic development suggests the primacy of intergenerational equity considerations in environmental discussions. Intergenerational equity considers the implications of current resource access and pollution for future generations. These issues have infused environmental policy debates with concerns over sustainability and sustainable development. Permanent biodiversity loss from habitat conversion associated with current levels of resource extraction and pollution demonstrates the basic concern of intergenerational equity: diminished environmental quality bequeathed to future generations as a consequence of current or historic resource consumption patterns.

Due to long-term natural variability in many indices of environmental quality, intergenerational equity impacts often defy rigorous evaluation and quantification. In other words, it is difficult to separate the environmental impact of human resource consumption patterns from the environmental changes wrought by natural variability. Despite the moral and political challenges associated with issues of environmental justice, natural resource access, and intergenerational equity, the equity dimensions of human-environment interactions remain a focal and growing concern in environmental policy and society.

Erie, Lake

LAKE ERIE IS the fourth largest of the five Great Lakes and the 12th largest freshwater lake in the world. The history of Lake Erie is complex. Approximately 2 million years ago, a basin, or lowland, in the present-day Erie basin served as the valley of a once east-flowing Erigan River. This drainage system was destroyed by the first of several major glacial advances that deepened and enlarged the basin. The problem for geologists was that each successive glacier destroyed the evidence of the preceding one, making a complete and thorough history virtually impossible.

A more detailed history of Lake Erie can be traced as far back as the retreat of the Wisconsinan—the last Pleistocene glacier—some 14,500 years ago. Scientists using radiocarbon-dated sentiments, detrital transport, hardwater, inorganic carbon contamination, postdepositional compaction, and other sampling procedures have added considerably to our understanding of Lake Erie's evolution.

In its present form, Lake Erie is relatively young according to geologists, with a lifespan of less than 4,000 years. Lake Erie has an elevation of 571 feet (174 meters) above sea level, a surface area of 9,940 square miles (25,745 square kilometers), a length of 241 miles (388 kilometers), and a breadth of 57 miles (92 kilometers) at its widest point. Its maximum depth is 210 feet (64 meters), its water volume is 116 square miles (484 square kilometers), and its residence time—the time lake water takes to renew itself—is 2.6 years. Its primary source is the Detroit River and primary outflow is the Niagara River into Lake Ontario.

Lake Erie has a number of interesting characteristics. Its basin is comprised of Devonian shale in the east and limestone and dolomite (Silurian and Devonian carbonates) in the west, which are more resistant to erosion. Hence, the lake is shallow in the west (averaging less than 25 feet) and much deeper in the east (reaching 210 feet) where glacial ice was able to remove the limestone. The basin is also shallow at its most southerly points (where it averages less than 25 feet) because that is where the glacial ice was thinnest pending its retreat. When glaciers flow over resistant bedrock, they leave scratches in the surface known as striations, which are produced by grinding stones caught between the ice and the bedrock. Striations of up to three feet are found commonly in Bass Island's hard Silurian limestone in western Lake Erie. Waves in shallow water also tend to be steeper than those in deep water, and thus Lake Erie is known for choppy waters during storms.

Lake Erie's ecology and hydrology also have some unique features. Because Lake Erie (like the other Great Lakes) is relatively young, its water contains relatively few species of fish. The food chains are short, relatively simple, and easily disrupted, such as when spectacular changes in lake levels result from tilting or imbalance of the lake surface produced by winds and changing barometric pressures. Consequently, Lake Erie has risen for hours or days over an appreciable area by as much as 8.4 feet. The lake also has small tides called *seiches*, which can be measured in inches rather than feet, that can last for days. Another unique feature of the Great Lakes including Lake Erie are seasonal thermoclines (often called *thermal bars*), which are horizontal interfaces that separate the warmer water at the surface, or *epilimnion*, from the colder deeper water, or *hypolimnion*. These thermoclines form during the spring and break up during the fall.

Like other lake ecosystems, Lake Erie was significantly transformed from its original state through a number of processes largely consequential of human activity. Oxygen depletion and eutrophication, namely the rapid aging and filling in of the lake caused by algal growth, increased sediment influx, and contamination with toxic materials are major dangers confronting the lake since the 1960s and 1970s. Eutrophication has resulted in the decomposition of algae, which has led to extensive seasonal anoxic areas in the lake (often called *dead zones*). In 1972, Canada and the United States entered into an agreement to reduce the runoff and dumping of phosphorus into the lake. Both governments and, in particular, the U.S. Environmental Protection Agency (EPA) are monitoring this problem. Lake Erie has also been impacted by a long list of invasive species: rainbow smelt, white perch, common carp, and alewife. Other additions affecting Erie include quagga and zebra mussels that have populated the entire Great Lakes ecosystem, pushing energy flow through the food web away from the pelagic zone and into the benthic zone.

Commercial fishing on Lake Erie is extensive and management of the fishery is conducted by consensus of all agencies with a shared interest in the resource: the Canadian province of Ontario, and the states of New York, Pennsylvania, Ohio, and Michigan. Commercial fishing is most active in Canadian communities, and the Ontario fishery is intensively managed with individual transferable quotas (ITQs). It also features the mandatory reporting of daily catches and intensive auditing of the catch system.

Eritrea

ERITREA, LOCATED IN the Horn of Africa, covers 121,320 square kilometers It shares boundaries with Sudan in the north and west, Ethiopia in the south, and Djibouti in the southeast. Topography is dominated by highlands, descending in the east toward a coastal desert plain, in the northwest to hilly terrain, and in the southwest to undulating plains. Altitude ranges from sea level to approximately 3,000 miles above sea level. The capital is Asmara. Eritrea's climate is categorized into semi-desert, arid, and moist lowlands, sub-humid zones, and arid and moist highlands. The climate is characterized as bimodal. The main rains, from June to September, affect the highlands and western lowlands. Short rains occur from November to March and affect the coastal, eastern, and southern escarpments. Average annual rainfall varies between less than 200 millimeters in the semi-desert and 900 millimeters in the sub-humid zone. Mean annual temperature varies between 18 degrees C in the highlands and 28 degrees C in the semi-deserts.

Eritrea was awarded to Ethiopia as part of a federation by the United Nations in 1952. Ethiopia's annexation of Eritrea as a province 10 years later sparked a 30-year struggle for independence that ended in 1991 with Eritrean rebels defeating government forces; independence was approved in 1993. Only five years later, tensions with Ethiopia sparked over economic policies and border disputes, which resulted in war, costing many lives and displacing more than a quarter of the Eritrean population. Eritrea has suffered damages to its weak infrastructure and economy, from which it has yet to recover. In 2000, Eritrea and Ethiopia signed a peace agreement, but the border continues to be disputed and Eritrea's relations with Ethiopia remain tense. Eritrea has become isolated internationally, mainly due to the totalitarian military regime.

The country has a population of nearly 4.8 million, with an annual growth rate of three percent in 2006. Eritrea is one of the poorest countries in the world, with more than half of the population surviving on less than $1 per day. Population density is highest in the highlands, where 60 percent of the population occupies 19 percent of the area. About 84 percent of the population lives in rural areas where the main sources of livelihood are subsistence agriculture, pastoralism, and fishing. The agricultural sector employs 80 percent of the population; but only contributes 17 percent to the gross national product. Eritrea's main exports are coffee, cotton, meat, and hides. In 2002, economic growth of two percent was contrasted with an inflation rate of 15 percent. Eritrea is largely reliant on external support, especially through remittances from Eritreans living abroad; foreign investments are low because of political instability.

Shrublands and grasslands cover around 64 percent of the land, while woodlands make up 11 percent and cultivated land nine percent. Grasslands are exposed to wind erosion during the dry season, and to water erosion at the onset of the rains. Reliance on natural resources and increasing population is leading to the expansion of cultivation into areas that are marginal for agriculture, resulting in land degradation. Even in years of sufficient rainfall, Eritrea only produces about half of its food requirements, thus, relying heavily on food aid. Food security is a national priority, but options to expand agricultural land are limited. Reliance on subsistence agriculture has made Eritrea vulnerable to droughts and locust invasions. Moreover, depletion of scarce natural resources has led to deforestation, overgrazing, and desertification. Due to lack of investment, the potential for livelihood diversification into non-natural-resource-based sectors remains limited.

Estonia

FOR MUCH OF its history, Estonia has been dominated by larger neighboring nations. Toward the end of World War II, for instance, Estonia was unwillingly incorporated into the Soviet bloc but gained its independence in 1991 after the breakup of the Soviet Union. Since joining the European Union (EU) in 2004, Estonia has been on the road to economic recovery and is making significant environmental progress.

The topography of Estonia is varied, with marshes in the lowlands, plains in the north, and hills in the south. Bordering on the Baltic Sea and the Gulf of Finland, Estonia has 2,464 miles (3,974 kilometers) of coastline and is home to more than 1,500 islands. The maritime climate produces wet, moderate winters and cool summers. Flooding is common in the spring of the year, increasing the potential for environmental damage.

Estonians enjoy the benefits of an economy based on strong electronics and telecommunications sectors and on strong economic ties to Finland, Sweden, and Germany. While nearly 70 percent of the population live in urban areas, 11 percent of the workforce are engaged in the agricultural sector. Estonia's rich natural resources include peat, phosphorite, clay, limestone, sand, dolomite, arable land, and sea mud. Estonia also has the largest usable deposits of oil shale in the world. With a per capita income of $16,400, Estonians enjoy a comparably high quality of life, and the United Nations Development Program (UNDP) Human Development Reports ranks Estonia 38th of 232 countries on overall quality-of-life issues.

Major environmental problems of the 21st century concern water polluted by untreated wastewater and air pollution resulting from the northeastern oil shale-burning power plants that release sulfur dioxide into the air. Progress is being made in both areas, and sulfur dioxide emissions have fallen 80 percent from 1980 levels. Likewise, water pollution has dropped to one-twentieth of 1980 levels in response to the erection of water purification plants. In addition to polluted seawater, the Estonian government is concerned about the potential for agricultural pollution of the country's 1,400 lakes. Because of heavy urbanization and a rate of 296 cars per 1,000 people, Estonia experiences carbon dioxide emissions of 11.7 metric tons per capita.

ENVIRONMENTAL IMPACT

The Soviet occupation of Estonia left an enormous impact on the environment, including the aftermath of hundreds of thousands of tons of jet fuel that were dumped in Estonia. At an air base near Tapa, for instance, it has been estimated that about two square miles (six square kilometers) of land were covered by a layer of fuel, and about four square miles (11 square kilometers) of water were contaminated. The Soviets also created an environmental nightmare by improperly disposing of toxic chemicals and dumping explosives and weapons in inland waters. Additionally, a uranium plant in Sillamäe discharged 1,200 tons (1,089 metric tons) of uranium and 750 tons (680 metric tons) of thorium into the Gulf of Finland. Overall, the Ministry of Environment estimated cleanup costs at nearly $300,000 (3.5 billion EKR).

With a new commitment to environmentalism, the Estonian government has protected 11.8 percent of its land. Of 65 species of mammals endemic to Estonia, four species are threatened. Bird species fare better, with only three of 204 species in danger of extinction. Improved environmental policies are due in large part to public awareness raised through the work of such groups as the Estonian Nature Conservation Society and the Green Movement.

Within the Estonian government, the Ministry of Environment oversees four units that consist

Exceptional National Parks

Estonia, the northern-most of the Baltic Republics, has a diverse natural history and has established five national parks which, because of the country's remoteness, have extensive unspoiled natural environments for flora and fauna.

The first and most well-known national park in Estonia is the Lahemaa National Park, which was established in 1971 and is located in the northern part of the country, 50 miles east of Tallinn, the capital. Until independence it was the only national park in the country, and it covers 1878 square miles (725 square kilometers), including 651 square miles (251 square kilometers) of sea. The park has a charter which calls for the preservation, research, and promotion of North Estonian landscapes, ecosystems, biodiversity, and natural heritage. Some 8 percent of the park is only accessible to scientists.

The Lahemaa National Park was chosen as a national park for its uniquely Estonian natural and cultural features, with 838 plant species—34 of them rare—found in the park, along with 37 mammals including the brown bear, the lynx, and the European mink, along with 213 species of birds and 24 different types of fish. In the middle of the park is the restored manor and parkland of Palmse where wealthy German barons once lived.

The Soomaa National Park, located in the southwest of Estonia, is nicknamed the "Land of Bogs" and contains five extensive swamps that are located in the catchment area of the Parnu River, one of the longest rivers in the country. In 1997 it was included in the nature protection areas of Europe, becoming a CORINE biotope area. It has also been a member of the Ramsar List of Wetlands from 1997, and in the following year moves were made to nominate it as a UNESCO World Heritage Site.

The other national parks in the country are the Karula National Park, the Matsalu National Park, and the Vilsandi National Park.

of administration, management, international cooperation, and nature conservation and forestry. In 1990, the Estonian Parliament passed the comprehensive Nature Protection Act and the Act on Sustainable Development to provide a framework for environmental legislation. Subsequent supplementary legislation includes the Public Health and Packaging Acts of 1995; the Energy, Chemicals, and Environmental Supervision Acts of 1997; the Ambient Air Protection and Waste Acts of 1998; and the Pollution Charges and Environmental Monitoring Acts of 1999. In 2000, Estonia adopted the Environmental Impact Assessment aimed at coordinating all environmental plans and programs.

The Ministry of Environment is also in charge of environmental research and development centers and the works closely with 15 county environmental departments. At the international level, Estonia participates in the following international agreements: Air Pollution, Air Pollution–Nitrogen Oxides, Air Pollution–Sulfur 85, Air Pollution–Volatile Organic Compounds, Antarctic Treaty, Biodiversity, Climate Change, Kyoto Protocol, Endangered Species, Hazardous Wastes, Ship Pollution, Ozone Layer Protection, and Wetlands.

Estuaries

ESTUARIES ARE KNOWN by many different names: bays, coves, inlets, harbors, sounds, and lagoons. Simply put, they are places where rivers meet the sea. Estuaries are, however, far more complex than merely areas where seawater is mixed with fresh. They are also ecotones, places where different ecosystems meet and boundaries overlap: terrestrial and aquatic, freshwater and marine, inland and offshore. They are dynamic regions of transformation, high productivity and species diversity. Estuaries act as buffers and filters, protecting upland habitats from storm surges and, preventing sediments and pollutants from reaching coastal waters. Estuaries contain diverse habitats: sandy beaches, rocky shorelines, mudflats, fringing salt marshes and mangroves, and provide critical habitats for many species.

Diverse definitions of estuaries have been proposed, emphasizing various sets of attributes, delineating landward and seaward ranges differently, but there is general agreement that estuaries are semi-enclosed bodies of water with freshwater inputs and some open connection to the sea, allowing for dilution and tidal exchange. The proximity of barrier islands, reefs, bars or peninsulas protects them from the full force of the ocean. Several geophysical processes give rise to estuaries and, as a result, estuaries exhibit different forms. Several types of estuaries have been delineated, encompassing those of glacial origin, known as fjords, those of tectonic origin, those formed from river deltas, flooded river mouths and bar-built estuaries where barrier islands or peninsulas form from sand bars, protecting river mouths from the ocean.

Environmental conditions in an estuary may be highly variable, unpredictable and extreme. Considerable variation can exist even within a given estuary. Due to tidal fluxes, river flows, topography, and weather conditions, estuarine waters experience dramatic changes, both regular and irregular, affecting salinity, sediment load, oxygen concentrations, and temperature. Salinity fluctuates, varying from brackish to almost fresh and in some arid areas, hypersaline. Waters may be well-mixed, or strongly stratified, with water layers of different salinities and densities, called a salt wedge.

Environmental conditions in an estuary may be highly variable, unpredictable, and extreme.

These physical extremes present physiological challenges for organisms, but species have adapted to the rigors of the estuarine environment. Estuarine productivities are among the highest in the world, due to high nutrient loads in water and sediments. Estuaries are critically important in the life histories of many species, including recreationally and commercially valuable species. Some species, particularly benthic invertebrates, live their entire lives within the bounds of the estuary. These include species of oyster, clam, and scallop. Some spend only a portion of their lives in the estuary, using them for reproduction, larval, and juvenile rearing. Other species, notably shorebirds, waders and wildfowl, utilize these areas for feeding. Salmon use estuaries as nurseries for juveniles and migrate through them as adults on their way to freshwater tributaries in which they spawn.

Humans settled around estuaries because they provided subsistence opportunities, good harbors, direct linkages between rivers and the sea, facilitating transportation and commerce. Settlements became cities and now several of the world's largest cities are found along estuaries. Estuaries are also considered attractive places to live for recreational and aesthetic reasons. In the United States, over 50 percent of the human population lives along the coast, which constitutes less than 10 percent of the lower 48's land. Globally, coastal density is approximately 40 percent. In either case, human populations are increasing in estuarine areas and, as a result, the ecological footprint of humans on the estuarine environment is significant and growing.

Some estuaries habitats and species have declined significantly. Eelgrass (*Zostera marina),* an aquatic flowering plant that provides habitat for many aquatic species, has declined dramatically, due to dredging, impacts with boat propellers, reduced water quality and clarity. More recently, dieoffs of salt marsh grass *(Spartina alterniflora),* an important primary producer in the highly productive foodweb of many estuaries, have been observed. The phenomenon, called Sudden Wetlands Dieback, may be caused by various factors such as pollution, drought conditions, elevated water temperatures, increasing sea levels as well as a non-local strain of *Fusarium*, a pathogenic soil fungus, acting alone or in combination.

Anthropogenic impacts such as pollution, habitat destruction and degradation, resource extraction, and the spread of invasive species are negatively impacting estuaries worldwide. Estuarine pollution comes in many forms and from many different sources, including both point and nonpoint source discharges. Pollutants encompass organic substances and nutrients from sewage outfalls as well as diffuse sources, which can create eutrophic conditions. Oil, synthetic organic compounds, heavy metals, radioactive substances, pathogens, large debris as well as excess heat, produced from electrical generating plants, also contribute to estuarine pollution. Upland land conversion, water diversions, dredging, beach defenses and modifications constitute some of the habitat changes impacting estuaries. Estuaries also provide sites for aquaculture and mariculture operations, with attendant releases of pollution, pathogens, and escapees. Invasive species threaten endemic species via increased predation and competition. Resource extraction occurs as both a directed and incidental activity. Subsistence, recreational and commercial harvesters take shellfish, fish, seaweeds, and various bird species from estuaries and harvest estuarine-dependent species in other areas, depleting reproductive stocks. Estuarine animals are killed by impingement and entrainment through cooling water intake during the operation of power plants.

However, the most serious threat facing the world's estuaries may be global climate change and its attendant increases in storm frequency, intensity and sea level. Although new estuaries will form at higher elevations, the rate and magnitude of change is critical. At high rates of sea level rise, newly flooded habitats may not be able to form and retain the fringing marshes and mangrove swamps, the various bioscapes that are so important to maintaining productivity and providing habitats for the diversity of organisms that currently utilize the world's estuaries.

Ethics

GROWING EVIDENCE OF human-induced environmental damage has raised popular awareness that we ought to act and think differently about nature. The bad effects of fossil fuel emissions, marine pollution, deforestation, urban sprawl, and unchecked population growth have raised a set of ethical questions. Is technology the answer to environmental problems, or should we transform our consumption patterns and production processes? Is population growth or unequal resource distribution a greater cause of land degradation? Are societies morally obligated to ensure the resource needs of future people? Do nonhuman entities have value beyond their usefulness to humans? Do animals and plants have moral standing and therefore rights?

In response to these and other questions, scholars and activists since the 1970s have forged the distinct and growing field of environmental ethics. This branch of philosophy reflects on society's conception and treatment of nonhuman nature in moral terms, offering both ideal codes of conduct and policy guidelines. It seeks to craft theories that explain the motivations and consequences of human actions on earthly life, and it proposes what ought to be done.

Environmental ethics took root in the 1960s, a decade of transformational politics and social consciousness. Frequently cited as a wakeup call to the world about the ruin of nature, Rachel Carson's *Silent Spring*, published in 1962, documented how industrial technologies—particularly the use of DDT—have harmed the planet's ecosystems and have jeopardized human well-being. Slightly later, Paul Erlich's *The Population Bomb* (1968) alerted the public to what he described as an impending crisis caused by unsustainable population levels at the global scale. While scholars in the United States, Australia, and Norway laid the foundations for environmental ethics in academia and political movements, key concepts—such as the virtue of sustainable resource use or wilderness protection—were articulated by earlier economists, naturalists, foresters, and artists, people like: George Catlin, Thomas Malthus, David Ricardo, John Stuart Mill, Ralph Waldo Emerson, John Muir, Gifford Pinchot, and Aldo Leopold. Leopold, especially, laid the cornerstones of an explicit "land ethic" in his *Sand County Almanac*, published in 1949. For him, the extending the concept of community to land involves an extension of morality beyond the purely human realm: "A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise." In addition to the problem of how humans should understand "community" (should we consider the concept holistically, ecologically?) scholars have deliberated on the moral standing of other sentient beings. The subject of animal liberation today constitutes an important subfield of environmental ethics. Debate on the question of animal rights draw on diverse ethical theories, including utilitarianism, a view that weighs and seeks to balance good and bad effects, or costs and benefits, and deontology; a theory that privileges questions of right and wrong rather than good and bad.

TWO THEORETICAL POLES

Generally speaking, environmental ethics spans two theoretical poles. One situates humankind within the biosphere and puts human interests on equal footing with the interests of other animate beings. The other subordinates the elements of the biosphere—"natural resources"—to the interests of humankind. The first perspective embraces holism or "biocentrism." The second is anthropocentric in that debates about environmental ethics tend to center on how our acts upon nature may enhance or worsen human life. At each extreme, thinkers propose ways in which to value the natural environment, and the terms *environment* and *nature* themselves reflect philosophical preferences. Anthropocentric ethics gauge the instrumental value of the environment, while the recognition of nature's "intrinsic value" suits holistic viewpoints.

Efforts to theorize intrinsic value reflects some scholars' dissatisfaction with existing moral categories and principles, which they find too limited in applicability or conceptual content. Regarding the conventional understanding of morals and ethics, for example, some argue that human practices upon the earth not only affect the living conditions of present and future people but also present and future nonhuman creatures. The concept of morality therefore must extend to include other species. Moral extensionism seeks to broaden the range of moral considerability beyond humans to plants and animals, beyond individuals to entire species, or even beyond species to ecosystems.

Conceptual limitations of existing categories include the idea of nature's instrumental value. Some ethicists argue that plants, animals, soils, waters, and forests possess value that is not solely derived from their usefulness to humans (including uses such as aesthetic appreciation or spiritual inspiration). They also possess an intrinsic value, a goodness in and of themselves without regard to their effect on other entities. Intrinsic value serves as a core principle of "deep ecology," a movement begun in Scandinavia by Norwegian philosopher, Arne Naess. Naess' term, *biospheric egalitarianism,* represents one of the key guideposts for deep ecology. In a similar vein, key issues of environmental ethics have inspired often politically subversive, intellectual movements. For example, feminist analyses have been brought to bear on environmental issues and have illuminated patriarchal patterns and effects in the human domination of nature. Also focusing on the negative effects of unequal social relations and power, Marxist-inspired environmental perspectives include the subfields of social ecology, which focuses on the problem of humanity's alienation from nature, as well as the expanding field of political ecology, which focuses on the effects of capitalism on nature and humanity, and on the effects of environmental change on social structures.

Ethiopia

DURING COLONIAL TIMES as European powers steadily exploited the resources of most African countries, the Ethiopian kingdom—situated in the Horn of Africa—maintained its independence except for a brief Italian occupation during World War I. The last emperor was replaced with a socialist military junta in 1974, setting the stage for two decades of fighting marked by massive famine. By the mid–1990s, Ethiopian rebels had overthrown the government and established the Federal Democratic Republic of Ethiopia. When Eritrea won its independence in 1993, Ethiopia lost access to the Red Sea.

Agriculture has a long history in Ethiopia, and scholars have traced the origin of coffee, grain sorghum, and castor bean to the ancient kingdom. While the constant threat of drought has frequently played havoc with Ethiopian crops, the region has a long history of prosperity and profitable linkages in pre-modern global trade.

Recently, however, a dramatic collapse of civil society, governance, and the regional economy has taken place. Less than 16 percent of the population is urbanized and 80 percent of the work force is engaged in agriculture and animal husbandry, which provide 50 percent of Gross Domestic Product and 60 percent of export revenue. Coffee has traditionally been the chief crop, but low prices and political unrest has resulted in a collapse in that sector. As a result of economic downturn and military conflict, Ethiopia has become the ninth poorest country in the world, with a per capital income of only $800. In 2001, Ethiopia was approved for participation in the International Monetary Fund's (IMF) Highly Indebted Countries initiative and had its IMF debt forgiven in 2005. Half of the population of Ethiopia lives in abject poverty, and 46 percent are severely undernourished. The United Nations Development Program UNDP Human Development Reports rank Ethiopia 170 of 232 countries on overall quality of life issues.

Although landlocked, Ethiopia has 7,444 square kilometers of inland water sources. Lake Tana in Northwest Ethiopia is particularly important because the Blue Nile, considered the chief headstream of the Nile River by water volume, rises there. Ethiopia shares land borders with Djibouti, Eritrea, Kenya, Somalia, and the Sudan. Ethiopia's terrain is marked by high plateaus with a central mountain range that is divided by the geologically active Great Rift Valley. Over time, rivers have cut deep gorges into the mountains. Ethiopia is subject to both earthquakes and volcanic eruptions. Elevations range from 125 meters at the Denakil Depression to 4,620 meters at Ras Dejen. The climate of Ethiopia is tropical monsoon with great variations according to topography. Natural resources are limited to small deposits of gold, platinum, copper, potash, natural gas, and hydropower.

Ethiopia's current population of 74,700,000 is undergoing great changes as Ethiopians return from the Sudan and refugees from the Sudan, Somali, and Eritrea leave Ethiopia and return to their homelands. Ethiopia is vulnerable to a number of the diseases of poor African nations. Suffering from a 4.4 HIV/AIDS rate, 120,000 people have died, and 1.5 million are living with the disease. Less than a fourth of the population has sustained access to safe drinking water, and only 6 percent of the entire population has access to improved sanitation. Consequently, Ethiopians have a very high risk of contracting food and waterborne diseases such as bacterial and protozoal diarrhea, hepatitis A and E, and typhoid fever and the respiratory disease, meningococcal meningitis.

Ethiopians are also vulnerable to contracting rabies from contact with infected animals and schistosomiasis from contact with infected water. In some areas, there is high risk of contracting vectorborne diseases such as malaria and cutaneous leishmaniasis.

Consequently, Ethiopians experience low life expectancy (49.03 years) and growth rates (2.31 percent) and high infant mortality (93.62 deaths per 1,000 live births) and death rates (14.86 deaths per 1,000 population). On the average, Ethiopian women give birth to 5.9 children. The abysmally low literacy rates (35.1 for females and 50.3 for males) combine with low school enrollment (36 percent overall) to make it difficult for officials to disseminate information on health and environmental issues.

In addition to problems with environmental health, Ethiopia's fragile environment has been seriously damaged by massive deforestation, resulting in the loss of 80 percent of forests as trees are cut for use in construction and fencing and for fuel use. The loss of so many trees combined with the leeching tendencies of the eucalyptus trees has created severe soil erosion and desertification. In some areas, agricultural mismanagement has led to severe water shortages and soil degradation. The agricultural sector has further degraded the soil and polluted air and water through indiscriminate use of fertilizers and pesticides. Some estimates place Ethiopia's stockpile of banned pesticides at 3,000 ton. In urban areas, industrial and domestic waste has produced extensive water pollution.

In 2006, scientists at Yale University ranked Ethiopia 129 of 132 countries on environmental performance, far below the comparable income and geographic groups. The lowest score was predictably in the area of environmental health, but low scores were also received in the areas of biodiversity and habitat and the production of natural resources. During the civil wars, four national parks were taken over to be used as ranger camps. The government has since protected 16.9 percent of land area. Of 277 mammal species identified in Ethiopia, 35 are endangered, as are 16 of 262 bird species.

Since the late 1990s, the Environmental Protection Authority has worked with the Ministry of Economic Development and Cooperation to implement Ethiopia's Environmental Policy and conduct regular environmental assessment impact studies. Current policies focus on promoting sustainable development through the employment of organic agriculture and responsible land management. The Rural Development Plan of 2002, for instance, incorporates environmental rehabilitation into the development process. By drawing local communities into the process, the government has succeeded in formulating policies that ensure protection of essential ecosystems and biodiversity.

Band Aid and Live Aid

In 1984 the Irish singer Bob Geldof was so concerned about the famine in Ethiopia that he organized Band Aid, along with Midge Ure, performing the song *Do They Know It's Christmas?* as well as other British and Irish singers.

After Geldorf viewed a report by British Broadcasting Corporation journalist Michael Buerk on starving children in Ethiopia, he immediately asked Midge Ure about the possibility of putting together a recording, which took place on November 25, 1984, and was released on December 3, going straight to No. 1 in the charts for record singles in the United Kingdom. In fact, it outsold all the other recordings on the chart put together, with one million sales in the first week.

This was so successful that it was followed in 1985 by Live Aid, a multi-venue rock music concert that was held on July 13, 1985. It was attended by 72,000 people who packed the Wembley Stadium in London, and by 90,000 who were at the JFK Stadium in Philadelphia. Acts were also performed elsewhere, including some in Sydney, Australia, and the Soviet capital of Moscow.

The concert started at Wembley Stadium on 12:00 GMT (7 am Eastern time), and just under two hours later started at the JFK Stadium. Altogether the concert lasted for 16 hours. In the United States, ABC was largely responsible for the broadcast, with the BBC providing the coverage in Europe. Paul McCartney, one of the surviving members of the Beatles, also took part, as did Bob Dylan, Mick Jagger, and other famous performers.

Altogether, Live Aid raised £150 million ($283.6 million) to provide money to alleviate the worst problems faced by the Ethiopians suffering from famine.

Ethiopia participates in the following international agreements on the environment: Biodiversity, Climate Change, Desertification, Endangered Species, Hazardous Wastes, and Ozone Layer Protection. Agreements on Environmental Modification and Law of the Sea have been signed but not ratified.

Ethology

ETHOLOGY IS THE study of animal behavior. It is a branch of zoology that focuses mainly on the role of anatomy and physiology in determining behavior, rather than analysis of psychology. The field emerged toward the end of the 19th century and was greatly expanded upon in the 20th century as a scientific study drawing on the parsimonious approach to explain animal behavior, which aims to find the simplest motivation for behavior and, thus, avoid anthropomorphizing animals. The nature of the behaviors explored depends on the animal concerned, its sophistication and structure, and the motivations it has to act in particular ways. Consequently, the ethology of simple animals with a low number of cells is significantly different from the behavior of primates, which involves sophisticated and complex social relationships.

One influential ethologist was Konrad Lorenz (1903–89), an Austrian zoologist who jointly won the Nobel Prize for Physiology or Medicine in 1973. Lorenz spent many years closely observing different types of animals, especially birds, and analyzing and describing that behavior. In his work with young geese and ducks, Lorenz observed that the young birds began to imitate their parents (or substitute parents) through a process he termed imprinting. This involved both visual and audio stimuli provided by the parents, which were mimicked by the young animals. It was possible for replacement parents to be used, and the young creatures would imitate a creature of quite another species. Lorenz also noted the adaptive and evolutionary behavior of animals, specifically with reference to changing behavior to survive in difficult or shifting environments. This led him to understand that aggression in human beings is also an innate form of behavior that exists for evolutionary survival purposes, and which may be changed with behavior modification techniques.

Ideas such as this have made ethology controversial to those people who religious beliefs inform them that humans are unique and distinct from animals. One of the joint Nobel Prize winners with Lorenz was Nikolaas Tinbergen, whose work focused on developing the issues of causation, development, evolutionary history, and function of animal behaviors and the ways they change. Sir Julian Huxley developed the ideas emerging from ethology to consider the future of human evolution and the cultural factors that he believed would influence its course. Again, his work was based on the scientific method and on the careful accumulation of observations and data.

Modern ethologists have adopted more concepts from other scientific disciplines, including sociobiology, comparative psychology, and ecology. This has enabled ethologists to take a more holistic approach. One of the most notable scientists workers in this field is Richard Dawkins, whose book *The Selfish Gene* outlines the ways that genetic programming causes behavior in animals, including humans, which is aimed at the long-term survival of the species. This means that there are occasions on which individual members of a particular species might behave in a manner that is personally self-destructive, but that is necessary for the species as a whole. Dawkins argues that humans are uniquely placed among all living creatures in being able to understand this genetic prerogative and may be able to escape from it through behavior modification techniques or through technological enhancement. While this form of ethology is aimed at humans and the higher primates, the lower forms of animals still offer many lessons for ethologists, particularly with respect to adaptation to changing environments, which may offer important lessons in dealing with global climate change and environmental degradation.

Eucalyptus

THIS GENUS OF trees and shrubs, with more than 700 species, dominates the tree flora of Australia. There are also a number of native species growing wild in New Zealand, Indonesia, New Guinea, and the Philippines, with many plantations established recently in Vietnam.

The word *eucalyptus* derives from the Greek, meaning "well-covered." In Australia, the trees are generally known as gum trees, or sometimes because of the fact that the bark seems to "peel" in the summer, they are referred to as *stringybark trees*. Although they grow wild, they are also common as trees providing shade in parks, on sides of roads and in the gardens of houses, as well as being planted in forestry plantations.

The leaves of eucalyptus trees are leathery because the tree often has to survive in areas of low moisture or water shortages. They hang either obliquely or vertically with the modified petals falling off as the flower opens and the woody cup-shaped fruits, called gumnuts, open at one end to release minute seeds.

The eucalyptus tree grows quickly and can achieve great heights, with some reaching 300 or more feet, and sometimes can have a circumference of up to 25 feet. Most of these very large eucalyptus trees survive in national parks. One peculiar aspect of the eucalyptus is that they tend to only have branches toward the top of the tree, partly because of their great height and partly because they can grow close to each other; lower branches have become superfluous.

During hot periods of the summer, the eucalyptus trees shed much of their bark and many of their leaves, allowing piles of dry leaves to form fuel for bush fires, which also happen during the summer. However, once the fire has gone through an area of eucalyptus trees, burning away all the undergrowth, the trees drop seeds that find fertile soil on the forest floor. The ferocity with which the leaves burn may have been one of the contributing factors to the Oakland Hills fire in California in 1991, as many eucalyptus had been planted in the area, close to housing.

Because the eucalyptus trees have to survive in dry climates, they have very deep roots, and this also allows them to generally survive the fires well. It was for this reason that many eucalyptus trees have been planted in Vietnam in areas affected by defoliants, because the much deeper roots can often penetrate soil that has not been as badly polluted by the chemicals as the soil closer to the surface.

Throughout Australia, eucalyptus has been used as fuel, but is also used for building, especially sheds and fencing. Joseph Banks, a botanist on the 1770 voyage of Captain Cook to Australia, took back some eucalyptus saplings, and there are now some eucalyptus trees growing in places with similar climates such as California, and also Galicia in Spain, Portugal, South Africa, and parts of Brazil, Morocco, and Israel.

The proverbial "gum tree," however, remains very much a part of the Australian identity, appearing in many paintings of Australia, and also in books, including the titles of many stories, and also in folk songs and poems.

Despite the importance and success of the species in its home range, the introduction of eucalyptus for environmental remediation and afforestation around the world has led to unforeseen negative consequences. The tree can tap deep aquifers and compete with other native species for groundwater, and it can grow aggressively in some contexts and compete for light. Some caution is now exercised before the species is recommended for plantation outside of Australia. Nevertheless, the remarkable adaptive qualities of the gum tree are widely recognized for a reason.

Eugenics

THE EUGENICS MOVEMENT emerged in the late 19th century as a social philosophy advocating for the improvement of human genetic traits through social and political intervention. Although its purported goals were to benefit humanity and save society's natural resources, the theory ultimately justified racism and state-sponsored discrimination. Selective breeding, forced sterilization and birth control, and genocide are examples of the types of social control that were advocated by early eugenicists. Eugenics relies on the belief that intelligence is associated with social class and that humanity benefits by maintaining racial purity. These beliefs were widely held by academics, doctors, professionals, and politicians up until the early 20th century. Today, these views are widely discredited due to advances in the understanding of genetics and greater recognition of human rights. The legacy of eugenics continues to pervade political debates, however, concerning the causes of poverty and overpopulation and their effects on the environment.

Sir Francis Galton coined the term *eugenics* in 1883 in his book *Inheritance of Human Faculties,* which made assumptions from the recent work of Charles Darwin and the theory of natural selection. Galton assumed that human traits such as intelligence and talent were genetically determined and therefore could be improved if proper breeding selection occurred among the most-fit humans—primarily the upper classes. According to this belief, any effort to aid the poor and underprivileged is at odds with natural selection and therefore is a disservice to all of humanity. He concluded that the poor were genetically inferior, and therefore dismissed the social and political questions of why poverty exists and how it can be alleviated.

The most notorious application of state-sponsored eugenics was in Nazi Germany during Hitler's attempts to create a pure German race. Forced sterilization and genocide were grossly carried out in the name of eliminating inferior races, while economic benefits were offered for Aryan women to produce more children. The Nuremberg Trials, which indicted these actions as war crimes, raised international attention to this form of eugenics and scientific racism. The second-largest eugenics movement occurred in the United States. In 1910, the Eugenics Record Office opened with a mission to collect family pedigrees and document unfit citizens, primarily from economically and socially poor backgrounds. This was an attempt to bolster the belief that classes were hereditary traits rather than social constructs. The U.S. Immigration Act of 1924 limited entry of people considered as coming from inferior stock, meaning people from certain parts of Europe that were not as "racially pure." In addition, states had rights to sterilize any citizens that were seen as unfit, such as the disabled. During the Cold War, eugenicists suggested that any political radical was "inferior" in an attempt to discredit socialism or other forms of political and social equality.

The worldwide attention that focused on these human rights violations—especially in Nazi Germany—began to discredit eugenics ideology. Politically motivated eugenics principles manifested in other ways, however, and began to focus on the environmental effects of overpopulation and common property ownership of natural resources. In a 1968 essay, Garret Hardin, a biologist and population control advocate, put forth a thesis known as the Tragedy of the Commons that relied on a population-centered logic that has bolstered some eugenic thinking. For example, Hardin concluded that large populations (typically of the poor) make excessive claims on public resources and that society should try to curb the fertility of poorer, high population nations.

The Tragedy of the Commons thesis thus argued that the poor degrade the public stock of natural resources. It has been used by less scrupulous thinkers to further argue for specifically racial and national population control. Ultimately, the Tragedy of the Commons argument combines current concerns of environmental degradation with issues of population that make it vulnerable to the legacy of eugenics by concluding that the only way to prevent the "tragedy" of overuse is to promote preferential distribution of rights to natural resources and reproduction. Although most scholars recognize eugenics as invalid, caution must be taken to ensure that contemporary policy debates that focus on ways to conserve nature or limit population growth do not employ the racist or classist undertones endemic to previous eugenics movements.

European Union

THE EUROPEAN UNION (EU) is a union of 25 independent states joined to increase economic integration and cooperation. The EU was established by the Treaty on European Union, agreed between 12 member states on November 1, 1993. The Treaty on European Union, or Treaty of Maastricht, was ratified by Belgium, Denmark, France, Germany, Greece, Ireland, Italy, Luxembourg, the Netherlands, Portugal, Spain, and the United Kingdom (UK). In 1995 Austria, Finland, and Sweden joined the EU, and in May 2004, a further 10 countries became members: Cyprus, Czech Republic, Estonia, Hungary, Latvia, Lithuania, Malta, Poland, Slovakia, and Slovenia. The member states have set up common institutions to which they delegate some of their sovereignty so that decisions on specific matters of joint interest can be made democratically at the European level.

The EU is commonly understood as an economic and political bloc, synonymous with the project of European integration, and Europe itself, when the question of European identity is raised. The Treaty on European Union grants European citizenship to citizens of each member state. Customs and immigration agreements allow European citizens freedom to live, work, or study in any of the member states. A single European currency was introduced in 2002 when the euro replaced the national currencies of 12 EU nations. Denmark, Sweden, and the UK have not joined the single currency, and national currencies are still in use in the country members that took up membership in 2004.

The EU predecessor was the European Community (EC), an organization composed of the European Coal and Steel Community (ECSC), the European Economic Community (EEC, often referred to as the Common Market), and the European Atomic Energy Commission (Euratom). The three institutions merged and created European Community in 1965 (effective from 1967) and established headquarters in Brussels.

INSTITUTIONS AND LEGAL FRAMEWORK

The institutions of EU are: the European Commission, the European Parliament, the Council of Ministers, European Council and the Court of Justice.

The European Commission makes policy proposals and presents them to the Council of Ministers, represents the EU in economic relations with other countries or international organizations, and manages EC funds and programs. It works as the executive body of the EU.

The European Parliament is the only body of the EU whose members are directly elected by the citizens of its member states. It meets in Strasbourg, though most of its committee work is done in Brussels and the secretariat is based in Luxembourg.

The 732 seats are allotted based on the population of each member state. In 2004 Germany had the largest representation with 99 seats, the United Kingdom had 78, and Ireland had 13.

The Council of Ministers is the main legislative body of the EU. It is composed of Cabinet ministers from the member governments. Summit meetings among the top leaders of the member states are called at least once every six months by the country holding the presidency of the Council of Ministers. This meeting of heads of state and government is called the European Council. The Court of Justice is the final arbiter in legal matters or disputes among EU institutions or between EU institutions and member states.

The EU represents a desire for peace and cooperation among sovereign European states. It maintains close links with 71 countries in Africa, the Caribbean, and the Pacific region (the ACP countries), which are affiliated with the organization and receive preferential economic treatment through the Suva Convention (2000). In 2004, European leaders signed a new EU constitution in Rome. Its key points included the election of a permanent EU president to serve for a term of two-and-a-half years, replacing the current rotating presidency; the appointment of a foreign minister; a legally binding charter of rights; and the adoption of common defense policies (though each country will retain a veto). The constitution was designed to take effect by October 2006 after ratification by each member country. It had been approved by Austria, Germany, Greece, Hungary, Italy, Latvia, Lithuania, Slovakia, Slovenia, Spain, and Luxembourg; however, in national referendums held in France and the Netherlands, voters decisively rejected the constitution, casting considerable doubt on its future implementation. Despite this setback, referendums continued and ratified the treaty in July.

ENVIRONMENTAL POLICY

The EU integrates environmental policy into all policies. The main policy body is the Environment, Public Health and Food Safety Committee. The European Parliament decided to set up an environment committee in 1973. It was the 12th specialist committee, added to those set up since the European Parliament first met in 1952. The demand to deal with the consumer concerns at a European level dates back to 1967, when the first member's written question pressed the European Commission to address the issue. The committee's first directive on motor vehicle emissions was issued in 1970, and the European environmental protection law was agreed to at a conference of heads of state or government in October 1972. The environment committee took on responsibility under cooperation procedure for a series of legislative proposals on consumer protection and food safety. The responsibility includes most areas of environmental, food safety, and public health under the 1999 Amsterdam Treaty. The Environment, Public Health and Food Safety Committee has oversight and political responsibility for the activities of the European Medicines Agency (EMEA), the European Environment Agency (EEA), the European Food Safety Authority (EFSA), the Food and Veterinary Office (FVO), and the European Center for Disease Prevention and Control (ECDC). It has established a multilayered network of political links with other European institutions and international organizations in the areas of environment, public health and consumer protection.

ENVIRONMENT 2010 PLAN

The basis of EU environmental action is "Environment 2010: Our Future, Our Choice," an action program that emphasizes confronting climate change and global warming; protecting the natural habitat and wildlife; addressing environment and health issues; and preserving natural resources and managing waste. The document serves as a strategic direction to the European Commission's environmental policy till 2010. It also acknowledge the importance of: enforcing existing environmental laws; taking the environmental impact into account in all relevant EU policies (e.g., agriculture, development, energy, fisheries, industry, the internal market, transport); closely involving business and consumers in identifying solutions to environmental problems; giving people the information they need to make environmentally friendly choices; and raising awareness of the importance of using land wisely in order to preserve natural habitats and landscapes and minimize urban pollution.

The EU rules, constantly updated, provide a framework for an equal level of protection throughout the union and policy that is able to take local circumstances into account. Recognizing the value of coordinated action to solve common problems, the EU has developed comprehensive policy measures across an extensive range of environmental issues.

The EU environmental policy is based on the "polluter pays" principle. The polluter may be required to pay through the investment needed to meet higher standards or by creating a system to take back, recycle, or dispose of products after use. The payment may also be a tax on business or consumers for using an environmentally unfriendly product, such as some types of packaging.

The document "Environment 2010: Our Future, Our Choice" clarifies EU strategy to combat climate change under the Kyoto Protocol. The EU has introduced the world's first emissions trading system. EU governments issue allocations to industrial and energy businesses authorizing them to emit carbon dioxide, the main greenhouse gas, up to a certain limit. Companies who do not use all their certificates can sell the surplus to firms that exceed their emissions ceiling. Firms that exceed their limits and do not have certificates to offset this face heavy fines. Obligations under the Kyoto Protocol run to 2012, but the commission has already launched consultation on post-2012 climate change policy.

In 2002, a single European currency was introduced when the euro replaced the currencies of 12 EU nations.

When environmental threats are potential rather than proven, the commission applies the "precautionary principle:" it recommends protective measures if the risk seems real even if there is no absolute scientific certainty. "The European Environment–State and Outlook 2005" document, a five-year assessment across 31 countries, points to challenges, with climate change being just one of them. Other areas of concern include biodiversity, marine ecosystems, land and water resources, air pollution, and health. The report says Europe's average temperature rose by 0.95 of a degree C during the 20th century. This is 35 percent higher than the global average increase of 0.7 of a degree C and temperatures will continue to rise. The EU has recognized this and set a target limiting the global temperature increase to 2 degrees C above preindustrial levels.

The European Commission provides funding for the several environmental institutions. Acknowledging that sustainable environment depends on individual citizens and public participation, it financially supports the European Environmental Communication Networks (EECN), where grassroots organizations get access to information. The eco-label scheme helps citizens make environmentally sound purchases of a score of goods and services and the companies and service organizations that want to demonstrate their high environmental standards participate in independently verified eco-management and audit registration scheme (EMAS). The European Environment Agency in Copenhagen monitors the state of the environment, provides early warning of coming problems, and supplies policymakers with information on which to base their decisions. It also promotes best practices in environmental protection and technologies and helps the European Commission to disseminate the results of environmental research. The aim of the European Environment Agency is to establish a seamless environmental information system and assist the EU in its efforts to integrate environmental aspects into economic policies.

Eutrophication

EUTROPHICATION IS THE process by which a body of water, usually a lake, becomes over-enriched by nutrients. The nutrients may comprise nitrates, phosphates, and or ammonia. The result is often an increase in the photosynthesis and growth of aquatic plants, particularly algae, followed by a decrease in plant and animal diversity. In more severe cases, dissolved oxygen within lakes may decrease to the extent that fish and aquatic plants die.

Eutrophication can be a natural process that is associated with the aging of a lake. This occurs through the erosion of mineral-rich bedrock or soil into the water. However, many more causes can be attributed to human impacts and this is sometimes referred to as *cultural eutrophication*.

Cultural eutrophication stems from various sources; one of the main causes is intensive agricultural practices, where both inorganic and organic fertilizers may either drain or be leeched into a lake. Many inorganic fertilizers are high in nitrates, which is a particularly damaging cause of eutrophication. The drainage of organic manure is also a potentially damaging factor, particularly given the high level of waste that is associated with intensive farming.

One of the most prominent drivers of eutrophication in contemporary agriculture comes from intensive livestock production in confined animal feedlot operations (CAFOs). Here, large numbers of animals are kept in small facilities where wastes are sluiced to holding ponds or tanks, sometimes unlined, and frequently vulnerable to flooding. During major rain events, organic nutrients can overwhelm nearby watersheds, resulting in massive eutrophication and large-scale fish kills.

Human settlements may, either directly or indirectly, also contribute to eutrophication. This is primarily through an increase in wastewater from treated sewage. More indirectly, recreational activities such as boating can also contribute to eutrophication through increasing the turbidity of a lake and bringing polluted sediments into suspension. Industrial discharges may also lead to eutrophication.

There are severe economic and social consequences to eutrophication. Lakewater may become undrinkable by humans, which, in turn, may cause the depopulation or abandonment of settlements that have limited access to transportable water or access via a well to underground water. Cattle and other animals drinking tainted water may die, an occurrence that has been reported in both Africa and Australia. Toxic secretions from some algae may be absorbed by fish, particularly shellfish, which are consumed by humans and have caused fatal poisoning.

In addition to drinking and agriculture, many lakes are also used for recreational tourism, although the processes associated with eutrophication may lead to a decline in recreational activities. Boating, swimming, and fishing have been negatively impacted in various areas as water quality changes to a much less aesthetically pleasing appearance and or smell. Boating and fishing may be hindered by the associated excessive growth of aquatic plants. The decline in the diversity of fish species may negatively impact recreational fishing. The result of one or more of these has affected property prices and settlement patterns as tourism shifts to less-affected water sources.

One well-studied area where eutrophication has both occurred and subsequently combated is in the Norfolk Broads in eastern England. The Norfolk Broads are a system of very shallow lakes and interconnecting rivers that are surrounded by marshes and fens. The lakes themselves are artificial, created through the excavation of peat and then subsequent flooding of the ensuing depressions in the 14th and 15th centuries. Problems started to occur in the first half of the 20th century, when water weeds began growing in open water areas. Sediment cores from the area show that the increase in the phosphorous content in the Norfolk Broads correlates readily with increases in both local human populations and farming activity and resulted in the loss of invertebrate and fish diversity and a reduction in aquatic plant and bird populations. Measures to combat the increased phosphorous began in 1977. Major sewage treatment works were especially singled out so that on one river the amount of discharged phosphorous was reduced by 90 percent. However, downstream of these major sewage treatment works, levels were only reduced by 50 percent. This discrepancy is most likely because motor boats that use the river created waves that brought the phosphorous-rich sediment, which had accumulated during previous years, into suspension. Even with the phosphorous reduction, the Norfolk Broads did not convert back to the desired status before eutrophication.

The levels of land use required to get phosphorous to the required levels would not be sustainable. Therefore, other measures need to be incorporated into the process, such as the encouragement of grazing zooplankton through the partial and temporary removal of fish populations.

Everest, Mount

MOUNT EVEREST IS the highest mountain in the world, at approximately 8,848 meters (29,028 feet) above sea level. The mountain is known in the Sherpa language as *Chomolungma* or *Qomolangma*, in Nepalese as *Sagarmatha*, and in Chinese *Zhumulangma Feng* or *Shengmu Feng*. The English name was proposed in 1956 by Andrew Waugh, the British surveyor-general of India, after his predecessor George Everest, and was officially adopted a few years later. Before that it was known by the British administration as Peak XV. The summit ridge is the border between Nepal and China. The first attempt to reach the summit of Mount Everest was by a British team in 1921. The first to reach the summit were the Nepalese Sherpa Tenzing Norgay and the New Zealander Edmund Hillary on May 29, 1953. Over 2,000 people have since reached the summit of Mount Everest, and close to 200 have died in the attempt.

Members of the Sherpa ethnic group (from *shar,* which means "east," and *pa,* which means "people") inhabit the Nepalese side of the Mount Everest region, locally known as Khumbu. Until the mid–1960s, most Khumbu Sherpa households were involved in trade, some in urban centers as distant as Tibet and northern India. However, that trade was undermined by Chinese policies in Tibet during the 1960s, and later gradually supplanted by cash-based formal markets. Tourism has since become the main component of the regional economy, and an important contributor to national gross domestic product. Climbing permits cost between $10,000 and $25,000 per person, and salaries for the crew go from $3,500 for a cook to $25,000 or more for a lead guide for each trek. In the Khumbu region, three-quarters of Sherpa households have at least one individual who is involved in trekking. Tourism has also had an economic impact beyond the region, since many of the construction workers, household servants, and agricultural workers are migrants. However, money has also brought with it more wealth differentiation, since not all households are able to take advantage of the influx of tourism, and trekking has brought with it a general increase in the price of foodstuff and energy.

The main environmental problems in the region are deforestation and the increase of litter by trekkers and Sherpa. In the late 1960s, the local forest management policies were abandoned because of the nationalization of the local forests and the implementation of less strict national policies toward forest use. After the creation of the Sagarmatha National Park in 1976, which contains the southern half of Mount Everest, deforestation slowed. Sherpas are now forced to obtain all timber to build their houses, except the beams, from outside the Sagarmatha National Park.

Also, since 1979, trekking groups are no longer allowed to use wood for cooking and bonfires; they must use kerosene stoves. However, tourist lodges and the Sherpa still use fuel wood. To reduce litter, trekkers are forced to bring gas canisters and to pay a tax, which is only returned if they return the empty canisters. Litter is the other major environmental problem in the Khumbu area. Since 1979, the Sagarmatha National Park regulations require trekkers to haul out their litter, but few follow these regulations, which has resulted in the continual accumulation of rubbish along the trails to Mount Everest. From the late 1990s, the Sagarmatha Pollution Control Committee has addressed the problem by establishing long-term disposal facilities along the major trekking routes.

Sir Edmund Hillary

Edmund Hilary was born at Tuakau, south of Auckland, on the north island of New Zealand. He became interested in mountain climbing while on a school mountaineering trip when he was sixteen. During World War II, Hillary served as a navigator in the Royal New Zealand Air Force, and in 1951 was a member of the British Reconnaissance Expedition to Everest led by Eric Shipton. This led to Hillary being chosen for the 1953 Everest Expedition. The news of the climbing of Everest was announced in London on the same day as the Coronation of Queen Elizabeth II, and he was subsequently knighted in Britain and given many awards. He also appears on the New Zealand $5 note, the only living New Zealander to appear on any banknote.

After climbing Everest, Hillary continued with mountaineering, returning to the Himalayas in 1956, in 1960–61, and again in 1963–65. In 1958 he also was a member of the New Zealand section of the Commonwealth Trans-Antarctic Expedition, reaching the South Pole on January 4, 1958. In 1985 he joined astronaut Neil Armstrong landing a small ski plane on the North Pole, making Hillary the first person to stand at both poles and also climb Everest.

Hillary founded the Himalayan Trust to help the Sherpas, and has been involved in advancing education in Nepal. In 2003 he was made an honorary citizen of the country, the first foreign national to receive this honor.

In 1975 Hillary had taken part in the general election and this was seen as preventing his nomination as Governor-General. However, exactly ten years later he was appointed as New Zealand High Commissioner (Ambassador) to India, Nepal, and Bangladesh, resident in New Delhi. After four and a half years in India, he retired. Edmund Hillary has written extensively about aspects of his life. His son, Peter Hillary, is now a prominent mountaineer in his own right.

Everglades

FLORIDA'S KISSIMMEE RIVER flows south into Lake Okeechobee, an expansive and shallow body of water in the south-central area of the state. At its southern end the lake slowly gives up its water to the Everglades, a vast and flat area of grasses and animal life extending southward to the Florida Keys. During the warm months, the water from Lake Okeechobee slowly flows in what has been characterized as a "River of Grass," three feet deep at its extreme and up to 50 miles in width. In the dry season, water flow is diminished and multitudes of wildlife—birds, alligators, and large cats—seek refuge near pools of deeper water until the flow of water again begins in the spring. The Everglades is a truly unique landform, and its existence was in danger following the transformation of the land south of Lake Okeechobee to agriculture and to urbanization along the Atlantic coast.

FRAGILE ENVIRONMENT

Extensive areas of vegetables and sugar cane capture large volumes of the water that perennially flowed south to the Florida Keys. As population quickly grew along Florida's Atlantic coast, vast amounts of water were moved along canals directly from Lake Okeechobee to West Palm Beach and the nearly continuous line of cities south to the Miami metropolitan complex. Robbed of its natural flow of water, the Everglades would not have survived without widespread public concern over its possible demise; and a series of governmental actions began in the 1970s. In 1972, a series of laws were passed in the Florida legislature to protect the fragile environment of the Everglades. Among them was the Land Conservation Act, authorizing the purchase of recreation lands and areas deemed to be environmentally endangered. The Save Our Everglades program was launched in 1983, which brought together federal and state governmental agencies and the South Florida Water Management District in a large-scale effort to restore the entire region to what it was 100 years earlier. Included in the program were the Kissimmee River Basin, Lake Okeechobee, the Everglades, and adjacent areas all affected by the diversion of waters from the ecosystem—the Big Cyprus Swamp; Florida Bay, the water body separating mainland Florida and the Keys; Biscayne Bay on the Atlantic coast south of Miami; and the Ten Thousand Islands, a mass of small islands off the Florida coast on the Gulf of Mexico.

Subsequent legislation created the Local Government Comprehensive Planning and Land Development Regulation, which was aimed at attaining sustainable state growth within a fully integrated planning process: local plans were required to be linked to the plans of adjacent communities and to fit well within comprehensive plans produced for the region and the state. An important plan emerged in 1987 aimed at the cleanup of polluted waters throughout the region. The Surface Water Improvement and Management Act of that year required every Florida water management districts to implement plans to ensure sustainable water quality throughout the region. As extensive as plans were through the 1980s, they paled by comparison to the scope of projects unfolding a few years later. A major redesign of the entire regional water management system was prepared for U.S. congressional approval in July 1999. The plan proposed the expenditure of $7.8 billion over a 20-year period to guarantee the life of the Everglades, the sustainability of Florida's economic growth, and a continued supply of fresh water to the burgeoning urban concentrations along the Atlantic coast.

An initiative entitled "Eastward Ho! Revitalizing Southeast Florida's Urban Core" in 1995 focused on ways to curb urban sprawl and to rejuvenate deteriorating sections of coastal cities. This initiative acts to slow down the continued loss of both wetland and valuable agricultural land to the spread of urbanization and to ensure the viability of the inner cities through gentrification programs. Perhaps no other natural region on the continent has received the degree of attention and the commitment of resources afforded to the Everglades. While experts have argued for the actual abandonment of large portions of the Great Plains, the Everglades has attracted billions of dollars in investment to maintain the unique "River of Grass" and its surrounding agricultural areas and the mighty cities along Florida's south coasts.

Evolution

EVOLUTION IS A theory of the origin and transformation of life forms over time. Plants and animals exist on earth in an enormous abundance of forms or species. Evolution seeks to explain scientifically the origin and the development of new species from old species, as well as the beginning of life itself.

The existence of enormous numbers of older species, most of which are now extinct, is supported by the evidence of fossils. The rise of newer species is supported by a variety of evidences, including their living existence. Evolution seeks to explain with only natural evidences that these enormous numbers of species (both extant and extinct) originated eons ago in the Pre-Cambrian Era as single-celled life forms. It also seeks to show that over the last 600 million years (when life first appeared on earth), those life forms have changed. The claim that life has evolved, that is, that species have changed from one kind of species into a new species, has been the subject of enormous scientific, religious, and political controversy.

The theory of evolution is closely associated with Charles Darwin, who published *The Origin of the Species* in 1859. Darwin's publication was subsequently followed by many others. However, his earlier work, *The Voyage of the Beagle*, described the five years that he spent as a naturalist circumnavigating the world. It was a public version of the journal he kept during his journey.

Darwin's journey aboard the *H. M. S. Beagle* had been his first job after college. In *The Voyage of the Beagle,* Darwin described how he began the voyage as a person who accepted the view, like many others, that the world was of a relatively young age: between 6,000 and 10,000 years old. The theory estimating the age of the earth at 6,000 or more years had been propounded by Bishop James Usher (1581–1656), who derived his calculation by counting the generations of people in the Bible.

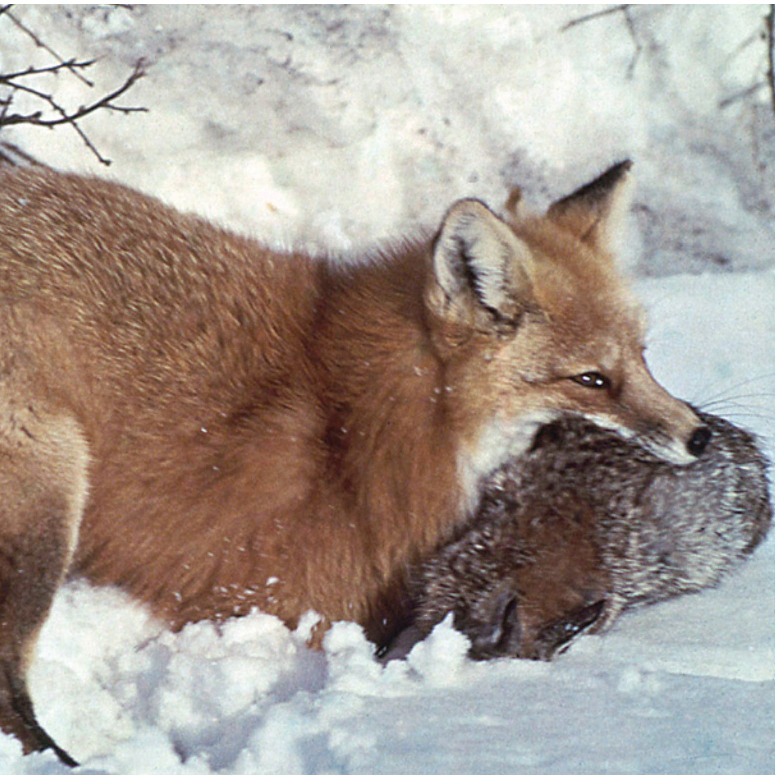
As the *Beagle* sailed south, it took Darwin on a journey that enabled him to see vast regions of the world, including much of South America in what was still pristine condition. Eventually, he was forced to extend the timeline for the age of the earth to make it longer and longer.

Darwin described how he saw thick beds of sea shells along the coast of Argentina and was unable to believe that these were the product of a single global flood. He visited older mountain ranges in South America and saw newer ranges, thus forcing him to conclude that it took enormous numbers of centuries for the natural phenomena that he was observing to have occurred.

While the crew of the Beagle was making soundings to create naval charts of the coasts of South America, Darwin as the professional naturalist explored inland in Brazil, Argentina, and Uruguay. He collected great numbers of specimens of birds, plants, animals, reptiles, and minerals. These were catalogued and shipped to England for analysis. There are warehouses today with this great collection of specimens available for comparison with the fauna and flora of the regions that Darwin first explored.

As Darwin traveled, he saw enormous geological formation and evidence of change. He was also exposed to a massive earthquake while visiting Chile. Afterward, he was able to see geological forces at work building mountains. His visit to the Galapagos Islands was crucial to the development of his theory of evolution. It led him to develop the idea that the species of plants and animals that populate the world are not fixed but change.

While preparing to publish, Darwin read Thomas Malthus's book, *Essay on the Principles of Population,* which postulates that populations grow geometrically while food supplies grow only arithmetically. The Malthusian principle is that life is a struggle for survival in the face of enormous competition for limited resources.



The natural selection in nature's struggle to survive was interpreted as the survival of the fittest.

In 1859, Darwin published his views on the mutability of the species. His theory was met with numerous responses. One reaction was ready acceptance of the idea, because the developmental philosophy (German Idealism) of G.F.W. Hegel had helped to prepare the way. Darwin's ideas influenced Karl Marx and his views on the development of world history and of human society. Using classes as his basic unit of analysis, he concluded that eventually the capitalist class would become extinct, and the proletarian class would take over the world.

In 1860, the theory of natural selection was applied to societies. The idea that people in societies struggle for survival was developed by Herbert Spencer. The natural selection in nature's struggle to survive was transformed into Social Darwinism and interpreted as the survival of the fittest. The fittest, it turned out, were the rich and successful. In America and elsewhere, Social Darwinism was used to justify numerous laws that were harmful to the poor.

A famous Supreme Court decision, centered on the evolution debate, was known as the Scopes Monkey Trial. The case pitted Clarence Darrow, a leading trial lawyer of the day, against populist champion, unsuccessful presidential candidate, and former Secretary of State William Jennings Bryan. The outcome of the trial was mixed.

The verdict went against Scopes for teaching evolution at school. However, public opinion went against Bryan and the opponents of evolution. The case was broadcast on radio and was the first electronic media event. Eventually being for or against evolution became a political litmus test, and the issue is one that is alive and well today.

Those who adhered to a strict creationist viewpoint won the battle, but lost the campaign. Other supporters have opposed evolution with the theory that the universe exhibits evidence of intelligent design, a scientific version of a teleological argument for the existence of God.

Darwin, along with his supporter Julian Huxley, engaged in a long debate over the nature of evolution. The idea was not completely new, as Darwin acknowledged in *The Origin*. At least the germ of the idea can be found in the metaphysical philosophy of the Greek philosopher-scientists, as early as five centuries before the birth of Christ. The Thales (624–548 B.C.) and Anaximande (588–24 B.C.), physical monists and members of the Miletian Schools, included developmental elements in their philosophies. The pluralist philosopher Empedocles (495–35 B.C.) saw fossils in the mountains of Sicily and suggested that life began in the sea along with others after them had espoused the idea.

The works of Aristotle were to give fodder to later opponents and supporters of the idea. From Aristotle, opponents took the idea of the fixity of the species and applied it to the Genesis account of creation. They interpreted the meaning of created "after their own kind" as an Aristotelian fixity of the species. However, during the Age of Discovery, so many new plants and animals brought new questions to help with understanding the enormous diversity of the species along with the idea of extinction.

In the 1700s, lawyer James Hutton applied the idea of uniformity to the development of species. In 1802, John Playfair published *Illustrations of Huttonian Theory of the Earth*. The idea of uniformitarianism was given further explication. Then Sir Charles Leyll published in 1832 *Principles of Geology,* which espoused inorganic evolution.

Inorganic evolution is the view that the inorganic world also has a biography that can be discovered and read. This view has been extended to the whole universe. The dominant theory today is the Big Bang Theory, which has a part of modern cosmology.

Organic evolution was espoused prior to Darwin by Jean Baptiste de Lamarck in *Philosophie Zoologique* (1809). He claimed that species adapted to life and then passed these adaptations on to their offspring. The Lamarckian theory seemed to apply nicely to the development of species. While this theory was also to heavily influence Social Darwinism, it was eventually to be refuted by the work in genetics of Gregor Mendel, a monk and a physicist. In order to help his fellow monks with their crops, he undertook crop experiments. With a mathematical eye to simple laws, he stated the conclusions of his experiments with breeding peas in a paper in 1865. Unfortunately, the paper was published in an obscure journal and was not widely read until 1900. By 1909, the term *gene* was invented to describe the hereditary particles that were described by Mendel in his paper.

EXPLAINING EVOLUTION

Darwin's theory explained that species show variation, which is a characteristic of all plants and animals. Darwin did not know that species undergo mutations, so he stressed slow incremental changes. He also observed that more individual organisms are born than there is food to support them, implying their struggle to survive in competition with each other and also against the vicissitudes of nature. In addition, the numerous variations presented by the members of different groups make it easier for some to survive and for others to fall by the wayside in the struggle for existence. The idea of the survival of the fittest therefore lies at the center of the process of natural selection. And as individuals survive, they are more easily able to pass these successful variations to their own offspring through succeeding generations.

The slight changes in the generations makes offspring better adapted to the changes in the environment that facilitate survival and propagation. Given enough generations, the changes can be significant enough that new species develop through the ongoing process of natural selection. The process of natural selection then can cause divides, so that one line develops characteristics that mark it as a different species from another line from the same parents that becomes a different species.

The intuitive appeal of Darwin's theory soon promoted its wide acceptance. It also continued to be rejected by others. One of the concerns addressed by some was that variations appear in many species that may be interesting but that have nothing significant about them. These variations neither help nor hinder the survival of the individuals with the characteristics nor enhance their survival. At the time of Darwin, this was a puzzle. Today, it is an accepted fact that these variations are simply non-adaptive differences controlled by genes.

Darwin's theory faced a different challenge after 1900, when the work of Mendel was discovered. Two corrections were made necessary by Mendel's theory of genes. The first was that to be useful for natural selection, genetic material must be inherited as a variation. Secondly, the fact of geographic or genetic isolation is necessary to prevent interbreeding.

The theory of evolution as espoused by Darwin did not include genetics; modifications were seen as evolutionary changes. However, the variations between living organisms that are caused by environmental actions are modifications, not permanent genetic changes that mutations in genes cause. For example, physical or chemical actions on an embryo may cause it to develop a congenital herniated diaphragm, a modification of the normal diaphragm. However, if the infant lived to reproduce that birth defect, it would not be transmitted to offspring. It is merely a modification of a physical feature that was probably caused by a chemical interference in the fetus' development. For each step in evolution to occur, an infant with a birth defect would have to have a line of descendants with the same defect.

Another feature of Darwin's version of the theory of evolution was that isolation was necessary for the members of a group to change so that a new species would eventually develop that could not longer breed successfully with other descendant of the original stock. Geographic isolation is the most common kind, and was what Darwin found in the Galapagos Islands as well as what primate researchers think is the source of the differences between chimpanzees and bonobos. Separated by the Congo River, they have followed different developmental tracks.

Another form of isolation is genetic isolation. If two isolated groups that were originally the same species are reunited and after breeding produce only sterile offspring, then genetic isolation has occurred. Ecological isolation can occur if the same species develops in close proximity, but in different local habits they may cease to interbreed. It may be due to such things as breeding at different times of the year as well. Darwin also assumed, erroneously, that variations were permanent.

Preadaptation, a theory of natural selection, recognizes that mutations occur randomly and does not have to be beneficial. It can be insignificant, or so harmful that it leads to a failure to survive. There are several types of mutations. Chromosomal mutations change the structure of the chromosome. Changes by addition or subtraction can produce polyploids that are larger and more robust than their parents. This feature of change has been used to produce bigger cultivated varieties of crops.

Darwin's visit to the Galapagos Islands was crucial to the development of his theory of evolution.

The theory of evolution is not without its difficulties, one of which has to do with prediction. It is virtually impossible to predict when genetic mutations or isolation events that will occur as the first step in the evolution of a new species. Another problem is that early evolutionists held to the idea that evolution was an almost deterministic straight-line path of progress, or *orthogenesis*. Investigators, especially paleontologists, have reported that the fossil record does not support this viewpoint. Rather, fossils show that orthogenesis is not normal and has probably never occurred. Species seem to flourish and then experience a massive extinction. The survivors of the few remaining species then repopulate and evolve a new set of species.

The late Stephen Jay Gould argued that the early understanding of evolution was deeply influenced by the idea of progress. This led to ideas that were rigidly deterministic and value-laden even when they appeared not to be. In fact, in the early 1900s, the idea of progress and racism were closely associated, and was assumed that progress was always from primitive to superior, which acquired a moral status: It was good, while the primitive was bad.

Another theory of evolution is *hybridization*. African bees bred with South American bees produce killer bees, a hybrid that is more aggressive and a better producer of honey than the gentler European honey bee. Whether this is a hybrid that will lead to future changes and new species of bees remains to be seen. If so, then it will support the idea that cross fertilization is what led to the development of the numerous species, at least in some cases.

At stake in the theory of evolution is the truth about the origin and development of life. Also at stake is the worth of people and of the world. If life is a mere cosmic accident, does that mean that there are only the values that the strongest impose? Or was life brought forth by divine fiat speaking the Word? If so, then humans created in the image of their creator are valuable and are worthy of respect. If not, perhaps anything goes in the survival of the fittest.

Expertise

EXPERTISE COMES FROM the Latin *experiri,* which means to experience something. An expert primarily referred to someone who acquired skills or knowledge through experience. However, the meaning gradually changed to designate a specialist in a specific area.

These specific skills or knowledge defining an expert are usually ratified by a diploma. The role of experts is to provide support for decision-makers (whether in policy, business, or court) by calling on their knowledge to elucidate the consequences of actions in complex areas; for instance, the case for technical matters such as energy policy, health, or scientific policy.

The word *expertise* appeared in western European countries in the 14th century, first designating people called in front of court in order to help judges to decide on certain matters when common knowledge was not sufficient. This practice has led to what is known today as expert witnesses.

MODERN DECISION MAKING

Modern expertise as practiced during most of the 20th century appeared during the 19th century as the ground for rationally governing emerging nation-states. Impersonal bureaucracies covering different fields of competences were built up in order to manage all the knowledge and skills required in each specific field. Experts working for these bureaucracies had to have a diploma or training recognized by the state, allowing an expansion of state authority by setting the official trainings as standard and ensuring that all expertise throughout the territory would be practiced on similar ground. It also led to closer bonds between the scientific community and civil servants in need of expertise. Modern experts supported decision-making through evaluating possible consequences of decisions through models or scenario analysis in order to reduce uncertainty. Based on this, officials would decide. In most cases, however, the way expert reports would be framed strongly influenced the decision-makers.

In the second half of the 20th century, especially after the 1970, the position of experts in decision-making procedure was more thoroughly put into question. Groups of citizen started to argue that experts were withholding some topics from democratic decision-making, giving thus the sense that one was living in a technocracy.

Environmental concerns played a very important role in questioning the use of expertise in decision-making. The growing awareness of harms caused to the environment by new technologies and scientific applications lead to a mistrust of the public toward experts because they were perceived as the ones who were implementing these technologies and applications in everyday life. This mistrust was reinforced by social critics' considerations on how technocracy was dispossessing people from their own life. Another reason for this skepticism was the growing sense of failure of decision-making system relying exclusively on expert knowledge. By the end of the 20th century, in several areas that had strongly relied on expertise, policy outcomes were very different from what had been expected. One example for this was agricultural modernization, promoted by most governments and international organizations in the postwar era in industrialized as well as developing countries, which hoped to increase food production but led to soil pollution and impoverishment. Other factors included major environmental catastrophes in policy area dominated by or relying strongly on expertise, such as nuclear power production.

Along with the growing awareness of environmental problems there have been new challenges on expertise. On the one hand, experts have to respond to critics asking for more democratization, and on the other, they must cope with the increasing complexity and uncertainty when dealing with societies and ecosystems. Rather than suppressing expertise, these new challenges have contributed to a proliferation and diffusion of expertise. Questioning of expertise often happens after scrutiny of expert reports, revealing inconsistencies or errors, and comes along with founded alternative propositions. This generalized the practice of counter-expertise, which has become a standard in policy procedures. This does not denote a tendency toward obscurantism, but rather a diffusion of scientific knowledge in broader parts of society. This corresponds to what some authors have named a social distribution of expertise, which has been spreading since the end of the 20th century.

The complexity of some matters, such as ecosystem management, results in a rise of expertise because of the number of scientific disciplines involved in such projects. For instance, the restoration of wetland habitats requires the competences of civil engineers, botanists, or hydrobiologists, each of whom might provide very different insights on a same problem, thus opening room for democratic debates.

New practices of expertise also tend to go back to the former understanding of the word and rehabilitate experience. Accordingly, a greater place is given to lay knowledge (or *indigenous knowledge*, in the context of development aid) within decision making. Lay and indigenous knowledge are specific to particular contexts or practices. These inputs are increasingly integrated in expertise, either because they are considered as a part or as a counterpart of expertise. They enable covering aspects of a problem that are not tackled by scientific disciplines, such as the affective, religious, or symbolic value of a place affected by a project.

Exploration, Age of

EXPLORATION ENTAILED DISCOVERY of unknown lands by a certain culture and recognition of environments favorable for settlement or valuable resources for trade and, ultimately, a market for elaborated products of the metropolis. It normally implied contact with distinct and distant cultures and sometimes with organized political structures so that, depending on the attitude of both parts, the contact could derive into conflict, cooperation, or assimilation. Exploration also meant confronting harsh environments, storms, famine, thirst, diseases and scurvy in the seas, cold and dry regions, and tropical forests.

Exploration has been a key component in the configuration of empires and states, preceding or accompanying political expansion. The motivations were a combination of commercial, political, religious, and scientific interests. Discovery and exploration commonly brought parallel progress in the fields of the natural sciences—biology, geology, geography, and anthropology, and determinately influenced innovation and improvement of transportation and navigation systems. Newly collected information on the territories helped to improve geographical representation on maps and portolans, which in

The most striking discovery in the age of exploration was the Spanish expedition of Christopher Columbus in 1492.

turn favored initiating new explorations and territory reclamation. Portolans were specially decisive for safe navigation; they represented directions, marine routes, principal physical ocean features, and ports. Exploration meant great expenditures, which required private and state investments for supporting presumably long and uncertain journeys, to remunerate manpower and disburse for transportation and navigation resources.

The age of exploration designates a phase in the process of European territorial expansion from the 15th to 18th centuries. During this time, Europe had a leading role in geographical exploration, which determinately contributed to connect almost the whole world and shape the geography of lands and seas.

The seven expeditions of Cheng Ho, from 1405 to 1433, supported by the expansionist strategy of the Chinese emperor Cheng-tsu, represented an isolated initiative but with a patent exploration mission. Within a tradition of contact and exchange with the Indian Ocean, Cheng Ho led a venture noted for its magnitude as for the lack of continuity.

Portugal and Spain took initiative within Europe. First, both became interested in the surrounding seas and discovered the nearer Atlantic islands of the Macaronesia (Madeira, Canaries and Azores) by mid-14th century. This area, the Atlantic Mediterranean, eventually became the base for future explorations in Africa and America.

The Portuguese developed a planned program—conceived by Prince Henry of Portugal (1398–1460)—which included a school of navigators and cartographers in Sagres, the manufacturing of navigation instruments, a ship-building industry in Faro, and adopted the caravel as a ship for oceanic sailing. They pretended to gain access to the sources of gold and slaves in the western coast of Africa and to the Indian species through an eastern route. Bartolomeu Dias rounded the Cape of Good Hope in 1497–98 benefited by the sub-equatorial Atlantic wind system. It was Vasco da Gama, in an expedition in 1498–99, who reached India and established an alternative route to that ruled by Arabs through the Red Sea and gave the Portuguese an advantage over the Spaniards. The early diffusion of Islam contributed to the commercial integration of the western Indian Ocean up to Indonesia by the 13th century. When the Portuguese navigator Francisco Serrao reached the Moluccas by 1512, a Portuguese monopoly on spices started and changed the situation. Despite this progress, the interior of Africa remained rather unknown to the rest of the world until the 18th century.

CHRISTOPHER COLUMBUS

The most striking discovery in this age was the Spanish expedition of Christopher Columbus in 1492—followed by other three voyages in 13 years—searching for an alternative western route to the Indies. The encounter with America started the colonization of a whole continent by Europeans. Columbus was supported by Isabel, the Queen of Castile, and he used the Canary Islands as a platform to ride on the northeast trades to cross west and the westerlies to return. Columbus was followed by a rapid process of exploration, colonization, and settlement. Hernán Cortés conquered the Aztec empire and explored the New Spain (Mexico) from 1518 to 1536, and established the base of the Spanish Empire in America. South America was explored through the Pacific and Atlantic Oceans. By mid-16th century most of the subcontinent was roughly explored. Francisco Pizarro (1524–33) occupied the Northern Andes; the Southern Andes were explored by Pedro de Valdivia, who reached Chile in 1541; and Diego de Rojas went through the Chaco and Tucumán in 1543. The search for El Dorado, an imaginary land of fabulous wealth, stimulated the exploration of the inland South America. Francisco de Orellana explored the Amazon between 1541–46. From the Atlantic, Pedro Álvares Cabral initiated in 1500 the Portuguese exploration and colonization of Brazil.

The rivalry between Spain and Portugal led to periodical sovereignty conflicts in Brazil and the Moluccan Islands. The Treaty of Tordesillas (1494) was an attempt gained by the Pope Alexander VI to resolve the territorial disputes between Portugal and Spain, a world repartition, which divided the Earth into two hemispheres—western for Spain and Eastern for Portugal. The different interpretation by the two parties led to the continuation of the conflict until the Treaty of Zaragoza (1529).

A southerly Atlantic passage securing Spanish access to the Pacific Ocean in the continuous search for an alternative route to the Spice Islands was found by Fernão de Magalhães (Ferdinand Magellan) in 1520. The expedition traveled through the Pacific Ocean with a northwest direction until getting to the Philipines. Magalhaes was killed in 1521, and his pilot Juan de Elcano continued west to reach Spain through the Indian Ocean and the Cape of Good Hope, completing the first circumnavigation of the earth.

The exploration of northern America was initiated by the Norse in the 10th and 11th centuries discovering Greenland, Labrador, and Newfoundland. European exploration from the north was pursued by Giovanni Cabotto (John Cabot) in 1497–98, with the backing of the port of Bristol, and although he did not succeed to settle he placed England in a position of interest in the Northwest passage to trade with Asia, a route to the Pacific. Until 1819–20 the passage through this labyrintic frozen area was not completed by Robert McClure from the west in 1850 and William Parry from the East. The exploration of the southern part of North America was carried out by Álvar Nuñez Cabeza de Vaca between 1528–36, starting from Florida,

Henry the Navigator (1394–1460)

The man whose inspiration and energy was credited with starting the Age of Exploration was Henry "The Navigator" who was the third son of King John I of Portugal. In 1415 Henry, having been trained as a soldier, took part in the capture of the city of Ceuta in Morocco in 1415—an event now seen as the first establishment by a European power of an overseas colonial empire. Henry was appointed as governor of Ceuta, but left after seeing that it was well-defended. He returned three years later when he heard that Moors from the Kingdom of Granada in Spain were sending reinforcements to Morocco to try to seize the city.

It was in 1418 that Henry started to sponsor a few small voyages—the first were very modest and involved two of his squires sailing to Madeira, which had been "discovered" by sailors from Genoa many years earlier. When Henry returned to Portugal, he became governor of the Algarve and established his own court attracting sailors, adventurers, astronomers, and cartographers. In 1420, he was appointed Grand Master of the Order of Christ, the order which had taken over from the Knights Templar in Portugal. Using funds from them and from other sources, he sponsored voyages to Africa with the dual object of trade and of converting people there to Christianity. He was to be supported in this venture by his brother Prince Pedro who came across a copy of Marco Polo's *The Travels.* The result was a number of early expeditions to the ports along the Atlantic coast of Morocco.

The first great voyage was by Gil Eames who, in 1434, rounded Cape Bojador, with subsequent voyages reaching what later became the Spanish Sahara (now southern Morocco). At the same time, other Portuguese sailed to the Azores. The capture of the Moroccan port of Tangier followed, as did further expeditions to West Africa. One voyage in 1441 brought back both gold and slaves, with another expedition four years later reaching the Senegal River. Much of Henry's life was taken up by court intrigue in Portugal and although given the title "The Navigator" by English writers, the Portuguese point out that he never went on any voyages himself.

through Texas and northern Mexico. The exploration of the interior of North America was accomplished by British and French explorers, these particularly along the Mississippi River and Labrador. After 1776, the United States began its own exploration. The Lewis and Clark expedition (1804–05) was the first U.S. overland expedition to the Pacific coast to gain knowledge of the American west.

The exploration of the Pacific Ocean started with Magalhães finding the southern passage and continued with more Spanish expeditions, but none were able to return back through the Pacific Ocean until Andres de Urdaneta was able to navigate sufficiently north to find the North Pacific Current in 1565, which took him back to New Spain. Other European countries, namely England and France, became soon interested in the area, and completed the gaps in the discoveries made by the Spaniards. Sir Francis Drake was commissioned by the Queen of England to circumnavigate the earth, which he did between 1577–80, and Louis Antoine de Bougainville completed the first French circumnavigation from 1766–69. Exploration of the north Pacific mainly took place in the last half of the 18th century, based on a dispute for the control of the fur trade between Spanish, Russians and British. Two main geographical questions were resolved, the confirmation of the peninsula character of California and the Bering Strait. The identification of a separation by sea between America and Asia by Vitus Jonassen Bering (1728) and Aleksei Chirikov (1741) made the world aware of a lack of a passage in temperate latitudes.

Terra Australis Incognita was an obscure land for a long time, and drove many expeditions. Luis de Torres crossed in 1606 the strait that separates Australia from New Guinea; but still the question of the insularity remained until Abel Tasman revealed its nature in 1642–44, particularly the southern separation, preceded by the surveys of the Dutch East India Company. James Cook, with his three voyages from 1768 until his death in 1779, completed the whole picture of the Pacific Ocean, discovered the Hawaiian Islands, reached the Antarctica and mapped New Zealand, and epitomized the end of an era where the main discoveries where completed.

Externalities

AN EXTERNALITY, ACCORDING to economic theory, is a negative or positive impact of a market transaction on people not involved in that transaction (i.e., neither the buyer nor the seller). An example of a positive externality is the construction of a beautiful building that adds to the attractiveness of a city. Environmental issues usually involve negative externalities, however, including air and water pollution, waste disposal, degradation of ecosystems, depletion of natural resources, and adverse impacts on human health. The main impact of externalities may occur at the time of the transaction, or later, such as acid mine drainage from abandoned coal mines.

Many economists regard externalities as an exception in economic activity. However, environmentalists disagree, because virtually every economic transaction involves the manipulation of natural resources, which are eventually returned to nature as waste, with an increase in entropy. The primary response by economists to this problem has been the call for "internalizing externalities." If every resource is owned by someone, then all costs of economic production will be internalized. For example, if people own clean air, then polluters must pay them for polluting the air, the costs of air pollution will be internalized by the polluters, and passed on to consumers of the products they manufacture.

Furthermore, according to Ronald Coase, it does not matter whether people have the right to a clean environment or polluters have the right to pollute and must be compensated for not polluting—as long as such rights are assigned, negotiations between polluters and the polluted will lead to an economically optimum amount of pollution. This optimum exists when further reduction of pollution would cost more than the benefits (e.g., the dollar value of better health). According to this theory, the government should assign property rights in all natural resources and could then allow the market to determine the amount of pollution. However, a critical caveat is that transaction costs (such as costs of enforcing property rights) must be minimal for this theory to apply.

In the case of nonexcludable resources such as air and water, this is rarely, if ever, the case. Furthermore, Coase's theory assumes that willingness to pay is an accurate measure of the value of resources to people. This assumption is open to challenge both because poor people cannot pay much even for a resource they value highly, and because, as David Bolliers points out, few people are willing to pay anything for something they regard as stolen property.

Nevertheless, Coase's ideas have been used in efforts to control air pollution where tradable rights to pollute are given away or auctioned off by the government, leading to more cost-effective pollution control. The government still sets the total amount of pollution to be allowed and enforces compliance, while the market determines which companies invest in pollution control and which methods they choose, allowing costs of pollution reduction to be minimized.

Peter Barnes has proposed that internalizing externalities is a good idea, but that it *is* important who owns assets such as clean air. He has proposed that such resources be made into the common property of a nation's citizens and administered by a trust that charges polluters and pays out the proceeds equally to all citizens. An institutional model is provided by a trust in the state of Alaska that distributes some of the state's oil wealth to its residents. Such a solution would internalize at least some of the externalities associated with resource depletion or degradation, with reasonably low transaction costs.

The notion of internalizing externalities can also be criticized because many if not most externalities can not be quantified in dollar terms because they affect goods that are not traded (e.g., human health and biodiversity), because the magnitude of the impacts is unknown (e.g., how many cancers a toxic chemical may cause), or because the most serious impacts may occur only in the distant future. Furthermore, many externalities involve irreversible effects, such as species extinctions, which cannot be internalized by market mechanisms, and require the involvement of collective institutions such as the state.

Extinction of Species

AS LONG AS members of a species survive and reproduce themselves, they perpetuate themselves. However, if all the members of a species die, then the species becomes extinct. Extinction is local if a species disappears from a part of its range, but still exists elsewhere. A global extinction is the total disappearance of all the members of a species so that none are left alive on the earth.

Paleontologists have discovered millions of species of plants and animals that experienced extinction in the approximately 550–600 million years that life has existed on earth. The fossil remains of living creatures show clearly that life was teeming on the earth during the Cambrian Era. Many scientists believe that life probably emerged in the chapter of the biography of the earth called the Precambrian Era. However, these were probably soft bodied-fauna and flora. In the absence of shells, skeletons, or hard body parts, they have been lost to the fossil record. What is certain is that in the Cambrian Era, life forms exploded in number. New species seemed to have developed very rapidly.

Despite the presence of life and of numerous species, it is now known from the fossil record that massive deaths of whole species also occurred. Paleontologist, biologists, and other life scientists have estimated that extinction is a fact of biological life. It is estimated that at least 99.7 percent of all the species that have ever lived on earth are now extinct. The law of life is extinction.

MASS EXTINCTIONS

There have been an estimated five mass extinctions in the history of life on earth. Fossil evidence strongly suggests that massive dying of species occurred in the Ordovician, Devonian, and Permian geological eras. The most obvious example is the disappearance of the dinosaurs. These mass extinctions have been uncovered by paleontologists as they have examined the fossil record. The pattern has been the development of a few species, then an explosion in the numbers of new species, followed by a period of little change, followed by a deep dip in the number of species. The extinction-causing event is followed by a new period of at first slow development and then an explosion in numerous new species and then another massive loss.

Mass extinctions have been best seen in the fossil record of marine animals. The sedimentary record is clearer because better fossil specimens have been deposited in marine sediment than in other kinds of sediment, and show that the Paleozoic Era of the Cambrian Period was a time of rapid expansion, which was followed by massive extinctions in the Ordovician Era. Approximately 50 percent of the animal families disappeared. This massive die-off included many trilobites.

Species continued to diversify between 500 and 350 million years ago when the Ordovician extinction was followed by a Devonian extinction. At that time, about 30 percent of the species disappeared in animal families. Again many trilobites disappeared, along with many agnathan and placoderm species of fish.

In the Permian Era, about half of all animal families vanished. These included many of the new species that had not been found in the fossil record prior to the Devonian extinction. Swept away were 95 percent of marine species, great numbers of trees, amphibians, most bryozoans and brachiopods and all trilobites. The Triassic extinction occurred about 180 million years ago. It destroyed many reptiles, animal families and many marine mollusks. It is estimated that 35 percent of the animal families disappeared.

The fifth of the natural mass extinctions was the Cretaceous extinction. It was the most destructive and to date most widely known by the public. In the Cretaceous Era, which lasted for 165 million years, the dinosaurs were the rulers of the earth. Then, not slowly or gradually—but suddenly—all of the dinosaurs and most reptiles vanished into the Cretaceous Night. Gone were Tyrannosaurs Rex and all of his prey. Along with the dinosaurs, numerous other species aslo disappeared.

AT ODDS WITH EVOLUTIONARY THEORY

The disappearance of the dinosaurs from the fossil record was disturbing to many geologists, biologists, paleontologists, and others because it violated the idea of evolutionary uniformitarianism. This philosophy of science views evolution as a process in which development of species proceeds very slowly through the workings of natural selection. New species come as each generation breeds its offspring and then allows them to find ways to adapt to nature's changes.

In the history of geology and biology, the idea of evolution as stimulated by catastrophes became repugnant very early. Eventually, the prevailing scientific orthodoxy became the evolutionary theory of uniformitarianism. The fact of a sudden disappearance suggested a catastrophe for evolution theory, which was resisted by many who felt they had much to lose. Scientific revolutions occur when the anomalies, or data that does not fit the accepted model, become so great that a new model of explanation is needed.

Evolutionists have historically proposed that species have slowly developed through a process of natural selection over vast stretches of time, and that the disappearance of many species was also a slow process involving long periods of time. However, increasing evidence has discovered that many species seem to have died out in very short periods of time. These mass extinctions seem to have often occurred *en mass* over very short periods of time.

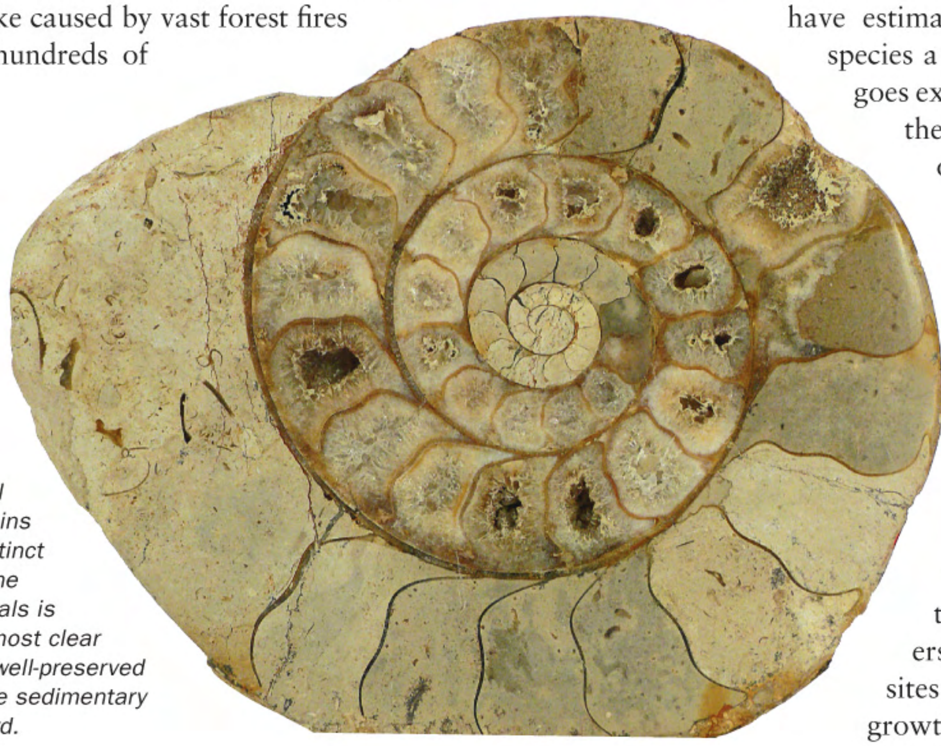
There is no doubt that a massive loss occurred at the end of the Cretaceous Period, which also ends the Mesozoic Era. In the case of the extinction of the dinosaurs, a catastrophe theory was proposed by an outsider to evolutionary sciences. Lewis Alvarez, a physicist, and his son produced The Alvarez Theory, which proposed that the massive extinction of the Cretaceous Era was the result of a catastrophe from outer space. A large asteroid or comet hitting the earth and creating a nuclear winter represented a revival of catastrophist explanations.

The Alvarez theory proposes that a massive asteroid hit in the Gulf of Mexico next to the Yucatan Peninsula with tremendous force, forming part or all of what is now the Bay of Campeche. The impact of the massive asteroid was so powerful that its explosion vaporized large quantities of rock, created massive tidal waves, and threw masses of dust into the sky. As the explosive plume of dust and smoke caused by vast forest fires for hundreds of miles rose to the stratosphere, it created a so-called nuclear winter. The dust particles blocked the light of the sun, reduced temperatures on earth drastically, stopped photosynthesis, and almost completely destroyed life on earth.

Supporting the Alvarez theory is the presence of iridium in the thin clay layer that separates the Cretaceous Period from the Tertiary Period and the beginning of the Cenozoic Era. Iridium is an element that is found concentrated in meteorites, but not very often on the surface of the earth. For it to be found in a layer marking the boundary between the Cretaceous Period and the Tertiary Period is evocative at the least. Attempts to prove that the concentration of iridium was due to leaching from water failed.

A competing theory is the volcanic plume theory. Its hypothesis is that a volcanic eruption occurred from deep within the mantle of the earth, originating somewhere between the crust and the core. The mantle plume was an enormous cloud of volcanic dust that created a nuclear winter. The theory of Gerta Keller is based on a variety of geologic and paleontologic observations, including microfossil assemblages found in core samples from deep in the earth.

In addition to major extinctions such as the dinosaurs, many species become extinct as a part of the background development of life. Scientists have estimated that on average, one species a year up to one per decade goes extinct, or has gone extinct in the past. What are the causes of species extinction? Species tend to favor certain food, habitats, nesting grounds, or behaviors. If these or other environmental supports are lost through natural actions, then extinction can occur. Species that are specialized or have a niche are most vulnerable. For example, the ivory-billed wood peckers lost their natural nesting sites and feeding sites in old-growth forests.



The fossil remains of extinct marine animals is the most clear and well-preserved of the sedimentary record.

The earth has enormous biodiversity. However, many scientists, biologists, oceanographers, zoologists, and numerous others who work in other scientific disciplines are very concerned that the earth may soon experience a catastrophic lost of great number of species. There are an estimated 10 million plant and animal species known today. Some scientists maintain that as many as 50 times that number may exist. Thus, there is a great danger is that numerous species may disappear before they are even discovered.

MASSIVE EXTINCTION LOOMING

Polls of biologists, environmentalist, naturalists, environmentalists, and other scientist report great concern that numerous species are not only threatened with extinction, but that a massive extinction is under way. Some have estimated that 20 percent of all species could disappear by 2040, with some estimtes as high as 50,000 each year. Many biologists expect species extinction rates to remain high for at least the next 100 years. Estimates are that 20 percent of the birds, reptiles, and mammals will disappear by the year 2100.

The single major cause of massive species extinction is widely believed to be human activities. These activities include the thinning of the ozone layer, global warming, hunting, farming, mining, pollution from industry, deforestation, logging, the introduction of invasive species, habitat loss, and degradation. Critics charge that the claims of massive extinction are exaggerated and alarmist overestimations derived from extrapolations based on the destruction of rainforests or other rich habitats. When asked in opinion polls, great numbers of lay people do not believe that mass extinction is likely to occur.

The relationship between extinction and human activity goes back thousands of years. At the end of the last Ice Age, about 30,000 years ago, the number of species was the greatest it has ever been in the history of the earth. Among the vast number of species were insects, vertebrates, and flowering plants that were more adapted to the environment than in previous geologic eras. About 10,000 years ago, as continental glaciation ended, there was a massive die-off of large birds and mammals. Smaller mammals were not affected.

This die-off occurred as human became more numerous. Since the rise of humans to global domination there has been an increase in the extinction of species, which began with prehistoric peoples. In the Americas *megafauna* (mammals weighing more than 100 pounds) such as wooly mammoths, camels, horses, and saber tooth tigers disappeared after humans arrived on the scene. Speculation suggests that these extinctions were caused by human hunting parties. Also of great importance is the human use of fire for clearing grasslands and forests. In fact, the slash-and-burn method of farming is still practiced by subsistence groups of people in Central and South America.

Not all human activity is immediately destructive. The vast forests of North America were logged over several centuries. However, the logging was always in local areas so that probably half of the forest was standing at one time. As a result, most species have been able to recover as farming and timber operations have changed.

Human activity can also increase the opportunities for survival of some species. Deer and doves prefer broken country where open ground provides cover and a variety of foods. Farming of cereal grains promotes opportunities for both. However, the reforestation in areas that were marginal farmlands has reduced deer and dove habitats, but increased them again for other species.

Studies have shown that the extinction of species began to increase with the European expansion to the New World, Australia, and elsewhere. Some of the cases of extinction were the direct result of the enormous settlements of new lands. Others were due to older population stocks in Europe, Asia, and Africa.

A feature of current extinction rates is that they differ from extinction rates in previous geologic eras. Usually before massive extinctions in the past, there was a great increase in the number of new species. However, the human-caused extinctions are not being matched by the development of new species. In fact, the present rate of human-caused extinctions exceeds by a large margin the natural extinctions of previous geologic eras.

Comparisons of background extinction rates and the present calamitous extinction rates is a revealing exercise. Natural extinction occurs even in the absence of human interference. So it is natural to ask the question: What is the natural extinction rate? How many species will disappear without human involvement?

Examination of the fossil record show that most of the individual species lasted from one to ten million years. With ten million species alive on earth today, the estimate of loss would be one in ten years, a natural background rate of 0.00001 percent per year. Analysis of marine animals has supported this analysis. However, the observed extinction rate among bird and mammals is about 1 percent per century. This currently observed extinction rate is 100–1000 times greater than the background rate. Some scientists have argued against the validity of these estimates of extinction, while others have used more conservative methods and have arrived at extinction rates ranging from 36–75 times those of the natural background rate.

The graver danger to *endemic* species (those found in one location and nowhere else) is the arrival of invasive species and of humans. Endemic species have a high risk of extinction in the face of invasive species. For example, island species have evolved in a limited location against a limited set of challenges. Small numbers of a species can easily be exterminated or decimated by invasive species from the mainland.

National parks and nature reserves are really habitat islands surrounded by hostile seas of unsuitable habitat. If the areas around a national park remain undeveloped, then the habitat space is widened. However, if suburban development engulfs a national park, even those kept as battlefield monuments, the species inside are squeezed into smaller habitats. Inevitably, species losses will occur.

Fragmenting forests or other wild areas into small island habitats is eventually destructive of species. Studies of extinction rates on islands have shown that when 50 percent of the habitat is destroyed, 10 percent of the island's species will also die out. However, increasing natural habitat to a state of 90 percent destroyed will result in the loss of 50 percent of the original native species.

Very vulnerable to habitat loss and species destruction are the world tropical forests. Plants and insects account for a large percentage of tropical forest species. Estimating their survival is difficult, but estimates are that at present rate of deforestation, up to 15 percent of plant species will become extinct by 2000. In Brazil, the Amazon is being cleared at a staggering rate. In some places, virtual warfare exists between those attacking the forests in order to clear land for cattle ranches and those

The American Lion

One of the animals which used to roam the North American continent, but which became extinct in about 8,000 B.C.E. was the American lion, sometimes known as the North American cave lion. It was about a quarter as big again as the modern African lion, and roamed many parts of North America. It is possible it did not have a mane.

The lion is thought to have lived in caves as did the Eurasian lion, its counterpart in many ways, and may have lined the dens with grass and leaves, as does the Siberian tiger. There have been many fossils of the American lion found in California, and as far east as Florida, and as far north as the Yukon. No remains have been found in northeast United States or eastern Canada.

Many of the animals that the American lion preyed on are still around, such as deer and the American bison, but others such as the North American horses and the young from the woolly mammoth are also extinct. It has been surmised by people who have studied cats, that because the bones of the lions in the La Brea Tar Pits, Los Angeles, California, are evenly distributed between males and females, they might have hunted alone or in pairs; African lions, in contrast, hunt in prides and have an extremely unequal distribution.

There are several theories about how the lions became extinct. The first is that their demise may have been related to the Holocene extinction, which wiped out most of the megafauna prey. Alternatively, with many lion bones found among refuse from Paleolithic Native American sites, it might have been hunting by humans that led to their extinction.

seeking to preserve the natural habitat. Estimates are that 12 percent of the birds will go extinct in the coming decades.

Extractive Reserves

EXTRACTIVE RESERVES ARE a form of conservation that originated in the Brazilian Amazon in the 1980s. Unlike national parks or other protected areas that often result in the exclusion of local populations for the benefit of national and international conservation goals, extractive reserves are attractive because they include concerns for locals that are directly impacted by natural resource management. Extractive reserves are one example of a larger shift toward community conservation that considers the needs and input of local residents about natural resources. Community conservation involves a number of initiatives, including community-based conservation, community wildlife management, collaborative management, community-based natural resource management, and integrated conservation and development programs (ICDPs).

BRAZILIAN AMAZON

The Brazilian Amazon has been a hotly contested region for centuries, with multiple actors competing to access rainforest territory and the various resources within it. Additionally, conservation and development organizations concerned with biological diversity have pressured the Brazilian government to protect the rainforest from continued modification. Estimates from satellite imagery and other sources suggest that roughly 20,000 square kilometers—or 2 million hectares—of territory is deforested each year, which results in often violent competition to gain control over the remaining land. These conflicts involve various stakeholders including cattle ranchers, logging companies, agriculturalists, indigenous Indians, and rubber tappers.

In response to these factors, a coalition of actors organized to put pressure upon the national government to protect traditional rights. The rubber tapper movement, consisting of the rural workers' union of Acre, and later the National Council of Rubber Tappers, organized from the 1970s to prevent expulsion and deforestation within the region. In the early 1970s, the Xapuri Union was founded and developed the *empate*, which was a nonviolent tactic aimed at resisting competing claims upon their territory.

In the 1980s, a coalition of rubber tappers, Amazon Indians and nongovernmental organizations (NGOs) proposed the extractive reserve conservation model. Extractive reserves were first discussed as a land use option at the meeting of the National Council of Rubber Tappers and Rural Worker's Union in 1985. The Brazilian Institute of the Environment and Renewable Natural Resources (IBAMA) defines extractive reserves as areas set aside for the sustainable use and conservation of natural resources by traditional populations. Most extractive reserves involve tracts of rainforest territory that have been set aside by the Brazilian government for protection.

The state assumes ownership and offers the land to traditional residents for use according to a sustainable management plan. Extractive reserves avoid the subdivision of land into private units that normally accompany colonization projects, favoring instead communal property based on traditional resource collection. Marine extractive reserves also exist, and are increasingly popular as a means of protecting both aquatic resources and their traditional harvesters. Extractive reserves were officially instituted as part of Brazilian environmental policy in 1990, and by 2005 there were 43 that covered an estimated 80,000 square kilometers or 8 million hectares.

Extractive reserves are a form of conservation with use, meaning that residents are permitted to live within the reserves and utilize the resources that they depend upon for their survival. Traditional methods of resource collection, particularly of natural rubber and Brazil nuts, are allowed to occur within the reserve. Extractive reserves are a promising attempt to balance the development needs of local Brazilians with conservation, however, they are far from ideal. As a number of scholars have noted, traditional extraction of rubber and Brazil nuts does not generate significant profit and leaves residents in a challenging financial position. Competing land use strategies, such as cattle ranching or logging, are more lucrative by comparison. Natural rubber has remained subsidized by the Brazilian government and the development of markets for these products has resulted in more efficient forms of production. Rubber plantations, for example, have been established in Brazil and southeast Asia as a way of generating profits from these commodities.

The wave of interest in extractive reserves in the 1980s was punctuated by the assassination of the rubber tapper movement's leader, Chico Mendes, in December 1988 by two cattle ranchers. The intention of his assassination was to deflate the movement; however, Mendes's death galvanized international attention to the land use problems and accompanying tension in the Brazilian Amazon, specifically in the state of Acre, which remains one of the primary locations of rubber tapper activism. Though his death was tragic, it served as a catalyst for extractive reserves and propelled them to new heights of interest.

Exxon Valdez

WHEN THE *Exxon Valdez* ran aground in Prince William Sound, it spilled over 11 million gallons (41.8 million liters) of crude oil, the largest single spill ever released in U.S. coastal waters. The spill occurred late in the evening of March 24, 1989. The ship left Port Valdez, Alaska, under the command of Captain Joseph Hazelwood. After leaving port, the captain left the bridge in charge of a third mate who was not licensed to operate in that particular area of Prince William Sound. The ship, having turned into the inbound shipping lanes to avoid ice from nearby glaciers, was supposed to return to the outbound lanes. For several reasons, including missing

Attempts were made to clean the oil on Prince William Sound's rocky beaches, but vestiges still remain today.

navigational markers and failing to disengage the ship's autopilot—the ship turned too late, and, just after midnight Alaska Time, the ship struck Bligh Reef, a well-known navigation hazard.

While Exxon and the Alyeska Pipeline Service Company—the firm established to build the trans-Alaska oil pipeline—sought to respond to the spill, the sheer volume of oil was simply too great to be contained. Compounding the problem was Alyeska's failure to maintain oil spill response equipment and material in the area, despite their promises to do so. This was made clear in initial media reports and was confirmed in later investigations; almost immediately after word of the spill reached the world, the news media converged on Prince William Sound, beaming pictures of oiled beaches and wildlife to a shocked and angry public. The spill served to mobilize environmental, fishing, and allied groups in efforts to enact more stringent regulation of oil tankers, and to enhance preparation for oil spills. For many of these interests, the *Exxon Valdez* spill was an event that had long been dreaded, and because of the impact of the spill on wildlife and fisheries, groups that had been suspicious of each other's motives were brought together in a common cause: anger at Exxon and a desire for some sort of compensation.

In the immediate aftermath of the spill, attempts to contain the oil were minimally successful. Exxon hired contractors who attempted to clean beaches of oil by using absorbent rags, and sometimes using superheated water, which may have done nearly as much damage as the oil itself. Even today, vestiges of the Exxon Valdez oil spill can be seen along the rocky beaches of Prince William Sound and south-central Alaska. The actual environmental effects of the *Exxon Valdez* spill are not fully known. Many otters and birds were killed by oil, and the salmon fishery was largely ruined for 1989 because of fears that any catch would be tainted by oil. The salmon have since recovered, but the very important herring fishery has never returned to pre-spill levels, although it is not clear whether the decline in herring was due to the oil spill. The oil spill had obvious socioeconomic consequences. Nearly the entire commercial fishing fleet in Cordova, the main fishing port in PWS, was idled by the spill, and while some fishers were able to lease their boats to Alyeska, many felt personal or community pressure to not take money from Exxon. Estimates of the economic impact of the spill ranged from $6 million to $43 million; longer-term impacts were higher.

The public policy impact of the spill was significant. The spill directly broke a 14-year legislative deadlock and triggered the passage of the Oil Pollution Act of 1990 (OPA 90), which provided for increasingly stringent regulation of tankers and other oil facilities. While the *Exxon Valdez* spill was spectacular and a key turning point in the history of federal oil spill policy, other large oil spills, such as the Santa Barbara oil well blowout in 1969 and the grounding of the Argo Merchant off Nantucket in 1976, also gained considerable attention, but without the same policymaking results. The importance of the *Exxon Valdez* in American politics can be attributed to the general proposition that symbols and images are very powerful in politics. The dominant symbols of the *Exxon Valdez* spill were of oiled otters and birds, the soiling of the "pristine Alaskan environment," and the image of a large, uncaring oil company, which employed a drunk tanker captain, spilled oil, and then failed to manage the cleanup. These images and stories focused on Alaska as a wild, pristine "last frontier," and made this event particularly compelling to many people and interest groups.

A particularly important outcome of the *Exxon Valdez* spill is the establishment of citizens' advisory councils under OPA 90. Two Regional Citizens' Advisory Councils (RCACs) were established, for the Cook Inlet Region and Prince William Sound. The RCACs are funded by assessments on the oil industry, and include numerous local interest groups. They have discretionary funds for research projects and have been able to promote policy change involving tanker escort and navigation, weather reporting, and air pollution controls.

Another significant outcome was the establishment of the *Exxon Valdez* Oil Spill Trustee Council, established to guide the spending of the $900 million fine assessed on Exxon for the oil spill as part of an agreement between the federal and state government and by Exxon. A $5 billion civil penalty was imposed on the *Exxon Valdez* in 1994, but the federal district court and the Ninth Circuit Court of Appeals have not yet resolved what the appellate court considers an appropriate figure; it has simply signaled to the lower court that $5 billion is too much. Civil claims continue 17 years after the spill.

Famine

IN THE PAST, famines have been defined as discrete events, where a large proportion of a population dies of starvation and disease caused by undernourishment. In recent decades, famines have been increasingly understood as more complex, open-ended processes that can have multiple outcomes. Famine can occur during events of chronic food insecurity, which represents a state of continuously inadequate access to food.

One of the worst famines in history, the Bubonic Plagues in 1345–48, claimed more than 40 million lives in Europe. While estimates are often vague, evidence suggests that at the end of the 19th century, somewhere between 30 and 60 million people died in famines in India and China. In the 20th century, more than 70 million people died in famines worldwide. Most deaths occurred in China and the Soviet Union. During the 20th century, famines shifted from Europe and Asia to sub-Saharan Africa, where large famines occurred in the Sahel and the Horn of Africa in the mid–1970s and mid–1980s.

In the 21st century, famines remain a widespread problem in the developing world. The Food and Agriculture Organization (FAO) reports that 842 million people in the world are undernourished, while the vast majority live in developing countries. Though global levels of food insecurity have slightly improved over the last decades, large regional discrepancies persist. Countries in Asia, the Pacific, Latin America, and the Caribbean have largely managed to improve their food security status; while food insecurity has been on the rise in sub-Saharan Africa, the Near East, and North Africa. The situation remains most critical in sub-Saharan Africa, where one-third of the population is chronically food insecure.

PERCEPTIONS OF FAMINE

In the past, famines have been associated with natural causes, such as drought and crop failure, and, to a limited extent, war. Up to the late 1970s, famines were considered supply side failures and resolution was attempted by increasing global food supplies through Green Revolution technologies. The recurring food crisis in parts of sub-Saharan Africa during the 1980s demonstrated the limitations of the supply-side focus, and showed that meeting demand alone was not enough. Food security became a crucial component of development as it became clear that national food security did not translate into food security at the local level, and that food security was also determined by effective demand.

In 1981, Amartya Sen argued that food insecurity was not persistent due to shortfalls in production, but due to the lack of effective demand. Sen introduced the concept of *entitlements* that referred to the condition of people lacking the means to buy or access food. In Sen's view, access was also related to structural, political, institutional, and socio-economic factors. Sen's work led to a paradigm shift that was crucial to the way that food insecurity was conceptualized.

Neither drought nor population growth are root causes of food insecurity, but exacerbate the problem, which can be caused by political, social, economic, and environmental constraints; armed conflict; uncontrolled population growth; low levels of literacy; poor access to water and health care; disease; poor or inappropriate agricultural practices; climate variability; and environmental degradation.

In the 1990s, when the understanding that food security is only one of a range of needs furthered the concept of food security, the *livelihoods* concept emerged as a result. The livelihoods approach focuses on assets and options people have to pursue alternative strategies to make a living, and has become important to provide for more effective intervention. Therefore, the risk of famine, especially when it is part of the daily struggle for survival, cannot be treated as separate from long-term development.

Chinese beggars pictured in 1909. In the 20th century, more than 70 million died in famines, many from China.

MEASURING FAMINE, VULNERABILITY

Famines are highly emotive and increasingly politicized. With humanitarian assistance turning into a large industry, and only highly publicized famines achieving global attention (such as Ethiopia, 2002; and Niger, 2005) there is increasing misuse of the term with disastrous consequences. As different levels of food insecurity demand different levels of responses, an exact definition of what constitutes a famine becomes increasingly important.

Famine vulnerability assessments are used to identify the susceptibility of populations to famines. Traditionally, vulnerability assessments aimed to predict short- and long-term changes in natural conditions (such as drought), in order to better prepare and respond. Benchmarks determine the levels of food insecurity, ranging from nutritional indicators (such as wasting, stunting, and mortality), to crop yield and food prices, to combined measurements of famine intensity and magnitude. Benchmarks are particularly controversial in situations of chronic food insecurity, where malnutrition is not a result of the lack of food, but of structural problems; these approaches tended to ignore people's own coping strategies. Now, increasing emphasis is placed on non-nutritional indicators, such as political conditions, social systems, and market indicators. More recently, emphasis has turned to monitoring livelihoods and understanding coping strategies.

Food aid is an important instrument in addressing food insecurity in terms of meeting emergency needs after disasters and addressing long-term concerns of vulnerability. However, it is highly controversial and has received wide criticism for various reasons. Food aid programs were largely driven by donor needs, mainly to dispose of North American grain surpluses. Food aid was given in a way that was hoped to advance foreign policy objectives in the Cold War era and to develop overseas markets to absorb future surpluses. Humanitarian concerns and acute needs were often secondary.

Farmers' Markets

FARMERS' MARKETS ARE public markets typically held outdoors, where farmers congregate to sell anything from fruits and vegetables to meat, dairy products, honey, baked goods, and cut flowers. Most producers who sell at these events are relatively small and often use fewer pesticides and herbicides than large-scale farmers. The popularity of these events in the United States has grown tremendously over the years. In 1970, for example, there were about 340 retail farmers' markets in the United States, and by 2005 that number had increased to almost 4,000. Similar trends are also recorded in the United Kingdom, where there were no farmers' markets in the early 1990s but almost 300 by the decade's end. Farmers' markets probably originated in Ancient Greece and Rome, where venders would locate in the center of the city to sell a variety of freshly grown commodities and other goods.

For farmers, the markets provide a market to raise and sell products. They also report satisfaction knowing that they are providing locally produced food to nearby communities. On the other hand, consumers are often motivated by food freshness. They also report that they value knowing the origin of their food. A sense of community and friendship is also developed by buying from and selling to the same people week after week.

Farmers' markets are often viewed as a counter movement to recent trends in agriculture. In 1935, the number of farms in the United States peaked at 6.8 million as the population approached almost 127 million. Today, the U.S. population is approximately 290 million, yet fewer than 1 million claim farming as their principal occupation. This changing structure of agriculture has been of significant consequence. Today, farms are bigger, more mechanized, and more reliant upon chemical inputs than ever before, which negatively impacts the environment through soil erosion and water pollution, and depletes rural communities as people leave agriculture for city employment. Because less than 1 percent of the population now lives on a farm (whereas nearly 50 percent did so 100 years ago), fewer people today have a connection to agriculture and the sources of their food.

Farmers' markets provide a market for smaller farms, and does not require large investments in inputs. Moreover, farmers' markets allow consumers to see who grew their food and to ask questions about how it was raised. Moreover, the revenue is retained by the farmer, versus a "middle man." The money is therefore likely to remain in the community.

This increase in the number of jobs in a community has led to the *economic multiplier effect* of farmers' markets, which also help benefit nearby businesses and regional farms. Some studies, for example, have reported an increase in property values in areas near the market, or the increases in tax revenues. Farmers' markets, because of their low economic barriers to entry, also allow for entrepreneurial activity.

Until recently, the majority of customers at farmers' markets tended to be from the middle class; markets were often located in, or near, middle-class neighborhoods. In 1992, Congress established the Farmers' Market Nutrition Program (FMNP) to provide fresh, locally grown fruits and vegetables to WIC (Women, Infants, and Children) participants and to expand the public awareness of farmers' markets. Forty-five different states now participate in this program, which also provides grants to state agencies. WIC coupons can be used to buy unprepared fruits, vegetables, and herbs from farmers' markets that are then submitted by the farmer for reimbursement. Such coupons resulted in over $26.9 million in revenue to farmers in 2004.

Many predict that the popularity of farmers' markets will only grow as consumers continue to turn toward alternative venues for their food, and seek a place to come together to learn about how their food was raised and who raised it. They help, in short, to place a face on food.

Farming Systems

FARMING SYSTEMS ARE the various methods of crop production to obtain human food and animal feed, fibers and other industrial products, or energy crops. Geographical differences are due to historical processes, environmental conditions, and the level of capitalization. Each farming system has specific production objectives, inputs and means of production, and a degree of intensification. Market farming is very input-intensive with pesticides, herbicides, fertilizers, and mechanization, while self-consumption farming ensures food for the household, and is very intensive in labor and land. There is also a broad range of combinations of agriculture with other production systems, such as livestock breeding, aquaculture, or forestry.

The most universal farming system is polyculture, which provides a diversity of food and maximizes labor and land occupation. Crop rotation increases soil productivity and reduces pest pressure. Less than a 25 percent of the product is marketed. The farming practices have a strong cultural component and are adapted to the local environmental conditions, producing heterogeneous landscapes.

Conversely, monoculture systems rely on a very small number of crops and an efficient use of inputs; they are very adaptable to market variations, but are vulnerable to changes in environmental conditions and produce homogeneous landscapes. Monoculture is common in large countries with a market-oriented economy.

Mixed agriculture, which combines polyculture with animal husbandry, is a widespread system because it generates various synergies: animals graze stubble and are employed for cultivating the fields, harvesting crops, transporting farm products, and manure is used as a fertilizer.

Swidden or shifting agriculture—locally known as *milpa* in Mexico or *fang* in Asia—is a remnant of very old practices, and its survival is threatened by sedentarization, the expansion of other agricultural systems, and cattle farming and forestry. It is an itinerant form of cultivation that sustains small communities in tropical rainforests in Central America, the Amazon Basin, Africa, southeast Asia and Indonesia. Small forested areas are cleared, vegetation is burned and seeds are scattered over ashes, a practice known as *slash and burn*. After the first harvest, productivity progressively decays in the following years so that, after four to five years, the community changes to another area to resume cultivation, allowing the forest to regenerate for 10–20 years.

Ley farming is practiced in areas with sufficient soil moisture or where irrigation is accessible. Cereals alternate with fodder or legumes, such as alfalfa, which biologically fixes nitrogen. Dry farming is an adaptation to climates with low precipitation—below 500 millimeters—using no irrigation; however, it entails a high risk of erosion.

Irrigated agriculture has some of the highest levels of productivity per unit area, as in the cases of Asian paddy rice fields and Mediterranean vegetable gardens. It is commonly a form of polyculture or mixed agriculture that combines with various livestock, depending on the geographical area: swine, cattle, fowl, or aquaculture. The areas of cultivation—valleys, flood plains, or slopes where land is scarce—are linked to water availability and elaborate systems of water storage. In monsoon and eastern Asia, small family plots yield two or three rice crops a year after multiple labor-intensive operations, with little mechanization and using organic fertilizer.

Multi-year tree and perennial plant cultivations are found in tropical and subtropical areas. In the Mediterranean, the most common crops are vineyard, dry farming, and irrigated fruit and olive trees. Plantation agriculture coexists with other long-established systems such as slash and burn. This commercially speculative agriculture, largely practiced in developing countries, is oriented to the market in developed countries. The most common crops are coffee, tea, sugarcane, bananas, cocoa, coconut, and tropical fruits; maize and soybeans; or industrial crops such as tobacco, cotton, or jute. Some countries are totally dependent on the products' income and vulnerable to price fluctuations. Coffee, the second world leading commodity and the livelihood of 25 million families, is a clear example. Episodic crises in prices are common as the result of systemic dysfunctions in supply or demand. It is very dependent on capital and labor, so large companies participate as farm owners, managers, or dealers. With a vertical structure, plantations have evolved to predominantly fragmented properties that sell to dealers, depending on the nature of the crop. The harvest is partially processed in situ before trading, to cut down transportation and labor costs.

EVOLUTION OF FARMING

Thomas Malthus considered population to expand separately, and typically faster, than agriculture. Ester Boserup's thesis of agricultural change, conversely, understands technology as endogenous, with population growth actually driving intensification and innovation in cultivation. As population rises, a reduction of the fallow period takes place while labor and technology increase to compensate yield decline. Population growth forces agricultural change in technology, followed by land reclamation and replacement by higher-yield crops. Clifford Geertz identified a process of "agricultural involution" in which poverty sharing may take place in conditions of population stress. Under conditions of demographic pressure, no incentives exist to introduce new technology because labor is abundant. As a result, yield per unit area increases at the same time yield per capita decreases.

Technology has led to innovative industrialized farming systems such as greenhouses, hydroponics, or genetic engineering. After the development in 1961 of a high-yielding, disease-resistant hybrid wheat, its use rapidly extended and made some developing countries self-sufficient and exporters. Recently, however, yield increases have stalled and in some cases, productivity has declined, due to exhaustion of soil and water resources and adaptation of pest species, leading to calls for a more sustainable form of modern agriculture.

Farmland Conservation

THE ISSUE OF protecting natural resources in agriculture has long been a concern for many American farmers. Farmland conservation began with the recognition that soil erosion reduced of soil fertility. For example, many of the staple crops historically grown in the United States for export—such as cotton, tobacco, and corn—have long been planted in rows to control weeds. However, this left the land bare to rainfall, precipiting soil erosion. Sloping and hilly land is also particularly susceptible to soil erosion.

A number of early agricultural reformers began proposing various soil conserving practices. Jared Eliot, Samuel Deane, and John Taylor (during the late 1600s and early 1700s) relied on personal experiences in suggesting pasture and crop rotations to increase fertility and lessen erosion by maintaining ground cover and improving soil tilth. These early conservationists were also quick to understand the advantages of the hillside plow and horizontal plowing. Called *contour farming* today, this method involves running the furrows around the hillside on a horizontal plane. Each ridge forms a mound that serves to reduce erosion.

Yet soil erosion continued to be a problem into the late 19th and early 20th centuries. W.J. McGee and N.S. Shaler wrote extensively about the problem, as did Chicago geologist T.C. Chamberlain (who spoke at the White House on the subject in 1908). It was not until the 1930s, however, when dust storms swept through the Great Plains, that the general public began to take notice of the issue of soil erosion in particular and farmland conservation more generally.

During the 20th century, greater attention has been placed on taking land out of farmland production in an attempt to not only preserve soil, but also wildlife, wetlands, and biodiversity. Some of these strategies include agricultural conservation easements, in which the landowner transfers certain rights, such as commercial development of the land, to a conservation organization or government agency. This option provides owners certain tax advantages as well as peace of mind.

The Conservation Reserve Program (CRP) came out of the Food Security Act of 1985. The U.S. Department of Agriculture provides an annual rental payment for landowners of highly erodible farmland to establish and maintain various types of perennial vegetation and agree to leave the land idle for the length of the lease. This helps to reduce soil erosion and sedimentation in streams and lakes, improve water quality, improve wildlife habitat, and enhance forest and wetland resources. Currently, there are about 35 million areas enrolled in this program.

The Conservation Reserve Program provides cash rent payments to farmers who leave highly erodable land fallow.

Developing suburban and urban areas pressure land values and tax bases, posing a threat to the continued existence of farmland. Initiatives in the form of growth control statutes, zoning, and easements at the state, county, and municipal levels have been instituted to protect farmland from conversion to residential and commercial development.

Fast Food

THE CONCEPT OF fast food developed in early 20th-century southern California in the context of economic and demographic growth, increasing dependency on cars, employment outside the home, and appreciation of novelties and convenience. Also important was the American society's admiration of technological "progress" and entrepreneurship, which began to support a centralized, homogenized chain of food processing. The model spread rapidly in the latter half of the century with the strengthening U.S. leadership in world politics, economics, and popular culture. The largest fast food corporations, such as McDonald's and Burger King, now have thousands of hamburger restaurants worldwide.

The typical location of a corporate fast food restaurant reflects its origins and logic. The search for "synergy" has led to collaboration between fast food companies, gas stations, major retail stores, shopping centers, movie theaters, and sports stadiums so that corporate burgers, fries, and pizzas now dominate the culinary options in many spaces. Irrespective of location, the knowledge of consistency saves time, provides comfort, and creates brand loyalty. Chain restaurants are identical to each another and closely resemble competitors. The restaurant space is orderly, predictable, tidy, and convenient, and is designed to maximize customer flow. An assembly-line task structure saves in training and production costs.

DIVIDED OPINIONS

For some, the global spread of fast food corporations, the supporting model of agribusiness, and their homogenizing influence on landscapes and behavior threaten cultural and ecological diversity. For others, eating corporate fast food is a social and fashion statement. Others shun corporate hamburgers but favor small, domestic, and independent fast-food businesses, such as kebab stands. Within countries, class, lifestyle, and attitudes play a role in relationships with fast food. Whereas one family considers a visit to a pizza parlor an affordable, fun evening out, another sees it as a tacky health hazard.

The more industrialized and complex the food processing chain, the more difficult it is to know what the food contains. Publicity has increased awareness of food-related health risks and fueled suspicion toward intensely processed fast foods.

Among the contested ethnical issues regarding corporate fast food are labor issues, franchiser rights, and marketing for children. Also controversial are the use of chemicals, hormones, antibiotics, fungicides, and pesticides in the mass-production of beef, poultry, and vegetables, and the treatment of production animals, ranchers, and land. Plenty of energy is required in packaging production and disposal, as well as mass production, transportation, and preparation practices. The resulting heaps of waste is usually not recycled or sorted according to biodegradability.

Disagreements between interest groups have led to lawsuits, consumer boycotts, acts of violence, and symbolic resistance in the form of a "slow food movement." One counter-trend to the homogenizing impact of corporate fast food is the growing popularity of local, regional, and ethno-culturally diverse foods that are quick to prepare and can be consumed on the move. In some countries, concerns regarding the change of cultural traditions have created market niches for local entrepreneurs, who offer traditional food items in a fast-food format. Examples include a chain of pelmeni restaurants in Riga, Latvia, and shops serving elaborate stuffed baquettes in Paris, France.

In an extremely competitive business, major corporations have relaxed uniformities in order to adapt to different cultural and legal environments. Comparisons of U.S. and European fast-food menus show how different regulations and production costs influence the price of the same meal. Regional tastes and lifestyles modify flavors; for example, to please customers in Finland, McDonald's offers a sandwich on dark, sour rye bread. Beer is also on the chain's menu in several locations outside of North America. Attempts to attract health- and image-conscious customers have met varying success. Image and target-marketing make a difference, because the nutritional value of the new product may not differ significantly from the previous options.

The visible, direct impact of the fast food industry on eating habits and on the environment are a tip of an iceberg. The corporate fast food industry continues to change patterns and practices of land use, agriculture, manufacturing, and the processing, consumption, and perceptions of food. Many of these changes proceed gradually as parts of a more comprehensive, complex transformation so that the role of one industry in the big picture is difficult to trace.

Fate and Transport of Contaminants

CONTAMINANTS ARE SUBSTANCES that carry the threat of contaminating the environment, and include nuclear waste, industrial by-products, and organic manure. The contamination threat may be short-term or long-term, and dangerous or nondangerous, depending on the nature of the substance and how it interacts with its surroundings. Nuclear waste, for example, is toxic to humans, remains dangerous for up to thousands of years, and its irradiated particles can pass through nearly all other substances. Organic remains, on the other hand, may be of only passing danger, and quickly degrade into inert products. The ways in which contaminants need to be transported from creation to dafe storage also vary considerably, with the resulting costs representing a disincentive for organizations to ensure safe transportation and storage. Governments often intervene to police a regulatory regime that requires contaminant-providers to bear the cost of safely transporting and storing waste.

Fate and transport also refers to the movement of chemical contaminants through groundwater, soil, gas, and the atmosphere. Research examines how fast contaminants can migrate in certain media and on the synergistic effects of chemicals within ecosystems; assesses risks to both humans and nonhumans from potential exposure; and informs management decisions for the movement and deposition of hazardous materials.

One notable example of the problems caused by inappropriate transportation of contaminants has been the continuous pollution of New York's Hudson River. In 2001, courts decided that GE Corp. was guilty of dumping polychlorinated biphenyls into the river, and that it should be responsible for dredging a 40-mile stretch of the river to ensure that the ongoing danger be mitigated, including the threat of causing cancers. This and related cases have also raised the issue of the corporate prosecution for negligence leading to seriously negative health impacts.

The detection of contaminants in the environment, often in the face of opposition from polluters, has become an important part of the task of environmental workers. This vigilance, combined with strong and enforceable laws, has helped to reclaim some areas from conditions that are dangerous to living beings. Nevertheless, the rise of newly industrializing countries, especially China, has raised fears that contamination will increase or has already significantly increased in states with severe government censorship of information. Since reporting is hindered, timely intervention to reduce problems is less likely.

Fecal Coliform Bacteria

FECAL COLIFORM BACTERIA are the naturally occurring bacteria found in the digestive tracts of most animals. These beneficial organisms aid in digestion, converting certain indigestible fibers and compounds into nutritious compounds. So long as they remain within the alimentary canal, these bacteria are harmless to their host. Fecal coliform bacteria are shed along with excrement, and can colonize other individuals or even species different than their original host. Infections from a foreign body's fecal coliform bacteria are typically nonfatal, although severe symptoms can lead to death. Two to four days following infection from fecal coliform bacteria, symptoms such as diarrhea, stomach cramps, headaches, and fever arise. Antibiotics can successfully treat fecal coliform infections, although there is some concern that antibiotic-resistant strains of fecal coliform bacteria are developing.

Outside of their preferred host environment, fecal coliform bacteria can survive for weeks; *E. coli*, one of the most common human fecal coliform bacteria, can survive in drinking water from between four to 12 weeks, and can lead to widespread human illness. Some fecal coliform bacteria can also become airborne, and can be inhaled or settle onto surfaces, later to be transferred onto new hosts and ingested or introduced onto mucous membranes.

DANGER IN THE WATER

One of the most damaging environmental effects of fecal coliform bacteria stems from contamination of aquatic systems, which can either be from the direct introduction of human or animal waste into waterways, or from wastewater treatment plants, septic systems, or agricultural runoff. Pet waste also contributes heavily to the contamination of freshwater systems by fecal coliform bacteria; some estimates suggest that nonpoint source, rather than point sources for fecal coliform pollution, represent a larger share of water contamination. Contamination of estuaries and marine systems with fecal coliform bacteria can halt shellfish harvesting and even lead to beach closures. Introduction in waterways and other aquatic systems can result in competition for resources with native bacteria, with effects noticeable in higher trophic levels. Additionally, the presence of fecal coliform bacteria typically indicates the incidence of more dangerous pathogens or parasites.

In aquatic environments, the source of the bacteria typically represents a rich source of nutrients, which, when decomposed, leads to lower oxygen levels and overabundance of aquatic plants and phytoplankton. This process, called *eutrophication*, in turn causes stress to aquatic organisms, and can even lead to fish kills. Furthermore, the higher turbidity of contaminated water can result in lower productivity of benthic aquatic plants, and settling particulate matter can smother filter-feeding organisms, such as bivalves.

Most of the documented cases of fecal coliform infection in humans has been a result of improperly handled, packaged, and prepared foods, typically ground beef. Fecal coliform bacteria are introduced through inadequate sanitary precautions at slaughterhouses, improper sanitation when handling food, and possibly even the spreading of animal manures onto fields. Lack of sanitary toilet facilities for agricultural workers also presents an additional source of fecal coliform contamination of food sources.

Federal Emergency Management Agency (FEMA)

PRESIDENT JIMMY CARTER created FEMA in Reorganization Plan Three of 1979, with the intent to make FEMA the single federal response agency for disasters, thus reducing any confusing, overlapping, and duplicative efforts from other agencies. This urgency was underscored by the March 1979 Three Mile Island nuclear power plant accident, which revealed shortcomings in federal, state, and local planning for emergencies. The executive order forming FEMA was signed days after the Three Mile Island incident.

FEMA thus took on the Defense Department's civil preparedness programs; Housing and Urban Development's Flood Insurance program; fire prevention programs and community preparedness programs from the Department of Commerce; and dam safety, earthquake, and terrorism programs from the Executive Office of the President. The first director of FEMA, John Macy, sought to knit together these disparate functions through a program called the Integrated Emergency Management System (IEMS) that would serve a range of emergencies, from natural disasters to nuclear attack.

During the Reagan administration, FEMA's focus tilted heavily in favor of civil defense under Louis Giuffrida and, later, General Julius Becton. The Loma Prieta earthquake and Hurricane Hugo shattered complacency about natural hazards in 1989. FEMA's response to these events was viewed as inept, and it became clear that FEMA's top management were mostly political appointees, not emergency managers, all of which set the agency up to fail.

REVOLUTION AT FEMA

In 1993, President Bill Clinton appointed his former Arkansas emergency director, James Lee Witt, to direct FEMA. Some have called the 1993–2001 period the "Witt Revolution," because Witt—the first FEMA director with emergency management experience—streamlined agency practices and knit disparate agency factions into a single agency with a mission oriented toward natural disasters. This management reform paid dividends during FEMA's generally successful response to the 1993 Midwest floods and to the 1994 Northridge earthquake in southern California. The 1993 flood in particular induced the agency to create the Mitigation Directorate; for the first time, substantial FEMA resources and attention would be paid to taking steps to mitigate the effects of disaster before it struck, rather than relying primarily on relief and recovery to ease the damage and suffering caused by disasters.

FEMA, however, stumbled somewhat in the mid 1990s when it failed to claim the primary federal role for managing national responses to terrorism attacks, a problem that rose on the agenda with the 1993 World Trade Center and 1995 Oklahoma City bombings. FEMA's role in terrorism was therefore never clear, even before the September 11, 2001 terrorist attacks. In 2001, President George W. Bush returned to the prior practice of political appointees to lead FEMA. Under his first FEMA director, Joe Allbaugh, FEMA discontinued a popular disaster mitigation program, Project Impact. To his credit, Allbaugh did recognize that FEMA would have a role in terrorism, and he reconstituted the new Office of National Preparedness (ONP) with a focus on terrorism.

The September 11, 2001 terrorist attacks changed FEMA and national emergency systems, although it is questionable that FEMA needed wholesale change. FEMA was made a part of the new Department of Homeland Security in 2003. Many of its functions were diffused throughout DHS, and most of its leadership had little or no emergency management experience.

The agency therefore appeared inept when, in September 2005, Hurricane Katrina revealed that FEMA and other participants were unable to effectively implement the new National Response Plan and the National Incident Management System created after September 11. By 2005, confidence in the agency's competence was severely eroded. President Bush's replacement of director Michael Brown with R. David Paulison, a fire and rescue specialist, suggests a shift toward emergency management experience. Some experts believe, however, that FEMA should be removed from DHS.

Federal Insecticide, Fungicide, and Rodenticide Act

THE FEDERAL INSECTICIDE, Fungicide, and Rodenticide Act (FIFRA) of 1972 was enacted in the United States to regulate the manufacture and use of pesticides, and represented a significant reworking of the existing law, which had been introduced in 1947. The most significant amendment was the Food Quality Protection Act of 1996, which requires potential and existing manufacturers to submit applications for licenses to produce goods for commercial use. The information required by the Environmental Protection Agency (EPA) includes the contents of any formulation, which is kept confidential, the tests that have been used to determine the safety of the product, and directions for use.

Federal law generally preempts state laws in connection with FIFRA to prevent unscrupulous manufacturers from taking advantage of loopholes or weaknesses in state regulations. Second, the use of pesticides affects people, livestock, and crops across state borders. However, it is argued that a decentralized structure is more appropriate for a market in which numerous products are introduced and many specific local conditions exist, which may require special provisions. Some have argued that the preemption of state regulations have unfairly benefited pesticide manufacturers, who gain protection from tort liability for problems or health issues resulting from labeling or usage of their products. Preemption was also involved in the attempt to use FIFRA to obtain recompense by veterans of the American War in Vietnam, whose health had been damaged by the military's use of Agent Orange. Foreign nationals are not empowered to use this legislation against American corporations.

The stakes are high in such legal debates because of the money involved in intensive agriculture, which often requires extensive use of pesticides. As scientists continue to provide new types of pesticides and methods of applying them, constant reevaluation of the regulations is required, even if the basic principles do not change. Some argue, however, that extensive safety tests and regulations unnecessarily restricts competition because only a few companies have sufficient financial resources to follow the process. Non-American companies wishing to import also dislike labeling and testing regulations that are deemed unnecessary in their home countries. The largest fine imposed by the EPA concerning FIFRA regulations was in 1998, when the Monsanto corporation was fined $225,000 for persistent mislabeling of products.

Federal Land Policy and Management Act (FLPMA)

AFTER THE BUREAU of Land Management (BLM) began formal planning for public lands under its charge in 1969, the Federal Land Policy and Management Act (FLPMA) of 1976 was passed due to congressional dissatisfaction with BLM land

and resource management. According to the BLM, "FLPMA is called the BLM Organic Act because it consolidated and articulated BLM's management responsibilities." The FLPMA is a BLM-specific law. The statute reduces agency flexibility, increases agency accountability to itself and Congress, and dictates an "intensive, but imprecise planning process" that requires "vast bureaucratic resources and produce[s] mountains of paperwork."

Under FLPMA, decisionmakers at the BLM are required to consider the interests of all public land users before they determine how lands will be managed. The statute was ultimately designed to address natural scarcity of both renewable and nonrenewable resources (grazing, timber, minerals, recreation, wilderness, fish and wildlife, watershed, and so on).

Section 202 of FLPMA broadly guides land use planning and does not detail the steps by which BLM should generate and revise land use plans. Some of the more important management requirements of FLPMA for the BLM to observe principles of multiple use and sustained yield; use a systematic interdisciplinary approach (physical, biological, economic, cultural); give priority to the designation of areas of critical environmental concern; consider the relative scarcity of the values and alternatives for realizing those values; weigh long- versus short-term benefits; comply with pollution control laws; and coordinate with other federal, state, tribal, and local government entities.

MANAGEMENT OF BLM LANDS

As the largest land management agency in the United States, the BLM is responsible for 175 million acres (70 million hectares) in the lower 48 states. The FLPMA is in essence a guiding statute for the management of those lands. The FLPMA also mandated that the agency perform a roadless area review for the selection of Wilderness Study Areas, study the areas, "and make Wilderness recommendations to Congress by 1991." After an incomplete review of only 25 million acres (10 million hectares), the BLM proposed 328 wilderness units totaling 9.7 million acres.

The FLPMA also requires that the BLM highlight the designation and protection of areas of critical environmental concern (ACEC). An ACEC includes lands where special management attention is required to prevent irreparable damage to important scenic values, fish and wildlife resources or other natural systems or processes. By the year 2000, the BLM had designated about 13 million acres of ACECs, with 5.9 million acres located in Alaska. Many of these ACECs are sensitive riparian zones around rivers or are important wildlife areas like the Big Morongo Canyon in California, which is a wildlife corridor, lambing area, and watering area for desert bighorn sheep.

The FLPMA's guidance of BLM's facilitation and management of public-lands livestock grazing is a very contentious issue between the BLM and conservationists, as many environmental advocates believe the BLM is understaffed and underfunded, leading to detrimental harm to the range resource. The FLPMA requires the agency to set grazing fees, analyze the value of grazing, grant 10-year grazing permits, and establish grazing advisory boards.

One of the more prominent outcomes of FLPMA was the creation of the California Desert Conservation Area (CDCA). The CDCA is a 25-million-acre southeastern California desert that has been heavily impacted by motorized recreation, mining, livestock grazing, utility corridors, illegal roads, and invasive species. The FLPMA recognized the CDCA as a highly vulnerable desert environment with unique ecosystems that are not only rare, but "extremely fragile, easily scarred, and slowly healed."

The BLM's management of this vast desert area has been marked by difficulties and public controversies since its inception. Multiple stakeholders interested in both the resource use and/or preservation of the CDCA have often clashed with each other and the BLM in the federal courts. In one such case in 2000, pressure and lawsuits from the Center for Biological Diversity resulted in the removal or restriction of cows and sheep on habitat for the desert tortoise, southwestern willow flycatcher, and Least Bell's vireo. These settlements also closed 550,000 acres of the CDCA to off-road vehicles to protect the Coachella Valley fringe-toed lizard, Pierson's milk-vetch, desert tortoise, and other imperiled species. Included were 49,310 acres of the Algodones Dunes.

Feedbacks

FEEDBACKS ARE PROCESSES within a system in which some proportion of the output is passed, or "fed back," as input to the initial conditions. Positive feedbacks enhance or reinforce initial perturbations of a system, resulting in the amplification of the output process, whereby small changes in inputs can cause large changes in outputs, possibly resulting in system instability. Negative feedbacks reduce or weaken initial agitations of a system, resulting in the reduction of the output; whereby small changes in inputs can cause the system to produce smaller changes in the outputs, possibly resulting in a steady state, or homeostasis, condition. A feedback loop is a process in which an output is returned to the system as input, often but not always originating from outside the system. Feedback loops are convenient places in the system to insert control functions to counteract, or balance, unwanted system reactions.

Feedback mechanisms are often seen in complex or nonlinear systems in which the dynamic behavior is influenced through negative feedbacks; whereby systems move to disequilibrium conditions through positive feedbacks. Organisms, including humans, respond to system changes or stimuli such as a change in the environment. Dynamic equilibrium results from the ability of organisms, or people, to detect change and to respond to the stimuli in an attempt to maintain steady state conditions or to reduce the amplitude of system perturbations.

Deforestation increases with farming, cattle pasturing, in-migration, subdivision of land, and commercial roads.

COMPLEXITY THEORY

Complexity theory holds that systems cannot be suitably understood without a focus on feedbacks and consequent nonlinearity. A complexity theory analysis of land use change aims at understanding feedbacks and changes in conditions through nonlinearities, and in relation to a dynamic and coupled human–environment system. For instance, social inequalities are seen at a regional scale as an outcome of household behavior relative to land use/land cover patterns and strategies.

In the Ecuadorian Amazon frontier, multiple stakeholders interact through endogenous and exogenous processes to create a dynamic land use/land cover system that is space- and time-dependent, where feedbacks between human activities, land use change, and ecological dynamics produce nonlinearity. The Ecuadorian Amazon is a direct product of past views, ideas, and actions at different degrees of social and landscape organization. A change in the land use/land cover system has occurred as a consequence of the influx of migrant farm families to the Ecuadorian Amazon frontier that resulted in families clearing forests to establish farms. As families acquired knowledge and skills to produce agricultural products—and as household demographics changed over time—additional land was deforested as farmers transitioned from subsistence agriculture to cash crops, as well as increased the area of land in pasture for cattle.

Further, as people continued to migrate into the region, available land was subdivided through land sales and kinship ties, resulting in land fragmentation, which in turn has feedbacks to land use/land cover. Meanwhile, substantial migration to local towns has increased markets for the farmers' products as well as providing growing opportunities for off-farm employment, both of which have feedbacks to farm land use. The expansion of oil production in the region has contributed to further growth of towns and the enhancement of the regional infrastructure.

Thus, land use/land cover patterns of colonists evolved and changed as a result of growing market linkages and contacts, increased oil production, and changing socio-economic and political dynamics of key stakeholder groups that reacted to a changing environment. These changing interactions and feedbacks are caused, for instance, by soil fertility declines on active farms, increased roads and access, and more markets for commodities.

Positive feedbacks exacerbate initial land use/land cover conditions through deforestation, agricultural extensification, and urbanization. Negative feedbacks are being changed through increased access to the region, which was initiated by petroleum companies building roads for pipelines and oil extraction. In the Ecuadorian Amazon frontier, the landscape continues to change in interesting and surprising ways, becoming more accessible and fragmented, thereby reacting to a feedback process involving in-migration and changes in land use/land cover.

Feminist Political Ecology

FEMINIST POLITICAL ECOLOGY represents the most recent movement to advocate for the equality of women in political, social, and economic settings, and for a substantial change in the recognition of women's role in society. Historical examples in this ongoing struggle point to Aristophanes' study of the strong feminist assertiveness in *Lysistrata*, the 19th century writings of Charlotte Brontë, and early feminist advocates like Emmeline Pankhurst, who worked to undo the political aspects of female subjugation and to bring about female suffrage.

A more activist and militant thrust to the struggle ensued with feminist movement, whose champions stated unequivocally that the social system was replete with blatant sexism. Books by Germaine Greer (*The Female Eunuch*) and Kate Millett (*Sexual Politics*) in the 1970s articulated the existence of social structures that guaranteed the oppression of women in psychological and biological ways.

Feminist political ecology uses gender as the codifying variable in its struggle for sustainable socioeconomic and political development in the quickly changing era of globalization. The field takes positions and concepts from a number of different feminist movements that have evolved over the past several decades. Among these are ecofeminism, feminist associations with environmentalism, feminist aspects of post-structuralism, and socialist feminism. Studies conducted in feminist political ecology avoid the context in which women are separate from the topical investigation underway. That is, in studies focusing on rural development, inputs of information from both women and men are solicited.

Both are considered as agents of change in efforts to maintain their locales and in making decisions about resource use, health care systems, and the sustainability of the place. Feminist political ecology considers that gender differences derive from differences in cultural and racial views of women and not from purely biological differences. This view especially distinguishes feminist political ecology from ecofeminism, which, in the jargon of the field, tends to “essentialize” and consequently “decontextualize” women.

As related in the edited book *Feminist Political Ecology* feminist political ecology uses an activist approach in striving to create and maintain healthy environments, manage resources, ensure just decisions in property disputes, and in working toward the elimination of environmental degradation. In all of these efforts, a form of “gender knowledge” prevails. In one example, a community objected to the location of a proposed sewage treatment plant in close proximity to a children’s playground. The decision to relocate the plant was based on the insistence primarily of women in the community that the sewage plant would be potentially injurious to the human health.

Another example where feminist political ecology brought about needed change centers on the conflict between colonial rules in Kenya and the alienation of women from taking full part in the economic system. The application of gender knowledge to this situation has brought about changes in this situation and a departure from the earlier system of male dominance in, and feminine exclusion from, the economic system. A further example from a Himalayan agriculture community illustrates how land ownership rights favor males and place women in a dependency role. As a consequence of this gender inequity women became marginalized and excluded from agricultural decision-making, which adversely affected the stability of the agricultural system.

In their attempts to derive theory to bolster the position of feminist political ecology, its advocates point to a number of generalizations to support the effort. These include the fact of interconnectedness at all levels of the global ecosystem and the need for equitable gender power sharing in decision-making about the environment. Neither male-dominated nor female-dominated approaches are appropriate. Implicit in the feminist ecological conceptual base is the belief that technology should not be used to dominate nature.

In addition, there is the recognition that particular cultural biases can skew access to knowledge and management of the environment. Decisions about development tend toward the direction of one gender or the other, and nearly always toward the male. The ultimate theoretical position defining feminist political ecology will certainly reflect that gender knowledge is integral to any set of power relationships that exist in political, social, and economic contexts from local to global.

Feng Shui

FENG SHUI (FUNG seui in Cantonese) is a technique of managing the landscape to maximize favorable circumstances and minimize misfortunes. Although it is uniquely Chinese, it has spread to other east Asian countries, and, very recently, to the rest of the world.

Feng Shui defies categorization. It has been erroneously called magic, science, religion, mysticism, and charlatanry, or "the art or pseudo-science of manipulating the occult forces that are believed to run through a landscape, site, house, or even room." It is also called "geomancy," but is does not resemble the ancient Greek and Near Eastern magical art of geomancy.

In Imperial China, Feng Shui built on the experience of billions of Chinese peasants. The roots of Feng Shui are pragmatic perceptions. These include the following guidelines: not building houses or villages in a floodplain or on a steep unstable slope; not building on good agricultural land; growing trees above and around villages for protection from wind and erosion and for provision of shade, fuel, and wood; having a reliable water supply; keeping a village difficult to reach, with a winding path to discourages invaders; encircling a village with hills like a womb, with the highest hills on the windward side, to block winds and storms; no undercutting of a steep slope; facing houses south, toward the warmth and light of the sun; and situating graves relatively far from settlements and with pleasant views, since traditional Chinese believe that parts of the spirits of the dead remain with the bodies.

A further set of rules, again based on common sense, applies within the home. An occupied room should not face the front door; the kitchen should be near the main door, bedrooms farther away; and furniture should not block lines of flow. Rules for room placement and arrangement can get very complicated, but in good Feng Shui practice the arrangements are grounded in practicality.

The "occult forces" concept results from perceptions of early Chinese thought, which seems to have been broadly animist. Every rock, hill, tree, and watercourse had its spirit, often a dragon, magical tiger, or other supernatural animal. These spirits had their own will and intentionality.

These beliefs persist today and do influence Feng Shui practice. Evil spirits travel in straight lines, for instance, hence the be winding paths to the house and blocking direct air routes with trees and religious structures. Failing that, one can set up a pottery model of a fortune-bringing animal on the roof; dragons and Buddhist "lions" are popular. A house must have symmetrical double doors, partly to provide a place to attach the spiritual door guardians. Painted images of Tang Dynasty generals have the power to repel ghostly evil, as the original generals repelled living enemies.

NATURAL AND SUPERNATURAL

Wholly impersonal and disembodied forces have also become basic to the system—perhaps in more recent millennia. These forces are "natural," in that they are fundamental to nature and can be studied and felt without recourse to ritual, worship, or prayer. They are, however, "supernatural" from the point of view of contemporary physics, because they do not exist in any verifiable or measurable way. These forces seemed similar to breath or wind, and thus acquired the name *qi*, "breath" or "vapor." Qi is usually a neutral energy or subtle breath running through and animating the world, but good and evil influences are also called qi, though they are different conceptually (at least in rural Hong Kong). Earthquakes, common in northern and western China, and their well-known effects such as mountain-building and valley creation, are credited to qi flowing through the landscape. The Chinese theory of qi is not totally incommensurable with modern theories of plate tectonics; energy does indeed flow through the earth and causes dramatic effects at certain points. While the ancient Chinese could not construct modern plate tectonic theory, they could at least make a start in the right direction through observation and inference.

Inference, however, ran on far beyond observation. People assumed that good luck, bad luck, wealth, health, and other benefits could flow along the lines of qi or be carried by it. Recent tomb finds show that something like Feng Shui was known 2,000 years ago. The logic was: We know that these matters are not under our control, but they must have some pattern and rationale.

Building on all this, Feng Shui experts developed many techniques to determine the lines of qi, the bright and dark forces, and the other unseen influences bearing on a site. They also sought to understand the ways of the dragons, tigers, and other power beings that live in hills and watercourses.

Thus, Feng Shui seems to have begun as grounded in folk-scientific observations, but it was soon mystified with a steadily increasing panoply of religious and magical practices. The result was a blend of science, religion, and magic. However, the Chinese do not see it as a blend, nor was it one historically. To them, it is a single institution and a single knowledge system. The categories of magic, science, and religion are modern concepts that simply do not apply to classical Chinese thought about such matters.

The label "pseudo-science" presupposes some real science to serve as the reference point. Feng Shui in premodern times, however, was not attempting to be a "science." The tests that would have disproved it had not been invented, and the definition of "science" that would have excluded it had not been elaborated. This sort of folk Feng Shui survives in China, Korea, and neighboring countries to this day. However, the Feng Shui practiced in the Western world today can reasonably be called a pseudo-science, with experts reaping great profits by purporting to use natural forces to bring about certain results.

A system that was once a whole peoples' best guess at how the natural world worked is now an anachronism, along with alchemy, stable continents, Freudian personality theory, humoral medicine, and countless other ideas that were once the best that people could do to make sense of the available evidence.

On the other hand, we can learn from the sound observations on which the system was originally based. In the floods of June 1966, all the traditional farming villages in the western New Territories were above the water, while all the newer farms were flooded. The new farms, built in an age when Feng Shui was considered "mere superstition," had been built in floodplains. More recently, China and Korea have urbanized vast tracts of farmland, and now have to import food on a large scale. Feng Shui taught earlier builders to avoid such places and protect farmland.

Similarly, Feng Shui for the home is now a booming business not only in Asian communities everywhere, but even among the many converts among the "host" populations. At best, it is rational planning for the home, based on common sense about lines of flow, arrangement of furniture, assignment of rooms' functions, and good environmental design. At worst, it is mystification, with unnecessary talk of qi and flying dragons.

Cheong Fatt Tze Mansion

It has been the aim for many architects to design a house which is perfect in terms of its Feng Shui. With many projects limited by budgets or difficult locations, this can be hard to achieve. However the Cheong Fatt Tze Mansion in Penang, Malaysia, is believed to have reached "Feng Shui perfection."

Cheong Fatt Tze (d. 1916) was a wealthy Chinese businessman who made his fortune in trade between Penang, Medan (Sumatra, Indonesia), Batavia (Jakarta, Indonesia) and south China. After the 1911 Revolution in China, Cheong Fatt Tze became a member of the Chinese Parliament and went to the United States to train industrialists to help build up Chinese industry. When Cheong Fatt Tze died, the house, with its well-known blue walls, was left to his family and gradually fell into disrepair. The mansion was extensively restored in late 1980s, and some of the French film *Indochine*, starring Catherine Deneuve, was filmed there. In 1995 it received the Malaysian National Architectural Award for Conservation. Five years later it won the UNESCO "Most Excellent" Heritage Conservation Award.

During a Feng Shui conference held in Penang, experts from all over the world visited the building and were impressed by the classical symmetry of the house, which ensured the "heart" remained in the central courtyard, retaining the energy of the building. The Cheong Fatt Tze Mansion exists not only as a tourist attraction, but also as a bed and breakfast, offering guests an opportunity to stay in one of the best-restored Chinese mansions in southeast Asia.

Fertility Behavior

AT THE ROOT of population growth, decline, and change lies the behavior of real women and men, making personal life decisions that reflect their socioeconomic circumstances, culture and religion. These choices, which regulate reproduction and childbearing, are together known as fertility behavior.

The concept of fertility behavior is among the oldest in social sciences, and its study, which began in the 18th century, explores it in relation to sociology, demographics, and population sustainability. Among the relevant factors are biology, behavior, society, economics, environment, religion, age, marital status, contraceptives, and family planning approaches. An example of how these elements are studied is the report made by Neeru Gupta and Iuri da Costa Leite, who found that residence and community were an important influence on fertility behavior.

Since many couples choose to have only two children, the idea of a possible third birth has become an issue in various contexts. Depending on cultural and religious traditions, couples may assign a special importance to the third birth, such as hoping for a particular gender. In some cultures, couple desire one child of each sex, whereas in other cultures, such as India or Egypt, couples prefer sons. In rural regions of China, couples who have a daughter first will be more likely to give her up for adoption, in the hope of having a male as for a second birth.

A fairly new phenomenon since the 1970s in Europe is women having their first child at age 35 or older. In France, which has the second highest birth rate in Europe (after Ireland), the number of French women having their first child beyond 40 years has doubled between 1962 and 2004, from 8 percent to 16 percent.

Related to the study of fertility behavior are the issues of infertility and celibacy. American sociologists Peter Bearman and Hannah Brückner have studied the phenomena of virginity pledges in the United States, which is often tied into teenager's identity decisions. The issue of infertility is so heartbreaking that it has been portrayed as far back as the silent era of moviemaking (G. W. Pabst's *Secrets of a Soul* in 1926), and continues into modern filmmaking (Woody Allen's *Hannah and Her Sisters* in 1986).

Fertility Rate

THE STUDY OF fertility is crucial to understanding the dynamics of population change. The term *fertility rate* refers to the actual reproduction in any given society, i.e., the number of children that are born to an individual or in a population in a given time period. This is in contrast to the term *fecundity*, which refers to the biological or physiological ability of individuals or couples to have children; some people in a society are unable to bear children because of disease or other biological, genetic, and environmental factors. The theoretical maximum fecundity for any given population is said to be 15 children per woman, but the actual number of children per woman rarely exceeds eight. There are several factors that explain the large gap between fecundity and the actual reproduction (fertility) and interfere with the process of human reproduction. The determinants of fertility include the value placed on children, cultural and social roles of women, and socioeconomic circumstances. For example, in less-developed societies, large families are often the norm as children contribute significantly to livelihoods and often take care of their parents in old age. More importantly, infant mortality rates are higher in these societies, as parents know that some of their babies will succumb to death. On the other hand, in highly developed societies, economic realities may deter parents from having large families.

The cultural, social, and economic determinants of fertility work indirectly to affect another set of factors, which demographer John Bongaarts termed the four *proximate determinants* of fertility. The four proximate determinants are the proportion married, the percent of women using contraception, the proportion of women who are infecund due to disease or prolonged breastfeeding, and the level of abortion. In highly developed regions, fertility rates are extremely low because of relatively high rates of contraception use and a low rate of marriage among women in their prime childbearing years. In the less-developed parts of the world, high fertility rates can be explained by low contraceptive usage and the promotion of early and universal marriage for women.

Demographers use different types of formulae to measure the level of fertility in a given society for a given time period. Measures such as the crude birth rate, the total fertility rate, the general fertility rate, the child-woman ratio, age-specific birth rates, the gross reproduction rate, the net reproductive rate, and others have been devised to gauge the level of fertility in different societies. However, the two most commonly used and reported measures of fertility are the crude birth rate (CBR) and the total fertility rate (TFR). The CBR is expressed as the number of births per 1,000 population—a crude measure of fertility, as the denominator does not distinguish the age or sex structure of the population. In a young population there will obviously be more births than in a predominantly older population. Thus, the TFR is a more refined measure of fertility that takes

In developed regions, fertility rates are low because of a low rate of marriage among women in prime childbearing years.

into consideration the age and sex composition of a population. The TFR summarizes the average number of children a woman would have if she were to have children at the prevailing age-specific rates as she passed through her reproductive years.

Using these two measures, the CBR in 2006 ranged from nine for a number of European countries to 50 for Liberia. On average, sub-Saharan Africa had the highest CBR, estimated at 40 children born in a year per 1,000 population, while highly developed countries in Europe and North America had a CBR of 11. The 2006 CBR for the world is estimated at 21, while the crude death rate is nine per 1000 population, resulting in a natural increase of 1.2 percent annually. The TFR ranged from 7.9 children per woman in Niger to a low of 1.3 children for a number of European countries such as Italy, Bulgaria, and Germany.

This has great implications for population growth. A TFR of 2.1 is considered to be the replacement level. In other words, a population with this rate has stopped growing and is simply maintaining itself from one generation to the next. A TRF of greater than 2.1 implies that growth is occurring, as is the case in Africa and other parts of the developing world. A rapidly expanding population in an already impoverished country such as Niger results in intense pressure on the limited resources with ultimate dire consequences for the environment and the economy at large.

Fertilizer

FERTILIZERS ARE CHEMICAL compounds that are added to the land to stimulate the growth of plants. Since soil is formed in many different ways around the world and is subject to many different types of erosion and leaching, then the optimal provision of additional nutrients will also vary. Most commonly, fertilizers will contain nitrogen, potassium, or phosphorus, which are the main plant nutrients, together with a number of trace elements that are also variously beneficial. Fertilizers are usually divided between organic and inorganic varieties. Historically, farmers have used manure from animals or other locally available substances.

The rise of industrialization during the modern age led to the creation of much more concentrated, nutritionally balanced, and efficient forms of fertilizers, and the understanding of which ones to use to promote the growth of specific types of plants. Fertilizers are now divided according to the ways in which they are taken up by plants (by roots or by leaves), how long they remain in the soil to release their nutrients, and the extent to which they are soluble. In general, agricultural fertilizers are usually comparatively long term in their release of important nutrients. Horticultural fertilizers tend to be much more short term in their intended impact and produce rapid growth in certain species for swift cultivation and sale. These types of fertilizers are more likely to enter into the plant and become, when the plant is a food item, part of the food chain. In common with insecticides and other chemicals, fertilizers can be partly responsible for regularization of size and shape of agricultural produce, since this makes the items more saleable.

This had the effect in some areas of removing the usefulness of local knowledge, often only slowly obtained over many generations, and leading to a sense of alienation. It also meant that commercial considerations became more important in determining what was to be grown than the natural configuration of the land and its soil. Although scientific studies suggest that the use of fertilizers does not have significant negative impacts if used appropriately, fertilizer is often, in fact, not administered appropriately, and farmers often do not have sufficient information or ability to apply it on a sustainable basis.

Although fertilizers are generally beneficial in that they promote plant growth and, therefore, help feed more people, they do have some negative impacts, especially when overused. These include the possibility of runoff, in which chemicals enter the water supply and contaminate it, as well as the eventual inability to sustain fertility of the land. The entry of fertilizers into waterways can lead to algal bloom, in which rapid growth of algae changes the water ecosystem and is harmful to fish and other marine creatures. Additionally, the success of some fertilizers in large-scale agricultural areas such as the U.S. midwest, as well as commercial incentives to provide ever-increasing growth of individual varieties, has increased the transformation of land cover and land use to monocropping—which has a tendency to lead to unsustainable and high-risk environmental circumstances. However, retail interests may lock farmers into long-term contracts, requiring them to continue to produce stipulated amounts of the individual species in order to profit.

Fiji

THE REPUBLIC OF the Fiji Islands consists of 320 islands covering 18,272 square kilometers. The great majority of the country's population live on the two largest islands, Viti Levu and Vanua Levu. Though Fiji comprises all types of oceanic island, Viti Levu and Vanua Levu are of volcanic origin with mountainous interiors and fertile coastal bands where most of the country's estimated 860,000 population (2005 estimate) live and where the majority of Fiji's agricultural activity, services, infrastructure, towns and tourist resorts are located. Approximately 80 percent of the country's rural population live within five kilometers of the coast.

Fiji faces a number of environmental threats and challenges resulting from the limited amount of available fertile land, the coastal location of much of the population and most economic activity, and the shift of the economy to a more industrial base. As such, Fiji faces multiple challenges, the most important of which include land degradation from intensification of economic activity, destruction of marine habitat and erosion of coasts, land and coastal-based pollution, unsustainable exploitation of marine resources, soil erosion resulting from more intense us of land (especially hillsides), and destructive fishing practices. In rural areas, the dominance of the sugar industry has meant an increasing use and reliance on pesticides and, coupled with more intense use of land for subsistence and commercial crops, has resulted in greater sedimentation and pollution of rivers and lagoons.

Fiji faces significant and pressing environmental challenges resulting from its transformation from a rural to an urban society. The urban population of Fiji is estimated to approximately half the national population. Cities are growing in terms of population but also their wider footprint. Suva, the principal city and national capital, extends to over 6,500 ha with an estimated population of at least 210,000. Urban growth has taxed the capacity of authorities to provide adequate services and infrastructure, particularly to the country's burgeoning squatter settlements that increasingly dominate the urban landscape of even smaller regional cities. In the mid–1990s only about 40 percent of Fiji's urban population had adequate access to water, proper sanitation facilities, and waste collection services. Levels of solid waste creation per capita are increasing in many of Fiji's cities but the machinery of collection and disposal is rarely keeping pace. Environmental and health conditions in informal settlements are increasingly degraded and deteriorating with growing populations. In addition to these environmental threats, Suva now faces an increased problem of air pollution.

Film, Representations of Nature in

WHEN THE VERY first motion pictures were shown to audiences in France during 1896, many people noticed with delight that "leaves on the trees seemed like they were moving" in Lumière's short film *Le déjeuner de Bébé* ("Baby's Breakfast"). Although there are many genres and various formats of films, there are also two opposite categories: those that idealize nature or take the defense of the environment, and those that show nature, animals, or space as dangerous for humans.

THE SILENT YEARS (1895–1928)

In the early 20th century, many films were short documentaries made by traveling cameramen, showing moving images of Paris, London, Rome, or New York to remote audiences in less developed countries, and then bringing back living images of Egypt, African countries and tribes, colonies, or exotic landscapes to more developed countries. An early science fiction story, Georges Méliès' *Le Voyage dans la Lune* (Trip to the Moon, 1902), confirmed the fairy imagery of space in the early century, as it was shown again in Fritz Lang's pioneering *Woman in the Moon* (1928).

Some directors became famous in showing an idealistic representation of men living in perfect harmony with nature, especially in some ethnographic documentaries. For instance, Robert Flaherty's *Nanook of the North* (1922) showed the daily life of an "Eskimo" living in Northern Québec, near the Hudson Bay (Canada). Memorable scenes showed the joyful character Nanook chasing, fishing, and sleeping in an igloo he had built. Flaherty's movies carried on with this romantic documentary genre: *Moana: A Romance of the Golden Age* (1926), about the daily life of Samoan islanders; and again in *Tabu: A Story of the South Seas* (1931).

In his masterpiece *Gold Rush* (1925), Charlie Chaplin showed a hard winter in Alaska, with famous scenes of men fighting against the powerful natural elements: a tramp followed by a gentle white bear, a little house blown away by the stormy wind. In F. W. Murnau's masterpiece entitled *Sunrise* (1927), the whole plot is centered on nature, as the film shows the passage from the rural zone toward the city, or vice versa. In the first part of the film, the calm beauty of wild nature surrounds all characters; while in the second half, the elements are against them: during a violent storm, the beloved mother disappears in the lake.

SURVIVING NATURE: THE TALKIES

Between 1927 and 1930, silent movies disappeared. More and more films had to be shot in the studio. But still, allusions to nature and the environment were made in some movies, sometimes as a metaphor for human feelings. However, every filmmaker had his own vision of nature. Shot in Northern Ireland, Robert Flaherty's *Man of Aran* (1934) also included scenes of a violent nature against men, in this case the tide hitting the fishermen and the presence of a shark that is attacked by the local men who live on the coast. In another case of the dangerous sides of nature, French novelist Sacha Guitry's film *Roman d'un Tricheur* (Confessions of a Cheat, 1936) shows the story of a child who had lost his parents, brothers, and sisters, because they all ate poisoned mushrooms from the woods.

Some directors have drawn a parallel between the uncontrolled forces of nature and the evil side of humanity. For instance, in Jean Renoir's masterpiece *La règle du jeu* (The Rule of the Game, 1939), a group of bourgeois who go hunting for rabbits as a prelude to the elimination of an outsider in their own circle. In *Lifeboat* (1943), Alfred Hitchcock imagines a group of shipwreck survivors adrift in a lonely lifeboat, lost on the sea during World War II. A few years after the end of the war, Roberto Rosselini shoots in Sicily a moving melodrama, *Stromboli, terra di Dio* (1949). An unhappy woman (Ingrid Bergman) wishes she could leave the hostile island where she lives, but feels the local population would stop her. On the day she decides to escape her brutal husband, a volcano starts to erupt and she is caught, alone on the top.

More than any other art form, cinema has given people the impression of knowing famous places like New York City or the Wild West without ever visiting them. Hence, Western genre movies have constructed a coherent environment for countless epic stories. John Ford created the most durable, mythical image of the American West, shooting most of his films in the Monument Valley studios, the largest open-air filming location that gave the Western its aesthetic definition for generations. John Ford's color films, from *Drums along the Mohawks* (1939) to *The Searchers* (1955), gave a magnificent vision of the West.

From the early 1960s, a few European movies began to question the dehumanizing effects of urban life and industrial societies. In Italy, Michelangelo Antonioni illustrated the difficulty of communicating in two masterpieces: *L'Avventura* (1960) and later in *Red Desert* (1964). Both films showed a beloved woman (Monica Vitti) who could not deal with her human and physical environments, both seen as superficial and artificial.

Some important directors such as Luis Bunuel have given a vision of nature as dangerous. In *La mort en ce jardin* (Death in the Garden, 1955), a group of bourgeois are lost in the jungle, seeing their belongings attacked by insects. That weird perspective reappears in Werner Herzog's *Aguirre, The Wrath of God* (1972), when a group of Spanish colonialists constantly face danger from the Peruvian highlands near the Amazonian jungle. The jungle has often been used as a symbolic location for a mysterious danger, such as in F. F. Coppola's *Apocalypse Now* (1979).

Apart from a few exceptions like Walt Disney's *Bambi* (1942), many fiction films showed wild animals as dangerous. In Steven Spielberg's *Jaws* (1975), the shark was not seen as an endangered species, but rather as a giant, evil, dangerous monster, as the many film versions of *Moby Dick*, from the 1926 version by Millard Webb, up to the John Huston version produced in 1956 from Herman Melville's novel.

The documentary tradition at the National Film Board (NFB) of Canada has enabled the creation of countless short films about men and nature. Among those, Arthur Lamothe's *Bûcherons de la Manouane* ("Manouane River Lumberjacks," 1962), showed some workers in Québec's lumber camps. However, a new, respectful attitude toward nature appeared in the early 1960s, for instance in Pierre Perrault and Michel Brault's *Pour la suite du monde* (also known as Moontrap, 1963), when a group of islanders living on Isle-aux-Coudres (on the St. Lawrence River) capture a small white whale, not to kill, but in order to renew a tradition of fishing that was lost in early 20th century. At the end of the film, the captured animal is sent alive to an aquarium in New York City.

In France, François Truffaut has created a film universe where nature is often present. At the end of *Les 400 coups* (The 400 Blows, 1959), the young Antoine Doinel escapes college goes to the beach in Normandy, for the first time in his life. In Truffaut's masterpiece *L'Enfant sauvage* (The Wild Child, 1970), a wild boy about 10 years old, who probably spent all his life in a forest, is taught how to live in society in the 18th century.

AN ERA OF CONTROVERSIES: 1975–2000

In the recent decades, an important number of documentaries about environmental issues has showed a growing conflict between environmentalists and industry, or opposing the state. Significantly, many debates about movies dealing with ecological issues have appeared outside the limited circles of film critics; even some governments felt they had to react to some challenging documentaries that criticized the government's attitude.

Some cases of environmental debates took international proportions. For example, on April 29, 1987, the *New York Times* reported that the U.S. Supreme Court confirmed the U.S. govenment's right to label three Canadian documentaries as "political propaganda:" *If You Love This Planet* (1982) by Terri Nash, *Acid From Heaven* (1982) by George Mully, and *Acid Rain: Requiem or Recovery?* (1982) by Seaton Findlay.

Perhaps Australian director Dennis O'Rourke produced the most stunning documentary about the dangers of nuclear research, *Half Life: A Parable for the Nuclear Age* (1985). In this obscure film made with archival footage, the consequences of many radiation experiments on a human population from the tiny atolls of Marshall Islands is seen, after nuclear testing in the Pacific Ocean during the 1950s. But possibly the most comprehensive film essay about risks to society in terms of nuclear hazards is Peter Watkins' *The Journey* (1987), 15 hours of documentary shot in many countries over three years. Watkins's message is that we do not know much about the risks surrounding us, and neither politicians nor the media tell us about the real issues. Moreover, demonstrations shown in the media represent those who challenge or oppose these decisions as strange, violent characters, often cut from reality.

In Canada, director Robert Monderie and songwriter Richard Desjardins produced *L'Erreur boréale* (Forest Alert, 1999), about how the wide forests in Québec are exploited by giant companies. That provoking documentary created a huge debate about the dangers of clear-cut logging in northern Quebec, and many politicians had to justify these practices after the film was screened.

In France, Claude Lanzmann directed and produced a moving documentary about the memory of the Holocaust, in a nine-hour film titled *Shoah* (1985). In this film, the author Claude Lanzmann visits former Polish and German Nazi death camps with some survivors. In some cases, these camps were not transformed into memorials; they were abandoned or destroyed, so nothing remains in the woods where thousands of corpses were buried and old railways still remain hidden under the grass. In only four decades, trees have grown where there used to be prisons for innocent civilians.

THE 21ST CENTURY: NATURE AS HERO

From the mid–1990s until today, a new awareness toward environmental issues is growing, and movies starring nature itself are appearing; staging a celebration of life, sometimes even without a human presence (or referring to humans as obstacles for animals and plants), in some cases using new technologies. Many of those movies became a huge success, especially in France, where many teachers brought their classes to watch films like *Microcosmos* (1996) by Jacques Perrin; *Le Peuple Migrateur* (The Traveling Birds, or Winged Migration, 2000), by Jacques Cluzaud and Michel Debats; and *March of the Penguins* (2005), directed by Luc Jacquet. In a few cases, these documentaries were quite successful in movie theaters, which is unusual in that genre. With DVDs and the internet, new modes of distribution can help these films find a wider audience.

Finland

FINLAND IS A sparsely populated country of 5.25 million people in northern Europe. The population and economic activity concentrate in the south, whereas large wilderness areas characterize the climatically harsher north and east. The origins of the national economy are close to the offerings of nature (forestry, agriculture, manufacturing of linen and wool), and forestry still plays a prominent role in the economy. A large-scale transition in Finnish society from agrarian lifestyle and migration from small towns to urban industrial centers only occurred in the 1950s and the 1960s. Post-industrial, service-based consumer society characterizes today's Finland.

Finns have a strong emotional relationship with nature. Finnish mythology is rich with symbolism and narratives representative of the Finnish landscape: forest, lakes, snow, and ancient bedrock. This thematic became prominent in identity-politically inspired art in the 18th century, in the context of awakening Finnish national sentiments. Nature continues to be a popular theme in Finnish art, design, and national iconography, for example on postage stamps and currency.

The natural environment is a favorite space for recreation and leisure. Most of Finland's half a million summer cottages are found on the Baltic coast and the Lake Region (south and east), and, increasingly, in Lapland (north), which are all popular destinations for foreign visitors. The positive economic impact of these seasonal homes is considerable on the typically small, rural host communities. Outdoor sports, hunting, and fishing are popular hobbies. In addition to municipal recreation areas, Finland has an extensive, government-managed network of conservation and recreation areas, the largest of which are national parks. The Ministry of the Environment coordinates Finland's environmental administration through research institutes, regional centers, and licensing and funding authorities. The duties include management of water and land resources, environmentally sustainable land use planning in built environments, preventive measures, and conservation.

Citizens' environmental awareness in Finland is at a relatively high level. Many consumers take environmental issues into consideration in their purchasing choices and recycle actively. Environmental health and risks, sustainable development, and responsible consumer choices are frequent and sometimes hotly debated topics. Environmental organizations range from small, informal activist networks to nationwide civic associations dedicated to nature conservation, animal rights, and environmental education. The Green League of Finland party attracts 8–10 percent of the vote in parliamentary elections, typically from well-educated, young urbanites.

Differing interests and views have also created tension in Finnish society. In integrating Europe, concerns about safety and sustainability focus on food and energy production and often depend on decisions made elsewhere in Europe. Recent environmental conflicts within Finnish society have included the acceptability and methods of fur production (between animal rights activists, producers, and retailers); land ownership, sustainable reindeer herding, and mining rights in Lapland (the indigenous Sami, the local majority population, the central government, and multinational corporations); and the sustainability of Finnish forest companies' actions at home and abroad (environmental activists, land owners, and multinational corporations). The scope of Finnish society in environmental matters is thus increasingly global, diverse, and, at times, controversial.

Fire

THE MASTERY OF fire separates humans from other animals. Our use of this chemical reaction—on landscapes, in hearths, and in industry—is one of our most fundamental and influences on the environment. Without fire, many of our foods and landscapes would be unrecognizable. But fire also destroys homes and habitats, and inspires or even expresses conflict between different people.

Fire is a chemical chain reaction akin to photosynthesis in reverse. Once sufficiently heated, fuels react with oxygen in the air to produce carbon dioxide, water vapor, and heat energy. The size, type, and moisture content of fuels, as well as the prevailing weather conditions (humidity, precipitation, temperature, and wind), are crucial in affecting the threshold for ignition and potential for spread. The most common fuels for fire are biomass like trees or grasses, and fossil biomass like coal or oil. Fires are more frequent in landscapes with both wet and dry periods, like seasonal tropics or Mediterranean climates. Biomass accumulates during wet seasons and then dries out. Deserts are typically too dry for combustible biomass to accumulate; humid temperate, boreal, and humid tropical regions only occasionally dry out sufficiently to allow fires to propagate.

Barring spontaneous combustion at high temperatures, most fires require external ignition to spark the chain reaction. Humans and lightning are the most common ignition sources, though falling rocks and volcanism also occasionally spark fires. Lightning's prevalence varies from region to region: while around 6,000 lightning discharges occur each minute across the globe, they are not uniformly distributed. Mountainous regions and places where lightning is not associated with drenching rainfall are particularly prone to lightning fire ignition. The western United States is one such place; 200–1,700 lightning fires occur each year on government forestlands in California alone.

In many places, humans ignite more fires than lightning. Humans first observed that the animals they hunted congregated on the flush of new grass after lightning-strike fires, or that useful plants grew in burned areas; archaeological evidence suggests that humans fully mastered the art of lighting and tending fires between 350,000 to 400,000 years ago. Our techniques evolved rapidly in recent centuries, beginning with sulfur-tipped matches in 1827 and moving toward tools like aerial bushfire ignition and turbocharged internal combustion engines.

Every human culture has stories and beliefs centered on fire, which has come to symbolize the links between humans and the divine, both in legend and in practices like cremation.

Fire can be divided into four broad categories. Landscape fires are natural landscape and anthropogenic landscape fires such as vegetation fires, biomass burning, or "wildland" fires; and point fires are domestic and industrial fires, which are contained to a single, man-made point, such as a stove, furnace, or engine.

LANDSCAPE FIRES

Natural landscape fires are ignited by nonhuman sources like lightning. Charcoal found in lake sediments and other paleo-ecological evidence shows that fires burned nearly everywhere before the arrival of fire-bearing humans.

However, humans now burn more lands than lightning, and have long relied on fire as a simple and effective tool to control and shape landscapes for a better life. Humans have also created combustible conditions by unleashing livestock or slashing vegetation. Fires renew and expand grasses crucial to both wild game and domestic livestock, and clear brushy vegetation to facilitate cultivation, travel, visibility, and security. Frequent, small, early fires are the best way to control wildfires, by avoiding fuel buildup. Fire also encourages (or discourages) specific plant types, flushes out animals for hunting or bees for honey collection, and uncovers mineral outcrops or wild tubers.

Anthropogenic landscape fires are common across the globe. For example, in Kansas, ranchers set tallgrass prairies alight each spring to improve grazing. In California, oak woodland managers copy the techniques of indigenous Yurok people, who burned in part to encourage a good acorn harvest. In Africa, wildlife reserve managers burn savannah grasslands to improve habitat for a variety of ungulates and their predators. In Scotland, hunters torch the moors to improve grouse habitat. In India, foresters use prescribed fires in *sal* forests to improve timber harvests; Florida foresters do the same in pine woodlands. In Mali and northern Australia, a mosaic of frequent fires throughout the year serves not only to shape the vegetation, but also to control the spread of later wildfires. In Oregon and Brazil, farmers burn crop stubble to facilitate the return of nutrients to the soil. In Madagascar and Thailand, farmers prepare crop fields by burning the standing vegetation.

Today, as a result of both natural and anthropogenic landscape fires, an estimated six million square kilometers, or four percent of the earth's land surface, burns annually. In some regions—particularly the savannas and grasslands of places like northern Australia, Sahelian Africa, or around the edges of the Amazon Basin—fires burn perhaps half the land each year.

POINT FIRES

Domestic and industrial fires are also an anthropogenic contribution. Domestic fires include campfires and home fires used for cooking, heat, and light. Fire allowed our ancestors to cook and cure foods, vastly expanding the range of edible foods and the possibilities for storage. Campfires at cave entrances protected prehistoric humans from dangerous predators. Their light expanded our productive capacities. Today, the campfire, fireplace, or barbeque remains an enduring site of human sociability.

Industrial fires are, like domestic fires, anthropogenic point fires, but differ in technology and fuel type. Technological advances in the past two centuries, and associated exploitation of fossil biomass fuels, contributed to the invention and rapid spread of different kinds of engines, furnaces, and factories. The campfires or wood stoves of our ancestors have, for most people, been replaced by a coal-burning power plant linked to an electricity grid, or by pipelines and bottled gas. Industrial fires are now at the root of most human productive and economic activities—from jet engines to automobiles, coal-burning power stations to gas furnaces. Humans now consume 400 million trillion joules of energy annually, or almost two-thirds of the earth's overall combustion budget.

The impacts of fire are complex and highly dependent on temporal and spatial scale. Short-term trends may not reveal major long-term effects, and vice-versa. In some ecosystems, such as oft-burned grasslands, vegetation and soil nutrients recover relatively rapidly from the immediate effects of fire; in other ecosystems, single fires can be major drivers of landscape change.

SHAPING VEGETATION COMMUNITIES

Both natural and anthropogenic landscape fires play a key role in shaping vegetation communities. At its simplest level, increased burning favors fire-adapted species. Grasses typically fare better than woody species, yet some bushes and trees display a wide variety of adaptations to fire, including the protection of thick bark, seeds that require fire to open or ash beds to sprout, the ability to re-sprout from epicormic buds, or the placement of significant plant parts underground.

In the savannah environments of Africa, early dry season burns every few years can a promote tree cover, while later fires reduce tree cover. Seed availability, grazing intensity, soil type, annual variability in timing and amount of precipitation all affect the outcome.

Many seemingly "natural" landscapes may owe at least part of their ecological character to people. Geographer William Denevan has argued that before the arrival of Columbus, the burning and cropping practices of indigenous Americans, then numbering in the tens of millions, had shaped landscapes all over the Americas. While some debate persists over this assertion, it is clear that American prairies, African savannas, or the Brazilian *cerrado* would look fundamentally different without fire.

Humans first visited the large Indian Ocean island of Madagascar only 2,300 years ago. The fires unleashed by settlers over the next millennium across this island increased grassland cover at the expense of woody vegetation, particularly in the highlands.

Fires associated with agriculture lead to even sharper vegetation changes, as people closely control the vegetation that succeeds a burn. Polynesian sailors settling new islands like New Zealand started a process of burning and clearing just as 18th century Scottish and Irish farmers used slash-and-burn agriculture to clear a foothold in America's heavily wooded Appalachian Mountains. Fires used for agriculture still play a key role in deforestation today, in places like Africa (for subsistence farming), southeast Asia (to establish oil palm plantations), and the Amazon (for the farms of colonists and ranchers).

SOIL AND WATER

Fires affect soils in several ways. Typically, erosion rates increase on burned plots for a limited time, though regular burning does not necessarily increase long-term erosion. In some ecosystems, however, fires may trigger erosion events that are major drivers of geomorphic change.

Trees display a wide variety of adaptations to fire, including thick bark and seeds that require fire to open.

Soil nutrients like nitrogen and potassium increase in the short-term after a fire, due to ash deposits and reduced plant uptake of nitrogen. Long-term effects depend on soil and vegetation type, fire characteristics, topography, climate, soil formation rates, and complex nutrient cycles. For example, in the closely studied tallgrass prairies of Kansas, where fires burn annually, researchers determined that while fire volatilizes organic nitrogen, this has no impact on grassland productivity as biological and biogeochemical feedback cycles serve to fill the gaps. Under a very different fire regime—slash and burn agriculture in tropical rainforests—soil degradation is usually minimal, except when the land in question is steeply sloped or permanently cleared.

Fire's hydrological impacts are highly ambiguous and context specific. In terms of water quality, influxes of ash and detritus are thought to be relatively short-lived. Recently burned areas can exhibit higher surface temperatures, higher evapo-transpiration potential, and less vegetation cover, leading to warmer water and faster runoff. Some impacts are counterintuitive. For example, in some South African watersheds, nonnative wattle trees lower the water table. Frequent burning can control these water-hungry trees and maintain a higher water table.

AIR QUALITY AND EMISSIONS

All forms of fire affect air quality. Since combustion is rarely perfect, fires release not just carbon dioxide and water vapor but also carbon monoxide, methane, nitrogen oxide, hydrocarbons, and various smoke particulates into the air. For humans, these emissions can be simple irritants or serious health hazards, depending on the scale. Large landscape burning events such as the 1997–98 fires in Indonesia impacted 75 million people. Health impacts like respiratory ailments led to the deaths of perhaps 16,000 infants and affected people's livelihoods.

Indoor cooking and heating fires, when poorly ventilated, contribute to a variety of diseases, including pneumonia, chronic respiratory diseases, lung cancer, and asthma. Smoke from domestic fires is blamed for over a million premature deaths per year around the world.

Fire emissions play a major role in atmospheric chemistry, radiation budgets, and climate change. Research summarized by the Intergovernmental Panel on Climate Change (IPCC) shows that increased emissions have demonstrably changed many aspects of the global climate since the pre-industrial era.

Prior to about 1940, the primary source of carbon dioxide and other greenhouse gas emissions was land clearing and cultivation. Since then, emissions from industrial fire—factories and vehicles—have far eclipsed these in impact. All the same, tropical land clearing, often through fire, continues to be major source of greenhouse gases; global landscape fires corresponding with the strong 1997–98 El Niño season were recently shown to have emitted 30 percent more carbon monoxide than vehicles and power plants during those two years.

CONFLICT OVER FIRE

The impacts of fire have long made it a topic of regulation and controversy. The pastoralist of lore, with his wandering herds and free-burning fires, occasionally clashed with those whose property his fires threatened. Villagers protected their crop fields, homes, or sacred groves from free-burning fire, and sought punishment for anyone who sparked a damaging fire.

With the Industrial Revolution came industrial fire, which freed many human productive activities from our dependency on landscape fires. fields are now fertilized with chemicals, not ashes. Along with industrialization, the 19th century also saw major advances in science, growing capitalist economies, and newly powerful state bureaucracies. These trends led to increased government and scientific intrusions into the management of many landscapes, removing them out of the hands of villagers. In such strategies, there was no room for fire.

Modern resource management in the 20th century were based on ecological theories of the day, particularly the idea of succession, which viewed change in vegetation communities as an orderly, staged progression from bare soil to a climax, usually forested. Fire was seen as an outside disturbance working against succession. Technological advances like tractors and bulldozers gave humans a mechanical means to clear vegetation instead of burning, as well as powerful tools to effectively fight fire. At the same time, state resource management bureaucracies gained further power over the management of far-flung landscapes.

EMPHASIS ON FIRE SUPRESSION

As a result, fire landscapes changed. Forest fire suppression was the core strategy for much of the 20th century in places in the United States, France, southeastern Australia, francophone Africa, and Indonesia. Fires were seen to threaten timber assets, infrastructure, and aesthetic qualities, to be anathema to economic development, and to degrade soils, water, and land cover. For example, after the massive 1910 wildfires that burned 12,000 square kilometers of forest in the northern Rockies, the U.S. Forest Service mobilized a massive fire-fighting campaign, establishing a network of fire towers, access roads, and firefighters. By 1935, stated policy was that all fires be extinguished by 10 a.m. the following day; in the 1940s, a charismatic cartoon character, Smokey Bear, was conceived to spread the fire control message to younger generations.

France took a similarly strong approach to fire suppression, even in its fire-prone Mediterranean regions, relying on impressive fire-fighting technology. In its tropical colonies, France sought to replace firestick farming with intensive agriculture and state forests. In the 1930s, the colonial rulers attempted to ban all fires in their African and Asian colonies. However, political and logistical realities forced officers to accept some pragmatic exceptions to the ban, like pasture renewal burns or preventive burning.

There were exceptions to the fire suppression approach. In America, farmers and ranchers continued to enlist fire as a key tool for managing Kansas prairies, California grasslands, and Hawaiian cane fields. Even the U.S. Forest Service continued to undertake controlled burns in the productive pine forests of the southeast. In India's *sal* forests, field foresters and local villagers convinced the British colonial forest bureaucracy that fires served a key role in the regeneration of these valuable trees.

Full fire suppression began to lose favor in much of the world in the second half of the 20th century. Already in the 1950s, colonial officers in Africa began to see fire as a "necessary evil" for range management. Lessons from field-based foresters and new ecological research began to tentatively change the paradigm in America in the 1960s. Californian forester Harold Biswell tirelessly argued for the benefits of prescribed burning. New policies emerged that allowed some "natural" fires to burn in wilderness areas, or that allowed resource managers to practice controlled, prescribed burns.

FIRE AND POLITICS

However, fire would continue to be politicized. Industrial fires fuel the growth of urban society, but lead to damaging impacts on air quality, health, and climate. Restrictions based on environmental concerns frequently clash with the use of fire as an efficient and affordable tool by a variety of land users. When city residents are forced to cough their way through a smoky fire haze, politicians call for rural land managers to stop burning. When images of slash-and-burn farming are associated with the demise of tropical forests, calls go out for an end to such techniques for the sake of biodiversity conservation. As a result, some countries reaffirmed strict suppression laws. For example, Mali outlawed all burning in the 1980s; Madagascar did the same in 2002.

Today's policymakers must deal with a number of important complexities. First, the fire suppression paradigm persists, often reflecting the concerns of an urban public. While resource managers and scientists argue for a legitimate place for some fire in some vegetation systems, public perceptions focus on the destructive side of fire. When treasured national parks burn, like America's Yellowstone in 1988, discussions of the ecological role of fire are often lost behind fiery headlines.

Nearly a century of fire repression means that many ecosystems suffer an overabundance of flammable fuel. When a lightning bolt or camper's match ignite a fire during a dry spell, the result is catastrophic. Fires burn hotter and bigger than they would in frequently burned environments. The legacy of suppression may be a key factor in the large number of catastrophic wildfires burning the forests of America, southeast Australia, and Mediterranean Europe over the past two decades. In turn, footage of raging flames and charred buildings from these events spurns continued political pressure to stop all fires.

Prescribed or controlled burning plays a key role in current fire policy. Fire is a difficult and expensive tool to master, and escaped controlled burns are not only frequent but also generate bad publicity—as when an escaped controlled burn almost torched New Mexico's Los Alamos nuclear labs in 2000. Resource management agency mandates are shifting from resource production to recreation and conservation, to the point that effective broadscale controlled burning is not always feasible.

In many wealthy nations, the spread of the rural-urban fringe puts large property assets at the risk of fire. Houses built in the forest or in abandoned farm country, whether in the foothills of the Sierra, the French Riviera, or Sydney's outer suburbs, pose a complex problem for fire managers, as fuels accumulate to dangerous levels.

Finally, fire management is vexed by the realization that there is no fundamental "right" or "wrong." The only constant is that the outcome is shaped by the decisions of humans and the vagaries of nature—unique fire creatures on a unique fire planet.

Fire Down Under

Australia was relatively unique among industrialized nations in never adopting a firm anti-fire policy. "Back-burning" is a widely accepted technique for fuel management and pasture maintenance around the continent. Foresters have been lighting prescribed burns in the forests of the southwest for half a century, pioneering the technology of aerial fire ignition. In the monsoonal tropics of the north, nearly everybody–from Aborigines to livestock-raising station managers to government park managers–uses fire to take care of the land. Aboriginal burning techniques, cleverly labeled "fire stick farming" by anthropologist Rhys Jones in 1969, are now widely recognized as well suited to the management of the native vegetation. It is only in the populous and more humid southeast, where fires regularly threaten suburban homes and productive timber forests, that fire suppression gained prominence and continues to hold significant policy weight.

Perhaps the most famous anthropogenic fire landscape is the "bush" of Australia. The frequent and widespread burning of the ancestral Aborigines, who arrived on the continent at least 40,000 years ago, contributed, along with climatic changes, to a vegetation shift from southern beech-dominated "rainforest" vegetation to eucalyptus woodlands. Much of the current vegetation exhibits typical signs of fire adaptation, like the fire-cured seeds of banksia or the prodigious sprouts of eucalyptus.

Fire Ant

SOLENOPSIS INVICTA, MORE commonly referred to as fire ants, are a particularly devastating invasive species to the southeastern United States. First introduced in the 1930s to Mobile, Alabama, the ants probably arrived via cargo ships from Brazil or Argentina. Since the 1930s, fire ants have spread to almost the entire southern United States, ranging from Florida north to Maryland and west to Texas, including Oklahoma, Arkansas, and Tennessee. More recently, fire ants have been discovered in California, southern China, Australia, and the Philippines.

Fire ants are typically more aggressive than native ant species, and swarm when disturbed. Although human death due to fire ant stings is extremely rare, swarming fire ants do kill small mammals and birds, particularly ground-nesting species, and can totally eliminate some species of birds from an area. In addition, fire ants have had an enormous impact on nonant arthropod diversity, in some cases reducing species diversity by 30 percent.

As fire ants have adjusted to their new environments, they have undergone several competitive adaptations. Because populations of ants are no longer limited by native pathogens and competitors, colonies of fire ants are larger in the southern United States than in Argentina. Fire ants favor disturbed habitats, such as agricultural fields, suburban developments, or other environments characterized by ecological alteration, where native species are under stress. Because of their aggression and lack of controlling predators, pathogens, or competitors, fire ants have devastated native ant communities in the southeastern United States. In Texas, for example, fire ants were found to have diminished native ant species diversity by 70 percent, and to have limited the total number of native ant individuals to 10 percent of their former levels. Native ants were able to survive in pockets of undisturbed and uninvaded habitats; no ant extinctions are documented as a result of the depredations of invasive fire ants.

Research has focused on controlling fire ant populations through insecticides or the introduction of species-specific South American biological controls, such as a microsporidian protozoan (Thelohania solenopsae) or the fungus Beauveria bassiana. In addition, two Pseudacteon flies, which parasitize Solenopsis ants, have been introduced into the southern United States: these flies lay eggs in the heads of worker ants, the larvae of which ultimately decapitate the ant. Because the Pseudacteon flies only affect worker ants, they serve as a limiting factor on the growth and size of fire ant colonies, and will not eliminate the species from the United States. The use and introduction of nonnative biological agents to control invasive species should be cautioned, however, as numerous cases of drastic and damaging consequences with this technique can be identified (mosquito fish and cane toads in Australia and parasitic flies for gypsy moths in the eastern United States). Efforts to control fire ants through pesticide and chemical insecticide application have impacts on freshwater systems and wetlands, as well as on other insects harmed by the chemicals.

Fire ants have caused economic damage as well. In Texas alone, fire ants are estimated to cost $1.2 billion yearly in health costs, management activities, agricultural losses, and property destruction. Fire ants even represent the leading cause of electrical shorts in traffic lights, as they chew through electrical insulation.

First Nations

INDIGENOUS PEOPLE AROUND the world historically have been referred to by a range of names, including those of their own traditional distinctions, as well as those colonially imposed (such as "Indians" for Native Americans). First Nations is a relatively novel term, coming to prominence in Canada during the 1970s, to refer to indigenous or native peoples. The term has been applied more generally to all pre-colonial peoples of both the Americas and Australia, though the term is by no means uncontroversial. The degree to which the term is tied to a notion of sovereign "nationhood" and the requirements of historical primacy (who is "first"), both make the term politically complex. Nevertheless, the experiences of native people, especially relative to environmental rights and experiences, is remarkably common throughout the world.

First Nations have long suffered the disproportionate effects of environmental damage. According to the Worldwatch Institute, 317 reservations in the United States are threatened by environmental hazards ranging from toxic wastes to clearcuts. In the United States, more than 300 Native American reservations have been targeted for landfills, incinerators, and other waste facilities. In New York and Canada, the Mohawk have suffered damage from polychlorinated biphenyls (PCBs), which were legal and used extensively by General Motors and other companies until the mid–1980s.

As demand for energy supplies increases, so does pressure on tribes that live in areas with vast amounts of resources. Many First Nations are terribly poor, so the promise of employment from mining or payment for allowing the government to strip the land or locate wastes or toxins is compelling.

Another environmental issue facing Native Americans is location of nuclear wastes. Reservations in the United States have been targeted for 16 nuclear waste dumps. Yucca Mountain in Nevada is scheduled to become the next High-Level Nuclear Waste (HLNW) site, despite the potential impact on the western Cheyenne who call the area home. Radioactive waste dumps also affect aboriginal people in South Australia and the First Nations of islands near Taiwan.

Testing of military weapons has also lead to environmental damage. In the last 45 years, more than 1,000 atomic explosions have occurred on western Shoshone land in Nevada, making it "the most bombed nation on earth." Over 3,000 nuclear weapons are stored on the Hawaiian island of Oahu, and unexploded bombs are all over. The army accidentally shelled one area of the island four times between 1987 and 1990.

Environmental cleanup, often slow and underfunded in general, is even worse on indigenous lands. The Indigenous Environmental Network says that most indigenous governments are 22 years behind in their development of environmental infrastructures.

In addition to toxic wastes on the land, Native Americans and First Nations face the pollution of their water, which consequently threatens fish, an important food source. In the Pacific Northwest, virtually every river is home to native peoples. Salmon is a major source of nutrients, but over 107 stocks of salmon are already extinct and 89 are endangered due to high levels of mercury and other toxins.

Many environmental problems involving First Nations are the result of overuse. In 1999, the Eastern Navajo filed suit with the Nuclear Regulatory Commission (NRC) to block uranium mining on their lands. There are more than 1,000 slag piles from abandoned uranium mines on Dine (Navajo) land, releasing radioactivity into the air and water. The Seminole tribe of the Everglades has seen their land and sacred animals, including the panther, significantly diminished due to overdevelopment of south Florida. In the Amazon area, one-quarter of the forest, home to indigenous peoples, has been demolished since 1900.

Too often, First Nations have little or no voice in matters of environmental pollution and degradation of their land. While wealthier people are able to cry "Not in My Backyard," most tribes have a contentious and murky relationship with the government. In many countries native peoples retain some sovereignty yet are also governed by the state, so their ability to use courts for redress is somewhat confused.

Yet some progress has been made. The 1992 United Nations Conference on Environment and Development (Earth Summit) recognized the importance of environmental justice for indigenous peoples. In the United States, President Bill Clinton issued Executive Order 12898, drawing federal attention to environmental justice in minority and low-income populations. Native groups have worked together to defeat proposals that would bring greater environmental damage. For instance, in the 1980s the Blackfeet Indians worked with a coalition of green groups to fight off two oil firms seeking to explore the Lewis and Clark National Forest.

Fish and Wildlife Service (U.S.)

A BUREAU OF the Department of Interior, the Fish and Wildlife Service is the federal government's lead agency in charge of wildlife and freshwater fish conservation. Although fish and wildlife presumptively fall within the jurisdiction of the 50 states, the federal government's role has increased significantly since the late 19th century through international treaties; the creation of national parks, forests, and wildlife refuges; the Commerce Clause; and the Endangered Species Act of 1973. Today, the Fish and Wildlife Service administers a system of 520 wildlife refuges and "waterfowl production areas" covering roughly 93 million acres of land (more than half of which is in Alaska). Its Ecological Services Division oversees endangered species protection (except for marine and anadromous fish, which fall under the jurisdiction of NOAA Fisheries in the Department of Commerce).

The Fish and Wildlife Service has a complex and rather haphazard administrative history, in which various tasks and mandates accrued to it in response to changing social pressures, legal decisions, and political opportunities. Its roots include congressional acts in the 1860s that were the first federal protections of wildlife (in the Yosemite Valley and the Pribilof Islands of Alaska); Executive Orders reserving certain federal lands from private exploitation beginning in the 1880s; and the creation of bureaucratic units to study fish and wildlife resources, such as the Federal Office of Commissioner of Fisheries (1871) and the Division of Economic Ornithology and Mammalogy in the Department of Agriculture (1885). Its institutional identity, however, revolves principally around national wildlife refuges, the first of which came into being in 1903 when Theodore Roosevelt proclaimed the 3-acre Pelican Island in Florida a Federal Bird Reservation. By 1909, Roosevelt had issued 50 more Executive Orders creating wildlife reservations. Congress created still others, including the National Bison Range in 1908 and the National Elk Refuge in 1912. The Migratory Bird Act asserted federal authority over migratory birds in 1913, the same year that President Taft ordered the reservation of the Aleutian Island chain in Alaska.

The acts, orders, and bureaucratic innovations responded to crises brought on by unrestrained commercial exploitation of fish and wildlife, and they reflected the interests of specific constituencies. Many early refuges were created as "overlays" on reservoirs being constructed by the recently created Bureau of Reclamation. Federal fish hatcheries and translocations had grown, since the 1870s, into an ambitious and politically popular system for increasing fish stocks for both sport and commercial purposes; in 1903 the Fish Commission was transferred to the new Department of Commerce and renamed the Bureau of Fisheries.

The coalitions behind this growth were unstable, however, reflecting larger tensions in the ends and means of Progressive Era natural resource management: first, between "conservation" to satisfy human needs and "preservation" for the sake of nature itself; second, between centralized, bureaucratic administration to maximize "efficiency" and the state or local level authorities favored by tradition and the Tenth Amendment. Sportsmen and naturalists allied against commercial exploitation in general, but frequently parted company over whether noncommercial or "sport" hunting would be allowed in refuges. Sites like Pelican Island could be effectively conserved by simple protection, but in other places nature had to be "fixed"—bison had to be shipped from the New York Zoological Society to the Wichita Forest Reserve and Game Preserve, for example—or actively manipulated to increase harvests, as with fish hatcheries and translocations. Meanwhile, Congress was reluctant to appropriate funds for federal agencies that seemed to be intruding on matters previously left to the states, although activities that yielded economic returns to local constituencies could sometimes find favor.

The Depression and New Deal forged compromises that set the basic framework for the next four decades. The Civilian Conservation Corps provided labor to improve habitat and infrastructure on refuges; some new refuges were created from lands acquired by the Resettlement Administration from bankrupted farmers. In addition, the Migratory Bird Hunting and Conservation Stamp Act of 1934 (better known as the Duck Stamp Act) created a reliable revenue source by requiring waterfowl hunters to pay a fee. In 1939 the Bureau of Biological Survey and the Bureau of Fisheries were removed from the Agriculture and Commerce Departments, respectively, and transferred to the Department of Interior, where a year later they were merged to form the Fish and Wildlife Service. The Fish and Wildlife Act of 1956 ratified the role of refuges in national fish and wildlife policy, and a 1958 amendment to the Duck Stamp Act and the Wetlands Loan Act of 1961 helped generate funds for refuge acquisition.

Federal fish hatcheries have grown into a popular system for increasing stocks for both sport and commercial purposes.

It wasn't until 1966, however, that Congress provided comprehensive legislative guidance for the management of refuges. The National Wildlife Refuge System Administration Act explicitly authorized hunting, recreation and other public uses on refuges provided they were "compatible" with the purposes for which the refuges had been established. These and other provisions were updated and further elaborated in the National Wildlife Refuge System Improvement Act of 1997.

Passage of the Endangered Species Act of 1973 (ESA) presented the Fish and Wildlife Service with a fundamentally new challenge, although it would take some time for this to become apparent. Refuges dedicated to fish, migratory waterfowl, and game species could generally be managed in tried and true Progressive Era fashion: by demarcating boundaries, enforcing permit requirements, manipulating habitat, and in some cases producing target species for stocking. The species first protected under the ESA generally lent themselves to this approach as well, and the creation of refuges for them seemed a simple extension of past practice. But as other types of species have been listed—plants, insects, crustaceans, and all sorts of nongame birds and mammals—the Fish and Wildlife Service has had to face challenges that refuges alone cannot surmount: How to protect species whose biology and ecology are poorly understood, whose habitats extend across very large areas and/or lands unavailable for refuge creation, or whose listing triggers complex legal and regulatory issues. As a result, the Fish and Wildlife Service's identity is once again in flux, with some calling for refuges to be split from Ecological Services.

Fish Ladders

FISH LADDERS ARE designed to allow fish passage around dams or other barriers by providing a series of relatively low steps that the fish may leap from one level to the next (hence the term *ladder*). Anadromous fish (e.g., salmon, sturgeon, and lamprey) need access to both the rivers where they spawn and the oceans where they spend their adult life. Dams have had such negative impacts on populations of anadromous fish because they fragment the river ecosystem, preventing adults from reaching their spawning grounds. This inability to reproduce has led to the decline or local extinction of many anadromous fish, including numerous species of salmon, steelhead, suckers, and lamprey.

Fish ladders have become the focus of political controversy on at least two counts. Some rivers, such as the Klamath River in California and Oregon, have no fish ladders. Thus fish in this river are totally blocked from habitat upstream of dams. The Klamath was once the third-largest salmon producing stream on the west coast of the United States. The fact that four dams block Spring Chinook salmon from 90 percent of their original spawning ground is cited as a chief reason that fishery is now in a state of collapse.

Fish ladders are also controversial because they are not as effective in creating fish passage as once believed. For example, fish ladders are more successful in allowing the migration of adult salmon swimming upstream to spawn than the juvenile fish who migrate downstream to the ocean. National Marine Fisheries Service reported that Fall Chinook juvenile mortality on the Lower Snake reservoirs could be as high as 20 percent per dam. Even adult migration in fish ladders is imperfect. The study further reported that up to 40 percent of adult fish in the Lower Snake fall back over the dam spillways or pass through the turbines after moving up the fish ladders. These fish are less likely to spawn. With four dams on the Lower Snake and four more on the Columbia the cumulative effect of these dams are problematic for salmon even with fish ladders.

In the Pacific Northwest, salmon are a cultural icon to Native American and other cultures. Native Americans still consume salmon, steelhead, lamprey, and other anadromous fish. The decline in these populations, however, has had significant health, cultural, economic, and social effects for these communities. Furthermore, salmon is the basis of a significant but heavily reduced commercial fishing industry on the west coast. In 2005 the inadequacy of fish ladders had been the basis for the three largest tribes in California demanding removal of four dams on the Klamath River in Oregon and California.

Fish ladders also work better for some species than others. Lamprey do not travel well in fish ladders either as adults going upstream or as juveniles attempting to reach the ocean. Although they do not have much appeal for non-Native American people, lamprey are an important food source for Native Americans. Pacific lamprey and other lamprey species have been considered for the Endangered Species status.

In 1997, the Federal Energy Regulatory Commission denied a new license to the Edwards Dam on Maine's Kennebec River on the basis that the cost to migrating fish denied access to upstream spawning grounds was greater than the benefit from the hydropower. Even if installed, it was found that fish ladders could only partially mitigate for some of the affected species. As a result, the dam was breached in 1999. One year after the Edwards Dam removal, migratory fish—including the alewife—returned by the millions to sections of river that hadn't seen them in 160 years.

Fisheries

FISHERIES ENCOMPASS THE variety of human activities to harvest aquatic animals and plants. The term includes the harvest of fish *per se* as well as crustaceans, seaweeds, mollusks, and marine mammals, but not aquaculture. Fisheries can be in either inland, coastal, or high seas environments. Globally, about 90 million metric tons of fish are landed yearly, about one-eighth from inland waters, the remainder from the oceans. Fishing gears or instruments for harvest are quite diverse: from static gears such as fish traps, weirs, hooks and lines, and gillnets, to mobile gears like spears, cast nets, haul and purse seines, trawls, and dredges.

Fishers can be differentiated into two main categories: artisanal and commercial. Artisanal fisheries are typically defined by low levels of capitalization and productivity and the use of catches for subsistence or localized markets, whereas commercial fisheries are defined oppositely as highly capitalized, efficient, and oriented toward global markets. These ideal types seldom capture the empirical reality of fisheries, as many fishers deemed artisanal have motorized boats, sell their catches for distant markets, and can be quite efficient; and many deemed commercial supply local buyers only, have small boats, and are engaged in fishing informally in concert with other sources of livelihood, a characteristic generally ascribed to artisanal fishers.

DEPENDENCE ON FISHING

There are about two million fishers in Africa—the vast majority artisanal—and this number is increased several times when marketing and processing jobs are included. Six million people are employed in fishing or fisheries-related jobs in India. Fisheries are of paramount importance for often-rural localities, as they can provide employment, a tax base for local services, and cultural value. Seafood (from aquaculture and fisheries) accounts for only a small percentage of total caloric intake in almost all countries, but in many countries it accounts for 20 percent or more of protein intake and is cheaper than alternative protein sources. Many southern islands and coastal nations and Japan are highly dependent on fisheries for their food security. People in Global North countries on average eat 27 kilograms of seafood per year, while those in the Global South, nine kilograms. The reasons for this disparity include differences in human population and fishery productivity, fishery exports and imports, and the harvest of fish by foreign versus domestic fleets.

Fish also contribute to human nutrition indirectly through fishmeal. Some 30 million tons a year, a third of global catches, are reduced into about six million tons of fish meals and oils; the majority goes to feeding livestock like pigs and chickens, while aquaculture and industrial purposes get smaller portions.

GEOGRAPHIC DISTRIBUTION

Geographic distribution of fisheries stocks is very uneven. Some species are immobile or localized, like mollusks or shrimp, while others like tuna are highly migratory. Estuarine and reef ecosystems can equal the most prolific terrestrial ones in terms of productivity. Upwelling zones—where currents at continental margins push up deep water and mix it with surface layers—are also highly productive. The oceans as a whole are estimated to produce two-fifths of the earth's total primary productivity. In marine ecosystems, a productive plant biomass feeds a proportionately larger standing stock than terrestrial ecosystms. Since much of that stock consists of zooplankton that are not harvested by people, fisheries are more dependent on secondary and tertiary consumers, which are more abundant in the water than on land per unit of primary productivity. Target species on the high seas tend to be trophically more distant from primary production than those of estuarine and inland fisheries.

For thousands of years, people have engaged in fisheries, but the extent of exploitation expanded with the increase in oceanic navigation in the 16th century. The Grand Banks fishery for groundfish was incorporated into European-centered trade networks at this time, and became a prize contested between the maritime powers. In the Atlantic world economy, salted fish was a cheap source of protein for poor Europeans and African slaves in the Caribbean. Whaling expanded to supply oil for lighting and the finest lubricants available for industrial machinery.

These harvests did little to exploit the potential wealth of the sea, however, nor did the artisanal fisheries that existed in most parts of the world. The limits of the world's oceans became more visible after the industrialization of Global North fisheries from the late 19th century on through advances in shipbuilding and the means to preserve, distribute, and market seafood. Worldwide fisheries production stood at some 45 million tons in 1945. Growth in production was rapid after this time, but has since stabilized and the majority of fish stocks are now presumed to be either fully or over-exploited. Foreign fleets, decolonization, and the prospect of offshore mineral wealth spurred a movement toward extending jurisdiction over the sea to 200 miles by coastal nations. These territories were enacted by the late 1970s and are now known as Exclusive Economic Zones (EEZ's). A lack of controls on new entrants and national fishery development programs in northern countries followed extended jurisdiction and quickly replaced or surpassed the excluded foreign fishing capacity. This high fishing pressure and the treatment of the nationalized sea as a resource frontier contributed to the collapse of many fisheries since this period, such as the cod fisheries of the northwest Atlantic in the early 1990s.

Another option for northern fishing fleets was to enter agreements with southern countries for access to their waters. The European Union, through its Common Fisheries Policy, enters into fishery access agreements with African countries, exporting European excess fishing capacity south and African fish north. These agreements, which are a major source of funds for many governments, are controversial because of conflicts between foreign fleets on domestic artisanal and commercial fishers and the diversion of fish from nations with many hungry people.

FISH TRADING

International trade in fish amounted to $71 billion in 2004, four-and-a-half times the amount in 1980. Over three-quarters of all fish landings are in the Global South, and south–north fish exports produced a net trade surplus for the south of $20 billion in 2004. Japan, the European Union, and the United States are the biggest seafood importers, taking fishmeal and high-value species and exporting cheaper fishes.

Economic-development aid programs to newly decolonized countries brought about considerable change to those nations' fisheries. The first of these projects, the Indo–Norwegian Project, begun in Kerala, India, in 1952, promoted motorization of traditional fishing craft; introduction of new boat types and fishing gears; and construction of freezing plants for export-oriented production where salting, drying, and fresh products for local markets previously predominated.

THE BLUE REVOLUTION

Fisheries modernization, often called the Blue Revolution, created commercial fleets in many southern countries and increased export earnings, and its new technologies were selectively adopted by many artisanal fishers. It also exacerbated conflict between fishing sectors as the new fleets, which received most international development aid and often enjoyed state support, harvested fish stocks utilized by the preexistent fishers and used destructive gears such as bottom trawls. The modern fleets had their own problems, and many became bankrupt during the era of structural adjustment that dismantled state support and increased the prices of imported inputs. Likewise, those small-scale fishers who adopted motorization found themselves in great difficulty meeting increasing expenses under structural adjustment.

Fisherpeople in places like southern India organized into social movements from the 1970s onward to restrict the activities of modernized fleets. These groups have won some victories and gained national and international awareness of their grievances, but most development assistance continues to privilege capital-intensive, export-oriented fisheries. While much modernization has taken place, artisanal fishing are still estimated to harvest a quarter of global landings.

Fisheries have a range of ecological effects on target and nontarget species. Fishing takes biomass out of the marine environment and changes the age profile of fish populations. It can alter predator and prey relationships and disturb benthic flora and fauna, which can have secondary effects. Overfishing can result from harvesting organisms before reaching maximum size or value, or reducing organisms' their ability to spawn or otherwise reproduce.

"Bycatch," or the harvest of unwanted, non-target species, amounted to some 27 million tons in a 1994 estimate, the equivalent of 30 percent of global fish landings. Most of this "bycatch" is not brought to shore but returned to the sea, often a large proportion dead or dying. Some fisheries, such as shrimp trawling, have on average high bycatches of several times the weight of target species landed, while others such as herring and anchovy have very little. Bycatches rearrange energy flows through marine ecosystems, with seabirds benefiting the most as witnessed by explosions in their populations correlated to increases in bycatch-intensive fisheries. "Bycatch" provoked the two most prominent international trade disputes over fisheries to date, the tuna–dolphin and turtle–shrimp cases, both of which involved the World Trade Organization or its predecessor in rulings over environmental concerns about harvesting practices.

Marine benthos, the organisms that live on the sea bottom, can be greatly harmed by fishing gears that interact with the seafloor. Sandy and muddy seafloors with little emergent benthic life can return to a pre-fished condition within six months or less, while areas with more surface roughness and abundant epifauna like immobile filter feeders could take many years to recover.

FISHERY SCIENCE AND MANAGEMENT

The twin goals of fishery science and management—developing fisheries resources and protecting them from overexploitation—form the foundation of bioeconomics, which aims for the maximization of surplus value from a given fishery while sustaining the conditions of production. To achieve these ends, managers sample fish populations to derive stock assessments and guidelines for harvest. One sampling technique is surplus population modeling, which shows the number of fish over natural mortality a fishery may harvest to reproduce the population. Management attempts to maintain populations at a rate of maximum surplus production, where neither too few breeding stock exist to reproduce nor too many adults to slow down rates of increase. The rate of harvest that approximates this condition is known as Maximum Sustainable Yield (MSY). Given that fishery population parameters are very difficult to know with certainty and environmental factors may alter conditions unpredictably, managers may set a Total Allowable Catch (TAC) according to a Maximum Consistent Yield (MCY) that factors in a precautionary margin. Another target often used in management is Maximum Economic Yield, the harvest that produces the greatest net return on aggregate capital investment.

The concept of "The Tragedy of the Commons" is synonymous with fisheries because of the common property nature of fishery resources. Open-access fisheries are prone to overcapitalization, where more is invested than necessary to harvest a fishery stock. This reduces overall fishery profitability and can aggravate tendencies toward overfishing. Mitigating these tendencies has taken many forms, most commonly limits on participation, restrictions on gear types, and time and spatial closures of fisheries. Marine Protected Areas (MPA's), where little or no fishing is allowed, have become increasingly popular. While proponents of fishery modernization have pushed for Individual Fishing Quotas to resolve common property problems through marketization of access, this trend is opposed by many fishers who see it as a means of dispossessing them from their livelihoods. Common property theorists offer an alternative prescription for co-management of fisheries through institutional mechanisms to control and allocate access to resources. Perspectives from political ecology that examine the distributional effects on producers from conservation programs are important to the future of fisheries as terrestrial natural resource management strategies are increasingly employed in aquatic contexts.

Flight

FLIGHT IS THE process of moving through the air. It occurs among many animals, notably birds, which employ true or powered flight through the use of wings and specially adapted bone and feather structures. Other animals and some plants can use gliding for flight with slightly less volition over direction and range of flight. Gliding relies upon a body or shape that offers resistance to the air and possibly using upwardly moving air thermals to maintain or increase height. The purposes of flight in nature include mobility, escape, ability to reproduce, and the search for food.

The human desire to achieve the freedom of flight inspired the imagination of many scholars and scientists over the centuries. Leonardo da Vinci sketched a flying machine reminiscent of modern helicopters. The first successful attempts to enter the atmosphere were achieved by large hot air or other gas-filled balloons which, obtaining a density of less than the surrounding air, float and can be maneuvered by machinery. The author H.G. Wells imagined such balloons used as weapons of war, which could fly the oceans to drop bombs on enemy cities. It was not until the early 20th century that powered, mechanical flight was first achieved; the brothers Wilbur and Orville Wright were instrumental in designing and flying such machines. This period coincided with the growth of mass manufacturing facilities that assisted in the rapidly increased production of airplanes for use in World War I. As weapons, airplanes were initially of little importance and were used largely for reconnoitering until the invention of the synchronized machine gun. Subsequently, the possession of air superiority has become an increasingly important military goal, and the technology and expense devoted to it has become of enormous significance in the global economy.

Notable developments in flight technology have included jet engines, guided missiles, large passenger airplanes, and the entry into space. Men have walked on the moon, but not on more distant astronomical objects. Unmanned probes have been dispatched with some success. In addition, the same form of technology has been used to set numerous satellites into space around the globe, which has helped spread telecommunications applications around the world.

Improvements in flight technology have enabled cheap air travel greater numbers of people able to travel long distances, which has intensified with growth in the number of budget air carriers. Flight has been very influential in the creation of a global tourism industry and international business. This has not been an entirely beneficial process, as large areas of land have been given over to creating airports and the flights are significant contributors to pollution. Noise pollution near airports is a major problem for residents and can cause health problems. The burning of hydrocarbon fuel by airplanes, among other byproducts of powered flight, makes them one of the biggest contributors to global climate change. Air flights have been threatened by terrorist activity, shot down by rockets, hijacked and used as a weapon, or blown up in midair. The terrorist attacks in the United States on September 11, 2001 are perhaps the most well known of a series of such attacks. One consequence of this is the increase in security in airports and the inconvenience to passengers.

Floodplains

AS RIVERS EXTEND from high areas to the lower lakes or seas, they pick up silt or alluvium and deposit it further downstream. The flow of water tends to decelerate as the amount of alluvial material increases, and because the slope along which the river flows tends to flatten. Depending on the kind of ground through which the river moves, the water may continue downcutting into the ground, or else build up the floor and walls of the river through alluvial deposits. Where the latter occurs, a floodplain may be created in which the river flows laterally and covers the land during times of high flow. In these cases, the flat floodplain can be rapidly flooded and thereby bring about large-scale displacement and drowning of people and livestock, and considerable devastation. The country of Bangladesh, in particular, suffers from the regular flooding of the dozens of rivers that criss-cross the country coming from the Himalayan Mountains to the north. Floods kill thousands, and millions are made homeless or marooned for extended periods of time.

The propensity of rivers to flood their plains in northern and central China has led not only to unknown millions of deaths, but also to the creation of immense engineering projects aimed at controlling the flow of water and providing irrigation for large-scale agricultural activities. This control of water has enabled the Chinese state to create and sustain a civilization lasting millennia. However, such engineering prowess has not been available to all states, due to to geographical reasons. The interaction between the variables that influence the flow of a river can lead to a very diverse range of floodplain surface development, buildup of vegetation, and the creation of natural, although often temporary levees.

The deposits of alluvial material, together with flooding, can create fertile land that is very valuable for agriculture, and can extend over very wide areas. The Mississippi floodplain, for example, extends up to 80 miles across and has an estimated total land area exceeding 50,000 sqare miles. Since flooding erodes existing topographical features and deposits soil in low-lying areas, the floodplain becomes increasingly flattened, which extends the reach of the floodplain and makes it easier to work for agricultural purposes. For many millions of people, the river and floodplain close to where they live represents both the source of their livelihood and the most likely threat to that livelihood.

Changing patterns of weather associated with global climate change and the unpredictability of emergent weather phenomena mean that the threat of flooding may be exacerbated in the future, and may affect even some of those floodplains for which adequate river management precautions have been put in place. The flooding of New Orleans as a result of Hurricane Katrina demonstrates the vulnerability of even one of the most technologically advanced societies in the world. The costs of designing and executing the engineering projects necessary to pacify rivers with the potential to flood are already enormous. Many states have sought to tame the rivers through the use of dams, which have the additional benefit of generating hydroelectric power. However, the justice of upstream-dwelling people restricting the flow of a resource on which perhaps millions of downstream-dwelling people rely (as in the case for example of the Mekong) is highly contested.

Floods and Flood Control

FLOODS OCCUR WHEN a body of water, e.g., a stream, lake, or sea, overtops its normal channel or basin because of excessive inflow of water or geophysical or atmospheric activity. The two broad categories of floods are stream flooding and coastal flooding. Most types of floods are a very normal part of the hydrological rhythms of water bodies. In fact, many riparian and coastal systems generally depend upon cycles of flooding to maintain a healthy ecology. Human societies in coastal and riparian regions have evolved agricultural and resource extraction systems dependent upon cycles of flooding to maintain productivity and sustainable livelihoods. Since the onset of the Industrial Revolution, urbanization, and increasing populations, however, the equation between human societies and floods has changed into a largely negative one.

TYPES OF FLOODING

Of the two broad types of flooding, stream flooding impacts more people than coastal flooding because of the higher concentration of human populations in river valleys. The world's great river valleys—the Nile, Tigris-Euphrates, Indus, Ganges, Huang He, Yangtze and Mei Kong were not only cradles of human civilization but also have extremely high population densities. Natural causes for stream and river floods include seasonal snow melt or precipitation, glacial slip and/or landslides in the headwaters. Glacial slip happens when a glacier in the headwaters of a stream breaks off and slips into the main channel, causing temporary damming of the channel. The dam inevitably breaks from the pressure, causing a wall of water to flow down the channel. Glacial slip and landsliding can cause some of the most sudden and devastating floods.

Sudden, high-level flooding is also called flash flooding, and can also be caused by intense precipitation. Flash floods have the most adverse impact for life and property. If the ground is fully saturated as a result of prolonged precipitation, even very small amounts of precipitation on saturated ground in a watershed can cause intense flood events.

Beyond the natural causes of flooding, human impacts on watersheds, such as urbanization, deforestation and agricultural activity further accelerate flood peaks. Smaller amounts of precipitation in a watershed naturally flows downhill as surface runoff. A considerable amount of precipitation is interrupted by a well-vegetated watershed, and is stored in the plants or reevaporated into the air, percolated into the ground, or directed into the water table. Urbanized surfaces with concrete and asphalt cause precipitation to flow out of the watershed as surface runoff, causing higher flood peaks downstream. Furthermore, agricultural or deforested surfaces lack vegetative cover to intercept the precipitation, or have been compacted to the extent that their absorptive capacity is much lower than a natural surface, causing similar impacts as urbanized surfaces. Human modification of watersheds all over the world is becoming a more important cause of downstream flash flooding.

MANIPULATION OF WATERWAYS

Human manipulation of streams for irrigation, flood control and navigation have also impacted the pattern of flooding in world's streams and rivers.

Increasingly, it is difficult to find streams or rivers that have not been manipulated. Part of the problem is increasing human occupancy of floodplains. The spatial extent of a floodplain is by definition the area along the stream channel, which may be flooded in the normal rhythm of flooding in a stream. Humans have occupied floodplains since the dawn of civilization because of the availability of fertile soils, hydropower, and river transport. Many preindustrial societies were well adapted to the cycles of flooding along their streams, but with higher population levels, urbanization, and industrialization, modern societies are increasingly inflexible in the face of cycles of nature. Consequently, modern societies have increasingly tried to control and tame streams and rivers instead of trying to adapt to their rhythms, with disastrous results.

Development of dams, canals, barrages, and other diversion structures on rivers for irrigation purposes is today considered an important and legitimate use of water resources—to an extent. As more and more water is withdrawn from streams, their normal flows are curtailed, leading to increasing deposition of silt in the stream channels, leading to lowering of the channel capacity of the streams. Even moderately high flows of water, which otherwise could have been accommodated in the stream channel, end up overtopping the banks of the channel, causing damage to life and property. Neither the Colorado River delta nor the Syr and Amu Darya deltas in Central Asia makes it to the sea in most years because of excessive water withdrawals upstream, causing loss of livelihoods for the people living in the delta and immense damage to ecosystems.

Dams are a popular means of water development for irrigation, power generation and flood control. Whereas dams have proved themselves effective in controlling low to moderate intensity floods, their impact on river geomorphology downstream has not been very positive for flood peaks. Dams serve to lower the channel capacity of the streams. Since all dams are subject to failure, in the event of large inflows of water, they can actually serve to accentuate flood peaks downstream from the dam site.

Levees are another popular means of flood control and maintaining navigability of streams. On many of the world's great rivers, from the Mississippi to the Indus to the Huang He Rivers, levees line the channels, facilitating human encroachment upon the flood plains. Levees, depending upon their capacities, are effective in retaining surplus water within stream channels in the event of low to moderate flooding. Levees ensure that rivers stay within a course that a society deems convenient. However, in the long run, as rivers and streams continue to deposit silt within their levee-enclosed channels, stream beds can become higher than the surrounding flood plain. In the event of a levee breach, the flood peaks in the flood plain can be much higher than expected. All levees are designed for certain flood peaks; a levee may be designed for a flood peak equivalent to a flood with a 100 year return period, or 1% chance of happening in any given year. The return period calculation based on histor-

Mitigating vulnerability of the population to the adverse effects of flooding is key to reducing damages.

ic floods is nothing more than a projection based on past record. But the role of levees in controlling low to moderate flood peaks, coupled with the inflated sense of certainty that the "return period" statistic conveys, instill a false sense of security among the floodplain residents. The result is more intense human use of floodplains, more levee building and greater devastation when the levees inevitably fail or are overtopped. Furthermore, levees require large capital outlays to build and maintain. Most societies can simply not afford the expense for their maintenance and hence must seek adaptation to flood hazard rather than outright control.

COASTAL FLOODING

Coastal flooding is growing in importance due to the increasing number of humans living in coastal regions. With increasing globalization, many of the world's largest metropolitan areas are in coastal areas. Furthermore, in countries like the United States, Netherlands, Bangladesh, and China, along with island nations, very high proportions of the populations live in coastal regions.

The main cause of flooding in coastal regions is tropical storm activity. Intense tropical storms are called hurricanes, typhoons or cyclones, depending on the region. Tropical storm activity is largely limited to tropical and subtropical regions, though storm systems can and do penetrate deep into the higher latitudes to cause damage.

Hurricanes can pack very high-velocity winds and intense rainfall, causing storm surges in coastal regions. Hurricanes draw their energy from the warms waters of tropical seas and they lose their energy very quickly once they come on land. Barrier islands and coastal mangrove swamps serve as natural barriers to storm surges. In the second half of the 20th century, however, there has been increasing human occupancy of barrier islands. In fact, in places like the southern United States, they are considered prime real estate because of their recreational amenities. Consequently, property damage has been increasing with every successive hurricane that has hit U.S. coasts. In developing countries, however, such as Bangladesh, people flock to the low-lying barrier islands because of economic necessity. With increasing populations and most of the prime inland land already taken over, the armies of landless have little choice but to move to the more dangerous, low-lying areas.

MITIGATING FLOODS

There is no known way of controlling a hurricane. Some engineering interventions can be somewhat effective, such as reinforced building construction and sea walls. But even these solutions have their limits, with the result that even in weathier countries, the best course of action in the face of hurricanes is speedy evacuation. With developments in meteorology, satellite-based forecasts, and the diffusion of media, societies have a much greater capacity to predict and disseminate information about the onset of hurricanes days in advance of landfall. This is particularly true in developed countries. Once the warning has been received, these countries also have the infrastructure to evacuate large numbers of people from danger zones. Recent experience of hurricanes in the United States, however, has shown that there are large segments of the population who either do not get warned in good time, or do not have the resources to evacuate—e.g., the poor, ethnic minorities, single-parent households, and the elderly.

In poorer countries, the reach of electronic media is relatively limited, compounded by absence of infrastructure and resources for a timely evacuation, even if the warning reaches the at-risk populations in time. In these countries, everyone who is exposed to the risk of hurricanes is not necessarily equally vulnerable to them. Vulnerability is a key concept to understanding the pattern of damage from all types of hazards, including floods. Vulnerability is defined as the susceptibility of individuals or groups to be adversely affected by environmental extremes and their relative inability to recover from those adverse effects. In the less-developed countries, women, children, elderly, and poorer segments of the population are more vulnerable to hurricanes. Women, particularly in patriarchal societies, may not have the education or confidence to make decisions on behalf of their households in the event of an impending emergency. The elderly and children, with their weaker immune systems and limited mobility, may be more exposed to waterborne diseases that may break out in the aftermath of coastal flooding.

In case of both riverine and coastal flooding, mitigating vulnerability of the populations to the adverse effects of flooding is key to reducing damages. Many researchers have documented the profile and location of populations vulnerable to flood hazard and the complex causes for their vulnerability, demonstrating that (1) human manipulation of stream hydrology in the name of progress has created new spatial distributions of flood hazard; (2) hydrological manipulations have often benefited a few powerful segments of the society at the expense of exposing larger, weaker segments to flood hazard; (3) flood protection for urban areas often accentuates flood peaks for upstream and downstream rural areas; and (4) segments of population are differentially more vulnerable even at the same location because of their limited access to resources, lack of education, marginal social status, age, and gender.

A different stream of research, also known as *pragmatist*, has been concerned with human societies' "range of choice" in the face of flood hazard, and was pioneered by Gilbert White in the first half of 20th century. According to pragmatist research, human societies have an infinite range of choices in the face of environmental hazards, which is curtailed by the exclusive focus on engineering solutions to hazards in general and flood hazard in particular. The key pragmatist insight considers multiple solutions through scientifically informed and reasoned public debate, including nonengineering solutions to flood hazard.

Nonengineering solutions found particular resonance in the policy field. In the United States, for example, public policy goes beyond building levees, dams and protective civil works to include flood insurance, flood plain mapping, flood warning, evacuation, flood-proofing of houses, and wetland restoration.

Nampho Dam

One of the largest dams to prevent floods is the Nampho Dam or the West Sea Barrage located near the port city of Nampho (or Nampo) in North Korea. Its primary task is to regulate the water level of the Taedong River to prevent the flooding of Pyongyang, the North Korean capital. Its secondary roles are to help with the irrigation of land, and stop the intrusion of seawater into freshwater.

The Nampho Dam is 10 miles west of Nampho and consists of a 6 mile long series of dams, three lock chambers and 36 sluices. Going across the mouth of the Taedong River it goes from the village of Schaegammun on the north, to the southern bank of the river, connecting with Phi Island. It will allow the passage of ships up to 50,000 tons and was completed in five years, work starting in 1981 and being completed in 1986.

Throughout recorded history there has been regular flooding of parts of Pyongyang and also the nearby areas. Indeed it was in the swamps near Pyongyang that the first U.S. ship into North Korea, the Sherman, ran aground in 1866. The Nampho Dam was a major accomplishment of civil engineering. It is visited by many international tourists to North Korea, among them being Jimmy Carter—a painting of Jimmy Carter with the North Korean leaders Kim Il Sung and Kim Jong Il dominates the tourist center near the dam. It is also often used as a backdrop for North Korean television news broadcasts and appears on some North Korean postage stamps. The estimated total cost of the dam has been put at about $4 billion.

CIVILIZATION AND FLOODPLAINS

Human civilization originated in the floodplains of the great rivers of the world and for good reason. Cycles of flooding replenished the fertile soils of great river valleys and allowed for increased agricultural production, as well as enhanced fisheries. Agricultural systems were well adapted to cyclical floods and almost depended on them for their sustainability. In the Nile River, the ancient Egyptian calendar was based on the cycles of the Nile's floods. In the Mei Kong River basin, entire cultures have developed around flood farming and fisheries that are made available by the floods of the Mei Kong.

Fluoridation, Drinking Water and

FLUORIDE IS ONE of the most abundant natural elements on earth, and is found in U.S. drinking water. Fluoride is located in the earth's crust as well as in the air and water. Fluoride is also a nutritional source for our body; it maintains our body's proper development and growth. The addition of fluoride to drinking water has been shown to assist in maintaining oral health by preventing tooth decays, when it is at a level prescribed as safe.

Originally, researchers and scientists found that the people living near drinking water supplies with natural enhanced fluoride levels close to 1.0 part per million (ppm) had fewer visits to the dentist for cavities than those who did not. Normally, the level of naturally occurring fluoride is usually too low to benefit oral health. *Fluoridation* is the process that augments naturally occurring levels of fluoride in drinking water so that the element is effective in preventing tooth decay.

Usually when the level of natural fluoride in water is greater than 0.7 ppm, then that water is considered to be naturally fluoridated. Throughout the United States today, 67.3 percent of the population has access to fluoridated water, mostly through the water fluoridation process. Grand Rapids, Michigan, was the first city to have manually adjusted the water fluoride level to 1.0 ppm in 1945.

Fluoridation of drinking water not only reduces tooth decay, in some cases it prevents teeth from decaying at all. It works by combining with saliva in the mouth to form a protective coating on topmost layer of human teeth, known as tooth enamel. Fluoride not only can help prevent cavities while the teeth are still developing, but even after the teeth have been completely developed.

Though there are many who praise the benefits of fluoridation, others are opposed to the idea of altering the percentage of fluoride in drinking water. Experiments were done on rats at different ages and those who were given the same dosage of fluoride had different results, depending on their age. The results of the experiments showed that those who were exposed to the fluoride before birth were hyperactive throughout their lives while others suffered depression. Some of the experiment subjects were even found to have brain and kidney damage. The level of fluoride in the water given the rats was 1.0 ppm, the same level that is considered the beneficial for humans. The reactions from the rats were considered toxic effects and humans could possibly have similar reactions. Throughout the United States today, many associations dispute the health benefits and potential negative effects of fluoridation.

Fodder

FODDER CROPS ARE plants grown exclusively or primarily for the purpose of feeding livestock. They include maize, clover, and alfalfa, which are favored for their palatability for livestock and because of their ability to bind nitrogen from surrounding atmosphere and soil, which significantly enhances the protein value of the fodder and hence increases rapid and healthy growth of the livestock. The three main classes of fodder crops are grasses, legumes, and root crops. Fodder may be grown on temporary meadows or in natural settings, but in societies with more advanced agricultural industries, it is likely that dedicated land will be set aside for regulated and intensified growth of fodder crops. Compound foods are more common for livestock in developed countries, which have resources to maximize rapid growth by mixing different types of input.

Widespread animal rearing in a region requires intensive fodder growing, which leads to the transformation of the land. For example, the clearances of the Highlands, when Scottish crofters (smallholders) were forcibly evicted by English landlords to make way for sheep to graze on the land, was a result of fodder crop growth. The extensive use of U.S. land for cattle is also inefficient in terms of overall food production value.

However, land use change, in which land of marginal value is claimed for fodder growth, has enabled increases in food security and improved health for many people. At the same time, the space for shifting cultivation around the world has been reduced as population increases and desertification processes reduce the amount of land available overall. In countries such as Laos, where livestock has traditionally roamed free in forest or jungle land because of the limited amount of naturally occurring fodder available for large herbivores, these shifts in land use are both increasing the amount of agricultural land as a whole while converting the ways in which people have lived for many generations.

The commercial opportunities from animal slaughter has led to the use of animal material in fodder. This is in itself unnatural, as it leads to some natural vegetarians ingesting meat-based ingredients; contaminated animal fodder has been linked with the spread of bovine spongiform encephalopathy ("mad cow disease") and other conditions. It is also believed that the use of fish meal for animal fodder on a commercial basis has also contributed to the denuding of oceans and the collapse of their ecosystems.

Food

WE MUST EAT in order to survive. Food contains energy, vitamins, and nutrients necessary for the human body to function properly. But people's eating habits vary considerably from one region and cultural sphere to another.

One reason behind this diversity is the global variation of the natural environment. The earth has a myriad of variably sized habitats and ecosystems, which affect the availability of foodstuffs. For example, people residing along waterways and coasts have traditionally eaten more fish than those living inland. Human curiosity, mobility, and the subsequent exchange of ideas and goods has greatly diversified these patterns. New food items and ways of preparing and consuming food have typically spread along trade routes, landing in the primary centers of exchange.

The dependency of cities on a continuous food supply from the countryside has further shaped the regional patterns of food production. Land around cities is typically more valuable, which directs agricultural production in these areas toward labor-intensive, easily perishable food items that need to reach their urban markets and processing facilities without delay. One example of this regional differentiation per land value, production costs, and demand is the dairy and vegetable production "belt" around the cities in the Great Lakes area and eastern seaboard in the United States. Meat, corn, and wheat can be produced farther away, on cheaper land, but still within good transportation connections to processing plants and urban centers.

Urban settlement is a direct result of agriculture. For an estimated 2.5 million years, humans lived as hunters and gatherers. The gradual development of agriculture enabled them to give up their nomadic lifestyles and cluster in settlements. The earliest evidence of planted crops include rice in what today is South Korea (about 15,000 years ago) and figs in the Jordan River Valley in the Middle East (11,000–12,000 years ago). Dogs, goats, pigs, and sheep were among the first domesticated animals.

Surplus food produced by the land encouraged a differentiation of tasks and increased trade between the settlements. Specialized professionals, such as makers of tradeable goods, administrators, merchants, and soldiers, were supported by the producers of food. Food thus became a strategic resource, guaranteeing survival, increased prosperity and power. The saying, "armies marching on their stomachs," is well known, for only well-fed troops stay healthy, disciplined, and capable of efficient combat. Mighty cities have fallen after their supply of food has been cut off and their defenders have faced starvation to death.

GLOBALIZATION

The trade of food between cities and countries expanded the scale of movement and business transactions, paving the way for what today is called *globalization*. Early international traders, such as the Greek and the Venetians, introduced new food items and their preparation methods to domestic and foreign lands. The colonization of the New World by Europeans added to the selection of spices and luxury consumables in Europe. "Fashion foods" in Europe of the era included New World drinks such as cocoa, tea, and coffee, and several fruits, which all led to innovations in kitchenware, serving styles, and socializing. As result of this globalization of food, diets, customs, landscapes, habitats, and economies changed dramatically on a global scale.

The commercial exchange and related rivalry between the world's superpowers created unstable dependencies, the legacy of which is still present in global politics and economy. Huge parcels of conquered land were turned into producers of raw materials and were designed to serve the needs of colonial masters. This production of export-serving "cash crops" often impoverished soils, homogenizing and limiting local agricultural production. The former colonies in Africa, Asia, and Latin America now have political independence, but their national economies may still depend on the production and trading patterns created during the colonial–imperial era. The contemporary world is highly unbalanced and unequal from the perspective of food production, distribution, and consumption. While some countries struggle to feed their population and children grow up malnourished, others try to resolve problems of overproduction and life-threatening obesity.

Beef from Brazil and lamb from New Zealand compete with domestic meat production in many European countries.

Food now travels across the globe faster and more comprehensively than ever before. Industrial mass production, trade, technological innovations, and expedient transportation and communication networks support a complex worldwide food system of supply and demand. Ease of travel allows for new culinary experiences, acquiring of tastes, and production of new customer demand. Migrants introduce new foods and foodways to their host populations, and create new demand for imports. A variety of import and export companies, specialty restaurants and corner groceries have sprung up in urban centers, diversifying local culinary landscapes. For the wealthy, everything is available all the time: fresh tropical fruit are sold year-round in developed countries, and beef from Brazil and lamb from New Zealand compete with domestic meat production in many European countries. Seasonality and food storage and transportation challenges have diminished significantly over the past few decades. Change has accelerated, as simultaneous global, local, homogenizing, and diversifying forces complement one another and individuals, goods, and ideas move to create global flows and patterns.

BOUNDARIES AND IDENTITY

The concerns and the tightening control over imports, exports, and national boundaries point to the continuous strategic importance of food and food safety to national interests. National governments seek to maintain self-sufficiency, reducing their dependency on outside supplies and guaranteeing continuity and quality of the domestic food supply.

Food-related safety concerns is a factor dividing the world into nation-states, countering some trends of globalization. Attention has turned toward local and regional production as an environmentally sustainable alternative to longer food chains, as a way to support employment, and as an expression of local, regional, and national feelings of belonging. This illustrates the importance of food for human identity.

Particular food items and foodways have thus gained strength as markers of local, regional, or even national pride and as profilers of their production regions. The European Union supports local and regional specialties in its member countries by protecting their name, traditional method of preparation, or geographical origin: Feta cheese of Greece, the prosciutto ham of Parma, Italy, and the Jersey Roy-

Food Safety and Ethics

Industrial mass production and processing of food, its global trade, and the year-round abundance are sources of ethical and environmental concerns. Also criticized are the treatment of animals and the usage of pesticides, fungicides, chemical fertilizers, growth hormones, and gene manipulation technologies. Ideologically motivated eating habits, consumer choices, and food boycotts are grassroots ways to manage concerns related to food items, their production, and consumption. Some choose a form of vegetarianism or veganism for ethical and moral reasons related to animal rights. Others object to the environmental costs, economic inequality, and health risks associated with agribusiness. They may therefore grow some of their own food, buy organic produce from local independent farmers, and select products distributed through Fair Trade networks. Particular companies may be pressured through boycotts to revise their production or marketing ethics and practices. Examples include consumer boycotts against Coca-Cola, Nestlé, and McDonald's.

Concerns about food-related health risks among Western consumers grew significantly in the late 20th century, when issues about animal diseases, growth hormones, antibiotics, and toxic residues in animal agriculture and food processed for human consumption made global headlines. Under the conditions of expedient mass production, open borders, and global trade, animal diseases spread faster than ever before, making consumers question the safety of their food.

Consumers began to avoid certain products, and governments issued warnings or set restrictions on certain food items and produce originating from particular countries. For example, the "mad cow disease" epidemic in Britain devastated the country's agriculture, export income, image, and lives of individual farmers, as animals were slaughtered en masse, farms and meat-processing facilities were shut down, and the world refused to import and eat British beef.

al potatoes of Britain. In the United States, place-specific food associations include Maine lobsters, Idaho potatoes, and the Philly cheesesteak sandwich. Culinary hybrids created through cultural contacts and experimentation have become integrated into "national" cuisines. For example, the stereotypical dishes of "Mexican" and "Japanese" food were first invented in the United States, then introduced to those countries whose cuisine they are perceived to represent. "National cuisines" are illusions in a sense that they typically are collections of regional specialties and imported ingredients, preparation methods, and dishes, which continue to evolve. However, they maintain strong national profiles, reputations, and stereotypes, such as Italians living on pasta and an English meal as incomplete without brown gravy and pudding.

CUSTOMS SHAPED BY ENVIRONMENT

Availability and customs steered by the environment (for example, preservation by drying, salting, or immersion in vinegar or oil) have influenced ideas of desirability and acceptability. The same consumer may be disgusted by one rodent (rat), but happily eat others (rabbit, hare, guinea pig). The same fish may be tasty for one person when seasoned with salt and vinegar, but will not go down dried.

The variety and relativity of food-related customs, preferences, and taboos confirm that these practices are historically, socio-culturally, and environmentally conditioned. Most Europeans and North Americans would typically not eat insects or dogs, but grasshoppers are a salty street snack in parts of Asia and Latin America, and a particular dog breed makes a prestigious specialty in parts of Asia. A variety of meats produced by other domesticated animals, crabs, mussels, snails, and frogs are delicacies for one, but disgust another. These boundaries are very strong.

For example, it is hard to see that the controlled farming of rats would help solve the world's protein deficiencies, even if the omnivorous, quickly reproducing rodent might be environmentally, ethically, and economically more sustainable than large, slowly reproducing and selectively eating farm animals. At the same time, preferences for particular types of fish and meats, and related economic profits, repeatedly lead to crossing of sustainable and ethnical boundaries, shaking the delicate ecological balance of entire ecosystems in particular areas and treating sentient beings as industrial commodities.

INEQUITABLE DISTRIBUTION

It is clear that the range of options and ability to choose are very unevenly distributed across the world. Whereas fashion foods and consumer boycotts may be routine for the privileged wealthy, much of the world's population still focuses on daily survival. Population growth, natural and human-induced environmental disasters, the complex legacies of colonialism and imperialism; and contemporary world politics and economies keep entire countries on the threshold of major humanitarian disasters. In many areas, the sustainable limits of the local environment have been exceeded and the balance may tip over from scarcity to starvation.

Dependency on exportable raw materials, outdated technology, immediate economic and human needs, political instability, unequal land ownership, and commercial greed complicate the improvement of these conditions and interfere with emergency preparedness. Emergency measures, such as international food aid, often come late, may create new dependencies, and cannot replace preventive, long-term approaches to sustainable development. Droughts, fires, overgrazing, overfishing, salinization of irrigated lands, and disastrous cases of mishandling hazardous or sensitive materials exemplify that a variety of natural and human hazards can affect any society, often sending cumulative shock waves across the world.

Food and Drug Administration (U.S.)

THE FOOD AND Drug Administration (FDA) was created as a governmental entity in the United States by virtue of the 1906 Pure Food and Drugs Act passed during the administration of President Theodore Roosevelt. Health problems caused by impure foods had plagued the country since its inception, with both imported and locally produced items responsible for a variety of poisoning incidents. The publication in 1906 of Upton Sinclair's novel *The Jungle*, which documented conditions in the meatpacking industry, was also influential. That book, though dedicated to exposing the harsh working conditions for immigrants, was largely received by the American public as a message about food safety.

The first national law concerning pure food had been passed in 1848 during the Mexican War. However, the growing sophistication of the food and pharmaceuticals industries in a large and rapidly modernizing economy required a much more comprehensive raft of legislation to deal with often predatory commercial interests. State-supported scientists helped farmers to improve their own produce and to introduce the modern scientific innovations in chemical additives and colorings appropriately, while also helping them to identify which of their industrial competitors may have been adulterating their products or otherwise producing sub-standard items.

From the passing of the 1906 act to 1938, the FDA in conjunction with the Bureau of Chemistry struggled to keep pace with the demands for regulation. In 1938, the FDA was greatly expanded in scope and size as a result of the Food, Drug, and Cosmetic Act (FDC) of that year. This act demanded high food safety standards and that new drugs be proved safe prior to them coming on the market. In 1962, in response to the Kefauver-Harris Amendments to the FDC, the FDA introduced new guidelines to ensure that drugs are proven effective before they are sold. In 1968, it acted to regulate microwave cookers and their radiation and subsequently followed this up by considering the safety implications of a range of catering and medical equipment. The FDA's mandate continued to grow as new types of products were brought under its jurisdiction. Between 1990–92, the FDA worked with consumer interest groups to help devise suitable nutritional guidelines with which food producers must comply. Also in 1990, the FDA was a leading figure in trying to create international standards on food and drug safety. In 2002, it was charged with maintaining the food security of the United States in response to possible bioterrorism threats.

The FDA has seen its mandate grow as new products are introduced and as a result of the internationalization of trade. In particular, advances in medical and pharmaceutical sciences have greatly increased the complexity and time required to administer and monitor resource-intensive testing procedures. Intensification of agricultural production has also raised the potential for problems such as bovine spongiform encephalitis ("mad cow disease") and avian influenza ("bird flu"), which demonstrate the dangers of improperly supervised livestock management. The FDA has been as active in monitoring food production facilities as it has been in considering licensing possible treatments for HIV/AIDS and other complex new medical complaints.

New legislative issues emerge from changes in diet and lifestyle, such as the plague of obesity and the threat of mature-onset diabetes. The FDA must navigate between its ability to regulate externally and its willingness to provide incentives to improve citizens' activities and methods. Realizing that safe and healthy products can provide a competitive advantage in the consumer marketplace has been a key finding, and is likely to become increasingly important for the FDA. At the same time, the FDA is also likely to wield increasing powers in obtaining recompense for consumers from companies adjudged to have provided improper goods.

The FDA has come to oversee an enormous part of the overall economy, and has had considerable levels of resources devoted to it in its routine work of testing, monitoring, researching, and formulating policy and legislation. It plans a leadership role for itself, both nationally and internationally, in the search for cures for presently untreatable medical conditions and innovative pharmaceutical delivery mechanisms. It plans to continue its regulatory approach for product testing and to help raise standards globally. A certain culture permeates the FDA and its mandate to protect the public from the myriad natural and unnatural dangers of the world; and some people, whether members of regulated industry or not, find this culture unhelpful and even confrontational. Additionally, ideology drives some to object to the size and the power of the FDA, and consider it to intervene excessively in the profit-making ability of commercial enterprises and that it should, therefore, undergo reform to reduce its power and influence.

Food Irradiation

FOOD IRRADIATION IS the process of treating food with ionizing radiation to eliminate germs and possible disease from the food. The need to treat food for the presence of germs has been known since the work of Louis Pasteur and the invention of the pasteurization process. Food irradiation is a technology that is generally supported by government agencies and food companies. It reduces the spoilage of food and increases the shelf life of a wide range of products. Various techniques are used in irradiation, including bombardment by electrons, x-rays, and gamma radiation. Some consumer groups are concerned with as yet unknown side effects of the process, and oppose food irradiation.

In the United States, a small number of foods are treated with irradiation for specific purposes. For example, pineapples and other tropical fruits from Hawaii are irradiated before importation to the mainland to prevent the spread of fruit fly pests. Other foods for which irradiation has been deemed suitable are spices and herbs, fresh and dried fruits and vegetables, and some types of meat and seafood, all of which are subject to infestation by microorganisms. When such foods are labeled clearly, the amount of consumer resentment to the treatment has been reduced. However, research indicates that consumer resentment increases when the labeling is unclear, unexplained, or appears misinforming. In the European Union, a number of food producers distributing products that have been irradiated, but not accurately labeled, have resulted in official action. However, the extent to which testing of products takes place varies significantly from country to country. Regulations govern the nature of the premises in which irradiation may take place.

Opponents of food irradiation maintain that the process creates harmful free radicals, reduces the quantity of vitamins and other nutrients in food, creates new chemicals within food that would not otherwise be present, and negatively affect the quality of the food. The issue has been subjected to intensive scientific research over the years and the majority has concluded that the process is safe. However, the increase in consumer awareness of global production processes and cynicism about many corporate activities mean that many people continue to treat irradiation with suspicion.

Food Webs (or Food Chains)

FOOD WEBS ARE depictions of the feeding relationships that exist among species within an ecosystem, indicating flows of energy and biomass between trophic levels. Although a food web is a more complex conception than a linear food chain, it remains a relatively static and binary depiction: species either interact or they don't. Despite these limitations, food webs are useful conceptual tools, providing insights into the organization of communities and the interactions among different species within them.

Food webs are organized into trophic (or feeding) levels. Species are categorized as either producers or consumers. Producers or *autotrophs*, literally "self-feeders," constitute the first trophic level—those species that synthesize their own food through processes of photosynthesis or chemosynthesis and includes most plants, algae, phytoplankton, and some species of bacteria. Photosynthetic species use carbon dioxide, water, and the light energy of the sun to produce sugar molecules as well as oxygen. Thus, these species are responsible for producing the relatively oxygen-rich atmosphere that exists on earth today. Chemosynthetic species produce carbohydrates via several different possible chemical pathways. Some use the chemical energy bound up in inorganic molecules (such as hydrogen sulfide), to produce carbohydrates from carbon (derived from carbon dioxide or methane), and oxygen.

Consumers, also termed heterotrophs, feed on other organisms, both living as well as dead. Those that eat the latter are *decomposers* or *detritus eaters*. All organisms eventually enter the detrital food web after they die and decompose or are consumed and their remains excreted. Herbivores, species that consume autotrophs, occupy the second trophic level. Carnivores are species that feed upon herbivores or other carnivores, with those that feed on herbivores occupying the third trophic level and those that feed on carnivores occupying higher trophic levels.

Food webs encompass a number of dynamic and interconnected food chains. A species may be an omnivore, consuming both producers and consumers, eat consumers from different trophic levels, and be preyed upon by a variety of species at different trophic levels, including fellow members of its own species. Some producers, such as Sundew and Venus Flytrap, supplement their primary production with the consumption of animals. There are also temporal dimensions to food webs. Predator–prey relationships may change both seasonally and through the life history of a species. For example, adult herring prey upon juvenile cod or eggs and may, in turn, be preyed upon by adult cod. In addition, some species, such as cod, cannibalize younger members of their own species.

Terrestrial and aquatic food webs are generally separated in space; however, some species facilitate cross-habitat fluxes of nutrients and detritus. Seabirds and some of the large vertebrate predators (humans, pinnepeds, polar bears) link marine and terrestrial food webs, transferring nutrients of marine origin to the land. Similarly, the migratory Pacific salmon grows to maturity in marine waters and returns to spawn and die in the freshwater environments where it was born, thereby connecting freshwater, marine, and terrestrial food webs. Salmon carcasses provide food for a wide variety of terrestrial animals, including bald eagles and bears, and are an important source of marine-origin nutrients in some freshwater streams.

The abundance of higher trophic level species is ultimately dependent on the productivity of autotrophs. A large proportion of the energy, as much as 90 percent, is lost in each trophic level transfer (as uneaten waste, feces, heat, consumer energy, and respiration, and so on). Because of this, there are limits on the absolute number of trophic levels found within an ecosystem. While the first and second laws of thermodynamics dictate that a substantial amount of bottom-up (nutrient driven) regulation of food webs exists, there is some evidence that top-down (predator dominated) control of food webs is or was important in some ecosystems.

HUMAN IMPACT ON FOOD WEBS

There are few, if any, food webs, on earth that have not been significantly affected, or even dominated, by human activities. Humans impact food webs in two general ways: creating deficits by extracting organisms from ecosystems; and by producing subsidies, concentrating and transporting wastes from one system to another. Agricultural production is significant in both respects. Plant-based agricultural systems replace natural systems, substituting monocultures for greater species diversity and extracting most of the primary production from the system for human consumption. The application of pesticides disturbs food webs, creating secondary outbreaks and resurgences of the targeted populations. On the other hand, industrial animal husbandry concentrates manure and other wastes, which if not managed adequately, may pollute aquatic systems, overfertilizing them and ultimately leading to eutrophic conditions.

Commercial and recreational fishing and hunting constitute significant impacts to some ecosystems. Removing predators from ecosystems can lead to trophic cascades, changing food web structure and dynamics, perhaps irreversibly. Pollutants, too, move through the trophic levels of food webs as animals eat and in turn are eaten by others through processes of bioaccumulation and biomagnification, causing problems for organisms at high trophic levels, and especially in northern latitudes, including birds of prey, marine mammals, and babies fed human breast milk. Global climate change may pose the greatest challenge to the stability of food webs, altering growing seasons, changing the geographical ranges of species, creating unpredictability in predator–prey relationships and ultimately threatening many species with extinction.

Forest Organic Act

THE FOREST ORGANIC Act of 1897 established the rationale and management authority for the first forest reserves in the United States. The act was in part a response to debates arising from the passage of the 1891 General Revisions Act, which repealed the 1873 Timber and Culture Act and included a rider granting the president of the United States power to set aside portions of the public domain for perpetuity as forest reserves. By failing to mandate authority for the management and protection of these lands, however, the 1891 act left as an open question the purpose of forest reserves in the United States. By the end of his term in 1893, President Benjamin Harrison had set aside approximately 13 million acres, intensifying the stakes for early conservationists and powerful western mining, timber, and water interests.

The Forest Organic Act stated that forest reserves in the United States were intended to secure "favorable conditions of water flows, and to furnish a continuous supply of timber for the use and necessities of citizens of the United States…" It called upon the U.S. Geological Survey to assess existing and potential future reserves in the public domain. The Department of Interior was named the active managing authority and required to carry out its duties according to systematic, objective, and scientifically driven principles of modern resource management. In this way, the act situated the new forest reserves within the utilitarian foundations of an emerging progressive conservation philosophy.

Following the recommendations of the 1896 National Forestry Committee of the National Academy of Sciences, the act laid out the initial framework for timber management on public lands. The secretary was not only required to protect the reserves from fire destruction, but also for the purpose of preserving growing timber and promoting younger growth, to develop a systematic process to designate, appraise, mark and sell "dead, matured, or large growth trees." Those appointed to prepare the sale can not profit from the sale in any way. In addition, the act stated this timber could not be exported, but sold to purchasers for use only in the state or territory in which it was situated.

The act also addressed the economic concerns of those wary of a persistent federal presence on public lands. Western mining and agricultural interests were appeased in the act's requirement that all forest reserve lands were subject to the "highest and best use." This meant specifically that lands deemed more valuable for their mineral resources or agricultural productivity could not legally be included within forest preserves. With presidential approval, the secretary could recommend returning existing forest reserve lands to the public domain if the land was found to be "better adapted" for other purposes. All reserves remained open to future mineral prospecting and development.

Private property owners were also protected under the law. A lieu lands clause allowed landowners to trade lands located within a forest reserve for lands of equal value located elsewhere. Those choosing to keep their holdings retained right of access to their property. Finally, all water resources, timber, and stone found on the reserves could be used "free of charge by bona fide settlers, miners, residents, and prospectors for minerals, for firewood, fencing, buildings, mining, prospecting, and other domestic purposes."

The Forest Organic Act was significant on at least two counts. First, in conjunction with the 1891 General Revision Act, it marked an historic departure in the general trend of U.S. public lands policy up to that time, from one based solely on the privatization of public lands, to a mix of privatization and the intentional federal retention of selected lands. Second, the act provided the early framework of utilitarian, multiple use, state-based, scientific resource management that continued to shape U.S. forest management through the 20th century.

Forest Management

FOREST MANAGEMENT IS concerned with a range of scientific and management activities involved in the husbandry and administration of forested areas in countries around the world. Forests offer a variety of resources that can be exploited for commercial development, but ineffective monitoring regimes in many countries have led to over-exploitation of the forests, often on an unsustainable basis. The teak forests of Thailand, for example, have been almost destroyed through overlogging.

The rate at which the extensive rainforests of the Amazonian region of South America and elsewhere are being felled not only damages the habitation of the people and wildlife living there, but also has a serious negative impact on global warming. When forest management efforts have sought to replant forests, there have been problems caused by the inability of this method to recreate the diversity of the original forest cover. Further, the loss of trees also reduces the ability of the land to hold water, which contributes to flooding, mudslides, and other problems, causing significant loss of life in many parts of the world.

Forest management aims to balance the opening of forestland to a reasonable degree of public use and commercial exploitation within a framework of sustainability. Forestlands in developed countries are often employed to provide aesthetic, tourist, and recreational opportunities, which places some pressure on a finite resource. In less-developed countries, forests may house valuable, or at least rare, wildlife species, necessitating assistance from governments and nongovernmental organizations (NGOs). Many people need forest resources for hunting, gathering, and fuelwood. Some semi-nomadic peoples practice swidden or slash-and-burn agricultural patterns, which have become unsustainable in the modern world in the face of population density and decreases in available forest land. Assistance is also required to help nomadic peoples adjust to new lifestyles on a sedentary pattern. In several parts of mainland southeast Asia, for example, a number of different ethnic minority groups have become accustomed to growing opium as a cash crop, which has been suppressed to a significant extent in recent years through aerial surveillance and multinational cooperation. Government schemes demonstrate alternative cash crops, including coffee and some types of vegetables. In other cases of inappropriate commercial exploitation of the forest, then the land may be designated a protected area and legal sanctions put in place to prevent the activity. These preserved areas may be combined with tourist destinations in some cases.

FOREST MANAGEMENT PLANNING

To plan for management of forestry, it is important to first map and document the existing extent of the woodland and its flora and fauna. This can be difficult, time-consuming, and expensive, especially when human resources and technical capacity are comparatively low. The mapping process has been considerably facilitated by the availability of satellite mapping services, which are now able to cover the surface of the earth with some accuracy. However, creating new maps does not always help to understand the past nature and extent of forests, before more recent forms of degradation took place. The best that can be achieved, in these cases, is to provide a representation of forests as they were a comparatively few years ago.

Ideally, the forest management plan should be drawn up with contributions from local people and all relevant stakeholders. This can be problematic in those countries lacking a sufficient democracy. Planning should take account of the identification and preservervation of water resources within the forestland, together with the physical infrastructure that may be required for tourism, for people still living within the forest, and any other purposes. Accurate evaluation of the nature, maturity and size of trees, animal life, and profit opportunities should be conducted. This information can empower and inform forest workers and persuade local people or commercial interests of the implications of such acts. Incentives should ensure that not only do they understand the implications of forest exploitation, but that they also have solid alternatives for income-raising activities. Some states have been exploring public–private sector partnerships in managing forests in this way.

Reforestation projects to replace depleted forests or areas that were not previously forested have been comparatively successful in terms of providing plantations of exploitable trees, but less successful in creating diverse forested areas. The use of single species, for example of eucalyptus trees in Thailand, has resulted in depletion of soil nutrients and damage to neighboring species.

Forests

FORESTS ARE ONE of the dominant forms of land cover on earth, and forested landscapes are central in constituting human environment relationships. Human relations with forests are also highly specific, complex, and dynamic, featuring considerable historical and geographical variation, making a universal definition of what actually constitutes a forest difficult.

Nevertheless, the Food and Agriculture Organization of the United Nations (FAO) does attempt to define and track forest cover: "Land spanning more than 0.5 hectares with trees higher than 5 meters and a canopy cover of more than 10 percent, or trees able to reach these thresholds in situ." Even in this basic definition, there is evidence of some subjectivity and convention, as these standards would seemingly exclude much of the far northern boreal forests. Forested regions are generally broken down into boreal, temperate, and arid and moist tropical types, although there is tremendous variation within these categories. Forests are also often classified according to whether they are dominated by coniferous trees (softwoods), deciduous trees (hardwoods), or a mix of each.

Overall, the FAO reports net deforestation on a global level, estimated to have amounted to the loss of 7.3 million hectares per year between 2000–2005. The primary driver of this loss continues to be conversion to agriculture, although the rate of net deforestation has slowed since the 1990s. In terms of forest use, roughly half of global demand for wood continues to come from fuel wood demands, driven by the dependence of one-third to one-half of the world's population on biomass as a primary fuel for heating and cooking. Other significant sources of demand for wood come from industry for the production of wood products such as pulp and paper, lumber, and veneer. Roughly one-third of global forests are managed specifically for the purposes of producing wood and non-wood products and commodities.

FOREST COVER AND SPATIAL TRENDS

Beneath the aggregate trends, however, there are pronounced regional disparities in both rates and drivers of forest cover conversion. For instance, there is actually net afforestation in parts of Europe and in Asia, particularly in China, driven by large-scale planting programs. The FAO also notes conversion in forest types within the forested category, generally from what the FAO calls "primary" or unmanaged forests and from what are called "modified natural forests" to plantation forest types. Although actual plantation forests only account for 4 percent of global forested area according to the FAO, relatively large increases in plantation forest area have been witnessed in the last 15 years in Asia and in North America. Attempts to track the conversion of species-rich, complex forests to typically simpler, plantation-style forests is important because of the pronounced implications for forest biodiversity and worldwide rapid rates of species loss.

Spatial unevenness disguised by these aggregate numbers, and the juxtaposition of net deforestation in some places with net afforestation in others, affirms the importance of understanding regional processes in and of themselves as well as in relation to one another. This includes critical interrogation of the ways in which afforestation may be enabled by or linked to deforestation in others (such as afforestation driven by recreational and conservation policies in one place abetted by the substitution of fiber from distant places). In addition, regional disparities and afforestation in some places reinforces that overgeneralizations about deforestation as a condition of human interface simply cannot be sustained, particularly when this interface is conceptualized in terms of raw population, e.g., "less people equals more forests." Things are just not that simple. Consider, for instance, that the defining feature of European land use since the development of agriculture, and later industry, may well be the clearing of woodlands. Yet over the much more recent past, Europe has become home to the most rapid rates of afforestation on earth, particularly of less intentionally managed forests that are reclaiming significant areas. The political ecology of small, fragmented savannah woodlands in Africa links the misinterpretation of these fragments as signs of deforestation (rather than as evidence of intentional afforestation by local forest users) to a pervasive global imaginary that posits forests everywhere to be in decline. Many undoubtedly are, but not all, and certainly not all for the same reasons.

There are highly specific cultural connotations of "forest," far beyond a word merely to convey a collection of trees.

HUMAN–FOREST RELATIONSHIPS

Forested landscapes constitute social relations and institutions, as well as of systems of meaning and representation governing human–environment relationships, in myriad and complex ways that make forests sites of rich, integrated political ecologies. For instance, forest conversion and management is not only an ecological process but also a human one, with distinct implications in the formation of property rights, political economies, and the reflection and reinforcement of ways that nature is understood. James Scott links the rationalization and ordering of European forests governed primarily for the purposes of commodity production to the territorial and administrative consolidation the modern nation-state.

These schemes represented not only ecological simplifications, but also social ones, as myriad and overlapping use rights and property claims on forested landscapes were rationalized and consolidated in the interests of efficient commodity production, and streamlined administration of increasingly simplified property claims organized in Cartesian grids of individuated and exclusive plots of land. Here we see the complex interweaving of ways of acting and understanding in relation to the natural world with ecological and political economic change. Work of this character also serves to highlight the fact that exclusive claims to individual parcels of land, whether individually owned or state controlled, are by no means typical of the ways in which forest access is controlled and managed in all social and cultural settings.

Rather, many forests (and agro-forestry systems) are characterized by complex and overlapping claims to particular forest species right down to the level of individual trees and shrubs. These specific systems of access may underpin the production of a rich array of wood and nonwood forest products, but they also reflect and reinforce social relations along axes of class, race, and gender.

In fact, the complexity and diversity of relations between humans and the nonhuman biophysical world characteristic of forested landscapes and their appropriation for spiritual, subsistence, and commercial purposes is one of the obstacles confronting seemingly objective, rationalist classification schemes used to organize knowledge of forests. These schemes tend to smuggle in culturally specific and often evaluative notions about what is and what is not a forest, what type of forest it is, and whether or not the forest is healthy or degraded. Visitors from North America to Germany's Black Forest, for instance, often comment on the strikingly ordered, almost sanitized character of the forested landscape, with trees typically of uniform age lined up in neat rows one after another, with remarkably little undergrowth, and with almost sidewalk-smooth paths. The disconnect speaks in part to highly specific cultural connotations of "forest." It is, evidently, not merely a word meant to convey a collection of trees.

In addition, different connotations are seldom innocent. Paul Robbins, for instance, very neatly demonstrates how specificity in knowledge of forests among different social groups can lead to very different systems of forest classification, and different measures of the extent of forest cover. He then implicates these differences in the material "production" of forested landscapes via policy incentives for land management.

Robbins examines forest cover classification in the Indian region of Rajasthan, asking local farmers and land users to classify the surrounding landscape, and then asking professional foresters to do the same. Grouping resulting classification schemes into roughly comparable typologies, he finds large disparities in the total area considered forested by these respective groups. Among the reasons is that a common but invasive woody shrub species called Mexican mesquite (*Prosopis juliflora*) is highly successful in the area, and is considered forest by the foresters. But the locals tend to consider this waste or scrub land, and exclude it from forest. Why?

One reason is that the species tends to crowd out all others, not least because of its poisonous effect on the soil around it, undermining local land uses. While local users tend to classify land as forested only if it is useful to them, professional foresters face institutional imperative from the state to encourage tree cover. If their views are accepted, Robbins notes, this will tend to encourage rather than curb the expansion of Mexican mesquite.

EVOLVING CULTURAL CONNOTATIONS

While cultural constructs of forests may be specific, they are not static. Evidence from English literature and historical records, for instance, indicates that the prevailing connotation of forests was once quite negative, and that forested landscapes in England were represented until relatively recently as dark, mysterious, and generally foreboding places. The emergence of this negative connotation may be linked to the enclosure of forests by landed elites, effectively barring access to peasant and working classes during the 17th and 18th centuries. This enclosure was violent, and violently resisted, lending to forest areas a connotation of danger and threat, at least for those whose rights of traditional access were removed. More generally, the association of threat and evil with forests is very much connected to a negative or threatening connotation of uninhabited wilderness, or "wilde" spaces in the English literary tradition as recently as the 18th century. Only more recently, and largely in the American environmental imaginary, has wilderness taken on an unambiguously positive light. This has been attended by the elevation of old-growth forest landscapes to iconic status. All of this points to the need to approach human–environment relations in forested landscapes with great attention to local specificity and context, while attending to the ways in which the "local" articulates with broader processes of landscape transformation and representation.

Forest Service (U.S.)

THE U.S. FOREST Service is the federal agency responsible for the management of 155 national forests and 20 national grasslands in the United States. A chief forester provides broad policy direction and oversees budgetary matters for the entire Forest Service. The chief reports to the undersecretary of natural resources and environment in the Department of Agriculture, and works closely with the presidential administration and Congress over budgetary and policy matters. The national forest system is divided into nine regions, usually encompassing several states. Within each region, a regional forester oversees management plans, budgetary issues, and coordinates various activities with the forest supervisors for each of their national forests. Each national forest is further divided into districts that vary in size from 50,000 to more than 1 million acres. Each district is run by a district ranger, who oversees a staff of 10–100 persons with specialized training in forestry, range conservation, travel management, resource economics, and anthropology.

The agency's mission consists of five parts: 1) to protect and manage natural resources on national forest system lands; 2) to conduct research on all aspects of forestry, rangeland management and forest resource utilization; 3) provide community assistance and cooperation with state and local governments, forest industries, and private landowners to help protect and manage nonfederal forests; 4) to achieve and support an effective workforce that reflects the full range of diversity of the American people and; 5) provide international assistance in formulating policy and coordinating U.S. support for the protection and management of the world's forest resources. Despite this diverse and broadly defined mission, much of the agency's history concerns the dominance of timber production and the challenges of bringing conservation management issues to the forefront.

The Forest Service was created in 1905 when the Forest Division in the General Land Office of the Department of the Interior was transferred to the Department of Agriculture. Management priorities included protecting water resources and providing an efficient and continuous supply of timber for the nation. The first chief forester, Gifford Pinchot, argued that the nation's resources could best be developed to serve the "greatest good, for the greatest number, in the long run" by replacing the short-term profit motives of unregulated industrial development with rational scientific management, carried out by state and federal agencies.

For the first four decades, the Forest Service worked closely with and realized mutual interests from players in timber, livestock, and mining interests. This arrangement (touted by some as a "iron triangle" or subgovernment), when coupled with athe acency's ideal of scientific objectivity in management decisions, presented a significant barrier to the adoption of new management priorities, constituencies, and interests.

PARALLEL GROWTH OF INTERESTS

However, just such new constituencies, and concomitant tensions, emerged in the post-World War II era. On one hand, rapid economic development, urban expansion, and the rise of new export markets created new demand for timber products. Timber production, which had already doubled during the war to approximately 4 billion board feet (bbf) per year, rose to 9 bbf by 1962, and reached 12 bbf by 1970. On the other hand, the newly expanding middle class increasingly looked to national forests as sites for recreation and relaxation. Environmental and outdoor recreation organizations, many pre-dating the creation of the Forest Service, gained renewed popularity and new political influence.

Concerned that proponents of a wilderness bill might succeed in removing lands from the national forests as wilderness areas, the Forest Service and timber interests promoted the 1960 Multiple Use and Sustained Yield Act. Hoping to pacify wilderness advocates, the act stated that the national forests "shall be administered for outdoor recreation, range, timber, watershed, wildlife and fish purposes." It implied that each use, including recreation and wildlife protection, would have equal priority in Forest Service management decisions. However, by leaving the interpretation of the law to individual forest managers, it resulted in little actual change. The passage of the 1964 Wilderness Act set aside 9 million acres of national forest land as wilderness and required the Forest Service to conduct a review of all unlogged, roadless areas for potential wilderness designation.

New laws such as the 1969 National Environmental Policy Act (NEPA) and 1973 Endangered Species Act also affected the Forest Service by requiring environmental impact statements that mandated public input (in the case of NEPA) and including citizen suit provisions. The latter allowed individuals to challenge federal agency management decisions in court, as evidenced in the 1971 report of the Forest Service's first Roadless Area Review Evaluation required under the Wilderness Act. The Sierra Club sued, arguing that the Forest Service study, which recommended that 6 million acres be set aside as wilderness, failed to examine millions of other potential acres. In response, the Forest Service conducted a second, 1977 study, which identified an additional 9 million acres for wilderness designation.

PUBLIC OUTCRIES

In the mid–1970s, public concern over the continued high volume of timber production on national forests, along with practices such as clear cutting and even age stand management, led to the passage of the 1976 Forest Management Act. The act authorized clear cutting, but regulated its use. Most significantly, it required long-term management plans for each national forest, once again mandating public input into the planning process.

Meanwhile, environmental organizations uncovered new problematic managerial practices, including below-cost timber sales. Tensions between ecological preservation and commercial timber production divided the Forest Service, as evidenced in the creation of Association of Forest Service Employees for Environmental Ethics (AFSEEE). The groups' publication, *Inner Voice*, raised critical questions about some Forest Service management priorities and policies.

These tensions reached a head in the conflict over the northern spotted owl and old-growth logging in the Pacific Northwest, where environmental organizations promoted listing the northern spotted owl as endangered. The timber industry framed the debate as a choice between jobs or the environment, although the local industry was already in decline. Nonetheless, the Northwest Forest Plan of 1994, brokered by President Clinton, sought to integrate habitat protection, forest restoration, and economic aid to local communities as part of a collaborative, ecosystem-wide approach to national forest planning and management.

A significant step toward adopting an ecological preservation management priority for the Forest Service occurred with the signing of the Roadless Area Conservation Rule in 2001, prohibiting road construction and timber harvest on over 58 million acres of national forests. The rationale was to protect the ecological integrity of these lands, which hold value as sites for recreation, wildlife habitat, and water resources. It also sought to halt the problematic situation of creating new roads for timber sales, whose proceeds would address a small fraction of an $8.4 million backlog in maintenance costs for 386,000 miles of existing roads.

The George W. Bush administration put the Roadless Area Rule on hold, passing decision-making authority back to local forest managers. In the wake of large wildfires in the early 2000s, the administration also promoted the 2003 Healthy Forests Restoration Act, which called for renewed increases in logging levels in order to reduce fuel for wildfires, applying to the entire national forest system. Because much of the timber is small diameter with little commercial value, the act encourages the inclusion of larger, more commercially valuable trees within restoration timber sales to help defray the costs. Critics see this as evidence of the continued priority of timber production.

Forest Transition Thesis

THE FOREST TRANSITION thesis suggests that as countries undergo a process of social and economic development, forest cover follows a u-shaped curve. At first, deforestation is rapid; but as the country develops, deforestation slows and finally reverses. The theory is of great interest because it suggests that one way out of the current biodiversity crisis of deforestation—which is often blamed on economic development—is to encourage more economic development. Since growing forests take carbon dioxide out of the atmosphere, the theory is also of interest in debates about the role of forest recovery in national carbon budgets and global warming policy.

The forest transition thesis was developed to explain historical forest cover trends in developed countries like the United States, Portugal, Denmark, Japan, and South Korea. In the United States, for example, the northeast and southeast are much more forested now than they were 100 years ago. Working with contemporary cross-national datasets, some analysts also find associations between development indicators and forest recovery rates; more developed countries have lower deforestation rates.

The theory holds that modernization brought about increased agricultural productivity, while industrialization brought improved urban labor opportunities; together, these changes transformed rural landscapes. Already-deforested regions with large expanses of arable and irrigable lands responded to mechanization and chemical inputs. In areas where topography, soils, and water constraints limited the application of new agricultural technologies, however, farming became increasingly marginal, especially as productivity gains in prime agricultural areas drove down prices and decreased the competitiveness of small-scale agriculture in the marginal areas. Meanwhile, industries and employment concentrated in the cities. As a result, rural households in marginal areas abandoned their small farms and sought a better life in the city. Forests regenerated on abandoned fields, and national forest cover increased.

The forest transition thesis also holds that modernization changed the ways forests were valued, such that forest mining was replaced with sustainable forest management and protection. Possible catalysts for this change included the substitution of fossil fuels and alternative energy for firewood, changes in attitude about the recreational and conservation values of forests, and improved forest management technologies. The most important mechanisms, however, were probably related to institutional change. As wood and forested lands became scarce, their value to society also increased. Governments passed laws, established protected forest areas, and funded forest protection bureaucracies, and landowners also began to plant trees and protect woodlands.

UNDERDEVELOPED VS. DEVELOPED

A central issue for forest transition theory in the current context of tropical deforestation and biodiversity loss, however, is whether forest transitions observed in developed countries reflect the situation in developing countries. With its emphasis on a seemingly unilinear, homogenous, and poorly defined process called "development," the forest transition thesis assumes that the future of "underdeveloped" countries will emulate the history of "developed" ones.

Several researchers argue that if there are tropical forest transitions in developing countries now, they will be significantly different from those observed in developed countries. They notice significant differences in current urbanization and industrialization patterns from those that took place historically, and place those changes in a context of globalization and an international political economy of agriculture that is also very different. The increasing internationalization of agriculture, for example, discourages small farmers from local markets. Meanwhile, migration patterns sometimes permit the maintenance of rural populations through remittances. Although opportunities for forest recovery and conservation probably exist in areas where current technology and international agricultural policy make farming marginal, these opportunities must be sought in the context of national and local institutional changes; they do not derive automatically from a process of national economic development.

Fortress Conservation

FORTRESS CONSERVATION IS a conservation model based on the belief that biodiversity protection is best achieved by creating protected areas where ecosystems can function in isolation from human disturbance. Fortress, or protectionist, conservation assumes that local people use natural resources in irrational and destructive ways, and as a result cause biodiversity loss and environmental degradation.

Protected areas following the fortress model can be characterized by three principles: local people dependent on the natural resource base are excluded; enforcement is implemented by park rangers patrolling the boundaries, using a "fines and fences" approach to ensure compliance; and only tourism, safari hunting, and scientific research are considered as appropriate uses within protected areas. Because local people are labeled as criminals, poachers, and squatters on lands they have occupied for decades or centuries, they tend to be antagonistic toward fortress-style conservation initiatives and less likely to support the conservation goals.

A vocal supporter of fortress or protectionist conservation is John Terborgh, a tropical ecologist. He asserts that when needs of humans are weighed against needs of the natural world, nature always loses. He warns that the urgency of biodiversity conservation requires protection of species-rich areas by whatever means necessary, even if this requires suspending all economic activity in and around protected areas.

Many social scientists, such as geographer Roderick Neumann, argue that conservationists' ideal of what "natural" landscapes "ought" to look like imparts heavy social consequences. It has facilitated the eviction and disempowerment of local people whose livelihood practices created the "natural" landscapes that conservationists seek to protect. This critique of fortress conservation points to the lack of scientific evidence to support conservation based on a separation of humans from nature. Drawing on nonequilibrium (or disequilibrium) ecological theory and recent advances in environmental history and anthropology, researchers have demonstrated that human interactions with the environment can play a valuable role in managing and maintaining biodiversity. James Fairhead and Melissa Leach challenge the contention long held by colonial and postcolonial scientists that the African savanna-rangeland's extensive climax forest has been reduced to savanna as a result of human mismanagement. They demonstrate that current islands of forest were in fact created by human settlement in a once vast savanna. Their analysis reverses the traditional understanding of the direction of environmental change in that region.

In his book *Fortress Conservation: The Preservation of the Mkomazi Game Reserve, Tanzania* (2002), Dan Brockington critiques the protectionist conservation model, yet laments that fortress conservation will continue to be widely used despite its failure to adequately protect biodiversity. He argues that the alternative models of community-based conservation have been even less effective than the protectionist ones because it is nearly impossible that the benefits realized from conservation will ever offset the cost of being displaced from homelands; those who pay the costs are politically marginalized; and communities are comprised of many diverse interest groups, and their agendas may not coincide with conservation priorities.

Opponents to fortress conservation argue that conservation can only be successful if the needs of the local populations are taken into account. Alternatives to fortress conservation come in many forms, including extractive reserves, joint forest management, community-based conservation management, and integrated conservation and development projects. Community-based conservation models promote benefit sharing, which seeks to compensate local people for the resources they have given up by distributing income, employment, and other benefits from tourism. In other community-based conservation models, local people are contracted to manage part of their land for conservation goals, thereby ensuring that the financial benefits of conservation do reach the community most affected by conservation.

Central to the debate is the question of who gets to decide what resources are protected and in what manner. Supporters of protectionist conservation argue that scientific knowledge should be the primary measure of the need for conservation. Opponents of fortress conservation counter that it is time to diversify the voices that decide how to use and protect natural resources.

Fossey, Dian (1932–85)

DIAN FOSSEY (1932–85) was born on January 16, 1932 in San Francisco, California. After a brief career in occupational therapy, Fossey pursued an interest in researching mountain gorillas (*Gorilla gorilla beringe*) in Africa. During the course of two decades, Fossey became one of the world's foremost primatologists specializing in gorilla behavior. Fossey's interest in gorillas was initially inspired by reading *The Mountain Gorilla* (1963) by zoologist George Schaller, and then during a safari to Africa that same year when she met the renowned paleoanthropologist Dr. Louis Leakey.

Dian Fossey lived in Rwanda for nearly 18 years among gorillas, eventually earning their complete trust.

Three years later, Fossey met again with Leakey, and he urged Fossey to follow through on her desire to study gorillas, telling her that long-term studies of the great apes were key to understanding their behavior. With funds that she has raised, as well as additional financial support from Leakey, Fossey returned to Africa in 1966. Fossey first visited Jane Goodall (who was conducting research on chimpanzees) to learn about her research methods, and then made her way to the Democratic Republic of Congo to begin observing mountain gorillas. However, difficult relations between Fossey and local authorities, as well as political unrest, led her to move her study site a few kilometers to the Rwandan side of the Parc des Volcans, a mountain reserve straddling the Congolese, Ugandan, and Rwandan borders.

Once settled in Rwanda, Fossey established the Karisoke Research Center in the Virunga Mountains. Fossey lived at Karisoke for nearly 18 years among the gorillas, eventually earning their complete trust by developing techniques to imitate gorilla behavior. Fossey discovered and publicized the peaceful nature and nurturing family relationships of the gorillas. The research center also brought in other scientists to study different aspects of gorilla biology. Fossey was a proponent of "active conservation," which involved the establishment of anti-poaching patrols in an attempt to stop the capture and slaying of gorillas, as well as the preservation of their natural habitat. Fossey preferred this active approach to "theoretical conservation," which included the promotion of tourism and gorilla capture for zoos, both of which she opposed.

FATAL DEDICATION

In January 1970 National Geographic published an article by Fossey about her work with the gorillas. The article's description of her favorite gorilla, Digit, as well as the explanations of the poaching problem, accompanied by a cover photo of Fossey with the gorillas, encouraged a large number of donations from readers. With this money Fossey established the Digit Fund and dedicated her life to saving the gorillas. Also in 1970, Fossey left Karisoke to pursue a doctoral degree in zoology from Cambridge University in England. Her dissertation summarized her work to date with gorillas. Upon completing her degree in 1974, Fossey returned to Africa and took on research volunteers, who extended her work.

On January 1, 1978 Fossey discovered that poachers had killed Digit, which sparked her high-profile campaign against gorilla poaching. In 1980 Fossey returned to the United States, where she taught briefly at Cornell University and also began writing her book *Gorillas in the Mist*, a popularized version of her research work. This book was published in 1983 and eventually made into a movie by Warner Brothers Pictures in 1988. Saying she preferred gorillas to people, Fossey returned to Karisoke to continue her gorilla research, as well as to her anti-poaching activities.

On December 26, 1985, Fossey's body was found in her cabin at the research center. The circumstances of her murder were never solved; however, local authorities believed poachers who were at odds with her anti-poaching efforts murdered Fossey. Another theory, by Farley Mowat, is that Fossey was murdered by somebody who viewed her "active" conservation efforts as an impediment to the potential financial gains to be made through tourists visiting the gorillas. Fossey's work contributed greatly to human understanding of gorilla behavior and their relationship to humans, as well as the threats to their existence. Today, the Dian Fossey Gorilla Fund (formerly the Digit Fund) is continuing to support ongoing efforts to protect gorillas. The government of Rwanda and numerous international organizations are also engaged in protecting the mountain gorillas of Africa.

Fossil Fuels

FOSSIL FUELS, DERIVING their name from the ancient remains of organic matter from which they are formed, represent the major energy source in the world today. A nonrenewable resource, fossil fuels exist in finite amounts in the earth's crust. The most widely extracted and economically viable fossil fuels are coal, petroleum (crude oil), and natural gas. All fossil fuels began as living plants and cellular animals; petroleum as microscopic plants and bacteria, natural gas as plankton and algae, and coal as more dense and fibrous trees and ferns. When these living organisms died, they settled to the bottom of the seas (in the case of oil and natural gas) and swamps (in the case of coal). Over many millions of years, layers of sedimentary material settled above this organic material. As the immense weight of the above-lying sediments increased over time, the resulting pressure and heat transformed the organic source materials into hydrocarbons. These hydrocarbons, forming the basis of all fossil fuels, have a molecular structure made up of mainly carbon and hydrogen.

Today, the vast majority of the world's energy comes from burning hydrocarbon-based fossil fuels. In the United States, for example, 85 percent of consumed energy comes from fossil fuels. Throughout the world, coal, oil and petroleum-based products (like gasoline and jet fuel), and natural gas provide the energy that powers agricultural and industrial production, modes of transportation, and electricity generation enabling lighting, heating, and cooling of homes and businesses.

COAL—POWERFUL AND POLLUTING

Of the fossil fuels, coal may have the longest history of human use as energy. Experts believe that as early as 3,000 years ago, coal was used to smelt copper in northeastern China. Coal's role as an energy supply grew as a source of power during the Industrial Revolution in England. When the mechanization and industrial technologies spread to the United States, the resulting second wave of the Industrial Revolution was powered by Appalachian coal. The advent of steam-powered ships and locomotives utilized coal to fuel steam boilers. By the late 19th century, coal was baked to produce coke, a vital fuel for the iron and steel industries.

Today, coal is widely used to generate electricity, to power industry, and to produce steel. Coal is mined through surface mining and deep underground mines. Coal is mined in over 50 countries—with China the top producer—followed by the United States, India, Australia, and South Africa. The largest reserves of coal in the world are found in the United States, followed by Russia, China, India, and Australia. Coal is used as an energy source in over 70 countries. The largest coal consumer in the world is China, followed by the United States, India, South Africa, and Japan. With a relatively high sulfur content, coal is the dirtiest and most polluting of all the fossil fuels.

NATURAL GAS—CLEAN AND SIMPLE

In contrast to coal, natural gas is the cleanest and least polluting of the fossil fuels. The use of natural gas as a fuel energy is a relatively recent phenomenon. In ancient times, the seepage of natural gas from the earth's crust, ignited by a bolt of lightning, would produce a burning flame originating in the ground. Ancient civilizations marveled at these wonders, and these "eternal flames" featured prominently in the ancient religions of Persia and India. England became the first country to economically exploit coal-produced gas, which illuminated streets and homes. In the United States, the commercial extraction of natural gas (not derived from coal) began in 1859 near Titusville, Pennsylvania. In what also sparked the beginning of the U.S. petroleum industry, Colonel Edwin Drake, using a derrick and drill, struck oil and natural gas nearly 70 feet below the Earth's surface. During this time, natural gas was used primarily for illumination. The 1885 invention of the Bunsen burner enabled natural gas to also be used safely for cooking and heating. Today, energy derived from natural gas is widely used to heat and cool homes, as well as to power cooking stoves and portable heating units.

Natural gas is primarily methane, the simplest of the hydrocarbon molecules with one atom of carbon and four atoms of hydrogen. The refining process also extracts ethane, propane, butane, and related condensates. Given its many uses, natural gas is an important natural resource. The global supply is relatively localized, with Russia having the largest proved reserves in the world. Other world leaders in natural gas proved reserves include Iran, Qatar, Saudi Arabia, and United Arab Emirates. The world's largest natural gas exporters are Russia, Canada, Algeria, Norway, and the Netherlands. As with oil, the United States is the world's largest consumer of natural gas. Other major consumers include Russia, Germany, the United Kingdom, and Japan. As with all fossil fuels, the burning of natural gas releases carbon dioxide, the leading greenhouse gas, into the atmosphere. In addition, methane itself is a green house gas, even more effective in trapping heat than is carbon dioxide.

PETROLEUM—CRUDE AND PURSUED

Petroleum, or crude oil, represents the most important energy resource in the world today. Early nonenergy uses included skin salve and other medicinal purposes, paint, and waterproofing for baskets and boats. Colonel Drake's successful strike of petroleum and natural gas in 1859 ushered in the oil industry in the United States. Henry Ford's invention of the automobile opened up a large new market for petroleum. Two World Wars solidified oil's geopolitical importance for fuel-powered ships, planes, tanks, and troop transports. As the post-war demand for oil increased, the 1970s OPEC oil embargoes revealed the vulnerability, particularly in the United States, to Middle East oil. Throughout the world, petroleum powers industry, global trade, and transportation systems, as well as providing the fuel and fertilizer for agricultural production and foundation for many consumer products. The world's current and future supply of oil is concentrated in the Middle East, with Saudi Arabia being the largest oil supplier. The largest proved reserves in the world are located in Saudi Arabia, Canada, Iran, Iraq, and the United Arab Emirates. Saudi Arabia again leads the world in oil production, followed by Russia, the United States, Iran, and Mexico. The top oil exporters in the world are Saudi Arabia, Russia, Norway, the United Arab Emirates, and Iran. The United States is by far the largest consumer of oil in the world. Other top consumers, though far below the United States, include Japan, China, Germany, and Russia.

BURNING ISSUE: ENVIRONMENTAL COSTS

The tremendous societal benefits derived from the burning of fossil fuels have come at a significant cost to the Earth's natural environment, although the total nature and extent of this cost is not completely understood. Burning fossil fuels in factories, automobiles, and power stations releases such compounds as carbon dioxide, nitrous oxide, and sulfur dioxide into the atmosphere. The world's rapid industrialization and population growth through the 20th century, and into the 21st century, has drastically increased the amount of these substances in the atmosphere. Carbon dioxide, for example, is thought to be the main cause of the anthropogenic (human-caused) greenhouse effect, the accumulation of greenhouse gasses which trap and re-radiate heat within the earth's atmosphere. The resulting temperature increases (global warming) may lead to climate changes, polar ice melting, sea level rise, and the disruption of the earth's ecosystems. Another major environmental problem linked to the burning of fossil fuels is acid precipitation in the form of acid rain and acid fog. Sulfur dioxide and nitrous oxide, released by burning fossil fuels, enter the atmosphere and react with water vapor to produce acids. These acids are re-deposited on earth in the form of precipitation, harming many of the earth's ecosystems. Oil tanker spills, air pollution, smog, and the defacing of the earth by coal strip mines represent additional environmental problems linked to the production and consumption of fossil fuels.

Framework Convention on Climate Change (FCCC)

THE FRAMEWORK CONVENTION on Climate Change (FCCC), which became effective in 1994, is a voluntary and nonbinding declaration of standards, goals, and objectives that represents international cooperation to reduce human-made greenhouse gas emissions that contribute to climate change (known also as "anthropogenic emissions"). This convention—modeled after the Vienna Convention on Protection of the Ozone Layer—established a general framework for emissions reductions.

The text begins with a series of declarations. The first states that "Parties" (participating countries) in the FCCC, "Acknowledge that change in the Earth's climate and its adverse effects are a common concern of humankind." The FCCC document is comprised of 26 Articles, ranging in issues from defining terms to the financial mechanism to requirements for the entry of the FCCC into force.

The objective of the framework is found in Article 2, which requires parties to "achieve stabilization of the greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system." This Article is intended to be the standard by which the parties' commitments under the climate regime are measured. It also states that "stabilization" should be pursued in an appropriate time frame for "ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner."

Articles 4, 10, and 12 address more specific commitments of the parties, based on "common but differentiated responsibilities." Article 4(2) of the FCCC text distinguishes between three groupings of parties to the convention, based on present levels of industrialization: Annex I Parties (all industrialized countries), Annex II Parties (all industrialized countries except those of the former Soviet bloc in the process of economic transition to market economies), and all Parties (including developing countries). Furthermore, Article 4(2)b notes that the aim for the Annex I countries is to return to 1990 levels of anthropogenic emissions. Articles 10 and 12 outline the rules by which Annex I Parties must "adopt national policies and take corresponding measures on the mitigation of climate change, by limiting anthropogenic emissions of greenhouse gases and protecting and enhancing greenhouse gas sinks and reservoirs." Moreover, Article 4 (3-5) notes that developed countries shall assist developing countries in reaching anthropogenic emissions reductions goals through technology transfer as well as various forms of financial assistance.

The text of the convention was adopted at the United Nations (UN) Headquarters in New York on May 9, 1992. It was then opened for signature by leaders at the June 1992 UN Conference on Environment and Development (UNCED) in Rio de Janeiro, Brazil, a conference commonly referred to as the Rio Conference or Earth Summit. Overall, 154 countries signed the FCCC. The United States, led by President George H.W. Bush, was one of the signatories, and the U.S. Senate ratified it on October 15, 1992. The FCCC entered into force on March 21, 1994.

The entry into force of the FCCC set forth future Conference of Parties (COPs) meetings to delineate more specifics of the treaty. Most prominent is the third conference of parties (COP3) that took place in Kyoto, Japan, and produced the Kyoto Protocol. This protocol outlines more specific targets and timetables for Annex I/II Parties to reduce anthropogenic greenhouse gas emissions. To date, the Kyoto Protocol has been signed by 140 countries, and, despite U.S. nonratification, entered into force in February of 2005.

SCRUTINY OF THE FCCC

The FCCC has endured much scrutiny. First, critics charge that the few specific obligations to curb anthropogenic climate change have allowed for considerable discretion in application. Second, the proposed emissions reductions are deemed to be merely symbolic as they do not significantly mitigate greenhouse gas emissions. Third, legacies of colonialism shaping contemporary inequality and associated levels of greenhouse gas emissions are underemphasized in this FCCC country-level emissions reductions approach, and rhetorical acknowledgments (such as the Berlin Mandate in 1995) have proven insufficient. Fourth, since the entry into force of the FCCC, there has been increasingly politicized discussion and debate over the precise meaning behind the statement in Article 2. Contestation has centered on what level of greenhouse gas concentrations constitutes "dangerous anthropogenic interference." Many climate scientists assert that this threshold has already been surpassed. For instance, as of 2006, atmospheric carbon dioxide concentrations have risen to approximately 381 parts per million (ppm), marking a 36 percent increase in emissions from preindustrial levels of approximately 280 ppm, and a level not reached in the last 650,000 years. However, proponents counter that this approach is a productive first step that encourages parties to be involved in the process, before then potentially signing on to binding agreements that follow.

France

FRANCE IS THE largest country of Western Europe (211,208 square miles, including the island of Corsica, in the Mediterranean) and one of the most populated (around 60 million people in 2006). Most of the physiography of continental France is dominated by plains and gentle rolling hills, occasionally altered by higher elevations in the central part (Massif Central) and especially in the south (Pyrenees) and the East (Jura and the Alps, where Mont Blanc, at 15,766 feet is the highest peak of the country and of Europe. Climate is generally mild in summer and cool in winter except in the Mediterranean, where it may be quite warm in summer, and in the mountains where cooler conditions predominate.

The main environmental challenges faced by France concern agricultural land use and food security; waste management (including nuclear waste); the growing impacts of energy use, transportation and urbanization; and the need to limit carbon dioxide emissions. With more than 44 million acres, France still has the largest agricultural area of Western Europe. Arable land and pastures, however, are being lost to forests (5 percent expansion between 1992 and 2002) and especially to urbanization (15 percent increase in the same period). In the first decade of the 21st century, the largest population and urban growth rates are being recorded in southern cities such as Perpignan, Narbonne, Montpellier, and Nimes, chosen by a growing number of French people to retire. Sprawl is becoming very common in these cities, and the metropolitan area of Paris is considered the most sprawled urban area of the world.

About 11 percent of the country enjoys some degree of environmental protection. France has about 1,200 protected areas (24 of them in excess of 247,109 acres) and 10 biosphere reserves. In 2006, new legislation was passed to enhance the protection of natural areas with a special emphasis on marine reserves.

Because of the importance of agriculture and the need to preserve the rural landscape, several policies have been implemented in order to contain agricultural decline. The so-called Contracts Territorials d'Exploitation (land use and production contracts) in force since 1999 are addressed to remunerate the various functions performed by agriculture, not just food production, but landscape conservation as well. Agriculture, however, still contributes substantially to water (especially groundwater) pollution. Nearly 30 percent of surface waters have bad or very bad quality levels according to European standards because of high nitrate concentrations, and about one-fifth of the French population drinks water with pesticide residues above the recommended levels of the European Union (EU). In the intensive hog raising areas of Brittany in northwest France, nitrate concentrations often exceed the 50 milligram/liter mark established by the EU. In 2001, the European Comission ruled against France for failing to comply with the Nitrates Directive.

Air pollution remains an important problem in most French cities, especially in Marseilles, Dijon, Montpellier, Lyon, and Paris. Technological improvements such as catalyzers have reduced carbon monoxide emissions by 30 percent and nitrogen dioxides by 10 percent during the 1990s. Nevertheless, increases in mobility, time traveled, diesel vehicles, air conditioning, and private transportation by truck have tended to offset these gains. Hence, some cities are pursuing policies to limit private transportation by car. The Paris City Council, for instance, has multiplied the logistic obstacles for private transportation in the downtown areas, and since 2002 it has added 12 miles of tramway lanes and increased the number of bike routes by 47 percent. Partially as a result of these policies, car transportation decreased by 14 percent between 2001 and 2005. The decline in coal mining and heavy manufacturing in the eastern regions has eased the acid rain problem that used to be very acute in Alsace and Lorraine.

Industrial hazards, however, persist and become more dangerous as urbanization progresses into formerly segregated dangerous activities. In September 2001, an explosion in a ammonium nitrate factory in Toulouse caused 30 deaths and extensive damage in nearby areas. This accident, together with the impact of natural hazards such as the heat wave of 2003 (responsible for as many as 30,000 deaths, especially among the elderly) and the numerous flooding problems of the Mediterranean rivers prompted the law on Risk Prevention and Mitigation of 2003.

France has 58 nuclear power plants (second in the world after the United States), which provide around 75 percent of all electricity generated in the country. While the dependency on fossil fuels is thus reduced, the country has not made substantial efforts in the development of alternative energy sources. While nuclear power is generally acceptanced by the French public, the country still fears that it will be unable to meet the reduction in carbon dioxide emissions (54 million tons by 2010) targeted in the Kyoto Protocol. To date, how to solve the issue of nuclear waste is still being debated.

Several French companies such as Suez-Lyonnaise-des-Eaux and Vivendi Environnement rank among the most important in the world in the provision of environmental goods and services. Both companies maintain leadership positions in urban water supply and wastewater management of cities in the United States, Spain, Germany, Japan, and Latin America.

Pont du Gard Aqueduct

The Pont du Gard Aqueduct was added to UNESCO's list of World Heritage Sites in 1985 and is one of France's major tourist attractions, with about one-and-a-half million visitors each year.

The aqueduct was built in the middle of the first century C.E., with the work attributed to Marcis Vipsanius Agrippa, the son-in-law of the Emperor Augustus. It carried water from springs near Uzes to the Roman city of Nemausus (present-day Nîmes). With a gradient of 1/3,000, it was capable of delivering 44 million gallons of water daily. The stones in the aqueduct were held together with iron clamps—no mortar was used in the design. A massive scaffold was used in the building of it and it is thought to have taken between 800–1,000 men about three years.

In the 4th century the aqueduct started to fill with deposits of stones and soil, and was not properly cleaned. By the 9th century there was no water coming from it and people started plundering the stone for constructing houses and farm buildings. It also started to be used as a bridge for people crossing the River Gard. Some pillars were narrowed to make this task easier, but in 1702 they were enlarged for safety. In 1743 a new bridge was built at a lower level, with the aqueduct being restored in the mid-18th century by which time it had become a major tourist attraction. The aqueduct survived the flooding of the region in 1998 and a massive project to develop the area and preserve the aqueduct commenced soon afterward.

Fuji, Mount

MOUNT FUJI IS Japan's tallest and most sacred mountain, and is also known as Fujiyama, Fuji-Yo-Nama and Fujisan. At 12,388 feet, Fuji is a cone-shaped volcanic mountain located on the Island of Honshu—the largest of four major islands of Japan—and eminently stands 70 miles west of Tokyo. Geologists consider the volcano active, its last eruption occurring in 1707.

Fuji is one of the many active volcanoes that form what is popularly known as the Pacific "Ring of Fire." The earth's surface crust is divided into irregularly shaped "plates" of various sizes and thickness, which are constantly on the move. The source of this movement is found at divergent boundaries where hot viscous magma from the interior of the earth pushes its way to the surface through rifts along ocean floors. Here it cools and hardens to produce new crust while moving older crust and consequently lithospheric plates away from the divergent boundaries and each other. Along other boundaries, plates converge—crunching against, or sliding along or beneath one another. Most volcanic activity and mountain building, known as *orogenesis*, occurs along these boundaries. Mount Fuji, like many other volcanoes along the "ring," formed at a convergent boundary where lighter, less dense crust of the Pacific–oceanic plate slides below the Eurasian–continental plate. As it does, the plates fracture, and fissures channel magma to the surface of the earth where it spreads as lava. Legend has it that Fuji rose from to its present height in just one night. However, it has taken thousands of years of successive lava flows to create what many have called the perfect composite volcano.

SACRED LANDSCAPE

Mount Fuji is sacred landscape to both the Shinto and Buddhists religions. For the Buddhists, Fuji, with its snow-capped peak, resembles the white bud of the sacred Lotus flower whose petals symbolize the Noble Eight-Fold Path to enlightenment. For the Shinto, the ethnic religion of Japan, Fuji stands as a beautiful Goddess and Supreme Altar of the Sun. Climbing the volcano is a sacred ritual and is usually undertaken during the months of July and August. Prior to the Meiji Restoration of 1868, pilgrims donned white robes, and were male only. Today, pilgrims and foreign tourists of all kinds make the relatively easy climb to the ancient temples and shrines scattered in and along the edge of the crater—which has a 2,000 feet diameter—to greet the rising sun and beginning of divine day. Just beyond Fuji's base, which has a circumference of 65 miles, are lakes and foothills where summer and winter recreational opportunities abound. Tens of thousands visit the area annually yet, unfortunately, the effects on the mountain itself have been deleterious. Although ancient myth asserts that soil and stone rolling down from pilgrims' feet are magically repositioned on the mountain during the night, erosion from trail walking continues to scare its face. Discarded plastic wrappers and bottles and cigarette butts along the trails have led one to dub Fuji the "sacred rubbish dump." Considerable efforts are being made by the Japanese government to maintain Mount Fuji's reputation as one of the most beautiful landscapes in the world—from both near and far.

Fungi

FUNGI ARE HETEROTROPHIC, unicellular or multicellular microbes that colonize both living and nonliving habitats. Fungi belong to the Eukarya domain of life, and the estimated 1.5 million species of fungi may be classified into one of five major groups: Ascomycota, Basidiomycota, Zygomycota, Oomycota, and Deuteromycota. These groups are classified on the basis of cellularity (multicellular, unicellular, or clonal), type of hyphae (septate or coenocytic), reproductive strategy, habitat (aquatic versus terrestrial), and life form. All fungi contain chitin in their cell walls, and other chemical constituents of fungal cell walls are used to classify fungi for ecological, industrial, and biotechnological purposes. All fungi are chemoorganotrophs, meaning that they lack the chlorophyll necessary to produce their own food; instead, fungi excretes extracellular enzymes that break organic material into new, simpler compounds that can then be absorbed by the fungus and used as carbon and energy sources. Many fungal species have a filamentous life form embodied as hyphae; hyphae that branch, intertwine, and grow together as tufts in soil and under decaying mats of organic matter collectively constitute fungal mycelia. Some mycelial mats are easily observable with the naked eye, but other soil fungi require chemical stains and microscopes to observe. Fungi have various reproductive strategies; all groups except the *Deuteromycetes* have some sexual reproduction through spores, while fungal groups that reproduce asexually produce asexual spores called conidia. Fungi colonize new areas both by the extension of hyphae—which may extend several meters from the original mycelial mat—and by spore dispersal, often over great distances.

NATURE'S MORTICIANS

Fungi grow in very diverse habitats, including fresh and salt water; however, most fungi are terrestrial and are commonly found in soils and on dead organic matter. Soil fungi, especially the *Basidiomycetes*, are instrumental in the decomposition of organic matter into simpler carbon compounds. The decay fungi are especially effective at decomposing recalcitrant (i.e., difficult to decompose) plant compounds such as cellulose and lignin. Certain fungal species are also important in the mineralization of organic compounds into inorganic nutrients and minerals that are in turn used by plants and other soil organisms. Pathogenic fungi are responsible for the majority of agricultural diseases, and can reduce crop yields and kill plants in natural systems. Many fungal pathogens of crop and noncrop plant species such as the powdery mildews (Ascomycetes), rusts (Basidiomycetes), smuts (Basidiomycetes), and blights (Ascomycetes, *Oomycetes*) are often transmitted by windblown spores. The fungal species *Ophiostoma ulmi (syn. Ceratocystis ulmi)* and *Cryphonectria parasitica*, which cause the tree diseases Dutch elm disease and Chestnut blight, respectively, have seriously changed the species composition of deciduous forests in the United States.

Most people associate fungi with the button mushrooms commonly used in cooking, or can envision fungal brackets that colonize dead trees or logs. Many fungi also have broad, lesser-known commercial and biotechnological uses. Secondary metabolites of the Deuteromycete fungus *Penicillium chrysogenum* are used industrially to produce penicillin antibiotics, and fungal metabolites have many other important industrial and commercial

Fungi grow in diverse habitats, but most are terrestrial and are commonly found on soils and dead organic matter.

uses. Microscopic fungi also colonize the surfaces of rock either alone or in symbiotic association with algae or cyanobacteria, and in this way play a central role in the chemical weathering of rock into soil particles. Many people are not aware that the greatest fraction of biomass of any terrestrial fungus exists belowground as mycelia. A remarkable example of the below-ground expanse of soil fungi is a giant mycelial mat of the Basidiomycete *Armillaria ostoyae*, believed to be the single largest organism on earth. This single organism colonizes over 10 square kilometers of forest floor in northeast Oregon, and is believed to be between 2,000 and 8,500 years old!

Gabon

AFTER WINNING INDEPENDENCE from France in 1960, the Gabonese Republic entered a period of political stability marked by one-party rule. Thirty years later, a multiparty system was introduced and a new constitution was ratified. Drawing on its rich natural resources—including petroleum, natural gas, diamond, niobium, manganese, uranium, gold, timber, iron ore, and hydropower—and on financial backing from foreign investors, Gabon has become one of the most prosperous countries in Africa. Some 60 percent of the work force is engaged in agriculture, and timber and manganese were the mainstays of the economy until oil was discovered offshore in the early 1970s.

Currently, the oil industry accounts for half of the Gross Domestic Product. With a per capita income of $5,800, Gabon is ranked 124 of 232 nations in world incomes. Gabon's income level is four times greater than that of most Sub-Saharan African nations. Poverty levels have declined, but income disparity endures. Over one-fifth of Gabonese are unemployed. Gabon is ranked 123 of 232 countries on overall quality of life issues.

Bordering on the South Atlantic Ocean at the Equator, Gabon has a coastline of 885 kilometers in addition to 10,000 square kilometers of inland water sources. The Western African nation shares land borders with Cameroon, the Republic of the Congo, and Equatorial Guinea. The narrow coastal plains of Gabon give way to a hilly interior and savanna in the east and south. Elevations range from sea level to 1,575 meters at Mont Iboundji. The tropical climate is always hot and humid.

Despite its economic superiority over many of its neighbors, Gabon is subject to some of the same environmental health hazards that plague much of Sub-Saharan Africa. The Gabonese population of 1,400,900 experiences an HIV/AIDS prevalence rate of 8.1 percent. Some 48,000 Gabonese live with this disease, which had had killed 3,000 people by 2003. While 87 percent of the population has access to safe drinking water, less that half of rural residents can sustain that access. Only 36 percent of Gabonese have access to improved sanitation. Thus, the population suffers from a very high risk of contracting food and waterborne diseases, including bacterial diarrhea, hepatitis A, and typhoid fever and malaria, a vectorborne disease. As a result of high incidences of disease, the Gabonese experience low life expectancy (54.49 years) and growth rates (2.13 percent), and high infant mortality (54.51 deaths per 1,000 live births) and death rates (12.25

deaths per 1,000 population). Gabonese women produce an average of 4.74 children each. While almost three-fourths of adult males are literate, just over half of adult females are so classified.

Due to the of the prosperity derived from oil and mineral reserves, Gabon has been able to maintain most of its rain forest, protecting the rich biodiversity of the area. Approximately 85 percent of Gabon is forested. In 2002, the United States partnered with Gabon to extend protection of the Gabonese rain forest with a contribution of $75 million. The government created a national park system that covered ten percent of the land area using a plan drawn up by the New York-based Wildlife Conservation Society. With the creation of 13 new parks, Gabon's park system became the largest in the world.

Of 190 identified mammal species, 15 are endangered, as are five of 156 bird species.

In 2006, scientists at Yale University ranked Gabon 46th in the world in environmental performance, well above the relevant income and geographic groups. Although not low in comparison with most African nations, the lowest scores were in the areas of environmental health and biodiversity and habitat. Despite an urbanization rate of 83.7 percent, between 1980 and 2002, Gabon reduced the level of carbon dioxide emissions per capita metric ton from 8.9 to 2.6.

Under the auspice of the National Environmental Action Plan, supplemented by the National Strategic Plan for the Conservation of Biodiversity and the Plan of Action for National and Tropical Forests, the Ministry of Forestry and Environment has the responsibility for implementing environmental legislation and regulations and monitoring compliance. In addition to widespread efforts toward protecting the rain forest, the Gabonese government is working to improve the quality of drinking waster and secure access to improved sanitation for the entire population. Gabon participates in the following international agreements on the environment: Biodiversity, Climate Change, Desertification, Endangered Species, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, Tropical Timber 94, and Wetlands.

Albert Schweitzer

Albert Schweitzer (1875–1965) was an accomplished Alsatian German philosopher and musician who decided to give up his comfortable lifestyle in Europe to become a missionary doctor at Lambaréné, Gabon, in French Equatorial Africa. In 1952 he received the Nobel Peace Prize for his efforts on behalf of The Brotherhood of Nations.

Schweitzer was born in Kaysersburg, Alsace, then a part of Germany, but now a part of France. His father was a Lutheran pastor and he studied philosophy and theology at the University of Strasbourg, gaining his doctorate in 1899. He then preached and also wrote his book *Von Reimarus zu Wrede* ("The Quest of the Historical Jesus") in 1906. This was globally acclaimed, and Schweitzer also became an organist in Strasbourg, keen on playing the work of J.S. Bach.

In 1905 Schweitzer announced that he had decided to become a missionary doctor and started studying medicine, becoming a medical doctor in 1913. He and his wife then went to Lambaréné in Gabon where, with the help of the local tribesmen, he built a hospital that he ran until his death, maintaining it initially with his own income; and later, helped by gifts from people and foundations all around the world.

After being detained as a German in World War I and released, Schweitzer carried on his work, also writing several philosophical works, the most famous being *Kulturphilosophie* ("Philosophy of Civilization," 1923). In 1924 he returned to Africa and started work on rebuilding the hospital, which had become derelict. He added a leper coloney soon afterwards. The hospital day began at 6:30 with a reveille bell, followed by regular mealtime, siesta, work, and curfew times.

By the 1960s, there were about 350 patients at the hospital, along with their relatives, and also 150 lepers, all served by local workers and 36 European doctors and nurses. Schweitzer continued to write on philosophy and theology in Lambaréné, and died there in 1965, aged 90.

Gaia Hypothesis

THE GAIA HYPOTHESIS asserts that the earth is a single living organism with the power of self-regulation. It was the brainchild of James Lovelock and Lynn Margulis, who chose to name their theory Gaia after the Greek goddess of the earth. While the idea that the earth is alive and is the great mother to all life has very ancient roots, the idea has traditionally been regarded as a kind of metaphor for the connectedness of life, rather than scientifically demonstrable fact. However, Lovelock and Margulis employed scientific arguments in their claim that life on earth was part of a great cybernetic system with complex feedbacks, and that these, in turn, regulated the system keeping it operating within narrow bounds. They claimed that life (the biosphere) regulated the composition of the atmosphere and this regulated the temperature of the planet. Such self-regulation demonstrated that the earth was an organism like any other. Gaia initiated a debate in scientific circles that still continues. Gaia also attracted attention from the media, certain environmentalists, the clergy, and even religious mystics.

Lovelock's unique background led him to the Gaia Hypothesis. He was an independent scientist and inventor who had also worked for NASA on the *Viking* program, the first satellite to land successfully on the surface of the planet Mars. One of the objectives of the *Viking* mission was to test the surface for evidence of life. This led Lovelock to a strange conclusion—that it was not necessary to probe the surface of Mars to test for life. If life existed, it would alter the composition of the atmosphere. Since the relative proportions of the gasses in the Martian atmosphere had already been determined by traditional astronomical techniques, there was no need to send a probe to the surface to look for life. The composition of the atmosphere indicated that it was a lifeless planet. In dramatic contrast, the mixture of gasses comprising the earth's atmosphere revealed that it was a living world. The high proportion of oxygen, the by-product of photosynthesis, was perhaps the best indication of life.

Lovelock claimed that the earth regulated its temperature by regulating the composition of the atmosphere. For example, oxygen has a historical proportion of about 21 percent. If this value were much lower, perhaps 18 percent, combustion could not be sustained in most cases. If this value were much higher, perhaps 25 percent, then fires would burn wildly. The very fact that the mixture of gasses in the atmosphere had remained within very narrow bounds for eons was extremely unlikely, in fact impossible; and therefore, required some regulatory mechanism connected to life processes. In addition, the sheer volume of oxygen as a free gas made the earth's atmosphere unusual compared to the other inner planets of the solar system, and indicated a kind of chemical disequilibrium in which it was continually destroyed and created. Oxygen was inextricably connected to the forces of life, specifically photosynthesis. Such regulation of atmospheric composition was more evidence that the earth was operating as a single living organism. However, critics charged that this was not evidence of regulation at all, but simply the result of the planet's interacting living and geophysical systems.

One of the most difficult criticisms to refute was the charge that the Gaian system was teleological, that is, preordained. The dictionary definition of *teleological* is that it concerns the study of evidence of design in nature. Teleology is a doctrine that nature or natural processes are directed toward an end or shaped by a purpose. According to this reasoning, Gaia was teleological because the plants and living systems were programmed to regulate the earth system.

To answer some of the critics, Lovelock resorted to creating a computer model of an artificial planet called Daisyworld. It was a simple planet, which had only one life form, the daisy, which came in two varieties: one light and one dark. The relative proportion of each determined the albedo or reflectivity of the planet. Albedo is critical in determining the temperature, because sunlight reflected back out to space is lost to the system. Only the sunlight that is absorbed serves to heat the planet. Lovelock tried to show that such regulation of the planet's temperature through the regulation of albedo by living organisms (daisies) was simply the result of a living system interacting and modifying its geophysical environment. It did not require any forethought or planning by the living organisms, and, therefore, it was not teleology. For the most part, the critics remained unimpressed, claiming that the Daisyworld model only reflected the assumptions underlying its construction and its relation to the actual functioning of the earth system was minimal or nonexistent. Lovelock believed that the critics ignored the power of the Daisyworld model. Some of his supporters praised his efforts for their simplicity and elegance in clarifying basic regulating mechanisms on an earthlike planet. Ultimately, the Daisyworld model became the basis for the popular computer game, SIMEARTH.

The power of the Gaia Hypothesis reached well beyond its scientific origins. Throughout history, people from a variety of religious backgrounds have viewed the earth as the mother goddess of all life. Furthermore, the idea that the evolution of the earth prepared the perfect habitat for humankind had a powerful appeal. Lovelock, who had now provided a scientific basis for such beliefs, was stunned by the attention Gaia received from beyond the scientific community.

The Gaian theory called attention to the role of the biosphere in the complex geophysical relationships of planet earth. The physical systems of the earth and the biological systems of the earth evolved together, and each affects the other. Life is vastly more important to the earth system than simply a passenger on a pile of rocks. The issue of whether Gaia is simply a provocative metaphor or genuine cybernetic system will never be completely settled.

Galápagos Islands

THE GALÁPAGOS ISLANDS (or *Archipiélago de Colón*) are located in the Pacific Ocean on the equator 600 miles (960 kilometers) west of South America. The archipelago is made up of 19 main islands with a total land area of 3,050 square miles (7,900 square kilometers), or slightly less than half the size of Hawaii. Geologically, the islands are a chain of volcanoes that have pushed up from the seafloor as the earth's crust moves over a stationary hotspot in the mantle. The Galápagos are one of the world's most volcanically active regions, and large basaltic lava flows can be seen. The climate is uncharacteristically dry for the tropics, with an average annual precipitation of 19 inches (500 millimeters).

The Galápagos Islands were discovered by the Spanish in 1535. (*Galápago* means saddle in Spanish, as the shells of the tortoises found on the islands resemble a type of saddle.) The islands were annexed by the country of Ecuador in 1832 and today are a province of that country. In the 1800s, the first permanent settlers arrived when the islands were used for whaling. During the World War II, the United States had an air base on Baltra Island. At various times, the islands were also used as a penal colony. Today, there are settlements on four of the islands, and the territory has a total population of 20,000 people. The largest town, with 8,000 people, is Puerto Ayora on Santa Cruz Island. In addition, 70,000 tourists visit the Galápagos each year.

The Galápagos is the most pristine and least-altered island chain left on earth. The archipelago retains 95 percent of its original species, many of which are endemic, or found nowhere else on the planet. They are home to the famous giant Galápagos tortoise, marine iguanas, finches, and flightless cormorants, as well as sea turtles, albatrosses, and boobies. The islands may be best known as the place where English naturalist Charles Darwin, sailing aboard the HMS *Beagle,* visited in 1835. Darwin's observations of the varied, unique, and harsh environments of the islands, and of how plants and animals rapidly adapted to them, contributed to his theory of evolution by natural selection.

In 1959, the Ecuadorian government created the Galápagos National Park, which encompasses 97 percent of the land area. In the same year, the Charles Darwin Foundation was established under the auspices of the United Nations. The foundation operates a research station, promotes environmental education, and works closely with the government on conservation. In 1978, UNESCO named the Galápagos a World Heritage site, and the islands were recognized as a biosphere reserve in 1984. In 1998, the Galápagos Marine Reserve was created, which encompasses 50,500 square miles (133,000 square kilometers) around the islands.

The three biggest threats to the Galápagos are introduced species, growth in the human population, and fishing. People have brought to the Galápagos, deliberately or accidentally, a range of nonnative species. Goats, feral pigs, cats, and rats are particularly damaging, as they denude the islands of vegetation and kill native wildlife. Hundreds of introduced plants also threaten the fragile ecosystem. A tortoise breeding program, eradication of introduced species, and habitat restoration are among the many ongoing conservation efforts. As the Galápagos gained a reputation as a tourist paradise, the human population grew from around 1,000 in 1960 to 20,000 today. Strict rules govern tourist activities. However, historically, the focus of the local population has been on resource extraction, with little concern for sustainability. The islands are home to 1,000 fishermen, and while commercial fishing is banned, small-scale fishing for reef fish, lobster, and sea cucumbers puts pressure on shoreline environments. Larger boats from the mainland frequently harvest shark fins illegally.

The Galápagos Islands are at a crossroads. The threats are grave and ecological degradation continues. Recent actions such as a quarantine inspection system and controlling immigration to the islands are positive. Ecoregion-based conservation planning is bringing together the government, private stakeholder groups, and international conservation organizations in search of a model for integrated long-term sustainable management. With decisive policies and effective conservation efforts, one of the world's magnificent natural areas can be saved.

The Galapagos retains 95 percent of its original species, such as marine iguanas, boobies, and sea turtles.

Gambia

GAMBIA REFERS TO an African river as well as to the country that took its name from one of West Africa's important waterways. Surrounded on three sides by French-speaking Senegal, The Gambia's political borders enclose the lower half of a river that begins in the highlands of Guinea and cuts a swath through the country before emptying into the Atlantic. About the size of Connecticut, The Gambia is one of Africa's smallest nations. It is just 15 to 30 miles (24 to 48 kilometers) wide and less than 300 miles (483 kilometers) long. In this Lilliputian political entity, one is never far from the Gambia River, its most outstanding geographical feature.

Nearly 50 years before Columbus crossed the Atlantic, Portuguese sailors entered the Gambia River, making it part of the expanding Atlantic economy. For more than three centuries, slavers from diverse European nations operated along the Gambia River. The Portuguese, Dutch, French, British, and even a Baltic principality (Kurland) established trading posts to facilitate the slave trafficking. After the Atlantic slave trade ceased in the early 19th century, European nations took their spheres of interest and divided Africa into colonies. The Gambia became British in 1889; it achieved political independence in 1965.

More than 1.25 million people currently live in The Gambia (2004 estimate). About one-third of the population reside near the 36-mile (58-kilometer) coastal strip along the Atlantic. Three main ethnic groups comprise the country's population: the Mandinka (40 percent), the Fulani (19 percent), and the Wolof (15 percent). One of Africa' poorest countries, in a continent known for some of the most impoverished nations on the earth, most Gambians make their living from agriculture. The country's preeminent farmers are the Mandinka, and the environments shaped by the Gambia River profoundly influence the way they farm and the crops they grow. The river, its tributaries, and associated wetlands cover about one-quarter of the land surface; a slightly larger percentage comprises the plateau, where agricultural production takes place only with rainfall. Despite the country's low elevation, a variety of transitional environments are found between the plateau and river floodplains that draw moisture from diverse sources.

AGRICULTURE

The rural economy and livelihood depend on agricultural practices and crops that are adapted to the distinctive environments of the plateau and wetlands. This in turn influences the way rural households divide work between males and females. On the plateau, men grow the country's principal export crop, peanuts, in addition to millet, sorghum, and maize for food. These crops are adapted to the four-month rainy season (mid-June to mid-October). However, throughout this region of West Africa, the rainfall pattern (31–43 inches [79–109 centimeters]) is highly variable. It is often badly distributed within a year; one in every four years, precipitation is typically below normal. For this reason, the floodplains and swamps along the Gambia River are extremely important to rural well-being and survival. And it is women who farm them, for rice is traditionally a female crop.

Rice has been grown along the Gambian wetlands since antiquity. The initial species, native to Africa, is separate from Asian rice, which only replaced the lower-yielding African seed over the past half century. Since at least the period of the Atlantic slave trade, rice has been a woman's crop.

Women's farmwork in rural Gambia thus takes place in an entirely different ecological setting than that of their husbands. They grow rice and some vegetables in a variety of tidal and lowland swamps that receive water from the Gambia River, its tributaries, and the high water table of the lowlands. Even their agricultural calendar is different from that of their husbands. The wetlands enable cultivation many more months of the year than the plateau, which increases the number of months women farm. In a drought-prone environment, the wetlands are the key to food availability and survival. For this reason, since the 1960s they have received a great deal of attention by development planners.

INCREASING CROP YIELDS

Lying between 13 and 14 degrees latitude north of the equator, The Gambia like many other countries south of the Sahara experiences occasional droughts. Development assistance to the country and its neighbors has targeted the region's wetlands for pump-irrigation schemes. The goal is to extract available river water to irrigate a dry season crop. The harvests of two annual crops in the wetlands holds hope for increasing production of rice, the regional dietary staple. Some 10,000 acres (4,000 hectares) of wetlands now are developed to irrigation projects out of an estimated 60,000 acres (24,000 hectares) farmed with traditional swamp rice methods.

However, the irrigation technology has largely failed to create a sustainable form of agriculture. In part this is because the high price of diesel has made the operation of irrigation pumps extremely costly in a society where the average per capita income hovers around $450 annually. This also affects the price of fertilizer. The most productive rice varieties demand significant amounts of fertilizer, and in just 20 years its price has quadrupled. Fertilizers are now priced beyond the means of most rural producers. Inappropriate technology transfer also occurred amid misguided attempts of development planners to attract Gambian men to rice cultivation. They awarded the developed irrigated plots to women's husbands rather than to the traditional female growers. As a consequence, women became laborers on the very fields they previously managed and used for income generation. Conflict between men and women erupted frequently in the implementation of pump-irrigation schemes.

Fortunately, many lessons have been learned. Technologically sophisticated irrigation systems similar to those in California are not feasible for cash-strapped rural populations. New approaches to raising African food production now center on building upon the ecological knowledge already held by rural people in farming diverse environments. One of the crucial lessons of Gambian wetland development is the significance of women's work and environmental knowledge for raising food production. Any project that aims to improve food availability in rural West Africa now assumes that men and women often work separately, with different crops, and frequently in dissimilar environments.

The Gambia River still defines the country and its people. A river that flows through parched landscapes is being once more returned to its custodians, the female rice growers. Development assistance now helps them level the floodplains in order to restore the river's natural reach. In improving its tidal reach, the river now flows unimpeded across women's rice fields, as it seeks its outlet to the Atlantic.

Game Theory

GAME THEORY IS the application of applied mathematics and evolutionary theory to understanding people's strategies in maximizing benefits. Game theory began as a system for understanding card games with its first practical application to economics in the early 20th century. Several human behavioral sciences (psychology, sociology, and anthropology) use game theory to understand why individuals may be in conflict or cooperation given specific situations.

The two main representations of game theory are *normal*, which is sometimes referred to as *strategic*, and *extensive form* games. In the normal form game, each player has two strategies—cooperate or defect. If player one defects and player two cooperates, the defecting player's payoff (reward) is higher (e.g., $6) than the player who cooperates (e.g., $0). If both player one and two cooperate, they receive an equal payoff (e.g., $3). If both player one and two defect, they receive an equal payoff (e.g., $0). The players do not know what the others' actions will be before they make their own choice, thereby limiting their ability to cooperate by prior agreement with each other. Each play does not connect to the next.

The extensive form game is structurally similar to a normal form game, but instead tracks player choices over time, thereby enabling the assessment of more complex decision-making strategies. Extensive form games also enable players to make decisions based upon what choice the other player has made. For example, if one player decides to cooperate, the second player may then decide to cooperate (both players' payoff is $3) or defect (player two's payoff is $6 and player one's, $0). In addition, if both defect, they both receive no payoff. Since players make decisions based on previous choices, extensive form games make use of diagrams, often tree diagrams, to represent the order and outcomes of choices over time.

There are several variations of the normal and extensive form games. In a symmetric game variation, the payoffs are the same for both players. In an asymmetric game variation, the payoffs are different for each player and the strategy for each player to do well in the game is different. A game may be zero sum, in that the result of the game always equals zero because when one player has a positive payoff, the other takes a negative payoff. To explore the impact of games on decision making, one may also change the length of the game, number of players, and strategies available to the players.

In environmental anthropology, game theory has been widely used in studies of the Tragedy of the Commons. Robert Axelrod applied the normal form game—the prisoner's dilemma—to the Tragedy of the Commons. Axelrod and others are concerned with the problem of explaining why and how cooperation evolved without central authority. By being able to explain the evolution of cooperation, it can be determined how much, and in what capacity, cooperation may avert the Tragedy of the Commons. With this knowledge, viable solutions relying on realistic expectations of cooperation should result in conservation of common resources.

As important as explaining the evolution of cooperation is to commons management, what is essential is an understanding of how to maintain cooperation in a community, because only through such understanding can a program succeed. The stability of a cooperative strategy, as understood within a prisoner's dilemma game, depends on the ability of a dominant strategy to resist invasion by a free-riding strategy.

Ganges River

THE GANGES RIVER, 1,557 miles in length, flows eastward along the border separating the Himalayan complex and the flat expanse of the Indian subcontinent. Known to Hindus as the *Ganga*, the river is a source of water for human consumption, agriculture, and industry. The Ganges is worshipped in the Hindu religion as a goddess. People bathe in the waters of the Ganges to be cleansed of sins and to ensure salvation. It is believed that drinking water from the river with one's final breath will deliver the soul to heaven. The number of people living along the broad Ganges river valley approaches 300 million. The Ganges is perhaps the most polluted river on the planet. The volume of raw sewage spilled into the river is gigantic. In addition, a variety of industrial wastes find their way into the river. One in particular is especially damaging: the leather industry located near Kanpur emits large amounts of chromium into the river.

The Ganges Action Plan, initiated in 1985, was established to address serious pollution problems along the river. The program includes the building of a number of solid waste treatment plants along the river in an attempt to reduce the enormous amounts of sewage absorbed in the water. Hindu politicians have traditionally not been very active in support of the plan. Some environmentalists believe that progress is being made on this program. However, the enormity of the situation will require an energetic and sustained effort well into the future in order to significantly reduce the danger from the dumping of raw sewage.

The Ganges provides water for an extremely productive agricultural sector. A variety of crops are grown in the extensive fields along the river's course. An intricate network of canals was built over the years to direct the water to the rich soils of agricultural fields within the river valley. The river has been dammed at several sites for water management in the agricultural regions and for power generation. The hydroelectric generation plant at Farakka near the junction with the Hooghly River and close to the border with Bangladesh is an important source of power for a region containing millions of people. The Ganges empties into the Bay of Bengal and its alluvial deposits over the years have created a gigantic delta formation, the largest in the world. The delta is known as the Ganges-Brahmaputra Delta, a 220-mile wide expanse of alluvial deposits. Kolkata (formerly named Calcutta) is a major Indian seaport in the region.

The delta is highly populated with nearly 150 million people living in this precarious area. The delta is prone to flooding during the monsoon season in the spring when warm moist air from the Indian Ocean is diverted over the Indian subcontinent, bringing much-needed rainfall to awaiting agricultural fields. The rainfall is frequently excessive and flooding can occur. In 1970, an enormous cyclone hit the delta, resulting in the death of an estimated one million people. In 1998, flooding on the Ganges killed over 1,000 people and left over 30 million homeless. During that year of flooding the entire crop of rice, the main grain of the region, was completely lost.

The Ganges Delta lies within the wet tropical climate zone. As a consequence of this location the region receives between 60 and 100 inches of rainfall per year. The region is essentially alluvial plain only a few feet above sea level. The combination of high rainfall, flat land, and frequent cyclonic storms can bring flooding conditions with regularity. The region is especially vulnerable, as well, to possible increases in sea level resulting from global warming. Should this change occur in the future, the impact on the Ganges Delta would be potentially disastrous to its millions of inhabitants.

Garbage

GARBAGE IS BOTH obvious and difficult to define. We know it when we see it, but how is it different from other objects? The technical definition of *garbage* is "the offal of an animal used for food," but it has also come to mean refuse in general. A more practical meaning would be that anything that has lost its usefulness and/or value is garbage. In this way, we also speak of garbage (and its siblings trash and rubbish) metaphorically—"Did you hear the garbage that candidate was saying," "Those basketball players were really trash-talking in the final game," "That book is pure rubbish." It would seem, then, that garbage is all around us. Despite its ubiquity, however, many aspects of garbage are poorly understood. The quantity of garbage produced by each person and each country has only been estimated. Collection and management of garbage differs by locality, and is therefore difficult to generalize. Further, the relationship between human beings, garbage, and the environment is a complex and little-understood one.

Addressing these issues is not any easier than defining garbage itself. No entity counts its garbage, per se. Some places, however, do keep track of the amount of solid waste they produce. If we use this as a stand-in for garbage production, we come to a better, yet very partial understanding of garbage dynamics. For example, consider the following. According to the Organization for Economic Cooperation and Development (OECD), municipal solid waste production among its member nations increased 14 percent between 1990 and 2000. There are, though, a number of problems with this statistic. First, not all countries use the same methods to measure their solid waste; many even use different definitions of solid waste to begin with. Second, many countries do not even keep or report statistics on waste. Even if we could solve these problems, we would still be left with the question of how representative the sample is; in other words, how well do the members of the OECD represent all of the countries in the world? The fact is that many of the members of the OECD are located in western Europe. The countries of North America (The United States, Mexico, and Canada) are also members. A few countries from Asia, Africa, Eastern Europe and Central and South America are included. Overall, though, the statistics from the OECD are based on a large group of (relatively) developed nations. So, what have we learned? It would appear that the amount of garbage (in this case as the proxy solid waste) increased significantly in the decade of the 1990s. But what is happening with the garbage production of all of the countries who are not part of this number?

GARBAGE MANAGEMENT

The truth is, we cannot really know, but we can make some assumptions. The amount of garbage each country produces is largely determined by the affluence of that country. Rich people and countries produce more garbage than poorer people and countries. On the face of it, then, it would appear that the less-developed countries of the world, many of whom are not part of the OECD, would produce less garbage than the more developed OECD countries. However, many countries of the world are developing quickly. This means that the rate of increase in garbage production in these areas (and therefore in the world) may be higher than the OECD claims. As garbage production increases around the globe, countries and citizens are faced with the questions of collection, treatment, and disposal. The model on which many countries base their garbage management is the system in the United States.

Garbage management depends on a number of factors. For many people, the most obvious of these include the availability of resources, the composition of garbage, and the level of technology. Just as important as these factors, however, are cultural norms about what constitutes garbage and appropriate technology for dealing with it; local, state, and national politics; and social habits of production, consumption, and environmental management. Thus, while the rest of this discussion focuses on garbage management in the United States, it cannot be assumed either that it would be the same in other places, or that the United States itself does not have its own cultural norms and social habits that shape its management of garbage.

The United States generates the most waste per capita (about 1,540 pounds/year) of any country in the world. It continues to produce more waste every year. In 1990 the country produced 247 million tons of nonhazardous waste, while in 2001 that number jumped to 409 million tons. This waste includes substantial amounts of paper and cardboard (40 percent), as well as yard waste (18 percent), metals (9 percent), plastic (8 percent) and other products. In the United States, it is still predominantly the city or county who is responsible for managing all that garbage, despite the recent trend toward privatization of such services. In the United States as a

Archaeologists of garbage argue that what a society throws away can reveal much about who they are.

whole, 64.1 percent of garbage is landfilled. There are regional differences in these statistics. For example, in New England only 36 percent of waste is landfilled while the rest is recycled or used in waste-to-energy facilities. On the other hand, in the Rocky Mountain region and the Midwest region, respectively 86 percent and 77 percent of waste is landfilled. The environmental impacts of such systems of waste management are much debated, but there is a general consensus that garbage contributes to air, water, and ground pollution.

NATURE-SOCIETY RELATIONSHIP

Garbologists, or archaeologists of garbage, argue that what we as a society throw away can tell us a lot about who we are. These researchers study the objects found in various locations from household waste receptacles to large municipal dumps. This garbage is then analyzed (weighed, measured, and identified) in order to address several broad themes, including social consumption practices and how they have changed over time, how these practices differ by location. The ability to understand particular people through their garbage is taken for granted in the cases of tabloid reporters and identity thieves who dig through VIPs' trash in hopes of a story or useable information. While the work of the garbologist is directed at a larger scale, the principle is much the same. Many archaeologists of garbage contribute to larger issues of waste management by helping policy makers better understand the waste stream.

In addition to analyzing the waste stream, there is also significant interest in the distribution of garbage dumps, incinerators, and other waste management facilities. Environmental justice activists, for example, argue that garbage and the negative environmental effects it causes are unfairly distributed. Further, some activists and scholars argue that such facilities are disproportionately located in minority and/or poor communities. Whether this phenomenon is the result of intentional practices of locating dumps and incinerators in the neighborhoods of least resistance, or is due to structural constraints or the price of land, is up for debate. In this area of research, there is an important link between garbage, society, politics, and economics.

While many environmental activists, including those advocating for environmental justice, consider garbage as a risk to the environment and public health, there are other groups who consider garbage as a resource. These are mostly comprised of people who participate in the informal garbage economy by collecting, selling or recycling other peoples' waste. In the United States, an individual looking for soda cans and plastic bottles to recycle is the most common form of this. Recreational dumpster diving, a popular activity in some U.S. cities, is another example. There are, however, many countries in other parts of the world where communities of scavengers live on large dumps and search for resalable items. It is important to note that this informal waste economy, in which garbage is considered a resource, often supplements formal recycling and disposal efforts. That is to say that many items are removed from the waste stream in this manner with no cost to the responsible government body. This reduces the amount of waste that needs to be disposed of in landfills and other facilities.

The need to manage garbage has long driven municipal policies in the United States and other areas. The existence of garbage in an urban area threatens the area's image at the same time it attracts disease vectors such as bacteria, mice, rats, roaches, feral cats and dogs. For this reason, garbage collection and disposal became an essential part of the first sanitation programs in major U.S. cities around the turn of the 20th century. The irony of society's garbage problem is that as the more developed a country becomes economically (particular in terms of replicating the mass consumer culture of the United States), the more garbage is produced. Garbage must be considered, not just a necessary side effect of development that can be managed with technology, but rather, an integral part of societies and environments that requires social, cultural, and political–economic understanding and solutions.

Garden Cities

THE CONCEPT OF the garden city is attributed to Ebenezer Howard in England, who developed the garden city concept in 1898 as a means of developing towns that had pleasing environments. According to his vision, garden cities were to be self-contained communities. Emphasis was on a manageable population size, neighborhood service centers, mixed land uses, much green space, pedestrian walkways, and a self-contained employment base. In other words, cities were to be socially, economically, and ecologically sustainable. He put his ideas into practice by founding two such cities in England: Letchworth Garden City in 1903, and Welwyn Garden City in 1920. These two cities, although far from fully realizing Howard's vision, continue to serve as excellent examples of healthy and livable communities. Ebenezer Howard is recognized as a pioneer of town planning whose utopian ideals were to establish a new social and industrial order via the establishment of garden cities. The principles applied to Letchworth and Welwyn were an experiment to try and overcome the problems of overcrowded, unhealthy cities, depressed rural areas, and the poor building standards prevailing in some areas by the end of the Victorian Era.

Ebenezer Howard's concept of the garden city had two aims: to solve together the problems of the congested city and of the "undeveloped" countryside. By mixing the town and the country together, residents would get the benefits of both. He suggested the optimum population for such a city to be 32,000 people with fewer than 30 houses per hectare. At the center of the city would be a central park or open green space surrounded by housing with factories on the edges of the city. The city would be then be surrounded by a green belt to check urban sprawl. Sewage would be recycled and put back into the land. He envisioned independent, but environmentally sound towns that were self-sufficient in almost everything.

Howard's ideas continue to guide urban planning, especially in the development of new towns that are intended to fulfill a number of functions, such as relieving overcrowding of large cities, providing an optimum living environment for residents, helping to control urban sprawl and preserving open land. Examples of such new towns influenced by Howard's work include Margarethenhohe near Essen in Germany, Sunnyside Gardens near New York, Chatham village in Pittsburgh, Radburn in New Jersey, and Reston in Virginia. Elsewhere in the world, new capital cities have been built utilizing this concept. These include Brasilia in Brazil and Lilongwe in Malawi. Other cities, for example Guayana in Venezuela, have been developed utilizing the self-contained ideas of a garden city to serve as growth poles for industrial and regional development.

Building upon Howard's ideas, one of the most important new philosophies in suburban design is the concept of New Urbanism. The philosophy stems from the unsightly nature of American urban sprawl and became very popular in the 1980s. New neighborhoods are designed to be people-friendly, with a diverse range of housing and jobs. The idea is to design neighborhoods that have pleasing and appropriate architecture and planning, and beautiful residences integrated with jobs. Such an approach to planning urban environments would reduce traffic and pollution, increase the supply of affordable homes, and contain urban sprawl. Examples of such new towns in the United States include the resort community of Seaside, Florida, whose planning follows the traditionalist approach with mixed-use neighborhood design containing gridded streets, front porches, sidewalks, and a village-like atmosphere where one can conduct daily business without the use of a car.

After a century of experimenting with Howard's ideas of the garden city, many countries have found it difficult to maintain and sustain such cities. However, such experiments have produced worthy information for designing and managing livable urban environments.

Gardens

GARDENS ARE IMPORTANT elements of human–environment relationships. Historically, people have managed gardens for food, medicine, income, and ritual reasons, as they do today. The continuous, and most likely early, existence of gardens attests to their usefulness in multiple environments. Spatially, gardens represent intensive management of social and biophysical areas and provide insight into human knowledge systems and environmental adjustment capabilities. T. Killion defines gardens as the "polycultural mix of cultigens and useful economic species grown on small plots where the cultivator focuses on individual plants and their microhabitats by small inputs of labor on a continuous basis." C. Kimber claims that gardens are a vegetation type that "is a cultural–biological complex that can tell us much about people as they express themselves in the plant world." The species cultivated or protected in gardens reflect an individual's and a culture's decisions about which resources are valuable and deserve labor.

Biophysical relationships are not the only operative forces in garden use and change. A garden that produces needed food or medicine affects a household's future allocation of resources, providing families the ability to use cash resources for out field fertilizer, a child's school supplies, housing improvements, or other needs. Thus, the garden, by allowing households more latitude to allocate resources than nongardening families in similar settings allows a family to affect land-use decisions. Plant productivity, both in gardens and in remote fields, affects the strategies that households adopt for well-being. For example, catastrophic erosion in a field can make garden production more important than previously, engendering higher labor needs and more intensive management schemes.

Demographic and economic factors also affect gardens. As J.F. Eder explains, "continued rapid population growth, coupled with the filling in of many remaining agricultural frontiers, has significantly diminished farm size in many of the world's agricultural systems and this trend is likely to continue." Thus, garden production, carried out on small plots holds current and future promise for agricultural production. Within commodity production systems gardens serve either to augment cash earning or to lessen the need for the purchase of agricultural products, thereby reducing costs to households. By providing space and resources for diverse activities, gardens optimize the limited land available to rural families, at times being the deciding factor in household success. B.L. Turner and W.T. Sanders explain that "gardens…are spaces for the cultivation of multiple species used for additional or emergency caloric and nutritional needs, medicinals, ornamentals, and other exotic production." In addition to growing needed crops, gardens create spaces for the education of children, experimentation with plant types and cultivation techniques, and family social activities.

In the developing and developed world, gardens are components of human landscapes. The utilization of space surrounding people reflects political, economic, social, and cultural aspects of societies. These pressures act on gardeners to ensure that each garden varies significantly from others. Spatially, gardens may be located near houses or at more remote locations. Garden areas nearest houses, however, tend to receive the most attention, both in terms of intended care and unintended influence from household members and visitors. Those near house spaces are not only places of production; they are places of occupation as well. People in or near gardens select certain crops over others through use, conscious and unconscious seed dispersal, and the elimination of unwanted plants or those that grow in human activity and footpaths.

Worldwide urban gardens garner considerable interest. Nestled in unpaved, open spaces, city dwellers use gardens to produce needed food, provide a connection with nature, and create social connection with other city dwellers. In parts of two-thirds of the world, for example, gardens in large cities to alleviate economic impoverishment, in space eked out of median strips, destroyed houses, or other spaces. In the economically rich areas of the world, gardening can occur for alternative reasons, for example to avoid pesticides or genetically modified organisms. While gardens produce needed resources for families, they also provide space for social activities where children play and learn about nature, create space set apart from the outside world, and enhance the sense of community or family solidarity.

Although agricultural intensity studies demonstrate that high labor inputs often bring lower outputs per unity of work, Eder notes that "intensive garden production may not bring lower labor productivity, due to the benefits of continued harvesting and associated 'fine tuning' of management strategies." Where climatically possible, gardens are in continuous production that take very little effort on a given day but receive high levels of input when taken over the entire growing period. Measuring garden productivity in terms of production of cash or volume ignores other factors that gardeners consider important. Gardens also return variety, reduce risk, grant prestige, and preserve land races of crops. Gardens possess a wide range of cultivars both within individual and across multiple gardens. The crop diversity found in gardens owes to economic, cultural, and ecological relationships, often inseparable from one another.

Importantly, gardens are sites of experimentation and learning for plant production. Gardeners, with nearly everyday contact with their plants, notice variation and encourage preferred changes. Gardens are thus in one sense traditional, in that they have a long history with the human species, but are also fully modern in the nearly constant change and adjustments made to them.

Singapore, the Garden City

The concept of turning Singapore into a "Garden City" had its origins in 1963, when the Prime Minister, Lee Kuan Yew, initiated a large-scale tree planting campaign. Singapore became an independent country two years later, and two years after that, a plan to turn Singapore into a Garden City was formalized. This coincided with major infrastructure projects throughout the country, and public, municipal and statutory bodies were encouraged to incorporate parks, grass verges, and trees into their building and landscaping plans. The result was a dramatic improvement in the aesthetic environment of much of the country. The Botanic Gardens and other places had ensured that long before the Garden City concept, Singapore had many flowerbeds and greenery. However, from 1967 there was a concerted effort to beautify the city with trees planted along roadsides, and flowerbeds constructed along many sidewalks, under overpasses, and outside shopping arcades.

Singapore has always been known for its orchids. To make the country a "Garden City," flowers from Arabia, East Africa, India, and Latin America were introduced, including the flamingo flower from Colombia, the crossandra from India, and the peacock flower from the Caribbean, which are all now quite common in Singapore. In addition, the frangipani tree and the lantana remain popular, as does Singapore's national flower, the Orchid *Vanda "Miss Joaquim."*

Gasoline

GASOLINE IS AN organic compound found in nature that is used to fuel gasoline engines. It is called *petrol* in Great Britain, or by other names such as *benzene* in other languages. Throughout the 20th century, the exploration and development of the global oil industry was a quest for oil that was used for refining into gasoline. Prior to about 1900, the primary product made from refined oil was kerosene. It was soon discovered that gasoline was a lower temperature distillate than kerosene—it required less refracting to be extracted. The invention and application of the gasoline engine to automobiles, boats, airplanes, and other machines stimulated the refining of gasoline. Henry Ford's development of the Model T and the assembly line to build them in vast numbers at affordable prices for working-class people provided inexpensive transportation for millions. Demand for gasoline quickly exceeded kerosene demand, creating a global quest for oil and a vast system of gasoline supplies to individual automobile driver purchases.

Internal combustion gasoline engines are a type of heat engine. They use energy at high temperature to do work. Much of the heat is then dumped so that the engine can continue to work. The gasoline engine uses the Otto cycle, which is named after Nikolaus Otto, to mix gasoline vapor and air in a cylinder-shaped chamber. The vapor and air mixture is compressed. A piston uses an adiabatic compression stroke to squeeze the air and gasoline into an explosive condition. However, if the gasoline is of good quality, an explosion will not occur spontaneously. Instead, a spark plug will be used to ignite the compressed mixture. The explosion inside of the cylindrical chamber will create a very hot pressurized gas that will push the piston out in a stroke that will turn a crankshaft to accomplish work. The octane rating measures the resistance of the gasoline to premature ignition.

Gasoline is used in great quantities. Individual cars use tons every year. The exploded mixture of air and gasoline is expelled from the automobile in the form of gas. Much of the waste gas is carbon dioxide. However, there are many other compounds in the exhaust fumes. These tons of gasoline fumes pollute the atmosphere and the in various atmospheric conditions create smog. There are many health problems caused by these fumes, including a great increase in asthma. Chemically, gasoline is C_8H_{14} plus other radicals that can or may be attached. It can be manufactured from anything containing carbon and hydrogen. These forms of gasoline are synthetic. It is also possible to obtain it from oil-bearing shale deposits and tar sands. Gasoline is found with the natural gas that accompanies petroleum. Natural gasoline is usually called *casinghead* gasoline, and is mixed with the enormous quantities of gasoline manufactured in oil refineries. Gasoline, depending upon the quality of the crude oil being refined, and many other products will come from the refracting process. These include gases, kerosene, diesel fuel, and a variety of oils, waxes, and tars. In addition, contaminants such as sulfur and metals may also be produced.

The gasoline sold commercially in the United States and around the world is gasoline plus other hydrocarbons. There are more than 25 compounds that are mixed with gasoline to make different kinds of fuels. Gasoline burns differently in different types of engines. Each engine's pistons have different compression and firing characteristics. High-compression engines and low compression engines will experience "knocking" or "pinging" from premature firing if the gasoline and the air mixture are not suited for that type of engine. The result is that gasoline for automobiles would not be the best fuel for boats, airplanes, or other gasoline-using engines. Knocking occurs in an engine when the gasoline

The octane rating reflects the percentage of hydrocarbons, which increases the tendency of a gasoline to "knock."

vapors and air in the cylinders explodes spontaneously rather than burning at a uniform rate. When knocking occurs, it causes a loss of power in the engine. Using a gasoline mixture that does not explode spontaneously as the temperature and pressure in the engine increases can prevent it.

Gasoline composed of straight chain of carbon atoms tend to knock badly when fired in a cylinder. However, gasoline composed of many branched carbon chains or those with rings have a greatly reduced tendency to knock. Straight-chained hydrocarbons have low octane ratings. However, ring-type hydrocarbons have intermediate octane ratings. The highest octane ratings are given to the high-branched alkanes and benzene ring-shaped (aromatic) hydrocarbons. Gasoline refiners can make gasoline blends composed of the branched and ringed forms of gasoline. These "designer" fuels have been standardized using standard test engines. The antiknocking characteristics of hydrocarbons used in gasoline are designated by an octane rating, which is a number that indicates the tendency of a gasoline to knock in a high-compression engine. The higher the octane rating, the lower is the tendency for an engine to knock. Iso-octane is a form of gasoline with an excellent antiknocking quality; its rating of 100 is used as a standard. In contrast, n-heptane has a zero rating because it knocks so badly. If a gasoline has a rating of 90, then it has a 90 percent mixture of iso-octane and a 10 percent mixture of n-heptane.

Lead is a soft metal that has been found to be useful in gasoline as an additive that will prevent preignition or knocking. However, while lead metal is not highly poisonous, lead can be rendered toxic when it combines with acids or oxides. The lead in gasoline expelled from exhaust pipes poses a major health hazard. A common form of lead additive was lead tetraethyl, $Pb(c2H_5)_4$. In the 1970s, state and federal governments recognized lead pollution. Despite strong resistance on the part of the petroleum and gasoline industries, steps were taken to eliminate the use of lead in gasoline. By the 1980s, most of the gasoline in the United States was no longer sold as leaded gasoline, reducing the amount of air pollution caused by automobiles. Many other countries have followed suit. Gasoline fuel engines have been the mainstay American transportation for decades. They are very likely to continue to be used as long as ample supplies of gasoline are available. However, alternatives are being researched. One of these is the hydrogen fuel cell.

Geer vs. Connecticut

GEER VS. CONNECTICUT is the 1896 lawsuit that definitively formed the basis for state law concerning the ownership of animals. The case was brought against Edward M. Geer, on the basis that he was attempting to sell animals in a state in which they would be considered illegally obtained, although he had obtained them in another state through legal means. The Supreme Court ruled that states should operate their right to wildlife as a trust for the benefit of the people.

In other words, individual states were confirmed as having the right to own and control flora and fauna above and beyond the abilities and rights of private interests. Unlike most of Europe, therefore, the bulk of the land of the United States is managed in trust by the state, which guarantees the rights of individuals to use the land and its resources in a responsible way. This means American citizens have the right to roam over the land and pursue hunting and fishing activities to a much greater extent than in most other countries, where private interests control access to those resources. These rights depend on the Court's decision that the state has inherent within it a proper "police power," which should be obeyed. This decision harked back to the precedent set by Magna Carta, in which again community rights were held to outweigh private rights.

Court decisions are subject to appeal and subsequent modification by later decisions, which may be taken in the light of new information or unanticipated environmental change as much as to correct any errors that may have occurred previously. Consequently, it is not surprising that *Geer vs. Connecticut* was overturned in 1979 by the case of *Hughes vs. Oklahoma*.

Gender

ACADEMICS AND RESEARCHERS find that gender, in relation to the environment, yields certain consistencies across cultures. For example, men and women participating in the Chipko movement found that their encounter with their environment was determined by their gender. While Chipko movement members all opposed forest commons's transfer to commercial cultivation, Vandana Shiva noted that women and men had different ideas about the forest's future development. Women wanted to maintain the trees they used for fuel wood and fodder; men wanted to plant commercial trees such as eucalyptus. In other words, women were interested in sustainability; men, in access to markets.

International nongovernmental organizations such as the United Nations Development Program (UNDP) collect data on women's and men's differential access to natural resources. The current UNDP Human Development Report (HDR), "Beyond Scarcity: Power, Poverty, and the Global Water Crisis," points out that states do not value investment in sanitation, so every day millions of women and girls collect water for their families's use. Their unremunerated labors maintain gender inequalities in employment and formal education. For example, the HDR notes collecting and carrying water is a time burden that explains gender gaps in school attendance, since girls experience a direct trade-off between the time they spend collecting water and time they spend in school. The HDR's researchers point out that school attendance levels in Tanzania are 12 percent higher for girls from homes within 15 minutes's walk to water, than from homes located over an hour away from water; variation in boys's attendance rates are not explained by distance to water sources. If the UNDP asserts that women and men encounter the natural environment differently, then how do the HDR's researchers know this?

Many researchers affiliated with international nongovernmental organizations (NGOs) such as the UNDP are members of the International Association for Time Use Research, which was established to promote and sustain time use surveys. By the time use survey research method, a specialist follows an individual in order to mark how they spend their waking hours on a chart that divides each of the hours of the day into 15-minute increments. These charts serve as the basis for assertions regarding what percentage of a population's laboring time is spent in common tasks. The time use survey method has proven to be a more accurate means of recording the ways women and men spend their labor and leisure time than self-reports, which tend to underreport the amount of time spent in such repeated or habitual tasks as domestic labor. Researchers developed time use surveys in industrialized countries to follow working men's use of leisure time, including George Bevans's *How Working Men Spend Their Time* (1913) and Maud Pember-Reeves's *Round About a Pound a Week* (1913). The Multinational Time Use Study (MTUS) is based in Oxford University's Center for Time Use Research. UNDP-funded time use surveys in background papers served as the basis for the HDR's general observations that girls's and boys's educations spend less or more time in the classroom, dependent on their proximity to water sources.

METAPHORS FOR THE ENVIRONMENT

Not only do women and men encounter the natural environment differently in ways that can be measured empirically, but gender also serves as a metaphor for the natural environment. Metaphors and other figures of speech serve as a convenient tool for thinking about women and nature; the two are frequently used as metaphors for one another. For example, Washington State University's American Studies Program offers a course on gendering nature in literature and the visual arts. Premodern culture linked female-identified deities Demeter and Persephone to the earth. Goddess of the harvest, Demeter, took her revenge on humans when Hades abducted her daughter Persephone; Zeus restored order, leaving humans to suffer frosty, unproductive fields for only half the year. The woman/nature connection established in Mediterranean mythology became all the more closely linked with the emergence of modern legal and property relations during the Renaissance. Botticelli's painting "Primavera" presents an allegory on the harmony between nature and humans. In this painting, female figures represent human values and virtues; but these female figures are barefoot, their feet rooted in the earth.

The gender metaphor for the natural environment is particularly potent under modern legal systems. In Britain, a series of Enclosure Acts extended the rule of law to property during the 18th and 19th centuries, transforming entire social classes's relationships with the natural environment. During the same historical era, modernist citizenship developed to protect men's experiences, until maternalist policies came to provide social rights for women in their domestic and reproductive capacities.

Carol Pateman's *The Sexual Contract* (1988) discusses how modern concepts about political power grew from understandings of paternal power. The "state of nature" serves as metaphor for the rational choice individuals make to take on citizenship's responsibilities. The key for her argument is the point that individuals encounter the law only in those aspects that have universalized masculine rationality. As Pateman writes, "The classic pictures of the state of nature also contain an order of subjection—between men and women." Sexual difference becomes political difference, in that the law excludes those aspects of human experience that are specific or peculiar to women (whether their reproductive fertility or their domestic labor). Modernist citizenship establishes public categories for women's equation with the nature that is beyond law.

The gender metaphor for nature is also particularly compelling for modern science. As one example, primate studies serve as the basis for understandings about relationships between human beings and the natural environment in natural history museums and zoos, on television programs, in advertising and science fiction, in cinema and on greeting cards. As Donna Haraway describes in *Primate Visions* (1989), "Monkeys and apes have a privileged relation to nature and culture for Western people: simians occupy the border zones between these potent mythic poles;" along this border, a view of nature is constructed and reconstructed in these animals, who serve as gendered and racialized surrogates for humankind. *National Geographic* magazine featured the photograph of a tool-making, omnivorous chimpanzee named David Greybeard, reaching to touch the hand of researcher Jane Goodall—the same year 15 African nation-states were admitted to the UN. For Haraway, such contribute to particularly compelling myths about gender, race, and belonging in the modern world. In this way, modern science studies have naturalized the equation between women and nature.

DUAL CRITIQUES

The ecofeminist movement appropriates the metaphor that conflates gender with nature for progressive ends. Ecofeminism emerged in French with prolific Francoise d'Eaubonne publication of *Le Feminisme ou la Mort/Feminism or Death* in 1974. During the following decades, a number of activists's and scholars's endeavors compliment one another as a feminist critique of environmentalism, or an environmentalist critique of feminism. Ecofeminists draw on feminist critiques of modernism's dualistic hierarchies: mind/body, male/female, human/animal, culture/nature, white/nonwhite. Such binary categories serve as the basis for patriarchy, racism, and other oppressive systems in laws, markets, and societies. With feminist philosophers such as Rosi Braidotti, ecofeminists argue that individual and collective liberation cannot be accomplished within the modernism's binary pairs. In other words, granting women the same political rights as men enjoy will not liberate them, since masculinity grants womanhood its meaning; likewise, the natural environment is defined in culture, and is unavailable for celebration outside of the terms in which it has already been set.

With its dual critiques of feminism and environmentalism, ecofeminism is poorly represented in the professional associations that sustain both. Rather, ecofeminist scholars have developed their discussions in specialized conferences, interest groups within professional associations, for example the 1980 conference, "Women and Life on Earth: Ecofeminism in the Eighties" held at the University of Massachusetts/Amherst; as well as the 1987 conference, "Ecofeminist Perspectives: Culture, Nature, Theory" at the University of Southern California. The ecofeminist movement appropriates the gender/nature metaphor to draw activist and academic commentators from different fields. Not confined to any one field of research, ecofeminism draws on historical, archaeological, theological, economic, and political studies. This diffuse group of methodologies and epistemologies sustain a series of discussions on biodiversity, reproductive technology, indigenous knowledge in the face of intellectual property systems based on the rule of law, militarization, and globalization.

ECOFEMINIST COLLECTIONS

Ecofeminists also tend to publish in edited collections, rather than establishing a monograph series with a single press. Significant contributions include Rosemary Ruether's *New Woman/New Earth* (1975, republished 1995), Mary Daly's *Gyn/Ecology* (1978, republished 1990), Susan Griffin's *Woman and Nature* (1978), and Carolyn Merchant's *The Death of Nature* (1980). Spinifex, a feminist press in Melbourne, published *Ecofeminism*, Maria Mies and Vandana Shiva's edited volume, in 1993. Recent contributions include Nancy Howell's *A Feminist Cosmology* (2000), Peter Scott's *A Political Theology of Nature* (2003), and Sherilyn MacGregor's *Beyond Mothering Earth* (2006). Ecofeminist contributions appear on the pages of feminist journals *Hypatia* (published by Indiana University Press) and *Signs* (published by the University of Chicago), as well.

Ecofeminist works have drawn criticism from mainstream feminism and mainstream environmentalism. Third-wave feminists, in embracing perspectives that emphasize the performativity of gender, distance themselves from such essentialist positions as those within ecofeminism. And the environmentalist movement is, in general, much more comfortable with liberal democracies's general emphasis on individuals's capacities for political participation and transformation, to be comfortable with the ways in which ecofeminists are dedicated to finding patriarchal structures in multiple locations. Furthermore, with the social sciences's commitment to diversity among researchers, some critics of ecofeminism note that it develops in predominantly industrialized countries, and perpetuates certain assertions regarding women and men of predominantly agrarian communities. For these and other reasons, ecofeminist work is better-represented within multinational institutions and the research they fund, than universities.

Gene Therapy

GENE THERAPY REFERS to a group of actual or future medical treatments that are aimed at changing the genetic structure of cells with defective genes that are causing disease. This may be attempted by trying to reverse the mutation of a gene, inserting a new genome into the genetic sequence, substitution of a normal gene for an abnormal (disease-causing) one and other techniques. The type of medical problem that can be remedied through this type of technology has customarily been untreatable until these advances were made. This includes genetic diseases, sickle cell thalassaemia, leukemia, and similar problems. Technical problems that have hampered the progress of gene therapy include the problems caused by the human immune system, which is designed to resist foreign intrusions into the body, the fact that some conditions result from multigenetic factors, thereby necessity multiple interventions, and the fact that therapies currently tend to be inherently short-term in nature and require substantial modifications to be made in order to become permanent.

In order to transfer the replacement gene into its desired position, it must be transported by what is known as a *vector*, which is customarily a virus that has been engineered for this purpose. The types of virus so far employed include adenovirus types similar to those causing the common cold, retrovirus and herpes simplex virus types. Of course, great care is necessary in dealing with this material. Various techniques have been developed for using the vector to transfer the genes, although practical difficulties mean that all remain complex and potentially expensive. Nevertheless, many people suffering from genetic disorders have had their hopes raised by the possibilities offered by gene therapy and some, for want of any alternative, are prepared to offer themselves as test subjects for unproven technologies. Theoretically, at least, the possibilities are immense.

Gene therapy is considered to present a number of ethical issues. First, it involves the issue of normality and the extent to which people with genetic disorders should be thought of as abnormal and to be cured. Second, the costs of the research are very high to the extent that the benefits of the research are likely to be rationed to the very rich. Third, the analysis and manipulation of cells, including stem cells, is considered by some to be unethical because of the ability of those cells to be part of an organism developing into an independent human being. Additional issues concern the extent to which human cells may be considered property on which experimentation may be conducted according to the dictates of the owners and the subsequent commercialization of products derived from such research. Attitudes toward these issues vary and in some cases have affected the location of firms undertaking research, which move away from states where their activities are unwelcome. Even so, commercialized products and techniques acceptable to national regulatory authorities have yet to appear.

Technological improvements have led to significant increases in the value and prospects of firms involved in providing commercial applications in the field. This has led to considerable investment in these firms and a number of attempts to sequester the possible financial advantages to be had from the technology through application of patents and other forms of intellectual property protection. This is controversial since many believe that any advances in medical technology should be made available to all the people of the world, albeit that some will add the provision of ability to pay. State governments are being required to formulate policy positions that connect both intellectual property and moral issues.

General Agreement on Tariffs and Trade (GATT)

THE GENERAL AGREEMENT on Tariffs and Trade (GATT) is a multinational agreement on rules designed to foster international trade. The GATT was established in 1947, and by the 1990s, had over 100 signatory nations. The agreement has been revised periodically since its inception through negotiations referred to as *rounds*, of which there have been seven. For most of its history, the focus of those negotiations was on the reduction of tariffs, taxes imposed on imported good. Although the GATT was a relatively weak entity where disagreements between nations were primarily settled through negotiation, the agreement did facilitate a decrease in average tariffs internationally from 40 percent to roughly 5 percent of the price of imported goods.

During the 1980s, the United States, the world's largest and most powerful economy, sought to use the GATT to open more markets to U.S. goods in order to reduce its growing trade deficit and to aid U.S.-based firms conducting business internationally. During the so-called Uruguay Round of negotiations, which lasted from 1986–93, the GATT expanded beyond its traditional focus on external tariffs on manufactured goods to include provisions on agricultural products, services, deregulation, and the protection of intellectual property rights. A significantly more powerful successor organization, the World Trade Organization (WTO), was also established during this round in order to enforce trade agreements.

While the United States was successful in adding many new provisions to the agreement, some measures met with stiff resistance from social movement organizations throughout the world. An international movement composed of environmentalists, farmers, consumers, and labor organizations has since mobilized in favor of "fair trade" in contrast to the "free trade" arrangements enshrined in the GATT/WTO. They argue that large multinational corporations reap most of the benefits from free trade agreements such as GATT, while workers and the poor suffer and domestic sovereignty is undermined.

Resistance to the free trade measures has come from several sectors. Small farmers around the world, but especially in Europe, opposed the elimination of agricultural subsidies called for in the Uruguay negotiations. Although the United States had originally supported the exclusion of agricultural goods from the GATT, costly agricultural subsidies were contributing to the U.S. budget deficit and Reagan Administration officials sought to reduce this public expense. It was also believed that larger U.S. farms would have a comparative advantage over smaller European farms in the international agriculture market, but corresponding European agriculture subsidies prevented unfettered competition. In the Uruguay Round, the United States secured the reduction, but not the elimination of farm subsidies, largely due to resistance from farmers in Europe and, to some extent, domestically.

Environmentalists, consumer groups, and some labor organizations also opposed measures included in the GATT negotiations. Free trade advocates sought to eliminate what they considered *nontariff trade barriers,* nontariff measures that in some way can serve to restrict imports or to favor domestic production. This includes laws such as those that require that products be produced with a given percentage of domestic content or policies that aid a certain industry, thus giving them an advantage over foreign producers. Some environmental regulations and health and safety measures could also be interpreted as nontariff trade barriers under GATT rules. Since an anonymous panel of free trade experts would be empowered to offer a binding ruling on challenges to such laws, critics of the trade agreement see this kind of measure as an infringement on domestic sovereignty and democratic control. In one case in 1991, the government of Mexico used GATT provisions to challenge the United States for restricting the importation of tuna caught using a technique that also caught and killed dolphins, a practice that was banned under the U.S. Marine Mammal Protection Act. The GATT panel that heard the case sided with Mexico. Free trade critics charge that import restrictions on the basis of abusive labor practices or safety concerns could also be challenged, thus threatening to undermine all manner of regulatory controls and policies. European restrictions on beef produced from hormone treated cattle and forest protection measures that ban the export of raw logs are other examples cited by critics fearful that free trade authorities could undermine domestic law.

Intellectual property rights measures included in trade agreements have also spurred controversy. The United States, a leader in the development of technology, sought greater protection for patented techniques and products, which are commonly pirated, especially in less-developed nations. Agricultural technology has been the subject of greatest conflict as corporations in the wealthy nations are patenting products derived from genetic material extracted from less-developed nations. Poor farmers in less-developed nations have protested the requirement that they pay royalties for the use of seeds made with genetic material taken, without compensation, from their own countries.

General Mining Law

THE U.S. GENERAL Mining Law of 1872 was created to encourage mineral exploration and development on federal lands in the western United States, offer an opportunity to acquire clear titles to mines already being worked, and to help settle the American West. The law permitted free access to individuals and/or corporations to prospect for rocks, ores, and minerals on public lands and allowed them, after making a discovery, to stake a claim on the deposit sanctioning the development of ores and minerals from that site (originally applying to all minerals except coal).

Federal lands acquired by treaty, cession, or purchase as part of the general territory of the United States, including lands that passed out of but reverted back to federal ownership, were specifically included in the mining law administration. However, those lands acquired from a state or a private owner through gift, purchase, or condemnation are not covered by the law. Under complicated circumstances, public lands may be closed to prospecting and mineral exploration.

The General Mining Law of 1872 was the principal motivation behind the sudden growth of mineral resources in the 19th-century American West as well the associated services and industries involved in mineral production. Hard-rock minerals development included gold, silver, copper, lead, molybdenum, and uranium, with major gold and silver mining districts built under the Mining Law in California, Colorado, and Nevada. In Arizona and Colorado during the early part of the 20th century, major discoveries of porphyry copper, molybdenum, and tungsten led to extensive development and industrial growth. The law continues to support much of the West's widespread mineral development on public domain lands and although it is not as wide-ranging, it represents a major revenue generator for the United States because most hard-rock mining occurs on federal lands.

MINING CLAIMS

Once a prospector has explored for mineral and ore deposits on public domain land, he may locate a claim believed to hold that important mineral. Claimants must then pay a yearly maintenance fee of $100 per claim to hold a claim in addition to a $25 "location fee" for first-time prospectors to record their claim. According to the Bureau of Land Management (BLM) in 2000, these fees generated $24 million representing a significant drop from $31 million in 1995 after a peak of $36 million in 1997, due primarily to a drop in gold and copper prices. Once the claim has been proven as economically recoverable, and at least $500 has been added to the development of the stake, the stakeholder may file a patent application to obtain title to all surface and mineral rights.

In 1989, a claim fee of $250 per application plus $50 per claim within each application were required. If the application is approved, the claimant may purchase all surface and mineral rights for $2.50 per acre for placer claims or $5 per acre for lode claims. Placer deposits are alluvial deposits of valuable minerals found in sand or gravel and are commonly limited to 20 acres. Hard-rock or lode claims may be larger than 20 acres. Although these fees were expensive in 1872, claimed land, minerals, and ore bodies now far surpass these amounts.

The following provisions currently apply to claims under the General Mining Law: (1) there is no limit on the number of claims one person can file, (2) there is no requirement that mineral production ever begins, (3) mineral production can take place with or without a patent or any payments to the federal government, (4) claims can be held indefinitely with or without production; however, they are subject to contest if not developed.

In 2000, most of the current U.S. mining activity and mineral claims under the General Mining Law were located in only five states. Of a total of 235,948 mining claims, 45 percent were in Nevada alone and 35 percent are in Arizona, California, Montana, and Wyoming.

The freedom with which claims may be staked, the relatively low fees associated with claims, and the lack of demands in the Law for remediation of mined sites, have led to a barrage of criticisms over the last century, with movements to amend or appeal the Law on many occasions. Specifically, critics suggest that the low fees do not account for externalized environmental costs associated with mining and represent a subsidy for development of otherwise pristine lands to large mining corporations, many of which are owned and operated from outside the United States. Congressional review of the Law during the late 1990s led to a number of suggestions for revisions, but environmentalist calls for its total repeal have gone unheeded.

Genetically Modified Organisms

ALTHOUGH HUMANS HAVE altered the characteristics of many other species over the years (most notably in plant and animal domestication), a watershed was reached in the early 1970s when biologists began to directly manipulate DNA. This "genetic modification" or "genetic engineering" involved altering, recombining, and transferring genes from disparate organisms. It is one of the most powerful technologies ever devised; it is also one of the most controversial because of the ethical, legal, political, economic, and biological issues it raises.

Even the basic vocabulary for the subject is contested. The term *genetically modification* first appeared in the 1970s to describe early experiments on bacteria. But by the 1990s, in response to portrayals of such creations as sinister and unnatural, some proponents began to label all domesticated crops as "genetically modified" since ancient farmers had modified the plant's genetic makeup. The term *genetic engineering*, preferred by some biologists, is resented by some engineers because of the uncontrolled aspects of the process. *Transgenic* is often used for organisms with recombinant DNA, although it is not strictly accurate in cases where an organism's own genes have been altered. Genetically Modified Organism (GMO) here refers to an organism containing genes that have been directly manipulated.

The biology of genetic modification traces to work in the 1950s showing that bacteria exchanged genetic material in the form of extrachromosomal rings called plasmids. In the late 1960s, biologists learned to use the "restriction enzymes" that bacteria use to cut up the DNA of attacking viruses; these enzymes could be wielded to cut specific genes out of DNA molecules. In 1972, Paul Berg succeeded in making a recombinant plasmid, or gene construct, containing cut sections of DNA. In 1973, a team led by Stanley Cohen and Herbert Boyer inserted a recombinant plasmid into an *E. coli* bacterium, making it the world's first GMO; this allowed the production of large numbers of the plasmids, which could then be used to modify different organisms.

HISTORY OF GENETIC MODIFICATION

The subsequent history of genetic modification cannot be understood apart from the history of intellectual property rights with which it is entangled. In 1972, corporate scientist Ananda Chakrabarty had altered a bacterium by manipulating the natural process of plasmid transfer. This work was not of particular scientific importance, and did not even involve recombinant DNA, but it became the subject of a landmark dispute over the patentability of the modified bacteria. In 1980, by a five to four vote, the U.S. Supreme Court's *Diamond vs. Chakrabarty* decision overruled the patent office's finding that, consistent with established legal principles, living organisms could not be patented. This ruling, combined with other decisions from around the same time, allowed private ownership of modified organisms and genes themselves. Several companies quickly began work to capitalize on the right to own genetically modified life forms, most notably St. Louis, Missouri-based Monsanto Company, which had started to build a biotechnology unit a few years before. Also in 1980, the United States passed the Bayh–Dole Act, which allowed results of federally funded research to be privatized, leading to a flow of licenses on genes and genetic technologies from universities to corporations.

Industrial uses of genetically modified simple organisms appeared quickly. One of the earliest was in cheese production: in 1981 a gene for producing chymosin (a key ingredient in the rennet used to solidify cheese) was inserted into bacteria, and in 1988 a genetically modified yeast was approved for chymosin production, allowing partial replacement of the rennet from calf stomachs. Pharmaceutical applications began at the same time, and in 1982 the U.S. Department of Agriculture approved human insulin produced by genetically modified bacteria.

Genetic modification of plants followed quickly. By 1983, parallel work at Monsanto and Washington University, both in St. Louis, Missouri, had succeeded in inserting an antibiotic resistance gene into plants, as had Belgian biologists. All had used a powerful new method of introducing foreign genes. *Agrobacterium temafeciens* is a natural genetic engineer, a soil bacterium that inserts its genes into plants as part of its reproductive cycle. The biologists hijacked this process, replacing the genes the bacterium intended to insert with their own genes of choice. A few years later, Cornell scientists devised a second method of introducing gene constructs into plants by using a gun-like device that shot materials into cell nuclei. Still, the process by which gene constructs became integrated into the target organism's genome remains a mystery, so biologists have to use the "brute force" method of trying to transform large numbers of cells and then isolating the genetically modified ones by killing the others. The most common way to accomplish this is to include a gene for antibiotic resistance in the construct inserted into the target organism; the cells are then exposed to antibiotics that kill off all cells except those containing the construct with antibiotic resistance gene (and therefore also the gene/s of interest). Again, developments in intellectual property law followed these scientific developments closely. The landmark Hibberd decision in 1985 extended patentability from bacteria to genetically modified plants.

Genetic modification of animals followed a different trajectory. By the late 1960s, biologists were able to inject embryonic cells from one organism into the blastocyst (early embryo) of another, and by 1980 several labs had succeeded with the direct microinjection of purified DNA into the pronuclei of fertilized mouse eggs. Following the Chakrabarty decision, academic biologists applied for a patent on a modified oyster; the ruling in 1987 by the Board of Patent Appeals and Interferences affirmed that animals too could be patented (although not humans—the rationale being that the 13th Amendment banned ownership of humans). The next year, the United States issued its first animal patent for the "Oncomouse," a mouse with an inserted gene predisposing it to mammary cancer (the patent was issued to Harvard University and promptly licensed to DuPont). Other countries have been more wary of animal patents; Canadian courts rejected the Oncomouse patent, while the European patent office issued conflicting rulings, eventually settling on a restricted patent.

The U.S. Agricultural Research Service was the first in the world to genetically engineer barley.

Therefore, by 1988, both plants and animals could be genetically modified; the resultant organisms could be privately owned; and findings from government-sponsored basic research could be licensed or sold to corporations. Numerous academic labs and corporations were experimenting with a wide range of genetic modifications of life forms. This was a historic juncture in science, and also in the industry–university relationship. It was also a juncture long anticipated in speculative fiction, which had pointedly asked whose interests would dictate what life forms would be created. In Aldous Huxley's *Brave New World* (1989), life forms were developed according to the interests of corporate sales and state control (as exemplified by the worker caste designed to love only those sports that required them to pay for transportation and sporting equipment). Development of GMOs is still in its early stages, but important patterns have emerged reflecting the interests controlling the technology.

In plants, world area of genetically modified crops was up to 90 million acres by 2005. The vast majority of genetically modified seeds were soybean, maize, canola, or cotton. By far, the most common plant modification has been herbicide resistance: a gene is inserted to counteract the effects of a particular herbicide, which can then be sprayed without affecting the crop. Herbicide resistant crops accounted for 71 percent of the global genetic modification area. By far, the most common genetically modified species is soybean, which accounted for 61 percent of the global genetic modification area. The Monsanto Company dominated global sales of GMOs with its soybean resistant to its own Roundup herbicide, and the main customers were commercial farmers who found the herbicide resistance convenient. The second most common genetic modification was insertion of a gene from *Bacillus thuringiensis* (Bt), which causes the plant to produce an insecticide. This replaced or augmented more environmentally toxic insecticides that have in some areas lost effectiveness to insect resistance. Again, most customers were large commercial farmers, but there was a growing market for Bt cotton among small farmers in India and China. After this there is a very sharp drop-off to the third-most widely used genetic modification technology, which induces virus resistance in produce in a small number of fruits and vegetables.

Development of genetically modified animals has progressed less quickly. The first commercial genetically modified animal in the United States, in 2003, was an aquarium fish made to fluoresce (banned in California as a life form genetically altered to amuse customers). Efforts are also underway to modify salmon to grow faster in fish farms.

Thus the first dozen years of GMO development have been heavily dominated by commercial interests; since GMO's require multiple genes and technologies, most of which are now owned by corporations, this situation is bound to continue. Yet much of the public discussion of GMO's centers on uses of the technology to improve nutrition in developing countries. There is a striking gap between voluminous media on theoretical humanitarian applications and the actual development of crops for such purposes. For instance, GMO-producing firms spent tens of millions of dollars advertising "Golden Rice," but years later, neither this nutritionally enhanced rice nor any other humanitarian crops had made it into farmers' fields. Humanitarian GMO's, which generally offer no major benefits to corporations except for public relations, have encountered serious problems with funding, biosafety testing, and intellectual property.

Nevertheless, laboratories continue to experiment with a wide range of genetic modifications reflecting the potential of the technology—bacteria to detoxify the environment and prevent HIV and perhaps cancer. The theoretical benefits of the technology are enormous, as is the question of whether these benefits will ever be realized.

Genetic Diversity

GENETIC DIVERSITY REFERS to a healthy and diverse gene pool for a specific species of either a plant or an animal. The term is also used to refer to the diversity of genetic material within an individual, a population, or an ecosystem. The latter is also and most often referred to as biodiversity (or biological diversity) and inevitably embraces all the levels of genetic diversity—namely genetic, species, community and ecosystem—needed to maintain the comprehensive health of an ecosystem.

Genetic diversity is important when discussing both micro- and macro-organisms. In terms of the former, public health intervention strategies to track the global spread of disease pathogens, to develop diagnostics and vaccines, and to understand the emergence of new and drug resistant vaccines are founded upon the insights provided by research into the genetic diversity of pathogens.

Individuals, species, and entire ecosystems are advantaged by high genetic diversity via their increased capacity to adapt. Such capacity is often referred to as *resilience*. Ecosystems, which are made up of many interacting species, are healthiest when species interactions are maximized or all relevant niches are filled. High genetic diversity is correlated with a healthy species and/or ecosystem in that it provides that species and/or ecosystem with the necessary materials for adaptation to environmental and physiological perturbations. Low genetic diversity is considered problematic in that it limits a specie's and/or ecosystem's ability to respond to changes.

A well known example of the dangers of low genetic diversity is the devastation that ensued when a virus infected and killed much of the potato crop of Ireland resulting in the 19th century Irish potato famine. Had there been more of a genetically diverse potato cultivation, it could have potentially averted this famine by allowing varieties resistant to the virus to continue. On an ecosystem level low genetic diversity is common in extreme environments (high latitude/altitude, overly dry) where only species with particular adaptations to those stressful environmental conditions can thrive. As global warming changes the temperature and water regimes of these areas, researchers are concerned about the native species' ability to adapt.

Biocomplexity is another term that is critical to understanding the role that genetic diversity plays in human-environment interactions, and refers to the multitude of biological, chemical, physical, behavioral, and social interactions that affect, sustain, or are modified by plants, animals and humans. Because all systems associated with life, both biological and human-made, interact and interdepend, they all exhibit biocomplexity.

ISSUES

As E.O. Wilson (and other scientists concerned abut the relatively rapid loss of biodiversity) tells us—"The human species came into being at the time of greatest biological diversity in the history of the earth. Today as human populations expand and alter the natural environment, they are reducing biological diversity to its lowest level since the end of the Mesozoic era, 65 million years ago"—humans are the biggest contributor to the genetic erosion that is imperiling life on earth. However, to the extent that humans have and continue to destroy that diversity, they also have the power to protect and enhance it.

Genetic diversity has gained a lot of attention in the last decades in almost parallel relation to two main human activities: increased destruction and/or fragmentation of natural habitat for human activities including resource extraction, settlement and food production and an increased reliance on centralized industrial agriculture. Both of these actions result from increasing human population pressure and the need to acquire more energy resources and space for human settlement and to grow more food through intensified industrial means.

Habitat loss and fragmentation result from the human drive to exploit resources and to provide areas for human settlement. Both activities permanently alter the ecosystem they invade. Resource extraction activities disrupt the ecosystem by removing plant communities and alienating resident fauna. Although often slated with the task of reclamation, resource extraction companies rarely achieve the level of species or ecosystem diversity that existed originally. In addition, genetic diversity is lost due not only to the removal of natural areas of habitation for plant and animal species but also through the consequent introduction of nonnative invasive species that enter the ecosystem and can work to highly diminish or wipe out a species.

One of the most destructive aspects of any resource extraction activity is the creation of roads into and out of an area. Most notably, roads work to fragment habitat into smaller and more isolated units, limiting the forage and breeding range of faunal inhabitants and thereby diminishing populations' genetic diversity. Similarly, roads invite the influx of nonnative plant and animal species, in some cases, the most destructive being squatters and other human populations that often overtax the biological resources in question. Roads also "fragment" a given area with their increased noise pollution and nonpoint source pollution to adjacent surface and ground water systems. These effects in turn also negatively affect resident plant and animal species.

Centralized industrial agriculture, a mode of mass producing food in monoculture environments with little or no human labor input, has also contributed greatly to the loss of genetic diversity in domestic and wild crop races. This is due to the reliance on fewer and fewer varieties of crops, chosen for such qualities as disease resistance, shelf life, and appearance. In the process of favoring a few varieties, the rest are not grown out lost. For example, in the last half century the United States alone has gone from depending on several hundred varieties of apple to less than a dozen. Similar changes have occurred in all major food crops. In tandem, industrial agriculture depends on a heavy use of fertilizers, pesticides, herbicides, and insecticides, which work to undermine the adjacent natural ecosystem, destroying more of the natural genetic diversity in the process. Genetically Modified Organisms (GMOs) are of major concern because they further threaten genetic diversity of both domestic and wild races due to their potential to invade a plants' genetic material via the same invasive characteristics that invaded the parent plant. GMOs also introduce ethical issues since they represent the first cases of the patenting of biological materials. Many multinational corporations, most notably Monsanto, have actually sued small farmers across the United States and Canada because they found canola plants in those farmers' fields that were patented GMOs belonging to Monsanto.

ACTIONS

There are many ways that humans can act to enhance genetic diversity, mostly by taking precautions to bolster biodiversity. Individuals/households can choose to purchase products grown in ways that preserve biodiversity. For example, buying certified organic produce is a way of not supporting the industrial agriculture paradigm as does buying locally grown produce at farmers markets or through a CSA (Community Supported Agriculture). Growing part of all of your own food also contributes. Communities can also be proactive by protecting local habitat from fragmentation that is threatened by unsustainable development. Although development cannot often be stopped completely, it can be planned is such a way that corridors and tracts needed to maintain healthy populations can remain. Lastly, policy makers need to be more proactive and forward-thinking by maintaining ecosystem integrity of areas designated as crucial to the perpetuation of endangered and threatened species.

Genetic Patents and Seeds

GENETIC PATENTS ON seeds refer to laws that grant private ownership of seed varieties. With recent developments in biotechnology, patent protection has been extended to include particular plant characteristics. Genetic patents have a long historical trajectory. In the United States, decreasing agricultural productivity in the early 20th century led to a series of official mechanisms establishing state support for basic agricultural research and laws to promote the interest of the agricultural seed industry. This included the Plant Patent Act of 1930, covering plant varieties that could be commercially reproduced asexually through techniques like budding, grafting, and cutting. From the 1930s on, there was increasing pressure from the agricultural industry to put stronger official laws in place. This culminated in the Plant Variety Protection Act (PVPA) in 1970, which granted proprietary rights to novel, sexually reproduced seed plants.

A decade later, key government decisions provided the legal architecture for the emergence of the agricultural biotechnology industry. These included the 1980 Supreme Court *Chakrabarty* decision, which granted patent protection for a microbe engineered to degrade crude oil and the 1985 *Hibberd* case, which established the patenting of genetically engineered plants. With the rapid development of biotechnology in the United States that followed, companies like Monsanto used the legal protection of patents to make increasingly broader ownership claims over genetically modified organisms (GMOs). To do so, they focused on securing early patents on key commercial crops and using these patents for leverage in licensing agreements.

Although adopting stricter regulations over biotechnology, western European countries were historically the first to coordinate regional patent efforts. In 1961 they established the Union for the Protection of New Varieties (UPOV), creating a framework for international plant-patent protection. UPOV has undergone three revisions (1972, 1978, and 1991). The United States joined in 1981 and from the mid-1990s through the present, membership has expanded to 61 countries. This is largely due to the General Agreement on Trade Related Intellectual Property Rights (TRIPS), created in 1994 within the World Trade Organization (WTO), requiring countries to adopt intellectual property rights as part of free trade negotiations.

CONTROVERSIAL ISSUES

Nevertheless, the patenting of seeds is controversial for numerous reasons. First, because much plant diversity originates in the global south, there are heated debates over foreign access to and the sharing of the economic benefits arising from genetic patenting. Critics assert that biotechnology companies' use of genetic patents to reap the profits from plants modified over hundreds of years with traditional breeding methods is a form of "biopiracy." Second, many fear that the enforcement of seed patents in the global South along with the continued opening of markets to subsidized agricultural imports from industrialized countries would displace subsistence farmers for industrial agricultural production. These concerns have been expressed in the International Treaty on Plant Genetic Resources for Food and Agriculture, approved at the 2001 meeting of the Food and Agricultural Association of the United Nations (FAO). Based on the Convention on Biological Diversity, this international seed treaty has the goals of protecting local farmers' rights of seed saving and sharing and ensuring that the economic benefits of patents reach local communities. Although the treaty came into force in June 2004, many countries, including the United States, have yet to ratify it. Critics fear the goals of the treaty will largely be subsumed under the mandate of the WTO.

Another controversial aspect of genetic patents on seeds are recent concerns over the legal implications of the cross-pollination of genetically modified plants with native varieties. North American farmers have already been prosecuted for patent infringement after genetically modified plants had unknowingly spread to their fields. The cross-pollination of genetically modified corn with native seedstocks in Mexico has heightened concerns that this genetic contamination, along with strict patent enforcement, could be disastrous for small-scale producers throughout the developing world. Industry efforts to prevent the transfer of genetically modified traits to wild plants and unmodified crops have resulted in even greater concerns over a method introducing a "terminator" gene into crops that eliminates seed fertility. Although touted as a means to address the problems of seed contamination, this gene could also spread via pollen, eventually destroying native seedstocks and wild plants. In this sense, the legal mechanism of patenting along with terminator technology could degrade the base of genetic material necessary for continued agricultural innovation.

Genetics and Genetic Engineering

THE TERMS *GENES, Genetics,* and *Genetic Engineering* all refer to the molecular units of heredity and variability in living organisms. Gene comes from the German word *Pangen,* which is derived from the Greek *pan* (all) and *genos* (kind, offspring). Genes are the units of heredity that are recombined and passed through reproduction; they express characteristics in living organisms and contribute to biological variability. Genes are found in the germplasm, specifically the chromosomes, and are made of a sequence of amino acids found in an organism's DNA. In the modern discourse about genes and genetics, life is shaped by sequences of information carried by genes. This information codes the production of specified proteins or enzymes.

THE STUDY OF GENETICS

Genetics is the study of inheritance and variation. It seeks to understand the units of genetic action, heredity, mutation, and recombination. Since Darwin's work on the evolution of pigeons, finches, and earthworms, natural historians had been looking for casual mechanisms to explain evolution. The theory of natural selection proposed by both Darwin and independently by Alfred Russell Wallace posited that populations that can adapt to their environment are more likely to pass on their traits to future generations or progeny.

By 1900, natural historians had a prime candidate for the casual mechanisms of evolution when Hugo de Vries, Erich von Tschermak, and Carl Correns rediscovered the basic laws of inheritance. Gregor Mendel, an Austrian monk studying in the 19th century, developed a theory of inheritance while studying the reproduction of peas from 1857–63. According to Mendel, the variation of an organism's characteristics is the outcome of combinations and expressions of genes. For each characteristic of an organism, each individual inherits genes called alleles from each parent. Each characteristic is an expression of an alleles' molecular synthesis. If the alleles differ, some alleles will be dominant with others being recessive. The presence of a dominant allele will express that particular trait, but the recessive allele will still be in the hereditary material of the organism. For a recessive allele to be expressed all the units of heredity must be the same.

Biologists distinguish between phenotype and genotype. The phenotype of an organism is the expression of the organism's traits like eye color or leaf size. The phenotype of an organism can also be affected by its environment, such as when some plants are stunted by exposure to excess light. The genotype is all the hereditary material carried by an organism including the recessive traits not expressed in the organism. The genotype is the coded information found in almost all living cells that are passed along through heredity. The genotype codes for the expression of phenotype, and the phenotype can subsequently altered by its environment.

Soon after the rediscovery of Mendel's work, William Bateson coined the term *genetics* in 1905. Thomas Hunt Morgan incorporated much of Mendel's work into his own chromosomal theory of inheritance where chromosomes carry hereditary materials. Morgan's work suggested a sex-linked model of inheritance based on the white eye mutation in fruit flies (spp. *Drosophila*), which has become the model insect for geneticists.

APPLICATIONS AND DISCOVERIES

One early application of genetics was in plant breeding, particularly corn or maize. Here the hybridization of maize was studied at public breeding stations until it became commercially profitable for private enterprise. By the 1940s, genetics shifted from statistical breeding techniques to techniques based on molecular biology and biochemistry. Griffith's notion of the transformation principle and Avery's research showing the ability of Deoxyribonucleic acid (DNA) to transform cells pointed to the centrality of DNA and its constitutive amino acids in inheritance. They resolved a contemporary debate regarding whether proteins or amino acids contained the hereditary information.

In 1953, Crick and Watson made their famous discovery of the double helix through X-ray diffraction. The race to solve the structure of DNA was quite competitive, with all parties agreeing that the timing of the discovery was immanent. Wilkins and

Genetic engineering has been extensively incorporated into medical practice, but not without social concerns.

Franklin took the first X-ray photographs of DNA at King's College in London and shortly thereafter passed the images on Watson and Crick, helping them solve the puzzle.

The discovery of the double helix through X-ray diffraction was a critical juncture in the marriage of genetics and physics. It was another demonstration of the superiority of reductionist model of science. It soon became common to describe the process of heredity as the passage of information, messages, and code. Life itself was simply characterized as a computer program built on a cybernetic feedback system. These mechanisms oriented molecular biologists, as the profession soon began to inquire about the ways that DNA was encoded in the cell nucleus.

Genetics as a discipline emerged in elite universities such as Caltech, MIT, Harvard, and the University of California at Berkeley; research centers like Cold Spring Harbor Labs, New York; and new centers of the information economy developing in places like Santa Fe, New Mexico, California's Bay Area, and Cambridge, MA. These places boomed as private and Federal research dollars were directed to the pursuit of new molecular sciences: immunology, virology, cell biology, biochemistry and microbiology.

DNA ANCESTRY

The tools of genetics were soon extended into areas of archaeology and anthropology. Attempts to understand historic human migrations out of Africa and into the Americas often rely on studies of mitochondrial DNA. All human have two sets of DNA. The first is found in the chromosomes found in the cell nucleus, while the second freely floats in the cell in the mitochondria. Chromosomal or nuclear DNA is inherited from both parents while mitochondrial DNA is only inherited through the female lines of inheritance. This means that every parent has contributed to an individual's nuclear DNA, but mitochondrial DNA is traced only through the mothers mitochondria. Those who share the same mitochondrial DNA are a member of the same haplo-group. This provides clues to ancestry, as certain haplo-groups will always have similar ancestors.

POLYMERASE CHAIN REACTION

The polymerase chain reaction (PCR) is a significant tool for geneticists working on a wide variety of problems including those in ecology and anthropology. PCR is a chemical reaction used to copy fragments of DNA. PCR has been used to map the genomes of many species including humans. The mapping of the human genome has raised considerable controversy as questions about what to do about genetic "defects" and alterations of the gene pool are constantly raised. Other controversies involve how genetics might be used as a tool for discrimination, genetic profiling, and the role that genetics might play in determining a genetic basis for human behavior.

GENETIC ENGINEERING

Genetic engineering is the term usually reserved for these molecular modifications that use recombinant techniques. With genetic engineering, scientists argue they can more precisely manipulate the units of heredity at the molecular level. Novel assemblages of genes can made by moving genes across the species barrier, bypassing the condition of sexual compatibility previously required for genetic recombination.

Genetic engineering introduces foreign DNA into the host organism in several different ways. The most popular way is to introduce the DNA into host with a viral or bacterium invasion into the host's nucleus. This virus or bacteria is known as the promoter. Transferring genes using a bacterium involves combining the desired gene with a plasmid, which is then carried by an agrobacterium. The agrobacterium inserts itself through the cell wall depositing the desired gene in the host organism. After gene transfer both the promoter and the desired gene remain in the plasmid. These plasmids are then cultured, and in the case of plants, moved to a greenhouse where it is determined whether or not the desired gene is expressed in the plant's phenotype.

Often this is done with a marker gene, which when expressed, makes it easy to identify which plants contain the desired gene. The most common marker genes are those for antibiotic resistance so that the determination can be done early. Antibiotics kill cells without the new genes. This has raised many food safety concerns about genetically engineered foods because it is unclear whether or not the antibiotic resistance affects human health or promotes resistance. Newer marker genes include traits of phosphorescence from jellyfish, where the desired trait can be ascertained from the organism's exposure to a black light. Other genetic engineering techniques use non-viral promoters. The particle gun technique uses gold or tungsten covered pellets coated with bits of DNA that penetrate the cell wall and randomly insert themselves into the hosts DNA.

Genetic engineering is used synonymously with the term *genetic modification*. The term is used politically to denote the precision of r-DNA techniques. Scientists often argue that much of plant breeding, for example, is a form of genetic modification. By proclaiming the practice as genetic engineering, scientists invoke a sense of control that was previously unattainable in molecular biology, medicine, and plant breeding.

CONTROVERSIES AND SOCIAL CONCERNS

Genetic engineering has been extensively incorporated into medical practice. DNA techniques are used to diagnose genetic diseases and to develop medicines such as human-made insulin for diabetics, promising treatments for breast cancer, and medicines to help kidney transplant patients avoid rejecting the new organ. However, these technologies have not been without social concerns. Concerns about social justice emerge with human engineering and the way that the identification of genetic "defects" will affect insurability of some social groups.

Genetic engineering is far more controversial in agricultural biotechnology where it has become embroiled in controversies in places as ideologically distant as Geneva and Mendocino County, California. Subsequent to the containment issues raised with the early r-DNA experiments, the deliberate introduction of genetically engineered organisms [GEOs; also known as genetically modified organisms (GMOs) or transgenic organisms] into the environment set off a host of new controversies.

In 1983, the deliberate release of the "ice minus" bacterium developed by University of California biologist Steven Lindow set off a new round of local reactions in the Bay Area cities of San Francisco, Berkeley, and Oakland. Lindow planned to spray potatoes in the Tule Lake area of Northern California with an "ice-nucleation active" bacterium that would inhibit the formation of frost on the plants. These field tests were approved by the NIH's RAC. Activist Jeremy Rifkin of the Foundation on Economic Trends obtained a court injunction to stop the release, arguing before the court that the experiment posed an environmental hazard.

In 1985, Congress decided that new regulatory agencies were not necessary, and that the existing regulatory system was appropriate for handling the classes of concerns raised by ecologists and activists. Many activists and ecologists simply saw this as an effort to manage GEO introduction instead of regulate them. The Food and Drug Administration would evaluate food safety concerns; the Environmental Protection Agency (EPA) would oversee concerns about toxicity; and the Department of Agriculture's Animal and Plant Health Inspection Service would regulate problems related to increased weediness and biological invasion.

Also in 1985, the Ecological Society of America released a position statement noting the potential ecological and environmental hazards associated with introducing GEOs into the environment. They noted that the products of r-DNA technologies, genetic engineering, posed no new classes of ecological hazards. But the novelty of the new technology warranted regulatory oversight, because there is the potential for more extreme and uncertain ecological hazards. Ecological and environmental problems may follow from intrinsic qualities of the plant itself, its interaction with its environment, and/or the practices associated with its cultivation. These hazards in many cases are the extreme versions of

Big Business

Genetics research became big business with the creation of the National Science Foundation and the National Institutes of Health after World War II. Now private companies and private researchers could benefit from government research contracts. Entire industries emerged around the development of scientific research equipment and materials. The new wave of innovation in all of the life sciences was driven by the privatization of research and eventually the privatization of molecular life itself.

In 1973, a University of California, San Francisco (UCSF) molecular biologist Herbert Boyer and Stanford molecular biologist Stanley Cohen conducted the first recombinant DNA experiments, which led to the new technology now know as *genetic engineering.* Using plasmids, they cut and spliced one living organism's DNA sequence in vitro to another organism.

The significance of this experiment was clear in several ways. First, it led UCSF, Stanford, and eventually other universities, to set up university-based patent offices. Second, coupled with the rollback of public funding for higher education, it provided the universities with a private means for funding public education. Third, it set off questions about the potential hazards of r-DNA experiments. Some r-DNA experiments were using viruses as vectors to introduce the foreign DNA.

At the Gordon and Asilomar conferences of the early 1970s, Paul Berg and about a dozen other leading molecular biologists called for a temporary moratorium of certain kinds of experiments. They also recommended that the National Institutes of Health (NIH) form the Recombinant DNA Advisory Committee (RAC) to evaluate the consequences of r-DNA experiments. In 1975, a second Asilomar conference focused on biosafety concerns was called upon to preempt any ethical or social considerations of r-DNA manipulations. By 1976, the RAC recommended guidelines for r-DNA experiments that included specific containment facilities and protocols for recipients of Federal funding.

The NIH guidelines served to publicize the dangers of r-DNA. The publicity generated by legal actions by environmental groups like the Environmental Defense Fund and Friends of the Earth generated debate in the U.S. Congress and the House of Representatives about Federal regulations on r-DNA experiments. In the end, Congress decided to do nothing; however, some local jurisdictions such as Cambridge, Massachusetts, began to regulate r-DNA experiments at the local level, sending a message to scientists that the overall health and safety of the community could be the basis for the regulation of scientific experiments.

Soon the guidelines were relaxed after more scientific understanding of the safety of the experiments was garnered. No hazards had materialized, weakening the arguments of environmental and public interest groups. The RAC furthered relaxed rules to protect the proprietary considerations of corporate laboratories and rules that distinguished between large-scale and small-scale experiments at the request of Eli Lilly. By the time these changes to the RAC guidelines in 1983, almost all r-DNA experiments could be considered exempt from oversight.

conventional analogs, but the novelty of some traits makes ecological effects even more likely. If the organism became endowed through gene flow with traits that improved its fitness, the organism could act as invasive plants do.

GENE FLOW

Gene flow is the movement of genes from one place to another as when seed is transported or pollen drifts and subsequently hybridizes. If gene flow leads to introgression, the subsequent backcrossing of two hybrids, the transgene may remain in the wild or weedy population potentially increasing weediness or invasiveness if the transgene confers fitness advantages.

Gene flow also poses consequences to genetic diversity as outbreeding depression or genetic swamping could result in the extinction of wild relatives in the Vavilov centers of genetic diversity. The potential for outbreeding depression would follow if short-term fitness advantages favor the increased presence of the transgene in the population but with long-term fitness consequences over time (e.g., reduced fecundity, increased disease susceptibility). Genetic swamping would occur where the receiving plants are relatively rare and exposed to high rates of hybridization. These concerns are paramount in the case of transgenic maize in Mexico, as there are instrumental as well as intrinsic values of biodiversity at play; small farmers as well as international research institutions depend upon the diversity of wild relatives and landraces for plant breeding.

GENE FLOW AND TRANSGENIC HAZARDS

Other hazards associated with the adoption of GEOs include those to agroecosystems. Widespread use of herbicide-tolerant (HT) RoundUp Ready™ and Liberty Link® crops could lead to the rapid evolution of resistance to herbicides like glyphosate and glufosinate in weeds, either as a result of increased exposure to the herbicide, or as a result of the horizontal transfer of the HT trait to weedy relatives of crops. HT crops could change the mix of herbicides used as some become ineffective, which could result in greater levels of overall environmental harm. Since herbicides differ in acute toxicity and persis-

Mexican Maize

In 2001, a University of California at Berkeley professor and his graduate student tested maize landraces grown in Oaxaca, Mexico, the center of crop diversity for maize, and found the presence of patented transgenes despite a moratorium on transgenic maize. Their study found not only the presence of transgenes in maize landraces, but also suggested that the transgenes inherited did not exhibit the stability ensured by the crop's developers and patent holders. Their initial findings were published in a brief article in the journal *Nature*. Shortly after publication, the journal came under fire from the scientific community, particularly those supportive of the life sciences industry and from within the discipline of molecular biology. *Nature* retracted the article, questioning the researchers' methodology and interpretation of evidence. When data were subsequently submitted supporting the findings, *Nature* refused to publish them, to retract the retraction, or to provide a forum to pursue earlier editorial commentary.

Despite concerns that transgenic crops may pose threats to biodiversity, the *Nature* controversy continues to be framed as one of academic practice and integrity. The point that GE traits were found in Mexican maize landraces, a Vavilov Center of crop-wild diversity, seem to be less a concern. Opponents were noticeably silent about the permeability of the food and seed systems in response to questions from NGOs, indigenous groups, and ecologists about the adequacy of regulatory institutions to control the deliberate introduction of GEOs.

tence, loss of some herbicides may be detrimental to the environment overall.

The introduction of transgenic crops also raises concerns about insect resistance. The naturally occurring microorganism *bacillus thuringiensis* (Bt) has been used as a pesticide for several decades, as it crystallizes and blocks the passage of food into the stomach of many species of Lepidoptera, effectively killing them. Its rapid degradation when exposed to UV light keeps it outside of the EPA's oversight, allowing it to be widely used in powdered form by organic farmers. However, many studies have shown that Bt resistance can evolve rapidly in agroecosystems. Incorporating the genes that produce Bt's endotoxin into plants and subsequently planting them on such a large scale could, unless properly managed, hasten the evolution of resistance, with implications for both organic and conventional farmers. Currently, industry argues that high dose-refuge model will suppress the evolution of resistance in Lepidoptera. They argue that the high dose of Bt will kill most of the pests and that the alleles that develop resistance will be "diluted" by the presence of a non-Bt refuge harboring Bt-susceptible Lepidoptera. However, this argument rests on two assumptions. The first is that Bt resistance is a recessive trait; the second is that farmers actually plant the refuge.

The impacts of transgenic crops on biodiversity from changes in farming practices may be to the detriment of the biodiversity near and in farms. In October 2003, the Royal Society of the United Kingdom published its findings from farm scale evaluations. Two out of the three crops studied demonstrated an association between transgenic crops and practices harmful to wildlife as well as a tendency to decrease biodiversity. The report attributed the impacts to changing in spray regimes of herbicides, finding that wildlife adjacent to GE crops were subject to increased exposure to agrochemicals such as atrazine, pointing to a significant difference in agronomic practices associated with GE and conventional varieties.

Nontarget effects of GE crops could threaten both biodiversity and agronomic practices such as biological control. Plants engineered to produce toxins in mobile tissue parts such as pollen pose threats not only susceptible species that enter into areas where the crop is grown, but also to the adjacent field margins where the pollen may drift as in the monarch butterfly controversy. Researchers suggested that Bt, *bacillus thuringiensis*, which drifted onto milkweed growing in adjacent to fields of Bt corn, increased the mortality rates of monarch larva. Toxic mobile plant tissues may impact soil biota as well. Bt has been shown to accumulate in the soil through the root exudates of transgenic plants. The impact of dosing the rhizosphere with the Bt endotoxin has not been evaluated for consequences to nontarget soil organisms or to soil health. Beneficial insects used in the biological control of pests are also subject to nontarget effects. One study suggests that the green lacewing, an insect beneficial to farmers because it predates the same pest that Bt is used against, suffers greater mortality rates after consuming Bt-fed prey.

Transgenic crops conditioned to produce viral-resistance potentially can create new or more virulent viruses through two mechanisms: recombination and transcapsidation. The former can occur between the plant-produced viral genes and closely related genes of incoming viruses; the latter occurs when nucleic acids from one virus are incorporated into the protein structure of plants. Both can result in viruses that infect a wider range of hosts, demonstrate increased virulence or lead to a biological resistance "arms race." Further, some viruses play an ecological role in plant community dynamics. For example, barley yellow dwarf virus resistance has been engineered into cultivated oats to prevent yield losses. It has also been shown to suppress invasive wild oats. The transfer of viral resistance in this case may increase the invisibility of wild oats in natural communities as it alters plant competitive interactions.

BIOSAFETY

GE animals and insects pose other questions about biosafety. Transgenic salmon engineered with genes from an ocean pout grow at rates six to ten times faster, because growth hormone production, which seasonally shuts down in salmon found in the environment, does not shut off. Because of the advantages of fast growth, these fish may out-compete native fish if they are released into the ocean. Researchers at the University of Purdue developed the Trojan gene hypothesis: Under this scenario, the fish out-compete naturally occurring fish, but suffer long term deficiencies associated with the growth hormone staying turned on. The critical question in the regulation of transgenic salmon is whether salmon grown in open sea aquaculture pens will be required to be sterile, or whether growing transgenic salmon will only be permitted on land.

Biosafety ecologists agree that ecological impacts are greatly unknown. Ecological risk assessment suggests that some organisms pose threats to the environment, while others will suffer greater fitness consequences from having their phenotypic expression altered. A more modest approach to evaluating the risks of biotechnology recognizes uncertainty, complexity, and incomplete knowledge while emphasizing the precautionary principle from post-release monitoring to designing rigorous ecological risk assessment.

Activists urge that assessments of genetic engineering be accompanied by analyses of the social consequences of these novel technologies. The history of technology adoption is littered with inequality and disproportionate burdens of impacts. To this end, many activists have been successful in using biosafety as a surrogate for getting at questions about access, control, and development of new technology.

Geographic Information Science

ORGANIZATIONS THAT HAVE a planning, research, management, operational, and/or regulatory responsibility at the local, county, state, or federal level are increasingly turning toward Geographic Information Science (GISc) technology as an approach to data organization, visualization, integration, synthesis, and modeling. GISc is an integrated set of tools, techniques, concepts, and data sets associated with a host of spatial digital technologies including Geographic Information Systems, Remote Sensing, Data Visualization, Global Positioning Systems (GPS), Spatial Analysis, Quantitative Methods, and Spatial Modeling.

GISc is routinely used in government agencies, corporations, environmental health and ecological consulting firms, planning organizations, and academic institutions. Together, and separately, GISc has gained prominence across the social, natural, and spatial sciences. As a rapidly growing computer technology, GISc supports many kinds of decision making and analyses, including environmental policy, marketing, planning, demographic analysis, resource management, ecological analyses, health care delivery, nutrition and diet, environment and health, epidemiology, and information technology. These spatial digital technologies offer the opportunity to gain fresh insights into the pattern of variables and the behavior of systems through, for example, the spatial, temporal, spectral, and radiometric resolutions of remote sensing systems that are capable of mapping a host of social and ecological landscapes; the analytical and data integration capability of Geographic Information Systems (GIS); the locational specificity afforded through GPS; the importance of data visualizations to characterize patterns and to relate scales of representation to processes influencing areal distributions recorded over space and through time; and the predictive power of quantitative models and the descriptive capacity of statistical relationships and spatial analyses.

GISc is a fundamental, spatial, and non-spatial informational framework and perspective used to understand the nature of geographic data and provide theoretical foundations for geo-spatial techniques.

GISc evolved from the computerized, geographic information systems of the 1960s and 1970s. The increased demand and availability of spatial data and spatial data analysis, together with improved computer power and algorithms and software functionality have transformed a spatial analytical perspective characterized as a simple toolbox to an information system, and now to an integrated approach to science (i.e., GISc). Central to GISc is a suite of spatial digital technologies, best exemplified by GIS, Remote Sensing, and GPS.

GIS TECHNOLOGY

GIS and the other spatial technologies operate synergistically to create a model of reality that reflects the informational requirements of the project and the data visualization needs of the user. To achieve this duality of information and presentation, paradigms of mapmaking have shifted from the communication paradigm to the analytical paradigm. This shift is marked by a departure from the physical map as the final cartographic product—in which base information has been transformed and symbology applied for graphical display—to an approach in which geographic data are stored in a computerized database to provide multiple views of the information to multiple users, and where the physical map is only one form of visualizing spatial pattern, distribution, and association. The power of the approach is based on its interactivity, integration, customization, and alternative visualizations. GIS technology offers an analytical framework for data synthesis that combines a system capable of data capture, storage, management, retrieval, analysis, and display. From a functionality perspective, GIS techniques examine spatial and nonspatial relationships through analytical tools and techniques that, in general, include attribute operations, overlay operations, neighborhood operations, and connectivity operations; represent an array of landscape perspectives through the integration of geographically registered spatial coverages; efficiently display such information through a variety of data visualization approaches for spatial and temporal pattern analysis; examine the co-occurrence of spatial and nonspatial data through database manipulations; display singular thematic coverages or composited coverages through cartographic and/or statistical approaches; and model the location and behavior of phenomena through empirical and process models.

REMOTE SENSING TECHNOLOGY

Remote Sensing is a surveillance and mapping science that is concerned with the observation and/or measurement of objects and features without having the measuring device in direct contact with the entity of interest. Remote sensing takes into account how energy and matter are interrelated at distinct spectral regions, whether collected on film or by digital sensors. Remote sensors are engineered to be sensitive to different parts of the electromagnetic spectrum (spectral resolution); map different sized objects and features (spatial resolution); and assess landscape characteristics using a quantitative range of response intensities (radiometric resolution), generally extending from 0 (low intensity of reflectance) to 255 (high intensity of reflectance). Remote sensing systems also are capable of rendering views across time (temporal resolution) as a consequence of their historical perspective of operation and their orbital specifications that periodically returns the satellite over the same geographic location for change imaging. Optical sensors are most commonly applied to landscape mapping. Optical sensors typically operate in the visible, near-infrared, and middle-infrared spectral regions of the electromagnetic spectrum, because of their capacity to discern important biophysical characteristics of the landscape including special properties of vegetation. In film products, information collected about the landscape is generally amalgamated into a single image by compositing the film layers, but in digital data sets, separate images or channels are retained for each spectral region so that the user can combine information about the landscape as appropriate.

GPS TECHNOLOGY

Finally, GPS involves the use of a constellation of 24 satellites that broadcast precisely timed signals to fixed and roving receivers to triangulate and transmit geographic coordinates for the characterization of positions recorded in the x-, y-, and z-dimensions. A host of applications rely upon

GPS technology including airplane, car, and boat navigation; ecological and engineering activities conducted in local and remote environments; and surveying and mapping for business and industry. Also important for linking people and the environment, Earth coordinates are collected at household dwelling units as part of a socioeconomic and demographic survey so that locational information are explicitly linked to household variables, land parcels associated with individuals and households are spatially referenced, and sources and destinations of migrants can be geographically described and linked to characteristics of people, places, and environment. In short, GPS technology effectively defines the "where" of a variety of studies and analyses that are conducted at local, regional, national, and international settings.

Geography

THE WORD GEOGRAPHY is rooted in the Greek and literally translates to "writing the earth." As a modern academic discipline, it is characterized by multiple traditions usually regarded as sharing a common concern for the spatial qualities and problems of the world, and the complex relationships between human beings and nature. Following a period of low academic profile, the discipline is apparently resurgent, especially as global environmental problems and issues have emerged center-stage and the spatial and scalar nature of contemporary social and economic problems has become increasingly apparent.

The foundations of the modern discipline of geography are found in other disciplines and throughout history. For example, ancient Greek writers—including Aristotle—frequently commented on the nature and order of the environment and society. During the 16th and 17th centuries, by uniting religion and academic observation of the world, theology played an important part in thinking about environment. Natural Theology, for example, assumed that since God made the world's features, studying them could enlighten humankind as to the character of God. These and other diverse bodies of academic scholarship made it possible to eventually build a discipline—geography—that is concerned exclusively with features of the natural and social world.

GEOGRAPHY AND DETERMINISM

Emerging in the 19th and early 20th century, geography used the world's regions as a basic explanatory unit on scales ranging from continents to the political and natural subdivisions of countries. At first, this regional geography purely described region's social and natural contents. Gradually, however, the interaction of the natural environment and human behavior was accorded dedication attention. Drawing on Darwin's work, the theory of Environmental Determinism, for example, argued that local environmental conditions determine the character of people and their activities. Such arguments were used to explain European "achievements" over peoples living under less ideal environmental conditions and, not surprisingly, served to reinforce European supremacy in the world. Meanwhile, other influential geographers such as the German Friedrich Ratzel and the Englishman Halford Mackinder examined the territorial growth of states and empires. In his 1904 paper *The Geographical Pivot of History* Mackinder introduced his Heartland Theory, which argued that in order to dominate the world and dictate world affairs, the world's heartland (Eurasia) must be occupied. He famously stated, "Who rules East Europe commands the heartland, who rules the heartland commands the world island, who rules the world-island commands the world." These kinds of ideas filtered into the turbulent and aggressive European politics of the era. At this time a divide was also growing between physical and human geography. The former being concerned with the working of the world's physical environment, the latter—as the above discussion of nation states indicates—being concerned with society and environment.

SPATIAL TO HUMANISTIC GEOGRAPHY

By World War II, human geography had begun to develop a scientific rationale and approach. In his 1939 book *The Nature of Geography,* Richard Hartshorne argued that geography existed purely to discover the functional spatial integration of phenomena. Based on these ideas, a growing assumption in the discipline of society being logically and geometrically distributed over space provided the theoretical basis of *spatial science,* which, as a paradigm, dominated geography until the 1970s. Assisted by emerging computer technologies in their attempts to articulate the world's various spatial orders, geographers focused their attentions on distances, directions, locations, and spatial associations. Geographers typically refer to the rapid emergence of spatial science in their discipline as the "quantitative revolution."

During the 1970s, spatial science was attacked and undermined from within the discipline. Many geographers were concerned that, through spatial science, geography was incorrectly privileging distance above all other relational features of social and economic life and moreover, in doing so, was isolating itself as an exclusive science of space. Another criticism of spatial science highlighted the abstraction of people and places in this research to dots on maps and numbers in equations. It was thought that this filtered the complexity of individuals and humanity out of geographical writing. Critics were also concerned about the assumption made in spatial science that people behave rationally, predictably, and economically. In this regard, critics emphasized people's capacity for individuality, irrationality, to follow fashions and act on their own tastes and whims.

From these critiques, a humanistic tradition grew in human geography and emphasized human agency and individuality. Humanistic geography pioneered a much more sensitive approach to the study of people, which remains in the contemporary discipline to this day. Moreover, they started to think about the complexities of places, beyond being physical locations or boundaries of human activity to being social phenomenon that facilitate human actions, interactions experiences, attachments, identities and possess symbolic meaning. The new subjects studied by humanistic geographers were diverse and included considerations of art, history, poetry, and fiction.

At the same time, in a search for explanations of fundamental social processes, a Marxist approach emerged within the discipline. This work was based on the observation that, to exist, Marx's political economy of capitalism depended on the production of a space-economy. David Harvey called it the "spatial fix of capitalism," referring to how capitalism is reliant on space, the availability of which determines its success and nature of its development. In terms of how this works out in the world, Marxist geography thought of urban space as being shaped by the unequal division of capital (owners and workers) and being contested by these respective classes.

During the early 1980s, the humanist paradigm was critiqued for its lack of theoretical depth and for its general descriptiveness. Meanwhile, Marxist geography was criticized primarily for privileging capitalism in determining societal orders to the neglect of other identities in society. Indeed, during the 1990s and into the new millennium, a growing number of human geographers have become interested in the relationship between culture and place. In a rapid disciplinary movement, postmodern theoretical perspectives and qualitative methods have been adopted by the discipline. Cultural geographers explore how language, meaning, experience, and subjectivity are related to place. Amongst geographers, these emerging interests have become known as the *cultural turn.*

MODERN GEOGRAPHY

Human geography is now composed of a number of highly overlapping subdisciplines, some of which are distinguishable by their focus on a specific type of place (for example, rural geography and urban geography), others that are more clearly distinguishable by their focus on a specific empirical subject or theme (for example, development geography, tourism geography, and health geography) and others that are more clearly distinguishable by their specific conceptual focus (for example, historical geography, feminist geography, and moral geography).

Moreover, overlapping the borders of many are recognized debates or bodies of literature (geographies of caring and emotional geographies). Meanwhile, physical geography has retained its scientific basis and approach and has escaped many of the paradigm shifts and trends outlined above. Its scope remains broad, investigating the spatial character and patterning of natural phenomenon such as vegetation, soils, landforms, climate, and various water masses. In terms of disciplinary connections, physical geography incorporates—and has obvious broad overlaps with—geomorphology, geology, hydrology, meteorology, climatology, and even oceanography.

Human and physical geography might be distinguishable, yet there are obvious overlaps, particularly in considerations of environment and society. Moreover, institutionally they are often taught together in universities and schools the world over.

Geology

GEOLOGY IS THE study of the solid, nonliving earth, including earth's materials, structure, processes, and history. Earth's nonliving materials and features are the result of geologic processes. Geologists study these processes, operating today, and in doing so interpret how ancient earth materials or features formed. By determining these processes, and the time at which they occurred, geologists interpret the history of the earth. The science of geology includes the following subdisciplines: mineralogy, the study of minerals; petrology, the study of rocks and their formation; geomorphology, the study of earth surface processes and landform development; sedimentology and stratigraphy, the study of sediment and strata; paleontology, the study of fossils and ancient life; structural geology, the study of rock deformation; geophysics, physics of the earth; and geochemistry, chemistry of the earth.

To environmental science, geology provides the knowledge base for several basic areas of study. Geology includes the study of geologic time and earth history. Information about ancient (prehuman) earth and its atmosphere, hydrosphere, environments, and geologic processes, is preserved in the rock record. Geologists interpret the information in the rocks and provide analyses of earth's ancient conditions. For example, information about the Precambrian atmosphere is interpreted from mineral assemblages and fossils contained in Precambrian strata. Similarly, the long-term record of global climate change, including global warming and cooling, is preserved in the rock record.

Geologic maps portray the surface occurrence of different types of rocks. These maps are the result of careful ground-based investigations. Geologic maps provide the locations of different rocks and sediment deposits on earth's surface. They can be used to predict the suitability of various places for different types of land use, and to show the surface occurrence of mineral and energy resources.

Geologic maps are also used, sometimes in conjunction with subsurface information obtained through drilling and geophysical methods, to interpret the location and structural geometry of rocks in the subsurface. Such information is used to find and assess the occurrence of mineral and energy resources in the subsurface. In addition, these configurations, together with information about the permeability of the rocks, control the presence and movement of subsurface fluids such as groundwater, oil or natural gas. For example, the direction and speed of groundwater flow, including any contaminants, may be predicted by understanding the nature and geometry of rocks in the subsurface.

Information about the surface and subsurface occurrence of rocks, sediments, and minerals is also important to the extent that these materials interact with water or other fluids. Through the process of weathering, bedrock contributes solid and dissolved constituents to groundwater, surface water and soils. These constituents may constitute basic nutrients or contaminants, depending on the constituent and its concentration. Some subsurface materials—such as sand or sandstone—may act as a natural filter, removing particulate matter and thereby purifying groundwater.

GEOMORPHOLOGY

Geomorphology is the study of landforms and their genesis through processes such as weathering and erosion. These processes include the agents by which the earth's surface is modified by the action of gravity, running water, wind, groundwater, glaciers, and ocean waves and tides. Sedimentology is the study of sedimentary depositional processes. The history of conditions that occurred at various places on earth's surface is preserved in strata. Stratigraphy is the study of these strata and the historical conditions they represent. Paleontology is the study of fossils and the conditions under which ancient life forms existed.

Geology includes the study of the tectonic process, which is driven by the interactions between earth's tectonic plates. These interactions result in earthquakes, volcanoes, tsunami, uplift or subsidence of the land surface, and long-term deformation of rocks. Plate tectonics is a relatively young discipline, and has been understood since the 1970s. Plate tectonics has revolutionized and unified the science of geology. We now know that mountain belts, continents, ocean basins, and the earth's crust are all formed by slow plate tectonic processes that have been operating for billions of years.

Geologic hazards are a major environmental concern. These hazards include earthquakes, volcanoes, tsunami, ground subsidence, floods, and landslides. Most of these hazards are the result of an extreme case scenario of an otherwise normal geologic event. For example, rivers usually flood every year. We don't notice many of these floods because they are a normal occurrence in the yearly variation in the flow of the river. However, conditions that control river flow, such as precipitation and runoff, may be excessive and may result in an extreme flood event. A 100-year flood is the maximum flood that occurred, or is statistically estimated to have occurred, over a 100-year interval. Similarly, most earthquakes have a low magnitude and are not noticed or have minimal effects. However, the less frequent, high magnitude earthquakes have been extremely destructive, as is the case for San Fransisco.

By determining geologic processes and timing, such as in rock strata, geologists interpret the history of the earth.

Time is an important dimension in geology. All geologic information must be understood in the context of geologic time. When and over how long a period did a geologic feature (mineral, rock, landform, mountain belt, etc.) form? Some geologic processes such as floods, earthquakes, and volcanic eruptions occur over observable time spans. Each of these processes, however, is part of longer term processes that occur slowly, over thousands to hundreds of millions of years. Floods are part of the process by which river landscapes are developed. Earthquakes and volcanoes—which themselves occur quickly—are involved in the long-term formation of ocean basins, or in mountain-building. These long-term processes can not be directly observed, but must be interpreted from the record preserved in rocks. The interpretation of these processes, and the time and duration of their formation, is a major emphasis in the science of geology.

Geomancy

THE TERM *GEOMANCY*, derived from Greek roots, refers to the earth (*geo*) and attempts to use attributes of the earth in a prophetic (*mantikos*) manner. Geomancy involves the use of the earth in a process of divination. A separate form of geomancy uses astrological symbols and indicators to derive the meanings to personal questions and concerns. Geomancy relates to particular times at which conditions in the cosmos are appropriate for revealing answers to the inquirer's questions. Divination is related in some contexts to the work of Carl Jung and his synchronicity concept. Jung's notion involves "meaningful coincidence" to provide explanations of the divination process, which uses a 16-symbol context similar to the system used in astrology. An African form of geomancy involves the tossing of dirt into the air and observing the pattern once it falls. A Chinese variant of geomancy uses an individual in a trance to interpret the markings on the ground. In a general sense, geomancy refers to the human ability to employ pattern recognition to determine the answers to personal questions.

Geomancy came to prominence during the Renaissance, as European cultures transitioned to the modern era. A prominent advocate of geomancy and an author on the subject was Henry Cornelius Agrippa, a 15th century philosopher. The system of geomancy involves the asking of a question of importance by an individual. In the next step, the inquirer concentrates on the question and proceeds to make a series of 16 rows of marks on the earth, continuing to do so until it feels right to stop. The resulting patterns of tracings can then be observed to determine the answer to the question posed. Geomancy in the Western world relied heavily on the attributes of astrology, and has been referred to as *astrological geomancy.* As such, the 16-element context uses Mars, Venus, Jupiter, the Moon, and other astronomical bodies in various combinations and at particular times to determine the answers to the inquirers' questions. Again, the process involves pattern recognition; in this case, the relative locations of celestial bodies at specific times.

Geomancy is related to certain forms of agriculture. The early 20th century agricultural researcher, Rudolph Steiner, wrote and lectured on the need for sustainable forms of farming, identified as *biodynamic agriculture,* which should avoid the use of artificial fertilization. He argued that fertilizers and pesticides were not inherently bad, but that the materials had "spiritual" shortcomings. Steiner believed that the world and all living matter in it were spiritual in nature and that living matter differed from dead matter. He believed that the farm was a living system and should be regulated to maintain that status. For example, a farm entity that was diseased should be treated within the context of the entire farm, and not addressed as an isolated occurrence. It is the spiritual nature of biodynamic agriculture that relates the practice to geomancy. Steiner's formula for proper farm operation extended to the use of specific forms of field preparation, weed and pest eradication, and compost development and application. An associated practice following the basic dictates of Rudolph Steiner is found in the practice of *biodynamic viticulture*. Biodynamic viticulture is practiced worldwide, and many grape growers attest to the improved quality of the grape, and the resulting wine, as a result of this belief and practice.

Geomorphology

GEOMORPHOLOGY IS THE science of Earth's landforms, exploring such diverse questions as how rivers erode sediment, what landforms were like when humans evolved, why rock surfaces have different colors, and where floods and landslides can be avoided. Teaching and research in the interdisciplinary field of geomorphology occurs in college departments of geography, geology, civil engineering, and sometimes archaeology, soils, and hydrology.

Any point on Earth's surface can go up in elevation, remain in place, or go down in elevation through erosion. Volcanic and tectonic geomorphologists focus on the building of relief through volcanic events, faulting, or folding rocks. Eolian (wind), coastal, and glacial geomorphologists study both the buildup of relief and its erosion. Weathering and soil specialists study the transformation of rocks into smaller fragments and eventually into soils. The decreases in surface resistance to erosion eventually allows the transport of weathered fragments by gravity through mass wasting such as landslides and through water transport called fluvial processes.

The table of contents of most introductory geomorphology textbooks reveals the sorts of topics studied: weathering (rock decay), mass wasting (landslides), fluvial (rivers) processes, groundwater, tectonic (earthquake) landforms, topographic expression of folded strata, topographic expression of joints and faults, landforms developed on igneous rocks, glacial processes, glacial landforms, Quaternary climatic changes and the Ice Ages, periglacial (ground ice) processes and landforms, shorelines, and eolian processes and landforms.

In every field of science, the orientation or perspective of the researchers drives what and how they investigate questions. Geomorphology is no exception. At the start of the 20th century, geomorphologists focused on reconstructing the sequence of past events producing today's landforms. The 1960s and 1970s started a trend still dominating the field today—of focusing on studying physical, chemical, and biological processes responsible for landform changes. The reconstruction side of geomorphology remains today, exploring such arenas as how to mathematically model landform change or how climatic changes in the last few million to thousand years affected landforms.

The two dominant journals are *Earth Surface Processes and Landforms* and *Geomorphology,* although important articles can be found in dozens of other scholarly serials. Geomorphologists typically belong to one or more of the following scholarly organizations: Geomorphology Specialty Group of the Association of American Geographers; British Geomorphological Research Group; Hydrology Section of the American Geophysical Union; and Quaternary Geology and Geomorphology Section of the Geological Society of America.

Like many disciplines of knowledge, geomorphologists struggle with trying to make advances in basic knowledge of the science, while also applying existing core knowledge to solve societal and environmental problems. Geomorphologists work on such applied research as understanding the effects of building a dam, why urban growth destroys beaches, the storage of toxic chemicals in river sediments, or how environmental changes can exacerbate landslides on top of houses.

Georgia (Nation)

THE NATION OF Georgia is located on the crossroads of world cultures in the Caucasus region between the Black and the Caspian Sea. About the size of the U.S. state of Georgia, the nation has a relatively small population of 5 million. In 2004, the Western-educated and U.S.-oriented Mikheil Saakashvili swept into power along with a government for national reform led by the National Movement Party. The goals of this new government have included the opening of markets, democratization, and the development of new investment. Progress in these goals has been challenged by Russian support of the two breakaway provinces of South Ossetia and Abkhazia, leading to sometimes-serious border disputes. A recent initiative for peaceful resolution of South Ossetia, however, was introduced in 2005. The restoration of peace in these regions will prevent further environmental degradation caused by constant, low intensity warfare.

Focused on raising standards of living and levels of external investment, especially in petrochemicals and pipelines, the nation of Georgia is faced with many serious environmental challenges, which will only increase if development is not managed carefully. Although a party to the Kyoto protocol, air pollution has built up to high levels in the industrial city of Rustavi. The Mtkvari river is also heavily polluted with industrial, agricultural, and human waste. As this waste is deposited into the Black Sea it further contributes to the environmental degradation of the Sea's fragile red algae ecosystem. A legacy of Soviet control and the remains of Soviet toxic dumps have led to the pollution of soil and watersheds. Closely associated with the United States in a region heavily influenced by Russia to the north and the Islamic world to the south, Georgia is in a fragile political position. The development of a sustainable environmental policy will be difficult in the light of current political and social demands. Nevertheless, further democratic empowerment and the flourishing of nongovernmental organizations may provide ways of highlighting important, short-term environmental concerns.

Geosphere

THE GEOSPHERE IS the nonliving inorganic portion of the earth, in contrast to its thin surface layer of living things called the biosphere. The geosphere is the whole inorganic earth, including the lithosphere, the hydrosphere, and the atmosphere.

The earth is roughly spherical in shape. Most of the interior of the earth is invisible to human observations. The term *geosphere* is used to point to the layers of the earth as a solid globe, as if an observer could imagine a cutaway of the earth from its central interior to the outer most limits of the atmosphere. The whole planet is in dynamic motion in terms of geological time. The core is believed to be solid dense metal surrounded by the semi-molten mantle. It has unevenly heated convection currents in the molten mantle that causes movements in the earth's crust that appear as plate tectonics on the surface.

Geologists believe that the earth's solid metal core is probably nickel, iron, and some other heavy metals. It lies at a depth of 1,800 to 3,100 miles (2,900 to 5,000 kilometers) from the surface. Above the core is the semisolid outer core. It is intensely hot, as is the core of the earth. The layer above it is the mantle. It is molten and composed of lighter elements that crystallize near the surface, becoming a layer called the *lithosphere*. It floats on the surface of the mantle, like the skin of a warm bowl of vanilla pudding. The lithosphere is the crust of the earth that forms the continents. It is rich in calcium, sodium, potassium, and aluminum. It has a lighter mass than the mantle or the crust of the ocean floor, which is chemically closer to the chemistry of the mantle, but with more silicon. Between the lithosphere and the mantle is the *asthenosphere*. It is about 110 miles (180 kilometers) thick. It is composed of the plates upon which the lithosphere rides over the mantle.

Both the ocean floor and the continents are covered by the *regolith*, which is a covering of rock much like a blanket. The soils of the earth are either formed by the regolith or by sedimentation. Regolithic erosion occurs when solid rocks rot due to chemicals, water, or wind. The *biosphere* is the thin layer of living plants and animals that cover the surface of the earth, and to a lesser degree the upper levels of the oceans.

The *hydrosphere* is the water blanket that covers much of the surface of the earth. This water blanket contains life, and is necessary for life, but it is not in itself alive. Some of the hydrosphere consists of the lakes, rivers, ponds, and other bodies of water found on the surface of the earth. The *atmosphere* as part of the geosphere is composed of gases, dust, and other particles, including floating mold spores and viruses. The atmosphere is also necessary for life.

Some natural scientists use the term *geosphere* in a restricted sense that is synonymous with lithosphere. Others use it to refer only to the solid earth—the core, the mantle, and the crust. Both of these definitions exclude the atmosphere and the hydrosphere as part of the geosphere. During the evolution of the earth, the geosphere has interacted in a variety of ways with the biosphere, as have the atmosphere, the lithosphere, and the hydrosphere. Of significance to natural scientists are the many ways these interactions of the geosphere-biosphere have happened. Geosphere interactions include the precipitation of minerals from superheated water moving toward the surface of the earth. The creation of life forms or geographical features is part of the interactions of the geosphere and the biosphere. Other interactions include how the hydrosphere has eroded the lithosphere to create sedimentary layers, or the interactions of water to change the chemistry of the lithosphere.

Geothermal Energy

GEOTHERMAL ENERGY IS derived from heat within the earth. Earth's internal heat is due to the residual heat that was produced when Earth formed, in addition to heat generated by radioactive decay. Earth's temperature increases with depth below the surface. The inner core has a temperature of about 4,000 degrees C. The increase in temperature with depth is referred to as the geothermal gradient. A normal geothermal gradient is 15 to 30 degrees C/kilometer. The geothermal gradient is much higher, double or triple, in areas of recent volcanic activity.

Generally, the higher the geothermal gradient, the higher the heat flow to the surface.

Generally, geothermal energy is tapped either by drilling wells into bedrock and allowing hot water and steam to flows up to turn a turbine on or near the surface. Usually the water and steam extracted is routed back into the subsurface to close the circuit and add pressure for extraction.

The world's major geothermal energy fields are associated with areas of active or recent volcanism. The Pacific Rim of Fire has many developed geothermal fields associated with subduction zone volcanism associated with the convergence of tectonic plates. Some of the popular geothermal areas include New Zealand, Indonesia, the Philippines, Japan, northern California, Mexico, and several countries in Central America

Iceland is located along the Mid-Atlantic Ridge, a divergent plate boundary. Icelanders use geothermal energy to the extent that, together with hydropower, they are able to supply electricity and heat to the entire island. Because of this, Iceland is independent of fossil fuels except as an automobile fuel.

The geothermal fields at Lardarello, Italy, are the oldest in the world. They were developed in the early 1900s utilizing dry steam. This geyser and hot spring area is associated with the recently active volcanism north of Rome. The geothermal fluids have a high content of boric acid, which is utilized along with the heat.

In areas of high geothermal gradient, the geothermal resources occur as hot or dry steam, or hot water that circulates through a permeable zone, such as Yellowstone National Park. The hot water or steam can be used as a direct source of heat or as a source of mechanical energy to turn turbines and generate electricity. Circulation is usually deep, but more recently the circulation of shallow groundwater in areas of high heat flow has been utilized.

Hot dry rocks occur in areas where magma or recently solidified magma is isolated from groundwater. Hot dry rocks require that water be pumped into the ground and recycled to extract the power. Temperatures can reach as high as 1,200 degrees C, depending on the type of magma.

Geopressurized systems are associated with areas of deep burial such as along the Gulf Coast of the United States, where the normal heat flow is trapped by insulating layers of sediment. Along the Gulf Coast, temperatures reach over 270 degrees C at depths of 4 to 7 kilometers.

Areas of normal geothermal gradient are extremely common but have a low level of energy. Geothermal heat pumps utilize lower geothermal gradient, and may therefore be useful in most areas, whether or not they are close to volcanic centers.

Geothermal energy is a relatively clean and environmentally friendly source of energy. Adverse effects occur mainly in the form of gas emissions, and thermal and chemical pollution from the wastewater. Geothermal energy is considered a renewable resource because there is no practical limit to the supply of this energy.

German Royal Forest Academy

THE GERMAN ROYAL Forest Academy (*Konigliche Forstakademie*) was the first public organization devoted to the scientific study of forestry, which began with the German Royal Forest Academy in the early 1800s. More and more students studied forestry and it spread around the world.

Noblemen have kept forested preserves for hunting and for wood products since the early Middle Ages. The dominance of forestry by hunting interests steadily declined after the mid-1800s, as the interests of German nobles turned to mining. Good-quality timber was needed to shore up mines, for smelting, and for cross ties for mine ore cars. However, it was soon recognized that the supplies of available timber affected mine profits. This gave rise to the concept of *sustainable yield*, and to the development of German forestry.

In Germany, especially in the lower mountainous areas, forests were common. Natural climate and soil conditions following the last Ice Age led to the development of these forests, dominated by the beech tree. It is very tolerant of shading by other species, such as oaks, maples, ash, cherry, popular, pine, spruce, and fir, except where the soil conditions are poor for beech trees. Other species were forced into areas of soil conditions that were excessively wet or dry, poor or very rich in nutrients, or located at high mountain elevations. By 1800 much of the original dense beech forest cover in Germany had been cleared for agriculture. Other areas had been virtually deforested. However, rural houses were usually built from wood, heated by wood, and by income derived from logging. Because there was a growing need for quality timber, afforestation programs began.

Over the following 200 years, the German forestry practice rebuilt the forests. The afforestation excluded the original beech in favor of oaks, pines, and other softwood trees. The softwoods were easier to grow and commanded a better price, but the oaks, while harder to grow, also commanded good prices. As these afforestation programs developed, large areas were in the hands of private landowners, whose interests were personal and commercial. As a consequence, timber companies own only a few German forest areas. In addition, the drive to increase timber yields and profits promoted the study of forests and forest management as a sustainable crop and as a family matter. As the 1800s progressed, the efforts to build sustainable timber lands in Germany led to the establishment of several forestry schools, the first of which was the German Royal Forest Academy established in Berlin in 1820. By 1900, forestry schools had been established in Prussia, Bavaria, Saxony, Wurtemberg, Baden, and Hesse. Several new sciences dedicated to the study of forest botany and management had also been established.

Heinrich David Wilchens became the first professor of forestry in Schemnitz, Hungary (today Banska Stiavnica, Slovakia). Other leaders who emerged to develop and spread the science of forestry included Carl Ludwig Obbarius, a forest warden in the Hartz Mountains who developed a school of forestry for one of the mining companies in Schweden. Dietrich Brandis went to India, where he laid the foundations of tropical forest management. Carl A. Schenck founded the Biltmore Forest School on the Biltmore Estate near Ashville, North Carolina. It was the first forestry school in the United States. At the time the only other scientifically trained foresters in America were Bernhard Fernow and Gifford Pinchot. Pinchot was the first chief of the United States Forest Service. Using money his father had gained from timbering, Gifford founded the Yale University School of Forestry in 1900. He was able to recruit and develop a professional cadre of foresters who were trained to engage in commercial forestry and conservation. He was also able to defeat John Muir's campaign to return vast areas to nature.

Germany

GERMANY IS ONE of Europe's most densely populated countries, with over 230 inhabitants per square kilometer. It also has a prosperous and technologically powerful economy, the fifth largest in the world. Despite its density and strong economy, both factors often compounding environmental problems, it ranks within the top 25 percent of countries categorized in the 2005 Environmental Sustainability Index (ESI). This index, developed by the Yale Center for Environmental Law and Policy and the Center for International Earth Science Information Network at Columbia University, looks at the ability of nations to protect the environment in the upcoming decades. The higher ESI score a country receives, "the better positioned it is to maintain favorable environmental conditions into the future," according to Daniel Esty. Within the European Union, Germany ranks 10th of 22 countries, and of high population density countries, in which over half the land area has a density exceeding 100 persons per square kilometers, Germany ranks second only to Japan. While Germany has a positive sustainable outlook, it has had to implement various laws in the past in order to deal with its environmental problems.

In 1970, the government issued an Emergency Program for Environmental Protection, which dealt with the control of air, water, and noise pollution, waste disposal, and the protection of nature. This program was based on three critical principles: the prevention principle, the polluter-pays principle, and the cooperation principle. The prevention principle aims at avoiding pollution and environmental risks before they occur, while the polluter-pays principle assigns the costs of pollution to the polluter who is responsible. Only when no distinct polluter can be identified will the government bear the cost. The principle of cooperation states that environmental protection is a task that must be shared equally by the government, citizens, and corporations. Also, it

Prior to the 1970s, acid rain was not taken as a serious environment threat until Der Spiegel ran a cover story in 1981 about Germany's forests dying due to acid rain. A popular call to action was likely due to the German cultural love for forests.

states that involvement by the community is crucial to the acceptance of decisions made by the governmental administration.

ENVIRONMENTAL MOMENTUM

As the environmental movement gathered strength in state politics, an amendment to Germany's Basic Law was added in 1972, which stressed the importance of environmental protection. The Basic Law, Germany's modern constitution of 1949, gave the 11 German states power to create laws concerning the environment. The amendment in 1972 added legislative jurisdiction over waste, air, water, and noise pollution to the existing duties of the federal government. This change also allowed for the creation of an environmental administration, called the Environmental Protection Division, set under the Interior Ministry. A further amendment to the Basic Law in 1994 secured environmental protection within basic institutional principles. The amendment states that the federal government has a responsibility for future generations, and therefore "it shall protect the natural basis of life" whenever a state entity takes action, according to the German Embassy in Washington, D.C.

Germany's environmental policy asserts, "protection of the environment can only be truly successful if it places equal importance on air, water and soil," as explained by the German Embassy in Washington, D.C. The ecological political party, the Green Party, have had a positive influence over Germany's environmental objectives, while impacting the phasing out of nuclear power, endorsing energy efficiency, reducing greenhouse gas emissions, and making alternative fuel sources possible. As a result, there are many examples of the government taking action to deal with the issues of clean air, renewable energy, climate protection, waste management, and the phasing out of nuclear energy.

While Germany has steadily advanced its environmental policy and management since the beginning of the 1970s, environmental problems, most noticeably air pollution, abounded in the late 1970s and early 1980s. Reliance on brown coal for electricity, heavy industrialization, and traffic harmed forests and air quality throughout Germany. Prior to the 1970s, acid rain was not taken as a serious threat to the envi-

The Bombing of Dresden

The British Royal Air Force and the U.S. Army Air Force bombed the German city of Dresden between February 12–15, 1945, destroying much of the city. It was one of the most intense bombings of a European city during World War II.

The British and the Americans decided to step up their bombing of German cities to help the Soviet Army, and had already decided to target Dresden, the old capital of Saxony, before the Yalta Conference began on February 4. One of the British concerns was to destroy the German lines of communication, and it was felt that unless Dresden was bombed, rail traffic could be diverted through the city. For this reason the railway yards in the city had been bombed twice already—on October 7, 1944, and again on January 16, 1945. The February raids were followed by two further raids on March 2 and April 17. The bombs were initially high explosives to blow off the roofs of buildings to expose the timber; incendiary bombs were dropped to set fire to the ruins. Finally, another large number of high explosives were dropped to hamper any efforts of fire brigades. The first bombing on the night of February 13 saw 1,478 tons of high explosives followed by 1,182 tons of incendiary bombs being unleashed on the city, followed by 800 tons of high explosives. Three hours later, 529 Lancaster bombers of the Royal Air Force dropped another 1,800 tons of bombs. Soon after midday on February 14, U.S. bombers dropped 771 tons of bombs, with another 466 tons dropped on February 15.

Some 78,000 houses were destroyed, along with damage to 200 factories. According to contemporary German reports, 21,271 were confirmed dead, with 35,000 listed as missing; 10,000 were later found alive. Published estimates of deaths range from 35,000–300,000. Even if the number was on the lower side, which is probable, the destruction of an historic city and the deaths of tens of thousands of civilians remain controversial. Since the war, much of the city has been rebuilt in the original style with significant aid from British and American groups.

ronment, until a 1981 cover story ran in the German magazine *Der Spiegel*. In the article, a German scientist hypothesized that Germany's forests were dying as a result of acid rain and thus the issue became highly publicized. This was a wake-up call for the German population and instilled a popular call to action, likely due to the German cultural love for forests. After German reunification in 1990, it was noted that air pollution, acid rain, and habitat degradation were particularly severe in the former East Germany. Additionally, the disparity of energy efficiency and air quality control between East and West Germany was enormous. A move away from the strong reliance on brown coal, improvements in energy efficiency, and the closing down of plants causing major pollution helped the environment recover in the Eastern states.

CLEAN AIR AND RENEWABLE ENERGY

Over the last decades, and largely in response to forest death from acid rain, Germany set up a clean air program to reduce harmful emissions output and eliminate certain elements contributing to air pollution. The program has been successful in reducing sulfur dioxide levels by more than 60 percent in the western states, and by 90 percent in the eastern states between 1995 and 2005. Further improvements will likely proliferate due to a ban in 2000 of all leaded gasoline. Recently, the EU has introduced the concept of sulfur-free fuels, which would reduce a car's fuel consumption by as much as 20 percent.

Another area in which Germany has introduced new laws pertains to renewable energies. The government under Chancellor Helmut Kohl (in power 1982–98) actively promoted the use of renewable energy through the Electricity Feed Act. This act was passed in January 1991 and regulated "the feed-in of electricity from renewable energies to the grid," according to the Federal Ministry for the Environment, Nature Conservation and Nuclear Safety. This act stated that the grid system operator was obligated to purchase the electricity at a fixed rate, a feed-in tariff. In 2000, this act was replaced by an act entitled the Renewable Energy Sources Act, which had a more expansive scope. This revised act required grid operators to feed in electricity from renewable sources as a priority, and pay the minimum fixed fee for the electricity.

Petra Kelly

The founder of the German Greens Party, Petra Kelly, was born in Bavaria in 1947 as Petra Karin Lehmann. When she was twelve she went with her parents to the United States, living there until 1970. She changed her surname to Kelly when her mother married her stepfather, an American army officer. In 1966 Petra Kelly started studying political sciences at the School of International Service, American University, Washington, D.C. Two years later, she campaigned for Robert F. Kennedy and then for Hubert Humphrey.

Moving back to Europe to study at the University of Amsterdam, Petra Kelly worked at the European Commission in Brussels, Belgium, from 1971 until 1983. During that time she became heavily involved in environmental issues and the peace movement in Germany. In 1979, Petra Kelly became a founder of *Die Grünen,* the German Green Party, and in 1983 was elected to the West German parliament, the Bundestag, for the Greens, holding her seat until 1990.

This was an important period for the environmental movement worldwide, with the Green Party in Germany holding a large number of seats in the parliament. The party was heavily opposed to nuclear power, and the increasing pollution of the environment, campaigning for a reduction in the use of private motor cars. She was the author of a large number of books about the environment and nonviolence, and had always been a great admirer of Martin Luther King, Jr.

On October 1, 1992 Petra Kelly was shot dead while she was asleep in Bonn. The body of her 69-year-old partner, the ex-N.A.T.O. general and Green politician, Gert Bastian, was nearby and it appeared that he had shot her and then turned the gun on himself. Petra Kelly's papers are now part of the Heinrich Böll Foundation.

Wind power is a renewable energy that has flourished in Germany. Currently, Germany has about 39 percent of the world's wind energy, making it the world leader in wind power generation. Since the Renewable Energy Sources Act went into effect, Germany's electricity grid operators have purchased over 500 million Euros of wind power energy. The addition of this renewable energy to the grids has had a positive environmental effect; in 2001, the use of wind power reduced CO_2 emissions by approximately 10 million tons. In addition to air pollution and renewable energies, Germany, as one of the worlds' industrialized nations, committed itself to drastically reduce greenhouse gas emissions in 1997 by signing the Kyoto Protocol. Germany has already reduced its greenhouse gas emission from 1990 levels by 18.7 percent, and the country plans to continue the reduction to 21 percent between 2008 and 2012.

ECO-TAX AND OTHER REFORMS

In 1999, Social Democrat Chancellor Gerhard Schröder, whose party governed in alliance with the Greens from 1998–2005, introduced Eco-Tax Reform. The goals of the Eco-Tax Reform included climate protection and employment generation. The Eco-Tax increased the general taxes on fuel, gas, and electricity for consumers, raised industry and farming taxes, and was to aid in the reduction of social welfare taxes from 42.3 percent to 40 percent of gross income. The Eco-Tax Reform was also put forward to decrease Germany's dependency on polluting energies and thereby create new environmental jobs. According to a study Commissioned by the German Federal Environmental Agency (UBA), the Eco-Tax Reform has helped Germany attain its goals. It cut CO_2 emissions by approximately 20 million tons and created 60,000 new jobs.

Waste management is another environmental issue that is being tackled by the German government. In 1990, German households produced over 38 million tons of waste, while commercial waste accounted for over 15 million tons. Due to the potential damage to soil and groundwater from this waste, the German Bundestag in September 1994 adopted the Closed Substance Cycle and Waste Management Act, which promoted "closed substance cycle waste management in order to conserve natural resources and to ensure environmentally compatible disposal of waste," according to Jürgen Giegrich. Waste-management laws focused on creating low-waste products and recycling, which the government hopes will eventually produce no waste at all, hence a closed cycle. Adhering to the polluter-pays principle, the waste stemming from products must be accepted for recycling by that product's seller or manufacturer. In order to accommodate this process, the Dual System was set up as a private enterprise to collect the various packaging materials. License fees permitting manufacturers and supplies of packaging material to place a Green Dot on their product finances this enterprise. The dot, while not an indicator that the product is made of recyclable material, simply tells consumers that the packaging should be recycled via the Dual System, which can be done in household curbside bins or municipal bins. For Germans, the commitment to waste separation and recycling is clearly seen by the four bins in front of every house: one blue, yellow, green, and gray, each of which is used to recycle a different type of material.

Germany's phasing out of nuclear energy has been a controversial topic. Regardless, in 1998, Germany announced its plans to phase out nuclear energy following the formation of the Social Democratic Party (SPD) and the Green Party coalition. The chief reasons for this move were the unacceptable risks connected with nuclear energy, specifically the disposal of radioactive waste and the potential for nuclear reactor meltdowns. In June 2000, a plan was announced that restricted the amount of future electricity production from power plants. A year later, the federal government and all energy suppliers using nuclear power had agreed that each nuclear reactor would be limited to producing 23.3 billion kWh at maximum operating capacity. This created a roughly 32-year phaseout period, and the last power station should go out of service in 2032. Germany operates 19 nuclear power stations, which provide about 30 percent of Germany's electricity requirements. This is up from only 12 percent in 1980.

While Germany has a long history of strong commitment toward environmental protection, it still has a long road ahead of it. Sustainability is one of the guiding principles cutting across all sections of government. The ultimate goal of this principle is to reach concord between economic growth and environmental preservation and protection, whereby sustainable development is compatible with present needs while not jeopardizing future generations. As the 2005 Environmental Sustainability Index suggests, Germany is heading in the right direction.

Ghana

GHANA'S ABSOLUTE LOCATION (Latitudes 4 degrees 44.2 N to 11 degrees 10.5 N and Longitudes 1 degree 12 E to 3 degrees 15.3 W) places the country—with a total area of 92,000 square miles (238,533 square kilometers)—within the tropical rain forest and tropical savanna biomes. This location provides Ghana with a specific combination of geology, climate, biota, soils, water resources, and ocean accessibility whose exploitation are critical to the economy. Export of gold earned over $600 million in 2002. Agriculture and fisheries activities currently constitute about a third of Ghana's economy and provide employment for over 50 percent of the economically active population in a population of 21.4 million people. Exports of cocoa products brought in an income of over $400 million in 2002. And products from the tropical forests earned an export income of about $170 million in 2001, and also generate activities that account for over 3 percent of the Ghanaian economy.

But Ghana faces enormous environmental challenges that are closely tied to the second aspect of Ghana's location—its relative location within the world system of core, semiperiphery, and periphery countries. Ghana's situation as a periphery/former colony, low income, dependent third world country presents a specific set of challenges. Most of the livelihoods of the people of Ghana and the incomes of local and foreign businesses depend upon the direct exploitation of the natural resource base. It is estimated, for instance, that Ghana's forests, which covered about 20 million acres (8.2 million hectares) in the late 19th century have been depleted to only 4 million acres (1.7 million hectares) of permanent forests. Another category of environmental problems in urban centers is related to the rapid population growth rate of 2.7 percent a year (1984–2000), which has fueled a rapid rate of urbanization.

To improve environmental governance, the government of Ghana established the Environmental Protection Council (EPC) in 1974 to coordinate environmental management activities. Since then, the government has more explicitly tied Ghana's development to environmental conservation. In a National Environmental Policy and its associated National Environmental Action Plan (NEAP) 1993, the government committed itself to environmental protection, which is defined as "all interventions that may be deemed necessary to maintain a high level of environmental quality, and which at the same time enhances sustainable socioeconomic development."

As part of the necessary interventions, the government established the Ministry of Environment, Science and Technology (1993), and the EPC was transformed into the Environmental Protection Agency (EPA) in 1994 to become the national environmental management institution with regulatory and enforcement functions (including those related to environmental impact assessments). Other EPA responsibilities include monitoring, setting environmental standards, research, and information dissemination. To further facilitate good environmental governance, the government of Ghana has proposed a decentralization of environmental management by assigning the local government units—the District Assemblies—with responsibilities for translating national policies and programs into local actions. Major environmental policies in Ghana include the Forest and Wildlife Policy (1994), Energy Policy (1996), Land Policy (1999), Sanitation Policy (1999), and Water Resources Policy (1999). Ghana is a signatory of various International Conventions, including the Convention on Biological Diversity and the United Nations Framework Convention on Climate Change.

Gibbons vs. Ogden

IN 1824 THE idea of a *United* States of America was still very new. Perhaps the most important issue facing the nation was the relationship between the power of individual states and the federal government. While the most dramatic conflict between state and federal power would play itself out in the American Civil War, several Supreme Court decisions—including *Gibbons vs. Ogden*—slowly eroded power claims of individual states. Chief Justice John Marshall, the famous leader of the Supreme Court who established judicial review of congressional laws, was active at controlling the attempt by states to assert too much power.

At first glance, the case of *Gibbons vs. Ogden* seems like a simple dispute between two freewheeling steamboat operators at the advent of the U.S. Industrial Revolution. Steamboat commerce between New York and New Jersey was a major source of transportation and development in the early years of the 19th century. Aaron Ogden had bought a monopoly in the steamboat route that the State of New York had granted to Robert Fulton and Robert Livingston. Odgen, the plaintiff, brought a lawsuit against a rival Thomas Gibbons who had built a competing boat service between New York and New Jersey, seemingly violating the monopoly agreement granted by New York. Aaron Ogden initially won his case but the decision was appealed to the Supreme Court. Quoting Article 1, section 8 of the U.S. Constitution, which reads that Congress has the power "to regulate Commerce with foreign nations, and among the several States, and with the Indian Tribes," Chief Justice John Marshall concluded that the New York Monopoly violated the power of the U.S. Congress to regulate interstate commerce, commerce "among the several States."

The precedent set by *Gibbons vs. Ogden* has led to several important Supreme Court decisions regarding environmental policy set by individual states. Significant among these are elements of the Clean Water Act, which gives authority over wetlands to federal regulators and the Army Corps of Engineers. Dredging and filling of wetlands, under Section 404 of that Act, is restricted, except where permitted and only where the loss of wetlands is mitigated. The legal authority of the federal government here is an extension of the diverse notions that stream flows are interstate, that migratory wetland birds move between states, and that waterways, even those isolated from major rivers, are navigable. This interpretation of the Commerce Clause stemming from *Gibbons v. Ogden* has not gone undisputed in recent years, with some arguing it is an over-generous reading of the Constitution. Nevertheless, this reading stands as a cornerstone of contemporary environmental protections in the United States.

Gibbs, Lois (1952–)

LOIS MARIE GIBBS is the founder and executive director of the Center for Health, Environment, and Justice (CHEJ) in Falls Church, Virginia. Gibbs first rose to public prominence in 1978, as the organizer and head of the Love Canal Homeowners Association in Niagara Falls, New York. Upon learning that the neighborhood elementary school her son attended had been built on top of a leaking hazardous waste dump, she and other residents of the Love Canal neighborhood—many with severely ill children or histories of reproductive abnormalities—organized to demand government assistance with health, safety, and welfare. In August 1978, President Jimmy Carter declared a state of emergency at Love Canal; the State of New York closed the school, announced the relocation of 239 families, and initiated a project to clean up the site.

Over the course of the next two years, Gibbs and other remaining Love Canal residents gained the attention of national and international media as they confronted the miscommunication and inaction of state and federal government agencies. In May 1980, shortly after the release of studies showing evidence of increased chromosomal damage among neighborhood residents, Gibbs and other members of the Homeowners Association held two EPA officials hostage in the association office and then released them in the presence of national television cameras.

In combination with the political pressures of an election year, the event helped prompt President Jimmy Carter to order and finance the permanent relocation of Love Canal residents later that summer. The Love Canal incident also led to the passage of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) of 1980—better known as Superfund. This law established and funded a new federal program to clean up hazardous waste sites throughout the United States, and Gibbs became known as the "mother of Superfund."

Gibbs subsequently moved with her two children to the Washington, D.C., area, and in 1981 she founded the nonprofit organization Citizens Clearinghouse for Hazardous Wastes (CCHW). The initial purpose of the organization was to share information, technical assistance, and organizing strategies with other communities around the country fighting to have hazardous waste sites cleaned up quickly and thoroughly. Although this purpose remains an important part of its mission, the organization—which in 1997 changed its name to the Center for Health, Environment and Justice—now leads and coordinates a diverse set of national environmental health campaigns. Over the years, these campaigns have addressed a variety of issues, including medical waste incineration in hospitals, precautionary approaches to risk, pesticides and toxic chemicals in schools, and the manufacture of PVC products.

As the "mother of Superfund," Gibbs fought for compensation for the Love Canal incident and its cleanup.

Gibbs has written or cowritten several books, including *Dying from Dioxin: A Citizen's Guide to Reclaiming Our Health and Rebuilding Democracy* (1995) and the autobiographical *Love Canal: My Story* (1982). She has also been the subject of documentaries and the made-for-television movie *Lois Gibbs and the Love Canal* (1982). Among the many honors Gibbs has received are the Goldman

Environmental Prize (1990), the Heinz Award in the Environment (1998), the John Gardner Leadership Award (1999), and an honorary doctorate from the State University of New York–Cortland.

Glacier National Park, Montana (U.S.)

GLACIER NATIONAL PARK is located in the northern Rocky Mountains of northwestern Montana along the U.S./Canadian border, and sits astride the "Triple Divide" of North America, from where waters flow to the Atlantic, Pacific, and Arctic Oceans. The Park was formed by an Act of Congress in 1910. In 1932, Glacier Park joined with adjacent Waterton Lakes National Park in Alberta, Canada, to form the Waterton–Glacier International Peace Park, the first such entity in the world. The Going-to-the-Sun Road that crosses the Park from West Glacier to St. Mary—a distance of 50 miles—is a National Historic Landmark that took 11 years to construct, with completion in 1932. Most visitors to the Park traverse this road, crossing the Continental Divide at Logan Pass.

Glacier Park is dominated by two mountain ranges, the Lewis and the Livingston, that trend northwest to southeast through its north-south orientation. Rocks that comprise these ranges consist of several sedimentary formations. A conspicuous geologic feature of the Park is the Lewis Overthrust fault that displaced older Proterozoic rock formations over 65 kilometers to the east and over younger Cretaceous sedimentary formations. Chief Mountain, an isolated outlier at the easternmost edge of the Overthrust, is a sacred site for the Blackfeet Indian Nation that borders Glacier Park to the east.

Elevations in the park range from forested valley bottoms of nearly 940 meters to rock, snow, and ice surfaces on peaks that extend to slightly over 3,000 meters. A maritime climate on the west side supports a more diverse forest, including Douglas Fir (*Pseudotsuga menziesii*), Western Hemlock (*Tsuga heterophylla*), and Western Larch (*Larix occidentalis*); than the distinctly more continental climate and associated forest on the east-side characterized by Lodgepole Pine (*Pinus contorta*) and Trembling Aspen (*Populus tremuloides*) at lower elevations.

Both rise through a distinctive alpine tree-line ecotone, a zone of transition that ranges from the closed canopy-forest through open-canopy forest and tree islands of five-needle pines (*Pinus albicaulis* or *Pinus flexilis*), Engelmann Spruce (*Picea engelmannii*), and Subalpine Fir (*Abies lasiocarpa*); to alpine tundra, which is the signature ecosystem of the park, varying across extensive drier patterned ground to more localized wet meadows. The spatial organization and composition of the vegetation in the park is largely shaped by the two climate regimes and made heterogeneous by lithology, topography, and local disturbances that include snow avalanches, debris flows, fire, and historically widespread insect outbreaks. This diversity of vegetation also supports a diversity of wildlife, including the charismatic megafauna grizzly bear (*Ursus horribilis*) and mountain goat (*Oreamnus americanus*).

The park is a focal point for work on global climate change, given that its glacial climate history appears to be heading toward the loss of all its current glaciers. These small cirque glaciers, which have been shrinking and disappearing since the late 19th century, are predicted to be gone by the year 2050. The distinctive glacial landforms including, for instance, U-shaped valleys, cirques, horns, tarns, paternoster lakes, and moraines, will continue to attract tourists to this "Crown of the Continent."

Glaciers

GLACIERS ARE THICK masses of ice that originate on land from the accumulation, compaction, and recrystallization of snow. Glaciers make up the cryosphere, the frozen part of the hydrosphere. The frozen water is temporarily removed from the hydrologic cycle. Glaciers occur more commonly at places on earth where temperatures are such that the glacial ice remains frozen during a sufficient part of the year, preventing the glacier from melting completely. These cold places occur at high elevations and at high latitudes.

Glaciers fall into two broad categories: alpine or valley glaciers; and continental glaciers, ice sheets or ice caps. Alpine glaciers occur at high elevations, on mountain tops. Continental glaciers occur at high latitudes, close to the poles. Alpine and continental glaciers are actually two ends of a spectrum. Many glaciers have characteristics of both.

Alpine glaciers exist on the tops of mountains, and therefore are subject to the force of gravity, which constantly pulls the glacier down the slope. As the glacier slowly moves down the side of the mountain, new glacial ice forms on the mountain top (accumulation). As the glacier reaches the higher temperatures that occur on the lower parts of the mountain, the ice melts (ablation or wasting). This system is like a conveyor belt where the glacier forms in the area of accumulation, then constantly slides down the mountain to the area of ablation where it melts and becomes outwash streams. The downslope movement is due in part to flow within the glacier, and also to sliding over the ground surface. The sliding produces significant erosion resulting from the abrasion of bedrock and the transport of the eroded material to the area of ablation where it is deposited as a moraine.

The moraine may act as a natural dam resulting in a glacial lake. Alpine glaciers are common today in many mountain belts such as the Alps, the Northern and Canadian Rockies, the Andes, and the Himalayas. An alpine glacier exists on top of Mt. Kilamanjaro (19,340 feet), illustrating that glaciers can exist close to the equator if the ground elevation is high enough.

CONTINENTAL GLACIERS

Unlike alpine glaciers, continental glaciers are not dependent on high elevations. Continental glaciers occur at high latitudes, on relatively flat, widespread areas that may cover a major part of a continent, hence the term *continental*. Today, continental glaciers exist on Antarctica, Greenland, and a small ice cap in southeast Iceland. The movement of continental glaciers is driven by flowage and sliding of the glacier outward from the area where the accumulation is the greatest. If part of the glacier moves into an area of lower latitude, ablation will occur as the glacier melts and deposits its sediment as a moraine, and the water becomes outwash streams. If the water is trapped behind the moraine, a glacial lake may form. The Finger Lakes of New York are a prime example.

The budget of a glacier is a concept relating its volume to the rates of accumulation and ablation (wastage). During cooler intervals, the rate of accumulation may exceed the rate of ablation, and the glacier will expand or advance. During warmer intervals, the rate of ablation may exceed accumulation and the glacier will shrink or recede. The terms *advance* and *recession* relate only to an increase or decrease in the mass of the glacier. They do not imply movement of the glacier. Regardless of whether a glacier is advancing or receding, alpine glaciers always move downslope, and continental glaciers always move outward from the area of maximum accumulation.

SPECTACULAR LANDFORMS

Glaciers produce distinctive landforms and landscapes that can be quite spectacular and beautiful. Landforms typically associated with alpine glaciers include horns, U-shaped valleys, hanging valleys, cirques, arêtes, and moraines (lateral, medial and end). Continental glaciers produce features such as drumlins, eskers, kettles, terminal and recessional moraines, and outwash plains. These landforms preserve the geologic record of ancient glacial conditions, and are used to reconstruct environmental conditions that existed during the Ice Age. The most recent Ice Age was first recognized in terms of the glacial landforms that are found in many places in the high northern latitudes, areas that are not glaciated today. As such, glaciers produce an important record of past climatic conditions on earth.

The occurrence and size of glaciers is directly dependent upon global temperatures. Today, glaciers cover about 10 percent of Earth's land surface. During the past 2 to 3 million years, the globe was alternately cooler and warmer, producing what is referred to as glacial and interglacial episodes of the Ice Age. During glacial episodes, alpine glaciers existed at lower elevations, and ice sheets extended further toward the equator. Some of those ice sheets were about 3 times as extensive as today. During the warmer, interglacial episodes, glaciers receded to higher elevations and higher latitudes.

Glaciers play a major role in the water available to the hydrologic cycle. Glaciers today comprise 2.2 percent of earth's total water budget, second only to the oceans, which comprise 97.2 percent. Changes in the volume of glaciers are compensated by change in the volume of seawater. During intervals of global warming, such as is occurring now, glaciers recede and sea-level rises. The opposite has occurred during times of global cooling.

Glacken, Clarence (1909–89)

CLARENCE JAMES GLACKEN (1909–89) was a prominent cultural geographer and a key scholar in the development of environmental history. His work in bio-historical studies during the mid-20th century ranks him with Carl Ortwin Sauer and Rachel Carson. Glacken's seminal work is his *Traces on the Rhodian Shore: Nature and Culture in Western Thought from Ancient Times to the End of the Eighteenth Century* (1967). In this book, Glacken contends that there have been three archetypal questions posed through time about the earth and human relationships with it: Is the earth the creation of a higher power? Has the earth's physical attributes (landforms, climates, the arrangement of its landmasses and water bodies) influenced both the social nature of its human occupants and the nature of human culture? And, In what ways have humans modified the earth? The third point became a central tenet within the discipline of geography as it developed in the late 19th and early 20th centuries and continues to hold that position. The theme of human-environment interaction provides a basic premise in geographical studies.

Glacken points out in *Traces on the Rhodian Shore* that the separation of humans from their physical setting (a culture-nature conceptual disconnect) is of long standing in Western thought. Aristotle drew the distinction between entities created by humans and those found in the physical world, which are not of human origin. This separation continued until Immanuel Kant expressed the view of nature as culture, which is a notion embedded in the concept of social constructivism (the social construction of nature). This focus suggests that nature is viewed through the "cultural lens" of the individual and becomes a subjective consideration. The view of nature as culture has long been embraced within the social sciences and the humanities in which aspects of culture provide the primary reference. The precursors to the emergence of the conservation movement in Europe and the United States in the 19th and 20th centuries are traced as well in Glacken's work. The conservation movement and the subsequent environmental initiatives in the 1960s could not have occurred without the development and acceptance of a unified concept linking nature and culture.

Glacken was a highly respected member of the geography faculty at the University of California at Berkeley from 1952–76. On the occasion of his retirement in 1976, Glacken was honored with a Berkeley Citation, an award given to the most distinguished members and friends of the university for rendering notable services. Glacken also published a book in 1955 on Okinawan village life.

Glen Canyon Dam

GLEN CANYON DAM is located in Arizona on the Colorado River just south of the Utah border. The reservoir behind the dam floods hundreds of side canyons and 180 miles (290 kilometers) of the Colorado River through Glen Canyon. It is the second-highest concrete-arch dam in the United States. When briefly full, Lake Powell was the second-largest reservoir in the Western Hemisphere. According to Steve Carothers and Bryan Brown, Glen Canyon Dam was originally designed to facilitate the delivery of water from "upper basin states" (Utah, Colorado, New Mexico, and Wyoming) to "lower basin states" (Arizona, Nevada, and California) and Mexico under the Colorado River Compact of 1922. Additional purposes include flood control, water storage, environmental and recreational needs, and power generation. The dam was approved in 1956, and after construction and much controversy, the lake began to fill in January 1963. Glen Canyon Dam has the capacity to generate 1,300 megawatts if the reservoir is full (elevation of 3,700 feet [1,138 meters]). However, Lake Powell took 17 years to fill and was only at its peak volume for five years (1980–85). Consequently, average power generation has been in the range of 500 megawatts.

CONTROVERSIAL IMPACTS

Glen Canyon Dam was controversial from the beginning and remains so today. Adverse impacts for the Navajo (or Dine) people include loss of religious and cultural sites throughout the flooded canyon. In 1974 members of the Dine sued the Department of the Interior (DOI), Bureau of Reclamation, and National Park Service (NPS) over flooding of religious sites and inability to conduct ceremonies in the vicinity of Rainbow Bridge. The few people of European descent who had floated down Glen Canyon described the hundreds of side canyons and glens as the most beautiful place any had ever seen. For novelist Edward Abbey, Glen Canyon was "the heart of the Colorado Plateau." Sierra Club Executive Director David Brower led a fight to prevent the filling of the reservoir. Although not successful in stopping the project, this conflict was extremely formative in the lives of many environmental leaders and shaped the direction of the modern environmental movement.

Water released from Glen Canyon Dam flows into Grand Canyon National Park. Significant ecological impacts in Grand Canyon include artificially low water temperatures (47 degrees F), blockage of sediment, and substantial fluctuations in flows due to power generation. The river currently fluctuates daily between 8,000–20,000 cubic feet per second (cfs). Until 1963, flows varied from 3,000 in fall and winter to 90,000 cfs during spring runoff. Floods brought sediment critical for building beaches, replenishing the nutrient base on the river's shores and creating backwater habitat for juvenile fish as the water receded. Endangered fish in the river now include the humpback chub, bonytail sucker, and razorback sucker.

Drought, increased water demand, and global climate change resulted in progressively lower lake levels during the 1990s. In 2005, the lake dropped low enough to expose famous sites, including Cathedral in the Desert, sites of importance to Mormon Pioneers, and sacred sites for the Dine nation. In the face of significant ecological impacts and lower lake levels, discussions over dam removal have begun. Arguments against dam removal include loss of hydropower, recreation activities and income, inability to regulate flows, and loss of the trout fishery below the dam. Those in favor of dam removal note ecological benefits to the ecosystem of the Grand Canyon, that scarce water is lost through evaporation and seepage into the porous sandstone, and that Hoover Dam could control the Colorado River without Lake Powell, thus producing more power, while saving money and increasing habitat.

Global Environmental Change

GLOBAL ENVIRONMENTAL CHANGE (GEC) refers to a multitude of environmental changes occurring at the global scale. Such changes include alterations to global bio-geochemical cycles, including carbon, nitrogen, and hydrological cycles; widespread alterations to land use and cover in multiple locations across the world with far-reaching consequences for soils, ecology, economy, and human health; and increasing losses of biological diversity globally. GEC is distinguished by some as systemic (changes that operate globally, such as global warming) or cumulative (local effects that accumulate until the overall impact is global, such as land use/cover change or biodiversity loss). Although the environmental movement faults human activity for the majority of GEC, many of the changes in question have both natural and human drivers and consequences. There is growing consensus, however, regarding the increasingly significant role that human societies have played in altering the structure and function of the planet's biosphere in recent centuries and decades.

EARTH SYSTEM SCIENCE

Much of the current research on global environmental change adopts an earth system science perspective. This perspective involves the recognition that the earth's oceans, land, and atmosphere constitute an intricately coupled system with its terrestrial and marine biota, and employs an interdisciplinary and integrative approach to studying its components, their interactions and systemic change and variability over time. Definition, characterization, and understanding of GEC are contingent upon spatial and temporal scale, since earth system processes span a range of such scales.

For instance, plate tectonic movements occur over large spatial extents (tens of thousands of kilometers) and long time scales (millions of years). On the other hand, seasonal variations in primary productivity in a temperate deciduous forest biome occur over a spatial extent of hundreds of kilometers and relatively short time scales (months). The definition of a system's mean behavior depends upon the choice of spatial and temporal scale over which to average

Human activities can interrupt the global hydrological cycle—the movement of water—through a number of activities.

that behavior; thus affecting conclusions about system change or variability. A change in a system is generally perceived as unidirectional, sometimes irreversible, whereas variation implies some form of oscillation or fluctuation around a mean value. Systems differ with regard to their stability (ability to retain system characteristics such as structure and function in the face of an externally induced perturbation), or resilience (a measure of a system's ability to return to its initial state following a perturbation). In addition, systems may be characterized as approximating an equilibrium state (homeostasis), typically involving negative feedbacks, or a non-equilibrium state characterized by stochastic and/or nondeterministic processes of change.

The International Geosphere–Biosphere Program (IGBP) was founded in 1986 by the International Council of Scientific Unions (ICSU). The IGBP constitutes an international, interdisciplinary scientific approach to pose and answer questions about the nature of the earth system and its biogeochemical cycles, its structure, function, and response to human-induced alterations (forcing functions); whether we can or should return to the system state preceding current episodes of human-induced system forcing, such as greenhouse-gas emissions led climate change; and how human societies and economies can achieve such challenges. The IGBP helps coordinate and synthesize research that elaborates key aspects of the earth's hydrological and biochemical cycles, quantifies rates and patterns of change within them and identifies critical drivers and consequences of those changes.

THE HYDROLOGICAL CYCLE

An important component of the earth system is the hydrological cycle—the movement of water through the distinct spheres of the earth—including the lithosphere, atmosphere and surface, and groundwater. This movement of water is driven by solar energy and the processes of evaporation, transpiration, precipitation, surface runoff, infiltration, and subsurface flow, and may be accompanied with changes of phase (solid ice or snow, liquid water, and gaseous water vapor). Approximately 97 percent of the earth's water is stored in oceans, 2 percent in ice caps and glaciers, and the remainder in ground and surface water reservoirs, the atmosphere, and the earth's biota. Most of the water in the atmosphere derives from evaporation, the solar-driven conversion of water from terrestrial or marine water sources into water vapor.

A smaller portion of the atmosphere's water derives from plant transpiration, the loss of water through leaf stomatal openings after it is drawn up from the soil by plant roots by the process of osmosis. Taken together, evaporation and transpiration (evapotranspiration) account for a large part of water loss from vegetated ecosytems and watersheds; however, the kind of vegetation greatly influences evapotranspiration rates. Water vapor in the atmosphere undergoes condensation in water droplets or ice/snow crystals and may move to different locations in the atmosphere by the process of advection. It may be precipitated over oceans or land. Precipitation over land results in surface runoff, some degree of water infiltration into the soil depending upon soil properties, and storage in artificial or natural reservoirs, as well as subsurface flow. Human activities can interrupt the global hydrological cycle through a number of activities, including: surface and groundwater withdrawals for basic water supply for increasing populations in urban and rural areas, agricultural diversion of freshwater, the construction of artificial reservoirs such as dams, and land cover changes such as deforestation and reforestation that alter evapotranspiration and condensation rates. Over half of the earth's freshwater is estimated to be directly or indirectly used by humans. Some functional aspects of the water cycle remain incompletely understood. Water vapor, clouds, and rainfall, for instance, alter local and regional rates of atmospheric heating and cooling, exerting an important influence on circulation and precipitation and, therefore, regional and global climate. Such dynamics are not well captured in global climate models.

NITROGEN

Nitrogen is an essential element in amino acids and proteins, a component of nucleic acids such as DNA and RNA and of chlorophyll, thereby playing a critical role in the photosynthetic pathway. Approximately 78 percent of the earth's nitrogen is found in the atmosphere in gaseous form. In order for living organisms to be able to use nitrogen, however, it must first be converted to a usable form, or *fixed*. Some nitrogen fixation from the atmosphere occurs in lightning strikes [approximately 10 teragrams (Tg) per year globally; 1 Tg = 1,012 g, or roughly 1 million U.S. tons]. Biological nitrogen fixation (approximately 100 Tg) is completed by free-living and symbiotic bacteria that convert gaseous nitrogen into ammonium ions, and subsequently into nitrite and nitrate ions through nitrification. Symbiotic bacteria form mutualistic associations with specific plant species such as legumes, living in root systems, fixing nitrogen in return for carbohydrates and able to increase nitrite and nitrate concentrations in their immediate soil environment. The large-scale agricultural cultivation of legumes thus releases nitrogen into soils (approximately 30 Tg). Nitrogen is also fixed naturally in marine environments (approximately 5–20 Tg). Nitrogen is fixed industrially during the production of ammonia fertilizer (approximately 80 Tg) and released in the combustion of fossil fuels (approximately 25 Tg). It is now estimated that the rate of human-driven fixation of nitrogen through fertilizer production, legume cultivation, and fossil fuel combustion exceeds that of natural pathways (Vitousek 1994). Additional nitrogen may be released by humans through land conversions such as biomass burning and the draining of wetlands.

Much of this excess fixed nitrogen finds its way into groundwater through the process of leaching following rainfall or irrigation. Increased concentrations of nitrogen, a limiting nutrient in many ecosystems, may lead to eutrophication, precipitate dramatic changes in ecological structure, composition, and function. For instance, increased nitrogen may favor the dominance of nitrogen-demanding species, thus reducing species heterogeneity and richness. It may increase productivity and biomass in certain ecosystems. It may drive local declines in abundance and distribution of particular species by affecting populations of consumers, predators, symbionts, decomposers, and parasites in addition to those of primary producers, and even drive species extinctions and forest diebacks, such as in Europe.

THE CARBON CYCLE

The carbon cycle is likely the most debated aspect of the earth's changing biogeochemistry, and most significant to debates over climate change and global warming. The carbon cycle consists of movements between the principal carbon reservoirs: terrestrial biota, sediments (including fossil fuels), the ocean, and the atmosphere. The carbon budget denotes the exchange of carbon among the reservoirs, the balance of inputs and outputs to each reservoir and, thus, whether a reservoir acts as an effective source of sink of carbon in the global cycle. Atmospheric carbon is predominantly in the form of carbon dioxide, which forms approximately 0.04 percent of the atmosphere, and is a greenhouse gas akin to methane and chlorofluorocarbons (CFCs). Carbon is fixed (sequestered) from the atmosphere through the process of photosynthesis or primary production; productivity rates are highest in young, growing forested ecosystems.

Accurate records of atmospheric concentrations of carbon dioxide maintained since 1957 at Mauna Loa, Hawaii indicate two principal patterns. An annual fluctuation reflects the seasonal growth pattern of northern forests, and is superimposed upon a steady upward trend over the longer term. Atmospheric carbon dioxide (CO_2) concentrations over the past 2,000 years have been recreated by analyzing air bubbles trapped in the Greenland and Antarctic ice caps. The ice core data fit smoothly into the dataset beginning in 1957, and indicate that global carbon dioxide concentrations were relatively constant until the 19th century. A sharp upswing in concentrations since the 1800s coincides with the Industrial Revolution and the dramatic increase in the combustion of fossil fuels for power plants and internal combustion engines. Industrial metabolism is one of the most significant proximate (immediate) anthropogenic sources of GEC. Radiocarbon dating confirms that most of the CO_2 increase is attributable to fossil fuel consumption [approximately 10 petagrams (Pg) per year globally; 1 Tg = 1,015 grams], and not deforestation-related CO_2 release. The missing carbon sink problem arises because the rate of increase in atmospheric CO_2 (approximately 3.5 Pg) does not match that of fossil fuel combustion.

CHANGING CONCENTRATIONS

Changing global concentrations of methane (increase of over 30 percent since preindustrial period) and CO_2 (increase of approximately 150 percent since preindustrial period) track well with fluctuations in mean annual and or longer-period averaged temperatures, indicating support for greenhouse-gas driven global warming. Global mean surface temperature has increased by 0.6±0.2 degrees C since the late 1800s, and is projected by climate models to increase by 1.4 to 5.8 degrees C from 1990 to 2100. Other explanations for observed warming trends hypothesize that the warming is part of natural variation or upswing following the conclusion of the Little Ice Age, or forced externally by solar radiance. Direct data on global temperatures from thermometer readings date to the mid-1800s; temperatures prior to that period are reconstructed from proxies such as width of tree rings, amount of snowfall over glaciers, and isotope records in various glacial and reef systems and calibrated with recent observational data. These longer-term data indicate a warming during the Medieval Warm Period (10th to 14th centuries), and a cooling during the Little Ice Age (14th to 19th centuries), although the global nature of these trends is in question.

Other research has used the Vostok ice core data to examine the anomalous (increasing instead of declining or stabilizing) trends in CO_2 and methane concentrations in the Holocene interglacial period relative to the previous three interglacial periods in the past 400,000 years, linking these trends to the only difference in climate forcing during that time, the human-led clearing of land for agriculture. Ruddiman also made the controversial suggestion that cooling during the Little Ice Age was too large to be accounted for by external (solar/orbital) forcings, but was driven by forest regrowth after outbreaks of bubonic plague.

DEBATE OVER GLOBAL EFFECTS

The Intergovernmental Panel on Climate Change (IPCC) was established in 1988 by the World Meteorological Organization and the United Nations Environment Program to assess the risk of human-induced climate change, its potential ecological and human impacts, and options for adaptation and mitigation. The general objectivity of the IPCC's assessments—which are primarily conducted through the analysis and compendium of peer-reviewed scientific publications—and the IPCC's emissions scenarios in particular have been questioned by some climate scientists who regard the panel as unduly influenced by political considerations and/or prone to overstate the rate of change in global temperatures.

The effects of increased atmospheric concentrations of CO_2 have inspired much lively debate, owing in no small part to the complexity of the earth system and difficulty of representing it realistically and precisely in climate models. In particular the regional variations in projected effects of climate change are large, making global generalizations suspect or less than useful from a policy perspective. Besides increasing global mean temperatures, other commonly considered effects of climate change include sea level rise and changes in rainfall patterns. Global warming trends are projected to cause melting of polar ice sheets and the expansion of water in the oceans, leading to rising sea levels. Models predict that a warming of 1.5–4.5 degrees C will lead to a rise in sea level of 15–95 centimeters. Positive feedback loops can exacerbate the consequences. For instance, melting ice sheets result in reduced albedo, increasing absorption of solar radiation by darker ocean waters and leading to further warming of the oceans and melting of ice sheets. Increased global mean temperatures may release methane trapped in Siberian peat bogs formerly under permafrost, increasing greenhouse gas concentrations and causing further global warming. Increased respiration from terrestrial ecosystems as a response to increased temperatures may release CO_2 to the atmosphere in another positive feedback. Global warming is projected to increase global mean precipitation over the 21st century, though regional variations are significant. According to the IPCC, global climate models project increases in winter precipitation in northern latitudes and over Antarctica, while lower latitudes will experience both increases and decreases in distinct regions, as well as increased variability from year to year in those regions. Another postulated effect of climate change is a link to increased frequency and intensity of extreme events such as hurricanes, although those results are highly debated in the climate science community.

Additional effects pertain to the impacts of climate change on ecosystems, human economies, and health. The effect of increased CO_2 on terrestrial biota, and the feedback effects to the global climate system, was the overall focus of the IGBP's Global Change in Terrestrial Ecosystems (GCTE) research effort that came to a close in 2003. GCTE focused

Deforestation: Desecration and Disease

The ecological consequences of deforestation may extend to loss of watershed protection and altered quantity and quality of flow in freshwater and coastal ecosystems. Increased erosion and runoff following deforestation may lead to nutrient enrichment and siltation in downstream areas, including coral reef ecosystems. Land cover may serve as sources or sinks for atmospheric CO_2, and changes to it can therefore affect the global carbon cycle. Tropical forests, for instance, are often cleared for agriculture or pasture development by burning.

Aside from the loss of a carbon sink by removal of the forest, the act of burning releases greenhouse gases into the atmosphere. Land use changes have been linked to increasing concentrations of atmospheric CO_2 in recent years and even dating back to the Holocene. Biomass burning also releases other greenhouse gases such as methane and nitrous oxide, and release aerosols that alter local and regional energy balance and affect air quality and human health across large areas. Changing land covers often create conditions for the spread of pathogens and vectors for crop, livestock, and human diseases. Global increases in morbidity and mortality due to parasitic diseases have increased with land use and associated changes. Deforestation, for instance, may increase proximity of humans and associated livestock to disease vectors and create progressively larger parasite reservoirs.

Deforestation can also aid the proliferation of small puddles of neutral pH water as opposed to the acidic water typically found under canopies. Such conditions favor the incidence and growth of disease vectors such as anopheline mosquitoes (malarial vector), sandflies (*leishmaniasis*), snails (*schistosomiasis*) and other species. Altered patterns of human migration and settlement often accompany or follow deforestation, bringing in migrant incomers to communities of local/indigenous groups. Migrant populations may serve as reservoirs of diseases native to their former homelands, to which local populations may not be adapted. On the other hand, migrants may become exposed to forest-dwelling parasites at the increasing forest edge areas, while indigenous populations may remain immune or resistant to such pathogens, or may have knowledge of behaviors and practices that diminish their exposure.

specifically on ecosystem physiology and the drivers of terrestrial carbon fluxes and pools; changes in ecosystem structure and the relations between vegetation dynamics and landscape pattern and process; impacts of climate change on food production systems and major crops such as wheat and rice; and the relationships among biodiversity and ecosystem function, including ecosystem resilience and stability with respect to natural and human-induced disturbances. Increased CO_2 concentrations may cause a fertilization effect, increasing carbon sequestration rates in terrestrial ecosystems. The efficiency of response to the higher CO_2 levels varies by photosynthetic pathway; C3 plants stand to gain a relative advantage over C4 plants, with significant implications for community and competitive dynamics. Plants with rapid growth rates stand to gain more than slower-growing species; yet, they would produce leaf tissue with lower nutrient content under such circumstances, with consequences for the health and abundances of herbivore populations and other members of the trophic system as well as system nutrient cycles overall.

Changing regional climate regimes (CO_2 enrichment, temperature, and precipitation) can have significant impacts on regional economies by affecting agriculture, forestry, and other production-related human activities and resource management systems. Despite predicted global increases in agricultural yields due to CO_2 fertilization effects and increased efficiency of water use, scenarios vary by crop and region. Northern latitudes may experience greater benefits to agricultural in general, and economies that are dependent on rain-fed agriculture will be more vulnerable because of the possibility of prolonged droughts. The effects of climate change on weed development and pest outbreaks can further affect agricultural yields and viability.

Increased temperatures can affect human health directly through reduced cold-related or increased heat-related health problems and mortality. Climate change can significantly affect the abundance and distribution of vectors of infectious diseases such as malaria, dengue, and rift valley fever. Such effects are likely to be felt disproportionately in less-developed countries that tend to be located in lower latitudes and are less equipped economically and administratively to prevent and/or respond to health crises.

POLICY RESPONSE

The policy response to climate change has focused on two main courses of action: mitigation and adaptation. Mitigation strategies aim at reducing the extent or rate of global warming by reducing fossil fuel use and greenhouse gas emissions through conservation and alternative energy sources such as solar, hydrothermal, and wind energy. Mitigation has also focused on increasing CO_2 uptake or carbon sequestration, including mechanisms for emission trading and carbon taxes.

The Kyoto Protocol to the United Nations Framework Convention on Climate Change (UNFCCC) is the international policy instrument to deal with climate change. Countries that ratify the treaty commit to reducing their emissions of greenhouse gases—including CO_2—or participate in carbon taxes (a tax on CO_2 emissions) and/or emissions trading. Emissions trading is a market mechanism for dealing with global reductions in greenhouse gases that allows the financial exchange of rights to greenhouse gas emissions between countries that expect to emit more than their allocated share under the Kyoto protocol with those that are under their allocated emissions quotas. The protocol was negotiated in the late 1990s and came into force in 2005 after ratification by Russia.

ADAPTIVE STRATEGIES

Adaptation to global warming, on the other hand, focuses not on reducing or stopping the change itself, but on blocking or responding to the change in a manner that reduces its negative effects on human or natural systems. Adaptation thus refers to the process of reducing the vulnerability to the negative effects of environmental change. The U.S. National Academy of Science (NAS) as well as the IPCC caution that adaptive strategies need to complement efforts at mitigation. Adaptation can be either engineered (planned) or endogenously generated; human societies have adapted to environmental changes in the past several centuries through population resettlement, changes in resources use patterns.

Adaptive strategies might include different modes of agricultural production, including alternative choices of crops and crop varieties, irrigation practices, policies that foster increased food security, the building of higher-capacity stormwater systems and levees in coastal/urban areas, increased use of air conditioning, improved building codes and land use planning, access to appropriate insurance mechanisms, and public health infrastructure to accommodate the negative human health impacts of GEC. Notably, developing nations that are lacking in resources, adaptive capacity, and strong institutions are also the most vulnerable to the effects of GEC and global warming.

HUMAN IMPACT

By overwhelming consensus, changes to the earth's biophysical (land) cover as a result of intensifying and diversifying human land uses constitute the most significant component of GEC. Land cover refers to the biophysical condition of the land: its soils, water, and vegetation; while land use refers to its intended human use. Thus, one type of land cover, such as a forest, may accommodate multiple uses such as forestry, recreation, and wildlife conservation. The same land use, on the other hand, may give rise to land covers that are distinguishable from one another, as when agriculture within a forested landscape uses plots in different stages of fallow rotations, generating fields of crops as well as various stages of secondary succession. Land use/cover change (LUCC) affects multiple biomes and ecosystems, including soils, forests, grasslands, wetlands, terrestrial, marine, and coastal areas, as well as global biogeochemical cycles and global climate. Most anthropogenic LUCC to date has been a consequence of the expansion and intensification of agriculture and pasture, and by forces of urbanization. Over 32 percent of the earth's surface is currently under productive use by humans.

Over the past 300 years, global extents of forests and woodlands have declined by over 18 percent and that of grasslands and pasture by approximately 1 percent. The world's croplands, in the meantime, have increased by over 466 percent in that period. Urbanization has also increased dramatically over the past centuries and decades. The Population Reference Bureau (2006) estimates that 47 percent of the present population of the world is urban; this population occupies 1 percent of the earth's surface and 6 percent of its settled lands. The biophysical transformations associated with urban form have large-scale implications for surface runoff, alterations to regional climate (temperature and precipitation regimes) and air quality.

Smog, such as that over Mexico City, contributes to increased atmospheric concentrations of CO_2.

Changes to land uses and covers can have significant consequences for ecosystems, climate, and human societies, often reaching far beyond the areas directly transformed. The reduction and fragmentation of habitat along with altered disturbance regimes results in changes to local ecosystem structure and function, declines in species and genetic diversity, and increases in the spread of invasive species. Invasive species often share physiological and life history traits that enable them to take advantage of LUCC as well as other aspects of GEC, such as increased CO_2 concentrations and nitrogen deposition. Invaders and exotic species can have devastating ecological as well as economic impact; for instance, an estimated 42 percent of the species listed as endangered or threatened in the United States are at risk primarily because of exotic invaders. The 50,000 invasive species present in the United States collectively cause annual environmental and economic damages in the order of $120 billion. Habitat fragmentation due to LUCC also leads to altered biophysical environments in proximate areas, generating new areas of edges, or ecotones, between the contrasting environments. In 1988, the area of deforestation in the Amazon basin was exceeded by the area within a 1-kilometer distance of existing deforestation, testament to the rising significance of edge effects and their ecological consequences.

Changes in land cover, such as deforestation, can alter solar reflectance patterns by reducing albedo, thereby altering local climate by increasing local temperatures and decreasing humidity. Such increases in regional temperatures in areas of LUCC can influence regional climate and vector populations; for instance, temperature can affect rates of mosquito development, feeding, and infection and incubation times. Urbanization has also been linked to increased average surface temperatures (the urban heat island effect) and decreased diurnal ranges in temperature over urban areas. A 0.27 degrees C (later corrected to 0.35 degrees C) per century increase in surface temperatures was found over all meteorological stations located at heights below 500 meters in the United States, attributable to urbanization and other land use changes. Using two sets of decadal comparisons over 1960s–70s and 1980s–90s, they further found a statistically significant difference in mean temperature increases between urban and rural stations, with urban stations reporting the larger increase in mean temperature.

INTERNATIONAL RESEARCH PROGRAM

In recognition of LUCC's far-reaching impacts and of the necessity of an interdisciplinary approach to the problem, the IGBP and the International Human Dimensions Program (IHDP) jointly founded the international research program on LUCC. The LUCC program initiated and consolidated research on empirical studies of changing land cover patterns, case-study derived understanding of the land use dynamics underlying the changing land covers; the development of regional/global datasets and protocols for land cover classifications; an analysis of scalar dynamics (e.g., how cover and use patterns and their drivers vary across scales), and the use of this information in regional and global models of LUCC and GEC.

PROXIMATE AND DRIVING FORCES

LUCC researchers often decompose anthropogenic activity implicated in land change into two broad suites of factors: *proximate sources* and *driving forces*. Proximate sources of LUCC refer to the immediate human activity and intended land use(s) causing alterations to the earth's land cover; these include, for example, agricultural or urban expansion, conversion of grasslands, forests, woodlands or other ecosystems to pasture, land cover changes due to the expansion of infrastructure—such as for road construction—and draining or filling of wetlands for development.

Driving forces, on the other hand, underlie such proximate sources of LUCC and emanate from fundamental social, political, economic, and cultural dynamics. Demographic, technological, socioeconomic, political/institutional, and cultural factors encompass the broad suites of driving forces that may act directly at local scales, or prevail at national/global scales but indirectly affect local areas.

POPULAR EXPLANATION

One popular explanation of GEC impacts dates to the 1971 formulation of the IPAT hypothesis (Environmental **I**mpact = **P**opulation **A**ffluence **T**echnology) by Paul Ehrlich and John Holdren. When treating the earth as a closed system, the IPAT formulation may serve as a shorthand proxy for explaining GEC at the global scale as a function of population size, per-capita consumption levels (affluence or poverty), and technological efficiency and appropriateness. The empirical validity of IPAT often breaks down at regional and local scales of analysis, however, since environmental transformations at these scales are the results of human agents operating within social structures, and involve complex effects of policies, markets, tenure, and other institutions as well as cultural beliefs and practices.

Economic driving forces of LUCC thus include market penetration and growth, relationships between production and consumption, growth in industrial and other sectors, and trade, foreign exchange and other indices of links to international markets and policies. Policy/institutional forces encompass land tenure and property regimes, state and local policies governing resource access, land management and economic development, and include policy instruments such as credits and subsidies, as well as considerations of policy failures. Technological factors include the technical and managerial strategies employed in production in agricultural, forestry, and other land use sectors, including concerns of efficiency and the allocation of labor and capital to the production process. Cultural factors pertain to a household, group or population's attitudes, values and beliefs; and demographic factors include population increase and density, age structure, and other variables.

The static formulation for IPAT does not take into consideration flows of materials, energy, people and economic resources between linked social and environmental systems. Furthermore, several suites of driving forces may interact at multiple scales, structuring how environmental resources are produced and consumed, and generating complex pathways to land transformations. In 2002, H.J. Geist and E.F. Lambin, for instance, undertook a meta-analysis of 152 subnational case studies of tropical deforestation (a significant proximate source of GEC) and found regional patterns of interacting causal drivers, contradicting the conventional wisdom that previously faulted population growth (driving force) and shifting cultivation (proximate source) as the main culprits. Economic factors were most frequently cited driving forces at the global scale when case studies from Asia, Africa, and Latin America were pooled, followed in order by institutional/policy, technological and sociocultural factors, with demographic factors cited least frequently. These global "average" trends, however, belie important regional differences. Institutional/policy factors are most frequently cited in case studies focused in Asia, while demographic factors prevail in African case studies, and economic factors dominate in studies based in Latin America.

GOING FORWARD

The LUCC program concluded in 2005; however, its insights and evolving research questions now inform the newly established Global Land Project (GLP). The GLP is the latest IGBP–IHDP collaborative project on linked human–land systems, and merges the agendas and insights from over a decade of research on the relationship of GEC to terrestrial ecology (GCTE) and to dynamics and models of LUCC. The use of models has been particularly instrumental in the understanding and prediction of the dynamics and impacts of LUCC/GEC. While models span a wide range of purposes, analytical techniques and disciplinary/methodological traditions, they can be combined to test and formalize various theories in order to improve our explanatory and predictive power, ability to be generalized, accuracy, and precision. Challenges to present and future modeling approaches to studying land change include the integration of social and natural factors and interactions at multiple scales, the incorporation of qualitative information in models, and overall integration of epistemological, conceptual, and methodological integration in modeling linked social-environmental systems.

Global Environment Facility (GEF)

THE GLOBAL ENVIRONMENT Facility (GEF) is a multilateral financial mechanism that promotes international cooperation around the protection of the global environment. It grew out of a concern for global environmental problems in the 1980s, particularly a growing awareness of transboundary environmental problems and recognition that efforts to improve matters would be costly. Today, GEF is the single largest grant-making institution for global environmental programs. It has allocated some $5 billion for more than 1,500 projects in 140 countries.

Projects are developed and financed through three implementing agencies: the World Bank, United Nations Environment Program (UNEP), and United Nations Development Program (UNDP). Executing agencies that implement projects on the ground include regional development banks and a number of UN specialized agencies. Governance structure of the GEF is centered around the GEF Council, a group composed of 32 representatives from member states who meet biannually to review, comment upon, and reject or accept GEF projects, future business plans, work programs, and policies. The GEF Assembly, composed of all GEF 176 member states, meets every three or four years to review and approve general policies, operations, and amendments to the founding GEF Instrument. GEF operations are coordinated by a Secretariat in Washington, D.C. The GEF has been applauded for its unique structural flexibility and strong ability to adapt in a changing environment.

FOCAL AREAS AND PROJECTS

The GEF promotes environmentally beneficial projects in developing countries through six focal areas: Biological Diversity, Climate Change, International Waters, Ozone Depletion, Land Degradation, and Persistent Organic Pollutants. The GEF acts as the financial mechanism for the following global conventions and international agreements: the United Nations Framework Convention on Biological Diversity, the United Nations Framework Convention on Climate Change, the Montreal Protocol, the United Nations Framework Convention on Combating Desertification, and the Stockholm Convention on Persistent Organic Pollutants.

The GEF provides concessional financing to cover the incremental costs necessary to achieve global environmental benefits in the six focal areas. Incremental costs are calculated by subtracting the costs of any national or local benefit from the total cost of the project to identify the cost of creating global environmental benefits that the recipient would otherwise have no incentive to fund. Cofunding is expected to cover the "national" benefits of the project. According to the GEF publication *Achieving the*

Millennium Development Goals: A GEF Progress Report, the institution's work reflects the "current thinking within the conservation movement," emphasizing management of ecosystems and cooperation with the "human communities found there." This signals a shift among all focal areas from a technological emphasis to an approach that considers both economic and life systems.

The First Decade of the GEF: Second Overall Performance Study (2002) of the GEF found that the institution's biodiversity program, specifically, made "significant advances in demonstrating community-based conservation within protected areas, and, to a lesser extent, in production landscapes." As the financial mechanism for the UN Convention on Biological Diversity, the GEF recognizes intrinsic and global benefits of biodiversity, and funds incremental costs that may otherwise dissuade countries from protecting biodiversity. Yet, the biodiversity program has received criticism for overly ambitious goals and inadequate local participation and its inability to address the root causes of biodiversity loss.

Global climate change impacts a wide array of consequences across a wide spectrum of communities; accordingly, the GEF pursues a synergistic model to address the consequences of climate change. It utilizes market development, sustainable business models, and demand-side incentives to complete projects that remove barriers to efficiency and conservation, promote alternative energy, reduce implementation and long-term costs of alternative energies, and support sustainable transport. For example, the Poland Efficient Lighting Project relied on the GEF's manipulation of market forces to subsidize the production of energy-efficient fluorescent lamps, thereby increasing the percentage of households that use energy-efficient lighting.

Action-oriented, on-the-ground projects with replicable schemes characterize the GEF's International Waters projects. Unencumbered by a global convention, the GEF can exhibit a high degree of autonomy in this area. The majority of the International Waters portfolio is dedicated to regional projects, in which education and dialogue are emphasized with the hope that future problems can be addressed collaboratively by neighboring countries. Recent research on these projects found success in building scientific knowledge and creating linkages across social, economic, and environmental issues but found less success in the GEF's ability to enhance the contractual environment and build national capacity.

Although the Ozone Program is the smallest of GEF programs, the impact of ozone-depleting substances (ODS) on earth's protective ozone layer is no small matter. The GEF is not officially linked to the Montreal Protocol, which limited the production of ODS; nevertheless, it has secured $138 million over the last 10 years to help countries with economies in transition to begin phasing out the use of ODS. Only countries that have ratified the protocol are eligible for GEF support.

Land degradation has deep links to global environmental change, among them the threat to biodiversity, the ability to induce climate change, and the disruption of hydrological cycles. GEF projects cut across focal areas to combat desertification and deforestation, with sustainable land management as the ultimate goal. The land degradation program exhibits greater recognition of poverty and economic development than other focal areas but lacks ingenuity: the GEF's *Second Overall Performance Study* noted that land degradation activities lack innovative approaches to policy and technological components, with projects tending to rely on old technologies and approaches.

Living organisms absorb persistent organic pollutants (POPs) through food, water, and air and accumulate these harmful compounds in their tissues. Exposure to POPs may affect immune and reproductive systems and neurobehavioral development and is connected to birth defects, cancers, and osteoporosis. As the financial mechanism for the Stockholm Convention on Persistent Organic Pollutants, between 2001 and 2004 the GEF funded more than $141 million POPs projects. The majority of the more than 150 projects center on implementation of the convention, and include the destruction of obsolete stockpiles of POPs.

THE GEF IN TRANSITION

Presently, officials at the GEF are preparing its fourth replenishment cycle. Since the GEF's first funding cycle in the mid-1990s, the United States, the GEF's largest single shareholder, has been holding down

GEF funding levels. Most recently, it required the GEF to adopt a new resource allocation framework as a condition of continued U.S. financial support. According to Raymond Clémençon, this controversial framework "allocates GEF funds to recipient countries according to their global environmental relevance and ties resource allocation to performance-based indicators." Under this new framework, to be implemented beginning in July 2006, countries will be ranked by a Benefits Index and a Performance Index. The highest-ranked countries in each focal area will get individual country allocation. The remaining countries will be placed into groups with collective access program funding. Undoubtedly, the new framework will change how the GEF conducts business. It is expected to seriously alter competition among project proposals. Indeed this change in the GEF's funding allocation structure, coupled with changes in GEF focal areas, will provide fertile ground to further investigate GEF projects and programs—and this institution's broader impact on the global environment.

Globalization

THE TERM *GLOBALIZATION* refers to the increased interconnectedness of people and environments around the world through the transfer and exchange of capital, ideas, money, labor, and commodities. Globalization encompasses global integration through investment and capital flows between nations; the emergence of new political territories; the diffusion of information and technologies; and the movement of cultural identities and practices around the globe.

Globalization therefore describes a transformation in the spatial organization of social, political, and economic relations between global actors. The term *globalization* is also a rhetorical tool used in public discussions about the state of global economic, social, and environmental conditions. The term is used by a variety of ideological positions including both pro-globalization and alter-globalization (oftentimes labeled anti-globalization) activists. Globalization is thus a set of distinct material patterns and processes as well as a debated ideological perspective on world affairs—including the changing relationship between humans and the environment.

The interface between globalization and the environment is multifaceted, and can be viewed as how the process of globalization—most prominently global economic development—affects natural environments and the social groups who use them; and the dramatic globalization of environmentalism—particularly manifest in the context of regional and global political governance.

IMPACTS ON THE ENVIRONMENT

One of the major events precipitating economic globalization was the Bretton Woods Conference of 1944, where number of institutions were formed that would eventually change the face of global trade, finance, and production. Perhaps the most important legacy from the Bretton Woods conference was the formation of the General Agreement on Tariffs and Trade (GATT), which eventually led to the formation of the World Trade Organization (WTO) and the subsequent lowering of barriers to trade between nations. Other important agencies created to manage global financial transactions and development projects include the International Monetary Fund (IMF) and the World Bank. Free-trade policies, increased privatization of social services, and reduced government regulation comprise neoliberal economic policy reforms. The opposite of protectionism, economic liberalization paves the way for corporations and governments to conduct business throughout free trade regions with minimal tariffs and government intervention.

Companies participating in free trade are often referred to as transnational corporations (TNCs) with headquarters, production, manufacturing, and resource extraction facilities spread horizontally around the world. Many private companies seek to establish comparative advantages with competitors by pursuing sourcing efficiencies. Raw materials, labor, and capital are efficiently "sourced" by moving assembly abroad to developing nations through foreign direct investment and the offshoring of jobs. Production costs are reduced primarily through offshore conditions characterized by cheaper labor inputs, less severe tax regimes, and lower environmental corporate performance standards—including less stringent noncompliance penalties. The process by which corporations, spurred

"Seattle" and Other Battles

The net effects of globalization on the environment are disputed. Globalization and its negative impacts on the environment are core elements of the alter-globalization activist movement. Perhaps the most famous (or most infamous, depending on the perspective) demonstration was the 1999 WTO protests in Seattle, Washington. Protests like "The Battle in Seattle" are notable because they mark a point of convergence between various social and environmental interest groups advocating in concert for "fair trade" over "free trade." Some of the major environmental concerns voiced by these groups include:

Globalization brings accelerated economic growth and structural change to various regions of the world, which is predicated on increased resource use, extraction, and degradation—practices that are enabled by free trade policies and the pursuit of sourcing efficiency.

Neoliberal development, poverty, and environmental destruction cannot be separated. Globalization and structural adjustment programs transform deeply rooted land use practices and exacerbate preexisting levels of financial debt in ways that further impoverish developing nations and undermine the livelihoods of subsistence land users—resulting in a downward spiral of poverty-induced resource depletion and environmental degradation.

Because developing countries compete to attract international investments from developed nations, and structural adjustment agreements tie the hands of national governments in an effort to liberalize trade, there is little incentive or regulatory infrastructure to impose strict environmental standards.

Globalization applies a wedge between the consuming core and the producing periphery, also known as "distancing," which diminishes the ability and desire of consumers to understand the consequences of their consumer choices.

by competition with other firms, seek to increase profit margins through the pursuit of ever-cheaper labor and less costly environmental standards has been labeled as downward harmonization or "race-to-the-bottom" economics.

Some groups suggest that globalization and responsible environmental stewardship are not mutually exclusive. The WTO clearly states this position in the Doha Ministerial Declaration of 2001, "We are convinced that the aims of upholding and safeguarding an open and nondiscriminatory multilateral trading system, and acting for the protection of the environment and the promotion of sustainable development can and must be mutually supportive." The WTO and other free trade advocate positions include:

Development and free trade bring wealth, which is a necessary ingredient for alleviating poverty and protecting the environment.

Private and market interests are more likely to curb environmental degradation than cumbersome and oftentimes corrupt state-run enterprises.

Globalization generates international pressures for reform through transboundary information sharing, leading to the formation of an increased scientific and global environmental awareness.

Globalization will diffuse product standards, capital, and technologies from nations with high environmental regulations to those with low regulations. NAFTA, and other free trade agreements, will lead to "upward harmonization" or the rise of environmental standards to the highest common denominator.

Advocates of free trade point to Mexico's ability to formulate substantive environmental laws and effective implementing regulations, standards, and institutional infrastructure since the inception of NAFTA. Supporters also refer to the 2001 Sustainability Index released at the World Economic Forum to show how the top-ranking countries such as the United States, European Union (EU) nations, and Canada contain liberalized trade policies. According to this index, nations like Libya and Saudi Arabia that rank near the bottom of the sustainability index tended to be those who isolated themselves economically through trade restrictions.

The environmental movement's popular use of global imagery has been criticized for obscuring poverty issues.

GLOBAL ENVIRONMENTALISM

Many environmental issues are international because of their geographical scope. Just as investments and information travel between political boundaries, so too do natural systems such as water, air, and migratory wildlife. Environmental issues such as global warming are truly international in scope. The burning of fossil fuels, which releases greenhouse gases into the atmosphere in one nation can, as numerous predictive simulation models suggest, "force" climatic shifts in other regions of the planet.

Other environmental issues, while not necessarily global in scope, encompass a set of international actors. Acid rain in Canada resulting from sulfur dioxide and nitrogen oxides pollution in the United States Midwest is a transboundary, international environmental issue. So too is the impact of water diversions on the upper Mekong River in China upon lower Mekong basin nations such as Cambodia and Vietnam. These cases illustrate how many environmental issues cross national boundaries due to the spatial reach of the natural system and social causes and consequences in question.

While the scale of the environmental system in question is a useful way to measure its international status, it is perhaps more instructive to measure the relationship between globalization and the environment in terms of how the environment is researched and managed in an increasingly global format. Today numerous international organizations, accords, and protocols on the environment exemplify the globalization of environmentalism in scientific, managerial, and activist capacities. Some environmental problems are endemic to local or regional environments—including isolated cases of water security, infectious diseases, and species extinction. Yet because of the globalization of environmentalism these have become issues of global concern. Environmental governance has broadened over the past 35 years in the form of multiregional and international organizations and commissions to bring awareness and action to diverse environmental issues.

INTERNATIONAL GOVERNANCE

International environmental governance occurs in a variety of overlapping categories: stipulations in international free trade agreements; international accords, frameworks, and agendas, also referred to as multilateral environmental agreements (MEAs), resulting from global conferences or "summits;" intergovernmental organizations; and the dealings of transnational nongovernmental organizations (NGOs). Regional and global governance has led to the diffusion of various environmental ethics, principles, and management strategies that uphold various discourses including sustainability, ecological modernization, and conservation.

Free trade is organized within formally agreed-upon regional economic blocks such as the North American Free Trade Agreement (NAFTA), the common market of the EU, and Mercosur (Mercado Comun del Sur or the Southern Common Market), the latter of which enables free trade between various South American nations. These economic policy arrangements signify a new form of governance where the nation-state is no longer the paramount broker of economic affairs, instead deferring to the authority of international governing bodies. Regional economic blocks contain a number of important policy dimensions, one of which is how to address environmental concerns in the face of transforming economic relations. The diminishing role of traditional political entities like the nation-state to govern environmental affairs represents a form of political deterritorialization, while NAFTA, the EU, and Mercosur mark the reterritorialization of new regional, political entities.

The North American Free Trade Agreement, through the formation of the North American Agreement on Environmental Cooperation (NAAEC) and the Commission for Environmental Cooperation (CEC), contains provisions for enhancing compliance with environmental laws and regulations and evaluating the environmental effects of NAFTA. The EU and Mercosur also contain transnational governing bodies similar to that of the CEC. For example, under the EU, the European Environment Agency serves as a clearinghouse for scientific information and policy recommendations. Mercosur also contains internal environmental protocols as part of the Treaty of Asunción. These wide-ranging protocols include frameworks for regional, sustainable, and cooperative management of shared ecosystems and the provision of mechanisms to enhance enforcement and participation.

Environmental stipulations associated with free trade agreements usually remain subordinate to MEAs. Principle 12 of the Rio Declaration on Environment and Development states that international agreement is preferable to national programs when tackling transboundary or global environmental issues. Significant MEAs include accords that manage wildlife issues and biodiversity. Examples include the 1946 International Convention for the Regulation of Whaling; the 1971 Ramsar Convention on Wetlands of International Importance; the 1973 Convention on International Trade in Species of Wild Fauna and Flora (CITES); and the 1979 Bonn Convention on the Conservation of Migratory Species. A number of other MEAs are intended to protect atmospheric resources. These agreements include the 1979 United Nations Economic Commission for Europe (UNECE) Convention on Long-Range Transboundary Air Pollution; the 1985 Vienna Convention for the Protection of the Ozone Layer, leading to the 1987 Montreal Protocol; and the 1992 United Nations Framework Convention on Climate Change, leading to the 1997 Kyoto Protocol. Issues pertaining to marine environments, chemical use, waste management, desertification, and forest conservation are all addressed by a variety of MEAs. Together these agreements create an international framework for governing specific activities that influence regional and global environments.

OTHER MEAS

Other MEAs are formulated as part of global conferences or "summits." The 1992 United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro (commonly referred to as the Earth Summit) was a watershed in the formulation of a global environmental consciousness among international delegates. The summit also advanced an international movement to manage the global environment by linking environmental degradation, poverty, and excess consumption around the world. Using the common language of sustainable development, 172 governments produced a number of important international frameworks for governing the environment, including Agenda 21 and the Rio Declaration on Environment and Development.

Some MEAs are not binding or enforceable and instead represent a collectively agreed-upon set of ethics and best practices. The Brundtland Commission report "Our Common Future" advocating sustainable development and the 1992 Earth Charter declaring a unified set of environment, global justice, peace, and democracy principles both articulate and prescribe global environmental ideologies. Each represents an attempt to organize the core ethics and principles of environmentalism along global lines.

Intergovernmental organizations (IGOs) help facilitate the organization and enforcement of MEAs. Perhaps the most prominent IGO is the United Nations Environment Program (UNEP). UNEP coordinates environmental activities and encourages sustainable development through a series of protocols and conferences around the world. For example, UNEP worked with the World Meteorological Society to create the International Panel on Climate Change. UNEP also played a crucial role in the organization of the 1992 Earth Summit and the 2002 World Summit on Sustainability.

NGO INVOLVEMENT AND CRITICISMS

Many environmental movements and management plans are initiated by transnational NGOs such as Greenpeace, Worldwatch Institute, World Wildlife Fund (WWF), Nature Conservancy, and Friends of the Earth. While the headquarters of these NGOs are typically based in a single locale, transnational NGOs are usually comprised of a complex network of subheadquarters located around the world. By definition, these organizations keep government money at arm's length in order to maintain a consistent institutional agenda and serve as a counterbalance to government action.

Over the past 20 years, transnational environmental NGOs have increased their level of involvement in global-scale accords and protocols. For example, the Earth Summit on sustainable development included the active involvement of over 2,400 NGOs in both monitoring and consulting capacities. These organizations also serve as advocacy groups for particular ideological positions on the environment—often participating in public demonstrations or "counter conferences" to protest and draw public attention to perceived government or IGO misconduct.

The environmental movement has used a variety of icons and slogans to capture the connection between societies and environments around the world. The formation of an international Earth Day, the effective use of global imagery in environmental advertising, the metaphor of "Spaceship Earth," and the slogan "think globally, act locally" are all examples of how environmental discourse has been advanced through an appeal to a shared global environmental consciousness.

Despite the popularity of these images and slogans, they are subject to critiques, especially from those questioning the role of power in representing the global environmental movement. For example, critics ask, who speaks for the globe and who defines a global problem? Others argue that the picture of earth seen from outer space obscures and in effect erases the uneven terrain of poverty-induced social and environmental disharmony around the world. Still others have argued that global images used to appeal to the public are deeply misleading. For example, representations of third world environments found in first world brochures and advertisements misinform the public because they present so-called "pristine" areas as devoid of people, even when those areas contain a long history of settlement and land use by indigenous and other local populations.

Others have critiqued the role of power in shaping the actions of the global environmental movement. These critiques suggest that global environmental governance is at best a way of ordering the world and prioritizing behavior in ways consistent with the concerns and expertise of powerful nations. At worst, the globalization of environmentalism is a form of neo-imperialism that gives developed countries an open passport to intervene and manage resources around the world for their own benefit.

Global Positioning Systems (GPS)

A GLOBAL POSITIONING (GPS) system is a radio-based, real-time navigation and positioning system with a global coverage that provides the exact position on the earth surface in almost any meteorological condition. It is formed by three components: satellite constellation, control centers, and a receiver.

There are various Global Navigation Satellite Systems (GNSS): NAVSTAR, GLONASS, and EGNOS, precursor of the European Galileo. However, the system that coined the term and first developed the concept was NAVSTAR (NAVigation Satellite Time and Ranging). It was developed by the Department of Defense of the United States in 1978 and became completely operative in 1994. It was initially conceived for the military, though it was eventually opened for civilian use. Its constellation of 24 satellites, which hold a highly precise atomic clock, orbit at 12,000 miles (20,000 kilometers) above the Earth in six orbital planes with four satellites, each at an inclination of 55 degrees, making two complete orbits in less than 24 hours.

The geostationary satellites of the system emit a continuous signal with information on the exact time it has been sent out, which allows a receiver to calculate the distance to each satellite in real-time by calculating the time invested to arrive. When at least three satellites of the constellation are simultaneously visible, the receiver calculates (by triangulation) its local position in geodesic coordinates (x, y, z) in the WGS84 Geodetic datum; with the distance to a fourth satellite height or vertical position that can be further calculated.

The control segment is a network of five stations around the world that permanently monitor, estimate the satellites orbit and position (or ephemeredes) the status of their clocks and the conditions in the ionosphere that affect signal transmission. This operation is coordinated by the Master Control Station at Colorado Springs, Colorado.

The GPS satellite transmits the signal at two frequencies: L1 (1575.42 Megahertz), and L2 (1227.60 Megahertz) or carrier frequencies. The signal is altered as it travels through the atmosphere, interfering in system accuracy. An L1/L2 receiver can compare both signals and correct the alteration. In nondifferential mode, both L1 and L1/L2 receivers will obtain the same horizontal accuracy; while in differential mode, L1/L2 receivers will perform better since they can determine and correct the atmospheric-, ionospheric-, and tropospheric-propagation error. L1 and L2 are modulated by the Precise/Protected code (or "P code") and the Course Acquisition code (or "C/A code"). L1 frequency carries the C/A code used for the standard positioning service (SPS), a service available without restrictions, and the P code used for the precise positioning service (PPS), a restricted service, while L2 frequency only carries P code.

The receiver holds a clock that calculates the difference between the time received from the satellite and the actual time, which allows it to calculate the distance to it, the positional sphere. The finest measurement is obtained when the satellites are 120 degrees to each other and the fourth in the vertical.

Signal quality was degraded by introducing digital noise to prevent military use by foreign countries with two security systems, Selective Availability (SA) and Antispoofing. SA is a process that limits accuracy to the SPS by changing information on satellite orbit data and/or clock frequency. SA was deactivated on May 1, 2000. Antispoofing (AS) is the encryption process of the P code, used for precise positioning, replaced by the Y code.

The Differential GPS (DGPS) performs a differential correction of the received signal to improve GPS accuracy. A base station with a known position tracks the satellites and receives the signal at the same time as the mobile receiver, calculates the error for each satellite, and allows the correction of the unknown locations collected. The correction can be accomplished in real-time, sending the information to the receiver or in post-processing, to obtain centimeter accuracy. Two modes are available, as single station or Local Area DGPS (LADGPS), and a network of stations or Wide Area DGPS (WADGPS).

Global Warming

THE TERM *global warming* refers to a warming in the earth's climate. Global temperatures have changed throughout earth's history; however, in common usage, the term *global warming* refers to the anthropogenic (human induced) warming that results from an increase in atmospheric concentrations of certain gases due to the burning fossil fuels since the Industrial Revolution. This phenomenon is also called the greenhouse effect, and is a specific case of the more general term *global climate change* (which also refers to climate cooling both human induced and otherwise). Average global temperature has risen 0.6 ± 0.2 degrees C over the 20th century. The Intergovernmental Panel on Climate Change (IPCC) reports that most of the warming observed over the past 50 years is attributable to human activities. IPCC also reports that the 1990s were the warmest decades and 1998 was the warmest year since 1861.

How does this happen? The earth surface absorbs energy from the sun and radiates it back into the atmosphere. An increase in "greenhouse gases," including carbon dioxide (CO_2), methane (CH_4), ozone (O_3), chlorofluorocarbons (CFC's), Nitrous oxides (N_20) and sulfur hexaflouride (SF_6) form a layer of insulation that traps the earth's outgoing heat, much as air is trapped inside a greenhouse. The increased concentration of these gases traps more heat and causes the earth's overall temperature to become warmer.

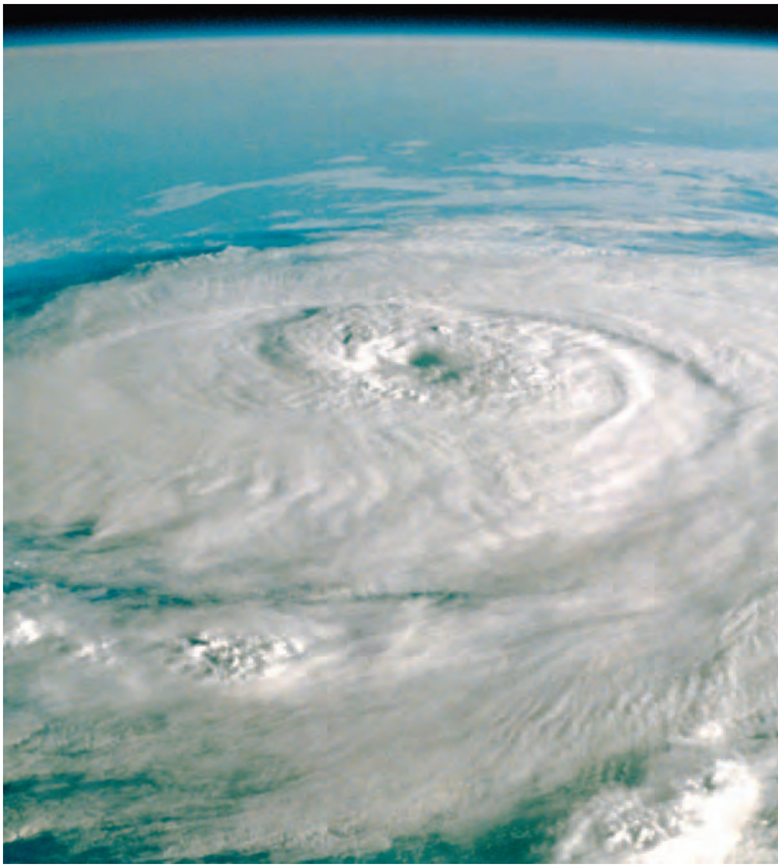
The atmospheric concentration of greenhouse gases has increased over the last century due to industrial and agricultural activity. The most significant greenhouse gas by volume is carbon dioxide. Carbon dioxide is released into the atmosphere through the burning of fossil fuels (oil, natural gas, and coal) in vehicle exhaust, coal-fired power plants and industrial processes. Since the late 1950s, measurements made at the Mauna Loa Observatory in Hawaii record an increase in carbon dioxide concentrations within the atmosphere. Data from Mauna Loa and other sources indicate that atmospheric carbon dioxide concentrations in the atmosphere are now the highest in 150,000 years. Similarly, methane concentrations have increased as a result of the production and transportation of fossil fuels, rice paddy farming, livestock production, changes in land use from wetlands, and emissions from municipal solid waste landfills as organic waste decomposes. Nitrous oxide is released from agricultural and industrial activities, and the combustion of both and fossil fuels and solid waste. Hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6), are greenhouse gases that are not naturally occurring, which are generated in a variety of industrial processes.

PHYSICAL CONSEQUENCES

Climate change is predicted to produce a wide variety of physical impacts to atmosphere, land and oceans including increases in overall global mean temperature, increases in storm severity, sea level rise, changes in ocean currents, glacial retreat, drought, and increased fire and hurricanes. Reduced winter snow pack will result in lower flows to river streams during summer. Climate models analyzed by the IPCC predict that between 1990 and 2100, global temperatures may increase by between 1.4 and 5.8 degrees C. The IPCC estimates that the combined effects of ice melting and sea water expansion from ocean warming are projected to cause the global mean sea level to rise by between 0.1 and 0.9 meters between 1990 and 2100. Because a high percentage of the human population lives along the coast, these increases in sea level will have enormous social impacts. For example, in Bangladesh, a half-meter increase in sea level puts some 6 million people at risk from flooding.

As a result of these widespread ecosystem disruptions, ecological productivity and biodiversity will be altered, leading to an increased risk of extinction for species already at risk. IPCC reports that "the stresses caused by climate change, when added to other stresses on ecological systems, threaten substantial damage to or complete loss of some unique systems and extinction of some endangered species." Changes in climate are more pronounced in the northern and southern most latitudes. In September 2005 it was announced that global warming is melting the ice in Antarctica faster than had previously been thought. Over 13,000 square kilometers of sea ice in the Antarctic Peninsula appears to have been lost over the last 50 years.

Climate change is predicted to produce a wide variety of impacts, including more frequent and severe hurricanes.



SOCIAL CONSEQUENCES

Social consequences from these physical changes are predicted to be widespread and potentially catastrophic as water shortages, decreased agricultural productivity, extreme weather events, and the spread of diseases take their toll. Flooding, severe storms, and drought will lead to increase in environmental refugees. The World Health Organization (WHO) estimates that already there are some 150,000 deaths per year connected to weather events. IPCC reports that climate change will produce human health threats ranging from heat stress and loss of life in floods, to indirect effects induced by expansion in the ranges of disease vectors such as mosquitoes and waterborne pathogens. Social impacts of climate change are exacerbated by other forms of environmental degradation including ozone depletion, population growth, and air and water contamination.

The people who are most affected by the global warming are least responsible for the emissions that cause the problem. This disproportionate relationship between who creates the problem and who pays the price is played out both globally and within the United States. For example, low income people living in tropical countries will be most at risk. Thus, in addition to being a major environmental problem, global climate change is a highly significant global environmental justice issue.

Climate change is an issue of global environmental justice on at least four dimensions. Wealthy industrialized countries of the Northern hemisphere contribute disproportionately to the pollution of the common global airshed. Low-lying geography and weaker infrastructure mean that consequences of global climate change will be worse for people who are poor, especially those in the poorer nations of the Southern hemisphere. People who are poor within the United States have less access to health care, may be less able to move rapidly from affected areas (mostly people without cars were left behind in the flooding of New Orleans). On an international level, poor nations that have weaker infrastructure are less able to respond in crises. People living in these places are even more affected by health or financial burdens. In terms of intergenerational equity, those alive today are negatively altering the

Impact on First Nations

Already the First Nations people who inhabit northern latitudes worldwide are experiencing disproportionate burdens of the impacts of a changing climate. Not only are the physical and ecological impacts of climate change most extreme in northern latitudes, but arctic indigenous people rely directly on plants, animals, and features of weather and climate for survival.

For example, the Inuit in Nunavut, Canada, rely on the ringed seal as a staple food source year-round. It is the only marine or terrestrial species that can meet their nutritional needs. Ringed seals and polar bears depend upon stable sea ice for breeding. Over the past 30 years, the average extent of sea ice has declined by 15–20 percent. Modest climate change scenarios project an acceleration of this melting with a nearly ice-free Arctic Ocean within the next 100 years. As the Arctic Climate Impact Assessment describes, "To hunt, catch, and share these foods is the essence of Inuit culture. Thus the decline in ringed seals and polar bears threatens not only the dietary requirements of the Inuit, but also their very way of life…Because ringed seals and polar bears are very unlikely to survive in the absence of summer sea ice, the impacts on indigenous communities that depend on these species is likely to be enormous."

earth's atmosphere and climate, reducing its capacity to sustain life for generations to come. Finally, there are issues of equity and justice regarding international negations. These often center around the question of equitable global distribution of green house gas emissions as related to economic development. Nations such as China and India are expanding their economies, doing so increases their fossil fuel emissions. Climate treaty negotiations have favored industrialized nations in terms of both outcome and process.

GOVERNMENTAL SOCIAL RESPONSES

Social response to information in climate change has ranged from the development of international agreements, relatively weak social movement activity in affluent Western nations, stronger social movement organizing from people on low lying South Pacific islands and in the Northern arctic, attacks on climate scientists and media spin, and the announcement of insurance companies that the increased claims due to global warming will bankrupt the insurance system in the not too distant future.

Due to the enormous ecological, social, and economic consequences of climate change the global regulation of greenhouse gases is highly politically charged. This is in part because nations from around the world have very different levels of carbon dioxide emissions and negotiating power. In addition to national governments, oil companies and environmental organizations are involved in negotiations. Issues of contention have included extent of overall emissions by each nation, process for emissions reduction, and the degree to which nations meet targets by using "carbon-removal" methods such as planting forests versus reducing actual emissions. International collaborative efforts on climate change began as far back as 1979 when the World Meteorological Office, the United Nations Environment Program (UNEP), and the International Council for Science held the first World Climate Conference in Geneva. This was followed in 1988 by the establishment of the IPCC, which was set up to assess scientific and social information about human-induced climate change. The IPCC released its first report in 1990. In response, the UN General Assembly launched a negotiating process to establish an agreement among industrialized nations to act to reduce their emissions of greenhouse gases.

In 1992, the UN Framework Convention on Climate Change was adopted at the World Conference on Environment and Development in Rio de Janeiro. The nations who signed the convention agreed to develop national inventories of greenhouse gas emissions, establish national programs to reduce emissions, and mitigate climate change. The Convention also required that the developed countries and countries with economies in transition (the "Annex I countries") reduce their greenhouse gas emissions to their 1990 levels by end of 2000. This was expressed as a voluntary, not binding, commitment. The convention was ratified by the United States and came into force in 1994.

It soon became clear, however, that voluntary commitments alone were not leading to emissions reductions. Negotiations for a new agreement that specified binding reduction targets culminated in a session held in Kyoto, Japan in December 1997, which became known as the Kyoto Protocol. Under the Kyoto Protocol industrialized nations are committed to legally binding reductions in greenhouse emissions between 2008 and 2012. Included are provisions for emissions trading among nations and so called "clean development mechanisms," which encourage industrialized nations to transfer technology to developing countries that would reduce emissions.

Conflict over many issues, especially the responsibility of China and India for greenhouse emission reduction, was so significant that only in the final hour did nations reach agreement. The Kyoto Protocol went into effect on February 16, 2005, ten years after initial negotiations began and without the ratification of the world's largest emitter of greenhouse gases, the United States (the United States is a signatory only). Ratifying the Kyoto Protocol would require the United States to reduce greenhouse gas emissions by 7 percent below its 1990 levels by 2012. The Clinton Administration announced it would not send the treaty to the Senate for ratification. In 2001 George W. Bush announced the rejection of the Kyoto Protocol on the basis that it was too costly for the U.S. economy. A highly criticized plan by the Bush Administration focuses on voluntary reductions in emissions, tax credits for emissions reductions, and increased research and development for new energy technologies. This plan allows for a 12 percent increase in greenhouse gas emissions by 2012 and has provided no mechanism for ensuring that this target will be met. There is, however, growing awareness in the United States Congress that action is needed to curb greenhouse gas emissions. Many U.S. states have enacted legislation and adopted policies that effectively reduce emissions of greenhouse gases while preserving economic viability. These include implementing renewable portfolio standards and mandatory greenhouse gas reporting.

PUBLIC RESPONSE

Despite the seriousness of the global warming, a notable pattern of meager public response in the way of social movement activity, behavioral changes or public pressure on governments is visible in all Western nations. Public "apathy" with respect to global warming has been identified as a significant concern by environmental sociologists, social psychologists working in the area of risk perception, and environmental writers. A number of studies have shown that Americans in particular know little about global warming.

Existing research assumes that a lack of information about the causes of global warming is the limiting factor in the public's failure to respond—an orientation that Harriet Buckeley calls the "information deficit model." Other explanations for the lack of action in the face of such a serious environmental and social problem target the problem from another angle: the desire and ability to avoid unpleasant emotions of guilt and helplessness may lead to denial about the global warming. Clearly, knowledge is necessary to generate public response, but is knowledge sufficient? There is evidence that fear about the future, feelings of helplessness about the ability to make change, and guilt due to knowledge of responsibility through fossil fuel consumption are barriers that discourage people from even thinking about global warming, much less trying to fix it. For privileged people, environmental and social justice problems such as the global warming are increasingly distant in time or space or both. At least in the short term, the people who are benefiting from the fossil fuel consumption are not the ones living on low lying islands or trying to survive off ringed seal in the Northern Arctic. Social inequality helps to perpetuate environmental degradation making it easier to displace visible outcomes and costs across borders of time and space, out of the way of those citizens who are most politically able to respond.

SCIENTIFIC UNCERTAINTY

How much certainty is there concerning the existence, causes, and consequences of global climate change? These are questions asked frequently by members of the American public. While climate modeling is complex and there are some scientists who disagree that human actions have played a significant role in increasing global temperatures, there is probably a greater degree of scientific consensus on the basics of the global warming than any other current scientific issue. There is more significant uncertainty regarding predicting future climate scenarios. The IPCC addresses the question of certainty throughout its 2001 report by rating predictions with low, medium or high confidence. A joint statement by scientists on the issue of climate science noted that, "There will always be uncertainty in understanding a system as complex as the world's climate. However, there is now strong evidence that significant global warming is occurring...The evidence comes from direct measurements of rising surface air temperatures and subsurface ocean temperatures and from phenomena such as increases in average global sea levels, retreating glaciers, and changes to many physical and biological systems. It is likely that most of the warming in recent decades can be attributed to human activities. This warming has already led to changes in the Earth's climate." They further note that, "The scientific understanding of climate change is now sufficiently clear to justify nations taking prompt action."

There is now evidence that the generation of uncertainty has been actively produced by those who stand to benefit from continued fossil fuel consumption, namely the oil and gas industry. In 2000, environmental sociologists McCright and Dunlap describe how conservative think tanks mobilized to challenge mainstream climate science by launching an attack on science, arguing that global warming will have substantial benefits if it occurs, and warning that proposed action to ameliorate global warming would do more harm than good. They examined how these countermovement organizations aligned themselves with prominent American climate change skeptics known for their affiliations with the fossil fuels industry. They conclude that a major reason the United States failed to ratify the Kyoto Protocol was the opposition of the conservative antienvironmental movement.

Journalist Ross Gelbspan, once a climate skeptic himself, has described the influence of fossil fuel industry on American media framing of global warming, documenting how oil companies have influenced science, policy decisions, and produced a sense of uncertainty in the American media and minds of America public.

Gobi Desert

THE VAST AND formidable Gobi Desert covers an area of nearly 500,000 square miles across southern Mongolia and northern China. The Gobi, one of the world's largest deserts, also holds the distinction of being the northernmost desert on Earth. Located centrally within the Eurasian Continent, this region experiences wide seasonal temperature extremes, with daily average July temperatures reaching 113 degrees F, and average daily January temperatures dropping to negative 40 degrees F. The Gobi's continental location is also largely responsible for its aridity. Great distances from the oceans translate into little moisture and precipitation reaching this desert. In addition, the Gobi desert is bounded by mountain ranges, including: the Tien Shan and Altay to the west, the Hangayn to the north, the Greater Khingan Range to the east, and the Yin and Pei Mountains to the south. Nearly encircled by mountains, the Gobi Desert's aridity is exacerbated by the loss of potential moisture as orographic precipitation empties on the windward edge of the mountains, leaving the region largely in an expansive rain shadow. Total annual precipitation varies across the desert, with yearly totals amounting to less than three inches in the west, to slightly more than eight inches in the east and northeast. The precipitation in the eastern- and northeastern-most areas of the Gobi occurs primarily in the summer during isolated, monsoon-like downpours.

Despite being sparsely populated by nomadic herders in Mongolia and more sedentary farmers in China, the Gobi Desert has a number of notable interrelationships with human society. The first European explorer of the region is thought to have been Marco Polo during his journey across Asia in the 13th century. Russian and British geographers and explorers mapped much of the region during the late 19th century. Perhaps the most famous expedition to the Gobi desert occurred in 1922 by a group of scientists led by Roy Chapman Andrews and sponsored by the American Museum of Natural History. The group located thousands of fossilized dinosaur remains, including nesting sites, dinosaur eggs, and skeletal *Proceratops* remains showing nearly all stages of the dinosaur's life cycle from newly hatched baby dinosaurs to old-aged adults. Later explorations in the 1990s reaffirmed the Gobi's place as one of the world's premier dinosaur fossil grounds.

Today, the Gobi Desert's unique ecosystem is threatened by the possible extinction of native fauna and a troubling rate of desertification and expansion of lifeless desert. Conservation efforts aimed at protecting the endangered wild Bactrian camel and the Gobi brown bear led to the establishment of Mongolia's Great Gobi Strictly Protected Area in 1975. Numbers of remaining Bactrian camels may be as low as 300, and Gobi bears may number less than 50. Other rare and endangered species include the Asiatic wild ass and Przewalski's horse. The negative human impact on the Gobi desert region can be seen with the growing problem of desertification, the overall expansion of desert conditions into former grasslands. Increasing human populations and unsustainable overgrazing by livestock have removed a steadily increasing amount of grasses and other vegetation, upsetting the delicate ecosystem balance, and resulting in the continuing expansion of the desert. Gobi desertification has triggered giant dust storms that have carried sand and dirt to China's heavily populated centers in the east, and as far away as South Korea and Japan.

Przewalski's Horse

Przewalski's Horse, otherwise known as the Asian Wild Horse or the Mongolian Wild Horse, is found in the Gobi Desert and is the closest living wild relation to the domestic horse.

Nikolai Mikhalyovich Przewalski (1839–88) was a Russian geographer and explorer who crossed the Gobi Desert in the 1870s and then traveled in Turkestan, before returning to the Gobi Desert in the 1880s. It was during this second trip that he tried to find the horse, having heard stories about it—it was endangered even in those days—and eventually was able to describe one. A number were found by Carl Hagenbeck in the late 1890s and many were captured for zoos around the world. The last herd was spotted in 1967, and the last horse in 1969.

With many of the horses dying in Russian zoos during World War II when they were killed by the Germans, and the horses in the United States also not surviving captivity well, in 1945 the only two captive populations were in Munich and Prague zoos. However, soon some started being caught for other zoos, contributing to a lessening of their numbers in the wild. In 1977, the Foundation for the Preservation and Protection of the Przewalski Horse was founded by Jan and Inge Bouman, who have been encouraging zoos around the world to allow their horses to be transported to other zoos for mating, to overcome problems over inbreeding.

This was successful, and in 1992 sixteen horses were released back into the wild. The area where they live is now the Hustai National Park southwest of Ulaanbaatar, Mongolia's capital, and their status in the wild has changed from being "extinct" to "endangered."

Gold

GOLD IS A yellowish, soft, transition metal with the atomic number of 79 and an elemental symbol of Au. Gold has had enormous social and economic significance worldwide. Gold has been the standard for many currencies. The majority of the world's gold comes from South Africa, while two-thirds of gold consumed in the United States comes from Nevada and South Dakota.

So-called gold rushes occurred across the western United States and Canada throughout the second half of the 19th century. These mass migrations produced enormous social and environmental consequences. By far the most famous was the California Gold Rush (1848–58), which drew gold-seekers from Mexico, China, Germany, and many other nations of the world. About 125 million troy ounces of gold were extracted, a value of more than $50 billion by today's standards. Although there was much wealth to be made, mining was a dangerous activity. It is estimated that up to 30 percent of miners died of disease, accidents, or violence.

Social, political, and environmental impacts of the California Gold Rush include the systematic genocide of American Indians, mass worldwide and internal immigration, California statehood (1850), the devastation of river ecosystems with hydraulic mining, the contamination of waterways with mercury, and the growth of major cities including San Francisco (whose population exploded from 1,000 residents in 1848 to 20,000 just two years later). In 1852, at the height of California Gold Rush, 20,000 of the 67,000 immigrants were from China. By 1880, Chinese constituted 22 percent of California's mining population, making them the largest single nationality engaged in gold mining. However, mortality, racially motivated violence, and the Chinese Exclusion Act reduced the Chinese population in California from 75,132 in 1880 to 45,753 in 1900.

The highest price of the California Gold Rush was paid by California Indian people. With more than 100 unique ethnic groups and several hundred politically autonomous nations, California Indians are extremely diverse. However, within two decades of the gold rush, California Indian populations plummeted by 90 percent. This period has been called the California Indian Holocaust. Indian people were killed both by individual miners and systematic, state-sponsored violence as gold mining gave way to further white settlement. In 1851 and 1852, the state of California spent $1 million per year to exterminate native peoples. California offered "Indian hunters" bounties of $5 per head. Population estimates vary, but in all accounts the genocide affected over 100,000 Indian people. Many tribes lost 90–95 percent of their populations in just a few years.

Gold was extracted using hydraulic placer mining. This technique was both highly effective and enormously destructive of the environment. Forests and hillsides were washed away as highly pressurized water flushed mud into rivers. An estimated 12 billion tons of mud and soil were washed into rivers, including thousands of acres of the best farmland in the state. The Sacramento, Yuba, and other rivers of the Sierra Nevada were so overloaded with silt that they could not carry normal rainfall, resulting in severe flooding. Farmers and city residents launched a campaign against hydraulic mining. After a significant political struggle, hydraulic mining was outlawed in California in 1884.

Because of its value and its continued usefulness in computers, aircraft, and communications technology, among others, gold continues to be harvested and traded today. While a significant proportion of gold is mined by small operators (perhaps one-quarter), contemporary gold mining occurs in large scale mining operations, run by prominent multinational companies. Beyond the difficult and dangerous labor conditions associated with production, environmental concerns include the disposal of "overburden," the mineral material through which the mine is dug. Another related problem is the disposal and management of cyanide used to dissolve and extract the mineral from the surrounding rock, which can potentially leach into soil and groundwater, presenting a risk for drinking water and for ecosystems connected to the aquifer. Environmental regulation of mining internationally varies. The Surface Mining Control and Reclamation Act in the United States is designed to address many of the environmental risks associated with gold mining, though the overall effectiveness of the act is debated.

Golden Rice

GOLDEN RICE IS the common term for rice genetically modified to produce beta carotene (the compound that the human body converts to vitamin A) in the endosperm. This invention represented a breakthrough in genetic engineering, and it also played a significant role in public relations campaigns to frame global debates on biotechnology. The impetus behind Golden Rice was the desire to mitigate Vitamin A deficiency among poor Asian populations with rice-based diets. Rice actually contains moderate levels of beta carotene in the bran, but this is commonly removed by polishing—the process of mechanically removing the bran from the endosperm to improve storability and taste.

The search for a biotechnological solution to this problem was led by Ingo Potrykus, a German biologist who had founded the Institute of Plant Sciences at the Swiss Federal Institute of Technology in 1985. Here he began work on nutritional enhancement of rice through genetic modification. By 1992, he had established a productive collaboration with Peter Beyer at the nearby University of Freiburg. Turned down for corporate funding, he and Beyer secured funding from the Rockefeller Foundation's Food Security program. Over the next eight years, they succeeded in introducing three genes (two from daffodil and one from the bacterium *Erwinia*) that produced the four enzymatic reactions making up the carotenoid biosynthetic pathway in the rice endosperm. The modified rice had a yellow endosperm (hence the name) and contained very small amounts of beta carotene. The invention was only a prototype; the level of beta carotene was too low to have an impact on nutrition, and the altered pathway was working only in one strain of rice used for experimentation. Nevertheless, the engineering of a biosynthetic pathway represented a significant advance in molecular biology.

The project also suggested promise for humanitarian biotechnology, but major problems with intellectual property were soon discovered. The development of genetically modified plants, especially with complex multi-gene transformations, invariably uses multiple patented genes and technologies along the way. Researchers routinely gain access to these technologies through contracts allowing restricted use for research but not for release. When the Rockefeller Foundation commissioned an "Intellectual Property Audit" to identify the patented technologies used in developing the Golden Rice prototype, the finding was that 70 technologies—owned by 32 companies and universities—had been used; any of these could potentially block the eventual release of Golden Rice. Although the number of technologies under patent protection in the target countries was much smaller, this was still a serious obstacle.

SAVING "A MILLION KIDS A YEAR"

In January 2000 the Potrykus–Beyer team described their accomplishment in *Science*, and in July *Time* magazine featured Potrykus on its cover with the claim that his rice could "save a million kids a year." The timing of this publicity was crucial. Reeling from Europe's rejection of genetically modified foods, the biotechnology industry had begun to promote its products on the basis of the potential to feed the hungry, and it had just started a $250 million public relations initiative called the Council for Biotechnology Information. The CBI seized Golden Rice as the centerpiece of an advertising campaign that included network TV and full-page newspaper advertisements. Tens of millions of dollars were spent by industry touting an invention that had resulted mainly from a noncorporate investment of $1.5 million.

The Golden Rice publicity led to developments with the intellectual property problem. Monsanto, which dominated commercial crop genetic modification, agreed to relinquish its rights on the viral promoter used in Golden Rice development (a promoter is a DNA segment that regulates gene activity); Monsanto then issued a press release that led many newspapers to credit Monsanto with the invention. A broader solution to the problem of patents was later achieved through a deal allowing free distribution of Golden Rice to poor farmers if and when it was released, while the Zeneca Corp. retained commercial rights.

The years following the original announcement brought some improvement in the Golden Rice construct. Molecular biologists at Syngenta (the descendant of Zeneca) replaced the Monsanto viral promoter and one of the daffodil genes what it called Golden Rice 2, greatly raising the level of beta-carotene. Halting progress was made in transferring the engineered trait into rice cultivars (using both genetic modification and backcrossing) in India, Phillipines, Taiwan, and the United States. As of 2006, the only field trial had been in Louisiana using a "golden" version of American rice. It was hoped that Golden Rice cultivars of agronomic value to Asian populations would be available by 2010.

Thus, several years after the invention was announced, Golden Rice had played no role in combatting malnutrition and indeed was still far from being available in a useful form, but it was still playing a significant role in the debates on crop genetic modification. While biotechnology firms and their allies continued to tout the invention, critics charged that Golden Rice was surrendered to the commercial and PR interests of the biotech industry; that the project and its publicity obscured the real causes of malnutrition such as loss of biodiversity; and indeed that it was a "hoax." Nutritionists pointed out that a simple increase in consumption of beta carotene would have little impact on undernourished children, as they often suffer from protein energy malnutrition and intestinal infections that impede the conversion of beta carotene to vitamin A. The editor of *The Lancet* suggested that "seeking a technological food fix for world hunger may be... the most commercially malevolent wild goose chase of the new century," and even officials at the Rockefeller Foundation complained about the claims being made for the invention it had sponsored. These charges pertain more to the commercial and rhetorical uses of Golden Rice, however, than to the original project itself, which was noncorporate and which was conceived by the Rockefeller Foundation only as one part of a broad-based initiative to improve food security.

Golf Courses

GOLF COURSES ARE areas of land reserved for the playing of golf, which is a sport invented in Scotland in the 15th century. The rules of the game, and hence, regulation of the size and configuration of courses did not occur until the 18th and 19th centuries. Each course now consists of 18 holes, generally measured out in long thin strips between approximately 90–550 meters long. The prepared part of the hole is called the fairway and the grass is kept comparatively low to facilitate play. The hole itself is surrounded by a patch of ground known as the "green," which is a heavily watered and maintained area made as level as possible. Golf course management can represent an intensive use of resources, particularly water resources, which may be expensive to obtain locally and for which local people may have a regular need. As golf has become an important international phenomenon, there has been increasing demand for new courses as part of tourist destinations. Land occupied by golf courses, when denied to local people, generally drive up property prices and this can be problematic for local people who cannot compete with the often internationally influenced economy. This is especially true when land resources are limited, as, for example, on island chains such as Mauritius or Hawaii, where most goods have to be imported and are therefore expensive, and the local economy has become integrated into the tourism industry. In addition, the need to maintain the courses in close to pristine condition has led in some cases to the heavy-handed treatment of flora and fauna through chemical pesticides, and this too can have implications for the wider environment.

Golf course management can represent an intensive use of resources, particularly water resources.

It is not known exactly how many golf courses there are internationally and how many people who play golf. About 50 million people play golf on 25,000 courses around the globe. Some courses represent valuable habitat for local animal species, although these are more likely to be suppressed if they might adversely affect the quality of the course. In recent decades, the game's popularity has increased greatly due to the rise in participation of people from East Asia, notably Japan and South Korea; it is anticipated that this increase will be intensified by the rise of new players in China and India, which are countries that also consider playing golf to be part of an elite, desirable, bourgeois corporate culture with an element of conspicuous consumption attached. As a result, more land is likely to be sequestered in desirable climactic zones of those countries, and further land used in tourist destination countries such as Thailand and the Philippines. Frequently, ethnic minority people inhabiting the desired land are marginalized by this change in use. Long-established golf courses may occupy valuable land and be surrounded by residential areas that have grown since their initial creation. In such cases, the use of the courses as additional housing land can outweigh the societal value of the courses. One example of municipal governments attempting to reclaim the privately owned land is in Caracas, the capital of Venezuela, where the city mayor, inspired by the policies of President Hugo Chavez, has launched an attempt to expropriate the courses and put them to public use.

Research into the impact of climate change on golf participation suggests that, depending on the location concerned, the golfing season will be lengthened or curtailed as the particular local conditions change. This will affect the demand and supply factors for existing golf courses and will have implications for future land use. This is likely to lead to increased tension between private land rights and societal need for usable land.

Goodall, Jane (1934–)

BASED ON HER primate research in the Gombe Game Reserve in Africa, Jane Goodall is the world's leading authority on chimpanzees and is considered a great conservationist. She was born in London, England, in 1934. When she was 11 years old, she decided she wanted to travel to Africa and possibly live there. In her early 20s, she found herself in Nairobi, Kenya, working as a secretary. About a year after her arrival, she met Louis Leakey, who was interested in studying apes and their relationship to humans. Both Leakey and his wife, Mary, began collaborating in their studies with Goodall. Leakey thought Jane would be the perfect person to begin a study of the great apes on the Gombe National Reserve in Tanzania, because she was not formally trained in ethology or primatology.

In 1960, Goodall arrived at the Gombe National Reserve and began her research, eager to develop a relationship with the chimpanzees. But after a few weeks of observation, she was discouraged because the chimpanzees would not let her get within 50 yards of them. This changed the day a male chimp wandered into her camp and began stomping and screaming after seeing a banana on a table. Eventually, the chimpanzees learned to accept the young researcher. They allowed her to follow them, and they would greet her with a touch or a kiss. She was able, through careful observation, to find commonalities between humans and chimpanzees.

Goodall married Hugo van Lawick in 1964 and they had one son, Hugo. She later divorced Lawick and entered into a second marriage to Derek Bryceson. Unfortunately, Bryceson died of cancer only five years later.

Jane Goodall received her Ph.D. from Cambridge University in 1965. Over the past four decades, Goodall has made a number of significant observations of chimpanzees at the Gombe reserve. She observed, and was the first person to record in 1960, that chimpanzees were meat eaters and to document chimpanzees making tools, the first recorded instance of tool-making by nonhumans. In 1964, Goodall noted that chimpanzees engaged in deliberate planning and used man-made objects for various purposes. In 1966, it was noted that chimpanzees could contract AIDS. During the 1970s, Goodall observed chimpanzees expressing awe, engaging in war and cannibalism, creating coalitions, and transferring a member to another group. In 1987, she observed a chimpanzee adopting an adolescent. In 1994, she observed chimpanzees engaging in short-term monogamous relationships and modeling tool-making behaviors of chimps in another community. One year later, she witnessed chimpanzees chewing on a medicinal plant believed to relieve stomach pain. Goodall has taught the public that chimpanzees are able to express emotions, engage in affection, and have personalities.

Today, Goodall is active in promoting conservation and bringing attention to the similarities between chimpanzees and humans. She travels 300 days per year talking to audiences about their ability to help other people, the environment, and animals. With regard to chimpanzees, she has set up halfway houses for injured and orphaned chimps in the wild. She advocates the ethical treatment of chimpanzees in research, lab settings, and zoos.

In 1977, Goodall founded the Jane Goodall Institute (JGI), a global nonprofit organization that focuses on empowering people, including youth, to make a difference. The JGI promotes creating healthy ecosystems and sustainable livelihoods for all living creatures, and focuses on nurturing and educating new generations of active, committed citizens throughout the world. The "Roots and Shoots" program, founded in 1991, is an example of the institute's efforts. The program ultimately encourages care and concern for animals, the environment, and the human community.

Throughout her long professional career, Goodall has written a number of children's books, books for adults, and scholarly articles. Her most recent children's book is *Rickie and Henry: A True Story* (2004). Her most recent adult book is *Harvest for Hope: A Guide to Mindful Eating* (2005). She has earned 27 honorary degrees and has received 79 awards for her work.

Gore, Al (1948–)

ALBERT ARNOLD GORE, Jr. is an influential American politician and statesperson who served as vice-president and was influential in the development of the Internet, as well as being a leading voice in the campaign for preservation of the environment.

Gore followed in the footsteps of his father, a politician, in the Democratic Party after completing his education and serving as a volunteer in the Vietnam War as a reporter. He entered the House of Representatives in 1976 and then took a seat in the Senate in 1984, serving the state of Tennessee. In 1988, he tried but failed to secure the Democratic nomination for president, which was secured by Michael Dukakis. In 1998, William J. "Bill" Clinton selected him as his running mate. Gore was subsequently for two terms vice president, the 45th of U.S. history.

Selected to run for president in the 2000 election, Gore was defeated only by court action after having won a majority of the popular vote across the country and as a result of intensely controversial vote-counting procedures in the state of Florida. Speculation continues as to whether he will make a further attempt to be elected Democratic president. He has earned a reputation in his political career for earnestness, attention to detail, and mastery of policy. However, he was not able to project himself as a popular communicator.

Since 2000, Gore has concerned himself to a considerable extent with the environment, to which he has given voice throughout his political career. In *Earth in the Balance*, first published in 1992, Gore expressed the opinion that human society was plunging the earth headlong into a total environmental catastrophe. While he argued that it was possible for capitalism and democracy combined to bring about solutions to the problems that have been caused, the type and nature of change required significantly outweighed the political will available to necessitate change. Consequently, it would be necessary for a groundswell of public opinion to emerge to demand radical political change.

While Gore has positioned himself in political life as a moderate, and while he has not often called for radical change, his more recent efforts have begun to assert more radical strategies. In *An Inconvenient Truth*, (2006), Gore outlines in detail the many forms of proof of global climate change, its causes, and likely implications. The book was accompanied by a multimedia campaign led by Gore, aimed at persuading those remaining members of the public of the facts and the science of environmental change (it became a widely viewed film in 2006). This campaign was aimed at stirring public consciousness and encouraging a mass movement determined for change, raising questions about source of the inertia that maintains the status quo. He has also spoken out against President George W. Bush's foreign policy, specifically with respect to Iraq. He personally commanded an attempt to rescue people from New Orleans in the wake of Hurricane Katrina.

Grand Canyon

THE GRAND CANYON, carved out by the Colorado River, is in the Grand Canyon National Park in Arizona, and is probably the most famous gorge in the world. The Grand Canyon is a total of 277 miles (446 kilometers) long, ranging in width from 0.25 miles (0.4 kilometers) to 15 miles (24 kilometers) wide. From a geological perspective, it is believed that the Colorado River basin, including the Grand Canyon, dates back some 40 million years, with the Grand Canyon being anywhere between 2–6 million years old. This makes the erosion caused one of the most complete geological features in the world. At the place known as the Vishnu Schist at the bottom of Inner Gorge, the erosion has exposed the last two billion years of the history of the Earth.

In spite of the exposure of such a long period of time in the rocks, not many plant or animal fossils have been found, because until relatively recently (in geological time) the only flora and fauna in the area were algae, mollusks, corals and only a very few invertebrates. There are currently many animals throughout the Grand Canyon, including badgers, bobcats, chipmunks, coyotes, foxes, rabbits, rats, and squirrels. Some of the plants include willows and cottonwoods. However, as the climate is dry and there can be periods of water shortages, many drought-resistant plants grow there, including agave, tamarisk, yucca, and many different types of cacti. On the North Rim and the South Rim of the Grand Canyon, there are many fir trees, pine trees, and also scrub oak, mountain mahogany, and sage bushes.

FIRST SIGHTINGS

The first recorded sighting of the Grand Canyon by a European was when García López de Cárdenas went through it in 1540, although Native Americans lived there for many centuries beforehand, with settlements still visible within the walls of the canyon. It is probably for this reason that the Hopi guides leading the Spaniards did not show them how to enter the canyon itself. Remains from the prehistoric period and early artifacts have been located there. The next European visitors were two Spanish priests and some Spanish soldiers who were exploring the area around southern Utah.

The next reported sighting of the Grand Canyon was when James Ohio Pattie and some trappers reached the area in 1826. The next verified visitor was Jacob Hamblin, a Mormon missionary who was sent by Brigham Young in the 1850s to establish the location for a river crossing in the Canyon; he mapped Lee's Ferry and Pierce Ferry in 1858. Other parties of U.S. government surveyors, explorers, and mineral prospectors followed. These included the John Wesley Powell River Expeditions and the Brown-Stanton River Expedition. The former involved extensive mapping of the Grand Canyon, with information being published on its botany, ethnology, geography, and geology. Theodore Roosevelt visited it on many occasions and urged for its inclusion in a national park. The Grand Canyon National Park was established in 1919, covering 1,904 square miles (4,931 square kilometers). The park was enlarged in 1975 to include the Grand Canyon National Monument, the Marble Canyon National Monument, and other nearby protected areas. Four years later the park was designated as a World Heritage site, and is now connected by a 215-mile (346 kilometer) paved road and a transcanyon trail stretching 21 miles (34 kilometers). There are still five Native American tribes living nearby.

By the 20th century, with road access, the Grand Canyon had become an important tourist site, and from then was regularly visited by tourists from all over the world. This gradually became regulated, but on June 30, 1956, the Grand Canyon became the site of what was then the worst commercial aviation disaster in North America when a TWA Lockheed Super Constellation and a United Airlines Douglas DC-7, both having left Los Angeles International Airport, collided above the canyon, killing all 128 crew and passengers from both planes. Wreckage from the crash fell into the eastern part of the canyon.

There are now about five million visitors to the Grand Canyon each year, with 83 percent from the United States. Some 3.8 percent of visitors come from the United Kingdom, 3.5 percent from Canada, 2.1 percent from Japan, 1.9 percent from Germany and 1.2 percent from the Netherlands, with 4.5 percent from the rest of the world.

From the 1870s until 2001, approximately 600 deaths have taken place at the Grand Canyon, of which 242 were from plane or helicopter crashes (including the 1956 collision); 79 from drownings in the Colorado River; 65 from heat stroke, heart attacks, dehydration, hypothermia, and other environmental causes; 50 from falls, including by photographers who were trying to get views of the Canyon from new angles; 47 from suicides; 25 from freak accidents such as lightning strikes or rock falls; 23 from murders; and seven caught in flash floods.

It was not long before athletes started to run across the canyon with a one-way trip known as "rim-to-rim," taking between five and seven hours, and the round trip, known as the "doublecross" or

García López de Cárdenas

García López de Cárdenas was born in Llerena in southwestern Spain, and went to the Americas with the expedition of Francisco Vasques de Coronado that set out from modern-day Mexico in 1540. When the party reached Cíbola, Cárdenas was sent to lead a special mission to try to locate a large river, which they had heard about from some local Indians.

Instructed to return after 80 days, Cárdenas headed north accompanied with Pedro de Sotomayor, who described this mission led by Hopi Indian guides. They marched north for 20 days but had many difficulties in finding the river. However, in spite of this failure, Cárdenas and his men found the Grand Canyon, reaching it at the South Rim between Desert View and Moran Point. When they located the canyon, Pablo de Melgrossa, Juan Galeras, and another soldier descended a third of the way into the canyon, but had to stop when they ran out of water. Subsequently, it has been speculated by historians that the Hopi guides deliberately did not lead them into the canyon itself, which they must have known about. Although the description of the Grand Canyon survived, the Spanish found no gold or evidence of great wealth, and hence nobody returned to the area for many years.

It seems likely that another conquistador, Hernando de Alarcón had explored the Colorado River some months earlier, but he did not record the visit; it was not until 1776 that any further Europeans reached the Grand Canyon. On that occasion, Fathers Francisco Atanasio Domi'inguez and Silvestre Vélez de Escalante, two Spanish priests, along with some soldiers, reached North Rim when traveling from Santa Fe to California.

the "rim-to-rim-to-rim," taking anywhere between 11 and 14 hours. The man with the record for the north to south crossing is Allyn Cureton of Williams, Arizona, who also holds the doublecross record with a remarkable time of under eight hours.

Grasslands

GRASSLANDS ARE AREAS of land that are dominated by one or more forms of grass, which is a family of plants that also includes cereals. Grasslands are one of the most common forms of land cover of the nonsubmerged land of the world. The intensification of agriculture in many parts of the world has significantly increased the proportion of land that is considered grassland. Natural grasslands are less prevalent, but still extensive, and have formed in areas in which climatic conditions in terms of water resources are not so beneficial as to permit the creation of forests, but are not so harsh as to lead to the formation of deserts.

The most important grassland areas are the steppe lands of central Asia and southern Russia, extending down to the Indian subcontinent. This area saw the emergence of a stream of nomadic peoples including the Huns, Mongols, Bulgars, and Scythians who, stimulated largely by climate change, launched waves of invasion and conquest over the settled peoples who occupied the surrounding ground. Other areas of grassland include the wide swathe of territory extending from west to east Africa that helped stimulate the creation of temporal states. The large area of central-northern Australian grassland is very lightly inhabited, although it provides a natural home for sheep. In the United States, the prairie is a form of grassland that extends through much of the central section of the country down to the southeastern coastline. This area has long formed a destination for settlers who wish to own land, and represents the center of the intensive agricultural system that sustains the rising population of the country.

Grasslands generally merge into similar forms of land cover at their margins, becoming savanna, scrubland, or other types as the climatic and water resources conditions vary. In some cases, these conditions can prevent grasslands forming in otherwise favorable conditions. For example, extensive flooding can inhibit the growth of larger plants while permitting grasses to flourish for most of the year. Climate change has also been influential in determining the extent of grassland and unanticipated change in status could be disastrous. The extensive burning of original forest by early settlers created the grasslands of the South Island of New Zealand, which sustain the nation's sheep industry. Fire is a regular occurrence in grassland during hot conditions, and these fires are capable of running out of control and threatening human habitation, given the close proximity with which people live to agricultural areas. Burning of stubble or abandonment of previously worked agricultural land might also change the nature of existing or potential grassland. The suitability of grasslands for supporting animal husbandry and cereal crops means that grassland management and manipulation have been studied in considerable depth, and productivity levels have been increased considerably.

Because of development and other land cover transformations from human occupation, grasslands are increasingly in decline throughout the world, especially in North America. The concomitant loss of floral and avian biodiversity that depends on these ecosystems represents a serious, and largely underappreciated, global ecological crisis.

Grazing

GRAZING IS THE consumption by animals of herbaceous vegetation at its place of growth, whether in pasture or on rangeland. In its noun form, *grazing* refers to the land where this takes place. The term shares etymological roots with *grass;* technically, grazing is a subset of herbivory and is distinct from browsing, which involves woody or brushy plants rather than grasses and forbs. In common usage, however, this distinction is often overlooked, with grazing employed as a synonym for herbivory, perhaps because many animals are both grazers and browsers. Grazing animals are diverse, including both wild and domesticated species and several taxa, including birds such as geese, insects such as grasshoppers, and mammals ranging from mice to kangaroos to elk. Here again, common usage often deviates from strict definitions, applying the term more narrowly to domesticated livestock, including some species that are technically browsers, such as goats.

Grazing animals and grasses coevolved, each adapted to the other. The animals developed digestive systems capable of converting herbaceous plant material into energy, and the grasses developed the capacity to withstand periodic defoliation and even benefit from it. Grasses' growth points are generally at or near ground level, beyond the reach of the animals' bite; removal of older leaves and stems can enhance grass growth (by allowing greater sunlight to reach growth points and because younger leaves are more efficient); animals can spread and fertilize grass seeds, and their hooves can increase seed-soil contact for germination. New growth on recently grazed grasses can in turn attract grazing animals. In some systems, grazing can benefit grasses indirectly by altering competition with other kinds of plants. On the other hand, overgrazing can occur, such that these symbiotic interactions break down. Compared to predator–prey relations, ecological theory regarding plant–herbivore interactions is poorly developed.

Whereas unfenced animals can vacate denuded areas, fenced animals may consume beyond the land's capacity.

Grazing animals also coevolved with humans; their interactions can be broadly classified as hunting, pastoralism, and ranching. The domestication of certain grazing species between 10,000 and 4,500 years ago, marking the transition from hunting to pastoralism, dramatically augmented human capacities for settlement and agriculture. In landscapes where crop agriculture was marginal, domesticated grazing animals made human inhabitation possible where it otherwise might not have been. The domesticated animals gained enhanced food provision (to varying degrees) and protection from nonhuman predators, while humans gained a reliable source of traction, transportation, manure for fuel or fertilizer, milk, blood, meat, skins, wool, and so on. The evolutionary sequence of plant and animal domestication is a subject of debate, but it is clear that they were complementary in their overall effect for both humans and the plant and animal species involved.

The relationship of grazing animals to grazed plants is among the most complex in ecology, notwithstanding its apparent simplicity and an enormous body of research on the subject. Although patterns are evident at numerous scales, exceptions are abundant and relationships across scales are exceedingly complex. One prominent expert, S.J. McNaughton, cautions that "no straightforward generalizations are possible regarding the immediate effects of herbivores on plant growth and resource allocation. Consequences of tissue damage are under the complex control of plant genetics, intensity and frequency of herbivore effects, plant developmental stage at the time of herbivore impact, plant tissues that are affected, and the modifying effects of such other environmental factors as light, nutrients, temperature, and water."

This inherent complexity is compounded by domestication and especially, in the rangeland context, by the advent of ranching, which exerts evolutionarily unprecedented rigidity in the spatial distribution of grazing through the exclusive allocation of land. Where this is achieved through fencing, the mobility of animals (with or without human herders) is curtailed to an area that may be several orders of magnitude smaller than the coevolutionary norm. Whereas unfenced animals track grass growth through space and time, vacating denuded areas, fenced animals may be forced to consume different plants, and more of them, than the plants (and, in extreme cases, the animals themselves) can withstand. In spatially heterogeneous and temporally variable landscapes—including a large portion of the world's rangelands—even very large ranch properties are generally too small to match the scale of the processes that drive plant–herbivore interactions.

It is not surprising, then, that grazing has been so politically contentious in the western United States, where the transition to ranching stretched over seventy years, from the Civil War to the Depression. Overcapitalization, insecure land tenure, and unfamiliarity with such highly variable climate together triggered widespread degradation during that period. The discipline of range science, born largely at government behest to respond to the crisis, was constrained by political and economic exigencies to work within a fence-and-lease reform strategy. The ecological theories and management prescriptions that emerged over the first half of the 20th century were derived from research in temperate sites such as the Great Plains and proved poorly suited to drier and more variable settings such as the Great Basin and the Southwest. During the Cold War, these prescriptions were exported throughout the world in international "development" projects, and in the past quarter-century, the desultory results of such projects have helped to provoke strong critiques of the conventional, equilibrium model of rangeland ecology and management.

Great Barrier Reef

THE LARGEST CORAL reef system in the world, the Great Barrier Reef, is located in the Coral Sea off the east coast of Queensland in northeast Australia, and was selected as a World Heritage Site in 1981. As coral is a living organism, it has been said that the Great Barrier Reef is the single largest organism in the world, although others argue coral is merely a collection of millions of small organisms. As a result, there have been some suggestions that the Great Barrier Reef could more appropriately be named the Great Barrier Reef Systems.

The Great Barrier Reef is believed to have started growing on top of an older platform about 18,000 years ago, at which time the sea level was about 330 feet lower than it is today. A few of the islands along the reef have old upraised coral rock as much as 25 feet above the low water mark. The Reef extends from the mouth of the Fly River in Papua New Guinea, down to Lady Elliot Island in Queensland. In the northern region the reef forms a continuous line along the edge of the continental shelf, and by the time one reaches the southern region, the reefs are well distributed over the marginal shelf. It stretches a total of 1,616 miles, and has been divided by scientists into about 3,000 separate reefs and 900 islands. As a result of this, there is a certain degree of reef diversity within a complex geological framework.

HAZARDOUS—AND WONDEROUS

Since its first discovery, the Great Barrier Reef has long been a recognized hazard for shipping. The HMS *Endeavour* of Captain James Cook ran aground on the reef on June 11, 1770, sustaining much damage. In 1789, when Captain Bligh was put in a longboat after the mutiny on the HMS *Bounty*, he had to be careful to steer his craft so that it did not hit the reef—a feat that he managed, making it one of the most remarkable open boat voyages in history. Unfortunately, the avenging HMS *Pandora* commanded by Edward Edwards was not so lucky. It hit the reef on August 29, 1791, and went down with a large loss of life—including some of the mutineers. The wreck was discovered in November 1977, and has been the subject of extensive archaeological work.

The first detailed scientific study of the Great Barrier Reef was in 1843 when J. Bette Jukes, a naturalist on HMS *Fly* compiled a survey. Since then there have been further studies and surveys, with the Great Barrier Reef Committee formed in 1922 to sponsor and also conduct its own investigations into the nature and the origin of reef. In 1928–29, the Royal Society in London conducted a large number of biological and geographical surveys, and a marine biology station was established on Heron Island, subsequently run by the University of Queensland. Another research station was subsequently built on Lizard Island, and run by the Australian Museum. James Cook University, which conducted the work on the HMS *Pandora*, runs the third research station on Orpheus Island.

The Great Barrier Reef Marine Park Authority was established in 1976 under the auspices of the Great Barrier Reef Marine Park Act 1975, which allows for no drilling or mining activity within the areas declared to be parts of the National Park. The Great Barrier Reef is now managed by the Great Barrier Reef Marine Park Authority, in conjunction with the Government of Queensland. They have conducted extensive surveys and introduced zoning restrictions on all of the reef area.

The reef supports many different species, including 30 different species of whales, dolphins, and porpoises, including the Indo-Pacific Humpback Dolphin, the Humpback Whale, and the Dwarf Minke Whale. There are also a large population of dugongs and six different species of turtles: the Flatback, Green Sea, Hawksbill, Leatherback, Loggerhead Sea Turtle, and the Olive Ridley Turtle. There are also about 17 different species of sea snakes, 150 different species of echinoderms, 350 different species of corals, 1,500 different species of fish (including the Clownfish, Red Bass, and Red-Throat Emperor), and some 5,000 different species of mollusks, 10,000 different species of sponges, and 500 different species of marine algae and seaweed. The terrestrial flora is limited to about 30–40 species.

The Great Barrier Reef is a major tourist attraction in Australia, and income from tourists generates as much as $5 billion each year. Estimates of the number of tourists have been put at two million, although this certainly involves some "double-counting" of tourists visiting one or more sites. Voyages to the reef involve viewing from ships, glass-bottomed boats, helicopters, and airplanes. Many others enjoy scuba diving around the reef. When Indonesian President Abdul Rahman Wahid was asked about his biggest regret at losing his sight, he replied that it prevented him from seeing the Great Barrier Reef.

Although much of tourism is controlled, there are also worries about the sheer numbers of visitors; some irresponsible people have damaged the reef. The Queensland government response has not been to ban or limit visits to the reef, but to better police and regulate them.

Greece

KNOWN AS THE "cradle of democracy," Greece won its independence from the Ottoman Empire in 1829 and subsequently began adding neighboring islands and territories to its holdings. After a repressive military dictatorship ended in 1967, Greece began moving toward democracy and abolished the monarchy in 1974. Greece joined the European Community (EC) in 1981. Despite rich national resources that include lignite, petroleum, iron ore, bauxite, lead, zinc, nickel, magnesite, marble, salt, and the potential for developing hydropower, Greece is underdeveloped relative to other nations in the European Union.

Bordering the Aegean, Ionian, and Mediterranean Seas, Greece has 8,479 miles (13,676 kilometers) of coastline. As a result of the temperate climate, the country experiences mild, wet winters and hot, dry summers. Major environmental concerns include extensive air and water pollution, and human resources are sapped by the sex trafficking and forced labor. A 2006 study by Yale University ranked Greece 19th of 132 countries in overall environmental performance, and the United Nations Development Program (UNDP) Human Development Reports rank Greece 24th among nations of the world in overall quality-of-life issues.

Much of the land area of Greece is mountainous, and some ranges extend into the sea, forming peninsulas and island chains. Destructive earthquakes are common, and the combination of winter and autumn rains and mountainous terrain results in significant flooding and soil degradation as 100,000 tons of soil is redeposited on lower levels. The practice of mixed herding, in which sheep and goats are raised together, has further contributed to land degradation as protective vegetation is stripped. Additional damage occurs during the approximately 1,000 fires that take place in Greece each year, some intentionally set. By the end of the summer of 1990, for instance, 1,358 fires had occurred. Consequently, the government established its first forest protection program.

The population concentration in urban areas has led to major air pollution. Around Athens, for example, a smoggy cloud known as *nephos,* composed of sulfur, nitrogen oxide, hydrocarbons, and dust, poses a constant health threat and sends hundred of people to hospitals. In 1987, a heat wave combined with *nephos* to cause several hundred deaths. In 1991 and 1993, Greeks were advised to stay off the streets of Athens when ozone levels soared. The greatest sources of the pollution have traditionally been steel works, cement factories, chemical industries, and refineries in conjunction with automobiles and central heating plants. In 1991, the government began promoting the use of environmentally friendly cars and moved toward eliminating all gasoline containing butane.

Water pollution has also presented a major challenge in Greece, particularly around the Saronic Gulf where waters were filled with sludge created by improper disposal of toxic metals and oil products. Before treatment systems were built in 1981, sewage effluents were released untreated into the gulf. Although tourism is essential to the Greek economy, the waters of the *Athens Riviera* became so polluted at one point that tourists were discouraged from bathing in the sea.

Oil tankers that pass through the Mediterranean each day are responsible for discharging some 650,000 tons of residues into the waters, and Greece works with 16 other nations to monitor this situation. To cut down on water pollution, toxic substances used in marine paint and pesticides effluents have been banned. Particular attention has been paid to the loggerhead turtle and the monk seal, which are threatened with extinction. Greek wildlife is also threatened by hunters who kill migrating birds as well as wild animals. Of the 255 bird species endemic to Greece, seven species are now threatened, and 13 of the 96 mammal species are in danger of extinction. The government has protected only 3.6 percent of the land.

During the latter part of the 20th century, a new commitment to environmentalism resulted in the passage of National Law 1650/86 and the adaptation of EC environmental regulations and directions. The Hellenic Ministry for the Environment, Physical Planning, and Public Works was given the responsibility of overseeing programs and policies designed to protect and improve the environment while continuing to promote the industrial, tourism, and agricultural sectors. In addition, the government established a system of fines so that polluters are forced to pay for the problems they create; the government also set up precautionary measures and instituted technological interventions to prevent pollution before it occurs.

Greece has expressed its commitment to the global environment by participating in the following international agreements: Air Pollution, Air Pollution–Nitrogen Oxides, Air Pollution–Sulfur 94, Antarctic–Environmental Protocol, Antarctic–Marine Living Resources, Antarctic Treaty, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, Tropical Timber 94, and Wetlands. Agreements on Air Pollution–Persistent Organic Pollutants and Air Pollution–Volatile Organic Compounds have been signed but not ratified.

Thessaloniki Fire of 1917

Nearly a third of the Greco-Turkish city of Salonika (modern-day Thessaloniki) was destroyed in a massive fire in August 1917, leaving as many as 70,000 people homeless, and resulted in the total reconstruction of the city.

The city of Salonika traces its origins back to 316 B.C.E., being named after the sister of Alexander the Great. Close to Byzantium, its has long been one of the major ports in the Eastern Mediterranean. It was a part of the Ottoman Empire until 1912 and was a multicultural trading entrepot with the population including many Sephardic Jews, Greeks, Turks and Bulgarians. Although Greece was neutral in World War I, it allowed Allied soldiers to land in Thessaloniki. A provisional Greek government based in the city supported the allies.

A subsequent enquiry found that the fire on August 18, 1917, started when a spark from a kitchen fire fell on some straw in the house of refugees. The lack of concern by the neighbors let the fire take hold, and fanned by a strong wind, it started spreading to other houses. Soon the fire was raging all around the main government building, the Diikitirio, which was only saved by employees being able to douse it in water. However, many other parts of the city were not so lucky. Most firefighting teams were privately owned by insurance companies, and their equipment was either old or nonexistent.

Allied soldiers were urged to help, with the French creating a “fire break” around the Diikitirio, but leaving soon afterwards; and the British using two fire engines to great effect. Soon afterward, several French soldiers were caught looting jewelry and were executed.

With a third of the entire city destroyed, Allied soldiers helped build temporary houses for many. Large numbers of residents left the city permanently. Charities around the world raised money as some insurance companies tried to claim that the fire was caused by German arsonists making it an “Act of War” that would have excluded them from liability. They eventually paid all policies completely.

Green Chemistry

RELYING EXTENSIVELY ON nonrenewable petroleum feedstocks, conventional industrial chemistry disseminates a cocktail of synthetic chemicals throughout the global environment, presenting substantial risks to humans and other organisms. In contrast, the emerging field of green chemistry develops chemicals to be benign. Rather than presuming to keep human and ecological exposures to chemicals within levels of toxicity deemed "acceptable," practitioners of green or sustainable chemistry aim to make chemicals that are inherently safe.

Principles of green chemistry include: Design chemical products that have little or no toxicity and that break down to innocuous substances after use so that they do not accumulate in the environment; use renewable feedstocks, such as corn and soybeans; design syntheses so that the final product contains the maximum proportion of the starting materials, with few atoms wasted; minimize use of solvents, separation agents, or other auxiliary chemicals—when these chemicals are necessary, use innocuous chemicals such as water; and increase energy efficiency by manufacturing at ambient temperature and pressure.

Examples of green chemistry in commerce include substitution of supercritical carbon dioxide for perchloroethylene (perc) as a solvent in professional dry cleaning. Water has replaced petroleum distillates in paint. And manufacture of ibuprofen no longer creates cyanide and formaldehyde as hazardous wastes.

No one knows exactly how far chemists and chemical engineers can go in learning to do their work with far less environmental harm. However, historians and sociologists studying technology find that technical systems usually are far more malleable than would first appear; and many green chemists suggest that the main barriers to chemical greening are economic and political rather than scientific.

Some of these barriers lie within the traditional field of chemistry itself. The American Chemical Society now houses the Green Chemistry Institute, but premier chemistry conferences still devote little attention to environmental sustainability. While the American Institute of Chemical Engineers code requires members to "serve their communities…and alert authorities to business practices that endanger health and environment," environmental sustainability is not a central part of the organization's goals. Most university chemistry and chemical engineering departments do not offer courses on green chemical design/production or require students to study toxicology.

Pfizer now has a vice president for green chemistry, DuPont is making more than 10 percent of its products from corn and other renewable feedstocks, and the carpet industry is learning how to make its products biodegradable. Nevertheless, the inertia of "brown" chemistry is evident across industry—for example, in aggressively expanded production of vinyl siding, doors, and windows despite significant toxic releases over the material's life cycle (such as in fires).

Governments also are moving slowly. The Toxic Substances Control Act has failed to keep dangerous new chemicals off the market since enactment in 1976. The U.S. government has refused to sign the Stockholm Convention on Persistent Organic Pollutants and has assisted chemical industry efforts to undermine the European Union's new unified regulatory system for chemicals. Meanwhile, only 7 percent of U.S. federal spending on chemical research and development is devoted to green chemicals, and with the partial exception of Greenpeace, environmental groups have been slow to take up the cause.

Altogether, green chemistry has great potential and dovetails with other environmental thinking, including cradle-to-cradle design, the Natural Step, clean production, and life-cycle assessment. Activating that potential would require some combination of pressure from environmentalists, improved coverage in the media, taxes on toxic chemicals, subsidies for green chemical research and development, and changes in university curricula. In the meantime, "brown" chemistry continues to prevail.

Green Consumerism

THERE IS SOMETHING that all of the following have in common: driving a hybrid car; eating organic and/or local food; building with certified "sustainably produced" wood; joining the "back to the land" movement; boycotting Shell Oil, Esso, and Nestlé; using nonchemical housecleaning products; investing in "ethical" stock portfolios; recycling aluminum cans and glass bottles; sourcing electricity from wind or solar energy; purchasing energy-efficient washing machines, refrigerators, and lightbulbs; and swaddling a child in cloth reuseable diapers.

While disparate activities, at a general level, these are different forms and means of *green consumerism*. *Green consumerism* works from the recognition that the Earth's resources are limited, environmental damage is directly and indirectly related to the exploitation of these resources, and consumer power and choice can be utilized to produce positive environmental change. It is argued that the market signals of green consumer demand encourage the sustainable production of goods and services by businesses and governments. This is characterized as (mostly well-off) consumers "voting" for environmental responsibility with their money. Green consumption has become an increasingly powerful but loosely organized movement in the last decade; to paraphrase Julie Guthman, a researcher on California organic food, the production and consumption of organic salad mix has done more to reduce pesticide use than all the organizing around pesticide reform.

Green consumerism is a broad and bewildering term given the vast nature of its forms, means, and meanings. It is closely allied with the concepts of *sustainable consumption* and, these days, the growing movement for *ethical consumption*. These are both subsets of green consumption: sustainable consumption includes a concern for social justice, and ethical consumption incorporates moral responsibility and care. All three are often used interchangeably, leading to potential confusion in policy and popular discussions. Clearly, however, green consumerism has shifted academic and popular debates around the even broader concept of *sustainable development*; how to make consumption greener, more sustainable, and more ethical has moved to the forefront of the problems and policies for sustainable development.

Coming out of the environmental movements of the 1960s and 1970s and gaining serious traction in the 1990s, the demand for and production of green commodities has expanded rapidly. One of the earliest statements was the publication of the wildly popular *50 Simple Things You Can Do to Save the Earth* (1989) in the United States. Published simultaneously in the United Kingdom (UK) was *The Green Consumer Guide: From Shampoo to Champagne—High-Street Shopping for a Better Environment,* which begins, "Every day, whether we are shopping for simple necessities or for luxury items, for fish fingers or fur coats, we are making choices that affect the environmental quality of the world we live in." Newer writings include *The Newman's Own Guide to the Good Life: Simple Measures that Benefit You and the Place You Live* (United States) and *The Good Shopping Guide* (UK), with the publishing trend spreading to *The Ethical Consumer* magazine (UK) and to the Internet. In addition, almost all of the major environmental organizations like the Sierra Club, Conservation International, and Friends of the Earth now urge their members to shop more responsibly.

There are different philosophical underpinnings that inform the diversity of green consumerism. Essentially, it lies along a continuum of philosophical positions and associated activities, from the most *eco-centric* to the most *technocentric*. *Eco-centric* green consumers advocate more radical lifestyle changes and economic relationships; some might even go "back to the land" to live "off the grid," producing their own energy and food. More *technocentric* green consumers, those with greater faith in green technologies, might advocate moderate shopping-style changes, perhaps purchasing a hybrid car and shopping for organic food. Most green consumers are between these extremes, for example, growing food in their backyard, or—while owning a car—riding a bike when feasible.

IMPACT ON BUSINESS AND CONSUMERS

This mainstreaming of green consumption has greatly influenced business. Companies now talk about measuring success through the triple bottom line—economic viability, environmental soundness, and social responsibility—which is more formally understood as the concept of *corporate social responsibility* (CSR). The ethos of CSR, while at one level led by consumers' concern for companies to "do well by doing good," has also been led by companies working to increase efficiency and boost revenues.

Below the surface, how does green consumption work? The dissemination of information is fundamental to the processes of green consumerism. This involves providing consumers with knowledge about various commodities and companies to assess their claims of environmental sustainability and give "greener" choices. Additionally, activists and journalists provide "muckraking" exposés of the environmental and human exploitation by corporations and commodities. This provides consumers with a sense of what to avoid, but also puts pressure on companies to change their products or supply chains. Examples of food-based "muckraking" include Eric Schlosser's *Fast Food Nation* and Morgan Spurlock's film *Super Size Me*. Exposing Nike's

The use of eco-friendly, nonchemical housecleaning products is one expression of "green consumerism."

labor abuses in footwear manufacturing is one of the most famous activist-led exposés.

Information is also provided to consumers on market shelves. This is a process known as *eco-labeling*: A product, through the use of logos, images, and descriptive language, decries to consumers its environmental-friendliness and/or its ethical properties by giving information about its sustainability. Eco-labeling allows companies to differentiate themselves and draw in new green consumers. Further, eco-labeling often utilizes an audit-type regulatory systems. For example, all U.S. foods labeled as "organic" must be produced to a United States Department of Agriculture (USDA)-regulated set of standards and certified by a USDA-approved certification agency. The Forest Stewardship Council has created a certification system for sustainably sourced wood. Standards and logos make production processes transparent to foster a verifiable trust between the green product, company, and consumer.

"Doing" green consumption involves two main activities: the *boycott* and the *buycott*. Boycotting is the active avoidance of particular products or a particular company to protest their actions or environmental record. The latest incarnation of the boycott, which targets consumerism as a whole, is known as the international "Buy Nothing Day." The buycott involves purchasing from a particular company or a particular commodity to "vote" with one's dollar for that company or product. For example, Seafood Watch (www.seafoodwatch.org), in suggesting "choices for healthy oceans," unequivocally states that, "You have the power…your consumer choices make a difference." The group supplies a list of seafood to buy "to support those fisheries and fish farms that are healthier for ocean wildlife and the environment." Green consumption can involve both the buycott and boycott. Seafood Watch lists which seafoods to avoid—an explicit boycott—while eating organic foods involves a buycott but also the implicit boycott of industrially farmed foods.

Recycling, while strictly different from green consumption in that nothing is "consumed" per se (except in the case of buying recycled products), is one of the most accessible forms of green consumerism. At the consumer level it is quickly expanding beyond bottles and cans to include plastics, green and food wastes, and clothes and appliances.

PROBLEMS AND CRITIQUES

There are many trenchant critiques of green consumerism that legitimately call it into question. The most obvious criticism leveled against green consumerism is that it individualizes the problem and solution of environmental conservation and makes it a function solely of consumer choice. Thus, in dealing with environmental problems, many of which are caused by corporations and governments in the first instance, these are lain at the feet (and wallets and hearts) of conscious middle-class consumers rather than at those that should be held accountable.

Individualization and the intensive marketization of conservation and social justice through green consumerism can be further questioned in these ways: (1) green consumerism cannot explain to consumers the complexities of environmental problems such as global climate change or confront such a multi-causal phenomenon though a change in shopping behavior; (2) green products are often more expensive and less accessible for lower-income consumers instituting a class bias into these markets; (3) in a lost irony, more consumption (of the "right" products!) is posed as the solution to what is clearly a function of overconsumption; (4) many purchases are narrowly based on personal risk, such as avoiding pesticides by eating organic, rather than a wider environmental and social ethic; (5) green consumerism further adds to the aestheticizing of society, trivializing the seriousness and severity of ecological problems; (6) there is a fashionability to green consumption (i.e., saving the whales one day, saving the rain forest the next) that targets "hot" environmental problems and specific species, but ignores more mundane and important parts of the environment; (7) many suggest that shopping for the latest eco-product has become a substitute for more "real" forms of political opposition and social change for greater environmental sustainability; (8) others argue that green consumerism and production merely treat the symptoms of environmental and social exploitation and do not address the root systemic causes of exploitation in capitalism's relentless drive for economic growth and profit; (9) and finally, one of the most well-known critiques of green consumerism is that of *greenwashing*, where large companies hide behind the marketing of one or two eco-friendly products or services, while causing environmental harm in other ways and in other locations.

In these ways, green consumerism might actually prevent the accountability of those truly responsible for environmental destruction and distract from more committed and deeper socioeconomic progress in the production of goods, how we relate to ecologies, and how we relate to each other across social, economic, and geographical divides. And, while the controversy over the effectiveness and authenticity of green consumerism will continue, there is little doubt that, while a beginning of some sort, there is a long and winding way for green consumerism to go for it to put us on the path to environmental sustainability and social justice.

Green Movement

SOCIAL MOVEMENTS ARE described as agents of social change. Green movements are collectives of actors pursuing environmental issues from a variety of political, class-based, and ethical persuasions whose tactics vary from direct action to policy reform. Green movements can be characterized as those that adhere or promote to one or more dimensions of environmentalism, which is seen as an interest group community. Green movements seek to promote social change based on a commitment to sustainability and environmental preservation, but for motivations that range from diverse sets of environmental values from the conservative Wise Use movement to the more radical Earth First!

In social movement theory, green movements are characterized as part of the new social movements. Separate from class-based movements, the specific grievances of new social movements are driven by changing ideas that permeate culture and society. Green movements emergence coincided with the emergence of the women's liberation, anti-Vietnam War, and other leftist counterculture movements. Green movements are unified along the axes of environmental problems, though they constitute a diverse set of political perspectives and ethical orientations.

Early antecedents to green movements organized around concerns about hunting and conservation of natural resources. Soon, urban policy questions around sanitation, clean water, clean air, and public health became the driving concerns of green movements. Some attribute the success of green movements to the spread of values emerging out of the counterculture of the 1960s, particularly the critique of capitalist consumer society.

Others note the importance of the image a fragile earth, from the early space missions and connecting that image to arguments about a finite earth, presented in the report from MIT scientists called the *Limits to Growth*. Much support for green movements emerged with Louis Gibbs' attention to Love Canal, where children were exposed to toxics in the soil below the site of a school that was previously a toxic dump. Soon after, green movements emphasized local issues and extended into households where mothers took up concerns about children's exposure to toxins.

The philosophical orientations of green movements range from the conservation-oriented utilitarians that look to preserve resources for human use to those preservation-oriented perspectives that attribute intrinsic value to ecological systems, biodiversity, and species. Utilitarian perspectives are often characterized as anthropocentric because they ascribe rights only to humans, while the eco-centric and bio-centric perspectives extend the domain of ethical consideration to living species and assemblages of species. The eco-centric and bio-centric perspectives have their origins in the Romanticism of Thoreau and others writing about nature in the 19th century. These views come into conflict with questions about the human use of natural resource management and wilderness preservation. This often leads to contradictory goals across different green movements.

GREEN MOVEMENT GROUPS

Given the diversity of environmental problems, green movements are quite diverse in their foci, although the political power of these groups often varies with their political power of the opponents they encounter. Green movements shape environmental outcomes in various ways, some using the political system, some focusing on the promotion of green consumerism and stewardship, and ecological modernization, while others use more violent tactics like ecotage. There are over 10,000 green movement organizations in the United States, with 44 million members, and income of $2.7 billion and assets of $5.8 billion as of 1995.

Green movement organizations come from a variety of perspectives raising a diverse set of concerns ranging from those that focus on local, "not-in-my-backyard" issues; mainstream Washington-based lobby and policy-oriented NGOs like the Union Concerned Scientists and the World Watch Institute; political parties like the U.S. and German Green Parties; legal-action groups like Friends of the Earth, the Center for Foods Safety, and the Defenders of Wildlife; donor and member-driven groups like the Sierra Club, The Nature Conservancy, GreenPeace, the Wilderness Society, and World Wildlife Fund; and radical "direct-action" groups ranging from Greenpeace to Earth First!

The Earth Liberation Front (ELF) is probably the most controversial group that could be characterized as a green movement, as the Unabomber's lone actions probably do not qualify as a movement. ELF is a radical environmental group that seeks to use destructive tactics to achieve their aims. Listed as a terrorist organization by the Federal Bureau of Investigation, the decentralized group has claimed responsibility for a handful of actions, including arsons committed in new suburban housing developments in Long Island and the widely-publicized destruction of new Hummers at a dealership in Southern California. Those acts of *ecotage* are inspired by the Edward Abbey classic the *Monkey Wrench Gang*, where a group of friends who gained inspiration from the wild, clandestinely sabotaged equipment used to extract natural resources. Sociologist Rik Scarce spent six months in jail for refusing to disclose the details of conversations protected under confidentiality agreements with ELF, demonstrating some of the challenges of studying green movements listed as potential terrorist organizations.

Radical environmentalists are often depicted as being adherents to deep ecology, an environmental ethical or worldview that advocates a duty to preserve nature. Deep ecology was coined by Arne Naess, a Norwegian philosopher and mountaineer who has gone on to write extensively on the moral philosophy of environmentalism. Deep ecologists have been criticized for holding onto pristine myths about nature and for pressing for American-style national parks and wilderness areas in developing third-world countries.

In some cases, disparate groups like Earth First! and the Sierra Club have worked on issues that saw their tactics complement the other. In one case of salvage timber operations in the Warner Mountains in Oregon, a group of Earth First! activists locked down fire road that led to the site of the salvage operations. While the logging operation was being delayed, a lawsuit brought by the Sierra Club was able to sue the Forest Service and temporarily reverse their policy on salvage logging.

POLITICAL AND ETHICAL CLOUT

Green movement popularity has also lent itself to the mainstream programs of political parties. Political parties from all persuasions now seek to claim the environment for themselves. Political parties like the German Green, *Die Grunen,* have gained a populist popularity. The German Greens have leveled a searing critique of industrial society and colonialism and have brought questions about the environment, public health, and military spending into the central planks of their platform. Ralph Nader's appearance as a Green Party candidate in the U.S. Presidential Elections of 2000 is often cited as the reason Gore lost to Bush. Former Vice President Al Gore characterized himself as a green movement leader because of the widespread popularity of environmentalism.

The sustainable agriculture movement is also considered a green movement. It overlaps with the appropriate technology movement that became an advocate of a new economy based on a reflection on the social consequences of technological change. The back-to-the-land movement was based on the influence of books such as Schumaker's *Small Is Beautiful*, Wendell Berry's *Unsettling of America,* Rachel Carson's *Silent Spring*, an attack on DDT serialized in *The New Yorker* in the early 1960s, and Murray Bookchin's *Our Synthetic Environment*, and demonstrated the overlap between environmental and agricultural concerns. Part of the sustainable agriculture movement is linked to the anti-genetic engineering movement that delivers a blistering critique of technological change in agriculture, drawing on the environmental implications of the Green Revolution and top-down third-world agricultural development.

The question about what to eat is perhaps one of the most controversial topics among green movement activists. Animal rights activists and sustainable food system activists often have clashing opinions, but many overlapping agreements. While they differ on the question of local animals in food systems, for example, they are in agreement regarding the cruel punishment and wastefulness in the industrial production of animals.

These groups look at the problems of the global economy and focus inward at remaking communities based on the ideals of small, more local production-consumption linkages in farming systems, for example. Through popular distributions of the Whole Earth Catalogue, environmentalism became more rooted in the consumption counterculture. It fashioned an entire alternative economy by instilling a commitment to collective agriculture, particularly organics. Today the promotion of green consumption is directed at shortening commodity chains through more direct purchasing, such as farmers' markets, to establish connections between producers and consumers of locally grown food as opposed to industrial and fast food.

Green movements have played a significant role discursively as well as materially in transforming the state to a green one. The heyday of the green movement is often depicted as the time period that saw the passing of the Water Pollution Control Act,

Ethical Consumption

Some parts of the green movement promote ethical consumption as a tactic for promoting sustainability and environmentalism. Perhaps the most widely recognizable form of ethical consumerism is vegetarianism, which seeks to motivate consumers on the ethical consequences of eating meat. This remaking of market relationships based on an ethical orientation toward environmentalism is referred to as *Green Consumerism.* Epitomizing green consumerism and the role of green movements is the international coffee situation, where a transition to full-sun coffee has led to declines in migratory birds that overwinter in the tropics where coffee has been traditionally grown in shade coffee systems. Green movement actors promote the consumption of bird-friendly coffee because shade plantations have demonstrated higher levels of biodiversity in birds, trees, and many other species. The promotion of labeling has become a widely used tactic in green movements from organic agriculture to fisheries conservation to timber certifications.

The danger of green consumerism is that reinscribing a commodity fetish based on the environmental characteristics of commodities may perhaps dilute the ideas that it intended to promote, or undermine sustainability in other dimensions. For example, organic agriculture is promoted for environmental benefits, but those benefits are limited to certain dimensions of environmental issues like pesticide use and take no consideration of scale-related issues, never mind the sticky problem of labor in agriculture.

the Clean Air Act, the National Environmental Policy Act, and the Endangered Species Act during the Nixon Administration of the early 1970s. However, the codification of environmental problems through the state served to take the green movement's momentum away from the left and take up environmentalism as a cause for the right. Nixon sought a consensus approach to environmental problems and his creation of a policy apparatus for environmental problems served to take away the political momentum of the left. While the EPA looked to regulate the harms of production practices, the failure to include the Department of Agriculture, Department of Energy, and Department of Transportation into the planning and regulatory sphere, leaving their interventions more at the whims of the market forces and political cronyism. The critique, entitled the Death of Environmentalism, blamed the failure of the environmental movement on a narrowly defined policy wonkism that fails to maintain political coalitions and win-win scenarios that promote jobs and environmental concern.

INSTITUTIONALIZED GREENING

Some have questioned whether or not the institutionalization of mainstream green movement organizations qualifies them as a social movement, which to some is a contradiction: you cannot have a movement that is institutionalized. The institutionalization of green movements has led to an increase in passive members who simply write checks in the name of some environmental organization, many of which have to maintain large overheads to stay afloat. Another concern is that environmental organizations move away from protest tactics and critiques of multinational corporations to a more collaborative approach. Yet it is unclear whether the deradicalization of green movements makes them more or less effective in dealing with environmental problems. There is also a concern that the institutionalization of the green movement has led to the scientization of environmental problems. This has led to a narrow focus on the science of environmental problem that often neglects their social origins.

Green movement concerns merge with those of development in the developing Third World. Successful green movements in developing countries include the Chipko Andolan Movement, who protected trees in Northern India through acts of civil disobedience against transnational logging companies. Often, these campaigns rest their success on bringing concerns about livelihoods together with concerns about the environment. Chico Mendez led a group of rubber tappers in Brazil on a crusade to link their practices to the preservation of biodiversity in the Amazon.

Some have even characterized the social unrest in Chiapas as coming out of political persuasions that include green movements. But not all developing country environmental campaigns have been successful. The Three Gorges Dam project in China is one glaring example of mass relocation and devastating environmental impact that green movements have found difficulty in challenging.

More recently, environmental justice groups have refocused attention to environmental concerns in urban areas and cities. An executive order by President Clinton in the 1990s required U.S. Federal agencies to evaluate the consequences of agency actions on the distribution of environmental burdens. Many urban green movements draw attention to the problem of environmental racism where communities are disproportionately exposed to negative environmental consequences. Green movements in urban centers around the world have been successful in promoting the idea of community gardens in some cities. With the rapid rise of urban populations around the world the promotion of sustainable cities has been cited as a high priority by many green movement actors.

Green Production and Industry

GREEN PRODUCTION INCREASES the efficiency of standard industrial practices while eliminating or minimizing wastes at their source, rather than after they have been generated. In industrial processes, green production includes conserving raw materials and energy, eliminating toxic raw materials, reducing the quantity and toxicity of emissions and wastes, and minimizing waste and emissions of the aggregate production.

Major changes in current industrial production and consumption systems are required to meet the needs of a growing world population while using environmental resources in a sustainable manner. To achieve a more rational and integrated use of resources, a reorientation of science and technology toward the objectives of sustainable development is necessary and achievable by incorporating green design into all facets of industry.

Green design is a growing industry trend begun in the fields of architecture, construction, and interior design and now moving to all aspects of industry and production. Green design is also referred to as "sustainable design," "eco-design," or "design for the environment." The broad principles are fairly simple: choose energy efficiency wherever possible, work in harmony with surrounding resources, and use materials grown using sustainable methods or recycled rather than new materials from nonrenewable resources.

To determine true sustainability, all production technologies and products should undergo a comprehensive life-cycle analysis (LCA), a means of quantifying energy and raw material use and the waste generated at each stage of a product's life. Ideally, an LCA includes quantification of material and energy needed for raw material extraction; manufacturing of all components; use requirements; generation (if any, as in the case of solar photovoltaic cells); end-of-use (disposal or recycling); and distribution/transportation between each stage. Based on LCA, methods are applied to reduce materials and energy required during a product's life cycle. LCA optimization not only means lower materials and energy requirements for a product but also encourages extending the useful life of a product.

Green design begins in the initial research and design phase. Unfortunately, the assessment of trade offs between the environmental attributes associated with competing processes or products is extremely challenging due to technical, societal, and cultural perspectives associated with environmental quality. In the green design process, designers may look at the source, makeup, and toxicity of raw materials; the energy and resources required to manufacture the product, and how the product can be recycled or reused. Balanced with other considerations such as quality, price, ease of production, and functionality, eco-designed products are environmentally and economically viable alternatives to traditional products.

ENVIRONMENT AND ECONOMY

The green industry movement has challenged the notion that environmental and economic goals are mutually exclusive. Green design and clean production have historically been encouraged and become financially viable where government regulation has been first introduced. Increased efficiency in green production, however, sometimes gives a company an advantage in the market. Green-designed reduction of energy and materials is generally economically feasible, as it often represents cost savings in engineering. Also, many green industrial patterns are beginning to include the "triple bottom line" in their business planning, which captures a spectrum of values including environmental and social concerns in addition to simple economics. The problem of externalities, however, which make waste affordable by shedding environmental costs, can still discourage transition to green production.

Green industry and green production are growing at explosive rates. The Greening of Industry Network

(GIN) has formed to coordinate this growth. The GIN is an international network of professionals focusing on issues of industrial development, environment, and society that is dedicated to building a sustainable future. In every country, some factories already operate at world-class environmental standards, and many profitable enterprises comply with national pollution regulations. The pinnacle of green industry will be reached when all products are designed without depleting natural resources using the current solar income and all waste is converted to food for another industrial system (e.g., industrial ecology) or for the natural systems.

To date, attempts to manage technology have been complex, involving statutes, tort law, technology standards, consumer behavior, and insurance. Most scientific efforts to manage technology have concentrated on banning or setting limits on pollutants. In the United States, the number of federal statutes concerning the environment grew exponentially from the 1960s, leading to a proliferation of regulations, not always appropriate and not always enforced. Generally these laws focus on pollution and health hazards and few efforts address resource depletion or environmental issues in a global context.

These trends may also be changing. A growing number of regulations now support green design. For example, several European countries require manufacturers to take products back from consumers at the end of the product's life, creating an incentive for manufacturers to design products for easy recycling or reuse or those that can be disassembled. Initiatives in the United States include the Extended Product Responsibility concept, which spreads environmental responsibility from designer to manufacturer to distributor to retailer. Future legislation will push for products that have built-in end-of-life options, requiring designers and manufacturers to take responsibility for their products.

A mature green industrial system would purify air, water, and soil rather than pollute them; retain valuable materials for perpetual, productive reuse rather than destroy or waste them; require no regulation; celebrate an abundance of cultural and biological diversity; enhance nature's capacity to thrive; grow health, wealth, and useful resources; and generate value and opportunity for all. Such a green industrial system, modeled on the natural world's abundance can solve rather than just manage the problems industry currently creates, allowing both business and nature to thrive.

Green Revolution

THE GREEN REVOLUTION refers to a major transformation in agricultural practices in the developing world based on a specific technological and institutional package, including high-yielding variety seeds (HYV's), fertilizers, and irrigation. The package parallels industrial agricultural practices that developed in the United States after World War II. Western institutions began promoting the package aggressively in the mid-1960's as an answer to the developing world's accelerating population growth and mounting hunger problem. They also viewed the Green Revolution package as a means to foster capitalist economic development and to solidify their ties to developing countries in the context of the cold war. Although the package continues to spread today, the most transformative period was around 1966–1972.

Initially, the Green Revolution focused on just two crops: wheat and rice. The most important trait that was bred into an HYV was dwarfism. Dwarfs that are well fertilized and irrigated focus their energy on the growth of their seeds and produce strong stems to support the additional grain. The HYV's are only high yielding, however, if they receive the correct amount of fertilizers, irrigation, and weeding. The technology must be supported by four critical institutional resources: an irrigation infrastructure; a financial system to help farmers purchase the seeds, fertilizers, equipment, water, and labor inputs in advance; a transportation and marketing infrastructure to connect farmers with input sellers and grain buyers; and an educational system to teach farmers the management techniques.

In its early stages, the Green Revolution impacted only those parts of the developing world that cultivated wheat or rice, and that could marshal the four critical institutional resources. South and Southeast Asia experienced a significant impact, whereas only small parts of Latin America and the Middle East and very little of Africa adopted this early package. Later, HYV's were developed for additional crops and environmental conditions, increasing its geographic range. Impediments remain significant, however, in regions that have difficulty developing the institutional infrastructure, particularly in Africa.

In adopting countries, assessments of its impact are controversial. Those supportive of the Revolution emphasize how agricultural output has increased rapidly enough to keep up with population growth and keep food prices low, particularly for the urban poor. As well, many farmers increased their income, spurring rural economic development. The high-yielding technology also averted some deforestation, as less agriculture had to expand into forested land than might otherwise have occurred.

Those critical of the Revolution argue that it worsened socioeconomic differences within adopting countries, bringing prosperity to a few and hunger to many. Large farmers proved better able to access institutional resources and were more profitable than small farmers, forcing many small farmers to sell out. Those small farmers, who had previously produced much of their own food, were now dependent on wage labor, which proved to be unreliable and insufficient for many, spurring rural to urban migration. Many of those who managed to keep their land found themselves deep in debt as periodic crop failures left farmers unable to repay the cost of their inputs at the time of harvest. As well, the Green Revolution monocrops increased the need for pesticides, causing environmental contamination and health risks to farmers and consumers.

Greenhouse Effect

THE GREENHOUSE EFFECT is a natural phenomenon of the earth atmosphere. Gases, in particular carbon dioxide, methane, and ozone, are present in the atmosphere in small quantities. They have the capacity to retain energy in a manner analogous to a greenhouse. However, the comparison is not exact because greenhouses and the atmosphere use different trapping mechanisms.

Greenhouses are made of clear translucent material such as glass or plastic that allows sunlight to enter. The ambient temperature outside of the greenhouse can be many degrees colder, but the temperature inside of the greenhouse will be much warmer. This happens because the sun's rays warm the atmosphere of the closed greenhouse, causing its indoor temperature to rise. Because the glass panes of the greenhouse act as insulating material, heat is not easily transferred from inside of the greenhouse to the colder air outside. In the earth's atmosphere, greenhouse gases create a similar warming effect, but it is not exactly the same as the warming that occurs in a greenhouse.

Earth, Venus, and Mars also have atmospheres, and a greenhouse effect as well. In the case of Mars, the effect is insufficient to warm the planet. For Venus, it is too much of a good thing. Because Venus is rich in carbon dioxide, it retains heat, producing an inhabitable surface temperature of around 850 degrees F. In the case of Earth, its atmospheric greenhouse effect has been just right, with an average global temperature of 59 degrees F, until recently.

A NATURAL PROCESS

The greenhouse effect is a complicated natural process that occurs in the earth's atmosphere, which has four major layers. The Troposphere is the thick layer extending from the surface of the earth to about 7 miles (11.3 kilometers). It holds the air life on earth breathes and most of the clouds. The Stratosphere extends from the top of the troposphere to about 30 miles (48 kilometers) above the surface of the earth. It has some high flying clouds, but its upper portion is the location of the ozone layer. The Mesosphere is the third layer of the earth's atmosphere. It extends to about 50 miles (80 kilometers). The final layer is the Thermosphere. The atmosphere is extremely thin, and extends to about 600 miles (965 kilometers) above the surface of the earth. Beyond is empty space.

Solar energy striking the earth is composed of more than just visible light. In the electromagnetic spectrum, the radiation leaving the surface of the sun is composed of short-wave X-rays and gamma rays. Gamma rays are deadly to humans for even a short period of time. However, these forms of radiation are absorbed in the Thermosphere by the time they have penetrated the atmosphere to a depth of about 100 miles (160 kilometers) above the earth's surface.

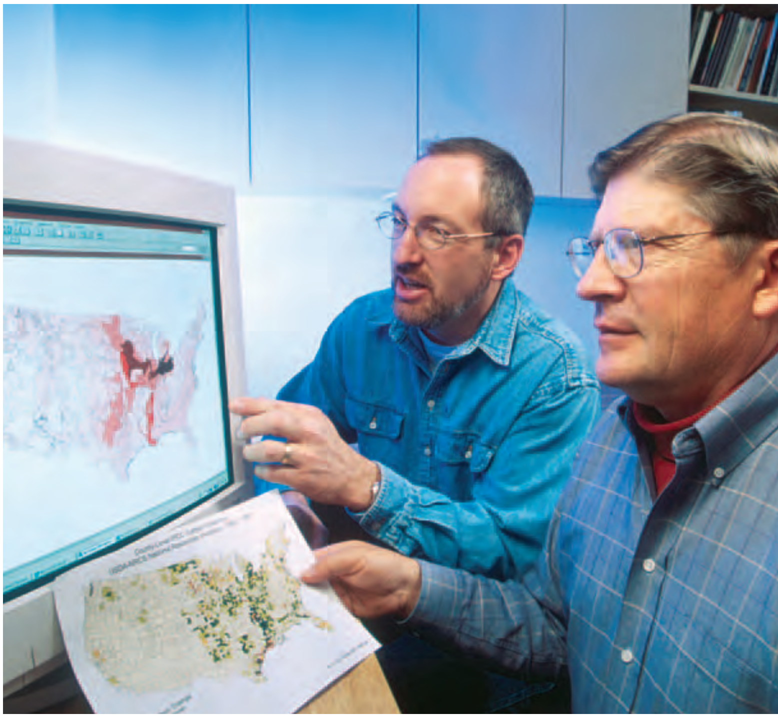
Ultraviolet (UV) waves are next to X-rays and gamma rays in wavelength. These wavelengths extend across the electromagnetic spectrum to violet light in the visible spectrum. UV waves are dangerous to living things. They cause sunburn and can kill plankton in the oceans. They are absorbed in the top of the Mesosphere by ozone. Without the ozone layer there would be an increase in damage to eyes and skin cancers.

The visible light spectrum as seen by human eyes ranges from purple to red in a spectrum of increasing wavelengths. Just beyond the visible red spectrum is infrared radiation. About 60 percent of the sun radiation is infrared, invisible to humans and to most animals. The tongues of snakes have infrared sensors to detect the heat of animals in the dark. Camera film has been designed to detect infrared radiation. It is this form of radiation that heats the earth.

Visible light and infrared radiation penetrate the earth's atmosphere as if they were light shining through a glass pane. Much of the radiation is absorbed by plants or by cultivated areas of the earth's surface or by the oceans. However, some of the radiation is blocked by clouds, and some it returns to space from bright surfaces on the earth like deserts or ice-snow fields.

As radiation warms the earth's surface, some infrared radiation is radiated back into space, but not all. The earth's radiation is heat energy in the form

Scientists look for ways and areas to sequester carbon dioxide, a greenhouse gas, with high-biomass crops.



of long-wave infrared radiation. The heat radiation waves have wavelengths ranging from 4–100 micrometers. The earth's heat radiation is much longer in wavelength than that striking the earth's surface directly as sunshine. The electromagnetic energy from the sun penetrates the atmosphere as if through an open window. However, the longer wavelengths of the earth's radiation act differently. The result is that the atmosphere is transparent to the sun's radiation, but not to the long-wave infrared radiation coming from the earth's surface. The earth's radiation is absorbed in the Troposphere by greenhouse gases. The gases, in effect, act like a blanket warming the earth.

GREENHOUSE EFFECT PROCESS

The greenhouse effect is caused naturally by the small quantities of carbon dioxide (CO_2), carbon monoxide (CO), ozone (O_3), nitrous oxide (N_2O); Chlorofluorocarbons (CFCs); water vapor (H_2O), and particulates of various kinds. In addition, in the atmosphere are some trace gases such as argon that also have a role in the greenhouse effect. Neither oxygen nor nitrogen hold the energy of the sun very well; however, these other gases do hold in the energy of the sun. These two gases constitute nearly 99 percent of Earth's atmosphere. The greenhouse gases compose less than one percent.

Carbon dioxide, water vapor, and trace gases all absorb some to the heat energy of the earth. Carbon dioxide absorbs infrared waves that are 13–100 micrometers. Water vapor absorbs infrared waves that are between 4–7 micrometers. Infrared waves that are between 7–13 micrometers, on the other hand—the "infrared window"—are not usually absorbed. Instead, they pass easily through the atmosphere and into space.

The infrared energy absorbed by the greenhouse gases is given off as radiation that returns to earth. In effect, these gases "trap" heat energy coming from the earth and return it to the earth. Without the atmospheric greenhouse effect, the earth would be a block of ice. Eventually, some of the radiation is radiated out into outer space. Historically, the natural system of the greenhouse effect has been in equilibrium. Without the effect, the surface of the earth might look like the moon, which at about the same distance from the sun as the earth, receives roughly the same amount of radiation. The temperature on the surface of the moon is 212 degrees F (100 C) in the sunshine, but –238 degrees F (–150 C) in the dark, on average.

EARLY OBSERVATIONS

The greenhouse effect was first observed by French scientist Jean-Bapiste-Joseph Fourier. He described the earth atmosphere in 1827 as being like a glass vessel that retained heat. In the 1850s James Tyndall, a British physicist, analyzed the earth's atmosphere in order to identify the greenhouse gas. He was surprise to discover that neither oxygen nor nitrogen hold the sun's energy. Most of the earth's atmosphere is composed of nitrogen and oxygen. This meant that 99 percent of the earth atmosphere was not involved in the greenhouse effect.

In 1938 George Callendar, a British coal engineer, published a study of global weather readings including temperatures. He concluded that the earth's atmosphere was gradually getting warmer. He attributed the atmospheric warming to the burning of fossil fuels since the Industrial Revolution. Distracted by World War II and by a downspike in global temperatures from the 1940s until the 1970s, scientists ignored the issue of global warming, or better put, "global climate change." Those who did consider the subject thought that the oceans would absorb the additional carbon dioxide because the oceans act as a carbon sink as great quantities of vegetation and animals sink to its depths.

During the Geophysical Year (1957–58) measurement of carbon dioxide were made Charles David Keeling of California, who developed a device for measuring in parts per million the amount of carbon dioxide in the atmosphere. He took reading from the top of the Hawaiian volcano far from an industry. His readings have been accumulated into the Keeling Curve, which since then have shown that the amount of carbon dioxide has increased significantly since the Industrial Revolution and that the amount in the earth's atmosphere is rapidly rising.

Carbon dioxide is part of the carbon cycle that is used by plants in photosynthesis. From tests done on ice core samples taken from Antarctica and Greenland that go back to 160,000 years ago it has been determined that carbon dioxide was present in the atmosphere at an average of 270 parts per million (ppm) until the advent of the Industrial Revolution. However, since then, carbon dioxide in the atmosphere has risen to around 380 ppm. The same increase is also happening with methane and other greenhouse gases. Their increases are predicted to cause global warming, which is better described as *global climate change*.

Scientists studying the greenhouse gases have noted that the infrared window is being "dirtied" by the increase in greenhouse gases. Some of these gases are much more absorbent of infrared radiation than is carbon dioxide—in the case of methane, 30 times as absorbent. Added to the increase in gases is global deforestation, and the increased use of nitrous oxide as a fertilizer.

Climate models are forecasting major global climate changes if the increases in greenhouse gases are not stopped. Some of the increases will be from human industrial or agricultural sources. Others such as the melting of the permafrost in the Arctic region will release huge quantities of carbon dioxide and methane from bacterial action on thawed plants.

Greenhouse Gases

THE EARTH SURFACE absorbs energy from the sun and radiates it back into the atmosphere. So-called *greenhouse gases* are gases that, when present in the atmosphere, form a layer of insulation that traps the earth's outgoing heat. This causes the earth's overall temperature to become warm, a phenomenon originally known as the *greenhouse effect,* now more frequently called *global warming* or *global climate change*. The latter is a broader term that includes other atmospheric changes besides the greenhouse effect. Principal greenhouse gases include carbon dioxide (CO_2), methane (CH_4), ozone (O_3), chlorofluorocarbons (CFCs), Nitrous oxides (N_2O) and sulfur hexaflouride (SF_6). While greenhouse gases are entering the atmosphere from both natural and human origins (the latter known as anthropogenic), the increase in human origins of such gases is most significant, and is thus driving the overall change in climate.

Atmospheric concentration of greenhouse gases has increased over the last century due to industrial and agricultural activity. The most significant greenhouse gas by volume is carbon dioxide. This is released into the atmosphere through the burning of fossil fuels (oil, natural gas, and coal) in vehicle exhaust, coal fired power plants, and industry. Similarly, methane concentrations have increased as a result of the production and transportation of fossil fuels, rice paddy farming, livestock production, and emissions from municipal solid waste landfills. Nitrous oxide is released from agricultural and industrial activities, and the combustion of both fossil fuels and solid waste.

Each greenhouse gas has a different per-molecule capacity for heat absorption. Methane traps over 21 times more heat per molecule than carbon dioxide, and nitrous oxide absorbs 270 times more heat per molecule than carbon dioxide. CFCs are also more powerful than carbon dioxide, however, emissions of CFCs have decreased significantly since the Montreal Protocol. There is significant public confusion between greenhouse gases that contribute to global climate change and gases that contribute to ozone depletion. This confusion is magnified by the fact that chlorofluorocarbons (CFCs) contribute to both ozone depletion and climate change.

REGULATION OF GREENHOUSE GASES

International coordination to reduce global climate change has been highly politically charged. This is in part because nations from around the world have very different levels of carbon dioxide emissions and will face different degrees of impact from the changing climate. In addition to national governments, oil companies and environmental organizations are involved in negotiations. Issues of contention have included extent of overall emissions by each nation, process for emissions reduction and the degree to which nations meet targets by using "carbon-removal" methods such as planting forests versus reducing actual emissions. International collaborative efforts on climate change began as far back as 1979 with the the first World Climate Conference in Geneva.

In 1992, the United Nations Framework Convention on Climate Change was adopted at the World Conference on Environment and Development in Rio de Janeiro. Signatory nations agreed to reduce and inventory emissions and to mitigate for climate change. Developed countries and countries with economies in transition were required to reduce their greenhouse gas emissions to their 1990 levels by the end of 2000. This commitment was voluntary, however, rather than binding. The convention was ratified by the United States and went into effect in 1994.

Voluntary commitments were not leading to emissions reductions, thus after years of highly charged international negotiations, the Kyoto Protocol went into effect in 2005. Under the Kyoto Protocol, industrialized nations are committed to legally binding reductions in greenhouse emissions between 2008–12. Included are provisions for emissions trading among nations and so called "clean development mechanisms," which encourage industrialized nations to transfer technology that would reduce emissions to developing countries. Conflict over many issues, especially the responsibility of China and India for greenhouse emission reduction, was significant. Furthermore, the Kyoto Protocol went into effect without the ratification of the world's largest emitter of greenhouse gases, the United States. In 2001 George W. Bush rejected the Kyoto Protocol on the basis that it was too costly for the U.S. economy, proposing instead a highly criticized plan that focuses on voluntary reductions in emissions, tax credits for emissions reductions, and increased research and development for new energy technologies. In contrast to the 7 percent reduction that would have been required under the Kyoto Protocol, this plan allows for a 12 percent increase in greenhouse gas emissions by 2012 and has provided no mechanism for ensuring that this target will be met.

Greenpeace

GREENPEACE IS AN international environmental organization that pioneered environmental direct-action tactics and has gone on to become one of the largest and most important global forces in the name of environmental protection. Greenpeace, which takes its name from its dual concerns of antimilitarism and environmentalism, was founded in Vancouver, British Columbia, in 1971. It was one of several new environmental organizations to grow out of the New Left activism of the 1960s, and it adopted a decidedly more confrontational approach to environmental protection relative to the conservation organizations that preceded it.

Its first action was characteristic of the tactics and style that would come to define the organization. A number of activists, along with invited journalists, sailed an old fishing vessel toward the Aleutian Island of Amchitka north of Alaska with the intent to draw attention to the underground nuclear testing that was being conducted by the United States in that area. Although the contingent was intercepted by U.S. forces and never reached the testing zone, the incident received a great deal of publicity and the activists successfully brought the issue of nuclear testing to the world's attention. International pressure spawned by Greenpeace actions eventually brought an end to nuclear testing in the Aleutians.

Using the Quaker notion of "bearing witness," Greenpeace activists would continue to use nonviolent civil disobedience to draw attention to practices that threatened the environment. Although some were critical of the masculinist organizational culture associated with the focus on daring stunts, the group's actions continued to attract media attention and win public support. For its first decade these actions focused primarily on nuclear issues and the protection of ocean mammals. Greenpeace activists campaigned against seal hunts and the whaling industry, sometimes placing themselves between whaling vessels and their prey.

HIGH-PROFILE TACTICS

Inspired by their high-profile tactics, new Greenpeace chapters were formed throughout the 1970s. But these remained largely autonomous and loosely joined during this period. Although there were internal conflicts about focusing on action versus formalizing the organization, in 1979 the six existing chapters were brought together more formally as Greenpeace International.

During the 1980s, Greenpeace expanded its agenda beyond oceans and nuclear testing to include issues such as energy and toxic waste. It was also during this period that Greenpeace was targeted by the French Secret Service. In 1985, French agents planted a bomb and sunk the Greenpeace vessel, the *Rainbow Warrior,* while it was docked in New Zealand. One crew member was killed. The incident received international attention and support for the organization grew significantly.

Greenpeace has played a central role in advancing a number of environmental causes. Its campaigns against nuclear testing and the ocean dumping of nuclear waste led to international treaties that banned many such practices. The group was also instrumental in achieving a ban on commercial whaling. In addition, Greenpeace played an important role in the protection of Antarctica. In 1983 it was among the first major environmental organizations to call for the protection of the undeveloped continent. In part as a result of their work on this issue, the 1991 Madrid Protocol to the Antarctic Treaty banned resource extraction from the region. Greenpeace also successfully campaigned to ban the production of chlorofluorocarbons (CFCs), gasses that deplete the ozone layer of the earth's atmosphere. Current campaigns include climate change, forests protection, fair trade, toxics use reduction, and the elimination of genetically modified organisms.

Greenpeace continues to work on nuclear issues. They have dramatized the security threats at nuclear plants, utilizing classic civil disobedience tactics that they pioneered in the 1970s. In 2002, Greenpeace activists easily gained access to and occupied the Sizewell nuclear facility in Britain vividly demonstrating before the media and the world that nuclear facilities are not secure.

Today, Greenpeace International is headquartered in Amsterdam, and has offices in over 40 nations. Organizationally, it incorporates elements of different types of environmental movement groups, which usually specialize in either professional lobbying and litigation or grassroots tactics. Greenpeace continues to be run by professional staff with little grassroots participation beyond letter writing. Direct action media events are carried out by a handful of trained activists. But professional staff members also carry out lobbying and litigation as well as international diplomacy. Although the organization is hierarchically structured, chapters retain a good deal of autonomy and are therefore able to respond quickly to local developments.

The organization is funded through foundation grants and individual contributions. Although no formal membership exists, contributors number over 2.8 million and many more participate in Greenpeace letter writing and Internet lobbying campaigns. Greenpeace continues to be a significant voice in international environmental politics.

Gross National Product (and GDP)

GROSS NATIONAL PRODUCT (GNP) is one of the most comprehensive measures of the overall amount of economic production taking place in a national economy. The first set of national accounts, prepared under Simon Kuznets, Nobel Prize Laureate in Economics, was presented to the United States in 1937. Kuznets helped the U.S. Department of Commerce to standardize the measurement of GNP.

Since World War II, GNP has been regarded as the most important indicator of the status of an economy. GNP is the sum of the different kinds of earnings permanent residents receive in a given country, plus any income earned by residents from investments abroad such as profits, interests, and royalties. While Gross Domestic Product (GDP) measures economic activity within a country's borders, the GNP measures the total income of a country's population. It adds rents, interest, and profits and dividends flowing into the country to GDP, while deducting rents, interests, and profits and dividends paid out to foreigners. At present, GDP is preferred to GNP because policy makers are usually interested in the level of economic activity within a country's borders. In most cases, GDP and GNP are approximately equivalent, although for some countries with a large foreign presence, such as Ireland, GNP is the preferred measure.

GNP in economics is a quantitative measure to assess a country's total economic activity. The GNP equals the GDP plus income earned by domestic residents through foreign investments, minus the income earned by foreign investors in the domestic market. GNP at current market prices is equal to gross national product at factor cost plus taxes on expenditure less subsidies. It represents the total expenditure on the output of goods and services of the national economy valued at the prices at which the expenditures are incurred. The expenditure is made up of personal expenditure on consumers' goods and services, net expenditure by central and local government on current goods and services, gross domestic physical capital formation (comprising fixed capital and stocks), and net expenditure by the rest of the world on goods and services originating in a given country, plus net factor income from the rest of the world. Economic and political life revolves around the GNP.

LIMITATIONS OF GNP

The GNP system has three main limitations. First, if there is no transaction, it doesn't affect the overall economy (GNP excludes nonmarket activities). All nonmarket activities are based on production and consumption that occur outside the market economy. Volunteer work and child care are two contributors to the economy that are not included in the GNP. Second, if there is no money involved, GNP is not concerned. Nonfinancial transactions receive no credit within the GNP system because the GNP is a measure of the movement of money through a national economy. For example, grandparents are the second largest group of child care providers, but their contribution receives no recognition within the GNP calculation, because they do not receive payment for their effort. Third, there are no value judgments on the market transactions. The GNP is simply a measure of financial transactions; it makes no value judgment on whether the transactions were socially useful. Crime and car accidents increase the GNP because of increased work for police, ambulances, and prisons. A reduction in crime reduces the GNP. The GNP contains no information about justice or social capital. Other limitations are that greater access to knowledge, better nutrition and health services, security against crime and physical violence, political and cultural freedoms, and so on are not fully captivated in the GNP.

As a specific measure of economic performance relative to the environment, the GNP is an especially poor indicator. Growth in GNP cannot in any way measure the concomitant impact that increased economic activity may have on the environment. Ironically, disasters such as bushfires, earthquakes, volcanoes, floods, and snowstorms boost the GNP, by driving expenditures for recovery and management. The GNP measures environmental damage only if people pay to clean it up. High levels of waste (or "throughput") in the economy, where consumers dispose of still-useful goods (washing machines, cars, etc.) to purchase new models also boosts the GNP, while actually representing poor ecological efficiencies. In many societies, the GNP is increasing while the condition of the environment is deteriorating.

While the GNP concept has many limitations, at the time of its creation, it was a major breakthrough in the development of system of national accounting. It has since enabled economic comparisons to be made between countries, and allowed governments and individuals to think more globally in an efficient way. Efforts to develop more robust "green" indicators for national income accounting are ongoing, however. By folding in measures of efficiency, deforestation, human development, or carbon production, alternative economic indicators in the future may better capture the trade offs between economic growth and environmental protection. Until then, GNP must be used with caution as an indicator of progress.

Groundwater

GROUNDWATER IS UNDERGROUND water found in the pore spaces and cracks of soil, sand, and rock. The source of all groundwater is precipitation, either through direct percolation into the earth's surface, or through replenishment from local surface water including lakes, ponds, wetlands or rivers. Sometimes groundwater also flows into surface water through a process called baseflow. The process of groundwater replenishment is termed *recharge*.

Groundwater is stored in and moves at varying speeds through aquifers. An aquifer is a water-bearing geologic formation that can store and yield usable amounts of water, and consist of permeable layers of soil, sand, gravel or fractured rock such as granite or limestone. They are classified according to type, areal extent, thickness, yield, and direction of groundwater movement. There are two types of aquifers: consolidated rock and unconsolidated rock. Consolidated rock aquifers are composed of limestone, sandstone or other rock. Some, such as granite, are almost impervious and yield very little water, while others, such as limestone, are very porous and can yield vast amounts of water. Unconsolidated rock aquifers are composed of granular materials such as sand and gravel and typically yield larger amounts of water.

Aquifers are also confined or unconfined. Unconfined aquifers are typically located near the land surface, are composed of permeable materials such as sand or gravel, and recharge quickly, making them susceptible to contamination. The area of the aquifer that is filled with water is termed the *saturation (*or *saturated) zone*; the top of the saturation zone in an unconfined aquifer is termed the *water table* or *phreatic surface*, where water pressure equals atmospheric pressure. The area between the saturation zone and the land surface is the *vadose zone*.

Confined or artesian aquifers are typically located at greater depths and below impermeable layers such as rock or clay. They are typified by little or no recharge. For this reason, they often contain what is termed fossil or geologic water, and are thus susceptible to mining. Groundwater mining occurs either when groundwater extraction exceeds recharge (as in unconfined aquifers) or when groundwater will not be recharged naturally as in most confined aquifers. Artificial recharge is also possible either through the direct injection of water into the subsurface as in California or through directed rainwater recharge as is increasingly common in northern India.

Contrary to popular myth, groundwater does not flow in rivers or channels beneath the earth's surface. The one exception is with Karst topography. Karst (an area of Slovenia) topography is where the solution of limestone, dolomite, gypsum, or marble, creates very erodable areas on the land surface or underground. It is possible for water to flow through the underground caverns created through this process. Karst is found in the U.S. states of Florida, Texas, and Kentucky, and in China, Slovenia, and Turkey.

Groundwater flows through aquifers toward lower elevations through the force of gravity. In confined aquifers, however, groundwater can flow up gradients, causing artesian conditions, where groundwater flows to the surface due to pressure created through the confined character of the aquifer. This occurs along the foothills of the Rocky Mountains in the United States, but is also common in other areas.

The source of all groundwater is either precipitation or through replenishment from local surface water.

The largest aquifer in the United States is the Ogallala Aquifer (also called the High Plains Aquifer). It is an unconfined aquifer located in the states of South Dakota, Wyoming, Nebraska, Kansas, Colorado, Oklahoma, Texas, and New Mexico. The thickness of this aquifer ranges from 1 (0.3 meters) to 1300 feet (396 meters) and covers an area of 175,000 square miles (453,250 square kilometers). The Ogallala is used mostly for irrigation, especially in the Southern High Plains, but also supplies water to many cities. It irrigates 20 percent of total irrigated area in the United States, or 11,000 square miles (28,490 square kilometers), with a yearly discharge of 12 billion cubic meters of water. It has been heavily mined in Texas, with smaller declines occurring in other states. The future viability of the Ogallala is threatened due to overdraft.

In many parts of the world, including parts of the United States, Europe, Australia, Southwest Asia (i.e., the Middle East), Mexico, China, and India, groundwater is overexploited, with extraction surpassing recharge. This is of serious concern as groundwater is highly relied upon throughout the world. For example, it provides 51 percent of all drinking water in the United States, and in India supplies 70 percent of irrigation water and 80 percent of its domestic water. The largest user of groundwater in the world is irrigation. The advantages of groundwater over surface water for drinking and irrigation purposes are many: it is reliable in dry seasons and during droughts; it is cheaper to develop, since when unpolluted it requires less treatment than surface water and can be tapped by individuals, decentralizing costs to individuals; and it can be tapped when and where needed, such as at the household level, reducing expansion (of capacity) and conveyance costs.

There are several concerns, however, with this massive reliance on groundwater. The first is overexploitation. Second, groundwater is very susceptible to contamination. Contamination is both human-induced (anthropogenic) and due to naturally occurring minerals. Anthropogenic causes of groundwater contamination include gasoline, oil, road salts, storage tanks, septic systems, hazardous waste sites, landfills, and industrial chemicals. One gallon of gasoline (3.8 liters) can contaminate one million gallons (3.8 million liters) of groundwater, making it unsuitable for drinking purposes. Furthermore, it is estimated that over 10 million underground storage tanks and over 20,000 abandoned hazardous waste sites exist in the United States. Naturally occurring sources of contamination include arsenic and fluoride. Arsenic contamination is a major source of groundwater contamination in the Ganges Plain of Bangladesh and northern India. As groundwater is withdrawn, naturally occurring mineral concentrations can increase, making groundwater unfit for human consumption or for irrigation. Third, saltwater intrusion may occur in coastal areas as groundwater withdrawal alters normal groundwater flow, inducing seawater to flow into nonsaline aquifers. Fourth, excessive groundwater withdrawal can cause the land surface to subside as it has in Mexico City, and in New Orleans, Louisiana, and Las Vegas, Nevada. Fifth, in many areas excessive groundwater withdrawal is substantially reducing baseflow to wetland and riparian areas, adversely impacting riverine and riparian species of flora and fauna. This has sparked fierce debate in the Platte River and the Ogallala Aquifer system in Nebraska, and also in the Edward's Aquifer and San Antonio River system in Texas. And finally, these issues all lead to the matter of groundwater governance.

Grounded in Ancient History

Groundwater use and exploitation has an ancient social history. Egyptians, Chinese, and Persians constructed wells as early as 2000 B.C.E. During this period, the Chinese dug wells as deep as 3,000 feet deep with drill bits constructed of bamboo. Qanats, which are human-built systems that tap underground mountain water sources and then transport this water underground often several kilometers, date back 2,500 years. They probably originated in Iran but then spread to Afghanistan, Africa, Europe (Spain), China, and South America. In India, within the Hindu caste system, entire castes called the Beldar are historically devoted to digging wells. Similarly, various forms of water dowsers (or diviners) abound in multiple societies. Also in India, informal institutions have evolved for the sharing and management of groundwater and wells.

GOVERNANCE OF GROUNDWATER

The greatest challenge for the 21st century facing groundwater is one of governance. When the first laws were created for water use, surface and groundwater were thought to be distinct. Historically, therefore, laws governing the use of surface and groundwater have treated these two separately, even though they are connected. This, in part, has led to a confusing set of legal institutions governing groundwater. Further complicating water law is the lack of legal standing for nonhuman uses, such as in-stream flow needs of fish and other flora and fauna.

Multiple formal and informal institutional arrangements have evolved for the management of groundwater. In the United States, groundwater regulation is the domain of individual states. Regulatory and rights structures vary by state, with much of groundwater management resting with local institutions as in Nebraska and Texas. There are four categories of groundwater rights in the United States. States east of the 100th meridian follow the Doctrine of Riparian Rights, while those west of the 100th follow the Colorado Doctrine (strict Prior Appropriation) as practiced in New Mexico; the California Doctrine (Correlative Rights Principle—a combination of riparian rights and prior appropriation) as practiced in California and Nebraska; or Absolute Ownership, as practiced in Texas.

The Colorado Doctrine of strict prior appropriation allows a landowner to use water based on historical precedent: "first in time, first in right." The amount of water provided with a water right is based on the amount of water historically diverted and put to beneficial use: "use it or lose it."

The California Doctrine applies the concept of "reasonable and beneficial use." The appropriative right/use must be deemed economically beneficial; otherwise, a riparian user has the right to co-opt its use. For example, a rancher using water to irrigate alfalfa could lose their right to water if an industry could produce more capital with it. This differs from strict prior appropriation in that it distinguishes by use, where as strict prior appropriation does not.

Groundwater rights in Texas are based on absolute ownership and the "right of capture." Under absolute ownership, the "landowner owns everything on his or her property from the land surface, up to the heavens, and down to the center of the Earth." In theory, there are no limitations on pumping for the current or future based on current or past use, and it is legal to sell groundwater. In Texas, local institutions have formed for the management of groundwater. The High Plains Water Conservation District Number 1 (HPUWCD) is one such local organization. Comparisons of the New Mexico state centered model with the Texas self-organized model of groundwater management indicate that state-managed groundwater usage is not superior to self-organized local management of the HPUWCD.

The most recent iteration of the debate surrounding the governance of groundwater boils down to essentially whether it is a public or a private good. Historically, water has been thought of as a public good, held in the public trust, for the use of all people for consumption, sanitation, aesthetic values, and environmental protection. Viewed as a private good, water can be developed, used, traded, and sold for economic productivity and financial gain. It is this latter view that is gaining currency around the world.

Under this second view, proponents follow the logic of Garret Harding that groundwater is an open access resource and is subject to the "Tragedy of the Commons." They argue that private property rights over groundwater should be established yielding transferable or tradable rights that under the laws of supply and demand will inevitably move water toward the highest value uses, while preventing the problem of open access. But to think of groundwater or any resource as open access is to ignore that they are actually common pool resources and are subject to localized rules of use and institutions, which govern their use, distribution, and protection. Furthermore, it is problematic because uses such as irrigation will always have lower value added than industrial production, shifting water away from important primary commodity production. This would have drastic effects in developing countries such as India, where peasant producers rely on small plots of land and groundwater irrigation, the rights to which would probably be transferred to a higher economic use. Similarly, in a market-based system there is little incentive to protect stream flows or others' property through reduced groundwater pumping. Groundwater is both a private and public resource. The solution is not, therefore, in either extreme but somewhere in the middle, taking into account local context and the local historical development of groundwater management expertise and institutions.

Guam

THE ISLAND OF Guam, located in the Western Pacific Ocean, forms the southern tip of the Mariana Archipelago. Guam is an unincorporated U.S. territory. While just larger than 200 square miles (518 square kilometers), it is the biggest and most economically developed island in Micronesia. With a year-round population around 160,000 and more than a million tourists annually, Guam is also the most populous island in the region.

Ferdinand Magellan landed on Guam in 1521 and Spain claimed the island in 1565. The native

Chamorro population, known for seafaring, hunting, and weaving, frequently rebelled against Spanish rule. There was considerable bloodshed as the Spaniards assumed power, followed by loss of life from diseases such as smallpox and influenza. Nevertheless, Chamorro culture remains strong. In the 2000 census, more than one-third of the total population of Guam claimed Chamorro ethnicity. Chamorro joins English as an official language on the island.

Spain ceded the island to the United States in 1899. Japan briefly invaded Guam in 1941, but by 1944 the United States regained control. July 21 is celebrated as Liberation Day, but as much as 80 percent of the structures on the island were destroyed in combat. Japan's wartime crimes were largely left uncompensated. A World War II Loyalty Recognition Act was introduced into the U.S. House of Representatives in 2005, but passage remains uncertain.

The island population voted in 1982 to become a U.S. Commonwealth, like the Northern Mariana Islands, but its status has not changed. Guam remains militarily and politically important for the U.S. position in the Pacific. Residents do not pay taxes to the United States, but around $1 billion is transferred to Guam from the U.S. government annually. Guam's currency is the U.S. dollar. Most food and industrial goods are imported. The island's economy is largely dependent on Japanese tourism and U.S. military bases. Guam's motto is "where America's day begins," due to the Chamorro Standard Time Zone.

The creation of Apra Harbor after World War II required significant ecological change. It is the only deep lagoon in the Marianas. The breakwater was built on top of reefs, and banks were formed to enclose the channel. The inner harbor requires frequent dredging. Artificial shorelines were also created. Guam's transportation infrastructure, such as the harbor, continues to be important to the United States, which plans to expand the island's military facilities.

Environmental policies on Guam have historically not been well monitored. A broad spectrum of environmental contaminates have been identified on former U.S. defense sites and active instillations. A currently unresolved issue is compensation for exposure to nuclear testing. Guam is downwind from the Marshall Islands, a testing site. The island's harbor was also used for the decontamination of boats used in the atomic tests. The U.S. Environmental Protection Agency (EPA) has recovery plans for some threatened species, such as a local fruit bat and the Mariana crow. The island is often used as an example of bioinvasion. The brown tree snake was introduced on military ships and decimated native fauna. The snake is an apt climber and a generalist predator. Scientists believe that some island prey did not instinctually flee because they evolved largely without predators.

Guatemala

WITH AN AREA of 42,085 miles (109,000 square kilometers), Guatemala is largest country in Central America. It is bordered by Mexico, Belize, Honduras, and El Salvador, as well as the Pacific Ocean and the Caribbean Sea. The climate and topography range from the hot and humid tropical lowlands of the northern Petén region and the narrow southern coast to the cooler mountainous regions of the west. With the largest tropical rain forest in Central America, Guatemala also has a diversity of flora and fauna increasingly being threatened by deforestation and pollution.

Guatemala lies in the heart of classic Mayan civilization, which flourished from about 800 B.C.E. to 900 C.E., with the rise and eventual collapse of great cities like Tikal. Following the Spanish conquest in 1524, the colonial government ceded vast tracts of land for agricultural production with forced indigenous labor. After Guatemala gained independence in 1821, a series of governments expanded to new cash crops like coffee and bananas, creating wealth for a rising elite class. Nevertheless, the coercive agricultural export model heightened economic inequality and repression was utilized to quell growing social unrest. An increasingly volatile political climate after 1954 led to 36 years of civil war, which ended with the signing of a peace accord in 1996.

Today, 40 percent of Guatemala's 12 million people live in urban areas, including the capital, Guatemala City. The official census shows that 60 percent of the population is of mestizo (mixed) descent with the other 40 percent comprising indigenous, largely Mayan groups. Other estimates assert the indigenous population is much larger. Fifty percent of the active adult population is involved in agricultural production including sugarcane, corn, bananas, coffee, and livestock.

Dropping prices for coffee, the country's largest export crop, have led to intensification of production and efforts to grow for organic and fair trade markets. Corn, in particular, has strong economic, social, and cultural importance for subsistence use. Guatemala City is the industrial center, manufacturing textiles, furniture, and chemicals. Petroleum and mining are also important although the biggest industry has quickly become tourism.

Redemocratization has signaled a number of changes. It opened avenues for social mobilization around a broad set of socioeconomic and environmental issues, and political stability led to renewed efforts in the promotion of economic growth through major infrastructure projects like Plan Puebla Panama. Although created under the guise of sustainable development, individual projects have stirred controversy. These include a series of hydroelectric dams proposed for the Usumacinta River, on the northwestern border of Guatemala with Mexico, which could displace 50,000 people as well as flood Mayan archaeological sites and the most biologically diverse areas of the country. The euphoria of the peace accords a decade earlier has subsided with the realization of the difficult tasks ahead. Rain forests in the Petén are being destroyed at some of the highest rates in the world for ranching and petroleum exploration. The Central American Free Trade Agreement (CAFTA) was signed in March 2005, amidst intense street protest over a host of environmental and socioeconomic concerns, among these the future of subsistence agricultural production. Social mobilization continues to mount despite violence against political activism reaching an alarming rate.

Guha, Ramachandra (1958–)

RAMACHANDRA GUHA IS a social historian of environmental change. Trained as a sociologist, he has also been called an anthropologist, ecologist, journalist, and historian. Born in Dehradun, India, in 1958, Guha studied at St. Stephen's College, Delhi, and took his doctorate at the Indian Institute of Management, Calcutta. Between 1985–95 he held academic positions in India, Europe, and North America. Since 1995 he has been a full-time writer based in Bangalore, India.

Ramachandra Guha's first book, *The Unquiet Woods: Ecological Change and Peasant Resistance in the Himalaya* (1989), is a social history of the Himalayan forests, from the 19th century to the Chipko movement in the 1970s and 80s. This seminal study explores the intersection of ecology, social structure, and peasant politics. Guha shows how the Chipko movement, in which Himalayan villagers protected their traditional forests from industrial loggers by hugging the trees, is part of a century of protests by villagers. For Guha, this contemporary environmental crisis in the Himalayas is not a new phenomenon, but a new expression of old peasant resistance against the ruling elite.

In *Varieties of Environmentalism: Essays North and South* (1997), Guha and Juan Martinez-Alier examine environmental philosophies around the world. The authors maintain that it is a mistake to see environmental movements only through the lens of the United States, where environmentalism is a middle-class concern for nature protection and is seen as a consequence of affluence rather than poverty. By looking at the "environmentalism of the poor," they show that environmental struggles in southern countries are about control over the land, forest, and water resources needed for subsistence livelihoods.

This book challenges the long-held twin beliefs that the United States is the home of the pioneers of environmental thought—such as Henry Thoreau, John Muir, and Aldo Leopold—and that the protectionist paradigm of wilderness conservation is the only valid global model. In sum, this book presents a very different view of environmental concerns and priorities in the Southern Hemisphere.

One of Guha's most influential essays, *Radical American Environmentalism and Wilderness Preservation* (1989) has been reprinted in more than a dozen anthologies on society and the environment. Here he decries what he calls the "imperialist manifesto" associated with northern conservation agendas as they are forced on southern countries. Guha feels this preoccupation with wilderness preservation compounds the neglect by the American environmental movement of more pressing environmental problems in the third world.

Guha's work contributes to two critical issues in environmental studies: how do we theorize the intersection of society and nature? And how can marginalized voices (ironically often the voices of the people most dependent on nature for survival) be brought into mainstream thinking on environmentalism? He worries that creative voices in the developing world are being pushed out of the current dialogue. By amplifying these marginalized voices, Guha challenges the assumption that the northern ideology of environmentalism is the best way to achieve sustainable resource use at a global scale.

Guha cautions contemporary environmentalists against extremist positions that demonize industry, government, and markets. Instead, to balance conservation with development, they need to work toward the ideals of economic efficiency, social equity, and ecological stability. Guha's idea of balancing ecology with social justice is best summed up in a poem by Cheradanaraju, used as the epigraph to *Ecology and Equity*, which Guha coauthored with Madhav Gadgil:

I will not stop cutting down trees
Though there is life in them
I will not stop plucking out leaves,
Though they will make nature beautiful
I will not stop hacking off branches,
Though they are the arms of a tree
Because—
I need a hut.

Guinea

SINCE WINNING INDEPENDENCE from France in 1958, the Republic of Guinea has been ruled by only two presidents. The first of these, Sekou Toure, served until his death in 1984. General Lansana Conte succeeded to the presidency after Toure's death led to a military coup. He was returned to office in 1993 in Guinea's first democratic election. Guinea's population of 9,690,000 has expanded partially in response to the influx of 141,000 refugees from the politically tumultuous Ivory Coast, Liberia, and Sierra Leone. In response to situations in these countries, a panic over food shortages led to riots in local markets in Guinea. Despite natural resources that include half of the world's bauxite reserves, iron ore, diamonds, gold, uranium, hydropower, fish, and salt, Guinea is essentially an underdeveloped nation.

Less than 35 percent of Guineans live in urban areas. Eighty percent of the population is engaged in the agricultural sector, mostly at the subsistence level. The mining industry is essential to the Guinean economy, providing 70 percent of export revenues. In 2003, most World Bank and International Monetary Funds were suspended. With a per capita income of $2,200, Guinea is ranked 175 of 232 nations in world incomes. Forty percent of Guineans live in poverty, and over a fourth of the population is undernourished. Income disparity results in the most affluent 10 percent of the population holding almost a third of the nation's wealth. The United Nations Development Program (UNDP) Human Development Reports rank Guinea 156 of 232 countries on overall quality of life issues.

Major social indicators reveal the vulnerability of the Guinean population. Life expectancy is low at 49.5 years. Infant mortality, on the other hand, is high at 90 deaths per 1,000 live births. The population is at risk from an HIV/AIDS prevalence rate of 3.2 percent that has killed 9,000 people since 2003. Only six percent of rural resident and 13 percent of all residents have access to improved sanitation. A little over half the population has sustained access to safe drinking water, but less than 40 percent of rural residents do so. Guineans experience a very high risk of contracting food and waterborne diseases that include bacterial and protozoal diarrhea, hepatitis A, and typhoid fever. Other threats come from schistosomiasis, a water contact disease, meningococcal meningitis, a respiratory disease, and Lassa fever—a disease caused by contact with infected aerosolized dust or soil. In some locations, high risks for contracting malaria and yellow fever also exist. With a fertility rate of 5.9 children per woman and a literacy rate of only 21.9 percent, life is particularly difficult for females.

Bordering on the North Atlantic Ocean, Guinea has a coastline of 320 kilometers. The sources of the Niger River and its tributary the Milo are located within the Guinean highlands. Guinea shares land borders with the Ivory Coast, Guinea–Bissau, Liberia, Mali, Senegal, and Sierra Leone. The terrain of Guinea is mostly flat coastal plain with a hilly to mountainous interior. Elevations range from sea level to 1,752 meters at Mont Nimba. The climate is hot and humid, with a monsoonal-type rainy season from June to November that is accompanied by southwesterly winds. From December to May, the dry season ushers in hot, dry, northeasterly harmattan winds that reduce visibility.

ENVIRONMENTAL DEGREDATIONS

Over several centuries, Guineans engaged in slash-and-burn agriculture that led to an annual deforestation rate of 1.14 by the mid-1990s. During the 1980s, approximately 89,000 acres were lost to such tactics, turning forests into woodland, grass, and bush and endangering plant and wild life. Irresponsible mining practices also led to major environmental damage, including pollution, soil erosion, and desertification. Guinea has a significant shortage of potable water and pollution caused by agricultural runoff and improper waste disposal further threatens water resources and leads to major health problems. Overfishing has threatened the food supply and damaged vulnerable marine ecosystems.

In 2006, scientists ranked Guinea 113 of 132 countries on environmental performance, in line with the relevant geographic group but below the relevant income group. The overall score was reduced because of the poor grade on environmental health. Over 28 percent of the land area of Guinea is forested, and the government brought over 100,000 hectares of forests under national protection in the early years of the 21st century, including the nature reserve on Mont Nimba. Of 190 endemic mammal species, 12 are endangered, as are 10 of 109 endemic bird species.

The National Directorate of the Environment is responsible for implementing and enforcing the environmental laws and regulations of Guinea. With an overall plan of achieving environmental sustainability, targeted goals include reducing poverty, improving health and education, increasing protected areas, and enhancing access to safe drinking water and improved sanitation. The National Directorate of Water and Forests is also involved in providing environmental assessment and in promoting sustainable forest management.

Through the government-sponsored Declaration of Policy on Land Tenure Security in Rural Areas and the activities of Non-Government Organizations and international groups, villagers have been trained in ways to practice sustainable development. Guinea participates in the following international agreements on the environment: Biodiversity, Climate Change, Climate Change–Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, Wetlands, and Whaling.

Guinea–Bissau

THE REPUBLIC OF Guinea–Bissau has experienced several decades of political unrest since obtaining independence from Portugal in 1974. From 1980–99, the brutal regime of Joao Bernardo "Nino" Vieira was marked by repeated attempted coups and massive political unrest. Removed from office in 1999, Vieira returned to power in 2005 through the electoral process. With a per capita income of only $800 and hampered by a devastated infrastructure, Guinea–Bissau is the 13th poorest country in the world. Over half the population lives in abject poverty. There is massive income disparity, with the poorest 10 percent of the population sharing only 0.5 percent of the wealth. At the other end of the spectrum, 42.4 percent of resources are held by the richest 10 percent. The United Nations Development Programme's Human Development Reports rank Guinea–Bissau 172 of 232 countries on overall quality of life issues.

Around 82 percent of the work force in engaged in subsistence agriculture. Rice is the major crop and is the staple of most Guinean diets. Guinea–Bissau is the sixth largest producer of cashews in the world. While 34 percent of the population lives in urban areas, industrial activities are limited to processing agricultural products and manufacturing beer and soft drinks. The largely unexploited natural resources include petroleum, fish, timber, phosphates, bauxite, clay, granite, and limestone. Survival is largely dependent on budgetary support from the World Bank and the International Monetary Fund, which provided over 80 percent of the 2004 budget.

Bordering the North Atlantic Ocean, Guinea–Bissau has a 350 kilometer coastline and 8,120 square kilometers of inland water resources. Guinea–Bissau shares land borders with only two countries, Guinea and Senegal. Except for the savanna in the eastern section of the country, the terrain is covered by a low coastal plain that turns to swamps in the west. Elevations range from sea level to 300 meters at an unnamed location near the northern border with Guinea. The tropical climate of Guinea–Bissau is hot and humid with a monsoonal-type rainy season from June to December that is marked by southwesterly winds. The dry season from December to May produces the harmattan, a dry and dusty northeasterly wind that reduces visibility and creates major environmental damage.

DISEASE AND DEGREDATION

Environmental health is a major issue in Guinea–Bissau among the population of 1,442,000, partly because of the 10 percent adult prevalence rate of HIV/AIDS, which threatens Guineans who are already beset by poverty and disease. By 2001, some 1,200 Guineas had died from HIV/AIDS, and another 17,000 were living with the disease. The people of Guinea–Bissau have a very high risk of contracting food and waterborne diseases that include bacterial and protozoal diarrhea, hepatitis A, and typhoid fever as well as the respiratory disease meningococcal meningitis and the water contact disease schistosomiasis. In some areas, there is also a high risk of contracting vectorborne diseases such as malaria and yellow fever.

High disease rates in Guinea–Bissau have resulted in low life expectancy (46.87 years) and growth rates (2.07 percent) and high infant mortality (105.21 deaths per 1,000 live births) and death rates (16.53 deaths per 1,000 population). Guinean women birth an average of 7.1 children each. Trying to teach the population basic facts about environmental precautions that could prevent many diseases is made more difficult by low literacy rates of 27.4 percent for females and 58.1 for males and a combined school enrollment of only 37 percent.

Destroying some 40,000 hectares of land each year, brush fires are a common threat in Guinea–Bissau and are a major cause of soil degradation and deforestation. Overgrazing has further damaged land area, just as overfishing threatens the food supply and marine life. Guinea–Bissau has one of the richest coastal ecosystems in West Africa, and it has not reached the level of degradation common among more industrialized neighbors. The World Bank has partnered with the government to institute the Coastal Biodiversity Management Program designed to promote sustainable management while promoting coastal biodiversity. The success of the project is tied to the participation of local communities.

In 2006, scientists at Yale University ranked Guinea–Bissau 120 of 132 countries on environmental performance, in line with the comparable income group but below the comparable geographic group. The lowest score was predictably in the category of environmental health, but Guinea–Bissau was also ranked below average in the field of biodiversity and habitat. Almost 78 percent of the land area is forested, but deforestation is occurring at a rate of 0.9 percent annually. Of 108 endemic mammal species, three are endangered. Bird species fare better as none of the 235 endemic species are threatened. Responsible management of the national park network that includes the Joao Vieira and Poilao National Park, the Orange National Park, the Cascheu Mangrove National Park, the Cufada Lagoon National Park, and the Cantanhez game reserve are essential to protecting the biodiversity of Guinea–Bissau.

ENVIRONMENTAL PROTECTIONS

In 1979, the government created the Ministry of Natural Resources with the responsibility for enforcing all environmental laws and regulations. It was not until 1993, however, that Guinea–Bissau developed a comprehensive National Environment Action Plan and established the advisory National Commission on Environment. The following year, the government created the position of Secretary of State for Tourism, Environment, and Traditional Arts, which was upgraded to the Ministry of Tourism, Environment, and Traditional Arts the following year and given greater environmental policy responsibilities. Under the Basic Law on the Environment, a number of laws and programs have been initiated to ensure that Guinea–Bissau remains committed to sustainable development and conservation of resources. The government also signed the following international agreements on the environment: Biodiversity, Climate Change, Desertification, Endangered Species, Law of the Sea, and Wetlands.

Gulf Stream

THE GULF STREAM is the ocean current that is active throughout the Atlantic Ocean and has kept northwestern Europe warmer than other lands of comparable latitude and has encouraged the development of civilization there. Changing global climatic conditions threaten the stable continuation of the Gulf Stream with far-reaching implications for human settlement. The water of the oceans continually circulates in response to tidal and geological processes. One major system, which gives rise to the Gulf Stream, is produced by the westward movement of water caused by the trade winds that drive water at up to four miles per hour through Florida in the United States and then northwards past the Bahamas.

This flow of water forms a kind of barrier or border between bodies of water of different temperatures or origins. It isolates the Sargasso Sea, for example, from colder regions that surround it and can cause water temperatures to vary by up to 100 degrees C over a comparatively small area. The water travels north toward the Gulf of Hatteras, and then east past Greenland, and ultimately to the continent of Europe. The force of the water has been much diminished by this time, and part of the way across the Atlantic it divides into two parts: one of which flows toward northwest Europe, and the other toward the Iberian Peninsula where it constitutes the Canary Current.

The Gulf Stream is one important example of the phenomenon of water movements throughout the world known as the Ocean Conveyor. The Gulf Stream causes waters of different temperatures to mix together and this results in turbulence in the water that increases the amount of salt and minerals present. Consequently, the amount of fish in the area is increased and this has made areas serviced by the Gulf Stream among the most commercially valuable fishing grounds in the world.

in the North Atlantic, the Gulf Stream's northern edge transitions from warm (deep blue) to cooler water.

Research has shown that during a previous ice age, more cold water was forced into the Gulf Stream as it passed between Greenland and Scotland and this caused a rapid decrease in temperatures, perhaps as much as five degrees C over just a few decades.

As global warming melts the Greenland ice sheet, a similar impact is expected. Increased fresh water (from melted ice) and precipitation associated with global warming will reduce the density of the water and this will force the Gulf Stream to lower levels at which its heat will further dissipate. It is possible that the Gulf Stream will then be interrupted or come to an end altogether. This would reduce the temperatures in northwestern Europe and provide more severe winters, which is likely to produce an increase in demand or energy for heating. However, current predictions suggest that the cooling effect will be more than compensated for by increases in atmospheric temperatures globally. Previous examples of abrupt climate change have resulted in the vulnerability of food crops and fresh water, and the destruction of civilizations.

Guyana

INITIALLY SETTLED BY the Netherlands, Guyana was turned over to the British in 1815. After slavery was abolished, indentured servants were brought from India to supply labor for the large sugar plantations of the colonial period. As a result of this complex labor history, one-half of the 765,200 population of Guyana is East Indian, while another 36 percent are of African descent. These ethnic differences have often fed political dissension. Boundary disputes with Venezuela and Suriname have also led to political tensions and to a lack of regional cooperation. In 1992, Guyana held its first free election since independence was granted in 1966.

The Guyanese economy suffers from the lack of skilled labor and the low level of infrastructure. The length of borders and low levels of policing mean that illicit narcotic transshipment is suspected. Much new industrial activity has been centered on logging the valuable hardwood trees in the interior, and mining for new deposits of minerals. Health and safety standards are generally low, and a number of injuries and deaths have resulted, notably at Omai in 1995. Conflict with the indigenous peoples occupying the land desired for exploitation by mining and logging organizers has also resulted in violence. Unchecked logging has resulted in a number of potential environmental problems, not least of which is flooding. Removal of trees means that tropical rainstorms deliver large amounts of water that are no longer held up by the roots and foliage surrounding the missing trees. Flooding, often on a wide scale, results. Efforts to clear land for ranches have also inspired similar problems. It was estimated in 2000 that 486 square kilometers of Guyana's land was being deforested annually, which represented about 0.28 percent of the total land.

With unemployment approaching 10 percent and significant underemployment, as well as low income levels—per capita GDP is approximately $4,600, but there is considerable inequity of distribution—Guyana needs to develop new industries and investment projects to help its people to attain better social and economic opportunities in the future. The Guyanese government must balance the opening of the economy necessary to achieve this with protection of the environment.

Habitat

HABITAT IS THE environment in which natural or human species live. In all cases, a habitat is an area where an individual or population exists or can exist. The Joshua Tree, for example, can only be found in its natural habitat, which is the Mohave Desert. Water lilies can only be found in aqueous conditions, while cacti can only be found in desert conditions. Certain types of fish reside only in the ocean's abyss while longhorn sheep live on mountains.

A habitat can consist of a single individual living alone on an island, such as the fictional character Robinson Crusoe, as well as the individual members of a species in an area. Habitats can cover wide or small areas.

A microhabitat can be viewed as the immediate surroundings in which a plant or animal lives. A goldfish in a fishbowl dwells in a microhabitat. If it lived in an artificial pond, its habitat would be the area in the pond where it can swim. The microhabitat for a plant in a home aquarium is the immediate place where the planted is located.

Scientists usually use the term *habitat* in a general sense to mean the ecology of an area where the species exists. The habitat shared by many species is usually termed a *biotope*. A *biome* includes all of the flora and fauna living in the habitat of a certain geographic area.

The destruction of habitat is a grave danger to many species. It may well be the leading cause of species extinction. This is especially the case for species that are dependent on unique ecological niches. For example, the ivory-billed woodpecker resided only in fully matured forests. However, the destruction of most of its habitat probably caused its extinction, unless reported sightings of ivory-billed woodpeckers around 2004 turn out to be true.

Ecological niches are descriptions of the role that a species plays in an environment. The way that a species gets its food, that is, "earns its living," can be of significance to other species. Some species such as panda occupy a narrow niche as do koala bears, which live entirely on eucalyptus leaves. Pigs, in contrast, are generalists and feed on almost anything.

Habitats can be destroyed by natural or human causes. Volcanoes can cover wide areas burying all living things under a layer of ash and lava. If a unique species has developed a special niche in the area of a dormant volcano that returns to life, it can be destroyed by geological developments.

Climatic changes have also changed the habitats of many species in the geologic ages of the earth's biography. The Sahara Desert was a grassy savannah with teeming wildlife 5,000–10,000 years ago. Numerous species that it supported lost their habitats because of the climatic changes that overtook the Sahara.

Habitats for some species can be greatly expanded as well as destroyed by natural or human activity. Geologic or meteorological forces can cause massive changes in the ecology of wide areas in a relatively short time. However, geological and climatic forces can also cause enormous changes in the habitat conditions. The great Sahara desert was verdant until a few thousand years ago. Climatic changes have made it into a desert without any apparent human intervention.

Human intervention has changed some of the Caribbean islands from wet to arid because of the destruction of the original vegetation. The destruction led to the loss of habitat for many species. Human activity can impact species. The snail darter is a small fish that needs clean gravel in moving water as a major part of its habitat. It was threatened with extinction by the building of the Tellico Dam on the Tennessee River.

The destruction of habitat is a grave threat to species like the North American mountain lion.

The building of dams can destroy some species, but it can also increase the habitat for others. There has been a marked increase of some insects and parasites behind the Aswan Dam in Egypt because their habitat has been increased. The same phenomenon happens when farming occurs or is abandoned. Heavily forested areas are more favorable habitats for some species, while broken country is more agreeable to others. The decrease in farming in the eastern United States has led to declines in the upland dove populations because the corn or other seeds favored as food are no longer available. However, the broken country of suburbs and the absence of hunting have led to an explosion in the deer population because the habitat is more favorable than previously.

Human intervention that creates—however unintended—a species invasion can have an impact on species. For example, the American grey squirrel was imported into England in the 1800s as a biological diversity addition. However, by the year 2000, it had virtually replaced the native English red squirrel. Its ecological niche is such that it feeds on acorns from oak trees in winter. However, because these oak trees are absent in some areas, the red squirrel has been able to survive. The difference is in how the two species "make their living." The red squirrel species may well become extinct because its habitat has been over run by a more prolific and aggressive similar species.

Habitat destruction is the gravest threat to numerous species at the beginning of the 21st century. The destruction of forest, wetlands, and other places that were home to unique species has led to their extinction. This was evidenced by the extinction of the passenger pigeon shortly after 1900.

Since the late 1800s, a growing number of efforts have developed to protect habitats influenced by the conservation and environmental movements. Programs to promote both government preserves and private land preserves have gained significant political support. Legislation such as the Endangered Species Act and other similar programs has allowed conservation groups to save numerous species. They have also found support in a ruling by the United States Supreme Court that has said that the destruction of critical habitats is as deadly as directly killing the plants or animals in a biome.

Current laws and programs allow habitat conservation plans to be adopted. In addition, species breeding programs have promoted the return of endangered species to habitats they were exterminated from previously. These programs allow for species recovery. The animals and plants that were eliminated earlier can be bred in captivity and later returned to their original habitat.

Habitat Protection

HABITAT PROTECTION REFERS to a range of human-initiated approaches, strategies, and interventions to avoid the potentially detrimental consequences of anthropogenic activities—such as harvesting, gathering, hunting, logging, mining, agriculture, and residential or commercial development—to habitats (the abiotic and biotic components) necessary for the survival of species deemed significant. In many cases, early protection efforts targeted the habitats of species with particular utilitarian value, such as charismatic wildlife or game animals; and unusual and rare species endangered or threatened with extinction. Historically, these efforts have been overwhelmingly focused on terrestrial species, neglecting freshwater and marine environments, and were undertaken by agencies of the nation–state, or in some parts of the world, by colonial administrators. For example, the U.S. Endangered Species Act largely has incorporated a species-specific management approach. In most cases, these efforts have focused on creating a range of management territories.

Increasingly, the scope of habitat protection efforts is broadening, both in terms of the ecosystem components included in efforts and the total area needed for adequate protection. First, this shift is the result of alternative ways of thinking about nature. Recognizing the importance of new concepts, such as biodiversity, there has been a shift away from the narrower focus on plants and wildlife valued for their utilitarian purposes to a broader focus on protecting ecological integrity and ecosystem health. As a result, efforts that consider multiple species at the same time—and their requisite habitats—are, in part, responsible for the fact that larger areas are under consideration for protection. This includes increasing attention to freshwater and marine ecosystems and the habitats that support complex webs of species interaction.

Second, new scientific insights into the ways that ecosystems change through time and the ecological processes that create and maintain particular habitats point to the importance of devising strategies that allow key ecological processes (e.g., flooding, fire, among others) to operate relatively unimpeded by humans. This has led to additional approaches that emphasize spaces that are more clearly reflective of physiographic or natural boundaries, such as watersheds, landscapes (heterogeneous areas of land composed of interacting ecosystem clusters), and entire ecoregions (large areas of land or water whose ecosystems contain regionally distinctive biodiversity).

Nature preserves, reserves, parks, and protected areas are the most commonly used management strategies to protect habitat. These territorial units rely largely on the creation of a central core area where human intrusions are kept to a minimum. According to principles of conservation biology and landscape ecology, this core area should be surrounded by a buffer zone that is designed to reduce the potential impacts of neighboring anthropogenic activities. Ideally, core areas will be connected functionally to other important spaces through the use of habitat corridors to facilitate the movement of species. In both cases, human settlements are located outside of these two zones, with local anthropogenic needs met by the areas within the buffer zone. Taken together, this management provides a mechanism for creating an integrated network of preserved areas that protect species habitats at the landscape and ecoregion scale.

In recent years, there has been a convergence by nongovernmental organizations (NGOs), such as World Wildlife Fund, the Nature Conservancy, Conservation International, and the Sierra Club, among others, on this idea of ecoregion-based conservation as a guiding framework for intervention. Thus, habitat protection is also undertaken by agencies at multiple levels of government within nation-states, and increasingly by NGOs, such as conservation organizations and private land trusts. For example, some state and local governments in the United States conduct habitat planning exercises to design protected area systems within their jurisdictions. These agencies, together with the help of NGOs, are actively purchasing lands outright or using conservation easements to ensure that important habitats will not be developed.

The sociopolitical impacts of habitat protection on human communities have been varied. In some instances, there has been a history of forced removal of local peoples (including indigenous communities and early settlers) by government agencies and colonial administrators to create national parks or wildlife areas in some developed countries and former colonies. Today, efforts to apply the core-buffer model in new places—or the "guns-and-fences" model as it is derisively labeled by some critics—is sometimes seen as a form of neocolonialism or ecological imperialism. In other places, emphasis on habitat protection has been viewed as a threat to private property rights and has spawned political opposition.

Hadley Cell

THE HADLEY CELL refers to a somewhat idealized vertical circulation of air in the Earth's atmosphere and comprises the principal component of the general circulation pattern of the Earth's atmosphere. The Hadley Cells are comprised of a trough of low pressure girdling the globe in an equatorial and tropical band (the intertropical convergence zone, or ITCZ) and its associated rising air and a ridge of high pressure (the subtropical highs) where the air subsides back to the surface. A Hadley Cell thus circulates roughly from between 0 degrees latitude and 30 degrees latitude, north and south, although the actual latitudes will shift over the course of the year as the subsolar point passes between the Tropics of Cancer and Capricorn over the course of the year. There are thus two Hadley Cells; both sharing the ITCZ as the zone of lifting, but separating into two separate circulations as the air settles into both the northern and southern hemisphere subtropical highs.

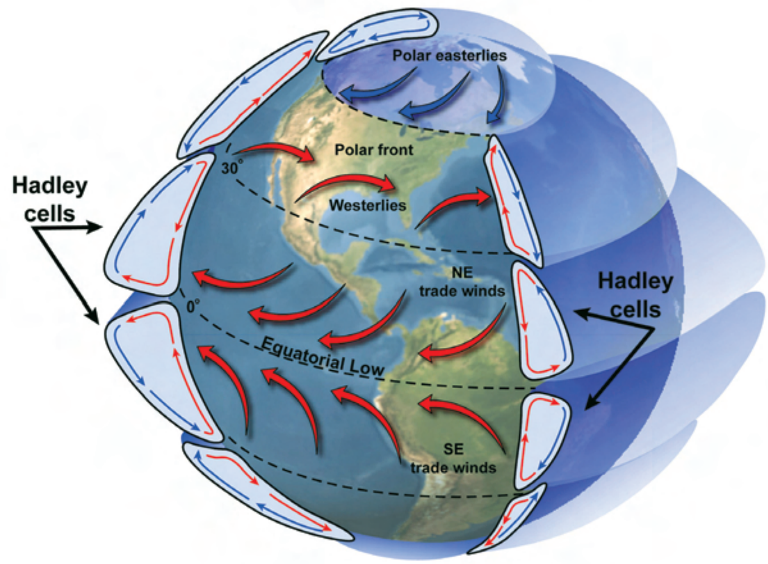
Solar energy drives the system, with the most intense heating of the Earth's surface occurring at the latitude receiving the vertical rays of the sun (the subsolar point). The heating of the surface causes the air above to warm and rise (convectional lifting), creating low pressure. The low pressure draws in surface winds from the higher latitudes (the northeasterly trade winds from north of the ITCZ, and the southeasterly trade winds from the south of the ITCZ). The northeast and southeast trade winds converge on the trough of low pressure, and the collision of these air masses forces the air upwards (convergent lifting), which further decreases pressure. At the surface, the air in the vicinity of the low pressure trough is warm and humid; as the air rises, it cools and the atmospheric moisture condenses into precipitation.

The rising air eventually reaches the tropopause (occurring at roughly 18 kilometers in altitude over the tropics, but descending in altitude to roughly 12 kilometers in the midlatitudes), which is the upper boundary of the lowest region of the atmosphere (the troposphere) and the stratosphere, the region of the atmosphere containing the ozone layer. The ozone is heated by the sun, and above the tropopause, air temperature begins to increase with altitude. The rising air from the ITCZ, having cooled while rising from he surface, encounters warmer atmospheric air (the stratosphere) upon reaching the tropopause; this temperature inversion prevents further lifting of the air.

The circulating air then spreads out along the tropopause, both latitudinally and longitudinally. The longitudinally spreading air becomes accelerated and contributes to the subtropical jet stream. The air spreading toward the higher latitudes along the tropopause are termed *antitrade winds*; the air now is cool and dry (having the moisture removed through condensation and precipitation), and settles back to the surface, forming the subtropical high pressure systems. As the air subsides, it warms such that the air reaching the surface is warm and dry.

The subsiding air spreads out along the Earth's surface, with the winds spreading toward the equator from the subtropical highs feeding back into the ITCZ as the easterly trade winds, and the winds spreading poleward from the subtropical highs being termed the *westerlies* and contributing to midlatitude circulation and the formation of extra-tropical cyclones. Technically, the Hadley Cell circulation strictly refers to the air rising over the ITCZ, circulating poleward as the antitrade winds, subsiding to the Earth's surface as the subtropical highs, and circulating back into the ITCZ as the easterly trade winds. Although the westerlies are functionally tied to the subtropical highs, they are not technically considered to be part of the Hadley Cell circulation system.

The Hadley Cell circulation influences many of the Earth's climate systems and biomes through its



The Hadley cells are composed of rising air in the heart of the tropics and sinking air in the subtropics.

effects on precipitation patterns. High levels of annual precipitation are associated with the ITCZ; the subtropical highs have a variable effect on precipitation, although it is generally associated with drier conditions. Where the ITCZ is present throughout the year, annual rainfall (152–254 centimeters) with no dry season, and defines the tropical wet climate and corresponds to the tropical rainforest biome, composed of broadleaf evergreen trees. With increasing latitude, the influence of the subtropical high tends to confer winter dry seasons of increasing length. Tropical monsoon climates (254–508 centimeters precipitation with 1–3 months of winter dry season) give way to tropical savanna climates (90–180 centimeters annual precipitation and 1–6 months winter dry season), and tropical rain forest gives way to tropical deciduous forest, which grades into the mixed trees, shrubs, and grasslands of the tropical savanna biome.

Poleward of these tropical climates, the subtropical high pressure system exerts the greater influence on climates, but the effect on precipitation is variable. Where the dry, warm air subsides over continental interiors, the climates are quite arid. Where the air subsides over the oceans, the warm air has a high capacity for moisture, evaporation increases and the air can become quite humid. Whether this translates into precipitation over the land is then a function of surface winds. Around high pressure systems, winds follow an anticyclonic circulation, which translates into a clockwise rotation in the Northern Hemisphere and an anticlockwise rotation in the south. On the equatorward margins of the subtropical highs, winds follow an easterly path (giving rise to the northeasterly and southeasterly trade winds). Thus, on the western coasts of continents, dry, warm air subsides over land and blows eastward as an offshore flow of wind, and maintains extremely arid conditions.

As one travels poleward from the tropics on the west coast to the center of continents, the tropical savannas give way to the subtropical steppe climates and subtropical desert, and the savannas give way to grasslands and ultimately low-latitude hot desert biomes. Along east coasts, however, the easterly flow of winds around the equatorward margins of the subtropical highs create an onshore flow of winds, and the moisture the subsiding air picks up over the oceans becomes expressed as precipitation overland. Regions thus affected exhibit humid subtropical climates, which support midlatitude deciduous forests. Although not technically part of the Hadley Cell circulation, the westerlies flowing poleward from the subtropical highs affect Mediterranean, marine west coast, midlatitude cold desert, and steppe and humid continental-hot summer climates and their associated vegetation. The Hadley Cell circulation thus governs the precipitation pattern of most of the Earth's climate systems.

For human societies, the Hadley Cells thus play an important roll in providing food security by supporting agriculture through precipitation. The majority of the world's developing countries are located in the tropics, are heavily dependent on agriculture, and thus dependent on the rainfall imparted by the ITCZ. In the arid zones affected by Hadley Cells, lack of precipitation in conjunction with growing demand for agricultural production and improved irrigation technology results in a growing dependence on groundwater, with groundwater mining (extracting groundwater at rates quicker than it can be replenished), aquifer collapse, and sea water intrusion being common problems in these regions, such as on the High Plains of the United States and in the Middle East. Severe seasonally flooding often accompanies the arrival of the monsoons in South Asia. Also, tropical cyclones form within the Hadley Cell system.

Additionally, variation in strength of the pressure gradient between the subtropical high and ITCZ across the South Pacific creates the El Niño-Southern Oscillation (ENSO) phenomenon. An increased frequency and intensity of tropical cyclones in the South Pacific, as well as locally severe droughts and flooding accompany these ENSO events.

Haiti

THE SOCIO-ECOLOGICAL CONDITIONS in present day Haiti are deeply conditioned by its past. During the colonial period, France developed Haiti into one of the most productive and profitable Caribbean islands. The emphasis on forestry and sugar exports led to the importation of slaves on a huge scale, massive environmental degradation, and eventually to a slave revolt. In 1804, Haiti declared independence, making it the only successful slave revolution in history. The legacy of underdevelopment, slavery, and the commodity economy has been persistent, however. Violence has continued to plague Haiti, which is the poorest country in the Western Hemisphere with a per capita income of only $1,600. The abject poverty rate of 80 percent and the fertility rate of 5.8 children per female are in large part responsible for the major health and environmental threats to Haiti's population of 8,121,622. Furthermore, environmental and health information are difficult to disseminate because of low educational and literacy rates (52.9 percent).

Two-thirds of the population has no formal employment. The country has a low life expectancy (52.92 years), high infant mortality (73.45 deaths per 1,000 live births) and death rates (12.34 per 1,000 population), and a low population growth rate (2.26 percent). HIV/AIDS (5.6 percent) is a growing threat to the Haitian people. Two-thirds of the populations have no access to improved sanitation, and almost 30 percent lack access to safe drinking water; the lack of potable water creates a major health hazard in Haiti. Despite the extreme poverty, irregularities have led to the suspension of millions of dollars in international aid. The UNDP Human Development Reports rank Haiti 153rd of 232 countries on general quality-of-life issues.

Haiti covers one-third of the island of Hispaniola; the remaining two-thirds is occupied by the Dominican Republic. Bordered by the North Atlantic and the Caribbean Sea, Haiti has a coastline of 1,771 miles (2,851 kilometers). The climate is tropical except for the semiarid area where mountains block the trade winds. The terrain is generally rough and mountainous. Because Haiti is in the center of the hurricane belt, the country is vulnerable to severe storms from June to October. Periodic droughts and occasional flooding and earthquakes pose additional threats to the environment and lives. In 2004, southern Haiti experienced massive flood damage, and the northwest was hit by Tropical Storm Jeanne. Thousands of lives are lost whenever such disasters occur. Many deaths and much environmental degradation are caused by landslides that result from the absence of trees to serve as natural barriers to eroding soil.

Deforestation is rampant at 98 percent. Despite efforts to prevent further damage, locals continue to clear forests for agriculture use. The battle for survival also leads Haitians to cut down trees for fuel. Nearly a third of Haiti is arable, and two-thirds of the people are involved in subsistence agriculture. Only the 38 percent of Haitians who live in urban areas

Citadelle La Ferrière

The "Citadel" in Haiti is the largest fortress in the Caribbean and was constructed between 1804 and 1817 with some 20,000 men working on the project. It overlooks Cap Hatien, in the north of Haiti and is one of the marvels of engineering the early modern period, although it was used as a castle, its original purpose.

The construction of the Citadel followed the Haitian Revolution in 1803, when Black slaves rebelled successfully against their French masters and on January 1, 1804, Jean-Jacques Dessalines proclaimed independence for Haiti, the first black republic in the world, and also the second independent country in the Americas. When Napoleon Bonaparte crowned himself emperor later that year, Dessalines did the same creating himself Jacques I, Emperor of Haiti.

Dessalines was worried that the French might launch a counterattack and try to retake Haiti, and for this reason started work on the building of the Citadel. To do this, large numbers of people were forced to help in the building of the castle, which could easily be defended against a French assault. Built at the top of a mountain, it has walls up to 43 feet thick, and has cisterns, reservoirs, and water storage facilities for thousands of gallons of water which would be used to sustain a garrison of up to 10,000 for a year. There were also 365 cannons, some being as heavy as 10 tons, and supplies of cannonballs.

Unfortunately, although Dessalines led a major slave revolt, and was partially influenced by some of the tenets of the French Revolution, he ruled as an autocrat regularly threatening laborers with dreadful punishments or even death if they did not comply with his demands. Dessalines himself died was killed in 1806 and replaced by other tyrants who continued the building of the Citadel.

As things turned out, Napoleon and the French were too concerned with events in Europe, and never launched an expedition against Haiti—they even sold Louisiana to the United States in 1803. The Citadel remains a major tourist attraction for visitors to Haiti.

have access to electricity. Haiti's natural resources include bauxite, copper, calcium carbonate, gold, marble, and hydropower, but the country lacks the infrastructure to adequately exploit these resources.

As a result of mass deforestation, desertification and soil erosion are widespread. It has been estimated that Haiti loses 36 million tons of soil annually. In 2006, a study by Yale University ranked Haiti 114th of 132 countries in environment performance. The country was substantially lower than both the relevant geographic and income groups. The lowest scores were received in the areas of biodiversity and habitat, environmental health, and air quality. Only .4 percent of the land area is protected. One-fifth of the 20 endemic mammal species are endangered, as are 14 of the 62 endemic bird species. Haiti's air supply is polluted by emissions of carbon dioxide from solid and liquid fuels, gaseous fuels and gas flaring, and cement manufacturing.

In 1994, the National Assembly created the Ministry of the Environment, which has been charged with implementing environmental policies and strategies that include forest management, conservation, national parks, buffer zones, mineral and energy resources, and water management. However, the lack of a comprehensive environmental policy and specific legislation has made it difficult to carry out much-needed change and reparations.

Haiti also has a National Commission for the Environment in which the prime minister ostensibly works with relevant agencies to implement the National Environmental Action Plan. Unfortunately, the plan has never been fully implemented due to a lack of funding and structure. Much of the work on Haiti's extensive environmental problems is funded by international groups and nongovernmental organizations (NGOs). For instance, international agencies such as the Inter-American Development Bank, the World Bank, and the UNDP have provided Haiti with funding to launch forest preservation programs and to establish a national flood warning system.

In line with endemic environmental issues, Haiti participates in the following international agreements: Biodiversity, Climate Change, Desertification, Law of the Sea, Marine Dumping, Marine Life Conservation, and Ozone Layer Protection. The government has signed but not ratified the Hazardous Wastes agreement.

Hamilton, Alice (1869–1970)

ALICE HAMILTON (1869–1970) shaped the field of industrial medicine in the United States beginning in the Progressive Era through research on the urban environment. She advanced knowledge of the health effects of chemicals, particularly lead, and successfully campaigned for protections such as workers' compensation and basic environmental standards. Hamilton staunchly supported labor movements, especially in their crusades for health and safety. Decades before the birth of modern environmentalism, she criticized industrial practices that harm human health.

Hamilton was born in 1869 and grew up in Fort Wayne, IN, in a close-knit and well-to-do family. She earned her medical degree—when women doctors were rare—from the University of Michigan. Upon joining the faculty at Northwestern University in 1897, she moved into Jane Addams's Hull House in Chicago. Settlement houses like Hull House served as community centers in poor, urban neighborhoods, where live-in activists from privileged families offered education, political organizing, and self-help opportunities. At Hull House, Hamilton provided health education and studied neighborhood illnesses including typhoid and tuberculosis.

Her investigations into tuberculosis, which she believed was exacerbated by factory conditions, led Hamilton to her career studying the "dangerous trades." Though the field of industrial medicine was at the time respected and active in Europe, industrial disease received little attention among American physicians. To take an interest in working conditions was to risk being deemed a Socialist or merely sentimental.

Both doctors and industrialists denied the importance of workplace illnesses such as phosphorus and lead poisoning. When they acknowledged disease, they often blamed workers themselves for neglecting proper hygiene or engaging in bad habits at home. Company doctors often seemed to favor their employers over their patients. Workers, furthermore, tended to hide their illnesses in order to avoid losing their jobs. Hamilton succeeded in reversing many of these circumstances, often cooperating closely with labor unions and activists, and sometimes industry leaders.

Hamilton conducted the first U.S. studies on lead in the workplace for the Illinois Commission on Occupational Diseases and the U.S. Bureau of Labor Statistics. Often shocked by the conditions she found, Hamilton confronted employers to urge immediate changes to the factory environment. While some employers were eager to comply, some resisted her work, and company doctors accused her of exaggeration and slander. The American Association of Labor Legislation used her findings to craft a bill, adopted by several states, setting basic standards for lead in the workplace. In later years Hamilton urged that industries substitute a less-toxic substance for lead, particularly in the 1920s, when gasoline companies began adding tetraethyl lead to their product.

In 1919 Hamilton became the first woman faculty member at Harvard Medical School. Harvard's creation of a program in industrial medicine was a sign of the growing recognition of the field. Hamilton continued her studies for the Bureau of Labor Statistics, examining trades that exposed workers to industrial solvents, mercury, granite dust, radium, and other dangerous substances. Increasingly granted access to the shop floor, Hamilton was able to work with employers and unions to devise remedies and alternatives to the hazards she found. She also systematized the practices of company doctors to ensure future surveillance of the health effects of industrial processes. Hamilton maintained a special concern about women's exposure to environmental hazards; she considered women more vulnerable and exploitable. This belief led her to take a controversial stance against the Equal Rights Amendment because she thought it would expose more working-class women to exploitation and gender-specific health effects.

Hamilton died at the age of 101 in 1970, the same year that Congress created the Occupational Safety and Health Administration, an agency that brought many of her ideals to fruition.

Haraway, Donna (1944–)

DONNA JEANNE HARAWAY is one of the leading contemporary theorists on environment and society. A professor in the History of Human Consciousness Program at the University of California at Santa Cruz, her research contributes to a vigorous discussion of how scientists' research of the natural environment construct modernist subjectivities and how natural processes are constructed as objects of research. Over her career, Haraway has published six titles that analyzed the international political economy of research into the natural environment, and the image of the world as a "scheming trickster." In a recent interview, Haraway compared her work with Bruno Latour, Evelyn Keller, and Alison Wiley.

Born in Denver in 1944, Haraway completed her doctorate in biology at Yale University, after which she held teaching posts at Johns Hopkins and the University of Hawaii; she joined the Santa Cruz faculty in 1980. Among her most influential works are the dissertation *Crystals, Fabrics, and Fields: Metaphors of Organicism in Twentieth-Century Developmental Biology* (1976); *Primate Visions: Gender, Race, and Nature in the World of Modern Science* (1989); and *Simians, Cyborgs, and Women: The Reinvention of Nature* (1991).

In a recent interview with Thyrza Nichols Goodeve, Haraway explained that she had written *Primate Visions* and *Simians, Cyborgs, and Women* simultaneously, with significant sections completed while she was in residence at the Institute for Advanced Studies in Princeton in 1987. Haraway said about *Primate Visions*'s leading idea, "So many issues in culture, history, politics come to be narrated as biological and evolutionary stories. And the reverse—in other words, the way biological and evolutionary stories are thickly layered with the tools of political economy." In a series of chapters that are as empirically based as they are theoretically-sophisticated, Haraway traces primate researchers from the industrial northern nations; because their study of monkeys and apes is located in the formerly colonized parts of the world, primatology becomes deeply enmeshed in sexual, racial, and national myths. In that same interview, Haraway confesses that, even as it has proved influential on how the field poses research questions, a number of primatologists have resisted her assertions.

Simians, Cyborgs, and Women brought together previously published works as a "cautionary tale." To bring these to closure, Haraway introduces a new metaphor for the natural environment as the object of study, describing nature as a "witty agent and actor," a "coding trickster with whom we must converse." Haraway agrees that the trickster "is also there to caution us against anthropomorphism. It's hard because even a word like *conversation* conjures up speech as we know it. But the trickster figure is about the world that is also nonhuman, about all that which is not us, with whom we are enmeshed, making articulations all the time."

Hardin, Garrett (1915–2003)

GARRETT JAMES HARDIN, born in 1915, was an ecologist from Dallas, Texas. Hardin graduated from the University of Chicago in 1936 with a BSc in Zoology, and in 1941 was awarded a Ph.D. in microbiology from Stanford University. He held the position of Professor Emeritus at the University of California, Santa Barbara, from 1933 until he retired in 1978.

Hardin wrote prolifically about environmental issues. In books such as *Nature and Man's Fate* (1959) and *Exploring New Ethics for Survival* (1977), he argued that unless human population growth is curbed, disease, starvation, and social disorder will result. He is best known for his landmark article, "The Tragedy of the Commons," which was published in *Science* in 1968.

In this essay, he used the example of an imaginary field in England where cattle herders have free and open access (the commons). He shows how each herder receives a benefit from adding one animal to graze the lands, while the cost of degradation to the field is shared by all. He thus argues that each herder has the incentive to put as many cattle on the land as possible. Hardin shows that while this may seem to be the most economically rational choice, exercising that choice ultimately leads to irreversible degradation, hence the tragedy of the commons. As he notes, "it is no use asking independent herdsmen in a commons to act responsibly, for they dare not. The considerate herdsman who refrains from overloading the commons suffers more than a selfish one who says his needs are greater."

Hardin uses this analogy to discuss the challenges of managing human populations and their impact on environmental systems, concluding that "freedom is the recognition of necessity," and that through the recognition of resources as commons in the first place, identifies the need for effective management.

PROVOKING CONCEPTS

His ideas have provoked a separate school of thought, especially from those who do not agree with Hardin's assumption that humans will always behave selfishly, or that privatization of resources will reduce negative human impacts on the environment. For example, E. Ostrom and F. Berkes have argued that community-based management offers a model where control of and maintenance of the "commons" can be achieved through community sanctioned and agreed to mechanisms and penalties.

While Hardin's Tragedy of the Commons has since been extensively applied within environmental and resource management programs and embedded within literature worldwide, Hardin himself focused on using his theories to advocate for the moral, ethical, social, and political dimensions of the population debate.

During the 1970s, Hardin developed his ideas on population with an analogy, describing societies as a lifeboat. Metaphorically, he argued, each rich nation amounts to a lifeboat full of comparatively rich people. The poor of the world are in other, much more crowded, lifeboats. He argues that the key challenge facing the world is how to reconcile the "ethics" of the lifeboat, namely, what should the passengers on the rich life boat do? His book, *Living Within Limits: Ecology, Economics and Population Taboos*, which develops these theories, received the Phi Beta Kappa Science Award in 1993.

In 2001, he argued that we need to teach "literacy, numeracy and ecolacy" in order to survive as a species. Hardin's last book, *The Ostrich Factor: Our Population Myopia*, published in 1999, argued for coercive constraints on "unqualified reproductive rights" as a means to address overpopulation.During his life he was active in community campaigning to progress his views, such as the 1960s campaign to legalize abortion, and was President of the Environmental Fund in 1980–81. Hardin died in 2003.

Hazards

HAZARDS ARE PROCESSES with a specific dimension to potentially have a negative impact on individuals, communities, or society. The nature of the hazard refers to the origin, being natural, manmade or social.

An urban and industrial society is based on technology. Technology should be understood as a system of interrelated components of design, building, management, and disposal components. A failure may happen at any stage, so the use of technology implies dealing with a hazard. Living in an industrial society means living at risk. A human failure is a malfunction of a component, not an isolated condition. More attention is paid to new and high technologies in developed countries, while low-technology accidents in developing countries are rarely reported. The transfer of technology to these countries to avoid labor or environmental controls relocates and increases risk for the destination's lax control.

PARAMETERS OF HAZARDS

The effects of technological accidents are complex: environmental or health-related in its nature; durable and extended to unborn generations, cumulative or temporary; and global, regional, or local in extent. In an event, the following are involved: a material: chemical, inflammable, or radioactive; a process: structural failure, fire, explosion, or a release; a sector: chemical, transportation, energy production, mining or agriculture, or simply a lifestyle.

Natural hazards and disasters are classified into a range of major categories: atmospheric (hurricanes, wind storms, tornadoes, heatwaves, droughts); hydrological (floods, snow avalanches); geological and geomorphological (earthquakes, volcanic eruptions, tsunamis, landslides, erosion); and biological (human epidemics, pests, wildfires).

The dimensions of a hazard are the magnitude of energy released, the complexity or potential level of hazard combination, the spatial dimensions as a real extent and diffusion, and the temporal dimensions as rate of onset, duration, frequency, and recurrence. Dimension is also a key element for public awareness, since media and governments usually draw their attention to rapid-onset, dramatic, and extreme events. Less attention is paid to slow-acting or biological processes like epidemics, famine, drought, or soil erosion, which have time-extended effects, concealed victims and environmental degradation over large areas.

Risk is a measure of the probable impact and the subsequent economic and noneconomic losses. An impact is an eventual interaction between a hazard and a vulnerable set of persons, goods, functions or resources. If an extreme event hits an unpopulated area, the effect on the society is null, while a slight change on a populated area—like snow in winter—may have a negative or positive impact.

The disaster is a disruption of the economic, social, institutional, and environmental functioning produced by an extensive loss as a result of a hazardous event. The criteria differentiating it from lower-energy accidents is the magnitude of the loss; the number of casualties, deaths and injured, and economic loss. This implies an administrative responsibility or financial liability, and the determination of whether the loss will be covered by individuals, insurance companies, administrations, or nongovernmental organizations (NGOs). Common criteria applied to droughts are looser, requiring a large number of people affected, even some reports exclude drought victims from ordinary natural disaster counts.

The differentiation between disaster and catastrophe is a matter of dimension. A country or a community recovers from a disaster with resources of their own, with some aid; but the magnitude of a catastrophe reaches a point that their own resources are not enough to cope with response and recovery. Losses are enormous and critical, for there is a general destruction of buildings and infrastructures, emergency facilities are not operational, administration is dismantled, and everyday life is interrupted. This was the case with hurricane Mitch in 1998 in Honduras.

Perception is an intervening factor in the definition of disaster. There is a band of tolerance within hazard dimensions, where some damages are not judged considerable. The relationship between earth processes and risk tolerance changes with time. Diminished resources—like drinking water availability—is always intolerant, causing increasing stress; however, an increasing tolerance diminishes stress.

The Celtiksuyu Boarding School lay in ruins after the May 2003 earthquake (Richter scale 6.4) hit Bingol, Turkey.

EFFECTS OF DISASTERS

The effects of a disaster are as complex as the causes. Primary effects on people are loss of life, injuries or impairment, together with damage or destruction of resources, property, heritage, and disruption of production, commerce, transport, lifelines, and services. Secondary hazards, such as urban fires or aftershocks following the destruction caused by an earthquake, are effects facilitated by vulnerability and insufficient preparedness. Social functions are interrupted, and the results are starvation, illness, unemployment, social violence, displacement and migration, unemployment, and inflation. Losses increase vulnerabilities to famine, diseases, debt, or homelessness. Side effects include displacement and a decline in fertility, although there is a contradictory effect—of returning to former homes—when memory vanishes.

The effects of a disaster in developing and developed countries are significantly different. While more commodities are at risk in developed countries, more people are at risk in developing countries. The Kobe earthquake in 1995 caused an estimated damage of $150 billion, the most costly disaster in the 20th century. In the developing world, the two most deadly events were the Bangladesh cyclone in 1970 with 300,000 fatalities, and the Tangshan earthquake in 1976 with 250,000 victims. Again, in Third World countries, the Indian Ocean tsunami in 2004 caused an estimated number of 275,000 deaths.

The impact of natural disasters is increasing, for there is a higher population growth rate in developing countries, particularly in urban areas. Population and affluence demand more land and drive up its value, putting more pressure on vulnerable and marginal areas. The process of economic and industrial relocation, in addition to financial mobility—inherent to the globalization process—has lead to an interconnectedness and interdependence of national and regional markets in distant geographical areas. A production or transportation crisis caused by a disaster has effects in distant areas, illustrated by market distortion. Technological development actually creates a vulnerability, as social functions are increasingly reliant on its quality, accuracy, and uninterrupted operation.

VULNERABILITY TO HAZARDS

Vulnerability is the human capacity of coping withthe impact of a disaster, and materializes as a disadvantageous response, defective resilience, and powerlessness. It is complex for its physical, social, economic, institutional, and environmental nature, and is variable depending on the dimensions, energy, and complexity of the hazard. Physical vulnerability is based on the quality, resistance, and design of construction. Social and economic vulnerability depends on social class, age, sex, ethnicity or minority. Casualties in earthquakes principally happen at community buildings and homes to women, children, and the elderly—although it is also dependent of other factors like the time of the day.

Poor people are more vulnerable, for they lack resources to contend with every phase of the risk process. Largely, they dwell in hazard-prone areas. They do not get ample information for they do not easily reach media, are not integrated in the risk preparedness system, and their low education levels conditions their perception of the environmental threats and the access to training. Evacuation is a challenge due to the reduced mobility of the young, the elderly, the impaired, and those with lack of personal transportation. Rural settlements and urban squatters are not priority areas for rescue and assistance, as well as for rehabilitation and reconstruction in the phase of recovery, even though shantytowns become overpopulated and built with unsuitable materials. The lack of risk and emergency management strategies in less developed countries is structural and reflects political and financial priorities when resources are limited.

External aid helps to stabilize the post-event situation and acts as a relief by providing temporary shelter, health, sanitary, and sanitation services. Sources of assistance are small-scale community aid in smaller events, and external and internal governments, international agencies and nongovernment organizations (NGOs). This support, however, discourages spatial relocation and local government responsibility for development, creating dependency. External aid is highly reliant on the interest of media in rapid-onset events to channel public and government attention, which declines in the post-event phases of rehabilitation and reconstruction. Critical recovery processes become very dependent on voluntary and external resources to organize aid donations after the event.

RESILIANCE TO HAZARDS

Resilience is a measure of the ability to return close to the previous state after an impact. The more resilient a population, the more efficient their previous adaptation to environmental change. Availability of assets, land, income, capital, skills, technology, insurance coverage, and access to information discriminate this capacity. But resilience is not only a post-disaster component; these factors also intervene in preparedness. Developed areas respond to disaster at various administrative levels, because they own resources; resilience is not only at the individual or household level. In less-developed regions, the capacity for coping with the impact of a disaster is almost exclusively at the household level.

The most frequent natural hazards—earthquakes, tsunamis, volcanoes, tropical storms, or desertification processes—have a clear zonal location component, shaping hazard regions. They are an additional factor restraining development in developing countries because the human and economic costs of response and recovery delay the effects of investments. Urban areas, with their high technology density and exposure, shape further regions of risk.

Health

MANY ACADEMICS AND health professionals look to the World Health Organization's (WHO) constitution for a definition of health. Here, health is recognized broadly as not merely the absence of disease or distress, but more positively as a state of physical, mental, and social well-being. It is also generally accepted that, although good health can be a collective goal and good for society on an individual level, different people have different needs for health, different ideas as to what exactly good health is and different thresholds for poor health (such as physical pain or mental distress).

The public have displayed a growing interest in health and body matters, particularly in weathier, Western societies. The media and the Internet have played a significant role in creating a consumerist health culture and sustaining demand through providing a wealth of information on diseases, products, treatments, and health maintenance. This has been mirrored by the increased interest shown in health by the private sector, which has begun to market a vast array of health-related products ranging from food supplements to fitness machines.

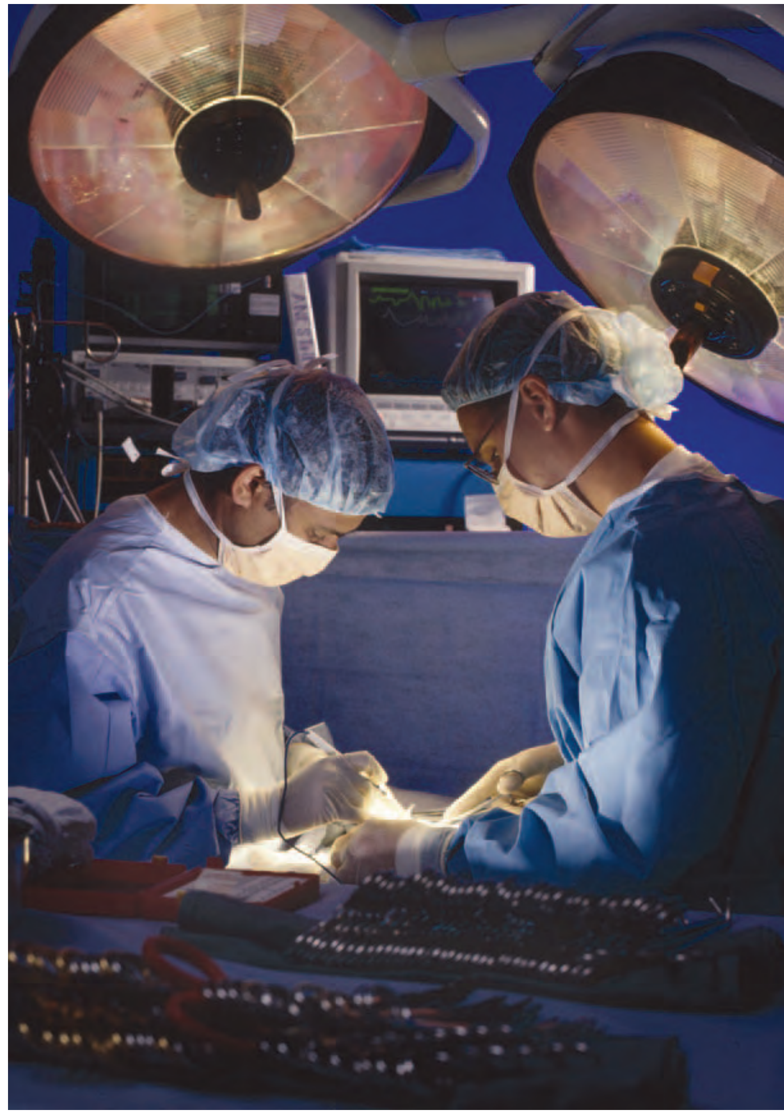
The fitness boom of recent years has involved higher percentages of people regularly partaking in activities to improve their health. Complementary and alternative medicine, often connected with nature and natural lifestyles, have become more mainstream. The "pull factors" include its holistic and personalized nature, the greater time spent in consultations, the spiritual dimension, and the wider identification with an alternative ideology or culture.

At the same time, a growing number of people are involved in health-harming activities such as drug use and high-fat and high-calorie diets. It has been necessary to target policy and public heath efforts against a wide range of unhealthy activities.

An array of complex measurement tools have been developed to define and measure health. Health economists have developed the QALY (Quality Adjusted Life Year) as a combined measurement of quality and quantity of life. Meanwhile, the SF-36 is a well known and widely used measure of health status. Hundreds of research studies investigate the many human activities that effect health. Concepts such as well-being and wellness, and subjects such as public health, sports, and fitness are increasingly scrutinized. Similarly, health systems and services now incorporate disease prevention and public health alongside their traditional clinical disciplines. A complex and interrelated array of health disciplines now coexist and focus on women, children, familes, nutrition, communities, and behavior.

ENGAGING WITH THE ENVIRONMENT

All of these engage with the environment in their own unique ways. For example, academic geographers have begun to explore the dynamics between health and environment. In 1992, Wil Gesler noted the positive psychological responses that people obtain from places, and how they affect physical, mental, spiritual, social, cultural, and emotional components of healing.



The public have displayed a growing interest in health and body matters, particularly in wealthier, Western societies.

An important debate over recent years has focused on the relationships between public health and the urban environment. Research has amply demonstrated the existence of geographical differences in mortality, morbidity, and health-related behaviors, but results vary on if health and health-related behavior in specific places is more greatly influenced by the characteristics of social composition—gender, marital status, employment status, income, and debt—or by the services and facilities available to them, such as the presence of primary care, particular retail outlets, and affordable and healthy foodstuffs. However, it is argued that, in contrast, the affluence and social and cultural norms of particular groups might affect their use of services and facilities within specific locales. This "collective" dimension to area-based explanations for health emphasizes the sharing of traditions, values, and interests—ethnic, religious, political, historical, cultural, and/or labor-based—within places. Such collective dimensions facilitate group actions and support that potentially impact health.

ENVIRONMENTAL HEALTH

The substantial field of academic research known as environmental health considers the impact of local environmental conditions on population health and health-related behaviors, and primarily focuses on environmental impacts on physical health. These range from relatively minor aliments and complaints to persistent, long-term conditions of varying severity (such as asthma and eczema), to others that are often terminal (such as Leukemia and lung disease). Meanwhile, a lesser number of studies focus on environmental impacts on mental health.

A great deal of research on the scales of environments focuses on health impacts on communities within broad regions—for example, states or provinces in North America—while some is focused on health in smaller locales, typically towns and urban neighborhoods. Often taking an epidemiological approach, research studies have identified the negative impact of toxic hazards on health. Air pollution has been a substantive issue for investigation. In particular, researchers have studies the impacts of area sources of pollution (such as radon and ozone); linear sources that are often mobile (such as traffic pollution); point sources (such as industrial pollutants); and a range of factors adding to local air quality.

A smaller volume of research has considered the spatial impacts of waterborne disease (such as cholera, schistosomiasis, and gastroenteritis) and chemical contamination (such as aluminum and arsenic) on health. During the past decade, environmental health concerns and research has expanded to include an attention to the public's health beliefs, localized environmental risk perception, community reaction and local health policy. In addition, researchers interested in public health have also extended their gaze and considered micro-scale individual polluting behaviors such as smoking. These studies engage with concepts such as social and moral responsibility and the roles of individuals and governments, and articulate the everyday conflicts that can occur within and over community spaces.

Heat (Balance and Capacity)

HEAT IS A transfer of energy. Heat is not contained in a body, therefore, but is instead a condition of energy moving from one body to another. The amount of heat to change the temperature of a specific substance one degree Celsius is its specific heat capacity. Heat balance occurs when the amount of heat coming into an object equals the amount of heat leaving it.

All matter is made up of atoms. The greater the energy level in the atoms and molecules of objects, the greater their movement. Objects that have rapidly moving molecules are hot, and those with slow molecules are cold. Temperature is a measurement used to indicate the internal energy level of an object.

Temperature indicates the energy transfer that will occur when a hot body comes in contact with a cold body. For example, two identical pieces of iron cut from the same bar are placed into either boiling water or a freezer for an hour, then placed on top of one another on an insulated board. The hot iron would have a higher internal energy level than would the iron from the freezer. The heat energy would flow from the hot iron to the cold iron. This transfer of heat would continue until both bars were the same temperature.

To measure the heat flow into an object, the specific heat capacity of a subject is used to measure how much energy it will take to make it hotter or colder. Scientists and engineers define the term *specific heat capacity* as the amount of energy (or heat) that it takes to raise the temperature of one gram of water one degree Celsius. Denser materials take more heat to raise their temperature one degree than do less dense materials.

Heat capacity as the capacity of a body to store heat is measured in units of joules per Kelvin. The *extensive quantity* of a body expresses the size of a body, such as an above-ground swimming pool versus a cup of water. Specific heat capacity is found by measuring the capacity of a material by its mass. The mass-specific heat capacity is an *intensive quantity*, which means that it is a measure that is not dependant upon the mass or type of material of an object.

Heat is transferred from one body to another in one of three ways. *Conduction* is the transfer of energy (heat) from molecules bumping into one another. If one end of a silver rod is put into a flame, the other end of the bar will soon warm, because the molecules conduct energy from one end of the bar to the other by bumping into each other.

Convection is the transfer of energy in liquids or gases. Because the molecules are too far apart to be effective conductors of energy, the energy is moved by currents in the fluid gas or liquid. A space heater warms surrounding air, causing it to rise as cooler air is drawn to the heater.

Radiation is the third way that heat is transferred. If the body is a metal, such as a cherry-hot iron or a glowing fire, it sends out infrared waves of energy.

Heat balance occurs when the energy output of a system equals the energy input in a specific place or specific system, creating an equilibrium. In natural systems of the earth, heat balance is very important. The sun's rays warm the earth and oceans. This produces warm water, evaporation of water into vapor to become clouds, and heated air from the warmed earth. The effect is temperatures that cause rising air and water vapor. The rising air creates a low pressure area into which cooler air, which is heavier, moves. Globally, this is a massive form of heat flux seeking a heat equilibrium or balance that is never finally achieved. If it were, the atmosphere would stagnate from a lack of circulation.

Heat as balance and capacity are also important factors in life. For example, sleeping bags are designed to trap and hold air around the body. If the insulation in the sleeping bag is effective, heat is not transferred from the body to the surrounding colder atmosphere. A heat balance is achieved, and the sleeper is warm all night despite the cold.

Heat Island Effect

HEAT ISLANDS OCCUR when urban areas experience higher levels of thermal heating than adjacent exurban and rural areas. Cities that maintain a higher average temperature than their surroundings can be viewed as islands of heat surrounded by cooler, nonurban landscapes. Around the world, many cities maintain air temperatures up to 10 degrees F (5.6 degrees C) warmer than surrounding areas. Scientists, urban planners, and historians are beginning to recognize that urban heat islands are not simply inconsequential environmental phenomena. Rather, the effects of urban heat islands are now being linked to processes of urban economic development and to levels of individual and community vulnerability.

Urban areas contain distinct physical properties that contribute to higher surface temperatures. The conversion of formerly vegetated landscapes to nonvegetated surfaces "forces" urban temperatures upwards by changing the thermal properties of urban environments in four significant ways.

First, vegetation absorbs solar energy out of the atmosphere in order to complete the process of evapotranspiration. Removing vegetation therefore eliminates an important cooling mechanism. Second, materials commonly used in the construction of asphalt roads and parking lots decrease the overall reflectivity, or albedo, of cities while simultaneously increasing heat-absorbing capacity. Third, the conversion of urban areas to nonimpervious surfaces facilitates the expedient removal of rainwater from the urban system. Because the evaporative capacity of water takes heat out of the urban environment, its rapid removal minimizes this important cooling process. Fourth, the replacement of low-lying trees and buildings with large structures that block natural wind patterns can diminish the role of wind as a natural cooling mechanism.

Urban heat islands can have negative health and environmental consequences. Increased average urban temperatures, especially during hot spells, create health hazards for many vulnerable urban residents. The 1995 midsummer Chicago heat wave resulting in approximately 525 fatalities. Researchers noted that while many urban residents experienced only minor inconveniences when daytime temperatures hovered near 100 degrees for over 5 days, others, such as the elderly and homeless, fell victim to the unrelenting heat.

Urban heat islands also increase photochemical reactions that lead to the production of harmful, ground-level ozone pollution. In Los Angeles, health risks from high smog levels increase when temperatures rise over 95 degrees F. Moreover, as temperatures increase, demand for air conditioning by urban residents goes up, which in turn leads to increased coal-fired energy production and more pollution. Higher urban temperatures can also disrupt local weather patterns. The city of Atlanta continues to experience heavier rainfall, increased thunderstorms, and locally generated winds as the city expands and the heat island effect becomes more pronounced.

A consortium of U.S. organizations, including the National Aeronautics and Space Administration and the National Ocean and Atmospheric Administration, use thermal sensory data to detect "hotspots" and evaluate existing surface characteristics in U.S. cities. The U.S. Environmental Protection Agency suggests a number of "smart growth" approaches for cities, including reducing large parking lots and other impervious surfaces, maintaining preexisting vegetation, promoting tree planting programs, and establishing educational outreach efforts for urban residents. Many municipalities have initiated programs to mitigate the production and/or effects of heat islands. These include promoting green roofs, aggressively incentivizing carpools, building with lighter surfaces, and strategically designing urban corridors that maximize wind channeling.

Heat Wave

A HEAT WAVE is a prolonged period of unusually warm and humid weather, lasting for a period of days to weeks; a minimum of three consecutive hot days is a common rule of thumb. Similarly, the temperature threshold that indicates a heat wave depends on what is normal for the region. In assessing the impact of a heat wave, the most useful measure is the *apparent temperature*, which is an index that combines air temperature and humidity to assess the total stress that individuals will experience.

Heat waves create uncomfortable conditions, and are often associated with increases in human mortality. The hot, humid conditions characteristic of heat waves raise the body temperature while simultaneously limiting evaporative cooling, producing discomfort and increased stress on the body. Heat wave deaths are higher among elderly populations, and are often attributed to cardiovascular and respiratory problems, exacerbated by the heat stress. Increases in death rates during heat waves are more common in northern cities, where air conditioning is less common and the population is not acclimated to high temperature and humidity. In southern cities, where high temperatures are typical during summer, unusually warm events tend to have less of an impact. In addition, there are socioeconomic patterns in heat-related deaths, as air conditioning and effective medical care are often less available to the poor. Overall, heat-related deaths tend to be more frequent than any other form of weather-related mortality, although the direct cause of death is often attributed to an underlying medical problem that increase a person's vulnerability to heat stress.

In addition to mortality, heat waves result in vast increases in energy consumption. Failures of the energy infrastructure due to increased load can contribute to discomfort and mortality. Economic impacts can include a decrease in shopping and worker efficiency. Agriculture is also affected: livestock mortality rises during heat waves, and the production of milk and eggs is reduced.

Heat waves tend to be a larger problem in urban areas than rural areas. Due to the urban heat island effect, cities can be several degrees warmer than the surrounding countryside. More significantly, cities do not cool off as much during the night due to the slow release of heat stored in concrete and other surfaces, as well as waste heat produced by transportation and industry. Unusually warm nights can be particularly important during heat waves. Nighttime normally provides an opportunity for the body to relax and recover. When nights are unusually warm as well, this recovery is limited and mortality can be increased. During a heat wave, the majority of excessive deaths tend to occur in the early days of the event, as the more vulnerable members of the population succumb. As the heat wave continues, the death rate tends to drop, due to the gradual acclimatization of the populace.

HEAT WAVES IN HISTORY

In recent years, several significant heat waves have produced excessive mortality in the United States and Europe. In July 1995, a period of high temperature and humidity was responsible for over 1,000 deaths in the U.S. Midwest, including over 500 in Chicago, which was ill-prepared for the severity of the event. Many of these deaths were attributable to extremely high nighttime temperatures, and disproportionately occurred among the elderly and poor residents in urban areas. Four years later, a similar heat wave affected nearly the same area with far fewer deaths. The reduced death toll in 1999 can be at least partly attributed to the improved responses of state and city governments, including better public notification, the opening of cooling centers for residents without air conditioning, and careful attention to electrical infrastructure.

In the summer of 2003, a record heat wave struck much of Europe and resulted in over 35,000 deaths, many of them elderly. This effect was exaggerated due to the demographic structure of many European countries, which have relatively high proportions of elderly people. As in Chicago, national and regional governments were not prepared for such extreme heat in a region that does not typically experience hot summers. Because heat waves are unusual, air conditioning is uncommon and people are not well-acclimated to high temperatures. In addition, the heat wave struck in August, a month when many people, including physicians and other health workers, traditionally vacation.

Of significant concern is the question of whether global warming will result in increased frequencies of heat waves and the associated mortality. Over the past century, the global average temperature has risen by approximately 0.6 degrees C (1.1 degrees F), and continued warming is anticipated. As much of this warming is expected to occur at higher latitudes, it is reasonable to expect that heat waves should become more common in northern cities. However, heat-related mortality has in fact decreased in the United States since the 1960s, despite the fact that stressful weather conditions have become more common. There are many possible explanations for this trend, including improvements in health care, the wider availability of air conditioning, better governmental responses to extreme weather, and a general acclimatization to heat in the population. Still, heat remains the largest weather-related killer and will continue to be a serious concern.

Heavy Metals

HEAVY METAL IS a term frequently used by environmentalists to describe a group of metallic elements that frequently have toxic effects. The heavy metals include elements such as mercury, lead, and cadmium. However, as a definition of a class of toxic compounds, the term *heavy metals* is somewhat problematic. The term implies the toxic material is in metallic form, whereas many heavy metals in the environment may actually be present as a compound, for example methylmercury.

Another problem with the term is that several elements that are sometimes encompassed in the category include the potentially toxic substances arsenic (a semimetal) and selenium (a nonmetal). The definition of "heavy" is also problematic. Various definitions consider metals with densities of anything from 3.5 to 7 g/cm^3 or above as heavy. However, some metallic elements that are actually "light" may also be of environmental concern, such as aluminum (density 2.7 g/cm^2) and beryllium (density 1.85 g/cm^2). Also, using density as a categorization is problematic as such a physical property can vary according to condition or state of an element.

Sometimes atomic weight is used as a defining characteristic of heavy metals; for example, an atomic mass of 63.5 or greater. This again would exclude several elements that are of environmental concern as heavy metal contaminants, such as chromium, nickel, and cobalt (approximate atomic masses 52, 58.7, 59, respectively) and would exclude metals with low atomic masses that form toxic compounds, such as beryllium (approximate atomic mass 9).

Sometimes the term *trace element* is preferred by many scientists to categorize inorganic contaminants; however, the term *trace* suggests that quantities of the element occur in the environment in very low amounts, or that even a "trace" of an element might be toxic. The term also may cause confusion with the language of nutrition, in the context of elements that may be required in "trace" amounts in the diet because they have essential functions within the body of organisms.

Many toxic heavy metals are not necessarily toxic in their pure, metallic forms, and the toxicity of the substance varies according to the state or valency of the element. For example, hexavalent chromium (VI) compounds (i.e., Cr^{6+}) can be extremely toxic and carcinogenic, whereas chromium (III) compounds are generally not a health concern.

Whereas some heavy metals have no known role in the nutritional needs of organisms, such as mercury, and even low levels may be of toxicological concern, several heavy metals are actually required in the diet and are trace essential nutrients, including cobalt, a component of vitamin B_{12}; iron, which is a component of hemoglobin, the pigment that carries oxygen in the blood; and zinc, a component of many enzymes that facilitates metabolic reactions in the body. However, high intakes of these elements may be toxic. High concentrations of heavy metals are problematic, but high concentrations of almost any substance in the environment, even relatively benign substances, can also be toxic.

Heavy metals are naturally occurring, and can be released into the atmosphere as the result of forest fires or volcanic emissions; as a gas, particle, or bound to the surface of dust; or they may be released from rocks by erosion and carried by water, in solution, as particles, or bound to the surface of a suspended substance, into rivers or the ocean. Anthropogenic activities also produce heavy metals, such as burning of fossil fuels in power plants or automobiles, as a by-product of mining, the dumping of heavy metal containing waste, or discharges by industry or sewage systems.

Heavy metals may also be transferred via organisms, and are not broken down by biological processes. Although plants and animals can regulate their metal content to a certain point, metals that cannot be excreted bioaccumulate—build up in an organism over its lifetime—especially long-lived species, concentrating in protein-rich tissues such as liver and muscle. Moreover, predators can absorb heavy metals contained within the tissues of their prey species, gaining even higher inputs of contaminants on up the food chain, until animals at the highest trophic level obtain the highest concentrations of heavy metals, a process known as *biomagnification*.

As humans are a long-lived, top predator, they are at risk from bioaccumulation and magnification of heavy metals. In humans, problems of heavy metal pollution were first brought to world attention with so-called Minamata disease in the 1950s. This primarily neurological condition was caused by consumption of mercury. However, many other so-called heavy metals have effects on the human nervous, immune, and reproductive/hormonal sysyems; for example, lead is of particular concern.

Hedgerows

HEDGEROWS ARE LONG, thin, organized rows of plants, mostly woody shrubs, which are used to divide areas of land. Hedgerows have been used especially in Europe for many centuries, and some are up to 700 years old. They have become important homes to many species of wildlife and are recognized, at least by some, as valuable working artifacts.

Woody plants used for hedgerows include holly, oleander, privet, and hawthorn. The number of woody plants found in a 30-yard stretch of hedgerow is roughly equivalent to its age in centuries. The exact composition of the hedgerows varies according to specific local conditions, as does their method of construction. They also represent effective barriers to most forms of wind erosion.

Where land ownership is divided into small lots, hedgerows may represent problems for subsequent land planning, such as road planning. Hedgerows have been used as evidence of boundaries for land ownership and so can be taken as legal proof. Careful examination of hedgerows in many parts of Britain reveals that many are constructed on the basis of multiples of 22 yards (approximately 20 meters), which is a traditional measurement known as a *chain*.

Many farmers have in recent years found that hedgerows occupy too much of a proportion of their land and also hinder their ability to use tractors or other large machinery. Dividing land into small parcels may also appear to be inefficient in terms of economies of scale. However, due to to the importance of hedgerows as objects, they are protected in Britain by the 1997 Hedgerow Regulations, which aim to maintain in their current form those hedgerows that are not wholly contained within a domestic garden. These regulations are made more complex by the provisions for distinguishing between trimming and pruning hedgerows for maintenance versus reducing them in scope. Even so, economic pressure on hedgerows means that they are still disappearing gradually, so conservationists have been conducting research to determine other benefits that can be added to the cost-benefit analysis of their preservation. These include the fact that hedgerows shelter some beetles and insects that assist in pest control; that they are comparatively difficult to vandalize or to damage; their ability to support rabbits, pheasants and other creatures that may be hunted; and their provision of shade for livestock.

Herbicides

HERBICIDES ARE CHEMICALS or biological agents used as pesticides to kill a weed, which is any plant growing where it is not wanted, usually those abundant enough to take over flowerbeds, gardens, or reduce yield in agricultural fields. Reasons for using herbicides include improving the aesthetic appeal of a landscape or ornamental garden, increasing crop yields, or to kill intoxicants or narcotic plants grown as illegal substances. Herbicides have also been used to expose enemy combatants in jungle areas.

Until the time of World War II, weeds were controlled mechanically. This included plowing, weeding by hand, or using a hoe. Cultural controls are methods used to cultivate the land so it is less hospitable to weed development. Altering the pH of the soil, its salinity, and its fertility are other ways to hamper weed development.

Some plants are natural herbicides. Sassafras trees (*Sassafras albidum)* act as herbicides with allelopathic toxins produced in their roots. Allelopathy occurs when one plant interferes chemically with the development of another. Other allelopathic plants include black walnuts, sagebrush, and sunflowers.

Most herbicides are synthetic chemicals manufactured for specific purposes. There are a number of ways to classify herbicides, such as by the kind of vegetation they control, the activity, use, chemical family name, or mode of action. Contact and systemic herbicides are "activity" herbicides. Contact herbicides kill plant tissue on contact. They are fast-acting and are generally most effective on annuals. Systemic herbicides work by being taken into the plant, which it then poisons. These herbicides are usually applied by spraying on the leaves or by applying it to the soil.

Preemergent herbicides are applied to the soil before the crop emerges to prevent weeds from germinating. Postemergent herbicides are applied after the crop has emerged. Some herbicides inhibit the biology, enzymes, or proteins of a plant, interfering with the mechanism of action of a weed. The ACCase (Acetyl coenzyme A carboxylase) inhibitors are used to kill grasses by interfering with the lipid synthesis in their cell membranes. Acetohydroxyacid synthase (AHAS) acetolactate synthase (ALS), inhibitors interfere with enzymes or with amino acid production in plants, causing them to slowly starve to death. Other inhibitors interfere with the production of amino acids in plants. Glyphosate, sold commercially as Roundup, is an enolpyruvuylshikimate 3-phosphate synthase enzyme (EPSPS) inhibitor. The first organic herbicide was synthetic auxin, which mimics plant growth hormones to interfere with plant development. Photosystem II inhibitors interfere with electron flow in photosynthesis.

Herbicides are used in enormous quantities in landscaping, landscape turf management, and in agriculture. They are also used along highways in maintenance programs to control vegetation, which are called total vegetation control (TVC) programs. Herbicides are also used extensively in the management of wildlife areas, in forestry, and in pasture management systems. They are also used to eliminate or reduce the growth of weeds in lakes. Most widely used herbicides are mixed with water and sprayed with various equipment, such as a container with a pumping sprayer for small garden spray units. Herbicides may also be sprayed in industrial volume. Railroad and powerline right of ways are often cleansed of weeds in this manner. Airplanes or helicopters can also be used to aerially spray a large volume over wide areas. Chemigation is the method for spraying herbicides through irrigation equipment.

Many of the large number of herbicides in use pose potential health effects on humans, some of them serious. Damaging effects can range from rashes to cancer to immediate death. If applicators are not used properly, gardeners or field workers can inhale aerial sprays. Traces of herbicides can also remain on foods and be consumed. Triazine herbicides have been listed as a human carcinogen, linked especially with breast cancer. Low levels of exposure are believed to disrupt endocrine production. The Environmental Protection Agency has issued a warning concerning the danger of high levels of exposure. Atrazine is an herbicide that has been linked to heart attacks, strokes, eye damage, and birth defects.

Aerial herbicide applications are used to control invasive melaleuca trees on large, remote areas of the Everglades.

Agent Orange was used extensively in the Vietnam War by the United States as a defoliant. Between 1962–71, about 20 million gallons of herbicides were sprayed on the jungles in order to expose enemy troop movements on the Ho Chi Mien Trail and other areas. In the process, American troops were exposed in sufficient doses to cause a number of illnesses.

Herbicides have also caused serious ecological damage. Surface runoff of herbicides has contributed to the pollution of lakes, streams, and rivers used as sources of potable water. Fish kills and other downstream negative health impacts have occurred because herbicides leached or were washed into watersheds. Negative effects from herbicides can also come from soil contamination. Many herbicides deteriorate once sprayed onto an area, but others remain for a sufficiently long period of time that they pose a long-term health danger.

Herders

HERDERS ARE PEOPLE whose lives revolve around the tending of animals and who, consequently, tend to have a seminomadic or nomadic lifestyle. They range from shepherds and cowherds who are found in a wide variety of agricultural settings to the reindeer herders of the north to the nomadic steppe tribes of Mongolia and Central Asia. Despite the name, nomadic tends to mean rotation around a set number of locations on a seasonal or yearly basis. Herders tend to have close knowledge of their environments and are aware of exactly where and when their livestock need to transfer to another location. This is based primarily on the exhaustion of existing food stocks in current locations and understanding the length of time needed for them to be replenished. The mobility of nomadic herders means they are capable of responding to environmental change or the prevalence of disease by rapid migration, which means they are less likely to suffer from the mass starvation that can affect more sedentary people, but which also can lead to conflict with peoples into whose territory they are required to move. It has been argued that such environmental change explains the rise of empires such as that of Genghis Khan's Mongols. In any case, herders and nonherders tend to have competing visions for land use, which can only with difficulty be made compatible and cooperative.

As the demands for greater agricultural production and industrialization of the world increase, combined with desertification processes, the space for herders decreases, especially in the case of those living fully nomadic lives. Since they tend to be poorer than sedentary societies, it is likely that they will be settled in some form of reservation in the same way that the Aborigines of Australia and the indigenous peoples of North America have been settled and are likely to suffer from similar social problems. The poverty of herders is both contributed to by, and results from, the low level of infrastructure and education among their societies, although there are exceptions to this. Efforts by the United Nations Food and Agriculture Organization (FAO), among others, to assist herders have often focused on raising their capacity to deal with state-level actors and to negotiate different living patterns with respect both to the environment and to their neighbors. This is necessary because of possible mistrust by government and also by those neighbors whose lifestyle may differ from the herders and who may feel threatened by or antagonistic toward them for historical reasons.

Because herders occupy lands that may be remote from central governments and have low technical capacity themselves, it is difficult to evaluate their numbers accurately.

Hetch Hetchy Dam

LOCATED IN CALIFORNIA'S Yosemite National Park, the eight-mile-long Hetch Hetchy Reservoir supplies the city of San Francisco, 150 miles to the south, with much of its drinking water and electric power. Formed by the construction of the 410-foot O'Shaughnessy Dam on the Tuolamne River where if flows through the steep walls of the Hetch Hetchy Valley, the reservoir represented one of the most massive construction feats of the early 20th century, promising an ample supply of fresh water and power to a city badly in need of both. To advocates of wilderness protection, however, the dam represented a dangerous incursion of the forces of progress into the nation's wildlands. The heated political debate raged for more than a decade, and provided early environmental advocates with their first national rallying point.

Plans for a reservoir in the Hetch Hetchy Valley had been on drawing boards of San Francisco's city planners since the late 1880s, but because the Valley was located within the boundaries of Yosemite National Park (created in 1890), the federal government rejected early requests, claiming the sanctity of the national park lands took precedence over the city's desire for water. Such claims were made much more difficult to support however, when on April 18, 1906 San Francisco was extensively damaged by a massive earthquake. Far more damaging were the many fires that swept the city in the days that followed, and in the ensuing months, Mayor James D. Phelan and other city planners successfully brought pressure to bear on the federal government. In May 1908, Interior Secretary James R. Garfield approved the city's plans for the damming of the Hetch Hetchy Valley.

FURIOUS OPPOSITION

Opposition to the dam project rose almost immediately. Led by Sierra Club founder John Muir and *Century* magazine publisher Robert Underwood Johnson, opponents of the proposed dam called upon the government to hold a firm line against the invasion of national park lands for purposes of progress and profit. Muir and his allies quickly took to referring to Mayor Phelan and other dam supporters "Satan and Company" and "the money changers," openly suggesting that their motives were driven by greed rather than a desire for a stable city water supply. Drowning the beautiful and pristine valley beneath several hundred feet of water in order to provide water and electricity for a distant city was, for Muir, tantamount to the destruction of a holy temple.

Proponents of the dam, including President Theodore Roosevelt's powerful Chief Forester Gifford Pinchot, saw the issue differently. They argued that few people had ever set foot in the remote Hetch Hetchy Valley—or ever would. Damming the valley to create a dependable source of water and power for citizens represented the greatest good for the greatest number of people, and because of this, issues such as aesthetic beauty or the sanctity of the National Parks should be secondary. Further, since San Francisco's current water and electric demands were met by the powerful Pacific Gas and Electric Company, Progressive Era politicians like Roosevelt and Pinchot saw municipal hydroelectric projects like the Hetch Hetchy Reservoir as an important step toward democratizing control of public utilities.

Debate over the dam proposal inspired a heated national dialogue over the proper role of America's wilderness areas. Muir and other wilderness advocates were able to establish Hetch Hetchy as a powerful symbol of the fate of America's remaining wildlands, and the American public seemed for the first time receptive to the notion of protecting these lands. "The conscience of the whole country has been aroused from sleep," Muir wrote. Members of Congress were barraged by letters and telegrams from all parts of the country, as an obscure mountain valley became the centerpiece of a national political debate.

Despite powerful opposition, on December 6, 1913 Congress passed the bill authorizing the damming of the Tuolamne River at Hetch Hetchy. Muir and others who had fought to preserve the valley suffered a crushing short-term defeat, but the Hetch Hetchy controversy had galvanized opposition to further incursion in the nation's wildlands, reversing a centuries-old mindset that unquestioningly valued technological progress over wilderness preservation. Perhaps more importantly, the controversy had given rise to the first stirrings of a national environmental movement.

Highways

HIGHWAYS ARE MAJOR roads used by the public that connect cities, historic or natural sites, or rural locations. There have been trails or rough roads throughout the world for thousands of years. The Roman Empire built highways that in a few cases are still in use. Other empires built similar road systems to aid communications and the movement of troops. In the 20th century, highways were built to facilitate the movement of people, goods, and military forces. The invention and development of gasoline engines that powered trucks, cars, buses and other vehicles led the United States to build highways.

The United States has the most extensive highway system in the world, some of which are county or state roads. Others are part of the numbered highway system. Even-numbered highways start in the east coast and grow in number toward the west coast, such as old Highway 66 (Route 66) one of the first such highways. U.S. Highway 1 runs from Maine to Florida. U.S. highways that run north and south, such as U.S. Highway 11 or 41, are odd numbered. U.S. Highway 101 runs along the California coast from Mexico to Canada.

Other highways in the United States are interstate highways, which are limited-access roads that are fenced to keep animals from crossing and being killed. Every year, millions of animals are killed on the roads in the United States. In Pennsylvania, the number of deer killed by traffic on the highways has in some years exceeded the number of deer killed by hunters in hunting season. The interstate highway system has been built with road grades that allow for high-speed travel. They have multiple lanes of traffic that are separated by a median to reduce the possibility of deadly head-on collisions. However, thousands of people are killed in highway traffic accidents every year around the world.

Highways in the United States are usually funded by gasoline taxes or tolls. Consumers pay two taxes when purchasing gasoline. The federal tax is uniform throughout the whole country and is applied to the Federal Highway Trust Fund, which supports road building in the states and public transportation. State gasoline taxes vary from state to state, and is distributed in the states in a variety of ways. The highway system has been a great boon to travelers, opening regions that can be seen by tourists. However, highways are also an ecological challenge. Every highway covers vast acreage with paving, which is lost to the environment. Highways also use great quantities of materials for paving—crushed gravel, cement, asphalt, fill dirt, metal, and plastics for rails and markings, as well as glass for lighting.

The design of highways is similar in that most have a dividing median and at least two lanes of traffic flowing in opposite directions. However, some have multiple lanes, and use various access controls such as entrance and exit ramps. Some of the world's most magnificent bridges are part of a highway system. In mountainous areas, tunnels permit easy movements where historically travel over high mountains passes was treacherous.

ROAD TO DEVELOPMENT

Highway development is increasing across the world, with China seeing the most rapid expansion. Some highways cross international boundaries. The Alcan Highway (Alaska-Canadian) runs from the United States through Canada to Alaska. It was built during World War II to provide a viable land route to provide protection to Alaska. Many American highways have been built for defense reasons. The law authorizing the interstate system in the United States is officially the Dwight D. Eisenhower National System of Interstate and Defense Highways, modeled after the German Autobahn. Highways have been beautified in many ways. On some, vast beds of flowers have been planted. However, the great increase in highway building has opened many primitive or rural areas to development, in some cases for vacation homes, hunting, or fishing. The opening of a new highway usually attracts businesses to service the needs of travelers, which then causes growth in areas that were previously undeveloped.

In addition to the direct impacts of highways on the environment, roads have far-reaching impacts on wildlife and their habitat. Passing vehicles create noise and chemical pollution that reach far beyond the pavement. By altering the physical environment, roads and highways modify animal behavior. To avoid them, many species shift home ranges, change movement patterns and even reproductive and feeding behaviors. Perhaps the most pervasive, yet insidious impact of roads is providing access to natural areas and encouraging further development. As our cities and towns sprawl across the landscape, more and more wildlife habitat is forever lost to strip malls and parking lots.

Himalayas

THE HIMALAYAN MOUNTAIN range separates the Indian subcontinent from the Tibetan plateau. The name comes from Sanskrit *himalaya*, which means "the abode of snow." The Himalayas stretch across five countries: Pakistan, India, Nepal, Bhutan, and China. It is the highest mountain range in the world and includes all 14 of the peaks above 8,000 meters ASL (the highest peak being Mount Everest at 8,848 meters ASL) and over 110 different peaks higher than 7,300 meters ASL. The Himalaya is one of the youngest mountain ranges in the world, resulting from the continental collision along the convergent boundary between the Indo-Australian Plate and the Eurasian Plate. The collision started in the Upper Cretaceous period about 70 million years ago, when the Indo-Australian plate was moving about 15 centimeters/year. The plate is still moving northward at about 6.7 centimeters/year, which results in the Himalaya rising by about 5 centimeters a year.

The Himalayan range is composed of three nearly parallel ranges, arranged by elevation and geological age. In the south, the youngest of the three is called the Outer Himalayas (also known as Siwalik Range), has an elevation of about 900–1,400 meters ASL, and is about 48 kilometers wide in the west and gradually narrows toward the east, until it nearly disappears in Bhutan and eastern India. Running parallel to this is the Lesser Himalayas (also called the Lower or Middle Himalayas). With an elevation of 2,000–4,500 meters ASL, and a width of about 80 kilometers, it is made up of a mosaic of forest-covered ranges and fertile valleys. The northernmost range, and oldest of the three, is called the Great (or Higher) Himalayas. It is about 24 kilometers wide, and with an elevation of more than 6,000 meters ASL, it is perpetually covered in snow or ice. It is here that the highest peaks are found. Between the Great and Lesser Himalayas there are numerous fertile valleys.

The Himalaya range has an effect on the climate of the Indian subcontinent and the Tibetan plateau. It stops dry cold arctic winds from blowing south into the Indian subcontinent, which causes the subcontinent to be warmer than other regions of that latitude. It also prevents the monsoon winds to travel northwards, limiting rainfall north of the mountain range, and causing heavy rainfall in the Terai region. Within the Himalayas, the climatic conditions vary according to location and elevation. In the southern foothills, average summer temperatures are about 30 degrees C and average winter temperatures about 18 degrees C.

In the Middle Himalayan valleys, average summer temperatures are about 25 degrees C and winters are cooler. In the higher parts of the Middle Himalayas, average summer temperatures are 15–18 degrees C and winters are below freezing. In the Greater Himalayas, at elevations above 4,880 meters, the climate is below freezing and the area is permanently covered with snow and ice. The eastern part of the Himalayas receives heavy rainfall, while the western part is rather dry.

The Himalaya region has hundreds of lakes, the largest of which is the Pangong t'so, which is spread across the border between India and Tibet, at an altitude of 4,600 meters and is 8 kilometers wide and nearly 134 kilometers long. The large number of glaciers in the Greater Himalayas includes the Siachen Glacier, the largest in the world outside the polar region. These areas are the source of several large perennial rivers, most of which combine into two larger river systems, the Indus Basin, and the Ganga-Brahmaputra-Meghna. The Yangtze, the Huang He (Yellow River), the Mekong, and the Salween rivers originate from parts of the Tibetan plateau, which is geologically distinct from the Himalaya mountain range, and therefore are not considered Himalayan Rivers. In recent years, glaciers in the region have retreated because of global warming. If this pattern continues, it will mean disaster for the millions of people who rely on the water from the glaciers during the dry season.

The Himalayas have been a natural barrier for people for millennia. The difficulty in traveling between the Indian subcontinent and China has prevented frequent contact, and has contributed to the significant differences in language and customs between these two regions. The Himalayas have also obstructed the development of trade routes, and limited the trade between the Indian subcontinent and its neighbors north of the Himalayas. The height and difficulty in traveling across the Himalayas range also prevented military expeditions. For example, Genghis Khan could not expand his empire south of the Himalayas.

Close to 40 million people inhabit the Himalayas, most of which are subsistence farmers with very low incomes. Agricultural land is concentrated in the Tarai plain and in the valleys of the Lesser Himalayas. Patches of agricultural land have also been carved out in the forested areas. However, cold winters and a short growing season limit the cultivation to one crop per year, most commonly potatoes, barley, or corn—except in the Tarai plain, where rice is grown in well-watered valleys. Economic changes and population growth are causing various environmental problems, such as deforestation in the foothills of the Lesser Himalayas, and overgrazing on the high pastures.

There are dozens of different ethnic groups in the Himalayas. Generally, however, the Outer Himalayas and the Lesser Himalayan valleys from eastern Kashmir to Nepal are inhabited by Hindus of Indian heritage. The Great Himalayas from Ladakh to northeast India are predominantly inhabited by Tibetan Buddhists. In the middle regions in central Nepal, at elevations between about 1,800–2,500 meters ASL, the Indian and Tibetan cultures have intermingled, resulting in different religious traditions with combinations of Indian and Tibetan traits.

Hiroshima

IN THE CLOSING days of World War II, President Harry Truman made the decision to approve the release of atomic bombs over two Japanese cities to force Japan to surrender after Germany surrendered on May 7, 1945. In addition to the 115,000 deaths that occurred at Hiroshima and Nagasaki, there have been major long-term environmental consequences that continue to be assessed. Cities with large civilian populations were specifically chosen for the attacks to increase the impact of the action so that Japan would be left with no choice but to end the war that caused the deaths of some 62 million people. The decision was effective; within a week, Japan surrendered unconditionally. Nevertheless, the use of atomic weapons has remained one of the most controversial actions in American history. Critics argue that the war would have ended shortly without the use of atomic bombs. Others insist that the blame for the bombing lies not with Truman but with Emperor Hirohito, who delayed surrender, hoping that the Soviet Union would come to Japan's aid.

Truman insisted that his decision was based on a desire to save American lives, and there is strong evidence that the Japanese had pledged to take out another 1 million Americans if Japan were invaded.

In addition to millions of casualties, Japan committed horrific atrocities on prisoners of war, civilians, and internees that included starvation, beatings, torture, rape, and burns. Because the Japanese destroyed most records in the days before the surrender, accurate tallies of atrocities and fatalities are not available, but it is estimated that some 130,000 Chinese were killed by the Japanese.

President Truman and his advisors had chosen the Japanese cities of Hiroshima, Nagasaki, and Kokura as possible targets for the bombs, depending on the weather. On the morning of August 6, 1945, the *Enola Gay* dropped a 10,000-pound uranium-fueled bomb, designated "Little Boy," on Hiroshima, a city of 250,000 people. Immediately, there was a flash of brilliant purple light. The resulting fireball covered a radius of 230 miles (370 kilometers) and raised the temperature immediately below it to 3,000 to 4,000 degrees C. Dust covered the city, where 90 percent of buildings were destroyed. Within minutes, half the population was dead or dying. Initially, deaths occurred as a result of the explosion, fires, and falling debris. Because there was no precedent for dealing with radiation, nothing was done to prevent others from entering Hiroshima in the days following the attack. For up to two weeks, radiation levels remained lethal and were present in the air and soil for an unspecified period.

After the attack, the Japanese and American governments began collecting data on *hibakusha* ("explosion-affected persons"). Because the data was classified, it was not until seven years later when the Americans pulled out of Japan that the full consequences of the bombs became known to the general population. Scientists identified what came to be called "atom bomb disease" because people were dying with no clear reason for their illnesses. Most of these victims died within four months of the attack.

By 1948, the Atomic Bomb Casualty Commission (ABCC) had been designated as the major American research arm of the Hiroshima followup, and scientists began conducting genetic testing on 70,000 children who had survived the attack. Tests revealed higher than normal incidences of conditions that included "radiation cataracts," certain cancers, blood disorders, and birth defects. Incidences of leukemia were particularly persistent, revealing that those who had been within two-thirds of a mile (one kilometer) of the blast were 150 times more likely to develop the disease than were those in the general population. In 1975, the United States and Japan formed the Radiation Effects Research Foundation

Wilfred Burchett

Wilfred Burchett (1911–80) was an Australian journalist and the son of a Methodist law preacher. In 1936 he moved to London and worked at a travel agency, being briefly involved in helping with tours of the Soviet Union. He subsequently moved into journalism and reported on the uprising against the Vichy French on the South Pacific island of New Caledonia. When the Japanese invaded Burma in December 1941, he then reported on Burma, writing several books on his experiences there.

In 1945 Burchett went to Japan, and traveled by train to Hiroshima, arriving on September 2, the day after the formal surrender of Japan on the U.S.S. *Missouri*. Burchett was the first Westerner to arrive in Hiroshima after the bombing and was horrified by what he saw. He sent his report by Morse code to the *Daily Express* newspaper in London. Entitled "The Atomic Plague," it was the first report to mention the effect of nuclear fallout and radiation sickness. It is also thought that Burchett might have contracted some radiation himself during his reporting.

Burchett continued to be a journalist for the rest of his life, managing to get access to the trials of Eastern European Communist leaders during the last years of Stalin. He also reported from the Communist side in the Koreas and in Vietnam. Burchett was accused of working with the communists, which was accentuated by his articles about the Soviet advances in science and economic reconstruction.

Always a controversial figure in his native Australia, Burchett fought a long battle with the Australian government about their refusal to issue him another passport after he lost his original. The author of many books, Burchett died in Sofia, Bulgaria.

to replace the ABCC and charged it with continuing the study of long-term effects of radiation on *hibakusha* and their descendants.

Historical Materialism

HISTORICAL MATERIALISM IS a methodological and explanatory framework for understanding social, political, and environmental conditions and change, based in the thought of Karl Marx. It suggests that the various forms of human institutions and social organization are dependent upon the "production of material life" in communities, and is described most famously in the preface to his *Contribution to the Critique of Political Economy* of 1859. There, Marx calls the ensemble of the material "productive forces" and their corresponding relations of production, as they exist at any one place and point in time, a "mode of production," and offers as examples "Asiatic, ancient, feudal, and modern bourgeois [capitalist]." Historical materialism is thus an explicitly materialist theory of history, for each of the social formations that make up the diversity of human history, "the social, political and intellectual life process in general" will be conditioned or derived from the "mode of production of material life."

The approaches to these relations we know today as political ecology, environmental sociology, and political economy of the environment would be unthinkable without historical materialism. The fundamental object of analysis in the environment–society relation is change: How does human life affect its environment (nature), and how does the environment affect human life? The way in which the mutual shaping of environment and society is critically approached today was largely rejected, even unthinkable, in the intellectual climate from which Marx emerged.

EARLY BEGINNINGS

Marx developed his theory of history as a critique of the idealism dominant in Germany when he began his career. Idealism asserts that human consciousness is independent of the world in which it exists. Within environmental constraints, human life is seen to be a product of human ideas, not of the material ways in which that life is lived. However, historical materialism shares G.F.W. Hegel's idea of historical "development." Hegel argued that society developed through the progressive overcoming of contradictions in human consciousness. Marx agreed with that assumption, but felt that "It is not the consciousness of men that determines their being, but, on the contrary, their social being that determines their consciousness." For Marx, what people are even capable of comprehending is a product of their material–historical life. An approach like political ecology, which attends to the myriad ways in which the environment is both a site of politics and highly politicized, is unimaginable without this central tenet.

Although Marx did not use the term *historical materialism* himself, there are several key ideas upon which historical materialism depends. The most contentious of these is the so-called *base-superstructure model*. Marx claimed that the "sum total of these relations of production constitutes the economic structure of society, the real basis, on which rises a legal and political superstructure and to which correspond definite forms of social consciousness." Also at issue is the process of social change. Marx argues that "at a certain stage of their development, the material productive forces of society come in conflict with the existing relations of production." This dynamic has massive repercussions for individual and collective life, since during "the change of the economic foundation the entire immense superstructure is more or less rapidly transformed." Further, Marx states the "epoch of social revolution" is driven by the "conflict between the social productive forces and the relations of production," which transforms "the legal, political, religious, aesthetic or philosophic—in short, ideological forms in which men become conscious of this conflict and fight it out."

This is the only place in Marx's huge corpus that he uses the terms *basis* and *superstructure*, but the idea has over time become the most widely known formulation of historical materialism, and is the main support for the many who claim Marx was an economic or technological "determinist." Many scholars of historical materialism reject these simplistic accusations. Marx makes it clear that the economic structure or base is not technology, but the social relations of the production of human life. For Marx, human life is produced at many sites like the home, the school, and what he called "nature."

Historical materialism has been crucial in informing a wide range of work on social and environmental change: Fernand Braudel is concerned with the slow, massive changes in human and biophysical landscapes; Piers Blaikie or Michael Watts with the vicious spiral of exploitation, environmental decay and social immiseration; and O'Connor with the inevitable crises precipitated by capitalism's destruction of nature. But in each instance, the conceptual framework is an environmentally sensitive historical materialism.

Marx sometimes described these dynamics as a struggle to subdue or control nature, and sometimes historical materialists do present human history in this manner. More often, however, what is at stake in historical materialism is the way in which it presents analytical categories for rigorous, engaged, socioenvironmental research. In other words, base–superstructure or environment–society can seem an overly simplistic relational model. But if we think of it as the name of a problem, as Fredric Jameson suggests, then we open up enormously productive avenues for thinking about how and why societies and their environments interact the ways they do.

History, Environmental

ENVIRONMENTAL HISTORY IS a study that intrinsically deals with nature and the human being, and the previous interactions between them. In order to understand the changing environment of present and future, it is essential to know about the environmental past. The environmental issues we are confronting today reflect diverse complexities whose roots are both natural and human.

A rapidly increasing interest in the phenomenon of the global environment has developed in the last two decades, along with a belief by some that we have entered an era of environmental crisis. This has stimulated a wider array of academics, scholars, and policy makers to reevaluate their concerns with a more ecological focus.

The prime goal of environmental history is to deepen our understanding of how humans have been affected by the natural environment in the past and how they have influenced that environment and with what outcomes. It provides a landscape record for scientists who intend to understand the current ecological system by learning about the past environmental framework.

Environmental historians typically address three clusters of issues. The first is concerned with the human intellectual realm, which comprises perceptions, ethics, laws, myths, and other mental constructions related to the natural world. The second area is the socioeconomic realm, which has an implication on politics, policies, and the economy through which these notions materialize in the natural world. The third area is environmental history, which concerns understanding nature itself, that is, the natural realm.

In the case of woodland history, environmental history is concerned with the way forest ecosystems have been working in the past, and how they were changed by human actions. The influence of human actions on the natural world causes a feedback that changes our ideas, policies, and economy. Within this structure, we attempt to alter reactions we do not like and continue practices, which in our view, are successful; this model depicts the separation between humans and nature. Although this division is an artificial one, it can be a useful tool for the environmental historian in identifying some key questions, the sources that might be able to answer the questions, and the methods utilized to study these sources.

BUDDING DISCIPLINE

Environmental history is a rather new discipline that came into being during the 1960s and 1970s. It was a direct outcome of the growing awareness of worldwide environmental challenges such as pollution of water and air by pesticides, depletion of the ozone layer, and the theory of a greenhouse effect caused by human activities. In this development, historians started to look for the origins of the contemporary problems, drawing upon the knowledge of a whole field of scientific specialization that had been cultivated during the preceding century. In modern environmental history, ecological concepts are used to analyze past environments and geography utilized to study the ever-changing face of the earth. At the beginning of the 20th century, geographers stressed the influence of the physical environment on the progress of human society.

Two other roots of environmental history are archaeology and anthropology, of which the latter introduced ecology into the human sciences. The emergence of world history put forward interdisciplinary and continental-wide, even world-scale, studies into history. Ecology and the interdisciplinary method later became two prominent features of environmental history.

Evidence of environmental issues is reflected in manuscripts, publications, and historical archives, under labels like public health, nature conservation and preservation, smoke abatement, municipal housekeeping, occupational diseases, water pollution, and air pollution. Most environmental historians have focused on regional or national affairs. Some of these richly illustrated studies trace how the

Field Studies

The field study in environmental history encompasses analysis of data on tides, winds, ocean currents, the position of continents in relation to each other, and geology, as well as covers the history of climate and weather and the pattern of diseases. Environmental history is also the story of human exploitation of the natural world, such as the consequences of agriculture on soil and landscape; the history of forests; the effects of hunting and grazing; and the environmental impact of mining, transportation, urbanization, and industrialization. Furthermore, environmental history is about unmasking myths and distorted perceptions of the past to make appropriate decisions to handle these problems.

Environmental historians sometimes need to apply some principles from the natural sciences like ecology, biology, and forestry to grasp events that happened in the past. However, the ongoing valuation of environmental criteria is different from those used in the past, which poses a threat to the way we interpret and value the past because the facets of sustainability, equilibrium systems, and biodiversity are modern ones. Environmental historians need to be aware that the present and its challenges influence how we perceive the past, and to recognize the historically defined character of values and ideas in historical sources.

natural impulses and resources have shaped societies on a global scale. The use and subsequent abuse of landscapes frequently crosses arbitrary political–cultural boundaries and even continents and oceans.

Some of the broadly shared historical processes that sped environmental change from roughly 1500 to 1800 C.E. include intensified human land use along settlement frontiers, biological invasions, commercial hunting of wildlife, and problems of energy scarcity. These issues are reflected in the case studies of specific places and activities such as the fur trade in North America and Russia, cod fishing in the North Atlantic, and whaling in the Arctic, as well as studies showing how humans altered the material well-being of the natural world through clearing forests; draining wetlands; transporting bacteria, insects, and livestock; hunting species to extinction; and reshaping landscapes.

In equally unprecedented and dramatic ways, humans are extending their reach and their numbers as they intervene in the world's natural environment. Despite the fact that environmental issues have become one of the most substantial parts of the global social fabric, there has been little historical aspect on environmental history until recent times.

The early period of environmental history can be divided into three distinct phases: Ancient Civilizations, Middle Ages and Renaissance, and Enlightenment.

ANCIENT, MIDDLE AGES, RENAISSANCE

In Ancient Civilizations, air pollution was common in large towns long before the Industrial Revolution. The pollution came from dust, wood smoke, tanneries, animal manure, and other things. Israeli and Hindu cities tended to have less water pollution due to strict religious codes about cleanliness. On the other hand, ancient Rome was notorious for sewage-filled streets. Furthermore, timbering stripped the forests of Babylon, Greece, Phoenicia (Lebanon), and Italy with the rise of civilization. While the wood energy crisis led Greeks to use passive solar energy by orienting their cities and houses toward the sun, Romans made some use of solar energy but imported wood for timber and fuel from as far away as the Black Sea. Both Greeks and Romans kept sacred groves of trees from being timbered.

During the Middle Ages and Renaissance, plague devastated Europe, but led to the beginnings of a public health system. Timbering in the forests of England, France, and Germany left large tracts totally denuded by around 1550 in England and the 1600s in Europe, forcing a switch to coal. In this period, soil conservation was not widely practiced in the Mediterranean, but cultures in China, India, and Peru understood the long-term effect of soil erosion and used terracing, crop rotation, and natural fertilizer to prevent it. Further, occupational diseases were investigated and began to be recognized as public health problems.

ENLIGHTENMENT AND PROGRESSIVE ERA

In the era of Enlightenment, reason began to be better appreciated as an antidote toward superstition. Ben Franklin's fight against water pollution, James Lind's fight against scurvy, and the movement to clean up slums and prisons started with an enlightenment philosophy that held individual citizens to be valuable. Nonetheless, food and resources ran out as populations exploded. Over time, new technologies created new pollution: town gas from coal dripped tar into the rivers, vulcanized rubber plants discharged noxious chemicals directly into streams, and coal smoke choked the air in big cities. In addition, chemical factories operated without thought to people downwind.

During the Industrial Revolution, living conditions in urban areas horrified reform-minded commissions in London in the 1840s and America in the 1850s and 1860s. While progress had been slow, the common interest in pure drinking water and sanitation was spurred by epidemics of typhoid and cholera. John Snow, a London physician, traced a part of the cholera epidemic to a contaminated water pump in 1855. Smog episodes also started killing residents of big cities like London. Moreover, conservation of wilderness areas began with the felling of an enormous tree, called the "Mother of the Forest" in 1851. The outrage over the act led to calls for a national park system.

In the Progressive Era, reforms were made in working conditions, slum housing, food adulteration, sanitation, drinking water, polluting industries, and more. Although U.S. President Teddy Roosevelt and forester Gifford Pinchot characterized the era with ideas about conserving large tracts of land and putting other forests to "wise use," John Muir opposed the wise use idea and fought for outright preservation of unspoiled wilderness. A number of new organizations like Women's Club and Sierra Club helped champion natural conservation and municipal reforms as well.

During the 1920s and 1930s, the National Coast Anti-Pollution League was formed under the auspices of municipal officials from Atlantic City to Maine, who were concerned about oil and sewage pollution detracting from tourism. Led by Gifford Pinchot, the league succeeded with an international oil dumping treaty passed by Congress in 1924. Radium Girls were dying of radiation-induced cancer, and court delays seemed outrageous to crusading journalist Walter Lippmann, who worked with Alice Hamilton to bring their case to the public. A settlement at least gave them medical care and compensation for their families. Over this time, while the Civilian Conservation Corps was founded by President Franklin D. Roosevelt during the Depression, the chemurgy movement was a Midwestern populist phenomenon. The major demands of this movement included replacement of petroleum with farm alcohol and other industrial uses for agricultural crops.

During the 1940s and 1950s, American development of synthetic rubber was blocked and leaded gasoline technology was handed over to the Nazis during the prewar honeymoon, and Midwestern corn helped roll allies to victory over the Nazis. Synthetic rubber and chemicals from renewable resources proved vital to winning World War II. The Sand County Almanac by Aldo Leopold, published in 1948 just after his death, expressed an expanding sense of human responsibility, not only for each other but also for the earth. Further, deadly smog episodes in London in 1952 and 1956, in New York in 1953, and Los Angeles in 1954 created the perception that an air pollution crisis was underway. While in 1955, the first international air pollution conference was held, increasing carbon dioxide buildup was one surprising conclusion of Scripps

A wire mill freely spewed smoke along the Monongahela River in Donora, Pennsylvania, in 1910. In the Progressive Era, reforms were made in working conditions, slum housing, sanitation, drinking water, polluting industries, and more.

Oceanographic Institute scientists working on International Geophysical Year projects 1957.

Throughout the 1960s and 1970s, the emergence of the field of environmental history was tied with the rise of the ecological and environmental movements. Rachel Carson's book *Silent Spring* (1962) struck a deep chord in the quickly increasing concerns about the environment. Another notable event took place in 1962: General Motors and Standard Oil (Exxon) sold off the Ethyl Corporation, the child of their partnership in leaded gasoline. The truth about leaded gasoline emerged dramatically in 1965 Senate hearings as scientist Clair Patterson testified about the obvious and apparently deliberate falsehoods in lead industry research. A burning river ended the decade as a dramatic symbol of an environment on the brink. Furthermore, oil and chemicals in the Cuyahoga River in Cleveland, Ohio caught fire in 1969.

BIRTH OF THE EPA

A decade of awakening and cleanup began during 1970-80 with the birth of the Environmental Protection Agency (EPA) and ended with the Appropriate Community Technology demonstration on the Washington Mall. Air pollution was cut back dramatically through use of catalytic converters on new cars that used only unleaded gasoline, but the predicted "pollution free car" proved to be chimerical. During this decade, water pollution was also severely decreased through a massive sewage treatment expansion program. The rivers that were once sewers now began a gradual return from the grave. In addition, toxic chemicals became more troubling. Corporations like Allied (manufacturer of Kepone in the United States) seemed to have deliberately endangered employees and the public for minor increments of profit. During the 1980s, Love Canal and other incidents also led to new regulations. While nuclear power safety was increasingly suspect after the Three Mile Island accident, energy crisis in oil supply led to reversals of some restrictions on refinery and oil pollution.

During the decade 1980–90, disasters showed the tenuous and fragile side of industrial technology. Among them included the Bhopal mass poisoning in India, the Chernobyl nuclear reactor disaster in Ukraine, and the Challenger shuttle explosion and the Exxon Valdez oil spills in the United States. Ozone depletion from fluorocarbons was ultimately taken seriously by world leaders, signified by the signing the Montreal Protocol in 1987. The legislation for cleaning up toxic waste passed Congress as well. In this decade, environmentalists gathered momentum.

Between 1971 and 1991, environmental policies began to have an increasing impact on trade. The impacts of trade on the environment had also become more widespread. This led to huge discussions and debates. For example, in 1987, the World Commission on Environment and Development (WCED) produced a report entitled *Our Common Future* (also known as the Brundtland Report), in which the term *sustainable development* was coined. The report identified poverty as one of the most important causes of environmental degradation, and argued that greater economic growth, fueled in part by increased international trade, could generate the necessary resources to combat what had become known as the "pollution of poverty."

As a result of these developments, the proposal of the Group on Environmental Measures and International Trade (EMIT) met with a positive response. Despite some countries' initial reluctance to have environmental issues discussed in the General Agreement on Tariffs and Trade (GATT), they agreed to have a structured debate on the subject. In accordance with its mandate of exploring the possible implications of environmental protection policies on the operation of the General Agreement, the EMIT group focused on the effects of environmental measures (such as eco-labeling schemes) on international trade, the relations between the rules of the multilateral trading system, the trade provisions contained in the multilateral environmental agreements (MEAs), and the transparency of national environmental regulations with an impact on trade.

A number of important events occurred during the contemporary epoch (1990–present). The Persian Gulf War saw environmental disaster when retreating Iraqi troops set fire to hundreds of oil wells. Ken Sara-Wiwa, a journalist and environmentalist, was executed in 1995 for his outspoken opposition to oil industry practices of Shell Oil in Nigeria. In the

United States, political standoff between conservative and liberal factions in Congress ended more or less in a draw. In addition, despite international protests, construction of China's Three Gorges Dam continued on schedule. Retiring President Bill Clinton set aside 58 million acres of forest and wilderness by the end of his presidency, beating the previous conservation record set in Teddy Roosevelt's administration.

The activation of the EMIT group was followed by further developments in the environmental forums. The 1992 United Nations Conference on Environment and Development (UNCED), also known as the Rio "Earth Summit," drew attention to the role of international trade in poverty alleviation and in combating environmental degradation. Agenda 21, the program of action adopted at the conference, addressed the importance of promoting sustainable development through, among other means, international trade. The concept of sustainable development established a link between environmental protection and development at large.

In most recent years, utility deregulation led to severe price spikes, consumer resentment, and a rethinking of electric utility deregulation. Another phenomenal issue is that poisoning emanating from leaded gasoline is being acknowledged to be crucial in developing countries by the World Bank and World Health Organization (WHO), while a step-by-step switch to other additives ultimately gets underway.

Environmental history is a resourceful collection of inquiries into the transformation of the natural world by human actions and the aftermaths for both nature and people. In a nutshell, it is a relatively new area of inquiry, but one that has much to offer.

Honduras

THE AREA THAT would become Honduras was home to the precolonial city of Copan. The ecology of the region was heavily modified by its pre-Columbian residents, though with the decline of the Classical Mayan civilization, the area was reclaimed rain forest and jungle. The country was later colonized by Spain, but not without the resistance of indigenous Lenca peoples of the central highlands. Following independence in 1821, the country fell under the influence of a number of large plantation-based corporate interests, including United Fruit. The unequal trade relationships and land management initiated in this period had a lasting effect on the socio-ecology of the country even into the late 20th century, when insurgency wracked the country.

The Republic of Honduras is one of the poorest countries in the Western Hemisphere, and 53 percent of the people live in poverty. With a per capita income of $2,900, Honduras is ranked 160th in world incomes. Inequality is rampant, and the richest 10 percent of Hondurans hold 42.7 of national resources. Some 28 percent of the population is unemployed. Around 61 percent of rural Hondurans are engaged in the agricultural sector, and workers involved in agriculture, forestry, and fishing make up one-third of the labor force. Honduran natural resources include timber, gold, silver, copper, lead, zinc, iron ore, antimony, coal, fish, and hydropower; but resources have been overexploited.

Honduras borders the Caribbean Sea and the Gulf of Fonseca in the North Pacific Ocean, resulting in a coastline of 508 miles (820 kilometers). The well-known Mosquito Coast is located along a section of the Caribbean border. Honduras is mountainous with a narrow coastal plain. The climate varies from temperate in the mountains to subtropical in the lowlands. Dry and rainy seasons are unpredictable. The Caribbean coast of Honduras is subject to damaging hurricanes. In 1998, for example, Honduras was devastated by Hurricane Mitch, which took the lives of some 5,600 people and racked up around $2 billion in damages. Although earthquakes are common, they tend to be mild.

The population of 6,975,000 has an increasing rate of HIV/AIDS (1.8 percent) that contributes to lower-than-average life expectancy (69.3) and growth rates (2.16 percent) and to higher than average infant mortality (29.32 per 1,000 live births) and death rates (6.87 deaths/1,000 population). Some 10 percent of the population lacks access to safe drinking water, and 32 percent have no access to improved sanitation. The United Nations Development Program (UNDP) Human Development Reports rank Honduras 116th out of 232 countries on general quality-of-life issues.

The urban population of Honduras is expanding, producing an increase in environmental problems. Massive deforestation is a result of logging and frequent clearing of land for agriculture. Mining, uncontrolled development, and poor agricultural management have led to land degradation and soil erosion. Water pollution is widespread in freshwater sources such as Lago de Yojoa and in rivers and streams. In 2006, scientists at Yale University ranked Honduras 52nd of 132 countries on environmental performance, in line with the relevant geographic group and well above the relevant income group.

In the 1940s, Salvadorans initiated a cotton boom in Honduras that led to the displacement of small farmers. During the 1960s, forests were destroyed to provide pasture for the growing livestock industry. In 1969, the "Soccer Wars" led to the expulsion of Salvadorans as Hondurans reclaimed their land. Both the Salvadorans and the Hondurans engaged in poor agricultural practices, using DDT, dihedron, toxaphono, and parathion. A 1981 study revealed toxic levels of pesticides in the bloodstreams of the population and in surface and groundwater. The production of cotton left a lasting legacy of soil depletion and erosion, increased numbers of harmful insects (leading to greater amounts of pollutants), and land and water contamination.

ENVIRONMENTAL COMPOSITION

Forests that range from montane to rain forests make up 48.1 percent of Honduras. Honduras is losing more forests than any other country in Latin America; from 1990 to 2005, 37.1 percent was lost. The government protects only 6.4 percent of the land, including the Tigra Cloud Forest Park near Tegucigalpa and the Copán National Park, where Mayan ruins are located. The Río Plátano Reserve has also been set aside to promote greater biodiversity, and ecotourism is viewed as a way to preserve the coral reefs of the Islas de la Bahía. Ten of 173 endemic mammal species are threatened, and five of 232 endemic bird species are in endangered.

During the 1980s, environmental groups organized, but internal corruption in the 1990s resulted in a withdrawal of international funding. The Ministry of Natural Resources works with a number of agencies to implement and enforce a body of laws that promote protection, conservation, restoration, and sustainable development. Enforcement of environmental laws has been difficult, due in large part to a lack of funding. Honduras participates in the following international agreements: Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, Tropical Timber 94, and Wetlands.

Hoover Dam

THIS MASSIVE DAM in the Black Canyon of the Colorado River, on the border of Arizona and Nevada, was built between 1931 and 1936, with a large hydroelectric plant generating electricity for many parts of Arizona, California, and Nevada.

Ideas about damming the Colorado River were realized in the early 20th century to solve two problems. The first was that there were regular floods when snow from the Rocky Mountains melted and the rising river levels would cause floods in farming communities; and the second was that a dam could also provide water for the growing city of Los Angeles, and the nearby areas. The major initial problem was that Arizona and Nevada felt that California would probably take up too much water, so the result was the forming of a commission in 1922 with the state governors of Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming meeting to agree on what became the Colorado River Compact, signed on November 24, 1922. Six years later it was finally approved by Congress, and signed into law by Calvin Coolidge. However the first money set aside by the federal government was not allocated until July 1930 when Herbert Hoover was president. A Congressional Act on February 14, 1931, had made the name *Hoover Dam* its official name.

The building of the dam coincided with the start of the Great Depression, and the construction schedule was advanced by the government to provide employment, with a new town called Boulder City established nearby. Work then began on diverting the river from its course, to allow for work to begin on the dam. This saw two massive diversion tunnels built, causing the river to change route. On June 6, 1933, work began on the dam itself. As no project of this size had ever been attempted before,

Elwood Mead

Elwood Mead was a professor, politician, and engineer who oversaw many major projects as the head of the Bureau of Reclamation from 1924 until 1938, including the Hoover Dam.

Elwood Mead was born in 1858 at Patriot, Indiana, and went to Purdue University, graduating with a science degree. He then gained his doctorate in civil engineering from Iowa State College, and taught mathematics at Colorado Agriculture College from 1883–84, and again from 1886–88. In 1888 Mead was appointed the territorial and state engineer of Wyoming, and drafted the water laws for both Wyoming and Colorado, becoming the chairman of the State Rivers and Water Supply Commission in Victoria, Australia, in 1907.

Returning to the United States in 1915, he became professor of rural institutions at the University of California, and then chairman of the California Land Settlement Board. In 1924 he was appointed chairman of the Bureau of Reclamation. It was in that position that he oversaw the building of the Hoover Dam, and also the Grand Coulee and Owyhee Dams.

Mead had a great interest in plans developed by Zionists to irrigate and develop British Palestine, and Mead went there twice: in 1923, and again in 1927. He married twice and had six children. He died in 1936.

there were worries about the stressloading of the concrete. Furthermore, some of the loose rocks on the canyon walls had to be removed in case they fell at a later date. This resulted in men having to scale the rock-face and work in extremely hazardous conditions. In fact, by this time there was massive controversy around the project itself, over its safety record, the low wages for the workers, their poor housing conditions and the lack of facilities for their families.

The dam was completed on March 1, 1936, and by October 26 of the same year was providing energy for Los Angeles. Controversy dogged its name—it was called the Boulder Dam until the death of Franklin Roosevelt, but was renamed the Hoover Dam by Harry S Truman. The dam is 1,244 feet long, and 726.4 feet high, making it the second highest dam in the United States. It contains 4.36 million square yards of concrete, is 660 feet thick at its base, and 45 feet at the crest.

Huang Ho (Yellow River)

THE ORIGIN OF the Huang Ho, also known as the Yellow River because of the voluminous ochre-colored sediments suspended in its lower course as it meanders through the North China Plain, is in two glacial lakes in the Bayankala Mountains in western China's Qinghai Province. The river begins its 3,400 mile journey by flowing east out of the high elevations and then making an abrupt turn to the north at the city of Lanzou. From this point the Huang Ho begins its circuit around the Ordos Desert, turning to the east and coursing through Inner Mongolia before heading south to its junction with the Wei Ho. At this point the river turns to the northeast and completes its final leg across the North China Plain and empties into the Bo Hai. The river has been alternately called "China's Sorrow" and "China's Pride."

The Sorrow designation is associated with the extensive losses of human life through massive flooding of the relatively shallow river at times in the past. Historians estimate that the severe floods in 1887 and 1931 resulted in the death of between two and six million people as the waters breached the man-made levies and spread quickly across the land.

The invocation of Pride relates to the role of the Huang Ho in agricultural development throughout the centuries and archaeological evidence that the origin of the Chinese civilization can be traced to the area surrounding the confluence of the Huang Ho and Wei Ho. This extremely fertile area is identified as one of the earliest culture hearths and clearly the agricultural region of longest continuous operation in the world. This agricultural center lies at the southern edge of the Loess Plateau, a region of highly fertile soil.

Loess is wind-deposited fine particulate matter deposited by winds coming across the Ordos Desert to the northeast. These winds are slowed just enough by the Tien Shan, a low mountain range south of the Loess Plateau, to allow the deposition of airborne material. Over the centuries, the accumulation of loess in some areas reached 200 feet in thickness. In some parts of the plateau, agriculturalists actually established homes within loess caves, a practice that proved disastrous during major flooding.

There is considerable concern about the fate of the Huang Ho because of a severe drought in the mountainous area where the river originates. The glaciers in the area are receding and the groundwater sources for the river are getting lower. Both of these negative outcomes have been attributed to global warming. Consequently, water availability at points downriver has been diminished. This unfortunate outcome impacts agriculture productivity, which has been a mainstay of the region for millennia. Another, more direct negative impact on the Huang Ho has been the incredible expansion in economic activity along the river and the growth of large urban places where none had existed before the era of rapid and prolonged industrial expansion. In order to meet the needs of agriculture and industry in northern China, there are plans to divert water from the Yangtze River to the Huang Ho through two major man-made canals. Water pollution is widespread within the lower course of the river as industrialization continues its virtually ceaseless expansion while demands for increased agricultural output also expands to keep pace with the growing Chinese population.

Air pollution in the industrial sector, associated with the burning of coal, contributes significantly to the environmental woes of China. The country ranks second only to the United States in the amount of carbon dioxide emitted to the atmosphere. With the Kyoto Protocol not requiring China to reduce emissions, China has been able to expand its industrial base almost at will. As the country's goal, is to develop its economic structure as quickly as possible before the ultimate reductions in working-age individuals necessary begins to fall, the Huang Ho and other areas of the environment will continue to be degraded.

Human Ecology

HUMAN ECOLOGY IS the study of the mutual interconnections between people and their environments at multiple scales and multiple time frames. The subject is informed by ecological and evolutionary theory in biology and by the concepts of landscape and spatial relationships in geography; but recognizes that humans have gradually achieved partial ecological and geographical dominance through their culturally given but continually changing technology and social, economic, and political arrangements. Human ecology subsumes such specialized approaches to these relationships as cultural ecology, political ecology, geography, ecological anthropology, environmental sociology, environmental economics, environmental psychology, and environmental history.

DRAWING ON HISTORY

Although the neologism "ecology" dates from the second half of the 19th century and the term *human ecology* first appeared around 1908, interest in human environment relationships goes back much farther. For example, the ancient Greeks were concerned with the impact of the environment on human health (*On Airs, Waters, and Places* was written by an anonymous author in the Hippocratic tradition). Plato speculated on the role of humans in reducing the forest cover of Greece. Such cartographers and geographers as Ptolemy and Strabo recognized spatial differentiation. Similar traditions existed in other ancient societies such as China.

Saint Francis's teachings suggested that humans could not consider themselves completely separate from and superior to nature. Chinese philosophy, poetry, and art, building on a base of shamanism, Buddhism, and Taoism, also stressed the relationship between human consciousness, society, and nature. These traditions include little in the way of systematic observation, however, or experimental testing of relationships. One important exception has been the development of agronomy, range science, and forestry based on long-term observations on soil fertility and pest management on the local scale. In societies with a written tradition, this has often resulted in a sophisticated literature; but even in societies with an oral tradition, the resulting "ethnoscience" has often been remarkably insightful. Another important exception has been the almost universal tradition of mapping surroundings using a variety of cartographic methods.

Beginning in the 15th century, European expeditions of discovery and conquest led to some of the first field-based systematic and comparative observations of human–environment relationships at a larger scale. Observers such as Cieza de León (who accompanied the conquerors of the Inca Empire) produced detailed geographic accounts of landscapes, land use, and resource management that are still used by human ecologists documenting environmental history. Colonial authorities produced detailed reports of local resource use (such as the *relaciones geográficas* in the Spanish empire), as well as maps at a variety of scales. European advances in census taking, in both Europe and its colonies, helped John Graunt and Edmond Halley develop some of the basic analytical methods of demography by the 18th century. At the end of the 18th century, Thomas Malthus pointed out the importance of the population resource ratio and warned of the persistent danger of societies overgrowing their resource base.

BIRTH OF THEORIES

Alexander von Humboldt represents the culmination and transformation of the tradition of colonial observers of resource management. His diaries and books based on his travels through the Americas at the end of the colonial period details climate, plants, animals, population, resource management methods, and even archaeology, utilizing the most advanced instruments and collection methods of his time. Moreover, he correlated his results using maps and diagrams, generalizing about both the environmental and political conditions of resource management. He also pointed out in detail the many impacts of colonial policy on resource use. He argued for an expansion of economic freedom, recognizing the importance of state intervention, and argued for a more local level of colonial administration.

Later, 19th century travelers and scientists such as Darwin, Wallace, Bates, and da Cunha further developed ideas essential for the later development of human ecology. Darwin was inspired by Humboldt to perform detailed fieldwork in South America, and was influenced by Malthus in his development of the theory of natural selection in diverse environments to explain the diversity of species. The application of Darwin's ideas to human affairs was at first crude, but by the beginning of the 20th century was an important influence on scientific human ecology. In human ecology, the concept of adaptation did not refer to the survival and reproduction of genetically heritable traits, but rather the continual process of choosing among and refining strategies of making a living (reproducing a way of life) in a changing world. In human affairs, behavior is typically adjusted through the intervention of economic and political incentives long before stark survival is at stake.

Karl Marx asserted that the social arrangements for the harnessing of natural resources (mode of production) have a decisive impact on the rest of society. Although he gave little attention to the role of nature in conditioning human responses, some of his disciples did. Wittfogel, for example, argued that the need for irrigation in dry environments led to "oriental despotisms" in contrast to the more feudal and eventually democratic arrangements in rainier climes.

"Environmental determinism" reached its pinnacle with the works of Ellsworth Huntington at Yale. In contrast, although Ellen Churchill Semple is often considered an environmental determinist, her works on Kentucky mountain folk and on the Mediterranean are nuanced studies of environmental conditions of human life. Her book *Geography of the Mediterranean Region* still provides an excellent background for the environmental study of the area.

The French geographer Vidal de la Blache (1845–1918) is usually credited with the idea of "possibilism," that the environment presents challenges and opportunities, and possibilities for human use, but that it does not per se determine human behavior. His work emphasized the study of regional landscapes (*pays*) in terms of ways of life (*genres de vie*) developed over time; he recognized the importance of long distance as well as local processes in this development. One of his students, Lucien Febvre, went on to write *A Geographical Introduction to History* and to cofound the *Annales* school, which was to focus on the long-term interaction of environmental, demographic, economic, and other factors on the history of places. The most famous member of this school, Fernand Braudel, was influenced not only by Febvre and de la Blache, but also by Semple, in writing his detailed study of the Mediterranean world in the 16th century. More recently, this tradition has included such figures as Immanuel Wallerstein, who has authored influential works developing "world systems theory." Although the sophistication of analysis of environmental factors has tended to weaken over time in this tradition, it still constitutes an important resource for the analysis of human ecology at regional and global scales.

Perhaps de la Blache's closest counterpart in the United States was Carl Ortwin Sauer, who (like Semple) began by studying American mountain folk. He came to focus on Latin America, where he pioneered the study of indigenous resource management and cultural landscapes. He early pointed out the destructive implications of short-term commercial agriculture. The first explicit mention of human ecology goes back to the very beginnings of the discipline of geography in the United States. In 1907 J. Paul Goode, one of the founding members of the Department of Geography at the University of Chicago, announced a course in "plant, animal, and human ecology." Goode defined human ecology as a new hybrid field for "the study of the geographic conditions of human culture" and argued for a partnership between sociologists and geographers to accomplish this goal.

Human ecology studies the mutual interconnections between people and their environments.

The theme remained important at the Chicago geography department, which not only trained Carl Sauer but also Gilbert F. White, whose 1942 doctoral dissertation, *Human Adjustment to Floods* (published in 1945), was highly influential. White argued for the importance of comprehensive adaptation to hazards rather than the deployment of narrowly defined engineering solutions. Through a long career in government and academia he influenced the development of Hazards research as an interdisciplinary subject essential for human ecology.

Parallel themes were developed around the world. For example, in Germany, Carl Troll focused his research on the detailed interaction of climate, soils, and plants at high altitudes, coining the term *landscape ecology* in 1939. He strongly influenced Karl Butzer, who built on Troll's focus on physical environment by adding the long-term analysis of demography, agricultural practices, and environmental impacts in places as diverse as ancient Egypt and colonial Mexico. Out of this work came his book *Archaeology as Human Ecology* (1982).

Sociology students at Chicago were required to take biology, geology, and geography as part of their training. By 1921, Chicago sociologists Robert E. Park and Ernest W. Burgess were arguing for the deployment of ideas from biological ecology as models for similar studies in human ecology. These scholars focused on the importance of fieldwork; some of their most enduring research results concerned the concentric geographical zonation of activities in cities.

The work of Park and his colleagues marked a high point of human ecology in the discipline of sociology; in the 1940s and 1950s sociologists tended to return to a focus on purely social explanations for social facts. In the late 1970s, sociologists William R. Catton and Riley E. Dunlap announced the revival of a "new human ecology" or environmental sociology that would be an improvement on the approach of Park, and discussions of the subject continue in that discipline. However, by the 1950s, anthropologists had taken the lead in developing human ecology and by the mid-1970s had established the key journal in the field.

GROWING IN COMPLEXITY

Anthropologist C. Daryll Forde had found it useful to relate cultures to their habitats, and in the United States, Leslie A. White was an early proponent of the application of evolutionary ideas to the evolution of culture, centered on the technological harnessing of energy (influenced by the Marxist notion of mode of production as well as Darwin). In the 1940s, American anthropologist Julian Steward (who also was trained in biology) was faced with the task of organizing a vast amount of data in editing the Smithsonian Institution's multivolume *Handbook of South American Indians*. During this experience (and previous research with North American peoples), he became convinced that the environment played an important role in the development of societies in particular places. His writings helped create the subfield of Cultural Ecology, which he defined as "the study of the processes by which a society adapts to its environment." He called particular attention to the cultural "core," those practices most directly related to making a living in a particular place (implicitly influenced by Marx's concept of mode of production). He also argued for the importance of "multilinear evolution." By the 1960s, Cultural Ecology was a flourishing paradigm in American anthropology and archaeology.

By the 1970s, the development of human ecology had become quite complex with multiple strands. Some (especially archaeologists, anthropologists, and geographers) pursued the paradigm of cultural ecology with detailed studies of particular cultures and civilizations in environmental context. The influence of Malthus in these studies was tempered by the influential book by the Danish economic historian Ester Boserup, *The Conditions of Agricultural Growth* (1965), which persuasively argued for the ability of farmers to produce more food with increased labor inputs. Chicago-trained anthropologist John W. Bennett's *Northern Plainsmen: Adaptive Strategy and Agrarian Life* (1971) showed how different groups used the same Great Plains environment in different ways. In subsequent publications, Bennett continued to urge the study of human–environment relations in terms of process and behavior, with full attention to questions of identity and long-term change.

Other studies focused on the emergence of the human species, the origins of domestication and agriculture, the rise of cities, and on the conditions and implications of such resource management strategies as mountain agriculture, irrigation, paddy rice, and raised fields. Authors such as Robert Netting also developed broader comparative themes such as the persistence of smallholder agriculture under a variety of larger political regimes. Scholars such as Harold Brookfield (Australia) encouraged the study of the conditions of development in the global south. Many of these studies were based on a methodology combining long-term field research, ethnography, and archival research, in a context of "progressive contextualization."

After World War II, biologists such as Aldo Leopold (*Sand County Almanac*, 1949) and Rachel Carson (*Silent Spring*, 1962) had written popular books arguing for the human stewardship of nature and warning about the destruction of habitat and introduction of untested chemicals into the environment. The greatest impact on human ecology, however, came from biologists Garrett Hardin and Paul R. Ehrlich. Hardin published in his influential article on the "Tragedy of the Commons" in *Science* in 1968, while Ehrlich published *The Population Bomb* in 1968. Both works relied on Malthusian assumptions as to the unlimited propensity to breed, and the limited ability to improve food production with increased labor inputs. Hardin also assumed that human societies historically have lacked the ability to manage common lands. Their works provided a strong stimulus to research, and all three underlying assumptions have been disproved.

Researchers following the lead of Boserup have demonstrated the ability to improve crop yields through labor and capital inputs. Demographer Frank W. Notestein suggested in 1945 that societies normally reduce birth rates as the cost/benefit ratio of having children goes up, resulting in the "demographic transition," even in the absence of modern birth control methods or proscriptive government policy. Many subsequent studies have confirmed Notestein's ideas, and research in traditional and ancient societies has shown that human fertility has seldom been uncontrolled. Finally, research has demonstrated that common lands have been effectively managed by traditional societies and that uncontrolled resource management has been rare in human history.

ECOSYSTEM CONCEPT

Of the many ideas coming from the biological sciences, the "ecosystem" concept has been especially controversial in human ecology. The majority opinion has been that it is useful to think in terms of multiple possible interconnections. The dynamic, adaptive nature of human behavior, however, coupled with the importance of policy and politics in human life and the constantly changing context of adaptation have meant that true stable homeostatic systems have seldom, if ever, emerged in human history.

Anthropologist Roy A. Rappaport in his 1968 study *Pigs for the Ancestors; Ritual in the Ecology of a New Guinea People*, argued that New Guinea society over the centuries had evolved to the point that even ritual was primarily oriented toward the regulation of relations with the environment. Anthropologist Marvin Harris popularized this and similar ideas (with strong Marxist underpinnings) in his popular books *Cows, Pigs, Wars & Witches: The Riddles of Culture* (1974), *Cannibals and Kings: The Origins of Cultures* (1978) and *Cultural Materialism: The Struggle for a Science of Culture* (1979). Most anthropologists and geographers have, however, rejected the notion that the environment has had quite the determinative power that Rappaport and Harris postulated. The notion that the environment provides a key to human history remains seductive, however, as demonstrated by the popularity of the UCLA geographer Jared Diamond's books *Guns, Germs, and Steel: The Fates of Human Societies* (1997), and *Collapse: How Societies Choose to Fail or Succeed* (2005).

POLITICAL ECOLOGY

One of the most powerful recent stimuli for the study of human ecology has been from those calling themselves "political ecologists." Influenced by such works as (Chicago-trained) Susanna Hecht and Alexander Cockburn's *Fate of the Forest* (a study of the long term influence of politics and policy on the Brazilian Amazon), and Michael Watts's *Silent Violence: Food, Famine, & Peasantry in Northern Nigeria*, political ecologists study the impact of colonial, liberal and neoliberal states and multinational corporations on resource management and environmental problems. These scholars have continued the critique of neo-Malthusianism, and have also often urged their own form of activist human ecology built around local identity politics.

There has been a great temptation to reduce human ecology to a subset of a single discipline. The term, however, still has utility in designating the social/cultural/political/environmental/geographical interface. Over time, it has become clear that fieldwork and mapping are important tools for understanding relationships at this interface. It has also become clear that since human ecology involves the interaction of otherwise unrelated systems, it has some surprising elements that do not lend themselves readily to modeling or systems approaches. Recent research suggests that human environmental problems can best be addressed by long term, place-specific research that combines multiple methodologies in a process of progressive contextualization. Furthermore, local people are the key to both understanding and solving environmental problems.

Human Genome Project

THE HUMAN GENOME Project (HGP) was a multinational, 13 year long project aimed at identifying the genes within the deoxyribonucleic acid (DNA) within human cells, together with related technical issues. The goals of the project were to identify and specify the 20,000–25,000 genes in human DNA, determine the sequence of the approximately three billion chemical base pairs within that DNA, and find a way of storing this information in a suitable database for which appropriate analytical and data transfer tools are made available. The HGP also aimed to address the numerous ethical, legal, and social issues (ELSI) that were brought about by the project and by the management and ownership of its findings. The U.S. Department of Energy and the National Institutes of Health in the United States led the effort, with the Wellcome Trust in the United Kingdom, and partners in Japan, Germany, China, France, and other countries. The HGP required considerable computational capacity and logistical management and was completed in 2003.

Prior to the launch of the HGP, considerable skepticism was expressed concerning the practicability of completing it, even though the value of the possible output was grasped early in the process. Technology had not yet progressed sufficiently for the genetic sequence of a much simpler organism such as a bacterium to be mapped. However, early proponents such as Walter Gilbert and Robert Sinsheimer were convinced that the project was both possible and necessary, and that the key was not so much in the complexity of the problem, but in organizing a sufficient amount of computing power and organizing networks of researchers to carry out the work in tandem. Managing this required not just organizational skill, but also the ability to persuade small and often fiercely independent research laboratories to work together and to share their results. This method of working was radically different from the usual competetion and pressure to maintain secrecy about their progress.

The commercial applications of the research intensified these concerns. Further, it was necessary to overcome the resistance felt by many that research is best undertaken through providing opportunities and incentives for individual scientists and their support teams to come up with projects on a bottom-up basis, rather than the large-scale, public sector mandated and top-down approach that was successfully managed. This international collaboration provided a model for using distributed facilities (computer-linked, but geographically-remote locations, each with their own responsibilities) to tackle large-scale projects. Even so, numerous interpersonal and interorganizational conflicts occurred during the project and overcoming these required extensive negotiation.

PRICKLY PROPERTY RIGHTS

Among the many thorny ELSIs, perhaps the most contentious has been that of property rights as resulting from the output of the HGP. An important principle within scientific research and intellectual property rights is that the first individual or team to publish in a reputable medium or in some other credible manner announce results has a claim to ownership of those results in any subsequent commercial exploitation. Yet, every person in the world has genetic information embedded within them. Concerns are raised regarding the possible ethical implications of ownership of such information and, particularly, with the exploitation of the knowledge in the future to enable health interventions that are not yet possible.

The HGP aimed to identify human and mouse genetic material in parallel, as well as some bacterial organisms, in order to broaden the methodological and statistical content available. As effective methods of identifying genes has improved, the attention of researchers has been increasingly taken by creating methods of using the data in profitable applications, rather than simply completing the task.

One issue that was persistently difficult to resolve was the fact that individual genetic units were identified in a partly random fashion, which meant that gaps existed between those blocks of data that were identified, and those that emerged. Identifying the remaining data blocks to form contiguous chains was a complex undertaking that prolonged completion of the project. The HGP has been one of the most important scientific undertakings ever, for the scale and scope of its goals and the ways in which it encouraged people to work together. The production of commercial applications, however, is likely to break up many of those partnerships.

Human Nature

THE GENERIC CAPACITIES and attributes that are universal, elemental, and unique to the human species constitute human nature. From a biological perspective, humans share commonalities with vertebrates, mammals, and primates, but these are not unique to humans. On the other hand, there is a combination of biological attributes that distinguishes the human species as Homo sapiens like habitual erect posture and bipedal gait, the fully opposable thumb allowing precision grip, brain size and structure, and the anatomy of the vocal apparatus.

What makes humans different, as well as the difference this makes, are the two pivotal questions in exploring human nature. A secondary set of questions includes the relative weight and the character of the relationship between these dualistic components that are variously implicated in conceptions of human nature: determinism and free will, matter and mind, nature and nurture, biology and culture, animal and human, natural and supernatural, civilized and primitive, evil and good, selfish and altruistic, competition and cooperation, and war and peace. Such matters have been pursued for centuries by numerous and diverse theologians, philosophers, scientists, and others. Furthermore, any culture or religion, and every ideological or political persuasion, has its own relatively distinctive view on human nature. In short, human nature is a vast, complex, and difficult subject, and there is no single answer to the primary and secondary questions revolving around it.

ONE ANTHROPOLOGICAL ANSWER

While anthropologists have no monopoly on knowledge and understanding about human nature, they certainly do occupy a special scientific and academic niche, because collectively they study humanity in all aspects, places, and times ranging from the local to the global levels. From the perspectives of primates and prehistory, anthropologists can trace the origin and evolution of human nature. Most important, humans lived as hunter-gatherers from some 6 million to about 10,000 years ago, the latter roughly marking the beginning of the emergence of the domestication of plants, animals, and landscapes. Therefore, whatever is universal, elemental, and unique to the human species is most likely related to the hunter-gatherer mode of existence, although human evolution certainly didn't stop there.

Some examples of attributes claimed by Donald E. Brown to be human universals are: fire, technology, artifacts, shelter, sexual modesty, gender, family, kinship, incest prohibitions, socialization, rites of passage, age classification, statuses, subsistence, economy, division of labor, property, reciprocity, food taboos, customs, hospitality, leaders, public affairs, politics, rules, rights, sanctions, conflict resolution, etiquette, morality, folklore, myths, worldview, rituals, magic, divination, medicines, theories of disease and death, mourning rituals, arts, aesthetic standards, body adornment, play, entertainment, stimulants, symbols, gestures, language, color terminology, binary discriminations, personhood, and group identity. Obviously, human universals are general themes, and in practice each is manifest in variations and details associated with particular cultures and their distinctive conditions, including creativity, history, and environment. Indeed, from the perspective of most anthropologists, culture as nurture dominates over biology as nature to an overwhelming degree, thereby rendering the idea of a single human nature a problematic oversimplification. In other words, the some 7,000 cultures existing today reflect as many different human natures.

PRIMITIVES AND "NOBLE SAVAGES"

According to proponents of primitivism, the "primitive" is not simply a more desirable condition for human society, but from an ecological perspective it is closer to nature and more in harmony with it; most primitives live in wilderness. A correlate is that such societies practice nature religion or eco-spirituality. Consequently, implicitly, if not explicitly, the societies and religions of civilization are criticized as unnatural and environmentally destructive. Thus, environmental organizations from the Sierra Club to Earth First! often consider indigenous people to be guardians of nature—so-called green primitivism. New Age religions, including neo-paganism, frequently contain elements of green primitivism.

The opposite of this so-called romantic view is often credited to English philosopher Thomas Hobbes, even though its roots extend far into classical antiquity. In this view "savage" life is poor, nasty, brutish, and short. The Hobbesian imagery of "primitives" is permeated with disharmony, conflict, and violence, both socially and ecologically. In modern literature, the "ignoble savage" is best exemplified by William Golding's allegorical novel *Lord of the Flies*. Most tragically, negative descriptions have often been used by colonials along with ideas of racial superiority as part of their rationalizations to conquer and exploit—if not even exterminate—indigenous societies who become obstacles to their capture of land and resources in frontier zones.

Paradoxically, both the positive and negative extremes are found in the work of a single famous British social anthropologist, Colin Turnbull, the Mbuti pygmies of the Ituri in the Congo region as "noble savages" in his book *The Forest People* (Doubleday, 1961), and the Ik in Uganda as "ignoble savages" in his book *The Mountain People* (Simon and Schuster, 1972). Turnbull describes the Mbuti as the epitome of the "ecologically noble savage" living in harmony in

"Savage" Reflection

Since the ancient Greeks and Romans, and most of all since the discovery of the New World by Christopher Columbus, the "savage" had supposedly reflected the original condition of "man in nature" for Westerners. In the history of anthropology and beyond, the term *savage* delimits "primitive" societies, those that are supposed to represent an early stage in cultural evolution, usually hunter-gatherers subsisting by foraging on wild foods. However, for half a century now the terms *savage* and *primitive* have been dismissed as ethnocentric and racist.

The French philosopher Jean-Jacques Rousseau (1712–78) is usually credited, but not always accurately, with the positive view that the "noble savage" enjoys a life of social and natural harmony. The "noble savage" encompasses a romantic image of a natural humanity that excels in innocence, simplicity, generosity, purity, goodness, peacefulness, and freedom. This ideal variety of humanity is supposed to dwell in a utopian society in a natural paradise during a golden age. This original society was envisioned as an egalitarian communal existence with property held in common instead of privately. "Primitive" societies exemplifying this Arcadian myth were supposedly discovered by European explorers in the Americas, Pacific, and elsewhere.

By the 18th century, this cult of exoticism emphasized self-analysis and self-criticism in scrutinizing European society, morality, and politics by glorifying the "primitive" in contrast to degenerate European civilization. Some primitivists even went so far as to reject civilization in their discourse, although rarely in practice. Most important, such idealistic images offered a set of alternative possibilities for society, identified variously as archetypal communists, ecologists, environmentalists, conservationists, spiritualists, healers, philosophers, and pacifists.

the forest. In contrast, he depicted the Ik as former foragers forced by the government to relocate, settle, and farm under increasing drought conditions with subsequent starvation from crop failure. As a consequence, the Ik degenerated to the point of a bare existence without sociality, culture, morality, and humanity, according to Turnbull.

HUMANITY'S PLACE IN NATURE

In the matter of the relationship between society and environment, the question of the place of humans in nature is vital. In the United States, within the context of the emergence of environmentalism, this question has been discussed and debated at least since the time of George Perkins Marsh, Henry David Thoreau, and John Muir. In recent decades, often this question has involved the issue of the "ecologically noble savage" and the related one of *Homo devastans*, labels coined, respectively, by conservation biologist Kent H. Redford and by ecological anthropologist William L. Balee; although neither agrees with the position that their particular label represents.

Redford was one of the first in recent times to challenge the idea that indigenous societies were necessarily always in harmony with nature. He asserts that indigenes are not necessarily conservationists, although they may be very knowledgeable about the ecology of their habitat. He claims that they have long had significant environmental impacts, even in pre-contact times, and that this increases with Westernization. Redford also asserts that indigenes have the same capacities, needs, and desires as Westerners; and that they have no cultural barriers or controls on their exploitation of natural resources. Any previous sustainability is coincidental because of conditions now rare, including low population density, abundant land, and little involvement if any in a market economy. Redford concludes that indigenes do not provide any viable models for the sustainable use of natural resources and environmental conservation.

Redford's assertions have raised critiques on several grounds. For instance, it is well documented that the environmental impact of many traditional subsistence societies was comparable to natural processes and did not lead to irreversible resource depletion and environmental degradation. Often, such societies have an archaeological and/or historical record extending back centuries or even millennia indicating their sustainability. Also, Western environmental impact is so much greater that it is qualitatively different. Although Redford has tempered his position considerably over time, some of the same thinking remains in various sectors of society and government.

A more recent example of an attempt to totally invalidate the idea of the "ecologically noble savage" is Shepard Krech's book *The Ecological Indian: Myth and History* (1999). He marshals striking negative examples from prehistoric and historic times, ranging from Pleistocene megafaunal extinctions to wasteful buffalo drives over cliffs by Plains Indians to the depletion of beaver populations by natives for the fur trade. In his survey, however, he fails to acknowledge the far more numerous counterexamples in which indigenous societies have achieved some degree of economic sustainability and ecological balance.

Balee adopts the term *Homo devastans* to refer to the extreme position that human nature itself is inherently and inevitably anti-nature, a position apparently held by many contemporary environmentalists. Advocates of this position assert that given a large enough population, advanced technology, and high levels of consumption and waste, then any society can irreversibly deplete its natural resources and degrade or even destroy its environment. Resource competition and human greed are presumed to be universals. In short, no human society is benign in its environmental impact; some are merely worse than others. Such a view can lead to extreme thinking, like the assertion that the only cure for the global environmental crisis is the extinction of the human species. This concept of *Homo devastans* ignores to the point of simplistic reductionism and gross distortion the tremendous variation and variability in cultures and in environments, including the varying vulnerability, resiliency, and other attributes of the latter.

In considerations of the "primitive" as the most basic expression of human nature, the general tendency remains to emphasize one extreme or the other, often to the point of distortion. Such representations need to be critically scrutinized, deconstructed, and demystified. In reality, the world is far more complex, varied, and variable than to sustain such simplistic antithetical postures. It is far more scientific and scholarly to consider the great diversity in the manifestations of human nature through examining particular cases. Human diversity is the practical reality that challenges many attempts at generalizations about human nature as well as about the place of humans in nature.

Humboldt, Alexander von (1769–1859)

ALEXANDER VON HUMBOLDT (1769–1859), a Prussian naturalist and explorer, is one of the founders of modern geography and meteorology. He was born Baron Friedrich Wilhelm Karl Heinrich Alexander von Humboldt in Berlin, Germany on September 14, 1769 as the youngest of two sons of a Prussian army officer and his wife, Elizabeth de Colomb. He lost his father at a young age and was raised by his mother. Humboldt's mother decided to train him for an administrative post in the civil service. It seemed like a good choice for a boy who was often ill and did not learn easily. Humboldt, however, wanted to enter the army. He did not become interested in the sciences until he was 16 and he wound up almost entirely self-taught. Yet, he spent a year at a college in Frankfort-on-the-Oder and then went to the University of Gottingen in 1788 to study engineering. Humboldt spent a further year studying mining and mineralogy at the School of Mines in Freiberg, Saxony.

After leaving school, Humboldt obtained a job in the Prussian government's Mining Department. He worked in the gold and copper mines in the Fichtel Mountains. He also began experimenting with stimulation of nerves by electrical and chemical means. Humboldt's experiments proved that nerves produced a substance that entered the muscle and triggered movement. He continued these physiological studies by investigating the effects of gases and liquids on living animals. The result was the discovery that breathing will stop if the content of carbon dioxide or hydrocarbonic gases in the air exceeds a certain limit. Upon being offered a promotion to director of mining, Humboldt refused the job to travel and conduct research. Always financially well-off, he did not need to work. In 1798, he crossed Spain while taking measurements. Humboldt found both that existing maps of the country were inaccurate and that the interior of Spain forms a high plateau. Humboldt then received permission to travel to the Spanish colonies in Latin America.

EXPLORER OF THE AMERICAS

Humboldt is best known for his explorations of Latin America from 1799 to 1804. With his friend, the French physician and botanist Aimé Bonpland, Humboldt traversed 5,000 miles of some of the most forbidding, dangerous, and bleakest terrain on Earth. They traveled along the coast of Venezuela. They followed the Amazon and Orinoco Rivers and discovered the only natural canal, the Casiquiare Canal, that connects two major rivers. They explored much of Peru, Ecuador, Colombia, and Mexico by the time their journey stopped. The two men collected plant, animal, and mineral specimens. They discovered the first animal that produced electricity, the electric eel. While attempting to explain the dryness of the interior of Peru, Humboldt measured the temperature and clocked the flow of a cold ocean current that runs along much of the western coast of South America. Called the Peru Current, it is now better known as the Humboldt Current although the explorer was not the first to discover it and he objected to being honored in this fashion. Humboldt did discover the importance of guano (the dried droppings from birds) as a fertilizer and gave his name to one of the producers of guano, the Peruvian or Humboldt Penguin.

Although Humboldt has not received the credit due him, he did achieve great fame in his day. Part of his reputation came from his extensive self-published writings of his travels and discoveries. One of his books, *Personal Narrative of Travels to the Equinoctial Regions of the New Continent During the Years 1799–1801*, inspired the English naturalist Charles Darwin. Descriptions, figures, reflections, and history are thrown together without any organization in a mix that is both fascinating and wearying. Running out of money, Humboldt became an advisor to the Prussian ruler in 1827. Invited to tour Russia, he described permafrost and recommended that the Russians establish weather stations across the nation. The stations, created by 1835, allowed Humboldt to use data to develop the principle of continentality, the idea that the interiors of continents have more extreme climates due to a lack of moderating influence from the ocean.

He also developed the first isotherm map, containing lines of equal average temperatures. Humboldt spent much of his later life giving public lectures in Berlin and working on a multivolume work, *Kosmos*, that would summarize everything known about the earth. Before he could complete it, Humboldt died, possibly of a stroke, on May 6, 1859. He is buried in Tegel, Germany.

Bonpland and the Yerba

One of the associates of Alexander von Humboldt was Aimé Bonpland (1773–1858) who was from La Rochelle, France. He became a surgeon in the French army and then traveled to South America where he accompanied Humboldt in his travels in Mexico, Colombia, and Brazil.

Returning to France, Bonpland was given a government pension and made the superintendent of the gardens at Malmaison, the mansion owned by Josephine and where Napoleon often stayed when in Paris. He wrote a number of books on plants and botany, including one on the rare plants at Malmaison.

Leaving Europe in 1816, Bonpland went to Buenos Aires, Argentina, where he became a professor of natural history and was active in botanical circles. In 1821 he went to the borders of Paraguay where he hoped to cultivate yerba, a plant used to make the herbal infusion known as *mate*. It was at that time the main export of Paraguay and the president of Paraguay, José Gaspar Rodríguez de Francia was keen that Bonpland did not manage to get any seeds that could lead to the plant being grown elsewhere, and thus erode Paraguay's major source of foreign currency. Dr. Francia was even more nervous when he heard that Bonpland had brought a large number of armed guards with him.

On the evening of December 8, 1821, four hundred armed Paraguayan soldiers headed over to Bonpland's encampment and on the following morning arrested him. There were protests that this violated international law, and Bonpland remained in Paraguay for ten years, returning to Argentina in 1831. Although many have sought to use the arrest of Bonpland as an example of the despotism of Dr. Francia, Bonpland was well-treated during his time in Paraguay. On crossing the border into the semiautonomous Argentine province of Corrientes, he had his horses stolen. Bonpland wrote in his diary "It was immediately apparent that we were no longer in Paraguay."

Humidity

HUMIDITY IS A measure of the amount of water vapor in the air and is a primary element of climate. Humidity can be expressed in a number of ways, including absolute humidity, specific humidity, mixing ratio, relative humidity, and dew point. Although water vapor rarely accounts for more than 4 percent of the total volume of the atmosphere, it is an extremely important component of the atmosphere. Atmospheric water vapor regulates air temperature by affecting the transmission of radiant energy both to and from the earth's surface and provides latent heat energy to fuel storm systems. The maximum amount of water vapor that the atmosphere can hold is a function of the temperature and pressure of the air. The moisture content of air increases rapidly as the temperature of the air increases. When a volume of air contains the maximum amount of water vapor at a given temperature and pressure, the air is said to be saturated.

Absolute humidity directly measures the amount of water vapor in a given volume of air and is usually expressed in grams of vapor per cubic meter of air. The absolute humidity of an air parcel will change as it expands or contracts even though there is no change in the amount of water vapor. Due to these drawbacks, measurements of absolute humidity are rarely used.

Specific humidity refers to the mass of water vapor in a given mass of air and is usually expressed in grams of water vapor per kilogram of air. Unlike absolute humidity, specific humidity has the advantage of not changing as air expands or contracts. The mixing ratio is closely related to specific humidity and is defined as the mass of water vapor in the air to the mass of dry air. Relative humidity is the most common and frequently used measure of humidity. Relative humidity is the ratio, in percent, of the amount of moisture in the air compared to the amount that the atmosphere can hold at a given temperature and pressure.

The relative humidity of the air changes throughout the day, usually reaching its highest value in the early morning hours and then decreases to a minimum in the early afternoon. Thus, relative humidity indicates how near the air is to saturation rather than the actual quantity of water vapor in the air. Another useful measure of humidity is the dew point, the temperature at which air becomes saturated if cooled without a change in pressure or moisture content. The dew point is always less than the air temperature unless the air is saturated.

Several types of instruments have been created to measure humidity. Humidity measurements are increasingly being recorded by remote sensing packages that transmit upper-air observations back to ground stations. An instrument commonly used to measure humidity is the psychrometer. It consists of a wet bulb thermometer that is kept moist by a wick soaked in water and an unmodified dry bulb thermometer. When the psychrometer is swung freely in the air or aerated by a fan, evaporative cooling lowers the wet bulb temperature. The amount of moisture in the air can be determined by calculating the difference between the dry bulb and wet bulb temperature. The hair hygrometer is another instrument used to measure humidity and is based on the fact that hair expands and contracts in response to changes in humidity.

Humidity greatly affects our comfort and health and can make the warmth of the surrounding air feel as if it is warmer than the actual temperature. If the atmosphere has a high moisture content, the rate of evaporation is reduced, which impairs the body's ability to maintain a constant temperature. Physical strength declines and fatigue occurs more rapidly in a humid environment. A heat index can be used to determine the apparent temperature caused by the combination of heat and humidity.

Hungary

PART OF THE Austro-Hungary Empire until the World War I period, Hungary became part of the Soviet bloc at the end of World War II. After the Soviets dispatched troops to prevent Hungary from leaving the bloc in 1956, the government instituted what became known as "Goulash Communism." Following the dissolution of the Soviet Union, Hungary transformed itself into a market economy. Although the Danube and Tisza Rivers divide Hungary into three unequal sections, the country is landlocked. Hungary has a temperate climate with cold, humid winters and warm summers. Half of Hungary's 35,652-square-mile land mass is arable, and the soils are fertile. Other valuable natural resources include bauxite, coal, and natural gas.

After joining the European Union (EU) in 2004, Hungary began upgrading waste management facilities and committed itself to improving energy efficiency and reducing levels of air, water, and soil pollution. In a 2006 study conducted by Yale University, Hungary ranked 33 out of 132 nations in environmental performance. The lowest ranking came in the areas of biodiversity and habitat protection. The Hungarian government has protected 7 percent of its land, but acid rain has endangered large areas of forest. Nine of 83 mammal species are endangered, as are eight of 208 bird species.

The population of 10,007,000 enjoy a per capita income of $15,900, but Hungary has a labor force participation of only 57 percent. The current unemployment rate is 7.1 percent, and 8.6 percent of the people live below the poverty line. Approximately 99 percent of the population have access to safe drinking water, and 95 percent have access to improved sanitation. The United Nations Development Program (UNDP) Human Development Reports rank Hungary 35th among nations of the world on general quality-of-life issues.

Around 66 percent of Hungarians live in urban areas, and less than 4 percent of the labor force are engaged in agriculture. Because of heavy concentration in urban areas, Hungary, like most heavily industrialized nations, has a problem with carbon dioxide emissions. With 259 cars per 1,000 people, Hungary is responsible for .2 percent of the world's carbon dioxide emissions. Until the latter 1980s, almost 40 percent of Hungary's population were regularly exposed to extensive air pollution from electric plants that burned high-sulfur coal. High winds carried toxic fumes into neighboring areas, resulting in widespread pollution.

Water pollution has also posed a major dilemma for the Hungarian government. In 1970, some 52.9 million cubic feet of polluted water were being produced each day. Effluents, which included waste from the chemical, rubber, iron, paper, and food-processing industries, polluted groundwater and caused major environmental damage to the waters of the Tisza, Danube, Szamos, Sajo, and Zagyva. Less than one-third of all waste was treated before disposal, and less than half of the people had access to proper domestic sanitation. During the 1980s, pollution levels in Hungary became even more critical as the government increased revenue by importing hazardous waste from Austria, Switzerland, and West Germany. Hungary was also negatively affected by Romania's practice of dumping phenol, oil, and other pollutants into the shared waters of the Tisza and other smaller rivers. The turning point came in response to public outcry, which forced the government to erect a nuclear waste incinerator.

It was not until the mid-1990s that major environmental progress was made. In 1995, Hungary passed the comprehensive Environment Act. Hungary's environmental policy is based on the premise that polluters should pay to correct the damage they cause and fund preventive technologies, but fines are relatively low. The 1995 law dealt with reducing levels of chemical substances in the environment, improving waste management, reducing pollutants, eliminating radioactive contamination of food, and increasing radiation protection. In 2003, the legislation was updated to bring environmental policy in line with EU standards.

Since joining the EU, Hungary has made great strides in improving its environment, but the government continues to be hampered by funding shortages. The Ministry for Environment and Regional Policy bears the responsibility for overseeing environmental policy, working with the Hungarian Environment Council and various nongovernmental organizations to plan and implement environmental policy.

Hungary has expressed its commitment to global environmentalism by participating in the following international agreements: Air Pollution, Air Pollution-Nitrogen Oxides, Air Pollution–Persistent Organic Pollutants, Air Pollution–Sulfur 85, Air Pollution–Volatile Organic Compounds, Antarctic Treaty, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, and Wetlands. The government has signed but not ratified the Air Pollution–Sulfur 94 agreement.

Hunter-Gatherers

HUNTING AND GATHERING can be defined as a method of procuring food from the environment through the gathering of edible plants and hunting wild game, including fish. For most of human history, human beings survived by foraging and hunting. It was only about 8,000–10,000 years ago when the domestication of animals and agriculture became a major source of food that people began to abandon a hunter-gatherer style of life. Archaeological evidence has greatly advanced our knowledge of hunter-gatherer communities in antiquity. Ethnographic and historical studies provide information about the way of life of both historic and contemporary hunter-gatherers. Hunting and gathering was the only way humans survived for more than a million years until the end of the Paleolithic period (Old Stone Age). During the era of hunting and gathering, humans depended on the year-round supply of wild edible plants and animals that they hunted with rudimentary stone tools and weapons. The roots of culture are attributed to hunter-gatherers who roamed in small bands hunting and foraging over considerable territory.

Contemporary hunter-gatherer societies tend to be relatively mobile, dependent on the ability of a given natural environment to provide sufficient resources. Where resources are scarce, the bands might only contain 10–20 individuals. Where resources are abundant, the bands might be larger,

For most of human history, human beings survived by foraging plants and hunting for wild game and fish.

comprising 100 people or more, and may form semi-permanent settlements. Often, hunter-gatherers shelters are constructed of impermanent building materials such as grass and leaves in rain forest environments, or they may seek caves for shelter in drier and mountainous environments.

Hunter-gatherer communities have simple, nonhierarchical, egalitarian social systems. It has been suggested that egalitarianism was one of several central characteristics of nomadic hunting and gathering societies, since mobility precluded the accumulation of material possessions for any one single member in the band. However, in areas where resources were plentiful, making a more permanent way of life possible, the simple social structure gave way to a more hierarchical social organization.

Furthermore, clear evidence exists concerning the sexual division of labor among hunter-gatherer groups. Females were primarily assigned the food-gathering chore, which resulted in their developing a keen sense for and the greatest familiarity with nutritive plants such as wild fruits and vegetables. Hunting activities became the domain of men. Furthermore the idea that hunter-gatherers lived a "solitary, poor, nasty, brutish, and short life" constantly at the mercy of the environment has been refuted by recent studies. For example, studies of the San people (Bushmen) in South Africa indicate that hunter-gatherer bands live well on the equivalent of a two and half day workweek, which gave them plenty of time to develop skills in working flint and bone tools, in developing regionally distinctive art and sculptures, and in making decorative beads and shells for personal adornment and trade.

Hunting and gathering is not completely gone in contemporary society. Many people, particularly in the developing world, continue to obtain food through gathering of wild edible plants and hunting wild meat. Although perhaps only a few thousand persons worldwide, some societies continue to entirely depend on this system for their subsistence. Usually these are found in isolated and remote pockets of the world such as the interior of New Guinea, interior and inaccessible parts of Southeast Asia, the Amazon tropical rain forest, small and isolated portions of tropical and arid Africa, parts of northern Australia, and parts of the Arctic regions. As a result of the now-global reliance upon agriculture, the few contemporary cultures that practice hunting and gathering usually live in areas seen as undesirable for agricultural use. For many of these peoples, their lifestyle is being modified or lost by contacts with the outside world. Intrusion of modern material goods such as plastics, metal, and clothing into their societies has made them part of the modern market economy and resulted in the erosion of their primitive way of life.

Hunting

IN VERY GENERAL terms, hunting refers to the activity of pursuing and killing free-roaming animals. It is often assumed that these are wild animals, but that is not necessarily the case. There are many reasons why human beings hunt. These range from a need to obtain protein-based sources of nourishment to the pursuit of recreation or of a thrill. People also hunt to collect raw materials that are used for industrial purposes, as in the case of the fur industry, or to collect trophies, amulets, or the ingredients for magic and aphrodisiac potions. Why people hunt, how they hunt, what they hunt, and what they do with the products of hunting endeavors say a lot about a society's social organization, economic systems, culture, and values. Some people in Western societies condemn hunting as an extremely inhumane form of unnecessary cruelty. Hunting may indeed seem unnecessary and cruel when animals are butchered and left half alive so that humans can extract a small part of their bodies to use as "good luck" charms. However, the social scope of hunting is far too wide to be reduced to such a reality. Three examples illustrate the range of possible forms of hunting and their relation to different societies, cultural premises, and ecological environments.

INDUSTRIAL HUNTING

The industrial hunting of many species of wild animals is directly related to the history of the Industrial Revolution and Western modernization. In this context, some species were hunted to the brink of extinction. Mainly between the 17th and the early 20th centuries, an enormous number of whales were killed so that their blubber could be extracted and for oil. This oil, in turn, was used to illuminate the streets of the world's first major industrial centers. Subsequently, whale-derived oil—especially the spermaceti of sperm whales—was used to lubricate the war machinery of World War II.

Today animals continue to be hunted for industrial purposes. This is the case, for example, of baby seals in Canada, which are hunted for the fur industry. Hunting for industrial purposes has been linked with different moral values at different historical junctures. Between the 17th and 20th centuries, most Western societies saw this activity as a perfectly legitimate means to satisfy human needs. More recently, many people contest industrial hunting as an immoral and selfish feeding of human whims. In either case, those values reflect the cultural worldviews that are most typical of a society at a given point in time.

RECREATIONAL HUNTING

Recreational hunting refers to the pursuit and killing of animals for the purpose of enjoyment. Sports hunting, as exemplified in the well-known case of fox hunting in the United Kingdom, is but one of many forms of recreational hunting. The analysis of recreational hunting can provide fascinating clues about a society's class relations, structures of power, and environmental understandings. The royal hunt, which was pursued in Euroasian countries until the 19th century, is one such example. Besides hunting, it was a means to train armies and to display the military power of a nation. The historian Thomas Allsen has studied the royal hunt extensively. His work shows that this activity also served the purpose of sending diplomatic signals to neighboring powers (as a display of strength) and to assert a ruler's mastery of the forces of nature. Clearly, the cultures of the societies where royal hunts took place viewed the human–environmental relationship as one of domination of people over animals and over nature.

The organization known as Ducks Unlimited is another interesting case that affords a view of a particular perception of the relationship between humans, hunting, and the environmental—although from a different perspective. This is an association of hunters who see their main mission as the conservation, restoration, and management of wetlands that constitute habitats for North America's waterfowl (the animal they hunt). A side effect of the conservationist efforts of this association has been the creation of many natural reserves that actually benefit other species of animals. Group members conceptualize hunting activities as a type of sport that is intimately associated with both a particular lifestyle that comes with the appreciation of nature, and the obligation to engage in sound practices of wildlife conservation.

SUBSISTENCE HUNTING

A third example is subsistence hunting, a practice historically common in many Western societies where most people no longer hunt, yet there are many examples of societies that still obtain most of their protein sources through hunting. The core characteristic of subsistence hunting is that its practitioners hunt for the purposes of feeding and clothing themselves and their community. They normally kill only the number of animals that they need in order to survive. More often than not, waste—hunting more than is needed—is considered immoral. So is the inflicting of unnecessary pain and cruelty on the animals during the hunting process.

Many hunters in subsistence economies perceive their relations with the animals they hunt as reciprocal. From their viewpoint, humans and animals communicate with one another during the hunting process. If the human being follows proper norms of conduct and sticks to culturally accepted values, the animal will collaborate by allowing itself to be killed. The main cultural premise in this context is that humans are not superior to animals, and that therefore humans should not have the right to attempt to dominate animals. These societies are normally structured so that any individual has access to the animals, although people often opt to divide labor between them such that some will hunt, others will gather fruits or grow cereals, others will collect water and so on. The products of these different activities are normally shared by means of reciprocity.

Huntington, Ellsworth (1876–1947)

ELLSWORTH HUNTINGTON (1876–1947), American geographer, was best known as the leading proponent of a school of thought commonly known as environmental determinism. Environmental determinism claimed that geographic controls and related environmental conditions dictated a predictable human response and, consequently, had a profound influence on the development of societies and the course of history. Professional scholars were critical of his work; nevertheless, his ideas had a certain force in the academic world. In addition, the sheer volume of these writings and their popularity with the public ensured a prominent place in the geographic and environmental intellectual milieu of the time.

Between 1897 and 1906, Huntington spent six years teaching, traveling, and exploring in Asia, where he conducted fieldwork in some of the most desolate and inhospitable deserts and mountains on the continent. He became convinced that the climate of Central Asia had become drier and that such desiccation had had a profound impact on the course of history and the development of civilization. These ideas formed the content of his first major book, *The Pulse of Asia*, published in 1907.

Huntington continued to develop his ideas that reached their pinnacle in 1924, in his work, *Civilization and Climate*. In his view, climate had not only impacted the course of history and civilization, it had also affected the character of societies and even individual human behaviors. He argued that civilization had moved from the salubrious climates of the subtropics like Egypt and Greece to the colder, but more "stimulating," climates of northwestern Europe. The cyclonic storm systems of the midlatitudes affect northern Europe throughout the entire year but only affect the Mediterranean region in the cooler part of the year. In his view, these frequent changes of weather provided a psychological stimulus lacking in warmer climates where the weather was more monotonous.

Huntington's last major work was *Mainsprings of Civilization* (1945), in which he argued that civilization derived from three principal pillars. These were genetic heritage, environmental situation, and cultural endowment. Critics came to question these three "pillars," as well as the relationships among them. For example, the critics claimed that Huntington's emphasis on heredity was, in reality, thinly veiled racism. His speculations about environmental cycles of various periodicities further compromised his credibility, especially as paleoclimatology matured. His work was dismissed for drawing too many conclusions from too few facts and for never letting contrary facts get in the way of his sweeping conjecture.

Huntington's work remains important for a few reasons. Writing at the time that he did and, with the recent colonization of much of the world by European powers, his work sheds light onto the relationship between global political economy and the academic and ideological systems that often undergird them. In addition, the work serves as a reminder that strongly held convictions cloaked in scientific credentials can have a strong hold over the popular press and media, as well as circles of policy. Finally, Huntington's work is a study in the dangerous elegance of simple arguments; environmental determinism maybe a discarded relic of the not-so-remote intellectual past, but no one did it better or more convincingly.

Hurricanes

A HURRICANE IS a particularly strong tropical storm; that is, a storm with winds in excess of 74 miles per hour. *Hurricane* is the term used for this type of storm in the North Atlantic Ocean; in the Pacific Ocean, these storms are known as typhoons, and in the Indian Ocean they are known as cyclones. The smallest hurricanes—Category 1 on the Saffir/Simpson scale—are relatively minor, with winds of between 74 and 95 miles per hour and a storm surge of about four to five feet. A Category 5 storm, on the other hand, packs winds of over 155 miles per hour; with a storm surge along the coastline of greater than 18 feet.

Current research suggests that Atlantic hurricanes begin with atmospheric disturbances near north central Africa. These disturbances move across the continent until they reach West Africa, where they can become storms known as tropical depressions, characterized by low barometric pressure. As the depression moves across the Atlantic, the depression can build and gain strength and become a tropical storm, and when it grows to sufficient strength, it becomes a hurricane.

Hurricanes are given names to aid in their identification. Originally they were given only women's names, but since 1979 they have been named for men and women, and in recent years care has been taken to add French and Spanish names to the list, given the fact that hurricanes can strike Spanish- and French-speaking areas in the Caribbean.

The "hurricane season," runs between June 1 and October 30. According to the U.S. Weather Service, an average of two major hurricanes hits every three years, and one Category 4 or greater hurricane strikes every six years. However, there is nothing to prevent a major hurricane from striking the same region two years in a row, or even twice in one season.

Hurricanes tend to strike most often in the southeastern United States. States at greatest risk extend from Texas to the Carolinas. The highest death toll from a hurricane in American history resulted from the 1900 Galveston hurricane, which struck a city that local boosters had claimed could not possibly be hit by a hurricane. When storms turn up the Eastern Seaboard, states from Florida to Maine can be affected, sometimes severely. Long Island (New York) and New England, extending eastward into the Atlantic Ocean, tend to bear the brunt of such storms. Hurricane Gloria in 1985, for example, barely brushed New Jersey, but did substantial damage to Long Island. A very powerful hurricane killed about 600 people on Long Island and in New England in 1938. Today, highly sophisticated weather forecasting and monitoring tools prevent substantial losses of life from hurricanes, because people can be warned to secure their property from high winds, or to evacuate areas that will be particularly hard-hit.

The most damaging hurricane—and the most damaging single natural disaster—in American history is Hurricane Katrina, which struck Louisiana and Mississippi on August 29, 2005. (It passed over south Florida in a much weaker size.) The storm grew to Category 5 before weakening, as many storms do, to a Category 3 storm when it made landfall between New Orleans, Louisiana and Gulfport, Mississippi. While wind damage was quite severe from this storm, particularly along the coastline, the major feature of Katrina was the very large storm surge that hit many buildings, and, in some cases, entire towns—along the Louisiana and

Mississippi coast. The surge pushed boats inland, drove water into buildings, and was so strong that it caused bridges along the Gulf Coast to collapse because of the upward pressure the waves exerted on the bridge decks, rather than the lateral pressure usually seen in high winds.

In New Orleans, the storm surge on Lake Ponchartrain was so great that powerful waves entered drainage and navigation canals. The levees along these canals failed, a result of inadequate design, planning, and maintenance, and about 80 percent of the city was flooded, in some places over 14 feet deep. The possibility of this happening was well known before Katrina, but politics, budget issues, and a lack of attention to the hazard made it impossible to strengthen the system against this storm. The storm surge from Hurricane Katrina was greater than typical for a Category 3 hurricane, which reveals a shortcoming of the Saffir-Simpson scale: the scale measures wind speed, not storm surge; the two are not a direct relation to each other. Some storms, like Hurricane Andrew (1992) in Florida, did most of their damage from high winds. Hurricane Floyd (1999), the most expensive storm in North Carolina history, did its damage primarily inland, when rains caused rivers to overflow and flood many cities and towns, and caused toxic runoff to flow into rivers from farms. Some scientists claim that the numbers and intensity of hurricanes will increase because of global climate change.

Hybrid Vehicle

A HYBRID VEHICLE is any vehicle that utilizes a combination of an internal combustion engine running on traditional fossil fuels and a battery-powered electric motor for propulsion. The most basic and common configuration is to simply place the electric motor in line with the main drive train, and to have the electric motor draw from battery power and aid the internal combustion engine while the vehicle is undergoing acceleration. The act of accelerating burns more fuel than simply cruising at a constant speed, so the assistance of the electric motor during acceleration acts to conserve fossil fuels. Likewise, as the vehicle undergoes deceleration, the reverse rotation of the electric motor acts to recharge the battery. The electric motor is utilized more frequently if the vehicle makes frequent starts and stops; hence, hybrid vehicles tend to have better fossil fuel efficiency in urban driving conditions.

Some hybrid vehicles utilize a transmission system that has a more complex interaction between the electric motor and internal combustion engine. These models are able to run as described above, but also have the ability to engage the electric motor as the primary drive engine while cruising, or to use the internal combustion engine as the sole drive engine while utilizing the electric motor as a generator to recharge the battery.

Hybrid vehicles are considered to be environmentally friendly from two points of view. These vehicles, by having a greater efficiency rating for fossil fuel consumption, have a lower level of emission of greenhouse gases and can therefore slow the rate of global climate change. Second, these vehicles are seen as being beneficial by reducing dependence on fossil fuel consumption, with the additional geopolitical benefit of reducing dependence on imported fuels.

Environmental concerns have been raised in regard to disposal of the batteries these vehicles utilize, once they become spent. Current technology uses nickel-cadmium batteries. Nickel is suspected of being carcinogenic, but is considered to be less of a threat than the lead used in standard lead-acid batteries. In addition to health concerns, environmentalists are concerned about the impact of nickel mining. Nickel-cadmium batteries are expected to be replaced soon by lithium-ion batteries, which are considered to be less of an environment and health risk.

CRITICISMS AND SCRUTINY

Environmentalists are critical of the automobile industry in implementing hybrid technologies. U.S.-based manufacturers have primarily created hybrid versions of their SUVs and light trucks, with a very small net increase in fuel efficiency. Environmentalists assert that this allows automakers to claim to be environmentally friendly with very small gains to overall fuel efficiency. Industry spokespeople counter that demand for hybrid vehicles with significantly increased fuel efficiency are niche markets; the increased costs of these hybrids exceeds the economic savings in fuel consumption and hence only people willing to spend the extra money on environmental values would likely buy them. The industry further argues that net fuel saved through implementing hybrid technologies on their largest-selling vehicles, although modest for any single consumer, would have a greater overall reduction in fuel consumption. Despite industry criticisms, demand for hybrid vehicles has been high, and the industry has not been producing enough to meet the demand.

Hydrogen Fuel

HYDROGEN, DESIGNATED AS H on the periodic table of the elements, is the simplest and most abundant of all the elements. A hydrogen atom consists of a single proton and an electron, and has the lowest density of all known matter. Hydrogen molecules combine to form a stable molecule of two hydrogen atoms and their associated electrons.

Hydrogen is an odorless, colorless, tasteless gas (H_2) that is not very reactive at ordinary temperature levels. It burns with a very hot, almost invisible flame, and can be used as a fuel in nuclear fusion and by chemical reactions. Nuclear fusion occurs with Deuterium combining at the proton level to form helium.

Hydrogen comprises most of the matter in the sun, which generates light by a process of nuclear fusion that combines hydrogen atoms into helium atoms. The amount of energy generated is enormous. Nuclear fusion has been weaponized in hydrogen bombs. However, the process has yet to be accomplished under controlled conditions so that energy can be obtained.

Hydrogen as a part of an energy-providing chemical reaction is simpler to accomplish than nuclear fusion. It is used in the production of synthetic ammonia, methanol, in the refining of petroleum, and as rocket fuel. The combination of hydrogen and oxygen is water (H_2O), which is a clean emission.

Hydrogen in the presence of oxygen is an explosive mixture if a spark ignites the mixture. The combustible nature of hydrogen was demonstrated when the zeppelin *The Hindenburg* exploded on May 6, 1937 at Lakehurst, New Jersey, while attempting to dock, killing 35 people and injuring others. The Hindenburg was held aloft by hydrogen gas, but was not using it as a fuel.

Pure hydrogen is a fuel for the oxygen-hydrogen torch. Pure hydrogen has also been a major fuel in the U.S. space program. Liquid hydrogen and liquid oxygen have been used on the second and third stages of the Apollo mission flights, and in other rockets.

Hydrogen *gas* is rare on earth. It must be extracted from water, hydrocarbons, coal, or biomass. To produce hydrogen from coal, it must be reduced to slurry, then calcium carbonate has to be used in reactions to free the hydrogen atoms. Hydrogen can be obtained from other sources, but most hydrogen is produced from natural gas. Research is being conducted to use one of several species of purple bacteria in the production of hydrogen, and other exotic methods are being explored. Hydrogen is present in most fuels as free hydrogen or hydrogen combined with other elements. Fuels abundant in hydrogen include coal gas, oil gas, natural gas, and other forms of methane.

The storage of hydrogen is a problem because it must be stored as a high-pressure gas or as cold liquid hydrogen and kept at a temperature just above absolute zero. Or, it can be kept as a slush of cold liquid and frozen solid hydrogen.

GREAT PROMISE

Hydrogen has great promises as a fuel that could replace petroleum, but cost has been an inhibiting factor. Fuel cells produce electricity from chemical reactions using a specially designed cell. William Grove invented the fuel cell during the 1830s in London. Fuel cells generate electricity like a battery. However, a fuel cell uses an external source for fuel. If the source is hydrogen, the fuel cell operates cleanly and efficiently. A gasoline engine captures 20 percent of its usable chemical energy, while a fuel cell is three times as efficient.

The simplest form of fuel cell is one that uses hydrogen as a fuel, and some kind of oxidant. Fuel cells, however, are not simply burning hydrogen. Instead, a chemical reaction is stimulated in which the hydrogen combines with oxygen. This chemical reaction imitates the explosive reaction in a gasoline piston. The difference is that an electrolyte solution facilitates the migration of ions and the capture of electrons for energy purposes.

Fuel cells using gasoline convert it to hydrogen, which is combined with oxygen to produce electricity and heat. The heat, unless it is captured by some cogeneration mechanism, is lost. The other exhaust product is water vapor. Because fuel cells using gasoline are not popular with environmentalists, some automakers and political decision makers have been reluctant to press ahead for their development and adoption. However, fuel cells that use ethanol or methanol are being investigated.

The safety of fuel cells is being investigated. Studies have found exposure to a ruptured hydrogen fuel tank that is ablaze is much less dangerous than if a gasoline tank catches fire or explodes.

Research and development of hydrogen cars has been conducted since the 1970s, and several automakers are developing fuel cell cars that have been sold since the early 2000s. It is hoped that once established, fuel cells will be useable in much larger transportation systems such as trains, buses, or even in submarines. In Europe, fuel cell buses operate in Madrid and other cities. Cities scheduled to receive fuel cell buses include Amsterdam, Hamburg, London, and Stockholm. Buses using fuel cells will need far less gasoline or diesel fuel, and they will produce much less pollution. Fuel cells are also being developed for use in buildings. A number of countries have or will soon have buildings that receive energy from fuel cells.

As naturally occurring oil is discovered and exploited, the supplies will inevitably decline. However, hydrogen fuel cells offer a much cheaper energy alternative. Whatever method of production used to produce hydrogen, significant environmental issues arise. Even if hydrogen is accepted as a substitute for gasoline, unforeseen environmental consequences may still occur.

Hydrologic Cycle

ALSO KNOWN AS the water cycle, the hydrologic cycle is a process of circulation of the earth's water and its storage in reservoirs as a continuous flux, powered by solar energy. In some cases, the term *hydrologic cycle* implies a change of state of water. The water cycle involves considerable exchanges of energy between the atmosphere and the oceans, and significantly contributes to other processes like the alteration and breakdown of minerals and rocks, known as erosion, and the transportation of weathered particles as solids or ions in solution from land surface to the oceans.

Water exists on Earth in the three states of matter: solid (ice), liquid, and gas (water vapor). The processes by which water changes from one state to another are known as evaporation (liquid changing to gas), condensation (gas changing to liquid), freezing (liquid changing to solid), and sublimation (the direct change of ice to water vapor, without first becoming a liquid).

The origin of the earth's water remains a controversial matter over whether it was released during a prolonged volcanic activity during the early stages of Earth, released through an outgassing process about 4 billion years ago, or has an extraterrestrial origin.

More than 70 percent of the earth's surface is covered with water; however, water only represents 0.025 percent of the planet's mass, which indicates the superficial nature of the hydrologic process. The total water circulating in the cycle is 332.5 million cubic miles (1,386 million cubic kilometers), although only 1 percent is in constant movement. Water is held in various reservoirs distributed all over the earth as follows: oceans and seas (96.5 percent), ice caps, glaciers, and permanent snow (1.74 percent), groundwater (1.7 percent), ground ice and permafrost (.022 percent), lakes (.013 percent), atmosphere (.001 percent), soil moisture (.001 percent), rivers (.0002 percent), and biological water (.0001 percent). The percentages of water stored in rivers and the atmosphere are very low and seem to be marginal, yet the relevance derives from the quantity that passes through those reservoirs.

The flux of water among the containers is continuous but highly differs in rate. The residence time measures the average time a molecule of water remains in a reservoir: 3,176 years in the ocean with respect to the atmosphere, 33,750 years in the ocean with respect to rivers, 1 year as soil water with respect to precipitation or evapotranspiration, and 1,377 years as groundwater with respect to rivers. Balances between the different reservoirs have varied as a result of climate change, particularly during glacial ages. During the last peak glaciation (20,000–18,000 years ago), 10.08 million cubic miles (42 million cubic kilometers) of water was trapped in polar ice caps, which lowered sea level by about 393.7 feet (120 meters) relative to the present day. Climate change produced other great modifications of the water cycle, like lower rates of evaporation and less precipitation.

When water vapor rising with air cools and reaches the saturation point, water is released by precipitation.

In the present day, important regional differences in the hydrologic cycle are also observed in regard to evaporation and precipitation, and the balance between the two processes differs at this scale. Evaporation is higher than precipitation in the subtropical areas, while the opposite is true at the Equator and the higher latitudes. Water moves from or reservoir to another by way of evaporation, condensation, precipitation, deposition, runoff, infiltration, sublimation, transpiration, melting, and groundwater flow processes.

Water goes into the atmosphere from the evaporation of water on the ocean surface (86 percent), the evaporation of falling rain and snow before the water droplets reach the ground—a phenomenon termed *rain fog*—sublimation in the ice covers, and as a by product from the metabolic processes of fauna and flora (transpiration by plants and respiration by animals). In general, evaporation exceeds precipitation over the oceans while precipitation exceeds evaporation over land areas. While in the atmosphere, water is stored in the form of vapor and small water droplets that form clouds.

Nevertheless, moisture is redistributed all over the world by a process of advection—the horizontal transport of water vapor by moving air masses—that modifies the moisture content of the air. On average, air contains 2–3 percent water vapor, although the variation between regions is broad. Humidity in the tropics is 30 times the humidity at the poles. Aside from air temperature, other factors such as vapor pressure and atmospheric pressure affect the rate and amount of evaporation that takes place. Air becomes saturated at a certain point when it contains the maximum possible amount of water vapor without starting to condense, so warm air can hold higher concentrations of water vapor than cooler air.

The change from a gaseous to a liquid phase is termed *condensation*. Water vapor condenses in the atmosphere on the aerosols—small airborne nuclei of dust, salt particles, or ions—yielding the formation of water droplets, visible as clouds and fog. As the air containing water vapor rises, it cools and reaches the saturation point, and excess water vapor is released in one of several forms of precipitation: rain, snow, or hail, depending on air temperature and atmospheric processes of crystal formation or coalescence. Air lifting is produced by convection when unstable, less dense warm air that is heated by the earth's surface ascends. Other processes that cause air to rise are convergence in cyclones, topographic elevation, and warm and cold fronts.

EVAPORATION-CONDENSATION CYCLE

The evaporation-condensation cycle is a transferring mechanism of heat energy horizontally from region to region and vertically between the earth's surface and the atmosphere. The movement of water vapor entails the transfer of energy in the form of latent heat—the amount of energy released or absorbed during a change of state—which is released into the atmosphere when condensation occurs. The opposite process happens when heat energy is used in the process of evaporation. When liquid water is evaporated, 600 calories of heat are absorbed and later released in the process of condensation.

Similarly, when ice melts, 80 calories of heat are captured and the same amount is released in freezing. The high heat capacity of the oceans, as opposed to the atmosphere, is an energy storage facility that helps to keep the global temperature relatively stable, shaping the earth's climate. This heat is constantly transported by the global ocean currents. Thus, changes in the hydrologic cycle as a result of climate change would cause critical alterations of the fluxes between reservoirs and energy transfer, with direct effects on water availability, weathering rates, nutrient transport, plant development, and indirect effects on agriculture production and economic development.

Rainwater is intercepted in its advance to the ground by canopy leaves and branches, leaf litter, small land formations, or as snow cover, reducing water availability and buffering the surface against erosion. The thin water layer deposited on the vegetation gradually descends to the ground by drippage or stemflow down stems and trunks, but stays exposed to evaporation for a certain length of time.

Infiltration is the process of vertical movement of water into the soil layer, which depends on various factors, such as soil properties, vegetation cover, and topographical properties, besides gravity and capillary action. Flat and rough surfaces with dense vegetation facilitate a prolonged retention of water for infiltration to take place. Next, migration is controlled by several soil features such as moisture content, the amount of open spaces (porosity), the texture, structure, and organic matter content. The rate of infiltration, or soil permeability, decays with saturation as the result of pore filling, expansion of clay particles and packing with small particles.

Soil water is not stationary; it continues moving downward under the pull of gravity and capillary forces. This process called *percolation* follows further the reach of the plant roots toward the bedrock and through the fissures and grains. It reaches the unsaturated zone, where still some air is present, and then forms the saturated zone when it encounters impermeable rock. Aquifers have a larger distribution than surface water, for they are in both dry and humid regions. Eventually, groundwater leaves the aquifer and flows back to the surface through springs or seeps, and discharges into terrestrial waters or the sea.

While at the surface, water is used by plants and eventually returned to the atmosphere by transpiration as water vapor. Plants pull water from the ground through the roots to transport nutrients from the soil, transfer sugars, and transpire water by means of the stomata to cool the leaves.

When the precipitation rate exceeds the infiltration rate of the soil, water accumulates on the surface, and subsequently starts to flow downslope, over land and is eventually channeled in a process termed *surface runoff*. Stream channels are organized hierarchically in networks that carry land water to the oceans or inland seas, a return flow that adds to the groundwater flow. Rivers and minor streams are located in areas of regular precipitation flow, while they exist only intermittently in areas of irregular precipitation.

Hydropower

HYDROPOWER INVOLVES CAPTURING the ability of moving water to generate power. This power may be generated in a variety of ways, including the driving of waterwheels and the powering of hydroelectric turbines. The technology has been used for many centuries and has helped to concentrate the settling of populations close to river systems and increased people's reliance on the rivers' predictability. In recent years, new developments have made it more possible to harness the power of tidal streams and of the waves of the open sea.

Waterwheels have been built according to a number of different designs in most civilizations of the world. The basic principle is to use the moving water to drive the buckets or panels that are used to create the wheel so as to power a revolving spindle, which then transfers the power to grinding flour or similar activities. The power provides a cost advantage over other forms of production and is used to replace human or animal labor, which remained in operation well into the industrial age. Waterwheels with a capacity of up to 100 horsepower have been developed.

Although superior to many other types of power production, waterwheels are limited in terms of their location, which may not always be convenient for coordination with other production activities. Even so, the use of water power to drive engines was sufficiently flexible to power iron-casting factories in ancient China, while tidal water wheels in medieval Europe were used to power grain mills. Europe saw the rise in development of the water wheel to its highest extent, perhaps because of numerous suitable locations and because of the rapid decreases of manpower caused by such disasters as the outbreak of Black Death. A single mill, if properly placed and employing the most advanced technology, is estimated to have provided milling capacity sufficient to feed many tens of thousands of people. Water wheels were also used to pump water from deep mines, while the wheels employed in some monasteries were in effect the power sources for very efficient and diversified factories. The potential for a large-scale revival of the use of water wheels and similarly powered turbines is likely to increase as the need for environmentally sustainable energy comes into sharper focus.

MODERN HYDROPOWER

Hydroelectric power uses the power of moving water to drive turbines, which then convert the energy into electricity. Commonly, hydroelectric plants are placed in large dams, which create substantial reservoirs that regulate the flow of water. This requires extensive areas of land, which may force resettlement and large-scale changes in agricultural patterns. Rivers flowing through borders raises issues of ownership of the river and its power, because income and protein supplies of people living downriver may be negatively affected by upriver hydroelectric power plants. The River Mekong, for example, originates in Tibet and China and passes through or along the borders of Laos, Thailand, Cambodia, and Vietnam. Chinese authorities are putting into place a series of dams and hydroelectric power plants on the energetic upstream river, which deny the downriver people of many of the resources of the river. There are many examples of the overextensive use of river water, such that even quite large rivers often cannot reach the sea for extensive periods of the year. These developments have stimulated the creation of large-scale protests against dam building and forcible movements of people.

Another area of concern is some governments' pursuit of hydroelectric power projects without adequate consultation with local people and evaluation of the impact on them and their livelihoods. Some commentators have argued that inadequate attention has been paid to the social and environmental impact of those projects. The accounting systems of these projects are complex and difficult to manage because of vast unknown or unpredictable factors, including future demand for electricity, future rainfall patterns, and the ability of people to adjust themselves to alternative forms of lifestyle.

The ability of dams to regulate water flow on rivers where the seasonal flow varies significantly and can lead to flooding or droughts is clearly beneficial. Even so, it does lead to changes in the lifestyles of river-dwelling people and may also affect a river's ecosystem in unpredicted ways. For example, preventing fish or other creatures from following their usual movement patterns can interrupt their breeding customs and interfere with the river food cycles.

Alternative energy sources include the creation of electricity via wave and tidal power, which also have the benefit of not emitting greenhouse gases or the other negative effects of hydrocarbon fuels. Unfortunately, it has yet to be demonstrated that they can be profitable without significant levels of government subsidy. Even so, future demands for nondamaging energy production may require such subsidies as a necessary investment. Small-scale energy production of this type can focus on local provision and meeting neighborhood demand rather than being distributed long distances or even across borders. New accounting methods may be required to take account of the opportunity costs associated with enhanced water management. An additional issue to consider is that of aesthetics, since a number of people complain about the impact of wind or water mills on the landscape and related issues concerning the value of their own property.

Ice Ages

ICE AGES ARE times in earth history when earth's climates were appreciably colder than normal and glaciers covered significantly larger areas of the earth compared to today. Ice ages represent conditions associated with the extreme cold periods and global cooling of an otherwise normally fluctuating global climate system. During an ice age, ice sheets, which normally occur only in high latitude areas close to the north and south poles, extend farther into the lower latitudes. Alpine glaciers, which normally exist at higher elevations, extend to much lower elevations during ice ages.

Ice ages occurred as far back as the Precambrian, and occurred sporadically until the present. Major ice ages occurred during the late Precambrian (800–600 million years ago); late Ordovician and early Silurian (460–430 mya); Pennsylvanian and Permian (350–250 mya); in addition to the Pliocene and Pleistocene (last 3 million years). The most recent Ice Age is the most well-known. The Pleistocene Ice Age, and probably also the ancient ice ages, had several glacial and interglacial episodes. Many consider the current warm global climate episode as being an interglacial episode following the last glacial episode.

Evidence of the Pleistocene Ice Age is found in the many glacial landforms in different parts of the world. For example, in the United States, glacial moraines that can be found as far south as Long Island, NY, and extending along a line that generally passes westward through most of the northern tier of states. North of this line, areas are covered with glacial tills and moraines, and bedrock surfaces are marked by glacial striations. This indicates that areas north of this line, including the northern tier of the United States, almost all of New England, and all of Canada were covered by an ice sheet. Similar Pleistocene glacial features are found on other Northern Hemisphere continents. In the Southern Hemisphere, the only continents close enough to the South Pole to be glaciated were Antarctica and Tierra del Fuego at the southern tip of South America. Ice ages older than the Pleistocene have been recognized based on more subtle evidence. Glacial tillites are interbedded with fossiliferous marine deposits or other deposits that can be dated, thereby establishing the age of glaciation.

Glacial deposits of Permian age are found on several continents. When these continents are viewed in the Pangean position (during the Permian), the glacial deposits cluster around the paleo-south pole.

In the oceans, seawater contains a certain ratio of two oxygen isotopes (O^{16}), and the heavier isotope

(O^{18}). During an ice age, when seawater is cooler, the evaporation ratio of these two isotopes is different than during warmer intervals. Therefore the oxygen isotope ratio of seawater, as well as minerals and shells that precipitate from seawater during glacial intervals, reflect this isotopic difference. As such, oxygen isotope ratios of ancient fossils and minerals may serve as a proxy for recognizing ancient ice ages.

There are several possible causes for global cooling. Milankovich cycles are oscillations in global temperatures that are caused by variations in the rotation of the earth and the revolution of the earth-sun system. Global temperatures are warmer during times when there is more carbon dioxide (CO_2) in the atmosphere (greenhouse conditions), and cooler when CO_2 levels are lower (icehouse conditions). Global temperatures are cooler when the atmosphere contains a lot of particulate matter from volcanic eruptions or meteorite impacts. "Glaciation" may also be more prevalent during times in earth history when continents drift into polar locations. It is thought that the Ice Ages may correspond to times when several of these causal factors coincide.

During an ice age, or even during times when global climates are generally cooler, several effects may result. Sea level drops as water in the global water budget shifts from the oceans to glaciers. During the Pleistocene, sea level was approximately 200 meters lower than today and most of the continental shelves were exposed as coastal plains. Because terrestrial and marine temperatures become cooler over the entire globe during an ice age, global climate belts shift toward the equator. Similarly, terrestrial and marine species and ecosystems shift toward the equator during ice ages. Atmospheric and oceanic circulation patterns—especially those that are driven by temperature or density differences—change during an ice age.

Ice Core

ICE FORMS AT different rates and in different ways. Over time, the ice recrystallizes and traps small amounts of air, which vary according to environmental conditions. Since new layers form over the top of existing layers of ice, it is possible to obtain an accurate historical record of the past by drilling an ice core sample through a long-standing ice field. The best places to take these samples are in polar regions where the ice has been undisturbed for thousands of years.

One of the most famous examples of ice core drilling and analysis was the Greenland Ice Core Project. Visual records of the past stretching back hundreds of thousands of years have been obtained using this method. Such ice core samples may be several miles in length or longer. Analysis of such samples must consequently be a cooperative affair. Identifying particles of dust, nuclear radiation, and different isotypes of, for example, oxygen and the cross-referencing of the presence of these particles with other known records (including sediments) helps to triangulate the data for even greater reliability. An ice core analysis enabled scientists to determine that the earth's climate is subject to sudden, abrupt changes such as the one that ended the last ice age within just three years. It has also been an important tool in determining the extent and rate of change of climate change in the modern world.

Mountain glaciers can also provide useful information. Global climate warming is putting these records at risk, however. Obtaining ice core samples necessitates burrowing deep down into the ice with a powered tube, which requires considerable amounts of power and expense. The retrieved ice core is extruded from the drilling device and sliced into convenient lengths for processing and analysis. Contamination and decompression of the sample are threats to the integrity of the ice. Chemical analysis, chromatography, and mass spectrometry are among the techniques that are employed to determine the contents of the core. Changes due to dramatic events such as volcanic eruptions and the dust produced by volcanoes may be evident in an ice core sample.

Iceland

ACCORDING TO THE United Nations Development Program (UNDP) Human Development Reports, the Republic of Iceland has the second-highest standard of living in the world. The country is greatly admired for its high income and literacy rates, long life spans, strong social cohesion, and extensive social welfare programs. One hundred percent of the population has access to safe drinking water and improved sanitation. Iceland is one of the few European countries that have elected not to join the European Union (EU). Surrounded by the Greenland Sea, the North Atlantic Ocean, and the Denmark Strait, Iceland has 3,081 miles (4,970 kilometers) of coastline. Because of the North Atlantic, Iceland's climate is temperate with mild, windy winters and damp, cool summers. The capital city of Reykjavik is the northernmost capital in the entire world.

Iceland is a land of kinetic steam because of its active volcanoes and geysers. The Askja volcano is one of the most important geographic features of the country. In 1875, fallout from this volcano created major economic upheaval as 20 percent of the population fled to Canada and the United States. Earthquakes occur on a daily basis in Iceland, producing new fissures. As a result, the landscape of Iceland rapidly changes as new islands appear and gradually erode to extinction. The country is mostly flat with intermittent peaks and ice fields, and the coast is broken up by bays and fiords.

Modern Iceland has embraced a vast range of new environmental technologies, and was one of the first countries to begin planning for the elimination of fossil fuels. The proposed 700-megawatt Karahnukar Hydropower Plant, consisting of nine dams, three reservoirs, seven channels, and 68 miles (110 kilometers) of underground tunnels, is planned to supply electricity for large-scale aluminum smelting. Environmentalists have strongly opposed the project, citing the potential environmental damage

Iceland is a land of active volcanoes and geysers; earthquakes occur on a daily basis.

caused by massive redirection water flow from rivers and tributaries.

With a per capita income of $34,600, Iceland is the 11th richest nation in the world. The most significant resource is the fish that produces 70 percent of all export earnings. Other resources include hydropower, geothermal power, and diatomite. Approximately 10 percent of the workforce is involved in agriculture, including the 8 percent involved in fishing. Over 90 percent of the population of Iceland live in urban areas. With 561 cars per 1,000 people, Iceland produces 7.7 carbon dioxide emissions (metric tons) per capita. The government has protected 9.8 percent of the land in Iceland. As a result, none of the 93 bird species endemic to Iceland are endangered, but six of the 11 endemic mammal species are threatened with extinction.

Environmentally, Iceland suffers from water pollution caused by fertilizer runoff and inadequate wastewater treatment. A 2006 study by Yale University ranked Iceland 13th among 132 nations in overall environmental performance, slightly higher than average among countries in the same income and geographic groups. The Icelandic government has pressured the owners of power plants and aluminum smelters to employ the most environmentally friendly technology in order to reduce toxic emissions and has enacted fines to force polluters to pay for cleanup.

In 1990, Iceland created the Ministry for the Environment and charged the minister with environmental monitoring and surveillance, as well as oversight of conservation, outdoor recreation, the protection of animals, wildlife management, pollution and fire prevention, weather forecasting, and protection from avalanches. Between 1990 and 2000, the government passed a body of environmental legislation that included the Fishery Management Act, Protection and Hunting of Wild Species Act, Organic Farming Act, Foodstuff Acts, Farm Afforestation Act, Act on Financial Support to Municipalities for Sewage Control, Act on Special Fee on Hazardous Waste, Nature Conservation Agency Act, Southland Afforestation Act, Public Health and Pollution Control Act, Public Lands Act, Nature Conservation Act, and the Environmental Impact Assessment Act. In 2003, the government also introduced a major conservation plan.

Iceland's commitment to the global environment is demonstrated by participation in the following international agreements: Air Pollution, Air Pollution–Persistent Organic Pollutants, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Kyoto Protocol, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, Transboundary Air Pollution, and Wetlands. The government has signed but not ratified the Environmental Modification and Marine Life Conservation agreements.

Ideology

THE WORD *IDEOLOGY* was first used by the French philosopher Antoine-Louis-Claude Destutt de Tracy during the French Revolution; he called it his "science of ideas" and intended that his study of ideas would transform France into a scientific and rational society.

While Destutt de Tracy enjoyed initial years of popularity, he was eventually scorned by Napoleon, who blamed his military defeats in part on intellectuals and the *ideologues*. The history and subject of ideology has since been controversial and the word may be used both formally or informally, positively or pejoratively.

Modern philosophy generally describes ideology in both positive and pejorative terms. In a positive sense, ideology is a system of values, beliefs, and ideas, unconscious or conscious, which organize and shape understandings and perceptions of the political and social world. It acts to justify, recommend, and implement collective action aimed at influencing public thought or political and institutional social structures. It is a set of ideas used to address truth and conduct, and that speaks for a class, nation, or other body of believers.

Anthropologists commonly describe ideology as a set of explanatory cultural beliefs that serve to unify morals, goals, and social relations and without which civilization would be impossible. Ideology is an ordered set of linguistic and cultural symbols through which people interpret and make meaning of the world. Every society has an ideology, and it forms common sense and public opinion. In this view, ideologies are beliefs that are consciously held. They enable groups of people in society to act in unison to direct societal and political change.

In a more subtle sense, anthropologists and sociologists describe how ideology and the sense of normalcy remain invisible to most people in society. They are unquestioned and taken for granted in our norms and assumptions. Seeing past this invisible and internalized logic requires an active process of analysis.

IDEOLOGY AND POWER RELATIONSHIPS

From a more critical position, the word *ideology* can be used as a pejorative whereby adherents are described as distorted, uncritical, and suffering under a delusion in something akin to superstition. In this view, ideology serves as much to conceal and mislead as to reveal and coordinate. Karl Marx adopts this view of ideology, concluding that ideology serves to conceal, and thus, identification of ideology is the first important step toward overcoming oppression.

Most ideologies emphasize social order and power relations as well. However formal or informal, ideology is concerned with intellectual and social order, rationality, power, conflict, coercion, and the subsequent authorized use of force. In modern times wars are rationalized by "isms." The balance of power is commonly fought amongst communism, socialism, capitalism, authoritarianism, anarchism, fascism, Nazism, and terrorism. Most ideologies contain an element that strives to recruit members to their perspective and gain commitment. The comprehensive nature of ideology frequently leads to extremism and violence.

Ideological systems contain the assumption that now that this (natural) state of affairs has been reached, things should be that way forever (externalization). For example: "Technological development is the system that can best address an environmental crisis; human history and evolution is a history of human technological developments; if enough resources are provided for new technological developments crisis will be avoided." We *assume* that technology is the best response to environmental crisis; we *interpret* history as one of technological development; we *assume* that more technology will solve an environmental crisis. These assumptions are ideological.

ANALYSIS AND POLITICAL IDEOLOGY

An ideological analysis of a text asks the following questions: What are the presumptions about what is right, just, and natural? What harmful elements are ignored? What do these assumptions conceal and distort? How is power and tradition made to appear good, normal, and unexamined? How is rhetoric like "good us" and "evil them" used and what is devalued? What experiences, classes, people, and values are silent? Who profits from this ideology?

A purely or rigidly ideological mind often alienating and distrusts, attacks, and questions other centers of power. It is totalistic in its aim to influence entire social systems, and it is futuristic in its belief that it is working toward a possible utopian ordering in which a "good" society will result. However, uncomfortable dissonance results when there is a discrepancy between what one believes *through* an ideology and what science or experience establishes as real. A common way to avoid uncomfortable dissonance is to selectively ignore those things that do not agree with the ideology, emphasize some aspects more than others, and frame questions and analysis so that discrepancies in the ideological system remain hidden. For example, the pro-technology ideology substantially exaggerates the contribution of technology while underplaying and ignoring the many technological disasters and challenges of the nuclear age.

ENVIRONMENTAL MOVEMENTS

Environmentally oriented ideologies include environmentalism, green politics, and bioregionalism. They are ideologies in that they represent unique valuing schemes with coherent systems of thought that organize and unite persons toward a common vision while offering consistent critique of other systems.

Environmentalists and environmental sociologists describe the culture of the Western world and the sources of U.S. environmental problems in both cultural and structural terms. Environmentalists see the structural sources of U.S. environmental problems in the laissez-faire capitalist economy, the polity of unrepresentative government that has an amicable relationship with large industrial polluters, and the system of social stratification that lends itself to environmental racism. They describe basic ideological cultural elements as a cornucopia view of nature, faith in technology, a growth ethic, materialism, and a belief in individualism together with an anthropocentric perspective.

Environmentalism is a social movement that uses education, activism, lobbying, and protest to influence the political process to protect the environment. While there is tremendous diversity within the environmental movement and related green politics, common positions include stances against nuclear waste, solid waste, water and air pollution, chemical pollution, population growth, genetically engineered foods, ozone depletion, the creation of greenhouse gasses, global warming, degradation of the land, deforestation, and unsustainability.

An environmentalist adheres to the goals of environmentalism and is frequently cautious about new technology because of concerns about how it will affect the environment. Environmentalists commonly adhere to the precautionary principle, which maintains that if the results of an action are unknown, but are judged to potentially have irreversible negative consequences, then it is best to avoid that action.

Politically active environmentalists commonly have strong views about the environment and identify themselves as *greens*, meaning they have green politics and may formally be members of a Green Party. The term may also be used to describe environmental scientists with a conservationist's view, a view that advocates for enhancement, restoration, or protection of the environment.

GREEN POLITICS

Green politics is a body of ideas within the environmental movement that strives to make sustainability a political goal. Green politics actively critiques what it sees as unsustainable practices. Green political thinkers also generally want an end to the war on drugs, which is seen to have a negative environmental impact and to be a violation of civil liberties and a waste of resources. They want an end to corporate welfare and subsidies to dirty industries. They are critical of pro-business, voluntary approaches to solving environmental problems. They think that environmental problems are not confined within political borders and that bad environmental policy leads to negative international implications and ultimately wars over precious resources. Many greens are also involved in the antiglobalization movement because they feel globalization is antienvironmental in that it is energy-intensive, creates social stratification, empowers global capital, weakens environmental and labor laws, works against bioregionalism, and rides roughshod over local environmental concerns.

Bioregionalism (or bioregional democracy) is the belief that social organization and environmental policies should be based on the bioregion rather than on a political or economic region. It is a group of reform movements intended to strengthen the political process to better protect the environment and sustainability on a local level. There should be local control over natural commons and resources; resources should not be controlled in the name of globalization.

Many of the positions supported by environmentalists are also commonly associated with feminism, pacifism, social justice movements, and liberal religious groups. Environmentalists with green politics commonly value and advocate for grassroots democracy, conservation, a green tax shift, increased consumption taxes, strong environmental protection and labor laws, moral purchasing decisions, full cost accounting, measuring well-being in quality-of-life terms instead of Gross National Product (GNP) or the consumer price index, heavy investments in human capital, investments in mass transit instead of highways, investments in cities instead of urban sprawl and land speculation, accounting reforms that would advantage small business and environmentally friendly industries, long-term vision, bioregionalism, and a biocentric perspective. The perspective of environmentalists is powerful, contains comprehensive theory, a defined set of values, and is supported by much empiricism. Environmentalism is thought by many to hold the prescription for a better and sustainable world.

As with any ideology, however, where environmentalism as a helpful, organizing intellectual tool leaves off and where bias and muddy minds begin has been a riddle of modern sociological thought. In heated discussion between individuals with different ideologies, one person's carefully thought-out empirical system is another person's naiveté, uncritical delusion, and indoctrination. Ideology can organize empirical inquiries but cannot be a substitute for empiricism.

India

MODERN INDIA IS blessed with some of the most diverse and rich environmental resources of any nation in the world. It has long had many environmental problems, however, stemming from its long colonial domination by foreign powers and mismanagement of resources after independence.

The oldest known civilization in India, located in the Indus Valley, flourished from 2500 until 1800 B.C.E. The reasons for its collapse is unclear, but environmental change may have been as conclusive factor, along with tectonic shifts in river course, and the onset of floods which ruined a large amount of agricultural land. The rise of a civilization of ethnolinguistic Aryan immigrants in the centuries following decline of the Indus "Harappans" has led to speculation that the alter civilization drove out the earlier one, though there certainly is no evidence of interaction, let alone warfare.

During the period from 1500 B.C.E., with the formation of Hindu India—and the introduction of the caste system—until the creation of colonial India, waves of invasions and wars between the various rulers of the subcontinent caused many problems but also led to rich hybrid cultural interactions and many environmental innovations and management systems, ranging from the use of the Perisan Wheel in agriculture to the magnificent Mughal Gardens, where complex water lifting and distribution systems were used to naturally air condition palaces and provide diverse and productive botanical gardens.

The arrival of the Portuguese, and later the British, Dutch, and French, saw the introduction of European cultures and values, and also the imposition of dramatic new political and economic systems, which stressed local environmental resources and led to dramatic changes in land use and productivity.

In 1827 and again in 1839 there were significant cases of wheat rust in India. There was a large cholera pandemic in India in 1891. The Spanish Influenza Epidemic of 1918–19 affected much of the world but India was the country worst affected. It seems likely that as many as 17 million people died, which represents about 5 percent of the entire population.

Other environmental problems caused regular famines in India—there were problems during the British takeover of India, and also after the Indian

Mutiny of 1857, when many of the crops were lost. A major famine took place in 1943 during World War II when India was facing a possible Japanese invasion, and large numbers of men were involved in the British war effort. This saw the deaths of 5 million people, being the most destructive of the famines in India before independence. Since the creation of independent India in 1947, there have not been any famines, with surplus stored in years of plenty and transferred around the country to feed people when harvests fail. Events such as the poison gas emissions at Bhopal have been highlighted as problems with Indian environmental protection legislation.

Weather conditions in India have presented problems since ancient times. There have been many stories set around the lives of people awaiting the monsoons each year. The Green Revolution has seen a huge increase in agricultural production throughout India, with increased rice crops, and this has alleviated problems that had been caused by the weather. Simultaneously, however, the high-input crops have led to soil exhaustion in many places and declining aquifers, raising questions about the sustainability of technology-centered solutions to India's agrarian development challenges.

Development and government mismanagement has placed a great strain on wildlife in India, with tigers and other wild animals finding their hunting areas significantly encroached upon. This has led to tigers attacking livestock and farm animals, and sometimes humans. At the same time, the value of tiger skin and bone products in adjacent China and elsewhere has led to increased poaching. As agricultural land has expanded, as a result of new irrigation technologies and expansion of export markets, coupled with increasing food demands, wildlife habitat has also been threatened, although a large number of national parks have been established throughout the country.

Reverence for animals in Indian culture means that many animals, wild and domesticated, live in the countryside and often within urban areas, including the ubiquitous cattle population in the streets of cities, towns, and villages, and countless temples dedicated to other animals such as monkeys, bats, and rats, which are free to roam about.

In recent years, with the establishment of national parks in India, there has been an increase in the number of ecotourists visiting the country. Large numbers of World Heritage sites exist throughout the country, ranging from the world-famous Taj Mahal, through to the cities of Jaipur and Jodhpur, the caves of Ajanta, and also many less well-known sites. These environmental locations draw many international tourists, though the booming indigenous middle class population of the country has become the mainstay of national tourism. The pressure of domestic and foreign visitors on ecotourist destinations raises questions about the sustainability of the industry.

Population and the Poor

As the second most populous country in the world, overpopulation has long been considered a problem in some parts of India. It has long been a country with vast differences between the wealthy and the extremely poor, and this trend has accelerated in recent years as globalizing India enthusiastically embraces world trade. However, most cases of hunger or resource scarcity are largely understood to be a product of poor distribution networks and unequal allocation of infrastructure and resources. Since independence, there have been attempts to reduce the birth rate, including the well-publicized campaigns by Indira Gandhi during the 1970s, with doctors performing sterilization vasectomy operations on men and women, especially among the poor and in country areas. The government of Kerala, in the south of India, has long believed that female education is a major influence on the birth rate, as do social policies such as better heath care and opportunities for women to work, leading to later marriage. Their policies have borne fruit with a dramatically reduced birth rate and near universal education, literacy, and access to health care.

Indian Ocean

NAMED FOR ITS proximity to the subcontinent of India, the Indian Ocean is the world's third-largest ocean. It stretches from Africa to Australia and Indonesia and from Asia and the Middle East to Antarctica. The Indian Ocean's marginal water bodies include the Andaman Sea, Arabian Sea, Bay of Bengal, Great Australian Bight, Red Sea, Gulf of Aden, Gulf of Oman, and Persian Gulf.

Continental shelves beneath the Indian Ocean widen to include Madagascar and Sri Lanka, the largest islands in the ocean. The Andaman and Nicobar Islands are also continental islands. The massive submarine Mid-Ocean Ridge divides the ocean floor into three parts of about equal size. A few peaks along the ridge's crest emerge as islands. The Seychelles and the Kerguelen Islands are examples. The Laccadives, the Maldives, and the Chagos are low coral islands. Mauritius, Réunion, Heard, and McDonald Islands are high, solitary volcanic cones. Featureless abyssal plains and low hills dot much of the ocean floor. A prominent exception is the Indus Fan, the world's largest deep-sea or submarine fan. Sediments carried by Indus River from the Himalayan Mountains to the ocean are building the fan. The greatest depth is in the Java Trench, south of Java, an island of Indonesia. The Sunda Trench, which lies west of Sumatra (another island of Indonesia), was the site of the devastating 2004 Indian Ocean earthquake that spawned the world's deadliest tsunamis, killing about 200,000 people.

The ocean's main surface currents are parts of a counterclockwise gyre (a large water-circulation system), which lies south of the equator. The gyre consists of an equatorial current, the Agulhas Current, the Antarctic Circumpolar Current (West Wind Drift), and the West Australian Current. A monsoon wind regime dominates the climate of the ocean. A dry northeast or winter monsoon emanating from a

Christmas Island Crabs

Christmas Island, in the Indian Ocean, was spotted by a British sea captain on Christmas Day, 1643. The first landing was in 1688 but it did not become a British possession until 1888. Nine years later, settlers started arriving to work for the Christmas Island Phosphate Company Ltd. It became a part of the Straits Settlements, administered from Singapore, and is now an Australian territory. About 12 percent of the island is covered by a National Park, which will eventually extend to cover 65 percent of it. Although there are thousands of birds on the island, Christmas Island is the home to about 120 million crabs. Indeed, crabs regularly appear on Christmas Island postage stamps.

There are, altogether, 14 terrestrial crab species on Christmas Island, and most of these are the Christmas Island red crab (*Gecarcoidea natalis*), which also lives on the Cocos (Keeling) Islands. Normally the crabs live in burrows, and breathe through gills, meaning that they have to keep themselves moist at all times. The crabs are well-known for an annual migration at the start of the monsoon season in November each year. During this time they leave the land to lay their eggs in the ocean. This results in millions of crabs packing the routes to the coast so densely that the numbers can be seen from the air. It is not unknown for crabs to clog the roads and have to be shoveled off them to allow cars to navigate the island. Although the red crabs are common, there are regular sightings of blue crabs, which are heavily protected. The crabs mostly live from eating fallen leaves and flowers, but they can also eat small animals, especially carcasses, and also are known to eat other crabs.

high-pressure air mass over Tibet and eastern Asia reduces precipitation over the ocean from December to April. The pressure over the land decreases from June to October, so that a moist southwest or summer monsoon flows from the western side of the ocean to India and Southeast Asia. The southwest monsoon supplies valuable rain to the Asian mainland. It also causes significant upwelling of cool water and nutrients for fish in waters east of the African and Arabian coasts. The seasonal reversal of the monsoons imparts a reversal in the direction of small gyres in the Arabian Sea and the Bay of Bengal. In summer, the gyres flow clockwise, but in winter, they flow counterclockwise.

The temperatures of the Indian Ocean are highest in the poorly circulated marginal seas of the Arabian mainland and lowest in the southern latitudes, where ships encounter pack ice and icebergs. Brine pools in the Red Sea have the highest salt content. Salinity is lowest in the Bay of Bengal due to a voluminous discharge of freshwater from the Ganges-Brahmaputra river delta. The Indian Ocean supplies energy (latent heat of evaporation) and moisture to extratropical and tropical cyclonic storms.

Regardless of the time of year, satellite images reveal a west-to-east passage of one or more extratropical storms in the Southern Hemisphere's zone of prevailing westerlies (40 degrees to 60 degrees South latitude). Australians call these storms willy-willies. Most of these storms do not make landfall because large landmasses generally do not exist where they travel.

Tropical cyclones (huuricanes) form closer to the equator in the summer and early fall over warm tropical waters off the northwest coast of Australia, in the Bay of Bengal and the Arabian Sea, and east of Madagascar. Like their North American cousins, Indian Ocean cyclones cause severe wind damage, coastal flooding, and human devastation wherever they arrive on shore.

The Indian Ocean has been strategically important historically for its location along seafaring trade routes between Asia and Europe. Marine resources of the region include oil and gas fields, fish, shrimp, sand and gravel aggregates, placer deposits, and polymetallic nodules. The Indian Ocean has serious environmental problems as well. It is home to several endangered marine animals, including the dugong, seals, turtles, and whales. Oil pollution is also a problem in the Arabian Sea, Persian Gulf, and Red Sea.

Indicator Species

SOME SPECIES ARE highly sensitive to toxic chemicals or changes in temperature or humidity, and others are particularly sensitive to changes in soil or water pH. Such species, when monitored regularly, can function as indicator species, analogous to water-salinity meters or pH readers. In 1989, for example, the *Exxon Valdez* oil spill in Prince William Sound, Alaska, devastated marine habitats and wildlife, and created conditions that demanded systems of monitoring to determine the extent of the problem and the effects over time of ameliorating efforts. In this case, mussels were sought, and their abundance and distribution were used to indicate the extent and change in environmental pollution.

The concept of indicator species has been welcomed by managers of protected areas because it allows the focusing of conservation efforts through the monitoring of particular species. The assumption is that an increase or decline in abundance of an indicator will point to similar changes in other species within that community of organisms. For example, declines in amphibian populations have led calls for frogs and toads to be recognized as indicators of wetland health, and many research studies have since resulted on amphibian diversity and ecology in the tropics. The concept of indicator species has its opponents too. Doubts were expressed by some biologists when the threatened northern spotted owl *Strix occidentalis* was designated an indicator species by the United States Forest Service. The objection was that the species did not satisfy the condition of strongly ecological association with other species. *Ecosystem health* may mean different things to different people, species richness being critical for some, while others believing in strict protectionism. Yet others, such as tribal people resident in or near a protected area, would see a forest full of edible fruit, seed, and root as a healthy ecosystem. The question of what exactly needs to be monitored and indicated has many interpretations; hence, the application of the concept of indicator species to conservation biology has been troublesome.

Certain species have been studied in detail and are widely accepted as environmental indicators. Prime examples are rock lichens, such as the endangered rock gnome lichen *Gymnoderma lineare*, known to be sensitive to heavy metals, ozone, and sulphur dioxide, a common air pollutant in industrial and automobile emissions. In aquatic systems, mollusks, which tend to concentrate toxic pesticides and heavy metals in their tissues, are considered indicator species, and include clams, oysters, and snails. Disease and organ failure resulting from toxins leads to a decline in the abundance of mollusks, indicating high levels of pollutants in the water. In Southeast Asia, butterflies, sensitive to changes in the structure of their habitat caused by logging, have been studied as indicators of biodiversity and forest disturbance. Some biologists also believe that monitoring the status and abundance of butterflies can indicate whether communities of plants and animals will remain stable or start to collapse by losing species over a period of time. The proposition that a single species or even a group of species from the same taxonomic group can indicate the richness or diversity within a whole ecological community is less and less promising. Instead, biologists are searching for indicators of species richness that are effective within geographic and taxonomic limits. Recent emphasis on the conservation of complete landscapes is a challenge to the rationale and necessity of discovering and monitoring indicator species for biodiversity conservation.

Indigenous Peoples

INDIGENOUS PEOPLES ARE often considered synonymous with aboriginal, tribal, or native peoples, and some would characterize the phrase even more broadly. There have been countless attempts to define the term “indigenous peoples,” yet in today’s complex world of interwoven ethnic identities, no one definition has ever been agreed upon. According to the Office of the United Nations (UN) High Commissioner for Human Rights, “there are an estimated 300 million indigenous people in more than 70 countries worldwide.” The UN clearly distinguishes “indigenous peoples” from “indigenous people” because the plural form carries a distinct legal meaning according to Article One, which recognizes the “principle of equal rights and self determination of peoples.” The phrase *indigenous peoples* refers to groups of people who share the same ethnic or tribal identity and who either currently inhabit or are descended from a known geographic area of their home country, often referred to as their ancestral lands. The UN International Working Group on Indigenous Affairs states that: “Today many indigenous peoples are still excluded from society and often even deprived of their rights as equal citizens of a state. Nevertheless they are determined to preserve, develop, and transmit to future generations their ancestral territories and their ethnic identity...” The UN also recognizes that indigenous peoples “are descendants of groups which were in the territory of the country at the times when other groups of different cultures or ethnic origins arrived there.”

Indigenous peoples traditionally live in a range of types of societies with varying strategies of adaptation to their environments. Due to a variety of factors, including loss of land to neighboring or dominant societies, most indigenous peoples are no longer able to rely on their traditional methods of subsistence, but in some cases they still adhere to these ways of life when possible. These include:

Foragers (also called hunters and gatherers) lived in small kin-based groups, had nomadic or seminomadic lifestyles organized into bands, and have no formal leader.

Horticulturalists (smale-scale farmers) cultivate crops using only human labor, practice shifting cultivation, and usually belonged to a larger tribe and had a formal or informal leader

Pastoralists survive primarily on herding animals such as sheep, goats, or cows, are nomadic, and usually belong to a larger tribe with a leader or chief determined by heredity.

Agriculturalists practice farming with the use of animal labor, are sedentary, often practiced irrigation, and have a class or a caste system and one or more leaders or chiefs. Agriculturalists come in a variety of types and political systems. There were even empires comprised of several chiefdoms and required that tribute be paid to their leaders through a centralized system of redistribution.

In the late 1800s and throughout the 1900s, anthropologists traditionally studied indigenous peoples in their homelands throughout the world and the effects that colonization by dominant societies had on their traditional ways of life. Beginning a few centuries earlier, and throughout this period, colonizers—primarily from European countries—attempted to conquer and control indigenous peoples they encountered in their explorations of other continents and islands in Asia, Africa, and the Americas. Once most indigenous peoples came into contact with those from an industrialized society, they usually suffered increased disease and deaths. Furthermore, indigenous peoples have been victims of intentional genocide since colonialism began.

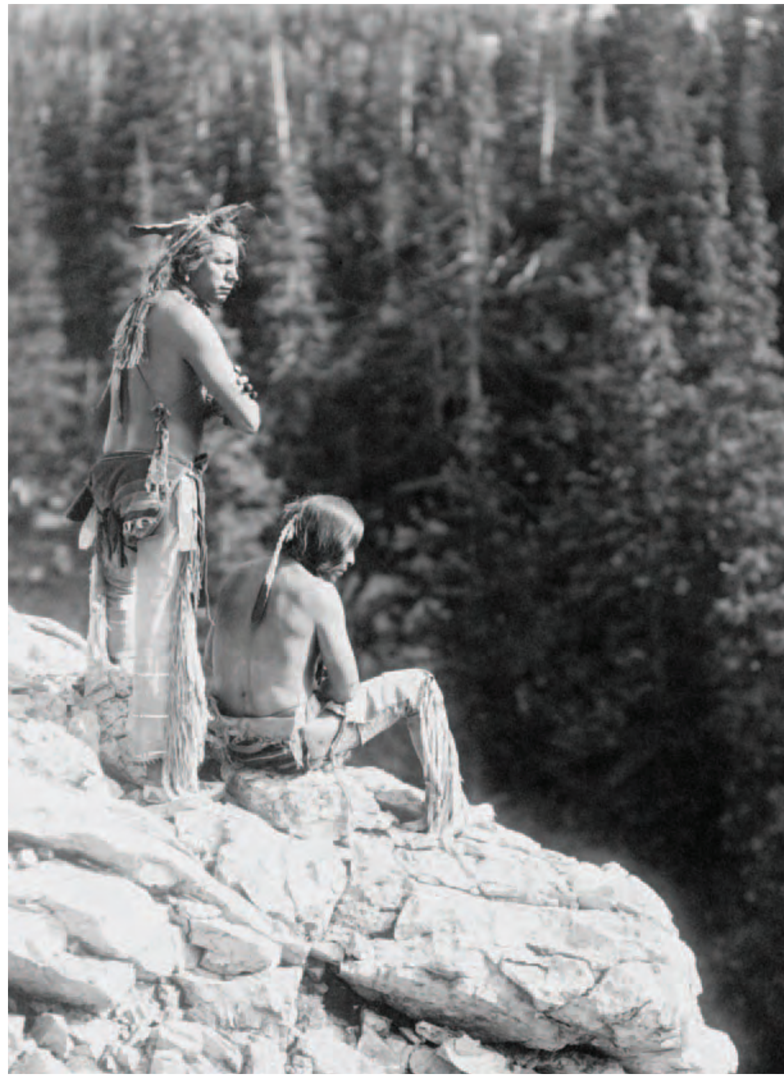
Prior to colonization by Europeans, indigenous peoples had their own problems of warfare and conflict, often resulting from similar quests for resources or territories, and also resulting from varying religious beliefs and ongoing feuds. For their part, European colonists justified their control of indigenous peoples because they believed that their model of society was far superior. These indigenous peoples did not cover themselves with as much clothing and did not yet live in an industrial, mechanized world. They were thought to be “primitive” or even “savage.”Throughout the 1800s and early 1900s, governments from Europe as well as the United States attempted to control territories occupied by Native Americans and indigenous peoples throughout the world.

As attempts were made to control native peoples, the United States—immersed in civil war and Indian wars—enacted legislation to create the first national parks and later served as an example for other nations interested in so-called “wilderness preservation.” The first parks were Yellowstone (1872) and Yosemite (1890), and were established with grave consequences for indigenous peoples of the areas who were expelled, starved, or burned out of their lands. Thus, the notion of a “protected area” as lands that are not occupied by any humans was embedded into the world’s view of nature preservation and exported from the United States throughout the world. It was further codified as stated in the 1964 U.S. Wilderness Act, which defines wilderness as a place “where man himself is a visitor who does not remain.” Throughout the 1900s, indigenous peoples throughout the world were evicted from their aboriginal territories to make way for protected area “nature” conservation. As indigenous peoples were forced to leave their traditional territories, policies and treaties in the United States as well as other nations began to establish lands, sometimes known as reservations, where they could live. National governments established agencies to oversee indigenous peoples and some were required or allowed to set up their own tribal governments.

In the 1960s and 1970s, anthropologists became interested in the subject of how indigenous peoples adapted to their environments, and researchers in the fields of ecological anthropology, cultural ecology, and ethnoecology realized that many groups of indigenous peoples had in—depth complex knowledge of the natural world that usually exceeded the level of knowledge western scientists had of those same geographic areas. Furthermore, as modernization progressed throughout the world, anthropological field researchers noted that there were many indigenous peoples who were able to survive using traditional small-scale shifting agricultural methods, or efficient hunting and gathering techniques that maintained a generally healthy environment for humans and landscapes. Yet, we also know that indigenous peoples did not always live in harmony with their environment. In fact, some groups of indigenous peoples, such as those called Ancient Pueloans (Anasazi) at Chaco Canyon, New Mexico, and inhabitants of Easter Island in the Pacific, were found to have overutilized natural resources to the point of causing irreversible environmental degradation and likely contributed to the collapse of their entire society.

In spite of some examples indicating indigenous peoples' practices as contributing to environmental degradation, a large number of studies found that indigenous peoples had successful adaptations to their environments, as demonstrated by cultural ecologists. These studies coincided with an earlier environmental movement of the 1970s; were later embraced and transformed by a resurgence of environmentalism in the 1990s; and were often a basis for environmentalist representations of indigenous peoples as "ecologically noble savages." Scholars and advocates have debated the validity and potential harmfulness of the use of this image in indigenous and environmental causes for over a decade. Nonetheless, indigenous peoples at times leverage this romanticized image of themselves as natural stewards of the environment to advocate for land claims and struggles for other human rights and social justice causes.

Indigenous peoples throughout the world continue to be displaced and marginalized due to encroachment of environmental degradation in the areas they occupy. Unfortunately, indigenous peoples also engage in conflicts with each other, especially when resources such as water and land are scarce. Despite some countries' offering reservations or territories to indigenous peoples, they have consistently had little control over the implementation



Colonists justified their control of indigenous peoples with the belief that their model of society was far superior.

of laws or policies which grant them territories. Throughout the 1980s and gaining momentum as a result of the 1992 UN Conference on Environment and Development (UNCED, also known as the Earth Summit), indigenous peoples began forming their own nongovernmental organizations (NGOs) or working with NGOs established by others to fight for indigenous rights. These organizations participated in a conference parallel to the Earth Summit, called the Global Forum. Despite the creation of some disingenuous NGOs, collectively NGOs have had considerable success in fighting for indigenous rights worldwide. Thousands of NGOs throughout the world have now been created by indigenous peoples. Official tribal organizations have also joined the fight for indigenous rights, including First Nations of Canada, the Navajo Nation of the United States, and the Aboriginal Government of Australia.

Indonesia

IN 1949, INDONESIA achieved independence from the Netherlands with the help of the United Nations (UN). The years following that event have been filled with poverty, terrorism, corruption, colonial revolts, shifting political alliances, and major natural and environmental disasters. In addition to these problems, the government has been forced to deal with separatist movements in Aceh and Papua. Indonesia's substantial oil resources have begun to decline, and the government was forced to import oil in 2005. This move led to a fuel price increase of 126 percent. In response to several terrorism incidents, the tourist industry also began to decline.

With a per capita income of $3,700, Indonesia ranks as the 150th wealthiest nation in the world. Indonesian income is unevenly distributed, with the wealthiest 10 percent of the population sharing 28.5 percent of available resources. More than 15 percent of the population of 241,974,000 live in poverty, which is particularly prevalent in rural areas. Indonesia is highly dependent on agriculture, in which 45 percent of the workforce is engaged. The high unemployment rate (10 percent) is indicative of deeper societal problems. The UN Development Program (UNDP) Human Development Reports rank Indonesia 110th of 232 countries in overall quality-of-life issues.

Located in southeastern Asia in an archipelago of 17,508 islands (only 6,000 are inhabited) between the Indian and Pacific Oceans, Indonesia has 33,924 miles (54,716 kilometers) of coastline and a total area of 741,096 square miles (1,919,440 square kilometers). An abundance of natural resources includes petroleum, tin, natural gas, nickel, timber, bauxite, copper, fertile soils, coal, gold, and silver. Most of Indonesia enjoys a tropical temperature, but the weather is more moderate in the highlands.

The land is composed of coastal lowlands with interior mountains on the larger islands. Elevations range from sea level to 16,498 feet (5,030 meters). Indonesia is subject to occasional flooding and severe droughts as well as to earthquakes, volcanoes, tsunamis, and forest fires. A volcanic eruption on Mount Tambora on April 10, 1815, killed more than 88,000 people. In December 2004, the infamous Indian Ocean tsunami hit Indonesia particularly hard at a cost of 131,000 known dead and another 37,000 people missing. Property damage was estimated at $4.5 billion, and environmental damage was incalculable.

Some 22 percent of the Indonesian population lacks sustainable access to safe drinking water, and 48 percent have no access to improved sanitation. As a result, Indonesians are at high risk for contracting food and waterborne diseases such as bacterial and protozoal diarrhea, hepatitis A and E, and typhoid fever. In certain areas, Indonesians are also vulnerable to vectorborne diseases that include dengue fever, malaria, and chikungunya. Some 100,000 Indonesians are living with HIV/AIDS, which has killed 2,400. A number of avian influenza cases were reported in Indonesia in 2005, creating a public scare.

Indonesia is currently facing a number of major environmental problems. First among these have been repeated widespread forest fires, massive enough to cast a pall of smoke over the southern Pacific Ocean for months in their wake. El Niño weather conditions set the stage for these fires, which created drought throughout Southeast Asia during the early 1980s and late 1990s. The fires, however, were almost exclusively anthropogenic, and set by plantation companies and large agribusinesses attempting to clear land for the plantation and extraction of palm oil, wood pulp, and rubber. Many of these firms, moreover, went unregulated in their activities, due to to their close and largely corrupt relationship to the ruling party.

These and their related deforestation have played havoc with the biologically diverse tropical forests. In 1983, for instance, 7.4 million acres (3 million hectares) of tropical forests were destroyed by fire in Kalimantan Timur Province. During the 1980s, Indonesia had the highest rate of deforestation in Southeast Asia. This process was checked to some extent through a joint Department of Agriculture/World Bank forestry management plan, but illegal logging continues to deplete Indonesian forests. It is estimated that 58 percent of Indonesian land is now forested. Even though the government has protected over one-fifth of the land area, wildlife is seriously endangered. Of 515 mammal species endemic to Indonesia, 147 species are threatened with extinction. Similarly, of 929 endemic bird species, 114 are endangered.

Extensive water pollution has occurred as the result of the indiscriminate use of agricultural pesticides, off-shore oil drilling, industrial effluents, and overall improper waste management. Air pollution is severe in urban areas, where 45.5 percent of the population resides. Indonesia generates 1.2 percent of the world's carbon dioxide emissions. This rate is expected to decline with the recent banning of leaded gasoline. The frequent forest fires generate smoke and haze in the air. Fish stocks have declined drastically, and the terburuk fish has virtually disappeared in some areas. Milkfish and young shrimp have been killed in Java. Coral reefs have been destroyed by silt deposits.

In January 1975, lasting environmental damage occurred when a Japanese supertanker spilled oil into the Strait of Malacca. In 2006, a study at Yale

Daendels in Batavia

The administrative capital of the Netherlands East Indies was the city of Batavia (modern-day Jakarta), established by the Dutch in 1619. By 1808 it was a city of 2,000 Europeans and 45,000 Asians, with effluent in the canals that cut through the residential areas.

In 1807 Herman Willem Daendels (1762–1818) was appointed as the 36th Governor General of the Netherlands East Indies by Louis Bonaparte, the French having recently taken over the Netherlands. Daendels arrived in Batavia on January 5, 1808, and found it an incredibly unhealthy city. His task was to modernize the defenses of the city in case of attack by the British, and also improve its sanitation. A massive barracks at Meester Cornelis was established south of Batavia, and housed most of the soldiers, who were previously garrisoned in the old castle close to the coast.

The other major change that Daendels organized was the clearing of many of the canals, a large number of which were stagnant. He also supervised the creation of the main square outside the Stadhuis, the residence of the governor. Nearby he also built a new hospital and drainage system.

Within the grounds of the city there had been a small cemetery that by this stage was not only full, but causing environmental problems for the people in the city. It was where many of the early governors–general of the Netherlands East Indies had been buried, and also where one of the survivors from the Mutiny on the Bounty had been interred. However pollution from it had affected the water supply of the city, resulting in Daendels closing and clearing the cemetery, and building the Museum of Old Batavia on the site.

He also established a new one at Taman Prasasti, near where the National Museum is now located. Many of the gravestones from the old cemetery were moved there, but some remain at the site of the old cemetery, now the basement of the Wayang Museum.

University ranked Indonesia 79th of 132 nations in environmental performance, below relevant income and geographic groups. Indonesia's rating was particularly low in air quality.

In 1997, the Indonesian government enacted Law No. 23, the Law Concerning Environmental Management, which provides a framework for all Indonesian environmental laws and regulations. The Minister for Environmental Affairs was charged with oversight and implementation. However, as Indonesia's economic situation has deteriorated, enforcement of environmental laws has been placed on the back burner. Some businesses no longer even attempt to meet environmental codes. Indonesia participates in the following international agreements: Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, Tropical Timber 94, and Wetlands. The Marine Life Conservation agreement has been signed but not ratified.

Industrial Ecology

INDUSTRIAL ECOLOGY IS a concept that advocates converting "waste outputs" into "resource inputs" to reduce the economic, social, and environmental costs of waste disposal while simultaneously preventing the need to take more raw materials for use in production. A 1974 paper by Harry Evan in the *International Labour Review* introduced the term as follows: "The term 'industrial ecology' might appropriately be applied to an interdisciplinary systems approach to environmental problems arising from industrial activities, i.e., the production, consumption and disposal of manufactured products and their raw material and energy inputs, as well as from related mining, agricultural, transportation and construction processes." According to Jouni Korhonen, industrial ecology uses "nature's model of material recycling, energy cascading and solar energy-based sustainable ecosystem in transforming unsustainable, fossil fuel-based and wasteful industrial systems into more ecosystem-like systems."

These definitions, and others, are based on the idea that the traditional model of industrial activity is immature and wasteful and should be changed to an integrated industrial ecosystem. This means that they should optimize the consumption of energy and materials, minimize waste generation, and use the effluents of one process as the raw material for another process. For example, while in natural systems the energy and/or matter produced by one species is consumed by another, surplus heat from industrial processes is commonly dissipated in the atmosphere and potentially recyclable products simply disposed of as waste.

This concern has led many leading environmentalists to critique both capitalist and socialist modes of economic production as being expansionist and linear. Pierre Desrochers used empirical analyses of earlier industrial eras and specific industrial activities to demonstrate that the perception of a linear process does not always accord with the historical evidence—many industrial practices in the late 19th and early 20th centuries involved extensive recycling behavior and the use of by-products in a myriad of ways.

Much work on industrial ecology tends toward the normative, analyzing what could be done in particular industrial situations. In policy terms, there has been a focus on implementing industrial ecology through the creation of linkages between firms in a specific geographic area. This latter vision, known as an eco-industrial park (EIP), E. Cohen-Rosenthal defines as a "community of businesses that cooperate with each other and with the local community to efficiently share resources (information, materials, water, energy, infrastructure and natural habitat)… leading to economic gains, gains in environmental quality and equitable enhancement of human resources for the business and local community."

Industrial ecology involves going into networking activities between firms. Jouni Korhonen labeled these approaches as the "product" (that is, the technical exercise within a corporation) and "geographical" approaches and notes that while these approaches are compatible in some ways, there are also tensions between them. EIPs can vary in form from a Green Industry Park (where individual industries are clean but have no synergies with other sites), to Integrated EIPs (geographic concentration of firms and synergies between facilities), to the Networked Eco-Industrial System (synergies but spread over a metropolitan or larger area). The challenge has been to develop suitable role models of EIPs. One model example often cited is Kalundborg, Denmark, which has developed around a coal-fired power station where a web of waste and energy exchanges has developed between the power plant, the local city administration, a refinery, a fish farm, a pharmaceuticals plant, and a wallboard manufacturer. However, Kalundborg relies upon nonrenewable fossil resources and produces carbon dioxide emissions, neither of which are compatible with the principles of industrial ecology.

The Kalundborg industrial complex emerged over a period of about 30 years and was achieved without consultants designing potential interactions, government financial support to encourage interactions, or a higher level of administration to oversee the interactions. While much of the literature has focused on emulating the design and interactions present at Kalundborg, Pierre Desrochers focuses on the processes of private sector investment and argues that rather than being an example of designed symbiosis, Kalundborg is a contemporary example of industrial symbiosis that has been occurring "long before the advent of modern environmental consciousness and regulation." While gradual evolution is one characteristic that is identified in nature and transferred to industrial ecosystems, there is nothing in nature to indicate whether this gradual evolution should be facilitated primarily through private planning, design, urban planning, or a combination of economic geography and urban planning/urban governance.

Industrialization

INDUSTRIALIZATION IS A process that introduces new technologies of production in a region or a country to increase the output of goods. Industrialization is strongly associated with the Industrial Revolution in England in the 19th century, where capital and resources from colonial expansion, technological innovations like steam power, and labor dispossessed from land or access to markets combined to create large-scale factory production. The shift from handmade manufacturing to machine production yields major changes in the societal division of labor in two ways. Increased use of machinery tends to make homogenize the types of labor performed by each worker (deskilling), and alter the gender division of labor by incorporating women into the paid workforce. Industrialization under capitalism affects relations between owners and workers by generating a supply of labor that is employed according to market forces, mobile within a nation-state, and often restricted in terms of international mobility.

ENVIRONMENTAL IMPACTS

Intensification of production generates pollution—including increased emissions, water and soil contamination—as well as unsustainable resource extraction. While industrial production is commonly evaluated in terms of growth and increased efficiency, the environmental cost is considered a secondary spillover effect, referred to in mainstream economics as a *negative externality.* Proponents of environmental regulation argue that the cost of pollution should be internalized, either through incentives that reward cleaner industries or punitive fines for polluters.

Mainstream environmental economists have constructed powerful models like the Environmental Kuznets Curve to assert that industrial growth and environmental protection are not opposite processes. They argue that while environmental damage is inevitable in the "take off" period of industrialization (low-wage, low-technology, polluter phase), once a certain level of per-capita income is reached, economic growth can be channeled toward cleaner industrial technologies (high-wage, high technology, "cleaner" industrial period). This view assumes that poor countries are primarily polluters, the market is capable of self-regulation, environmental regeneration is guaranteed, and the effects of environmental damage on the livelihoods of affected populations are reversible. This assumption is facilitated by a strong link between the concept of industrialization and key ideas like progress, development, and modernity in Western thinking.

This idea of stage-like industrial development works poorly when considering economic development in former colonies, often referred to as the global South. Colonial capitalism fostered both dependency on primary products (natural resources and cash crops) and a global economic system that devalued so-called "primary" products. This colonial production—including resource extraction and plantation agriculture—was in many cases industrial, involving expensive technologies, capital investment, as well as a complex division of labor, both free and slave.

These industries were part of a system that extracted wealth exclusively for local elites and the "mother" country, in turn creating conditions for industrialization in Europe. For many former colonies, shifts in global production as a result of decolonization were associated with deindustrialization, capital flight, and a more informal economy. Oft-cited examples include the Zambian copper belt in southern Africa and the Caribbean plantation system.

In the post-World War II period, industrialization became synonymous with development policy dominated by a debate between two strategies: import-substitution industrialization (ISI) and export-oriented industrialization (EOI). In both cases, industrialization refers to shifting economic activity from agricultural production to manufactured goods. Both strategies face the challenge of generating or attracting capital investment, technology, and business organization—a process that often leads to dependence on foreign banks and multinational corporations. The difference between the two approaches lies in their market "orientation." ISI encourages domestic production for the national market through industrial subsidies and protective trade barriers to reduce the level of imports. EOI subsidizes domestic and foreign investment in sectors that can produce goods for foreign markets with more purchasing power, like the United States and Europe. Struggles over EOI versus ISI generally do not address the question of environmental impacts of industrialization.

Another use of the term "industrialization" in post-World War II development policy refers to the promotion of "scientific" or "industrial" agriculture in the global South, a strategy referred to as the Green Revolution. New technologies—such as hybrid seed varieties, fertilizers, pesticides, and mechanization—were introduced with significant negative impacts on the environment, patterns of land tenure, and women's central role in small-scale agricultural production.

Industrial Revolution

THE TERM *RÉVOLUTION industrielle* was first used by French historians at the beginning of the 19th century, but later on it became a widespread phenomenon. *Industrial Revolution* became well known, especially by the Arnold Toynbee's *Lectures on the Industrial Revolution in England* published in 1884. His term referred to the application of power-driven machinery to textile manufacturing in Britain. In the 18th century, all of Western Europe (especially England) experienced the process of rapid economic change that transformed all aspects of human life.

Toynbee was not a historian, and his ideas have been criticized by leading historians such as Rondo Cameron and A.P. Usher, but his ideas have largely influenced our understanding of modern history. None can deny the profound and aggressive economic and social change in Britain, which has never been seen anywhere else before and created the modern framework of capitalist economies. During the decades of rapid economic, social, and cultural changes, a number of new inventions were contrived and utilized in industrial production. At the same time, an accelerated urbanization took place and new centers of industrial production were created, worsening the working conditions of workers and the necessitating child labor. At the same time, many argue about the revolutionary nature of those changes, since the growth of economy and the transfer of technology was much slower than in contemporary economies.

One of the key reasons why the industrial unfolding happened in Britain was the lack of timber and the large deposits of coal in the country. English forests begin to vanish by Roman times, and the size of forested territory has not changed much since the Middle Ages. Timber was an expensive commodity, and chimney smoke shadowed the sky in 13th-century London and other cities all around Europe. Parisians faced serious wood shortages already in 1595, when bakers had to use alternative materials to provide adequate amount of fresh bread. However, there was an abundant labor supply to mine coal and iron, a large fleet, science-based technical know-how, and colonies to provide raw materials and merchants with capital to invest. The utilization of that scientific knowledge accelerated throughout the period and by the late 19th century; theories of chemistry and electrical engineering created the basis of new production methods and branches of industry.

The English countryside changed as well between 1760 and 1830. The open-field system of cultivation gave way to compact farms and enclosed fields, which led to migration to cities. The present rural landscape dominated by large open fields, hedges, and fences are all originated from this time.

A number of agriculture-related inventions appeared. Nitrogen-fixing agricultural advancements led to the growth of agricultural productivity. Jethro Tull not only popularized the importance of root crops such as turnips and potatoes, but was an inventor of the seed drill and horse hoe. Townshend, another agricultural reformist, was famous for his introduction of the four-course rotation of wheat, turnips, oats, and barley. Robert Bakewell pioneered in the field of systematic stock breeding for food. Intensifying discourse over agricultural advances led to the establishment of the Board of Agriculture in 1793. Growing agricultural productivity had a great importance of the changing human relationships with nature.

FROM STREAM TO STEAM

New methods of glass and clock making had already appeared in the 17th century, but a more profound change followed the diminishment of guilds in England and the arrival of a new power source. Wind and hydropower were used in mills, sailing, and even in industrial production, but the steam engine became the landmark of the industrial development. Refining the principles of Thomas Newcomen's bulky 1705 invention, in 1763 James Watt designed his steam engine, which revolutionized production methods in the next 100 years. Watt built over 500 of them in 25 years by 1800.

Water power continued in use, but the factory now had an alternative. Steam engines were large, heavy, and hardly transportable, but still successfully used in ships and mines. Robert Fulton made a successful experiment with a steam vessel on the Hudson in 1807. Many entrepreneurs recognized the importance of the steam engine, and the use of such machines in manufacturing was becoming widespread by the beginning of the 19th century. Since steam engines had a number of technological problems, they were first only supplemental power sources. Their efficiency was also low, and therefore burned tons of coal per day and produced high emissions. Despite of all the disadvantages, they were used successfully in pottery and grinding, and revolutionized the textile industry along with a number of other inventions.

By the time steam engines became more efficient, their importance in transportation began to be recognized. Since the large steam engine required a significant amount of coal, attempts to adopt steam vehicles for road transportation failed notoriously.

The arrival of the railroads facilitated industrialization in Europe, but had serious social and environmental implications. During the early 19th century, mine tracks were transformed into transportation corridors around and between commercial and industrial centers. By the early 1830s, George Stephenson's famous train pulled cars from Liverpool to Manchester.

The railway boom came to Britain by the mid-1850s, when cheap raw materials and adequate technology enabled investors to compete successfully with other means of travel. Soon trains were faster, safer, and more convenient than any other way of traveling. Information spread faster along railway, which made business safer. Trains were fast, although none of them could cover more than 45 miles per hour. The invention of the telegraph quickened information flow, and by the 1870s, telegraph cables connected continents and global transactions took only minutes. At the same time, steamships became more and more widespread in international waters. By the 1840s, technical problems with the flammability of vessels and bulkiness of machinery were solved. Soon, transatlantic travels became regular, which hastened the transportation of goods from both sides of the Atlantic.

Until the 19th century, most of the world's population was rural and urban places had limited importance. However, factories and commercial centers created a never-before-seen demand for a labor force in urban areas. By the mid-19th century, half of England lived in cities, and Britain's population increased more rapidly than ever before. By the beginning of the century, a similar phenomenon was observed in most European countries and in the east coast of North America. However, earning a living in an English city during that time was not an easy task.

According to the 1851 census abstracts, 22 percent of the total 9.4 million population of Britain earned its living from agriculture; at the same time, 39 percent were engaged with manufacturing and 25 percent with services. Only 50 years later, in 1901, services became predominant and only 9 percent of the total population was engaged with agriculture in Britain. Industry was producing a wide range of products from textile products to metals and from food products to chemicals.

During the course of the 19th century, services became more and more important as transportation, banking, and trade developed. Cities became crowded. The scale and the type of industrial pollution that appeared during the late 18th century was unprecedented. Besides small workshops and domestic users, large factories gained their energy from burning coal. Smokestacks became landmarks and sources of smoke, which shadowed the sun regularly. Emissions from factories found their way into rivers and polluted them constantly.

Cheap, company-built housing was inevitable for workers, but factory owners gained a strong control over communities by ownership. A great proportion of the workforce was engaged with low-paying jobs and lived in overcrowded and poorly lit accommodations. Sanitation conditions were poor in these areas, with bathrooms often shared by many members of various generations. Such conditions resulted in high rates of mortality and disease among workers. These classic slums were characteristic in all cities of Britain. The inadequate understanding of hygiene worsened the situation, but the association between ill health and poor living conditions soon became evident for much of the society.

in 1763 James Watt designed his steam engine, which revolutionized production methods in the next 100 years.

By the 1830s, many British towns suffered of cholera, smallpox, and other epidemics. At the same time, many workers were affected by industrial pollution caused by dusty and damp conditions in factories. Many of the locals united in campaigning groups. Local physicians organized Boards of Health, often following after epidemics, to improve living conditions. These boards pointed out the importance of hygiene and that many of the cotton mills and factories were the hotbeds of epidemics.

During the early days of industrialization, a number of children were also employed within such conditions, which reduced their life expectancy significantly. Health conditions had improved by the contribution of cleanness campaigns, efforts of sanitation engineers for better drinking water and sewage services, and individual achievements such as garbage bins with lids to keep flies out. The well-organized collection of horse manure was also essential for the city's health, but created serious disposal problems. Furthermore, untreated effluent running into rivers posed further problems of water pollution and urban water supply. Many of the large industrial centers were suffering from polluted waters, such as Manchester, London, and Chicago. To gain improvements in sanitation and sewage, sophisticated infrastructures were created.

The environment saw unprecedented changes during the years of the Industrial Revolution. After 1750, the large number of industrial cities grew and aroused a number of problems of the relationship between the society and environment. Remarkable growth of production and population created the need for a number of infrastructural developments, such as expanded canals and railway lines throughout Britain.

Water pollution resulted from the increased amount of solid and dissolved industrial and household waste being discharged into rivers. Waste accumulated in some of the river basins and caused a thick scum of dirty froth, unpleasant smells, and problems during floods. Despite all the negative effects, the politicization of such environmental issues did not make waves until the 1960s. However, many citizen groups became concerned about the environment through human health issues or social problems.

As early as the Middle Ages, problems with air were reported in some of the big cities due to the increased use of charcoal and wood for heating. But in the 19th century, significant problems with air pollution led to related health issues such as bronchitis and other respiratory ailments. Air pollutants came both from industrial sites and domestic hearths. The rise of the steel industry caused further troubles for many cities all over the world in the beginning of the 20th century. Concentrated point source emissions of steel factories, chemical plants, and electric power stations did not end until the 1980s in many Western European and American cities. Britain's Manchester, Germany's Ruhr region, France's northern east in Europe, and Pittsburgh, Milwaukee, east Chicago, and Gary in the United States experience similar environmental problems during the 20th century.

Coalbrookdale

This settlement in the parish of Madeley, Shropshire, in the west of England, was one of the birthplaces of the Industrial Revolution.

There had long been an iron industry at Coalbrookdale, with a large furnace, known as the "Old Furnace" built there by Sir Basil Brooke in 1638, just before the English Civil War. In 1709, Abraham Darby built a furnace there to make iron goods. Darby lived at Madeley Court and was from a prominent local Quaker family. Six years later, he built another furnace, but his death two years after that saw the works end up in the hands of Thomas Goldney of Bristol, and managed by Richard Ford.

They brought back Abraham Darby's son, also called Abraham Darby, and started making steam-engine cylinders. All these people were Quakers, and indeed Quakers were to have a major impact on the industrial revolution elsewhere in England and also in the United States.

It was in 1768 that the forges at Coalbrookdale started to produce iron rails for railways. Coalport China was also made there. Ten years later Abraham Darby III, grandson of the man who built the furnace in 1709, started work on the first cast iron bridge—Iron Bridge—which opened in 1780 and was to lead to the settlement of Ironbridge. It was from this that Thomas Telford gained the inspiration for his projects that followed, including the nearby Buildwas Bridge. Telford also redesigned the parish church of Madeley. In 1837 Charles Hulbert, a visitor to the area, described it as "the most extraordinary district in the world." The Ironbridge Gorge Museums record the first decades of the Industrial Revolution, and are major tourist sites for the region. The whole area is now a part of the township of Telford.

Industry

INDUSTRY IS THE term used to describe all of the businesses making a particular product or providing the same service. Product industries include the automobile industry, munitions industry, textile industry, construction industry, shipbuilding industry, and thousands of others. Service industries include the insurance industry, banking industry, stock brokerage industry, retail industry, and real estate industry.

Historically, most goods before the Industrial Revolution were part of a cottage industry, in which goods were made in private homes of the poor. The Industrial Revolution took vast number of poor people from small villages, farms, and cottages and put them into large-scale production centers. The first industry organized in this way was the textile industry.

Wool production increased dramatically with the enclosure movement, which drove small-scale farmers off of their lands and into growing factory towns like Birmingham, England, which were located near sources of cheap energy such as water power or coal. They were soon filled with cheap housing that disintegrated into slums. The factory system had many negative consequences for workers, but the factory system created a huge flow of cheap finished goods for the global market.

MODERN INDUSTRIAL NEEDS

Natural resources use by industry are either renewal or nonrenewal. Corn is a renewable resource that can be planted every year to make corn syrup or a great many other products. In contrast, the resources needed by the service industry, such as financing or insurance, are far fewer.

Capital is a resource needed by industry to build capital goods like production machinery and to hire people as managers or laborers. The canning machinery or the electrical motors for running an operation are also capital goods. Some industries are capital-intensive, such as an oil refinery, which requires few very skilled workers but a vast investment of money for the oil refinery equipment.

Industry needs at least some human labor. In labor-intensive service industries such as hospitals or law firms, a large number of skilled workers solve medical or legal problems. They are also capital intensive in regards to human capital.

Management in industry is typically highly skilled to supervise the vast number of steps in the making of complicated goods or the delivery of services. Each worker in an assembly line or in the manufacture of other goods does only a small part of the total part of the work; this specialization of labor magnifies human productivity. This was recognized by Adam Smith in his book, *The Wealth of Nations*. Smith concluded that the wealth of nations was the productivity of their people; he described his visit to a highly productive pin factory, where its productivity would have been a great deal less if each single worker had to undertake all of the steps in making a pin.

Technology is composed of the unique skills acquired from practice, tools, machinery, and techniques used by industry. Technology also multiplies the productivity of an industry.

In the developed countries of western Europe, North America, and Japan, industries have employed people almost since the beginning of the Industrial Revolution. In other regions, such as Asia, Africa, or Latin America, there are still huge populations in rural villages. Since China changed its economic policy to promote a market economy, thousands of industries have opened. Industry in the Third World or developing world has been undergoing developmental problems since its beginnings. One of the major problems is the environmental impact of consuming huge quantities of raw materials.

Another major problem is supplying energy to the great new cities of Asia. Japan is increasingly supplied by nuclear power, but in China, with huge supplies of coal and also with the damming of a number of rivers, including the Three Gorges Dam, there has been an enormous increase in energy supplies.

As China, Japan, and other newly industrializing countries prosper, there is also an increase in the demand for transportation and consumer goods, including automobiles. This makes necessary the building of new roads and railroad lines.

The environmental impact of industry, whether in manufacturing or in farming since the end of World War II, has been tremendous. The used of pesticides, herbicides, and the burning of fossil fuels have had negative consequences for the environment. In order to deal with the pollution created by industry, great expenditures have been made for eliminating or cleaning up pollution such as chemical waste dumps.

Food industries, such as cattle ranches, poultry farms, and hog operations, have all become industrialized with the use of exact mixtures of feeds, as well as vitamins and antibiotics to prevent disease. While keeping the cost of meat low and feeding billions of people, these industrial farms also generate huge quantities of waste that must be disposed of safely.

Debates, political strife, and lawsuits have been part of the response of those concerned about the pollution caused by modern industry. However, the money made from industry, as well as the global competition for jobs, has made this difficult. Industry can relocate from a country with strict environmental protection laws that require costly capital investments to environmentally lax countries of the developing world, where jobs are more important in the beginning than the environmental consequences.

"Making a living" also implies ethical treatment of people and of the environment. The excuse that pollution is necessary to meet the competition is a rationalization to justify harming people, plants, and animals. The challenge is clean industry, which does no harm but is also one that is highly productive and profitable.

Infant Mortality Rate

INFANT MORTALITY REFERS to the death of infants in the first year of their life. It is measured by the infant mortality rate (IMR), which is the ratio of the total number of deaths to the number of children under the age of one year for every 1,000 live births. IMR is often broken down into three components based on time of death. First, the perinatal mortality rate measures the ratio of the number of late-fetal deaths (at or after 28 weeks gestation) and deaths within the first 7 days after birth per 1,000 live births. Second, the neonatal mortality rate refers to the ratio of the number of deaths within 28 days after birth (per 1,000 live births). Third, the postneonatal mortality rate is the ratio of the number of deaths from 28 days to the end of the first year per 1,000 live births. The distinction between perinatal, neonatal, and postneonatal mortality is important because the risk of death is higher close to the delivery date, and the causes of death near the time of birth/delivery are quite different from those later in infancy.

Though the world's infant mortality is 54, differences across the world are substantial. Africa's rate (88) is 15 times higher than the average rate (6) for developed countries. Sierra Leone has the highest rate of IMR (165) in Africa. Though on average, the rate for Asia is 56, Afghanistan has highest IMR (172) in the world. On the other hand, Hong Kong's rate (3.2) is very low, illustrating that the most variation in infant mortality level occurs in Asia. Both Europe and North America have low levels of infant mortality, with average rates well under 10.

While the causal relationship between infant mortality and level of socioeconomic development and environmental conditions is not perfect, the infant mortality rate is commonly used as a general indicator of socioeconomic well-being and of general medical and public health conditions in a country. IMR is included as one of the components of "standard of living" evaluations of countries. Developed countries can provide the basic requirements for infant survival namely clean water, sanitary surroundings, adequate food, shelter, and access to basic health care services. On the other hand, the major proportion of infant mortality in underdeveloped countries is due to improper sanitary practices and inadequacies in the diet of mothers, resulting in infectious and communicable diseases.

The causes of infant mortality vary over the time of infant deaths and between developed and underdeveloped countries. Postneonatal mortality, which is predominantly due to socioeconomic and environmental conditions, is more common in underdeveloped countries than developed countries. The major causes are infectious diseases, such as pneumonia, tetanus, malaria, and dehydration. These diseases are in turn consequences of improper sanitation at the place of delivery; traditional types of attendants and practices during prenatal, natal, and postnatal periods; poor nutritional status of lactating mothers; age of mothers; income; and educational levels. At the individual level, mothers (and fathers) with lower income and education are less likely to possess knowledge of sanitary behaviors and the money for adequate food. In addition, they are less likely to take their babies to a health service if needed. This is especially important for information about Oral Rehydration Therapy, which is effective in saving babies from dying from the dehydration that accompanies diarrhea.

Another cause of infant mortality is violence. Research conducted in two areas in India show that wife beating, closely linked to patriarchal social structures, leads to both pregnancy loss and infant mortality. Other violence, such as infanticide, the deliberate killing of infants, is extremely difficult to document, but it seems likely that some portion of the "missing girls" in India and China were the victims of infanticide. When infanticide is practiced, it is most likely a response to difficult economic circumstances (and coercive population policy, in the case of China) in conjunction with male-child preference.

Neonatal mortality, in contrast to postneonatal mortality, is less likely to be the direct result of socioeconomic and environmental conditions. Major causes of neonatal mortality include low birth weight, premature birth, congenital malformations, and sudden infant death syndrome (SIDS). In developed countries, most infant mortality is concentrated in the early neonatal period, with the aforementioned causes of death predominant.

Influenza

INFLUENZA IS AN extremely contagious disease caused by the influenza virus. It causes infection of the respiratory tract and can affect millions of people every year. There are three types of influenza viruses. The influenza type A virus can infect humans and other animals, while influenza B and C viruses can only infect humans. Type A is responsible for the annual outbreak of influenza; the virus was first detected by a British bacteriologist Wilson Smith in 1932. Effects of the influenza virus C are very mild and do not cause epidemics. Influenza viruses are constantly changing, producing subtypes or strains. These strains are different from the main viruses, but retain some of their characteristics. These influenza strains may vary year to year, requiring flu vaccine modification every year.

In the Northern hemisphere, influenza epidemicity occurs during October–March. With the warming trends, the episode dies down. It surfaces in the tropics in March and April and during their rainy season. In May and August, the influenza episode moves to the southern hemisphere. By September, the episode comes back to the tropics. This annual cycle of influenza persists, and is different from measles, vermicelli, mumps, rubella, infestus, hepatitis, and smallpox.

Influenza usually is much more severe than the common cold. The virus takes about 1–2 days from the time of exposure to develop symptoms. This period is known as "incubation period." The influenza (flu) comes on suddenly, causing symptoms such as fever, often as high as 104 degrees F, severe sweating, body and muscle aches, headache, fatigue, loss of appetite, dry cough, nasal congestion, and sore throat. The illness lasts up to 1–2 weeks, although fever generally lasts only 3–8 days. Most people recover without problem, but sometimes the ailment can lead to a bacterial infection such as bronchitis and ear/sinus infection.

One of the most severe complications of flu is bacterial pneumonia caused by *streptococcus pneumoniae* (the pneumococcus) and *staphylococcus awieus*. Pneumonia caused by flu is not common, but requires immediate hospitalization. Each year about 10,000–40,000 Americans die of influenza or influenza-related pneumonia, and over 90 percent of deaths occur in the 64+ age group. Influenza can be prevented by getting immunized with an influenza vaccine each year in the months of October and November. FluMist, a live virus vaccine in the form of nasal spray, can be an alternative to flu vaccine for healthy children and adults between the ages of 5–49, excluding pregnant women.

Scientists are actively looking for new drugs to prevent or treat flu. Two drugs such as Nimantadine and Amantadine have been in use for a number of decades. They are only effective against influenza type A and not type B. These drugs stop the flu from producing copies of itself once it has invaded the human cells. Zanamivin (trade name Relenza) and Oseltamivir (trade name Tamiflu) are the most recently discovered drugs, and are used to treat both flu types A and B.

Bird flu (avian influenza) is caused by complex flu viruses with a number of subtypes and strains. These viruses are classified as having high to low chance of causing disease. Scientists do not yet know just how these subtypes affect humans, but

Spanish Flu Pandemic

Flu epedemics have occurred in the world with great severity in a 5–10 year span. The “Spanish Flu Pandemic” of 1918–19 is estimated to have killed between 50–100 million people worldwide, and is commonly thought to have died out after 18 months.

The pandemic did not in fact originate in Spain, but gained the title because of the massive publicity given to the disease in Spain, which had not taken part in World War I. Allied governments prohibited printing of negative materials so that troop morale remained high.

It is believed that virus might have originated from Fort Riley, Kansas, where poultry was raised for the local market. The disease then “jumped” from birds to humans and quickly spread around the world. Portugal was also struck followed by Denmark, Norway, Sweden, and the Netherlands. After Bombay, India received a ship from Europe, the flu affected men working in the dockyard; the disease then spread to the city. Long-distance rail connection from Bombay to Calcutta, Madras and Karachi brought the disease to these cities following an expansion–diffusion route. From Calcutta, the disease was carried to Rangoon by boat. Soon, the disease spread to Shanghai in China, New Zealand, and Australia, following the routes of oceanic lines. With the movement of the British Fleet, disease was also carried to Algeria, Egypt, and Tunisia. Raging by the end of October 1918, before the end of World War I in Europe, the close proximity of large numbers of men on troop ships—possibly with their immune systems weakened by combat and chemical warfare, as well as the dislocation of the population from war—exacerbated the disease.

In the United States, it is estimated that 28 percent of the population suffered from the influenza virus, with between 500,000–675,000 dying. In France, a country already devastated by war, 400,000 died, with 200,000 in Britain and 10,000 in Australia. In Fiji, some 14 percent of the population died in a fortnight, and 22 percent of the people in Western Samoa succumbed.

The country worst affected was India, where it is estimated that 17 million died—about 5 percent of the total population at the time. It particularly affected returning soldiers, their families, and people living nearby.

highly pathogenic viruses cause serious problems with a large number of deaths occuring both in animals and humans.

The virus does not infect people easily, and it almost never spreads to other humans. Bird Flu is mostly an avian disease. It has infected tens of millions of birds, but fewer than 200 people; and almost all of then caught it from birds. When a very nasty bird flu virus, A(H5N1) infects people, it can kill young people, devouring their lungs. The 2005 bird flu virus, A(H5 N1), has been steadily advancing from China to other parts of Asia, then to Europe and Africa. The latest country to report human cases is Azerbaijan, where out of seven people infected, five have died.

Insects

INSECTS ARE INVERTEBRATES that are divided into 36 groups called *Phyla*. Phylum Arthropoda includes the class Insecta, which is further subdivided into 29 orders. Diptera (flies), Coleoptera (beetles), Phasmida (stick insects), Dictyoptera (cockroaches and praying mantids), Hymenoptera (wasps, ants, and bees), and Lepidoptera (butterflies and moths) are some examples. About 95 percent of all the animal species on earth are insects. They have a very small body, can survive on very small amount of food, and can multiply very quickly.

All insects have three body parts: a head, thorax, and abdomen. They have six jointed legs, two antennae to perceive the world around them and an exoskeleton (outside skeleton). The multilayered exoskeleton, which is composed of hardened layers of protein and chitin, form their body shape. The exoskeleton has the capacity to protect the insect from the environment or natural enemies and has several sense organs for detecting light, pressure, sound, temperature, wind, and smell, which makes them very successful survivors. Most insects have one or two pairs of wings, but wings are not an essential characteristic to be classified as insects.

Insects use their head for eating, sensing things, and gathering information. They use their antennae to feel, smell, and taste. The thorax is where three pairs of jointed legs, and in many insects, one or two pairs of wings are located. The abdomen has the organs of digestion and reproduction. Insects have open circulatory system and its body fluid circulates around inside the exoskeleton. It has a heart and a few blood vessels, but blood simply flows around inside the body cavity.

Air enters through spiracles located in the exoskeleton and circulates through the breathing tubes, which spread out everywhere in the body. The digestive system is very simple, consisting of a long tube. This tube is usually divided into three parts. The brain is very small and is located in the head, and processes information, but some information is also processed at nerve centers at different places in the body. The nervous system sends messages from the sense organs to and from the brain. Insects have compound eyes, containing thousands of six-sided lenses, each of which can work independently. There are some insects that can perceive ultraviolet light, which is invisible to humans.

INSECT TYPES

Five groups of insects are based on their food habits and nutrition intake. Scavenger insects feed on waste material such as decomposed animal and plant material, and even products from other insects like oils and waxes.

Omnivores such as cockroaches seem to eat just about anything, from bookbindings to fellow insects. Herbivore insects eat leaves, and include caterpillars, butterflies, and bees. Carnivore insects are blood suckers and also feed on other insects.

Parasitic insects obtain nutrition from their hosts. The true parasites, like fleas and lice—as well as parasitoids—are only parasitic as larvae.

POSITIVE EFFECTS ON ENVIRONMENT

Insects contribute to maintain ecological balance. Plants and insects are important to each other's existence. Insects transmit pollen from plant to plant as they feed on the plant's nectar. Insect diversification may have led to the radiation of flowering plants.

Insects keep earth clean by means of an efficient recycling system, because of their ability to reprocess dead plants and animals. Several insects work as decomposers. The carpenter ants, wood-boring beetles, and termites reduce logs, limbs, and leaves, which fall on the forest floor. Insects also eliminate animal waste, but in the case of fly larvae, it can also be a way of spreading disease. Decomposer insects can also improve the texture and quality of soil by adding humus (decayed vegetable and animal matter). The humus provides nutrients for the plants and improves the soil's ability to retain water. Some ant species of Panama build their nest in the shape of an upside-down arrowhead to let the rain slide off, showing an adaptation to nature. These ants are natural enemies of termites and protect the trees against their insidious invasion. Humans are also greatly benefited by insects, as they produce honey, silk, wax, and other products.

DETRIMENTAL EFFECTS

Insects are also major pests of humans and domesticated animals because they destroy crops and carry different types of diseases as transmitters or vectors. The World Health Organization identifies eight major insect-borne diseases. Sleeping sickness is transmitted by the tsetse fly, with 55 million people in Africa at risk. Leishmanisis causes elephantitis and disfigures legs, arms, and genitals, and is transmitted by culex mosquitoes that infect about 120 million people in Africa, South and South East Asia, the Pacific Islands, and Latin America. Chagas disease (American trypnosomiasis) is caused by *T. cruzi,* transmitted to humans by a bloodsucking traitomine bug, and infects 18 million people in the Americas, excluding Canada. Malaria is caused by a bite from an infected female mosquito when human blood is infected with malarial parasite, and is endemic to about 90 countries, mainly in Africa and South and East Asia. Dengue fever is caused by viruses transmitted by the andes aegypti mosquito, affecting 100 countries except Europe with 20 million cases annually. Yellow fever virus is carried by haemagogus mosquitoes and transmitted to humans in tropical South America and Africa, causing illness to 200,000 people annually. The mosquito vector *culex tritaeniorhynous*, associated with rice-producing areas of

Many insects are major crop-destroying pests, such as these Mexican fruit flies laying eggs in grapefruit.

the world, transmits the Japanese encephalitis virus to humans, causing sickness to an estimated 43,000 occurrences. And Plague, which caused Black Death and wiped out about one-third to half of the European population in the 14th century, is caused by the bacterium *yersinia pestis*. Rat fleas carry this pestis to other rats and humans. The world is mostly free of this deadly disease now except for an occasional outbreak. Although misery delivered by insects to humans is tremendous, only 1 percent of the world's insects are considered pests.

Changing climatic conditions resulting from global warming have enabled different disease-carrying insects, including mosquitoes, to survive and multiply in colder northern latitudes and higher elevations all over the world, which increases the possibility of spreading tropical diseases to temperate regions. Global warming has affected the population of a particular migratory bird, the pied flycatcher, and subsequently its prey, the caterpillar. The flycatchers' population has plummeted to an astonishing 90 percent over the past two decades in some parts of the Netherlands. When hatchlings emerge, the parents feed them mostly with caterpillars, which are most abundant during an approximately three–week period after Dutch plants have flowered. However, due to warming average temperatures, plants in some parts of the Netherlands flower an average of 16 days earlier in the spring, knocking the prime caterpillar season off by nearly a week. This creates inadequate nourishment, leading to the death of birds and falling population.

Institutions

INSTITUTIONS ARE SOCIALLY constructed relationships that form the foundations of societies. They shape contemporary environment-society interactions by framing the behavioral opportunities and expectations of individuals and organizations. Institutions explain, for example, when it is acceptable to take whales for human consumption and when it is not. They dictate how much of an ecosystem can be transformed for, say, a housing development, and still maintain its status as an ecosystem. Institutions can be formal (laws) or informal (the 50-year tradition of science, natural or economic, as an adjudicator of environmental policy decisions). They can be created by political fiat, or evolve over time through experience (such as private property rights). Thus they include the laws that are codified through the courts (common law), laws developed by administrative agencies and legislative bodies, (statutory law and regulations), or they can be comprised of organizational entities. The state is an institution. There are also private institutions, such as the International Standards Organization (ISO), which acts as a certification and oversight agency for firms who seek to have higher worker safety and environmental protection standards.

As mechanisms that mediate our daily life, institutions are highly contingent. The European Union is clearly different from the United States, and Massachusetts differs from Oklahoma. Moreover, different states may view the same institution differently. Massachusetts and Oklahoma, for example, may interpret the role and intent of the Endangered Species Act differently in their efforts to protect red-tail hawks. This contingent nature of institutions has more conceptual implications for environment-society analysis.

Institutions are important analytical entry points for environmental analysis because they can reveal the embeddedness of a society's most tacit assumptions about environment/society relationships (such as the relationship between climate change and industrialism) as well as provide a key for understanding historical change and explain differences among institutional practices.

The earliest work on institutions comes from the neoclassical economic tradition, particularly the work of Thorstein Veblen. It was his research into the "conspicuous consumption" of American elites in the 1890s that led him to come out against the neoclassical orthodoxy and suggest institutions, not individuals, could best explain economic activity—an important break from traditional social and later environmental analysis. Until Veblen, neoclassical economists had largely focused their analyses on optimal structures of exchange.

OPTIMAL STRUCTURES OF EXCHANGE

In the conventional sense, optimal structures of exchange are those market conditions that enable individuals to generate the most wealth from finite resources. In terms of the environment, wealth maximization typically comes when the environment is a factor of production, such as a primary commodity like timber, gold ore, or land that is transformed for agriculture or housing. If, through the institution of property, an individual has knowledge of possible land use, and what the responsibilities to adjacent landowners are, then a decision that maximizes the value in the land can be made. The important tacit assumption for institutional analysis is the social origins of the institution of property remains unexamined. Institutions are not understood as socially constructed. Rather, they are formulaic relationships between trans-historical economic agents that define clear, rational guidelines.

The institutionalist position, in contrast, positions institutions and people in a historical context. Institutions, then, "are patterns that evolve over time and form the necessary background for any intelligible action at all," according to T. Barnes. The cultural elements involved in the theoretical scheme, elements that are of the nature of institutions, human relations governed by use and wont, are not subject to inquiry, but are taken for granted as preexisting in a finished, typical form and as making up a normal and definite economic situation, in terms of which human intercourse is carried on.

For Veblen, institutions are those tacit "noneconomic" relationships or "settled habits of thought" that neoclassical economists take for granted in their mathematical models of supply and demand. As Rostein put it in 1977, mathematical functions squash flat difference, making nonmarket institutions appear as "fictitious or ephemeral in nature" rather than the concrete and enduring phenomena that institutionalists consider them to be. Institutions thus provide the rationale for activities that seem "radical" such as mountaintop removal in coal country in the eastern United States, or compulsive corporate buy-back legislation in Germany, and those that appear prosaic, such as the use of pesticides on the American lawn. They are the crystallization of certain habits, customs, and instincts that form the basis of our environmental relationships.

COUNTER-ORTHODOX APPROACHES

Despite the work of the institutionalists throughout the 20th century, the concepts of rationalization, equilibrium, and maximization remained dominant in economics. By the 1990s, though, resurgence in counter-orthodox approaches emerged, including a renewed interest in institutions—most recently, the revival of indeterminate analysis of the institutionalists in economics. In contrast to the early institutionalists who had theoretical and epistemological concerns, the scholarship of this coterie of resurgent institutionalists gyrates around traditional economic concepts such a property, price, and firm relations.

An understanding of neoclassical debates and approach to institutions is crucial for students of environment/society analysis. Neoclassical economics has been so dominant in Western public policy and institutions that many subsequent environmental analysts have responded to the limitations of the neoclassical philosophy and approach. Neoclassical economic thinking has been institutionalized in Western environmental policy and practice. Risk assessment, toxic substance policy, wetlands protection, and Western water allocation practices are all founded on various neoclassical institutions such as private property, maximization, and wealth generation. While social-environmental analyses exist largely outside the neoclassical approach, they do bear Veblen's mantle that institutions, whatever their form, are socially constructed and have empirically observable economic implications.

In the 1960s, the geographer Gilbert White was increasingly concerned with the use of America's publicly owned natural resources, especially for what he called the widening gap between knowledge and practice. White recognized that from economic perspectives, efficiency criteria for public investment had been advanced in recent years. Yet, White observes, "These improved methods of weighing various resource allocations nevertheless leave much to be desired in explaining present allocations and in indicating the conditions in which wiser allocations might be achieved." For White, the poor allocation decisions needed an explanation and a policy response.

In his analysis, White focused on the individual natural resource managers in public institutions. For White, then, resources were identified by their "human assessment of possible use." These assessments were codified in various laws, from the General Mining Law of 1864 to the 1960 Multiple Purpose Forest Act. But resource managers are not omniscient economic agents. This is significant in terms of an institutional analysis because, for White, resource managers have a limited knowledge (a "practical range of choice") of the options they have for making resource allocation decisions. Because managers are restricted in their knowledge, they mediate the optimal structure of exchange. Thus, regardless of the institutional goal of efficiency, in practice, the knowledge of actors involved in allocation decisions affects the final policy outcome.

SAME GOAL, DIFFERENT BASIS

Another important form of institutional analysis from an environment-society perspective is the way different institutions with ostensibly the same substantive goals can alter natural resource allocations. Analysis of water allocation regimes in the Great Plains region of the United States examined the differences between the form of common law (through the concept of "reasonable use") and the statutory law in the allocation of stressed resources. Previous work examined the substantive institutional changes, such as shifts from common law approaches to improving air quality, and statutory approaches serving the same end. In contrast, their form and function analysis revealed that these institutions have distinct ideological underpinnings, even when seeking to promote the same goal.

They also examined how reasonable use differs in terms of function. In the case of common law, the courts adjudicate claims on a case-by-case basis, thereby ensuring the rights of individuals. Statutory law, in contrast, establishes concrete rules that are administered by expert agencies. One farmer could take, for example, three acre-feet of water per year and no more. In theory, the administrative function would apply the same rule to all users. In each case, what is "reasonable" has different implications for individual rights and despite their similar interest in local community stability.

Ideology has shaped the final focus of environmental institutional analysis. A contemporary view of institutions that comes from post-structuralist and network theory posits that institutions are not just containers of historical perspectives and actions; rather, they focus on the dynamic and contingent role of actors in shaping institutional responses. In particular, this view focuses on the social construction of networks and the ability of individuals to use these networks to contingently create meanings.

This view allows for analyses beyond range of choice, to the realms of power, gender, and science. One study of the Kumbhalgarh Wildlife Sanctuary in India shows, for example, that the state does not act at the exclusion of local people; rather it "seizes and reproduces locally powerful knowledges and enforces management through alliances with locally powerful groups." In another case, examination of the institutional construction of nature in Montana's gold mining laws shows how the agency of nonstate actors, discourses of the environment, and even the agency of nature has implications for the taking of certain resources for human use.

Instrumentalism

BROADLY SPEAKING, THE term *instrumentalism* is a view that all ideas (theories, laws, concepts, beliefs, identities, and so on) have value beyond their precision or ability to espouse truths. Instead, ideas hold value as instruments serving a larger purpose or agenda. Instrumentalism, similar to pragmatism, rejects the notion that ideas are best evaluated in terms of their ability to represent reality. This stands in contrast to scientific realism, which holds that scientific inquiry in its most accurate form produces theories and laws that exactly describe reality.

Instrumentalism holds a second broad meaning in the context of the environment. Natural resources are used instrumentally to support the foundations of economic growth and to uphold the economic ideologies that stand behind such development. Under this logic, it is the property-owning ruling class that stands to benefit most from these uses. In this sense, instrumentalism contrasts with pluralism and other forms of egalitarian approaches to distributing wealth.

In the philosophy of science, instrumentalism is the view that although theories are typically produced to explain some aspect of the world and are legitimated by their accuracy, ideas also hold value in their ability to explain and rationalize other phenomenon. An example is the discovery of the persistent, cyclical relationship among ultraviolet light, chlorofluorocarbons (CFCs), and stratospheric ozone (O_3). While this finding revealed a series of important chemical reactions, its meaning held wider value in discussions by scientists on the behavior of CFCs in the stratosphere. The findings were instrumentalized to support a larger set of scientific theories concerning the persistent contribution of CFCs to ozone depletion—despite substantial skepticism over the accuracy of long-term CFC observations.

In a more political sense, instrumentalism considers theories valuable in their ability to reach the political ends they were meant to serve. Consider two opposing plans for the Arctic National Wildlife Refuge (ANWR). The preservationist will espouse theories of ecological fragility and costly impediments to development in order to prevent drilling for oil. The development agency will appeal to public sentiment citing theories of low impact drilling and U.S. oil independence. In this case, both groups articulate theories to the public about ANWR that may or may not be entirely true. Under an instrumentalism view, the validity of these claims is less important than their ability to advance the larger ideological agenda they are reaffirming. Both the preservationist and development interest groups use their theories as instruments for advancing a particular agenda and discrediting the agenda of their adversaries.

While theories about the environment are used as instruments to uphold political agendas, nature in its material sense is controlled, manipulated, and used as an instrument of economic growth. Diverting, damming, and channeling water; mining for minerals and metals; grading and displacing soil; and logging forests are all examples of converting nature into an economically productive form.

One of the most common applications of instrumentalism as a lens for viewing society–environment interactions is in the context of rapidly urbanizing areas. Cities face pressure to meet the service-oriented and infrastructural demands of fast-paced regional, national, and increasingly global economies. Over the course of their history, major metropolitan areas are literally carved out of and built into the surrounding environment in order to keep up with these demands. The exploitation of nature, as a "natural resource," is instrumental to meeting the demands of scalar economic growth and the ideologies driving such economic policies. Often this leads state and private interests to secure property rights over valuable resources such as water and lumber. Under elite control, environmental resources become instruments for securing and consolidating material wealth among the capitalist ruling class.

Integrated Pest Management (IPM)

INTEGRATED PEST MANAGEMENT (IPM) is a collection of techniques used to control pests in agricultural production while protecting against long-term damage to the environment, human health, and property. In contrast to conventional pest control, which has relied heavily on chemical pesticides and short-term economic return, IPM involves the use of a combination of nonpesticide methods for the reduction and control of pests.

IPM relies upon both preventative methods for avoiding pest problems along with biological, mechanical, and cultural controls for addressing pests. It is a system in which pest problems are controlled and reduced to acceptable levels, but not necessarily eliminated. Acceptable levels of crop loss are established in advance, and then a program is implemented to manage pests accordingly.

No unified program exists in IPM; the combination of approaches used in different cases depends upon the specific conditions in a particular growing area. Thus, careful monitoring and ongoing study is needed in order to implement the ideal combination of techniques in a given area facing a particular pest problem. Growers must carefully monitor their crops and maintain accurate records. Intimate knowledge about pest life cycles, reproductive habits, feeding preferences, and predators is then used to limit pest problems.

The first element of any IPM program is preventative: to grow crops species or varieties that are suited to the particular environment and that are resistant to pests common in the area. Maintaining healthy crops through proper irrigation, fertilization, and pruning also serves to guard against pest vulnerability. When pest issues do arise, mechanical, biological, and cultural approaches are the preferred means to address them. Mechanical pest control methods can involve simple manual removal of pests by hand or with the use of mechanical devices such as vacuums. Pest traps can also be used as part of an IPM system as can the construction of physical-barrier designs.

Biological controls can include the introduction of predators that feed on pests in order to reduce the pest population. The release of sterile pests can also be used to disrupt reproduction and lower pest populations. Cultural controls are also used to disrupt pest reproduction in IPM systems. Crop rotation can reduce pests by interrupting pest life cycles as host plants are replaced with alternatives that do not support the pest species. Tilling can also be used to undermine pest reproduction.

IPM systems can also involve the use of chemical pesticides, but this is undertaken according to pre-established guidelines that specify when pesticide use is necessary, and are viewed as a strategy of a last resort. Even when synthetic materials are used, however, efforts are made to limit their health and environmental consequences. Pesticides that are the least toxic alternatives, as well as those that most narrowly target the pest species without harming other plant or animal life, are used. The application of pesticides is also minimized in terms of frequency and area. Although the other elements of IPM systems are commonly used in organic farming, pesticides are not used in organic agriculture.

Because of its environmental, health, and economic benefits, the U.S. government has encouraged IPM research and implementation for over 30 years.

Yet, while many growers claim to be using some variant of IPM, some research suggests that the full implementation of IPM programs is very rare and that most growers in the United States are still overly reliant on synthetic pesticides. The same is true in other parts of the world, such as in Africa, although elsewhere, IPM is widely practiced. IPM has been adopted by many small rice growers in Asia.

Interdependence

INTERDEPENDENCE IS THE doctrine of mutual dependence among all of the actors within a situation for the survival and success of that situation. It is most commonly used to mean that the people of the world and the institutions they have created both depend on and are depended upon by the earth's environment. Consequently, it is necessary for any decision related to economics also to integrate the environmental impact into the decision-making process, while decisions relating to the environment cannot ignore the economic aspects. In practical terms, it is necessary to cultivate a holistic mindset that can integrate all aspects of society and all aspects of the surrounding environment in order to determine optimal forms of behavior.

This form of thinking can be applied to a wide range of disciplines, including international relations, poverty alleviation, globalization, and democratization. While empirical research can be difficult to manage according to this paradigm, some studies suggest that the intuitive concept of interdependence does have some valency in complex situations. Interdependence is abundantly relevant to natural environmental situations in which negative impacts on one species of flora or fauna can have significant and often unanticipated results for many other species occupying the same or related system.

Religious, philosophical, and social thinkers have talked about the importance of interdependence for centuries, but often from metaphysical perspectives that are not widely considered to be relevant to the modern world. At the same time, the importance of animals and the natural world was often downplayed or else assigned to the control of humanity as a chattel. James Lovelock's concept of the earth as the Gaia system represented a breakthrough in popular thinking in terms of interdependence. The growth of low-cost international travel and the prevalence of the Internet have helped people to understand cultures and societies from around the world and begin to appreciate how actions in one place resonate in others.

Attempts to create international organizations, which could represent the viewpoints of the people of the different countries of the world, have proved to be of only limited success. The United Nations has helped to create agencies that have raised standards of living for many people around the world in different ways, as for example with the case of the International Labor Organization and the Food and Agriculture Organization. However, the World Trade Organization has been bedeviled with arguments and the unwillingness of some members to accede to multilaterally reached decisions. In the 21st century, the willingness of the executive of the United States to act unilaterally has significantly damaged the ability of international organizations to deal with interdependence in the world system, with often-disastrous results.

Intergenerational Equity (IE)

INTERGENERATIONAL EQUITY (IE) broadly refers to theories, principles, laws, and economic models concerned with the issue of equity and fairness to future generations. IE emphasizes that future generations have a right to at least the same general level of ecological, cultural, and economic resources enjoyed by preceding generations. Many argue that IE is the central idea behind demands for sustainable development: ensuring a clean environment with adequate resources so that future generations have the capacity to lead meaningful lives. Thus, IE is relevant to issues such as the conservation of biodiversity and cultural diversity, the maintenance of ecological health, and equal access rights to the product of past generations.

Researchers have pointed out that most previous generations were considerably poorer and had lower living standards, yet left considerable infrastructure and probably saved more in relative terms. However, over the past century there have been significant increases in population growth and affluent consumption, along with the development of resource-intensive and potentially destructive technologies. The combined effect has been a fantastic rise in human resource consumption and waste generation (as well as a decrease in saving), raising concern about the implications of continued growth for ecosystem health. This concern, and subsequent ecological research, led to debates over the "limits to growth" of modern economies. These debates called into question the assumption of infinite economic growth, and forced recognition of resource limits and the irreversible modification of ecosystems essential to human welfare. One of the many concepts that emerged out of the debates was IE.

Following the publication of *Our Common Future*, many environmentalists seized upon the concept of IE, arguing that it is fundamental to building a sustainable society. A popular quote argues for "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." Integrating IE into policy discussions increases the time horizon when considering social and ecological impacts and can therefore profoundly influence the path of technological development and social organization.

Regarding energy production, for instance, governments would shift decisively away from excessive use of nonrenewable resources, such as coal, oil, and nuclear, and focus instead on expanding the potential for solar, wind, tidal, and other renewable energy sources. In this case, IE necessitates reducing nonrenewable energy sources because of potential adverse future effects, such as irreversible changes to the global climate and the harsh reality of millions of years of radioactive waste storage. For environmentalists, as well as ecological economists, IE is an ethical issue informed by scientific consensus.

Proponents of IE have strongly criticized the conventional economic practice of "discounting" because it is seen as a major obstacle to incorporating sustainability principles into economic decisions. For economists, discounting provides an objective, though clearly contentious, approach to the problem of valuing future resource flows. Under certain key assumptions, such as the substitutability of money for any resource, a short-term time horizon, net present value (NPV), and steady, continued growth in the economy, a case can be made for individual discounting. One practical argument for discounting is that people do it "naturally" as a result of time preference. For example, there is typically little concern about events that will happen long after a person dies and access to certain goods now, even with interest, are worth less in the future.

Difficulties arise when individual, short-term discounting is distinguished from *social discounting*, defined by Herman E. Daly and Joshua C. Farley as "a rate of conversion of future value to present value that reflects society's collective judgment, as opposed to an individualistic judgment, such as the market rate of interest." While most economists agree with the latter distinction and have attempted to construct alternative models, recent ecological work (e.g., ecological footprints) implies that critical assumptions of the "objective" social discounting approach must be jettisoned completely. This comes with recognition of finite growth, limited substitutability via technology, decreasing opportunities for productive investment, and "profitable" investments today resulting in future ecological costs.

Some have expressed concern over the efficacy of IE in the context of alarming poverty growth, or intragenerational inequity. Recent developments around the issue of global climate change bring this criticism into sharp relief. On December 7, 2005, Inuits submitted a nonlegally binding petition to the Inter-American Commission on Human Rights urging that the United States—as the largest emitter of greenhouse gasses—cooperate on the Kyoto protocol. This came after a four-year, 15-country study undertaken by 300 scientists warned that the Artic is especially vulnerable to warming and mammalian extinctions, threatening not only the integrity of ecosystems but the very existence of Inuit in the Arctic. The debate raises critical questions about the role of IE in international law and global governance.

Since at least 1988, proponents have argued for the integration of IE into international law, highlighting the temporal aspects of the Universal Declaration of Human Rights. While a limited "intertemporal" doctrine (connecting past to present) already exists, IE proponents are seeking to strengthen and broaden this doctrine to include the relation between present and future generations. Given the fact that people in poverty, by definition, have less access to sustainable resources and are disproportionately impacted by ecological imbalances, these efforts recognize the critical importance of an intragenerational dimension in crafting new law. That there has been little progress applying IE in international law, especially regarding issues like global climate change, is unsurprising considering that powerful nations consume most of the world's resources.

Intergovernmental Panel on Climate Change (IPCC)

THE INTERGOVERNMENTAL PANEL on Climate Change (IPCC) was established in 1988 by the World Meteorological Organisation (WMO) and the United Nations (UN) Environment Program (UNEP) to assess the growing body of scientific evidence related to human-induced climate change. The mandate of the IPCC is to assess all the scientific, technical, and socioeconomic evidence of climate change, establish what its likely impacts would be, and what options are available to the world on how to mitigate emissions and adapt to any changes.

Membership of the IPCC is open to any member country of the WMO or the UNEP. The structure of the panel consists of a plenary, bureau, and three working groups. The plenary meets yearly and has the power to make major decisions affecting the workings of the IPCC. The bureau membership consists of 30 experts in the field of climate science. The three working groups represent the IPCC's core objectives. Members of Working Group 1 review all the scientific data, members of Working Group 2 assess all of the information related to climate change impacts and how to adapt to it, and members of Working Group 3 focus solely on mitigation.

In 1991, the IPCC formed a task force to establish National Greenhouse Gas Inventories. The aim of the task force was to develop a globally-consistent methodology for all nations that will measure and report on emission levels of climate changing gasses and how effective mitigation strategies are.

The IPCC does not produce any of its own science. It reviews and synthesizes the peer-reviewed data that is produced by the world's scientific community. Since its formation in 1988, the IPCC has reported three times on its assessment of risks associated with human-induced climate change. The first set of assessment reports were published in 1990 and formed the basis of the UN Framework Convention on Climate Change. These reports found that human activities were greatly increasing the amount of greenhouse gases in the atmosphere and that they were responsible for causing (and would continue to), a warming of the Earth's surface. Importantly for policy makers, the reports established that global emissions of long-lived greenhouse gases, particularly carbon dioxide, would have to be reduced by 60 percent to stabilize at 1990 levels.

The second set of assessment reports were published in 1996 and formed the foundation for negotiations of the Kyoto Protocol. The third report was published in 2001 and found that the evidence of warming was much stronger, confidence to predict future scenarios of climate change had increased and that global average temperatures were expected to increase by 1.4 degrees C to 5.8 degrees C by the year 2100. The IPCC is expected to release its next assessment on the state of knowledge on human-induced climate change in the first quarter of 2007.

Intermediate Disturbance Hypothesis

THE INTERMEDIATE DISTURBANCE hypothesis (IDH) predicts that the highest levels of biotic diversity are to be found at intermediate levels of disturbance and at intermediate time spans following the disturbance. Other influential ideas about species diversity include island biogeography theory, the time hypothesis, niche partitioning/diversification, and productivity–stability hypothesis.

Disturbances to ecological systems can emanate from diverse sources that may be natural or anthropogenic, including fire, wind, grazing and predation, human management regimes, land cover change, chemical, and thermal contamination, tides, floods, tectonic activity and other forces. According to IDH, relatively low numbers of species may be expected to prevail in ecological systems that are undisturbed or usually subject to very low levels of disturbance, as well as in ecosystems that suffer highly frequent or intense disturbances. Ecosystems characterized by intermediate levels of disturbance, by comparison, are predicted by the IDH to exhibit the highest species richness and diversity (species richness and abundance). A graphical representation of the diversity–disturbance relationship, according to the IDH, would approximate an inverted U-shape when diversity is mapped along the Y/vertical axis, and disturbance intensity/frequency along the X/horizontal axis.

NONEQUILIBRIUM THEORY

The theories explaining the IDH and its inverted U-shaped relationship between disturbance and diversity are linked to concepts derived from community ecology and ecological succession, and the IDH may be seen as one among several nonequilibrium theories of biodiversity. In the IDH view, the prevalence of disturbance in ecological communities prevents them from reaching equilibrium states. Disturbance in a system results in the creation of gaps and spatial heterogeneity, and opens up spaces for various species to colonize. The gaps and the ecological community then begin a trajectory along a new successional sequence, or revert to a sequence similar to the pre-disturbance succession.

At very high levels of disturbance, the ecological community and its gaps do not progress beyond the pioneer stage of the successional sequence. The species composition is dominated by a few early successional, pioneer species often referred to as "r-strategists" for their life history strategies geared toward high population reproductive rates (r) rather than adaptations geared toward competitive advantage. Such dominance leads to low species diversity.

At very low levels of disturbance, on the other hand, successional pathways are quickly followed to the final climax/equilibrium stage. This leads to the dominance of later successional species, often referred to as "K-strategists" for their prevalence at or near the population carrying capacity (K). Such species are adapted to compete successfully for limited resources, and thus exclude other species, leading also to low species diversity overall in the ecological community.

At intermediate levels of disturbance, neither pioneer nor late successional species manage to dominate, and the species mix reflects a higher diversity than expected under lower or higher levels of disturbance.

An early formulation of the IDH was presented by J.H. Connell (1978), who studied species diversity patterns within local areas rather than across large-scale geographic gradients such as temperate to tropical ecosystems. Specifically, Connell focused on tropical forests and coral reef ecosystems, hypothesizing that such systems were characterized by disturbances that maintained them in nonequilibrium states, which helped maintain and explain their high levels of biotic diversity. He also sounded a cautionary note about human disturbance, stating in his article that although the IDH proposed diversity benefits of disturbance regimes, many anthropogenic disturbances—such as mass-scale tropical deforestation or chemical pollution—were in fact qualitatively different from many natural disturbance regimes to which organisms had the opportunity to adapt over long periods of time. Therefore, he warned, such human-caused disturbances had the capability to cause species extinctions, particularly in highly diverse tropical ecosystems with low species populations.

Since Connell's article, several studies from marine and freshwater ecology as well as terrestrial ecology have produced evidence corroborating IDH, while others have presented empirical data and/or simulation models contradicting the hypothesis. For instance, disturbance in the form of selective logging often leads to a loss, rather than an increase in the number of understory deciduous plant species. Another important factor is the effect of changing spatial scale. In certain tallgrass prairie ecosystems, for instance, intermediate levels of disturbance (annually burned versus unburned or burned once every few years) are linked to lower within-site diversity of vegetation; but the relationship reverses when larger spatial areas are considered.

Other experiments in tallgrass prairies have garnered support for the lesser-explored component of IDH, temporal scale (time elapsed since disturbance), while contradicting the disturbance-diversity predictions of IDH. Scale dependence is also seen in coral reef systems. Additionally, coral diversity may often be high in deeper zones or under greater coral cover despite the fact that deeper reefs and greater cover are usually subject to or reflect lower disturbance.

In most cases, a complex of several factors may interact and collectively influence diversity patterns: disturbance, soil fertility and/or nutrient versus limitation, resource partitioning, native vs. invasive/exotic species assemblages (and their evolutionary/life history characteristics), climate change and seasonality.

Internal Combustion Engine

INTERNAL COMBUSTION ENGINES are the family of engines that confine fuel in a chamber, then burn it to convert the expansion of the resulting high temperature gases into work energy through pistons, rotors, turbines or other means. Although the range of fuels for an internal combustion engine (or ICE) is limited only by the need to produce combustion gases, petroleum derivatives are the preferred energy source due to their availability, high energy return, and portability.

Although there are many varieties of ICE, the most common is the Otto Cycle, or four-stroke, engine used in nearly all automobiles and trucks produced today. It is a reciprocating design where one piston drives others through a cam shaft, and the function is as follows: the first stroke of the piston draws in a fuel and air mixture by moving down the combustion chamber; then on the second, upward stroke the piston compresses the aerosolized fuel to the point of combustion (in the case of a diesel engine) or until the mixture is ignited by an electric spark (in a gasoline engine). In both, the expansion of the gases following combustion drives the piston downward, comprising the power stroke of the cycle. A fourth stroke returns the piston upward, and expels the contents of the chamber, preparing the chamber for the next stroke, which commences the cycle again. The two-stroke engine, common in smaller and portable mechanisms, operates using the same principles with the exception that a valve near the bottom of the chamber allows gases to escape at the bottom of the power stroke so that there is no need for a cycle to expel exhaust.

Gasoline engines first found widespread use operating farm machinery and as stationary power sources in factories. A lack of dependable fuel supplies and stations, and some engineering problems, prevented ICEs from out-competing steam and electric power in automobiles until the beginning of the 20th century. The expansion of refinery capacity and improved mechanical efficiency and reliability granted gasoline engines the edge necessary to capture the largest part of the automobile market in the first decade of the century, particularly after the in-

The most common ICE is the Otto Cycle engine used in nearly all automobiles and trucks produced today.

troduction of the Model T in 1908. The basic design of the production gasoline engine has changed very little since it was standardized by the automobile industry in the 1910s, the major structural change being the replacement of carburetors with fuel injector systems. Most changes have instead come in materials, fuel, and peripheral components, often to meet either fuel economy or emissions regulations.

The advantages of petroleum-fueled ICEs in transportation is that they provide significant power using a compact fuel source in a highly reliable format, and allow the consumer to operate within unparalleled economies of scale. However, for almost a century, automobile and oil companies have consistently been among the largest and most profitable, and in the United States they have also been the recipients of large subsidies from the federal government. The disadvantages of widespread ICE use is the unprecedented changes to society and the global climate.

SOCIETY AND ENVIRONMENT IMPACT

Socially, the introduction of the automobile coincided with a major shift in the urbanization of the American population. According to many, the automobile changed the traditional "walking city" with its busy pedestrian streets and close-knit neighborhoods into a noisy and dangerous "machine space" engineered to facilitate the efficient movement of motor traffic to the exclusion of other uses. The automobile is also blamed for the flight of residents from the city to suburbs, atomizing the old neighborhood framework and replacing it with a more insular and less community-oriented society.

On the positive side, the arrival of the ICE signaled the end of the era of animal-powered technology, lowering transportation times and costs, and requiring minimal maintenance when idle. Lower transport costs and portable power have linked ICEs directly to the dramatic decrease in real costs for many consumer goods. Affordable personal transportation is now a key component of the American dream, permitting the majority of the population to forego the high urban densities and high property costs common to the walking city for ownership of a freestanding house and yard. The Los Angeles metropolitan area in particular became an icon of car culture in the decades following World War II, and a model of urban development with land uses dedicated to freeways, drive-through conveniences, and single-family homes. Since the oil crises of the 1970s, concerns have arisen about the hidden social costs of dependence upon ICEs, including sprawl development, growing fears of disruption and exhaustion of petroleum supplies, and a reevaluation of the social impacts of automobile-driven development. Solutions include restructuring society away from dependence upon personal transportation and the current standards of dispersed, single-use zoning that encourages sprawl. The current popularity of form-based codes and New Urbanism reflect many of these concerns by encouraging community spaces that de-emphasize reliance upon automobiles.

ICEs are also central to the debate over air quality and global climate change. Long targeted as the majority of nonpoint source air pollution, most changes to ICE design have targeted reducing emissions and improving fuel efficiency. Early improvements included raising piston compression and preheating the fuel/air mixture to return more power and eliminate the products of incomplete combustion, and the addition of catalytic converters to exhaust systems to capture hydrocarbons that still escape the combustion process. However, improvements in engine compression and quality of combustion created new, unintended products that are less immediately noxious but remain dangerous including nitrous oxide (NO_2), carbon monoxide (CO), and ozone (O_3), which are particularly important causes of urban air pollution and damaging to human health. More recent improvements include computer control of the engine and fuel injection, as well as experiments with hybrid technology that uses the surplus heat energy of the Otto-cycle to generate electricity. These changes were sufficient to drastically reduce the amount of particulate and hydrocarbon emissions produced by ICEs; however, they only partially address the fundamental problem ICEs pose through global warming.

The optimal emissions of a hydrocarbon fueled ICE is a combination of water vapor and carbon dioxide, both of which identified as primary agents of climate change. Improvements to ICE efficiency only forestall the onset of global climate change, but do little to prevent it. This is true also of the alternatives to petroleum fuels, although some attempt to redirect the basis of energy into renewable sources. Because of their relative scarcity, other uses of ICEs have not attracted the same attention as their use in personal transportation, yet pose similar concerns. Commercial aircraft are especially criticized for polluting the upper levels of the atmosphere.

International Monetary Fund

THE INTERNATIONAL MONETARY Fund (IMF) is an international financial institution created to assist member states to resolve their short-term monetary, exchange, and balance-of-payments problems. It was founded along with the World Bank at the Bretton Woods conference of 1944 by representatives of 44 of the world's core economies, after contentious negotiations chaired by the United States.

PURPOSE AND MAKEUP

The IMF formally came into existence in 1945, when 29 countries signed on to the IMF's six-point Articles of Agreement:

(i) To promote international monetary cooperation.

(ii) To facilitate the expansion and balanced growth of international trade.

(iii) To promote exchange stability.

(iv) To assist in the establishment of a multilateral system of payments.

(v) To give confidence to members by making the general resources of the Fund temporarily available to them under adequate safeguards, thus providing them with opportunity to correct maladjustments in their balance of payments.

(vi) To shorten the duration and lessen the degree of disequilibrium in the international balances of payments of members.

The IMF mandate is thus to safeguard international financial and monetary stability by conducting surveillance, providing technical assistance, and making short-term loans to member countries. The capital for these loans was initially collected, and is periodically enhanced, through payments of quotas by member countries. In 2006, the Fund's total holdings amounted to $60 billion, including $9 billion in gold reserves. The Fund also grows by charging interest on its loans; for instance, in 1987, the IMF received a surplus of $8.6 billion from loan repayments over what it lent out.

Today the IMF is comprised of 184 member countries and employs almost 2,700 staff members, mainly economists based at IMF headquarters in Washington, D.C. The Fund is generally directed by the Board of Governors comprised of one governor from each member country (typically the minister of finance), which gathers once a year. Theoretically, board decisions are made by consensus, but the unequal distribution of voting rights gives disproportionate power to Europe and the United States, which enjoy *de facto* veto power (even small European states hold more votes than India or Brazil). By tradition, the IMF's managing director is always a European.

LENDING ACTIVITIES

These inequalities matter because the IMF is arguably the world's most powerful nonstate economic actor. The Fund's powers stem from its capacity to dispense loans and its annual evaluations of member states' economic policies. The IMF extends loans through contractual arrangements that designate policy measures that must be implemented by the member country before loan disbursement. A country that receives a poor bill of health in its annual IMF evaluation will have a difficult time raising affordable capital on finance markets. In this way, the IMF's surveillance, lending practices, and policy recommendations are tightly linked to the practices of the World Bank, regional development banks (such as the Inter-American Development Bank and the Asian Development Bank), as well as private banks. In 2006, the IMF held $71 billion in outstanding loans to 82 countries, mainly in the Global South (Turkey is presently the IMF's largest debtor). While in an absolute sense, outstanding IMF credit peaked in 2003, in a relative sense—debt measured as a percentage of global trade—the Fund's loan portfolio was greatest in the mid–1980s. With the onset of the debt crisis in 1982, the IMF came to serve as judge of the creditworthiness of most developing economies, dispersing economic policies and advancing loans to those member states that accepted its conditions. After the creation of Structural Adjustment Loans (SALs) at the Belgrade IMF/World Bank annual meeting in 1979, SALs rapidly spread throughout Latin America, Africa, and much of Asia (no core capitalist economies were subjected to structural adjustment). Most SALs were said to be needed to overcome balance-of-payments problems caused by high oil prices and rising interest rates on debt incurred in the 1970s.

SALs come with numerous conditions that became widely practiced during the 1980s as structural adjustment programs (SAPs) became the *de facto* development strategy of the Global South. These typically include: currency devaluation, intended to reduce imports and spur exports; trade liberalization (slashing tariffs and quotas); strict austerity in state spending on social services (e.g., health, education, and environmental programs); and financial liberalization, or the freeing of capital from state discipline. These measures aim at increasing the creditworthiness of the developing economy by suppressing domestic demand and productive investment while freeing up capital to repay external debt on imports and loans. SAP policy conditions tend to cause slower economic growth, a shift of domestic capital investment away from production (into trade and finance), and an increase in socioeconomic inequality.

Rather than leading to a resolution of the import-financing problems that gave rise to SAPs, by the mid-1990s most economies in the Global South were saddled with more debt than before the era of structural adjustment. Many environmentalists have criticized the IMF for the negative effects of SAPs on the environment. The emphasis on increasing exports and repaying loans, coupled with the reduced capacity of the state to discipline capital, often causes unsustainable resource extraction (e.g., deforestation to increase timber exports).

PROPOSED IMF REFORMS

A transnational social movement emerged in the 1990s calling for the fundamental reform, if not the elimination, of the IMF. Reform proposals have ranged widely, but tend to focus on reducing the purview of the IMF and placing it under popular, democratic control. The IMF's status suffered a serious blow from the East Asian and Argentine economic crises of the late 1990s—crises that the IMF antagonized rather than prevented. In the early years of the 2000s, the IMF faced greater scrutiny from all sides, a shift away from economic liberalization across South America, and reduced borrowing by member states (the loan portfolio contracted as states grew wary of relying on the IMF's funds and advice). Thus the influence of the IMF has declined. The IMF has even ceased practicing structural adjustment in name, and schemes for debt rescheduling have been discussed. But the Fund is unlikely to disappear soon. Like the World Bank and the World Trade Organization, it remains one of the few institutions that can be said to regulate capitalism on a global scale.

International Tropical Timber Agreement (ITTA)

THE BEGINNINGS OF the ITTA date to 1966, when the United Nations Conference on Trade and Development (UNCTAD) and Food and Agriculture Organization (FAO) proposed the establishment of a tropical timber bureau. By 1973, the emphasis had broadened from market requirements and the availability of tropical timbers to include forest management considerations. Intergovernmental meetings under UNCTAD failed to reach agreement in 1978. A second round of negotiations in Geneva involving 50 countries in 1982 was successful. Here, against the backdrop of two seasons of dramatic fluctuations in supply of tropical timbers on European markets, Japan urged the creation of a commodity agreement to regulate global trade in tropical timber products.

Finally signed in 1983, the ITTA combined commodity trade and nontimber products as well as noncommercial concerns in a single agreement. It was intended to simultaneously serve as an agent of forest conservation by assisting in the creation of a viable forest industry and forest sector, thus restricting the major cause of tropical deforestation—clearance of land for agriculture. The ITTA was serviced by the International Tropical Timber Organization (ITTO), based in Yokohama, Japan.

A new ITTA signed in 1994 came into force in 1997. Membership was extended to include most of the tropical timber producing and importing countries, including Brazil. Now the ITTO broadened its approach to sustainable forestry management to include social forestry and biodiversity considerations. A detailed study was also made of Sarawak. A third ITTA involving 180 countries was signed in January 2006 to be effective for 2008–17.

Environmental groups initially were critical of the ITTA and the ITTO, pointing to insecure funding and slow progress. They also recognized that significant producers and consumers were not members of the ITTA, which detracted from its effectiveness. To some extent this situation no longer applies. Environmentalists regarded the ITTO as Asian dominated even though much of the funding came from grants from the governments of Switzerland, the United States, and Japan. Furthermore, they suggested that many tropical timber-producing countries were not vigorously pressing for sustainable use of tropical forests. Having participated in earlier ITTO council meetings, the World Wildlife Fund withdrew from the 1994 session. Although the ITTO has been quite active in promoting sustainable forest management and developed a number of manuals and protocols, it cannot compel member countries to adopt these at a national level. Even so, the ITTA, by its enduring existence and global reach, may be poised to exert greater influence on the sustainable management of tropical forests, particularly in terms of assisting states to confront illegal harvesting and improve governance.

Inter-Tropical Convergence Zone (ITCZ)

THE INTERTROPICAL CONVERGENCE zone is a trough of low pressure in the tropics that circles the globe in an east-west direction. Its location shifts roughly between 23.5 degrees north and south latitude and tends to follow the subsolar point over the course of the year. The low pressure results from the intense heating of the vertical rays of the sun, which causes the warm air to ascend and causes the northeast and southeast trade winds to converge on the zone of lifting. The warm air is extremely humid, and as it rises along the convergence zone, the air cools and the moisture condenses, forming precipitation. The ITCZ represents the primary engine of the global circulation of the atmosphere, since it is the only global pressure system arising from direct solar heating. Additionally, the ITCZ represents the cyclonic portion of the Hadley Cell circulation system.

The latitudinal displacement of the ITCZ over the course of the year varies according to the variable character of the Earth's surface. Land tends to increase in temperature more rapidly than oceans, so for any given latitude, temperatures tend to be greater over land than the oceans. As a result, the ITCZ tends to shift further toward higher latitudes over land than over oceans. Additionally, warm ocean currents tend to flow poleward along the east coasts of continents and cold ocean currents flow equatorward along west coasts of continents, such that, for any given latitude, temperatures off the east coasts of continents tend to be warmer than the west. The ITCZ thus tends to deflect further toward the higher latitudes along the east coasts.

The shift of ITCZ over the course of the year brings seasonal precipitation. Equatorial regions receive rainfall year-round (152–254 centimeters annually) under the influence of the ITCZ, and is a defining characteristic of the tropics. At the latitudinal extreme of the tropics, the seasonal retreat of the ITCZ corresponds to the advancing influence of the subtropical high pressure system with its characteristic dry, subsiding air. The climates in these regions are characterized by a marked dry season of varying length. The Tropical Monsoon climates of South and East Asia are characterized by heavy rains brought by the ITCZ during the summer months (254–508 centimeters annually) and a short, marked dry season of up to three months. Tropical Savanna climates have a less pronounced wet season (90–180 centimeters) and a dry season of up to six months.

The inundating rains of the ITCZ are important to the developing countries of the tropics, many of which rely on agriculture as a mainstay of the subsistence and market economies. In South and Southeast Asia, the rains from the ITCZ support wet-rice production in irrigated paddies. Additionally, severe seasonal flooding often accompanies the rains. During the summer of 2005, monsoon rains in India killed over 100 people, disrupted transportation networks, and left over 150,000 people stranded. The rains of the ITCZ are important to the livelihoods of the societies that receive them, but the rains constitute a hazard as well.

Invasive Species

DEFINING BIOLOGICAL INVASIONS is challenging due in part to the proliferation of terms, especially among biological disciplines, that usually describe a set of ranging and different concepts. Depending on the author, a species in the invasion might be referred to as: *alien, exotic, invasive, non-indigenous, imported, weedy, introduced, nonnative versus naturalized, endemic* or *indigenous*. Some of the terms employed evoke anthropocentric concepts such as *aggression, assault,* and *attack,* which have normative implications. These implications and the lack of consistent uses of terms contribute to confusion.

Invasive species in general are defined as species that occupy or are in the process of occurring in regions where they have not been present historically. Specifically, invasive species are defined by their origin and distribution. An invasive species might spread into native plant communities and cause environmental harm by developing self-sustaining populations and disrupting the structure and functioning of the system. What characterizes invasive organisms is the ability to take hold of a habitat and become aggressive and dominant. It could be that either invasive species have extraordinarily wide distributions around the world, or that they are distributed locally with very high population densities affecting the endemic biota of specific regions. Invasive species are usually alien species, meaning they are able to reproduce outside their native ecosystems, and whose introduction is more likely to cause environmental harm.

Plants and insects are the most common orders in terms of their invisibility. From a population biology point of view, invasive plants tend to produce reproductive offspring, often in very large numbers (e.g., seeds, spores) and disperse them at considerable distances from parent plants. Invasive species also spread successfully through the use of roots or rhizomes (for example, more than 2 meters/year for taxa spreading), and such strategies enable them to spread over a considerable area. This definition also concerns species that have spread previously but not currently because of competition. These species are still considered invasive species because once local competition disappear, it may lead to re-invasion.

DIFFERENT APPROACHES

Research questions on invasive species range with discipline with extremes in population biology and ecology to economics. Ecological approaches center on how the biological aspects of invasive species related to the biophysical environment. Due to the complexities of such relation, the human linkages are less explicit and only mediated through disturbance processes. Concepts such as competition, disturbance, homogenization of habitats and species capacity are at the core of ecological research. Among social scientists, economists have attempted to understand the linkages between human activities and the spread of invasive species. Economic theory tends to be helpful in diagnosing human sources of invasion problems, to provide information on the risks associated with invasions, and to evaluate the damaging effects of invasions on public goods like biodiversity or common-property lands. Economic analyses are useful to prescribe when, where, and how to control invasions; at estimating the expected benefits of various control programs; and in minimizing the costs of controlling invasions that have already taken place. The links between invasion and effects on ecosystem services is usually descriptive and not normative, and its links with economic activities are through monetary value. Such utilitarian perspective is problematic, especially from a conservation perspective; improvements, however, could be made if nonmarket valuations of the ecological and social processes are included in such analyses.

A cultural and political ecological approach to invasive species considers human aspects to be central to the understanding of the patterns and process of biological invasions. Humans alter habitat conditions where exotic species can succeed, and the mobility that allows larger and faster movement of species across the world. The process of invasion is not only an ecological process, but a social process that needs to consider not only the current cost–benefit analysis or tradeoffs in economic terms, but also recount of the humanized natural history. Under this perspective, invasive species benefit as well as harm societies. Nonnative species are so much part of human livelihoods and traditions that is difficult to picture such societies never experiencing them.

For example, foods like potatoes and tomatoes in Europe are not native to these environments, but from South America; however, they are very much an integral part of certain European cultures. On the other hand, invasive species could create dire political and economic consequences. Classic Ecological Imperialism shows how disease and other species brought from Europe to America factored in destroying native populations and transforming the landscape in dramatic ways. Understanding the biological character of invasions is critical to understanding the political ecology of such process, which involves an understanding of the cultural complexities and the potential uneven impacts of invasion in society.

Inversion, Temperature

GENERALLY, THE HIGHER in the atmosphere air is, the cooler it is. However, there are some circumstances in which the opposite process occurs and a band of warmer air overlays cooler air. This is known as temperature inversion. A permanent temperature inversion occurs at the edge of the troposphere, with warmer air above it in the stratosphere after the barrier of a temperature inversion known as the troposphere. However, several other methods of creating a temperature inversion exist, which are temporary phenomena. One result of temperature inversion is that particles in the air are unable to rise up into the sky and instead form a layer following the contours of the inversion. When a temperature inversion occurs above an industrial area, therefore, it can trap atmospheric emissions and create smoke and gloomy weather, which can have negative health outcomes.

Ways in which temperature inversions can form include the differential degree of conduction between ground and air. If the ground cools rapidly, its greater level of conduction means the air closer to it is cooler than that some way above. This is known as ground inversion. Turbulence inversion occurs when a layer of turbulent air becomes cooled by interacting with upper layers of cooler air and therefore loses average levels of height compared with a higher level of calm air. A frontal inversion occurs when two bodies of air of different temperature meet at approximately the same height. Since the warmer air is lighter, it is forced up by the cooler air, which sinks beneath it. Finally, a subsidence inversion occurs when a body of air of the same temperature sinks. The top level of the body passes through a greater range of pressure change and so becomes warmer than the lower levels. All forms of temperature inversion are associated with the creation of clouds, humidity, and precipitation. Without an inversion, particles continue to rise and clouds are not formed.

Temperature inversion can have many different impacts on activities taking place on the ground. Ground temperature inversions can, for example, create frost that can damage or kill sensitive plants and crops. Widespread inversions can create extensive areas of pollution that can affect the health of people, animals, and plants. Since inversions tend to occur in the same places repeatedly, poorly located areas can suffer from persistent and pernicious pollution. Microclimate regions can occur in, for example, upland regions that regularly experience ground inversion.

Researching the presence and nature of inversions involves the use of satellites, thermal imaging, advanced statistical modeling, and physical measurement of atmospheric conditions in a range of different locations. The complexity of weather conditions across the earth means that it has not yet been possible to model inversions accurately in all conditions. However, awareness of their likelihood and effects can be used in planning the locations of industrial, residential, and agricultural activities.

Iran

FORMERLY KNOWN AS Persia, the Islamic Republic of Iran has long been the site of political struggle, especially for the control of oil, under the influence of foreign powers. In 1953, for example, after the Anglo-Iranian Oil Company was nationalized by the democratically elected government, a traditional monarchy under a shah was reinstated with support from the United States and the United Kingdom. The country received worldwide attention in 1979 by expelling the ruling shah, a strong ally of the United States, and taking over the American Embassy in Tehran. Between 1980–88, Iran carried on a war with neighboring Iraq, ultimately facing the U.S. Navy in 1987–88. Recent elections have further cemented conservative power in Iran and have produced clashes with international organizations over nuclear capabilities. In February 2006, Iran's Atomic Energy Organization contracted with Russia to develop a joint uranium enrichment project. Two months later, the Iranian government announced that it would not yield to demands of the United Nations (UN) Security Council to halt such activities, but would begin producing nuclear fuel on an industrial scale.

Despite Iran's collecting around $40 billion in foreign exchange oil reserves, 40 percent of the Iranian population of 68,017,800 lives in poverty. With a per capita income of $12,900, Iran is ranked 99th in world incomes. More than 11 percent of the labor force is unemployed, yet Iran is experiencing a shortage of skilled labor. Some 27 percent of females and around 11 percent of males over the age of 15 are illiterate. Almost one-third of the workforce is engaged in agriculture, chiefly at the subsistence level. Seven percent of the population lack sustained access to safe drinking water, and 16 percent lack access to improved sanitation. Even so, the country has a strong and growing middle class and a large and widespread set of opportunities in education for both men and women. The UN Development Program (UNDP) Human Development Reports rank Iran 99th of 232 countries on quality-of-life issues.

Strategically located in the Persian Gulf and bordering the Gulf of Oman and the Caspian Sea, Iran has a coastline of 1,513 miles (2,440 kilometers). Iran shares land borders with Afghanistan, Armenia, Iraq, Pakistan, Turkey, and Turkmenistan as well as Azerbaijan and the Azerbaijan-Naxcivan exclave.

The Persian Royal Road

In the ancient world, the Achaemenid Empire was one of the largest empires, and communications between empires were difficult. To help messengers travel around the empire easily, Darius I of Persia (reigned 522–486 B.C.E.) built a 1,677 mile (2,669 kilometer) road across the empire, making the Greek historian Herodotus claim that "there is nothing in the world that travels faster than a Persian courier."

Unlike many other national highways, the Persian Royal Road linked the major cities of the empire, so it often did not follow the shortest possible route. In the west, the road began at Sardis, in the west of present-day Turkey. It then heads through Phrygia to Gordium, where Alexander the Great cut the famous "Gordium Knot." The road continues eastwards to Comana, then cuts south to Mazaca, to Maras in southeastern Turkey, and then to Gazientepe, going eastwards to Edessa.

From Edessa, the road follows the route of an Assyrian road to the former Assyrian capital of Nineveh, near present-day Mosul, in Iraq, and then continues to Arbil, Kirkup and then through southern Media to Susa in the land of the Elamites, in present-day Iran. From there it continues southeast to the Persian capital at Persepolis.

It seems probable that the road incorporated many previously existing roads, and was largely to help control the Achaemenid Empire as it spread westward. It certainly helped unify the empire, and was not only used by the Persians, but was also used by the men of Alexander the Great's army, and the armies during the Diadochi Wars that followed Alexander's death in 323 B.C.E. The road was still in use during Roman times, and at its easternmost, it joined with the fabled Silk Road to China. Parts of it were later used by Marco Polo.

The terrain varies from rugged mountains to a high, central basin with deserts giving way to small, isolated plains along the coasts of the gulf and the Caspian Sea. Except for the area along the Caspian coast where the climate is subtropical, Iran's climate is either arid or semiarid. In addition to large deposits of petroleum and natural gas, Iran's most valuable natural resources are coal, chromium, copper, iron ore, lead, manganese, zinc, and sulfur.

Iran experiences periodic droughts and floods, and sand and dust storms are common. Earthquakes are a constant threat in Iran, such as the quake registering 7.5 on the Richter scale that hit the southeastern city of Bam in December 2003. The quake caused the deaths of more than 40,000 people and displaced an additional 100,000 individuals, who are still struggling to regain equilibrium. In March 2006, three new earthquakes struck Iran, causing 66 deaths and injuring over 1,000 people.

MASSIVE AIR POLLUTER

The UN has identified Iran as the country with the heaviest air pollution in the world, largely because of emissions from vehicles that have not been designed to limit pollution. Between 1980 and 2002, carbon dioxide emissions rose from 3.0 to 5.3 per capita metric tons. Iran produces 1.4 percent of the world's total of carbon dioxide emissions. At times, the air pollution level is so high that schools and government offices are forced to close. Iranian air is further polluted by refinery operations and the release of industrial effluents into the atmosphere.

Water in Iran has been contaminated by raw sewage and industrial waste products. Pollution is particularly heavy in the Karoon River, the source of almost a third of Iran's surface water resources. According to the World Bank, health problems related to contaminated water are responsible for 90 percent of illnesses in children and are believed to have contributed to 15 percent of deaths among children under the age of five years. In 2003, the World Bank approved $20 million in loans to help the Iranian government reduce air and water pollution.

The Iranian environment has also been damaged by deforestation, overgrazing, and desertification that is common in underdeveloped countries. The Persian Gulf has been heavily polluted by oil spills. Soil degradation has resulted from both human and climatic activity. Wetlands have disappeared following prolonged periods of drought. Like many countries in the area, Iran suffers from a shortage of potable water, particularly in rural areas. In a 2006 study conducted by scientists at Yale University, Iran was ranked 53rd of 132 countries in environmental performance, slightly above the comparable income and geographic groups. Iran's scores were particularly low in the areas of air quality, sustainable energy, and biodiversity and habitat. Varied forms of wildlife are found in the mountains of northwest Iran, in the central plateau, and in the forests near the Caspian Sea. Of 140 endemic mammal species, 22 are endangered, as are 13 of 293 endemic bird species. Some 4.5 percent of the land area of Iran is forested, and 4.8 percent of land area is under government protection.

In order to deal with environmental pollution that has threatened human life as well as Iranian flora and fauna, the government has made pollution reduction a top priority in its current five-year plan. The authority of the Department of Environment to monitor and enforce existing environmental laws and legislation has been strengthened, and nongovernmental organizations (NGOs) have begun pressuring the government for additional change. Educating the public on environmental issues is seen as a key strategy in dealing with environmental problems. Iran's participation in international agreements on the environment is limited to: Biodiversity, Climate Change, Desertification, Endangered Species, Hazardous Wastes, Marine Dumping, Ozone Layer Protection, and Wetlands. The government has signed but not ratified agreements on Environmental Modification, the Law of the Sea, and Marine Life Conservation.

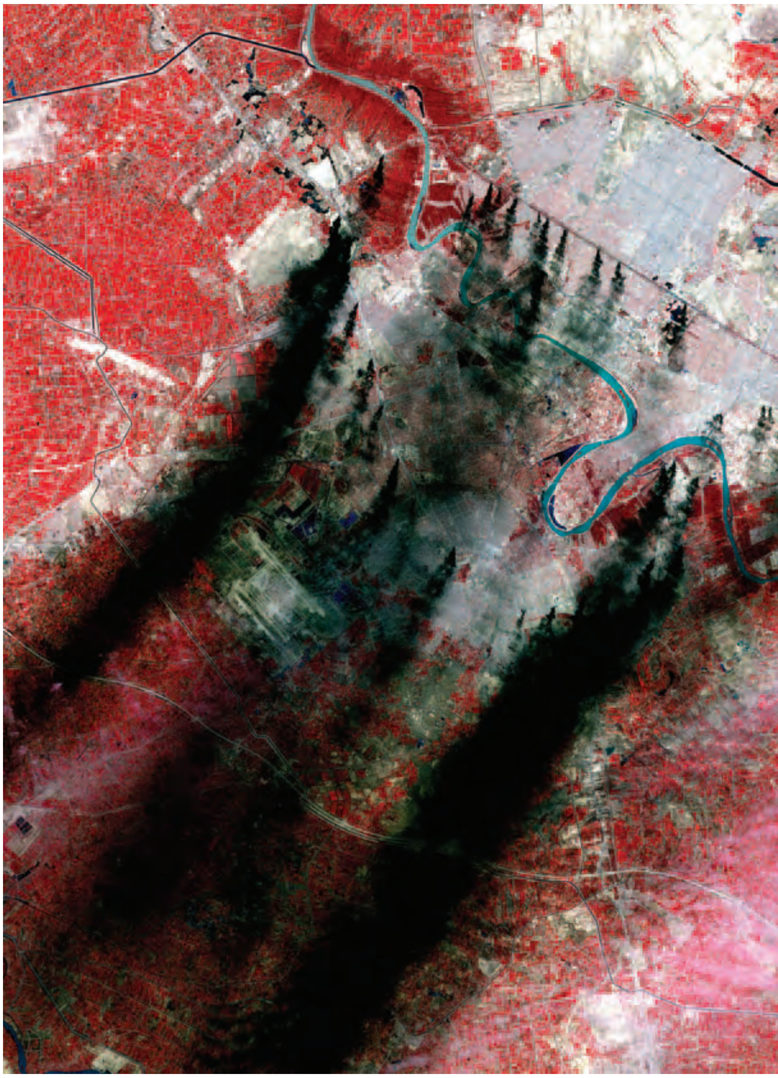
Independent scholar

Iraq

HISTORICALLY PART OF the Ottoman Empire, the League of Nations placed Iraq under British administration at the end of World War I, artificially creating the nation's borders by combining multiple regions of Ottoman administration into a single country. After achieving independence in 1932, the Republic of Iraq was ruled by a series of military governments, including the repressive regime of Saddam Hussein, which was unseated by American-led forces in 2003. In April 2006, Hussein was formally charged with genocide and the murder of at least 50,000 Kurds. Iraq and the United States had previously clashed in 1991 after Iraq invaded Kuwait. The United Nations (UN) conducted inspections after the war, despite some resistance from the regime, to try to ensure against the construction of nuclear weapons.

In December 2005, the Iraqi interim government formally transferred power to a elected government. The political situation remained unstable despite the continued presence of United States and coalition forces, as guerrilla warfare continued. Ongoing sectarian violence has resulted in the displacement of at least 100,000 Iraqis. The Bush administration has been harshly criticized for justifying the invasion of Iraq on the grounds that the country was stockpiling nuclear and biological weapons. However, the U.S. 9/11 Commission Report has concluded that no concrete evidence of weapons existed.

In addition to the petroleum and natural gas reserves that give Iraq its strategic importance and provide 10 percent of the world's total, natural re-



Black smoke from burning pipelines plumes over Baghdad in May 2003. Vegetation appear red in thermal imaging.

sources are limited to phosphates and sulfur. The oil industry accounts for 95 percent of foreign exchange earnings. Roughly 13 percent of Iraqi land is arable, but agriculture makes up only 7.3 percent of the Gross Domestic Product (GDP). With a per capita income of $3,400, Iraq is ranked 153rd of 232 nations on world incomes. In 1996, the United Nations instituted an oil-for-food program designed to alleviate human suffering; however, prolonged war has hampered economic recovery.

Although no official poverty level is available, social indicators suggest major threats to human health. Life expectancy is only 68.7 years, and infant mortality is high at 48.64 deaths per 1,000 live births. The high death rate among children is partially responsible for the fertility rate of 4.28 children per female, which further threatens the livelihood of the poorest Iraqis. Between 25 to 30 percent of the population of 26,075,000 is unemployed. Over three-fourths of adult females and 44 percent of adult males are illiterate.

One-fifth of all Iraqis and 48 percent of rural residents have no sustained access to improved sanitation. Half of rural residents and 19 percent of all Iraqis lack access to safe drinking water. The UN Development Program (UNDP) Human Development Reports do not rank Iraq's standard of living because of missing data. In addition to a 36-mile (58-kilometer) border along the Persian Gulf, Iraq shares borders with Iran, Jordan, Kuwait, Saudi Arabia, Syria, and Turkey. Most of Iraq consists of broad plains, but reedy marshes that include large flooded areas are found along the southern border with Iran. The northern sections of Iraq that border Iran and Turkey are mountainous. These areas experience cold winters and may see heavy snows that melt in the spring, producing extensive flooding in central and southern Iraq. Elsewhere, the Iraqi climate is typically desert with mild to cool winters and dry, hot summers. Elevations vary from sea level at the Persian Gulf to 11,844 feet (3,611 meters) at an unnamed peak in the northeastern corner of Iraq. Dust and sand storms are common.

The most serious prewar environmental problem in Iraq was created by the government's draining and diverting feeder streams and rivers away from the inhabited marsh areas near An Nasiriyah. With 85 percent of the Mesopotamian wetlands destroyed, indigenous groups have been displaced and wildlife has been threatened. The shortage of potable water has had enormous health and environmental consequences. Drawing on the resources of the Tigris and Euphrates Rivers requires cooperation with Turkey, and the two countries have had a rocky relationship. Urban areas of Iraq experience extensive air and water pollution. With 67.2 percent of the population urbanized, Iraq produces 0.3 percent of the world's supply of carbon dioxide emissions. Outside urban areas, soil degradation and erosion further threaten the fragile environment, as does the desertification common in the Middle East. The government has not protected any of the land area. Eleven of 81 endemic mammal species are threatened, as are 11 of 140 endemic bird species.

The environmental cost of the current war has not yet been tallied, but it is certain to be extensive because much of the infrastructure has been destroyed. UNEP has identified potential problems with disease-causing pollution, waste management, and unexploded munitions. Insurgents have deliberately set fire to oil wells, producing a thick haze of dark smoke that exacerbates respiratory conditions.

Hanging Gardens of Babylon

The Hanging Gardens of Babylon, and the walls of the city were, according to tradition, constructed by King Nebuchadnezzar II in about 600 B.C.E. They were described by many Greek writers including Strabo and Diodorus Siculus, and were regarded as one of the Seven Wonders of the Ancient World. They remained until about the 1st century B.C.E., when they were destroyed in an earthquake.

Nebuchadnezzar II was said to have ordered the gardens to be built for his wife Amyitis, the daughter of the King of the Medes. She found the relatively dry land around Babylon depressing, so the king began work on lush rooftop gardens and an artificial mountain that would remind Amyitis of her homeland.

There has been some controversy about the gardens with several historians suggesting that they were, in fact, in Nineveh, the Assyrian capital. This comes from mention in cuneiform tablets of gardens at Nineveh, whereas there is no local contemporary account of the gardens at Babylon. It seems likely that there were, in fact, another set of gardens there. Those at Babylon did exist—certainly Strabo describes them in some detail. The term "hanging gardens" comes from the fact that the greenery from the plants "overhung" the buildings on which it was constructed, with the nearby River Euphrates being used to water the plants.

After the Persian Gulf War of 1991, Iraq's electric, transportation, water, and sanitation systems were verging on total collapse.

In the ancient city of Babylon, river reeds have encroached on historical sites such as the Tower of Babel and the Hanging Gardens, and signs of military occupation and fighting are everywhere. Habitats have been destroyed by war activity and human encroachment.

The Environment Protection and Improvement Council is the Iraqi government agency that bears major responsibility for implementing and monitoring environmental laws and regulations. In connection with other government agencies, this ministry has initiated programs designed to promote water conservation; prevent further damage to fragile ecosystems; and check air and water pollution, desertification, and soil degradation and erosion. International agencies continue to work with the Iraqi government in implementing these policies. Because Iraq is not fully integrated into the global community, the government has ratified only the international agreement on the Law of the Sea. The agreement on Environmental Modification has been signed but not ratified.

Ireland

IRELAND IS AN island country, the third largest in Europe, at the edge of the northwestern European continental shelf. It is surrounded on the north, west, and east by the Atlantic Ocean. The Irish Sea separates it from Britain. Four-fifths the size of South Carolina, it has an area of 27,136 square miles (70,238 square kilometers), stretching 290 miles (465 km) north to south and 177 miles (285 km) east to west.

Topographically, Ireland has three main features—coasts, lowlands, and mountains. The Irish coastline surrounding is 1,738 miles long (2,797 kilometers) are cut by numerous inlets and bays, especially on the northern and western sides.

The Shannon River runs through the center of the country into Galway Bay, where the ports of Limrick and Galway are located. Bantry, Clew, Dingle, Donegal, and Sligo Bays are also on the western side of Ireland along with hundreds of islands. The most important of the western islands are Achil Island, Aran Islands, and Valentia Island. Dublin Bay is on the east coast, with Cork and Waterford are on the south coast. The north coast of Ireland has in recent decades become an important vacation center with its long sandy beaches and miles of dramatic chalky cliffs beaten by sea waves.
