50 Therapeutic penetrating keratoplasty

Prashant Garg, Gullapalli N. Rao

The term 'therapeutic keratoplasty' is used for a surgical procedure performed either for restoration of structural integrity of the eye or to resolve an infectious and inflammatory keratitis refractory to conventional medical therapy. The procedure can be a full-thickness penetrating keratoplasty (PKP) or a partial-thickness lamellar keratoplasty. The term 'tectonic keratoplasty' is used when the procedure is performed primarily to restore the structural integrity of the eye. The surgery is most often performed as an emergency procedure on an inflamed eye. Therefore, the surgical procedure, postoperative course, and chances of graft survival are different from optical keratoplasty. It is critical to understand various aspects of the surgery and postoperative care in order to maximize optimal outcome. It is also important to discuss these various aspects, including the expected outcome, with every patient before subjecting him or her to the surgery. In this chapter, we will discuss these aspects, including indications, preoperative evaluation, anesthesia, surgical procedure, and postoperative care.

INDICATIONS

MICROBIAL KERATITIS

Corneal blindness secondary to infectious keratitis is a major problem in developing countries.[1] Early diagnosis, better understanding of pathogenesis, and the availability of potent antimicrobial drugs have improved the chances for medical control of corneal infections, particularly those of bacterial origin. However, virulent and resistant forms of some bacteria,[2–5] fungi,[6–11] and *Acanthamoeba*[12–14] can progress inexorably, even with maximal medical therapy, and these may necessitate PKP. In addition, conditions such as infectious crystalline keratopathy and mycobacterial keratitis often require keratoplasty.[15–17] In general, the indications for PKP in infectious keratitis include the following circumstances (see Box 50.1 for details): (1) conditions that are refractory to maximal medical therapy; (2) advanced cases that carry the risk for scleral extension; and (3) instances of threatened or actual perforation.

Miedziak et al found that older age, delay in referral to a corneal specialist, topical steroid treatment, past ocular surgery, poor vision at presentation, large size, and central location of the ulcer are important risk factors in active microbial keratitis leading to PKP.[18]

The goal of therapeutic keratoplasty in these cases is to completely remove or reduce the infective inoculum to a level at which anti-infective therapy and host defense mechanisms can be effective.

HERPES SIMPLEX KERATITIS

Therapeutic keratoplasty for herpes simplex keratitis is indicated in patients with severe stromal keratitis refractory to medical therapy or progressing to perforation. In some cases, keratoplasty may be required to remove antigenic material responsible for recurrent inflammatory episodes.[19–21]

NONINFECTIOUS KERATITIS

In addition to infectious keratitis, keratoplasty may be required in cases with noninfectious keratitis resulting in progressive stromal loss. Such situations can occur in neurotropic keratitis, exposure keratitis, and severe dry eye of various etiologies.[22–25] In all these conditions, a nonresponding persistent epithelial defect progresses to stromal melt and perforation. Although the primary treatment in these conditions is directed toward the etiology, we need to provide local treatment that will promote epithelial healing, protect healing epithelium, and avoid further damage to epithelium. In cases with persistent epithelial defect, stromal loss can lead to perforation. Such cases require keratoplasty for tectonic support. Therapeutic keratoplasty performed for tectonic purpose in patients with either impending or actual perforation is also termed 'tectonic keratoplasty'. The goal of the surgery in these cases is to preserve or restore the structural integrity of the eye.

The decision about whether to perform keratoplasty in all these indications is fraught with great risk, however, and the risk-to-benefit ratio must be appraised carefully. A review of the literature clearly highlights the low rate of success that is associated with active cases of infectious keratitis.[26–29]

BOX 50.1 INDICATIONS FOR PENETRATING KERATOPLASTY IN THE TREATMENT OF INFECTIOUS KERATITIS

Bacterial keratitis

- Progressing despite maximal medical therapy
- Extensive corneal involvement
- Descemetocele or perforation
- Resistant to conventional medical therapy
  - Infectious crystalline keratopathy
  - *Mycobacterium* keratitis

Fungal keratitis

- Progressing despite maximal medical therapy
- Threat to the integrity of the globe
- Scleral involvement

***Acanthamoeba* keratitis**

- Failed medical therapy
- Threatened integrity of the globe
- Scleral involvement

However, advances in eye-banking methods and surgical techniques, and improved availability of effective pharmacologic agents for postoperative care have significantly improved the outlook for PKP in these cases. Proper donor corneal selection, the use of meticulous surgical techniques, and close postoperative follow-up are fundamental to the success of this procedure.

PREOPERATIVE EVALUATION

OCULAR EXAMINATION

Once the decision has been made to perform PKP, a detailed presurgical examination is mandatory for proper surgical planning. A detailed slit-lamp evaluation is required to determine the size of the infiltrate and its relation to the limbus. This evaluation facilitates planning of surgical details, such as the size of the trephine that can be used and its optimal placement in the recipient bed to ensure excision of the diseased cornea. A note should be made of the degree of thinning, including the presence of actual perforation. Extreme care is required in handling cases with gross thinning and perforation. You may want to apply tissue adhesive to ensure adequate pressure in eyes with actual perforation before trephination. The status of the anterior chamber should be assessed; cases with a flat anterior chamber or the presence of anterior synechiae must receive intravenous mannitol to control intraocular pressure and reduce vitreous volume. In such cases, entry into the anterior chamber needs to be guarded to prevent injury to the lens in phakic eyes. Retinal evaluation should be attempted, if at all possible. When an adequate view of the retina is not possible and the integrity of the globe is not compromised, an ultrasonography examination is mandatory. The status of the vitreous is very important owing to the potential for concomitant endophthalmitis, particularly in cases of fungal keratitis, cases with perforation, and in patients who have undergone cataract surgery. Intraocular pressure should be evaluated and controlled. All patients with high intraocular pressure must be given intravenous mannitol and must have a very careful entry into the anterior chamber to prevent sudden decompression and choroidal hemorrhage. Patients with a large perforation may require surgery under general anesthesia and therefore may require general medical evaluation. In all patients with gross thinning or perforation, the anesthetist must be informed about the ocular condition and the risk of perforation with expulsion of intraocular contents. This will help them to take appropriate precautions during both peribulbar and general anesthesia.

PREOPERATIVE TREATMENT

Patients with culture-proven keratitis must receive antimicrobial treatment directed against offending microorganisms. If an etiologic diagnosis has not been established, antibiotic coverage with combination therapy or with a broad-spectrum variety should be provided. We recommend therapy with both topical and systemic routes in cases with corneal perforation and fungal and *Acanthamoeba* keratitis and in patients with scleral extension. Use of antibiotic prophylaxis is controversial in sterile corneal melts and perforation; however, one must choose the least epithelial toxic antibiotic under such circumstances. Although Killingsworth et al[27] and O'Day et al[30] have recommended the use of topical and systemic steroids before therapeutic keratoplasty, even in cases of fungal keratitis, one must be aware of the potential for steroids to make the infectious process worse.

DONOR MATERIAL

Criteria for the selection of donor corneas are similar to optical PKP except in circumstances where waiting for cornea of good quality may further complicate the clinical situation. Corneal tissue of excellent grade offers the following advantages:

1. Healthy tissue with intact epithelium minimizes the risk of reinfection in the graft.
2. Compact and clear tissues permit monitoring of the anterior chamber reaction during the immediate postoperative period.
3. Because of the greater likelihood of extensive inflammation and elevated intraocular pressure that is associated with the treatment of large perforations, the use of healthy endothelium is critical for the survival of the graft.

Under emergent circumstances, corneas of poor quality or that have been in storage media longer than recommended can also be used; however, make sure that all appropriate medical standards are fulfilled.[31] Similarly, donor cornea qualities are not as important in patch grafts that are of small size and are off the visual axis.

SURGICAL TECHNIQUES

Although corneal transplantation for infectious keratitis follows the basic surgical technique of PKP, special attention must be given to certain details, which are highlighted here.

PREOPERATIVE PROCEDURES

The transplantation can be performed using local anesthesia, except in eyes with large perforations, which may require general anesthesia. It is important to obtain a good hypotony, akinesia, and anesthesia to avoid problems related to positive vitreous pressure, to facilitate relatively prolonged surgery, and to keep the patient comfortable all through the surgery. Peribulbar injection of a mixture of 1% lidocaine with epinephrine and 0.75% bupivacaine mixed with hyaluronidase and sodium bicarbonate produces a good aki-

nesia and long anesthesia. In patients with no risk of perforation, gentle digital massage or other measures to obtain a soft eye may be considered.

SURGICAL PROCEDURES

Penetrating keratoplasty

The various steps of the surgical procedure are shown in Figure 50.1, *A* to *E*.

Exposure

Lid sutures or self-retaining speculum can be used to obtain good exposure. It is important to avoid external pressure on the globe, especially in cases with corneal perforation. Whenever possible, a Flieringa ring should be used to provide scleral support. In eyes with very low intraocular pressure suturing of the ring may be difficult. In cases of large ulcers that reach up to the limbus, peritomy is required, and hemostasis is achieved by the use of wet-field cautery.

Preparation of the recipient bed

The goal of therapeutic keratoplasty is to excise all necrotic or infected tissue. Therefore, it is critical to choose a right size of trephine for recipient bed preparation. Measure the involved area using a caliper (Fig. 50.2, *A* and *B*). A trephine that is at least 1 mm larger than the size of the lesion will increase the chances of a stable and noninfected recipient bed (Fig. 50.3, *A* and *B*). Place the appropriate trephine over the cornea and create an indentation in the epithelium to further verify the appropriateness of trephine diameter. Trephination of the recipient bed can be technically difficult, especially in cases with corneal necrosis, gross thinning, and actual perforation. Applying pressure on the globe can lead to extrusion of intraocular contents and expulsive choroidal hemorrhage. It is, therefore, important to use an extremely sharp trephine and apply minimal pressure. Suction trephines can be advantageous under these situations. In eyes with a perforation, initial tectonic support can be obtained by applying cyanoacrylate glue during surgery.

A side-port entry with a sharp blade provides access for filling the anterior chamber with a viscoelastic before actual trephination; this will prevent a sudden decompression of the globe.

Occasionally, the lesion may be located near the limbus. An example of this situation would include infections of cataract wound, infection or perforations after pterygium surgery, and peripheral inflammatory disorders. In such cases, if the lesion is small a corneal trephine can be placed straddling the limbus. However, if the lesion is large, there is a large perforation, or the entire cornea is involved, freehand dissection of the recipient after marking with a trephine will be the option.

We recommend 80% depth trephination followed by a guarded entry into the anterior chamber with either a no. 11 surgical blade or any other sharp blade. Excision of diseased cornea can than be completed in the usual manner with right and left Castroviejo scissors. Leaving a relatively wider posterior ledge (nearly 1 mm), especially in large grafts, provides support and reduces the risk of postoperative wound leaks.

In all cases, the corneal specimen should be subjected to both microbiologic and histopathologic investigations. We divide the excised corneal button into two halves through the lesion; one half is sent for histopathology examination in 20% formaldehyde and the other half is sent in a sterile vial for microbiology evaluation.

Clearing the anterior chamber of exudate

Irrigation of the anterior chamber is done using a balanced salt solution. Elimination of all exudative material from the anterior chamber helps to prevent the recurrence of infection and reduces complications such as glaucoma. The membranes over the iris are dissected gently by the irrigating cannula and are removed with forceps (Fig. 50.4). Any membrane covering the iris surface should be removed very gently, and every effort should be made to arrest bleeding from the iris surface. Intracameral antibiotics or antifungals can be used whenever required.

Additional procedures

Performing two large peripheral iridectomies can prevent pupillary block. Careful examination of the iris may reveal septic foci that can be excised and sent for microbiology evaluation. Other intraocular procedures are best avoided. Removal of cataracts should be deferred because the lens forms an effective barrier that may prevent the spread of infection into the vitreous. However, removal of the crystalline or intraocular lens may be required in cases with concomitant endophthalmitis. When vitreous involvement is diagnosed, open sky vitrectomy is indicated and the vitreous sample is sent for microbiologic investigation, followed by intravitreal injection of appropriate antibiotics. The anterior chamber is reformed with a viscoelastic substance, and the margin of the recipient bed is trimmed.

Preparation of the donor cornea

Donor cornea preparation is similar to optical PKP. However, in therapeutic keratoplasty donor cornea trephination is performed only after excision of recipient cornea because necrosis of the wound edges may require additional trimming and may alter the size of the graft that is required. It is therefore important to measure the recipient opening with a caliper before trephining donor cornea.

In cases of total keratoplasty or sclerokeratoplasty, freehand dissection of the donor cornea is performed.

Suturing

In therapeutic keratoplasty wound closure should be accomplished using interrupted sutures. Sutures should pass through at least 75% corneal depth and not full thickness to prevent conduit of infectious organisms from the cornea to the anterior chamber. It is not uncommon to use a greater number of sutures and longer bite in recipient cornea than are used in optical keratoplasty in order to get proper wound closure (Fig. 50.5, *A* and *B*). In order to prevent cheesewiring of sutures it is important to maintain a moderate suture tension. At the end of the procedure, it is critical that the integrity of the wound is ensured to prevent the possibility of leakage from a necrotic recipient bed.

Modified surgical techniques under special circumstances are:

1. *Sclerokeratoplasty*: Sclerokeratoplasty with the use of a corneal scleral graft to replace a large area of excised diseased corneal and scleral tissue and restore structural integrity was first described by Castroviejo in 1951. However, these large grafts were associated with a high incidence of rejection and glaucoma. To ameliorate glaucoma Cobo et al proposed the use of sclerocorneal dissection avoiding internal angle structures, coupled with the use of angle-supported mattress sutures to maintain the angle and preserve trabecular meshwork function.[32] The technique as modified by Cobo et al consists of following steps:

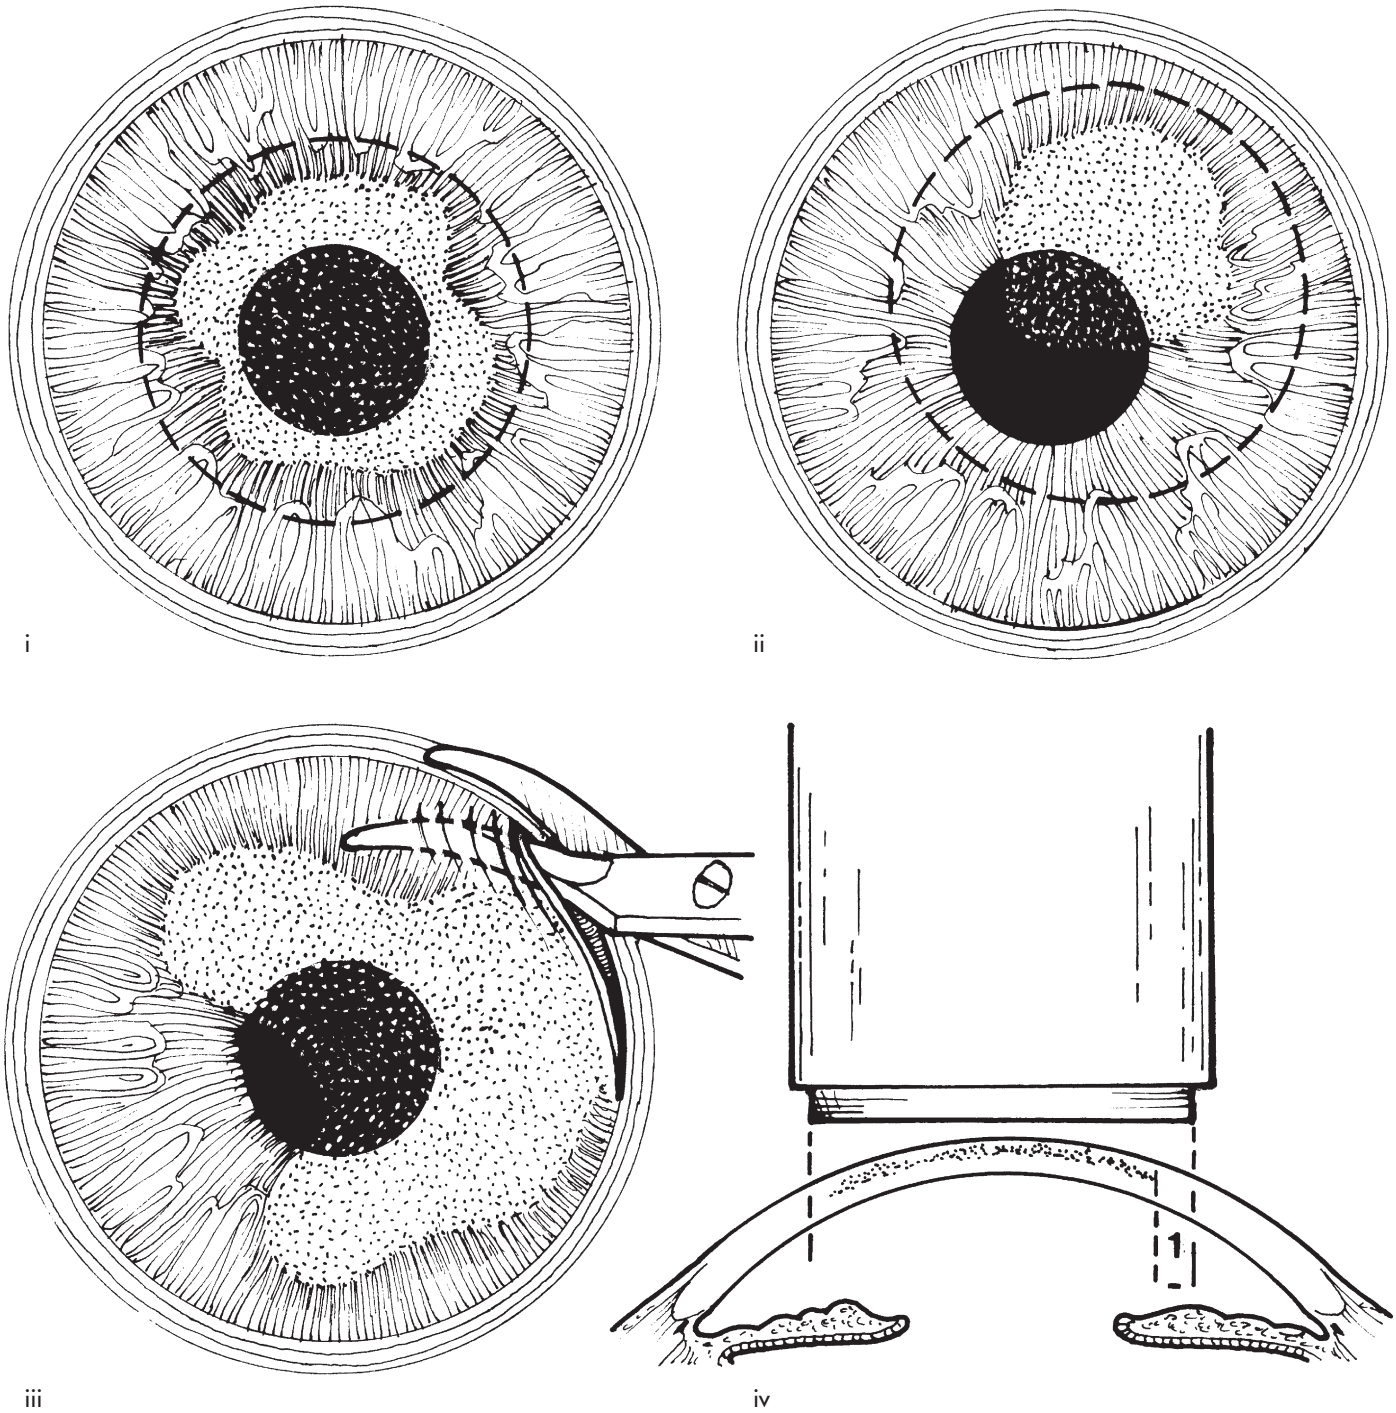

Figure 50.1. Surgical steps of therapeutic penetrating keratoplasty. *A*, Preparation of recipient bed, depending on the extent and location of the infiltrate. (i) Trephination concentric to limbus. (ii) Eccentric trephination. (iii) Freehand dissection. Figure 50.3. Trephination of infiltrated cornea. *A*, Trephine in place; *B*, cornea after partial thickness groove made by trephine. Note that the size of trephine chosen is 1 mm larger than the infiltrate size.

- A 360° peritomy to reflect conjunctiva from limbus followed by cauterization of bleeding vessels.
- A 14 mm or larger trephine is used to outline diseased corneoscleral tissue.
- A 360°, 50% deep lamellar dissection of sclera is carried out up to limbus before entering into anterior chamber.
- Anterior chamber is entered anterior to the trabecular meshwork with a sharp knife, and Vannas scissors are used to complete the internal corneal incision. The diseased corneoscleral tissue is removed. A 1–2 mm lip or remnant of peripheral corneal tissue (posterior stroma and Descemet's membrane) is left for 360°.
- Donor tissue is prepared in a similar manner using either whole globe or a corneoscleral tissue over artificial chamber.
- Four equally spaced 10-0 prolene or nylon double-armed sutures are placed through the internal corneal lip in a mattress fashion, passed through the donor cornea, and tied. The

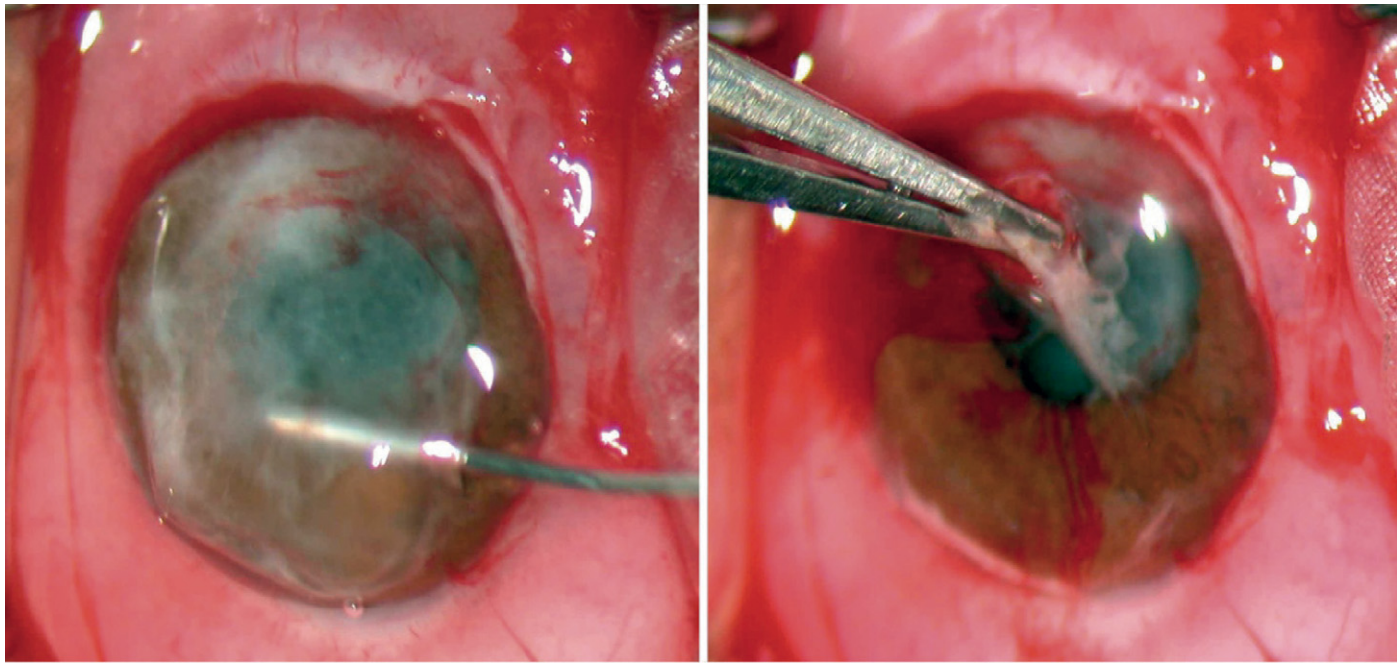

Figure 50.4. Clearing exudates over iris using gentle irrigation and forceps.

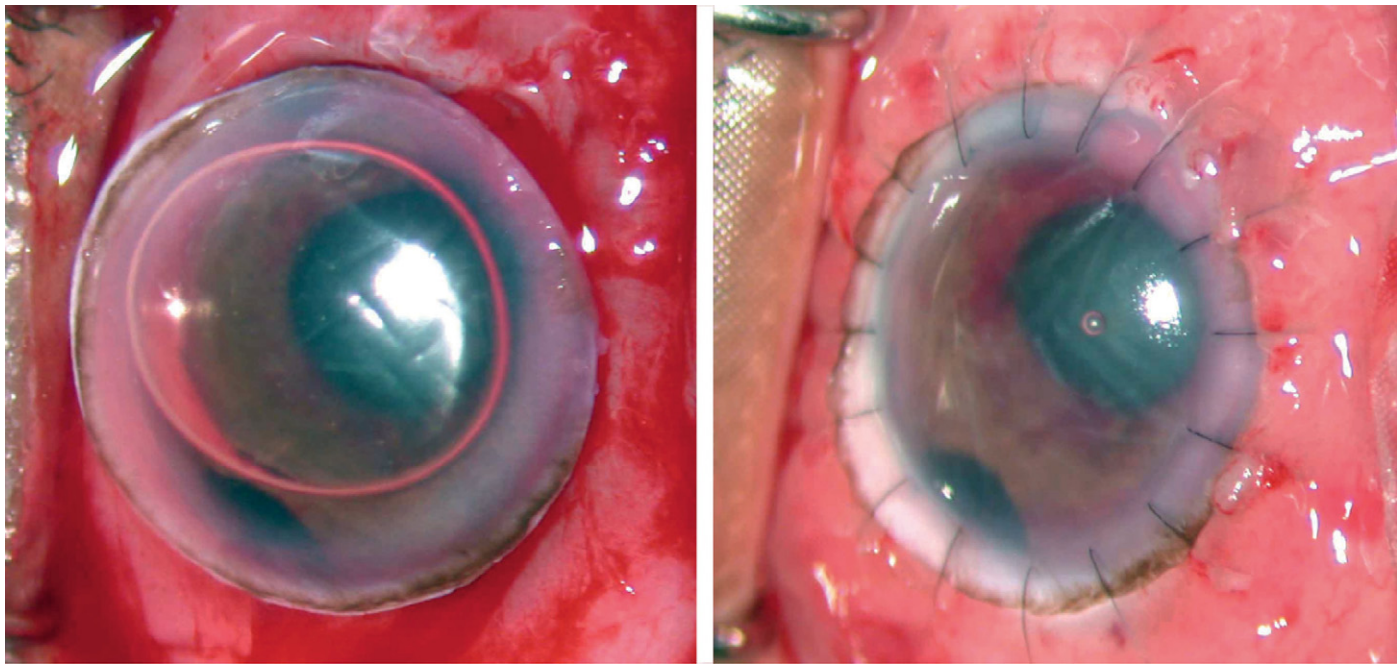

Figure 50.5. Suturing donor corneal button to recipient bed using 10-0 nylon suture. *A*, Donor cornea on recipient bed; *B*, cornea after completion of suturing.

scleral incision is closed using interrupted 10-0 nylon suture and covered with conjunctiva.

2. *Corneal debulking for corneal perforations*: This technique is described by Vajpayee et al.[33]
   - A vacuum trephine of size ranging from 7.5 to 9 mm is used to make the initial cut on the host cornea up to 75% depth.
   - Thereafter, lamellar dissection is performed at the level of posterior stroma using corneal lamellar dissectors such as crescent knife. The dissection is started peripherally and proceeds centripetally, with care taken to prevent perforation at the site of the iris incarceration. On completion of lamellar dissection, the superficial portion of corneal button, including the epithelium and the bulk of stroma, is removed.
   - The anterior chamber is then entered gently with a 26-gauge needle attached to a syringe containing viscoelastic, through the area in which iris is not incarcerated. The tip of the needle is directed tangentially between the deeper cornea lamella and the iris.

Figure 50.6. Surgical steps in therapeutic lamellar keratoplasty. *A*, Preparation of recipient bed. (i) Use a trephine that is at least 1 mm larger than the size of the infiltrate; (ii) make a partial thickness groove with the trephine. *B*, Perform a lamellar dissection so as to remove the infiltrated corneal stroma leaving behind a healthy bed. *C*, Preparation of donor button. (i) A blunt lamellar dissector is introduced through a small incision at limbus and a plane of cleavage is obtained. The dissection is completed by gently moving the spatula from side to side within the cleavage plane. (ii) When dissection is complete a trephine of suitable size is used to cut the graft. *D*, Lamellar donor cornea is sutured to recipient bed using (i) interrupted 10-0′ nylon suture. (ii) Suturing principles are the same as in optical keratoplasty.

- The deeper portion of the cornea and the overlying fibrous membrane are then gently dissected and peeled away from the iris tissue, taking care not to avulse the fragile iris. Viscodissection with 2% methylcellulose and a fine iris spatula release peripheral iris adhesions.

The principle of lamellar separation is based on the fact that the amount of force required to remove an adherent cornea from the underlying iris far exceeds the amount the iris can tolerate, resulting in iris tear and hemorrhage. This is because the total mass of the corneal tissue is greater than that of the adherent iris. With preliminary lamellar separation and excision of the superficial portion of the corneal button, the bulk of corneal tissue is significantly reduced. The integrity of iris tissue is essential to provide protection to the lens during surgery, formation of anterior chamber, facilitating implantation of intraocular lens, and preventing postsurgical photophobia and glare. However, one must keep in mind that the damaged iris is floppy and has a tendency to form adhesions with the graft, resulting in vascularization of the graft and subsequent rejection and failure. Moreover, the corneoiridic adhesions can result in the development of secondary glaucoma, which can further jeopardize the success of the corneal graft.

Lamellar keratoplasty for therapeutic indications

Paufique and Philips in 1950 first demonstrated the value of a tectonic lamellar keratoplasty in preserving the integrity of the globe.[34] Although there are reports of lamellar keratoplasty in active microbial keratitis,[35,36] it is preferable to avoid lamellar surgeries in active microbial keratitis as microorganisms may reside within the stroma well beyond the clinically involved cornea. This has been shown for fungal and *Acanthamoeba* infections of the cornea.[37] However, in cases of sterile or noninfective keratitis, lamellar surgery can be performed. Examples include ulceration occurring in Mooren's ulcer, Wegener's granulomatosis, polyarthritis nodosa, systemic sclerosis, and Stevens–Johnson syndrome.[38–40]

The surgical steps for lamellar keratoplasty are shown in Figure 50.6.

1. *Preparation of recipient cornea*: For lamellar keratoplasty the recipient cornea is dissected first. The extent and depth of dissection are designed to remove all affected corneal tissue while preserving as much healthy host tissue as possible. The limit of the area to be resected is first defined by either a circular trephine or a free hand using a sharp blade or diamond knife. This incision is then deepened to the required depth in one quadrant of the cornea or sclera to permit a lamellar dissector to be introduced parallel to the surface of the cornea (Fig. 50.6, A). Lamellar dissection is then carried out, undermining the edges at the margin of the resected tissue and approaching the thinnest or perforated area last. When the dissection is complete the lamellar flap is carefully grasped with forceps and peeled off (Fig. 50.6, *B*).
2. *Donor button preparation*: For donor button preparation a whole globe is preferred. If using a corneoscleral rim, we can use an artificial chamber to facilitate donor cornea preparation. A small incision of appropriate depth is made near the limbus. The graft material is cut so that thickness of donor material exceeds the depth of the recipient bed. A blunt lamellar dissector is introduced through this incision and a plane of cleavage is obtained. The dissection is completed by gently moving the spatula from side to side within the cleavage plane (Fig. 50.6, *C*). When the dissection is complete, a trephine of suitable size is used to cut the graft. In most circular grafts, a donor corneal button that is 0.5 mm larger than the recipient is used to avoid wound tension.
3. *Suturing*: The graft is then sutured into the lamellar bed with interrupted 10-0 nylon sutures (Fig. 50.6, *D*).

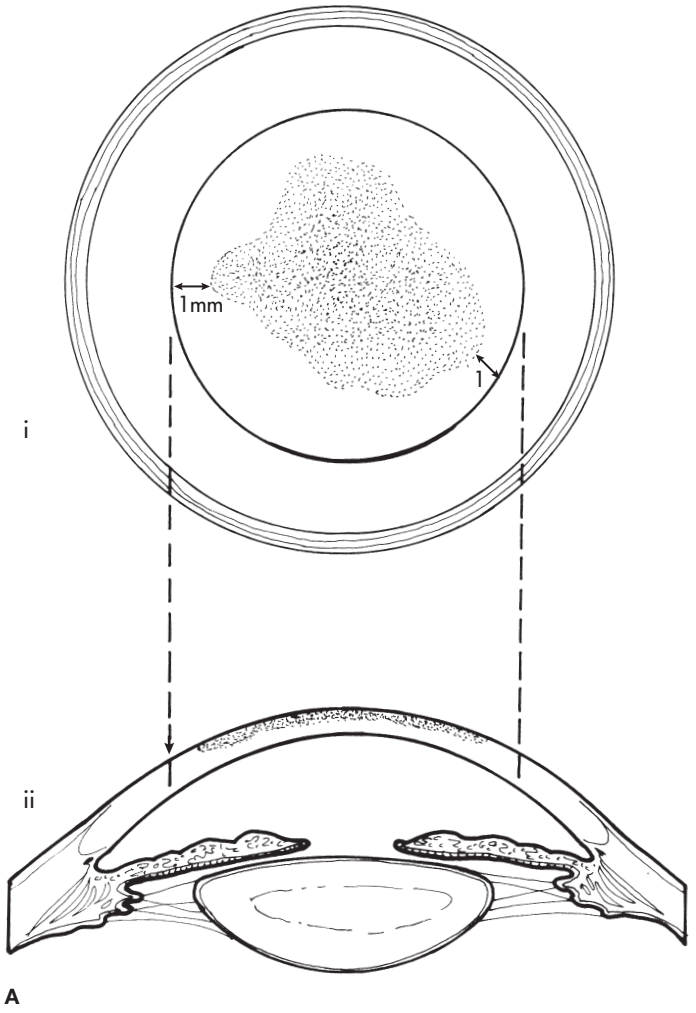
Lamellar keratoplasty offers several advantages over a PKP in eyes with active inflammation.

- A lamellar keratoplasty permits the preservation of the maximum amount of host tissue and adds to the thickness of the cornea. This may reduce the risk of recurrent perforation if the corneal melting process reactivates.
- As the endothelium is not transplanted, visually devastating endothelial immune rejections do not occur, and stromal rejections are rare.
- If perforation has not yet occurred, a lamellar graft is essentially an extraocular procedure, thus avoiding complications of intraocular procedures such as cataract and endophthalmitis.
- Because the quality of the donor endothelial cells is not an issue with lamellar keratoplasty, donor corneas deemed unsuitable for PKP may often be used.
- Lamellar keratoplasty serves as a stop-gap measure to stabilize the eye, giving it a chance to quiet down before a vision-restoring PKP is performed at a later time. Lamellar grafts are thus useful in the treatment of severe corneal melts, not only by providing structural support but also by buying precious time until systemic immunosuppressive medications have a chance to halt collagenolytic corneal breakdown. However, the procedure is technically more difficult because the inflamed stroma is soft and fragile and requires careful handling. Furthermore, the interface scarring will be a problem if the dissection plane is not uniform.

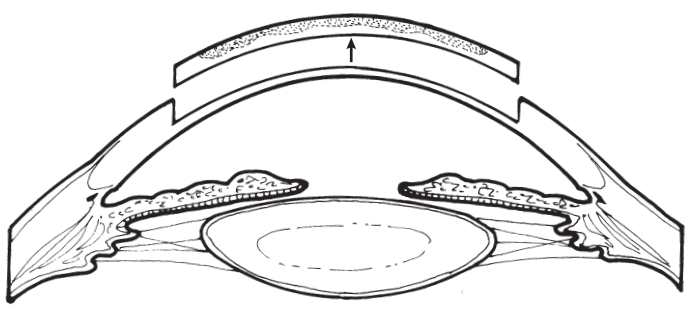
POSTOPERATIVE MANAGEMENT

The postoperative management of therapeutic keratoplasty is as challenging as the surgical procedure. One must pay attention to the following important issues:

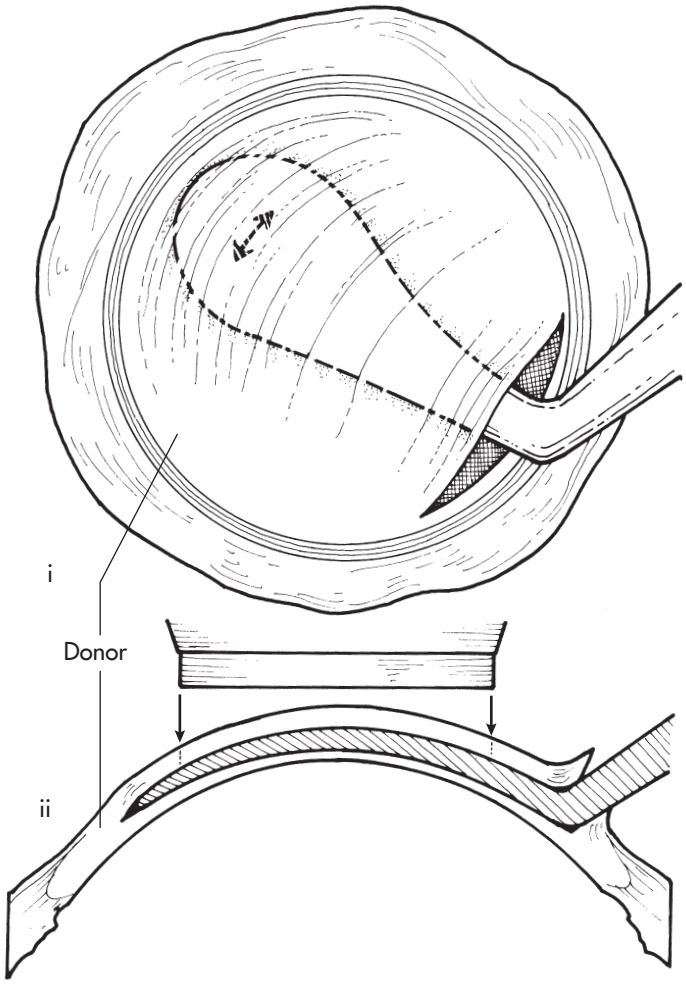
1. *Prevent recurrence of infection*: Continue anti-infective therapy postoperatively in all cases where surgery has been performed for active infectious keratitis. Selection of the most appropriate antimicrobials and the duration of the therapy will depend on the pathogen. In cases where etiological diagnosis could not be made before PKP, histopathology and microbiology evaluation of the excised button can be helpful in guiding



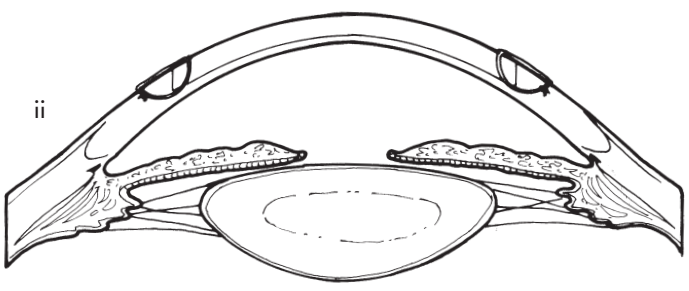
A

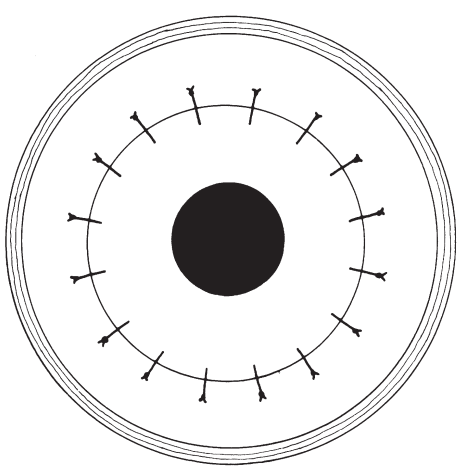


B



C





D

therapy. In general, cases with fungal and *Acanthamoeba* infection require more prolonged therapy to prevent recurrence of infection.

2. *Promote re-epithelization and protect corneal epithelium*: Epithelial integrity is very important for the success of corneal transplantation. This becomes critical in therapeutic keratoplasty because the surgery is performed in an inflamed eye. Unless absolutely essential, avoiding epithelial-toxic agents in the postoperative period is appropriate. Nonpreserved tear substitutes are used to treat epitheliopathy. Paramedian tarsorraphy and punctal plugs can be of great help in managing epitheliopathy in difficult situations.
3. *Control of inflammation*: The use of corticosteroids after therapeutic keratoplasty for infective keratitis is controversial. Since most antibacterial drugs are bactericidal, we believe corticosteroids can safely be used in keratoplasty for bacterial keratitis. In contrast, in fungal and *Acanthamoeba* keratitis corticosteroids must be used with extreme caution. One must start corticosteroids only after being sure of eradication of infection. In noninfective indications, both topical and systemic corticosteroids can be started safely immediately after the surgery; however, one needs to monitor epithelial healing.
4. *Intraocular pressure*: Since therapeutic keratoplasty is being done on an inflamed eye, we may often face aggravation of inflammation with consequent rise in intraocular pressure. Other factors such as large diameter graft and formation of peripheral anterior synechiae may further increase the risk of postoperative glaucoma. It is therefore very important to monitor and control intraocular pressure in the postoperative period.

The general guidelines for postoperative management of keratoplasty for infective keratitis are shown in Box 50.2.

BOX 50.2 GUIDELINES FOR POSTOPERATIVE MANAGEMENT OF CORNEAL TRANSPLANTATION

Bacterial keratitis

Antibiotic with most sensitivity given hourly and topically
Combination therapy or a broad-spectrum antibiotic sensitivity is unknown
Topical corticosteroids—every 1–2 h initially
Cycloplegics
Antiglaucoma medication, if intraocular pressure is elevated

Fungal keratitis

Topical antifungals—every hour initially
Systemic antifungals—oral ketoconazole 200 mg two times daily initially
Topical nonsteroidal anti-inflammatory drugs
Corticosteroids—only under extremely special conditions in which removal of the entire infected area is ensured
Cycloplegics

***Acanthamoeba* keratitis**

Topical amoebicidal drugs—every 1–2 h
Topical corticosteroids given judiciously
Cycloplegics

No organism in corneal scraping

Based on microbiologic and histopathologic report of half corneal button, an appropriate antimicrobial may be used

In conclusion, PKP has achieved a definitive place in the therapeutic armamentarium of infectious keratitis and other noninfective keratitis characterized by progressive thinning and perforation. Although the results are not encouraging in patients with active cases, judicious patient selection, careful planning of surgical technique and appropriate follow-up care can enhance the chances of a successful outcome.

51 Intraoperative complications of penetrating keratoplasty

Jason S. Rothman, Juan Carlos Abad, Ernest W. Kornmehl

Most intraoperative complications of a penetrating keratoplasty (PKP) can be avoided if meticulous attention is given to each step of the procedure and the surgical plan is reviewed prior to surgery.

ANESTHESIA

In the majority of cases, regional anesthesia using either a retrobulbar block or a peribulbar with lid block can be performed safely under monitored anesthesia care.[1] Possible complications of retrobulbar anesthesia include globe perforation, orbital hemorrhage, and optic nerve trauma. In rare cases, inadvertent intradural injection can be associated with seizures, respiratory arrest, and brainstem anesthesia. Inadvertent intravenous injection may result in cardiac arrhythmias. Preoperative assessment identifying eyes with a posterior staphyloma is important, given their increased risk of scleral perforation.[2] The risk of an orbital apex injury is lower with peribulbar anesthesia, although the risk of scleral perforation persists.[3] General anesthesia is indicated for patients with a higher risk for a choroidal hemorrhage, those with a ruptured globe, or other circumstances such as young age or mental impairment.

FIXATION RING

The use of a fixation ring to stabilize the globe is common in pediatric patients (due to their elastic sclera), aphakic eyes, or in eyes rendered aphakic during the operation. The fixation ring helps prevent scleral collapse and facilitates intraocular manipulation and suturing of the donor cornea. The fixation ring may also induce unwanted astigmatism.[4]

Typically, an 18–20 mm Flieringa ring is fixated to the episclera overlying the pars plana with radial sutures passed from the periphery toward the limbus. Although rare, the sclera may be perforated creating a retinal hole. If a perforation is detected, cryotherapy should be applied and the patient observed carefully in the postoperative period. Bleeding in the angle may occur if the ciliary body is perforated, although this usually resolves within a few minutes.

DONOR CORNEA DAMAGE

The donor cornea needs to be handled with extreme care. While some surgeons wait to trephine the donor tissue until after preparing the recipient bed, in our opinion it is preferable to prepare the donor button prior to trephination of the host cornea. Then, if there is a complication during the preparation of the donor tissue, the surgery can be aborted and postponed until another donor cornea is available. The donor tissue should be centered with the endothelial side facing up and then cut in one pressing stroke with the trephine. Unnecessary manipulation increases the risk of endothelial cell loss. A sharp single-use trephine is preferred, as a dull trephine can detach Descemet's membrane (Fig. 51.1). The trephined graft should be kept on the Teflon block and covered with storage media and viscoelastic to help avoid desiccation. We recommend placing a plastic cover over the donor button for further protection while the surgeon is preparing the host corneal bed. The donor corneal button should be carefully brought to the surgical field on a Paton spatula, carried over the cupped hand of the surgeon.

Layering dispersive ophthalmic viscosurgical products over intraocular structures and the endothelial surface of the donor prior to suturing the donor button will help prevent endothelial damage.[5,6] The combination of Viscoat and Healon may be more protective against endothelial cell loss than Healon alone.[7]

COMPLICATIONS DURING TREPHINATION

For most PKP procedures, the donor button is oversized by 0.25 mm to improve coaptation and decrease the risk of glaucoma.[8,9] When the donor cornea is cut endothelial side up with a trephine, it measures approximately 0.25 mm smaller in diameter than a host cornea cut from the epithelial side with the same size trephine.[10] Albeit unusual, the trephines may be accidentally reversed and the smaller trephine used to cut the donor. If the recipient cornea has not been trephined or is partially trephined (without entrance into the anterior chamber), the host cornea can be trephined using a trephine

Figure 51.1. Localized area of corneal edema at the 11 o'clock position resulting from Descemet's membrane detachment.

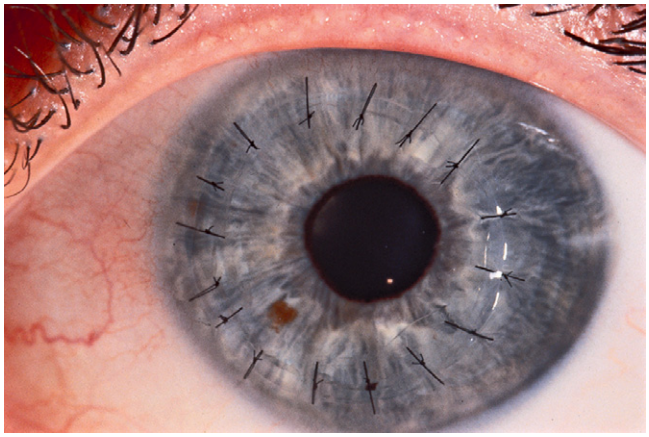

Figure 51.2. Nasally decentered graft in a patient undergoing penetrating keratoplasty for keratoconus.

0.25 mm smaller than the prepared donor button. If the host has already been trephined, the smaller button must be carefully sutured in place. The surgeon must ensure that there is no leak at the end of the procedure and that the hyperopic shift is taken into account by increasing the power of the intraocular lens by 2 or 3 D. The tighter sutures required to secure the smaller graft may deform the trabecular meshwork and increase the risk of postoperative glaucoma.[8] Should this complication occur, the graft can be replaced by an appropriate-sized graft at a later date.

Trephination of the host cornea should be centered on the geometric center of the cornea to ensure that the donor tissue is equidistant from the vascularized limbal tissue. A small adjustment can be made for eccentric pupils. When using a vacuum trephine, care must be taken to prevent the trephine from slipping, which may result in an eccentric graft (Fig. 51.2). If a handheld trephine is used, adequate counter-traction should be applied to the globe or ring to avoid eye rotation during trephination. Eccentric trephination of the host cornea may result in increased postoperative astigmatism.[11,12] If the surgeon recognizes the eccentric placement of the trephine prior to entering the anterior chamber, a larger trephine with proper centration may be used. If the host cornea is trephined with a larger-size trephine than originally planned, the size of the previously prepared donor button needs to be taken into account as previously described.

Occasionally, the anterior chamber is entered in a very asymmetric fashion during trephination, perforating the cornea in one quadrant and barely scratching the surface in the opposite quadrant. This is caused by failure to align the trephine perpendicular to the recipient corneal plane. The dissection must then be completed using scissors with no or minimal grooving of the host bed. This can lead to poor wound apposition and irregular astigmatism.

If the patient's cornea is highly vascularized, there may be bleeding during epithelial debridement or trephination. Measures to counteract this include partial trephination with delayed entry into the anterior chamber to allow time for clotting, using topical neosynepherine to induce vasoconstriction, and preoperative photothrombotic occlusion of the corneal vessels using corneal argon laser photocoagulation (CALT).[13,14] It is preferable to use the interrupted suture technique in vascularized corneas; this allows for selective postoperative suture removal from one region of the graft without altering wound integrity in other areas.

Descemet's membrane can easily be stripped from the overlying stroma of the host cornea during blade or scissors entry into the anterior chamber (Fig. 51.3, *A–C*) and inadvertently left behind.[15,16] This typically occurs if the anterior chamber is not entered with the trephine and the scissors remain above Descemet's membrane during excision of the corneal button. The iris should be thoroughly inspected with forceps or a cellulose sponge to ensure that Descemet's membrane was removed. This is more common with edematous corneas or corneas with a thickened Descemet's membrane. After transplantation, this may result in a pseudoanterior chamber, with aqueous between the retained Descemet's membrane and the donor cornea (Fig. 51.4). If there is apposition of the retained Descemet's membrane to the graft endothelium, the graft will likely fail. A retained Descemet's membrane may become opacified over time and require removal. A neodymium:YAG laser may be used to create a central opening in the membrane.[16]

IRIS DAMAGE

The iris may be damaged during trephination, during entry of the super-sharp blade into the anterior chamber, or during excision of the corneal button with scissors. This is more common in thin or perforated corneas. Some surgeons advocate making a paracentesis and injecting viscoelastic into the anterior chamber prior to trephination in order to protect the intraocular structures.[17,18] To reduce the risk of iris trauma in the setting of a ruptured globe, the anterior chamber should be reformed with viscoelastic and the corneal wound sealed with cyanoacrylate glue prior to trephination.[19,20] Some surgeons have had success using tissue adhesive to glue a custom polymethylmethacrylate hard contact lens over a corneal perforation to facilitate trephination.[21]

The authors prefer to perform a partial trephination, enter the anterior chamber focally with a blade, fill the chamber with viscoelastic, and remove the corneal button with scissors. When completing the dissection of the recipient cornea with scissors, it is preferable to maintain slight upward pressure to minimize the risk of iris and/or lens damage. Some surgeons prefer a slightly beveled cut, creating a posterior wound ledge, which helps to facilitate a watertight closure. Other surgeons cut the host cornea perpendicular to the corneal surface to minimize postoperative astigmatism.

Should inadvertent damage to the iris occur, this should be repaired with a 10-0 polypropylene or nylon suture. Iris bleeding can be controlled with viscoelastic, fine-tipped underwater diathermy, topical application of 1:10000 epinephrine or 1:100 thrombin on a soaked cellulose sponge.

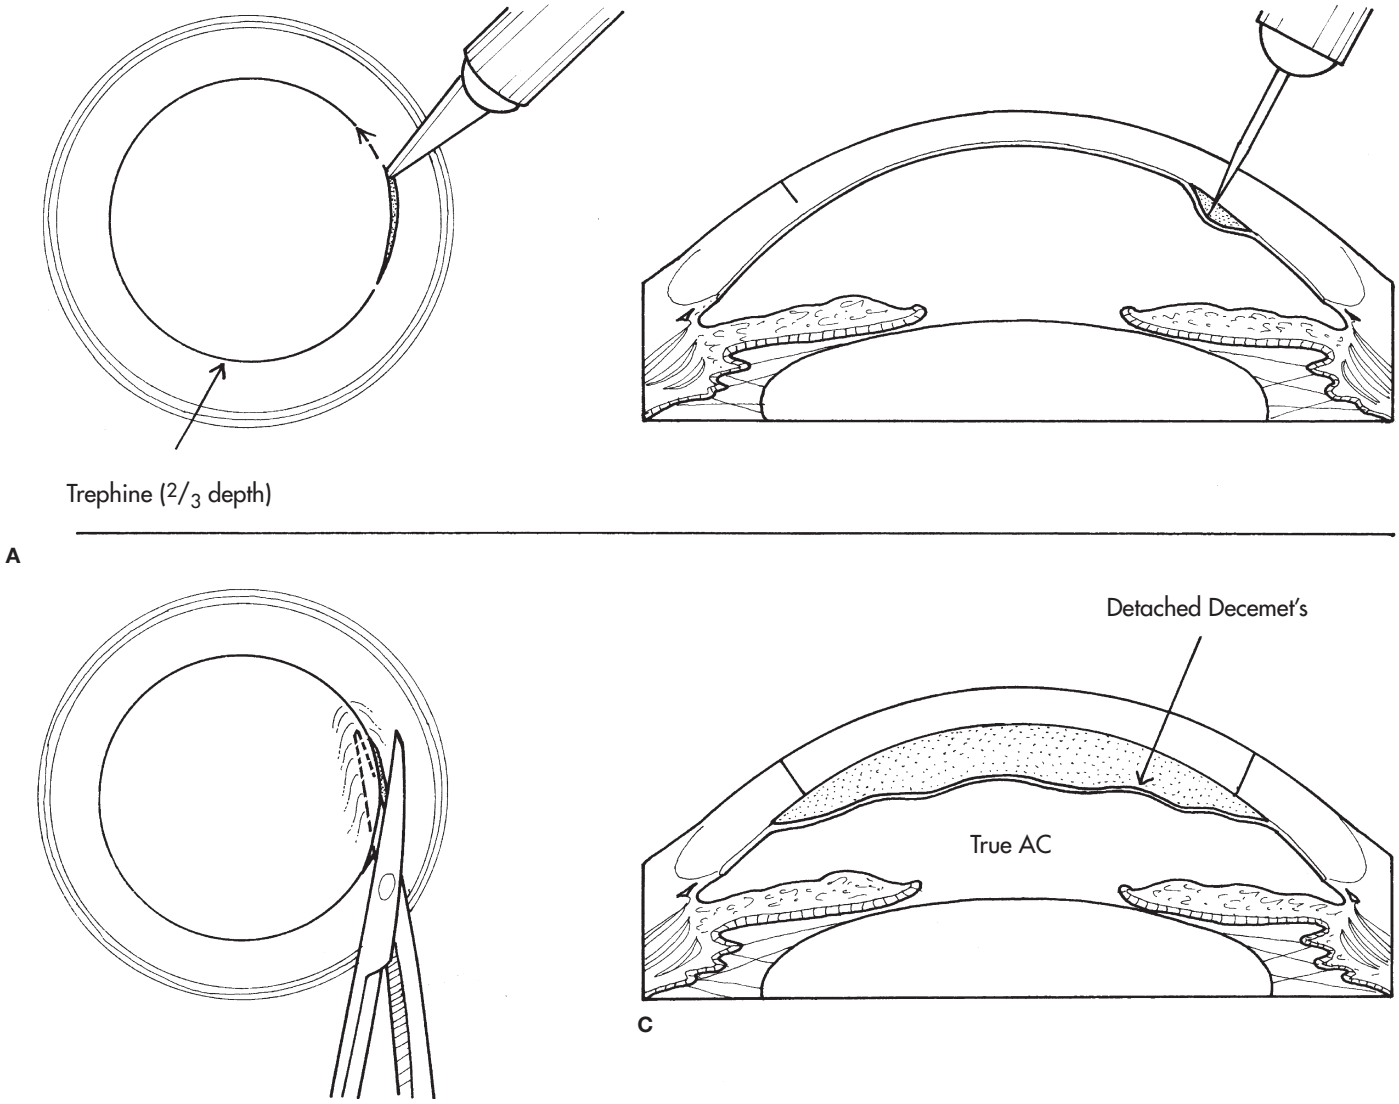

Figure 51.3. *A*, After trephination, a sharp blade incompletely enters the anterior chamber. *B*, A false anterior chamber is created. *C*, Scissors insertion further enlarges the chamber, resulting in retained Descemet's membrane.

LENS DAMAGE

Corneal trephination in a phakic eye is best performed with the pupil constricted prior to surgery with pilocarpine. If the anterior lens capsule is perforated during trephination, a cataract will develop, requiring an extracapsular cataract extraction. Inadvertent anterior capsular damage may also occur with the super-sharp blade or scissors. It may be prudent to take axial length measurements before a phakic PKP. If this complication occurs, the power of the intraocular lens can be estimated. Other alternatives include using a standard +21.00 D lens or to defer lens implantation to a later date. If the lens is not removed, the flocculent cortical material will likely result in chronic inflammation and elevated intraocular pressure.

INTRAOCULAR LENS EXPLANTATION

If a closed-loop anterior chamber intraocular lens (ACIOL) is present at the time of surgery, it should be removed and be replaced. If it is not removed, the graft will likely fail.[22,23] The IOL haptics should be cut from the optic and carefully threaded out from their adhesions in the angle to avoid bleeding or disinsertion of the iris.[24] If an iridodialysis occurs during removal of the haptics, it must be repaired. Haptics that are embedded in the angle and unable to be slid free from their attachments may be trimmed and left in place. Options for lens exchange include placement of a sulcus-fixated posterior chamber IOL, a scleral suture-fixed posterior chamber IOL, an iris-fixated posterior chamber IOL, a flexible open-loop anterior chamber IOL, or an iris-claw lens.[25–27] If an ACIOL is implanted, the haptics of the new IOL could induce further peripheral anterior synechiae (PAS), resulting in elevated intraocular pressure. If there is a shallow anterior chamber or insufficient iris tissue, a posterior chamber IOL would be the best choice.[28]

POSTITIVE VITREOUS PRESSURE

When the cornea is removed, the mechanical barrier to vitreous expansion is lost. If the vitreous swells, it may cause the anterior

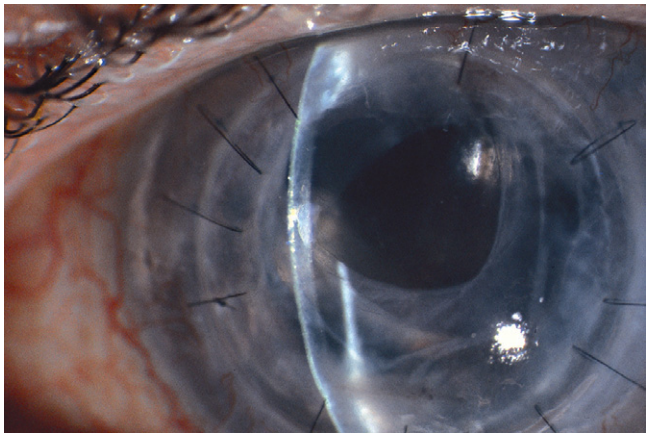

Figure 51.4. Retained ring of the host's Descemet's membrane at the graft periphery. The central cornea remains clear.

chamber to shallow with protrusion of the lens. Increased posterior pressure will significantly increase the risk of complications during a combined PKP and cataract surgery. The risk of positive vitreous pressure can be reduced by mechanical, medical, and surgical methods to decrease intraocular pressure.[29] Preoperative preparation to reduce intraocular pressure in these cases cannot be overemphasized.

Preoperative continuous pressure on the globe can mechanically reduce vitreous pressure. This may be carried out manually,[29,30] with a Honan balloon,[31] or with a super-pinky. An additional measure is to position the patient in reverse Trendelenburg, decreasing the orbital venous pressure. Medically, vitreous pressure can be reduced with a diuretic such as mannitol. Mannitol should be administered intravenously over 1–2 min while prepping the patient. Its greatest hyperosmotic effect will be about 10–15 min after administration, roughly the time when the eye will be open. Mannitol is dosed according to a patient's weight and medical status; caution needs to be exercised in patients with congestive heart failure. For a combined PKP and cataract extraction, we advocate using a Honan balloon for 20 min at 30 mmHg before starting surgery and intravenous mannitol administered just prior to draping the patient.

If positive vitreous pressure is encountered intraoperatively, without evidence of a suprachoroidal hemorrhage or effusion, it is commonly due to pressure transmitted from the lid speculum. This is very common with a wire lid speculum; a Schott lid speculum or Jaffe lid retractors do not exert as much pressure on the eye. Lifting or repositioning the speculum, or providing anterior traction on the globe with the fixating sutures of the scleral support ring should be performed first. If the vitreous face and posterior capsule are intact, some surgeons advocate performing a limited pars plana vitrectomy with an automated vitrector. Others recommend performing a pars plana vitreous aspiration with an 18-gauge needle attached to a 3 mL syringe to locate and tap a vitreous lake,[32] although with an open globe this is risky and may generate more posterior pressure.

CATARACT EXTRACTION

When a patient requires cataract surgery and a PKP, many surgeons prefer to perform these together as a triple procedure. If the cataract is removed using the open sky technique, reducing posterior pressure preoperatively is critical. During capsulorrhexis, positive vitreous pressure can make the advancing flap tear toward the lens equator. Pressing on the center of the crystalline lens with a cellulose sponge may facilitate the maneuver. The lack of a closed system and anterior bowing of the posterior capsule will hamper aspiration of cortical material. If the posterior capsule is torn and the vitreous face is violated, an anterior vitrectomy should be performed using an automated vitrectomy device. A guillotine-type cutter is preferred, as this will minimize vitreous traction. The surgeon should ensure that there is no vitreous in the anterior chamber or coming through the capsular tear.

As described above, when capsular support is inadequate for the placement of a posterior chamber IOL into the capsular bag or within the ciliary sulcus, an open-loop ACIOL, scleral suture-fixed posterior chamber IOL, or iris-sutured posterior chamber IOL are appropriate alternatives. There is debate in the literature about which alternative has the best outcome.[26,33–36]

SUPRACHOROIDAL HEMORRHAGE

A suprachoroidal hemorrhage has the potential to be the most visually devastating intraoperative complication during a PKP. The surgeon must always be aware of this possible complication and be ready to treat it immediately. Factors that predispose a patient to have a suprachoroidal hemorrhage include hypertension, atherosclerosis, inflammation with vascular congestion, intraoperative tachycardia, and long-standing glaucoma.[37] Valsalva maneuvers during surgery may also lead to an expulsive hemorrhage. Eyes undergoing a PKP are at an increased risk of an expulsive hemorrhage due to sudden globe decompression with an 'open sky' communication with the atmosphere (Fig. 51.5, *A–C*). During a suprachoroidal hemorrhage, the intraocular contents may extrude without resistance.[38]

If a suprachoroidal hemorrhage is recognized, the surgeon should be proactive and the open sky wound be tamponaded as quickly as possible with a finger or, if available, a Cobo temporary keratoprosthesis.[38–40] At the same time, a posterior sclerotomy into the suprachoroidal space (5–15 mm from the limbus) needs to be performed to drain the blood and decrease the forward pressure on the vitreous, retina, and lens. Several sclerotomies may be needed in four quadrants, usually beginning temporally, unless the clinical situation dictates otherwise. They need to be large enough for the expression of blood and clots, and should be left open to drain blood into the subconjunctival space. The prognosis depends on the status of the remaining intraocular contents. If anatomical reattachment is achieved, the potential visual acuity may be limited due to the disorganization of the blood supply of the outer retina. Immediate recognition and prompt treatment of a suprachoroidal hemorrhage are critical in managing this devastating complication.

SUTURING

When a running suture is used, the suture may break. Given this possibility, some surgeons advocate using a double-armed suture which, although technically more difficult, allows suturing in a direction opposite of the first when needed. Another option is to splice a new nylon suture to the broken suture and continue with the new needle. If the suture breaks near the needle, there may be adequate length allowing the spliced knot to be pulled

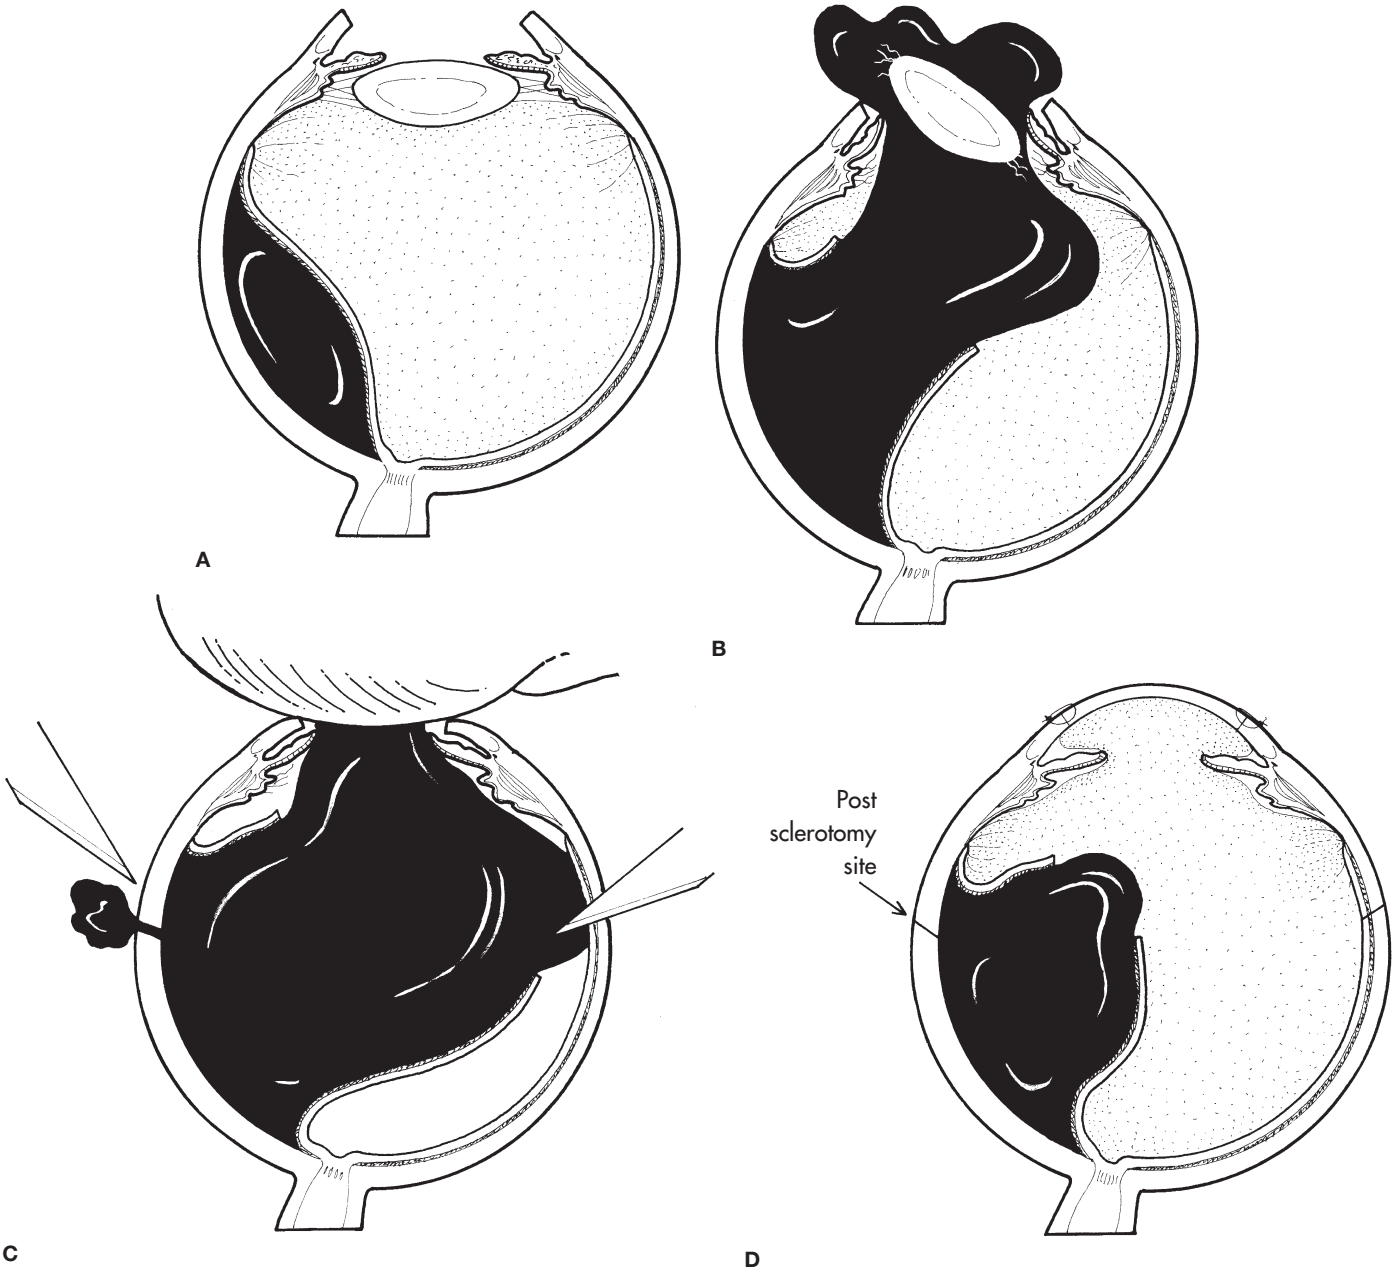

Figure 51.5. *A*, Choroidal detachments developing during keratoplasty often are seen through an operating microscope. *B*, Expulsive choroidal hemorrhage occurring after removal of diseased cornea. *C*, Closure of wound with fingertip and posterior sclerotomy for expulsive choroidal hemorrhage. *D*, Cornea sutured in place, normal anterior segment architecture restored, and posterior sclerotomy left open.

through, resulting in one rather than two knots. If two knots are required, the first spliced knot should be buried. The suture should then be tightened and adjusted in two sections.

The wound must be water tight and checked after reforming the anterior chamber with balanced salt solution. If a leak is noted (Fig. 51.6, *A–C*) because of a loose running suture, the knot should be exteriorized, slack taken out of the suture, and the suture cut and retied. Additional interrupted sutures may also be placed if necessary.

Most complications during keratoplasty can be prevented with meticulous attention to detail. If a technical error occurs, it can usually be corrected at the time of the initial procedure.

52 Penetrating corneal transplantation: early postoperative management

Jeremy E. Levenson

While many surgeons are comfortable with the technical aspects of performing corneal transplants, it is the appropriateness of the care provided in the postoperative period that determines the outcome of corneal transplant surgery.[1] Identifying the minor and the major complications that can and often do occur in the postoperative period can make the difference between surgical success or failure.

POSTOPERATIVE CARE

There are probably as many postoperative care regimens as there are surgeons performing corneal transplants. Whatever the specific approach taken, the following factors must be monitored in the early postoperative period: signs of infection, evidence of a wound leak, thickness of the graft, status of the corneal epithelium, depth of the anterior chamber, intraocular pressure, degree of inflammation, presence of synechiae, and pupillary block.

SCHEDULE OF EXAMINATIONS

Patients are examined on the first postoperative day, an opportunity to discover any major surgical complications. During this examination, the patient should be questioned about the presence and degree of any pain experienced. The visual acuity should be determined, a careful slit-lamp examination undertaken, the intraocular pressure measured and, if possible, indirect fundoscopy performed. Based on the findings at this examination, the frequency of the visits for the next 1 or 2 weeks is decided. Even in an entirely uncomplicated case, the corneal epithelium will probably not be completely healed.[2] Because establishing complete corneal epithelialization is a major step in securing a clear corneal graft (as will be discussed in detail later), the patient should be seen frequently until this condition has been achieved. As soon as a stable state has been reached, a reasonable schedule of postoperative visits includes seeing the patient every 1 or 2 weeks for the first month and then every 2–4 weeks for the next 3 months. Because complications can develop between visits and their early treatment can be critical to successful surgery, patients are instructed to promptly report any change in the status of their operated eye, such as increased pain, redness, or decreased vision.

PATCHING

The surgical dressing is removed on the first postoperative visit. Many surgeons then continue full-time patching until the epithelial layer on the corneal transplant has completely healed. For most cases, this takes 1–3 days.[2] Although there is a trend toward not patching traumatic corneal abrasions, and at least one study found that patching does not speed healing,[1,3] the immediate postoperative transplant is anesthetic, and the protection of mild but effective pressure patching may be beneficial. The eye is protected in the longer term with eyewear during the day and a shield at night[4] for 2–3 months.

GRAFT THICKNESS

Most corneal grafts show some edema in the immediate postoperative period. This edema is manifested by increased corneal thickness with pachymetry readings exceeding 0.6 mm.[5] The amount of swelling is affected by the age of the donor, the death-to-preservation time, the amount of time preserved, the type of storage medium, the amount of surgical trauma, the nature of the condition requiring transplantation, the status of the endothelium and epithelium, and the intraocular pressure. The edema is caused by endothelial 'pump' dysfunction resulting from a combination of metabolic insult and actual endothelial cell loss. Epithelial edema may not be present because of the absence or thinning of the epithelial layer. Classically, corneal transplants in phakic eyes tend to have more endothelial cell loss than transplants in aphakic eyes, presumably because of the 'washboarding' effect of rubbing the donor button against the lens–iris diaphragm during surgery in the former.[5] The use of viscoelastic agents during surgery has removed this difference.[6] In the uncomplicated case, a gradual thinning of the graft should be anticipated, with most of the folds in Descemet's membrane gone by 2–3 weeks after surgery. Peripheral, circumferential folds may persist near the wound margin because of the compression of tissue by the corneal sutures and the use of an oversized donor. These folds tend to disappear with time or with removal of the corneal sutures. If there is normal endothelium on the patient's own cornea, longer-term thinning of a thicker than normal graft may occur

because of the gradual migration of endothelium from the recipient bed onto the donor graft.

MEDICATIONS

Routinely, corneal transplant patients receive topical steroid and antibiotic eye drops. On the evening of surgery and the following morning, if a significant amount of viscoelastic has been left in the eye or if there is a concern about the possibility of glaucoma, an oral carbonic anhydrase inhibitor can be administered, assuming no medical contraindications.[7] Starting on the first or second postoperative day, a topical steroid such as prednisolone acetate 1% or the equivalent can be prescribed four times per day and a topical antibiotic such as tobramycin 0.3% or fluoroquinolone two to four times per day. Combination steroid and antibiotic drops are popular but have the disadvantage of inflexibility because it is often necessary to use a steroid drop much more frequently than an antibiotic drop. In addition, many of these combination drops include neomycin, which can prove to be especially toxic to the unstable graft epithelium.[8] Some surgeons prefer to administer these drugs in ointment form. In the routine, uncomplicated case, the steroid drops are tapered after the postoperative inflammation is controlled, usually in 3–4 weeks. Typically in phakic grafts, by 2–3 months after surgery the steroid drops can be discontinued. In aphakic or pseudophakic eyes, where the complication of cataract formation is not a concern and intraocular pressure remains controlled, many surgeons continue a drop or two of topical steroid indefinitely in hopes of decreasing the long-term chance of graft rejection (Fig. 52.1). Use of steroids after surgery may vary greatly from case to case. In addition to the usual steroid side effects of cataract formation and secondary glaucoma, their effect on decreasing wound healing must be kept in mind.[9,10] Obtaining a wound of adequate tensile strength, especially in the elderly, is already a concern in corneal transplantation, and the intensive and prolonged use of steroids can exacerbate this problem. The steroidal effect on depressing local immunity can lead to opportunistic infection with bacteria and fungi, which are known to correlate with the development of crystalline keratopathy.[11] Still, until a good prospective study determines its relative value, low-dose, long-term steroid use in nonphakic patients is probably warranted. The use of topical antibiotics can be discontinued once the epithelial layer completely covers the cornea, typically in 3–4 weeks.

Many patients require frequent artificial tears to help stabilize and protect the delicate epithelium on the surface of the graft. If used more than four times per day, nonpreserved tears should be prescribed. If ointments are used, these too should be nonpreserved.

The use of topical cycloplegics is usually not routinely necessary. On occasion, a short-acting drug such as cyclogyl 1% or homatropine 5% can be used. Long-acting cycloplegics, such as scopalamine or atropine, limit the ability to manipulate the pupil pharmacologically, which can be necessary in the postoperative period to break synechiae. In addition, they have been implicated in the development of fixed, dilated pupils after surgery in eyes that have undergone corneal transplantation for keratoconus.[12] However, this cause has been seriously called into question by more recent studies,[13] and it seems more likely that the fixed, dilated pupil seen rarely after keratoplasty in keratoconus is the result of iris ischemia developing from posterior pressure.

Although not universally accepted,[14] the use of an antiviral is recommended for a patient with a history of herpes simplex keratitis (Fig. 52.2). Most surgeons use a drop of trifluorothymidine four or five times per day while steroids are being applied.[15] It must be kept in mind, however, that these agents are metabolic inhibitors and can only be effective if they are continuously present in adequate concentration. The studies that have been published concerning the prevention of recurrent herpes infections in patients using topical steroids used these agents in full dosage.[16] However, in full dosage these agents can be very toxic to the epithelium,[17,18] and, because they empirically seem to be effective in lower dosage, this trend will probably continue until studies to the contrary are presented. As soon as the steroid dosage has been decreased to one drop daily, the antiviral may be stopped. To avoid the toxicity of topical antivirals, oral acyclovir has been shown to be effective as prophylaxis against recurrent herpes simplex keratitis in patients receiving topical steroids after surgery.[19] Starting with an initial dose of 800–1000 mg in divided dosage, acyclovir can be gradually tapered over 12 months or more. Presumably, the newer oral antiviral agents, famcyclovir and valacyclovir, would be at least as effective.

ACTIVITY

Modern corneal transplant techniques have allowed early ambulation of the patient beginning on the day of surgery primarily by

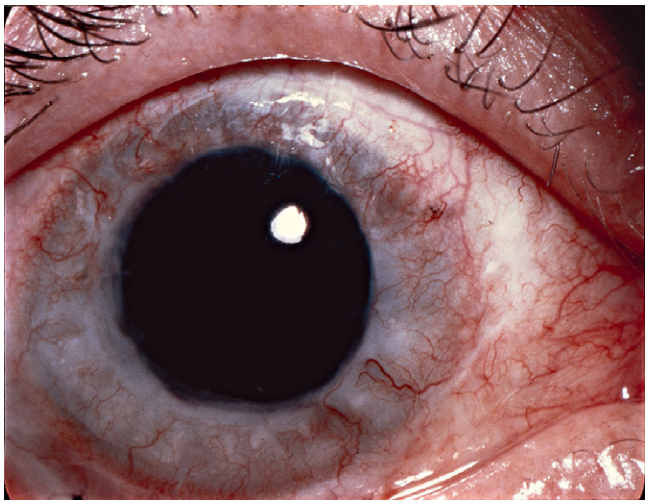

Figure 52.1. When a graft is placed in a vascularized bed, steroids must be continued indefinitely to prevent rejection.

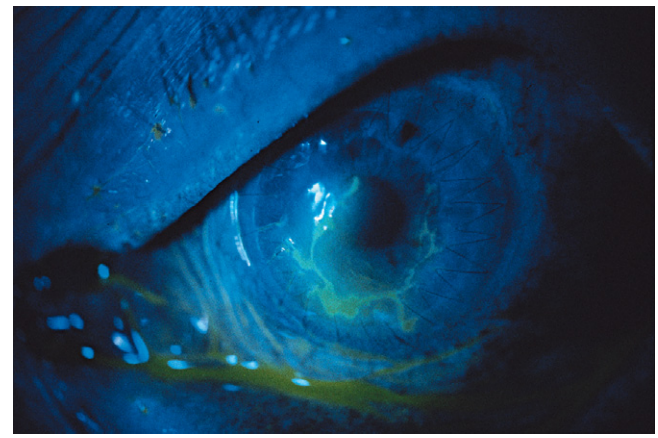

Figure 52.2. Recurrent herpes dendritic keratitis in a graft. This patient was given steroids without antiviral coverage.

producing wounds of sufficient integrity. Patients may resume taking care of their personal needs as soon as they have recovered from the effects of anesthesia. They should be reassured that the sutures holding their wound are sufficiently strong to permit them to return to the activities of normal living. Most wounds can withstand the stress of coughing, sneezing, and usually even vomiting. At the same time, patients must avoid a direct blow to the eye. Eye protection should be worn at all times, even when sitting at home. Protective eyewear usually consists of a sturdy pair of glasses during the day and a taped-on shield at night. This practice should be continued for the first 2–3 months after surgery. Patients should be instructed to avoid situations where there is a risk of trauma to the eye, such as large crowds, contact or racquet sports, skiing, and so forth. Heavy lifting or straining that could lead to increased intraocular pressure through the Valsalva maneuver or eyelid squeezing should be avoided for the first 2–3 months.

Patients should be made aware of the need to protect their eyes from potential sources of infection during the initial weeks after surgery. Wearing an eye patch until the epithelium is healed is part of this protection. Patients can have their hair washed, but this should be done with the head back so that the soapy water does not enter the eye. Bathing is permitted, but again dirty water should be kept out of the eye. As soon as the surface of the graft has fully epithelialized, usually by 2–3 weeks after surgery, these restrictions can be eased. During this same period, patients should be discouraged from working on their hands and knees in their garden and from swimming.

The amount of time a patient is away from work must be tailored to his or her individual situation and is determined in large part by the patient's type of work and the level of vision in the unoperated eye. In practice, most patients who are not engaged in heavy manual labor or do not work in a dusty, contaminated environment and who have adequate vision in their opposite eye can return to work as soon as their level of comfort permits, usually 1 week or less. For those who perform manual labor, 6–8 weeks of leave may be required. For those requiring the vision of the operative eye to be able to work, a number of months may be needed.

COMPLICATIONS IN THE EARLY POSTOPERATIVE PERIOD

Complications in the period after corneal transplantation can vary from the minor to the true ophthalmic disaster, resulting in the loss of the eye. The best chance for a successful outcome occurs with early intervention, so close and meticulous follow-up of the corneal transplant patient is essential. Recognition and treatment of the following complications, not necessarily in the order of frequency or potential severity, are discussed in this section: endophthalmitis and infectious keratitis, wound leak, epithelial defects, filamentary keratitis, synechia formation, hyphema, excessive iritis, pupillary block, glaucoma, vascularization, retained Descemet's membrane, and primary graft failure.

ENDOPHTHALMITIS AND INFECTIOUS KERATITIS

The risk of infection is inherent in the nature of corneal transplant surgery. Certain risk factors can, however, significantly increase the possibility of postoperative infection (Box 52.1).

Endophthalmitis can occur both immediately after and late in the course after corneal transplantation. The incidence, which has been reported to be between 0.1%[20] and 2%,[21] is low and similar to that of cataract surgery.[22] This is surprising because cultures taken from donor eyes before processing have been reported to be positive for contamination at a rate of between 12.4%[20] and 100%.[23] A wide variety of Gram-positive and Gram-negative bacteria and fungi have been isolated from cases of postkeratoplasty endophthalmitis.

Patients with endophthalmitis may report intense pain, lid swelling, marked conjunctival hyperemia, and hypopyon with even more corneal edema and clouding than typically found in the patient who has undergone cataract surgery.[22] At other times, the onset of endophthalmitis can be more insidious.[21]

Although no series has been reported to date in corneal transplantation, the laboratory diagnosis and treatment of endophthalmitis should probably follow the recommendations of the Endophthalmitis Vitrectomy Study Group,[24] with early vitreous aspiration followed by intravitreal antibiotics and possibly vitrectomy in nonresponding patients. Because the donor graft can be a potential source of infection,[25] all donor cornea-scleral rims should be cultured at the time of surgery. Information obtained from these cultures may provide a head start in choosing appropriate therapy should an infection develop after surgery. The prognosis for endophthalmitis after corneal transplantation has been very poor despite treatment.[21]

Given the high incidence of positive cultures from donor rims and the low incidence of actual postoperative infection, the surgeon not infrequently faces the situation 1 or 2 days after surgery of being informed that the rim culture is growing out a contaminant (most often *Staphylococcus epidermidis*, but occasionally a fungus). Having already seen the patient and believing that the postoperative course is uncomplicated, the surgeon is unsure how to proceed. Because most positive rim cultures do not translate into active infection,[22] in most cases, nothing more than continued observation is required.

BOX 52.1 RISK FACTORS FOR POSTOPERATIVE INFECTION PREOPERATIVE CONDITIONS

Keratitis sicca	Graft failure
Blepharitis	Previous herpetic keratitis
Acne rosacea	Ocular adnexa and lid abnormalities
Cicatricial conjunctival disease (ocular pemphigoid, alkali burns, and Stevens–Johnson syndrome)	Pre-existing corneal or external infection
	Systemic diseases (atopic disease, systemic immunosuppression, diabetes, rheumatoid disease)
Trichiasis	
Trachoma	
Intraoperative factors	
Contaminated instruments or solutions	Extensive tissue manipulation
Contaminated donor tissue or storage media	Aphakia
Postoperative factors	
Epithelial defects or severe punctate keratopathy	Wound dehiscence
Exposed or loose sutures	Corticosteroid use
Soft contact lens use

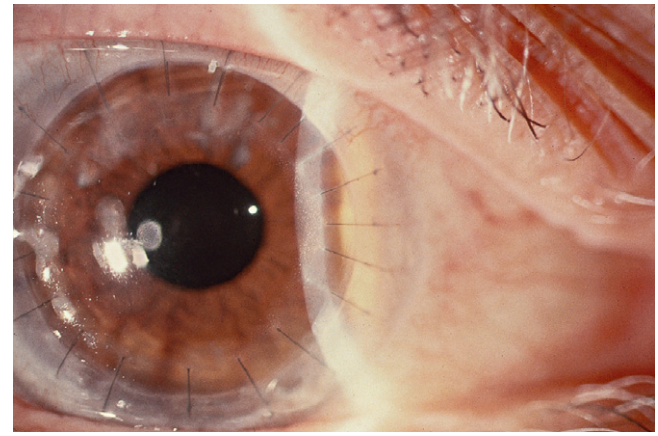

Figure 52.5. Minute white dots, sometimes referred to as Kaye dots, frequently develop in the epithelium in the base of the furrow near the wound margin. They are best seen here in the slit-beam light, between the 2 and 4 o'clock positions.

Infectious keratitis has been reported to develop after corneal transplantation with an incidence between 1.8%[26] and 4.9%[27] in the USA. Preoperative conditions that can lead to corneal infections are listed in Box 52.1.

Most agents that cause postkeratoplasty infectious keratitis are Gram-positive bacteria, but the full spectrum of agents associated with corneal ulceration (Fig. 52.3) are described in Box 52.2.[27–29] The prognosis for corneal graft infections that have progressed beyond a localized stitch abscess is very guarded.[27,30] Scarring or the associated irregular astigmatism even when the scarring is not directly in the visual axis can dramatically limit the final vision. Corneal perforation, wound dehiscence, and endophthalmitis occur more frequently than usually seen with corneal infections in otherwise normal corneas (Fig. 52.4).[28] Regrafting, either on an emergent or on an elective basis, is a common outcome.[31] Whether and how to modify steroid use in the setting of infection can be a quandary. Steroids may help prevent graft rejection and preserve graft clarity, or at least prevent or limit vascularization of the graft bed, allowing a better prognosis for a regraft. On the other hand, the immunosuppression may potentiate infection. Most treating physicians compromise by decreasing the steroid dosage but not stopping it, at least initially.

Other white lesions can develop in the graft after surgery, which are noninfectious in origin. The most common are the myriad of tiny, discrete, white, nonstaining dots that frequently appear in the epithelium in the furrow at the base of the ridge created by the corneal sutures (Fig. 52.5). These dots have been shown to be composed of degenerating epithelial cells.[32] These appear several weeks after surgery and usually persist until the sutures are removed or until the cornea assumes a more normal contour.

Of greater significance are the white to grey-white infiltrates that occasionally appear along the corneal sutures early in the postoperative course. They seem to be an immune response to the suture material or to a substance on its surface. Unlike the usual isolated stitch abscess, these infiltrates are minute foci of white cells located along many or all of the suture loops. Affected eyes tend to be moderately inflamed. The epithelium, unlike in the situation found with a stitch abscess, is usually intact over the sutures. Treatment consists of increasing the steroid dosage to a drop every 1–2 h until the inflammatory response is brought under control followed by a slow taper.

WOUND LEAK AND SUTURE PROBLEMS

Wound leaks and suture problems are uncommon with modern suturing techniques but often are related when they do occur. A patient with a broken running 10-0 nylon suture in the immediate postoperative period before there is significant wound healing will need to have the suture repaired. This should be completed quickly, even if there is no leak, because of the great risk of further unraveling of the suture with loss of the anterior chamber or the development of graft over-ride. The repair should be performed under the microscope in a sterile setting because of the danger of infection. A new segment of 10-0 nylon suture must be added, making several bites across the wound. It is then tied to both ends of the broken suture that have been withdrawn a loop or two on either side to provide enough suture for tying. This maneuver is made easier if the new suture is passed for several bites before the original suture is disturbed to lessen the chance of anterior chamber loss, if it is still formed. Before tying the final knot, tension on the sutures is adjusted appropriately. A broken running suture occurring a few months after surgery, as from mild trauma, does not necessarily need to be repaired. If it shows signs of loosening, the suture can be protected from the movement of the eyelids by a bandage soft contact lens. A broken interrupted suture can usually be removed without replacement unless there is evidence of wound gape.

A wound leak may be found on the first or second postoperative visit even with an intact suture or sutures, particularly when an attempt has been made to avoid an excessively tight suture. Checking for wound leaks is an important part of the postoperative examination and is carried out by placing a concentrated drop of fluorescein over the graft wound. A positive Seidel test occurs when a rivulet of fluorescing yellow-green dye is seen emanating from the wound under the cobalt blue light. This leak may be either from the wound itself or along a suture track. If the anterior chamber is of normal or near-normal depth, the patient can be treated with mild pressure patching or a bandage soft contact lens for a few days. Many small leaks will spontaneously close, particularly those around sutures, as the epithelial plug grows into the wound. If there is a running suture in place, a persistent leak can often be managed with a suture adjustment, as described above, tightening the suture in the area of the leak and distributing the released suture tension evenly about the wound. Occasionally, if the entire running suture seems too loose, the suture can be saved by tightening the suture all around and leaving one large loop of excess suture material. This loop is then attached to the peripheral cornea near the limbus with a single suture of 10-0 nylon whose knot is buried. A mattress suture of 10-0 nylon has been described that can be placed as a compression suture about a leaking suture tract but should rarely be necessary. A leaking interrupted suture tract can be resolved by removing the suture and replacing it if needed. Interrupted sutures can always be added to close the graft wound if needed. These can be placed under sterile conditions, taking great care that the side of the needle does not cut a running suture, if present.

If the anterior chamber is very shallow, the wound leak should be repaired promptly, depending on the level of inflammation, limiting formation of synechiae. A totally flat chamber requires an immediate wound repair.

EPITHELIAL DEFECTS

Obtaining an intact, stable epithelial surface covering the fresh transplant is the first step in obtaining a successful outcome of surgery. Unfortunately, a number of factors operate to interfere with this goal. First, the donor cornea may have had epithelial sloughing during the period from death to preservation, particularly if the eyes were not taped shut and cooled with eye bags while waiting for the corneas to be harvested. Second, depending on the storage media and the length of storage time, epithelial viability can be compromised.[33] Third, intraoperative trauma, either mechanical or through drying under the bright microscope light, can lead to further loss. For these and other reasons, many patients will not have an intact epithelial layer when seen for their first postoperative visit.[34]

Delayed or incomplete epithelialization of the corneal transplant can lead to potentially disastrous results (Fig. 52.6). After approximately 1 week, there can be damage to Bowman's membrane which, even if epithelialization occurs later, may leave the transplant with superficial haze and scarring. With a further delay, melting of the stroma begins to result in a graft with a depressed scar, which is even more optically disturbing. If the problem is still not corrected, continued melting will lead to perforation, necessitating additional surgery. In addition, epithelial defects are often the precursor of infection. Active and aggressive treatment of all epithelial defects, whether present initially or developing during the postoperative period, is mandatory.

Prevention of epithelial problems begins in the preoperative period. Lid problems, such as entropion, ectropion, trichiasis, lagophthalmos, or blepharitis, should be corrected. If tear production is deficient, punctal occlusion and topical cyclosporin should be considered. Certain conditions, such as ocular pemphigoid, Stevens–Johnson syndrome, and alkali, acid, and other chemical burns are notorious for resulting in postoperative epithelial problems. Unless such steps as limbal stem cell transplantation can be undertaken,[35] the prognosis in these conditions is very guarded. During surgery the epithelium should be left on the transplant, even though there are conflicting studies as to whether its removal lessens the long-term risk of graft rejection.[36,37] The epithelium can be protected from drying with a small amount of viscoelastic.[38] When epithelial problems are anticipated, as in patients with dry eye or rheumatoid disease, punctal occlusion or a tarsorrhaphy can be performed at the conclusion of the operation.

After surgery, treatment of epithelial defects can be approached in a stepwise fashion. Initially mild pressure patching can be attempted, even though one study found that small defects healed as fast without patching.[3] Care must be taken to ensure that the lids do not open under the patch, and this may be helped by directly

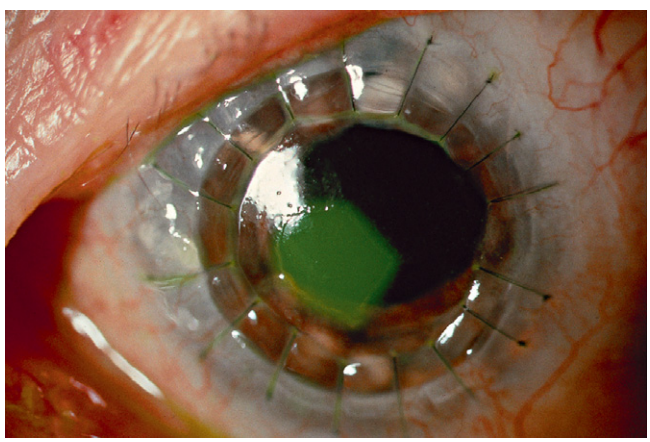

Figure 52.6. An epithelial defect, such as that shown above, requires prompt treatment to prevent secondary complications.

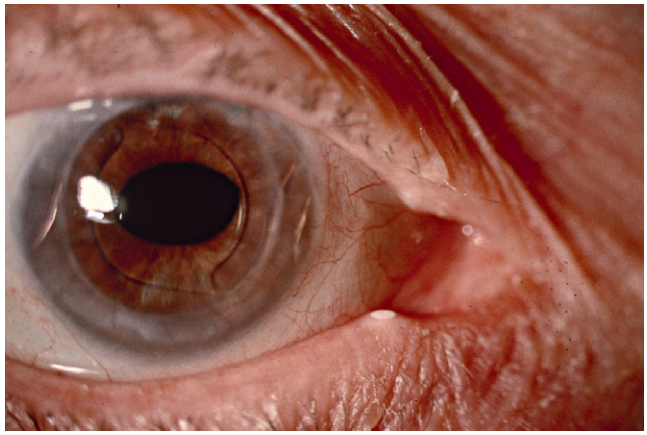

Figure 52.7. Punctal plug placed in a patient with dry eye to help protect the graft epithelium.

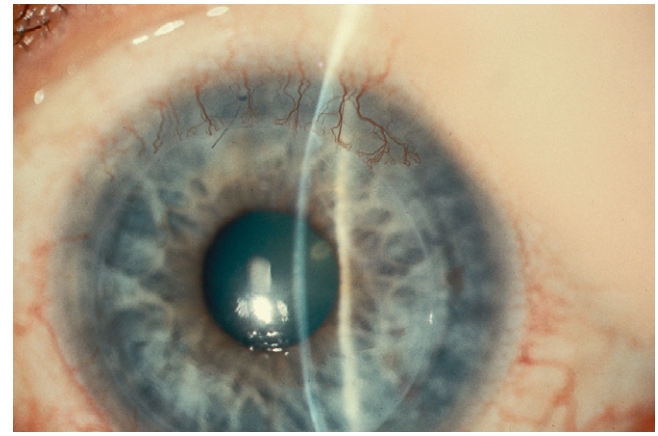

Figure 52.8. Superficial vascularization of the cornea after the placement of a bandage soft contact lens for chronic filamentary keratitis.

taping the lids together before applying the patch. The patch may be left in place for 24–48 h without being disturbed, if active infection is not a concern. Sutures with exposed ends should be removed or the exposed suture material amputated.[39] Aberrant lashes or lint trapped under a suture should be removed. Topical lubrication with frequent (every 30–60 min), nonpreserved artificial tears, nonpreserved bland ophthalmic ointment, or both can be used. If not already performed in the patient with dry eye, punctal occlusion either permanently with cautery or reversibly with punctal plugs should be attempted (Fig. 52.7). Because topical medications can contribute to poor epithelial healing, a re-evaluation of all eye drops the patient is receiving is in order. Any medication containing neomycin should be changed to a less epithelial toxic antibiotic.[40,41] Use of prophylactic topical antiviral agents should be considered carefully. Topical antiglaucomatous medications, in part because of their preservatives, can be toxic[42]; switching to a nonpreserved agent (unit-dose timolol) or using an oral antiglaucomatous agent should be attempted. Topical steroids might retard epithelial healing and their use minimized. In short, use the least number of drugs possible, in the least dosage.

If epithelial healing has not taken place after several days of conservative management, a more aggressive approach must be adopted. A soft contact bandage lens can be placed over the graft.[43] Obtaining a proper fit can be difficult because these corneas do not have a normal curvature, often being flat centrally. At times it is necessary to fit a large flat lens to obtain centration, despite a significant risk of infection. In addition to the usual factors causing corneal ulceration with extended soft contact lens, there is the increased risk of an already present epithelial defect and the immunosuppression induced by topical steroids.[44] These patients should be given a topical antibiotic such as moxifloxacin every 3–4 h and observed carefully. Once the defect has healed, an attempt should be made to remove the lens, because long-term use of soft lenses in corneal transplant patients has been associated with a high rate of infection and corneal vascularization (Fig. 52.8).[45]

In patients not responding to the above measures, a tarsorrhaphy should be performed. This can be carried out with a simple frost suture, by forming a temporary adhesion between the eyelashes of the upper and lower lids using cyanoacrylate glue,[46] or a permanent lateral tarsorrhaphy (Fig. 52.9). For those patients who have already had a lateral tarsorrhaphy, a medial intermarginal tarsorraphy can be added.

Figure 52.9. This lateral tarsorrhaphy was extended further medially because of continuing epithelial breakdown.

Once corneal melting has begun, the optical outcome for the transplant is compromised. At this point, if the condition of the donor tissue itself is believed to have contributed to the epithelial problem or if any contributing factors can be corrected, consideration should be given to replacing the graft. If it is believed that a further corneal transplant would produce the same result, a conjunctival flap can be pulled to save the eye from corneal perforation.

The possibility that a late-appearing or nonresponding epithelial defect actually represents a herpes simplex infection must be kept in mind. These ulcers tend to occur near the wound margin, often do not look like a typical dendrite, and may even occur in a patient without a known previous history of herpetic disease (Fig. 52.10).[47] When suspected, viral cultures and immunofluorescent staining for herpes is indicated. If herpes simplex virus is found, appropriate antiviral treatment can be started.

FILAMENTARY KERATITIS

Filamentary keratitis has been reported to occur in at least 25% of patients after keratoplasty.[48] This finding is not surprising because many of the conditions in which filaments occur (inflammation, increased mucus production, anesthetic cornea, patching, etc.) are present in the postkeratoplasty eye. Filaments consist of strings of

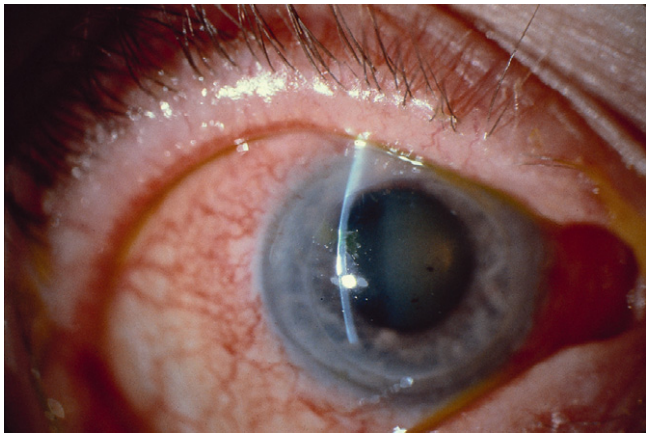

Figure 52.10. A late-appearing, irregularly shaped epithelial defect on an otherwise clear graft cultured positive for herpes simplex virus.

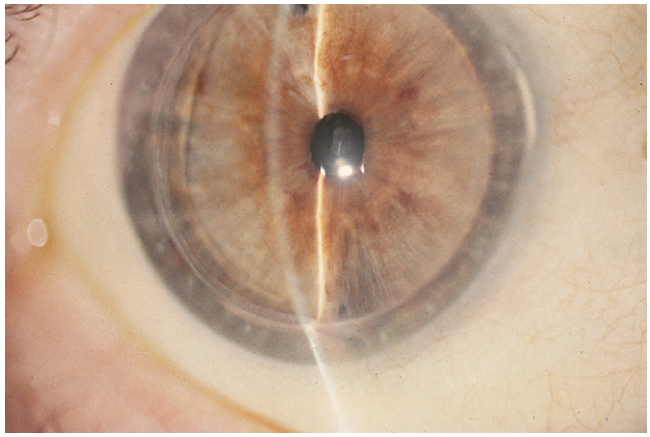

Figure 52.11. Limited anterior synechia to the graft wound that has been present for years without adversely effecting graft survival.

mucus with a few epithelial cells attached to receptor sites on the epithelial surface. They occur most frequently near the wound margin and may come and go over many months.

Patients experiencing filament formation may experience initial symptoms of irritation and foreign body sensation, particularly if the filaments occur near the edge of the graft. The eye tends to be slightly injected. The filaments stain poorly with fluorescein and brightly with rose bengal.

Treatment of filamentary keratitis proceeds in a stepwise fashion. For mild symptoms, the use of hypotonic artificial tears may give temporary relief. If used frequently, nonpreserved tears are indicated. For more pronounced symptoms, the filaments can be removed at the slit lamp under topical anesthesia, using fine jeweler's forceps. Care should be taken not to pull off surface epithelium with the filament. For recurrent problems, acetylcysteine diluted to a 10% solution in artificial tears can be attempted as a mucolytic agent. A bandage soft contact lens can also be applied. Fortunately, the frequency of filament formation decreases after suture removal.

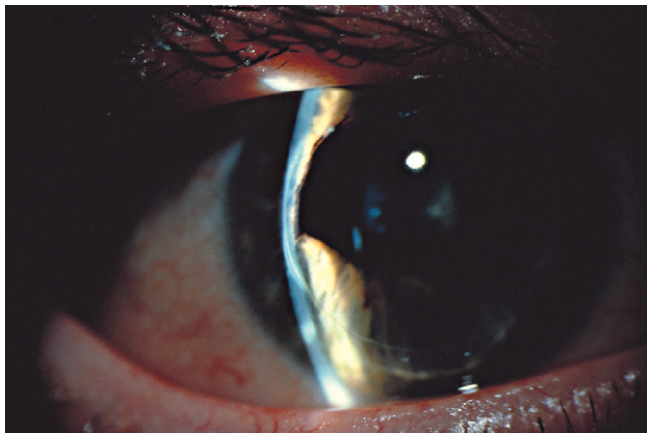

Figure 52.12. Iris incarceration (without prolapse) and loss of the anterior chamber from trauma in a patient with Down syndrome. It was elected not to repair the wound as the chamber reformed spontaneously. The graft has remained clear for years.

ANTERIOR SYNECHIAE

The significance of anterior synechiae depends on their location, their extent, and the time frame of their appearance. Anterior synechiae may develop at the peripheral cornea, in the corneal wound itself, or may extend from one to the other. The greatest problem with synechial formation occurs when operating on inflamed eyes with excessive fibrin in the anterior chamber. Synechiae to the wound found on the first postoperative visit were probably left in place at the time of surgery. It is much easier to deal with this problem on the operating table where the wound can be approached directly and any synechiae pushed back with a viscoelastic agent on a fine cannula. Anterior synechiae may form later as the result of a wound leak with a flat chamber, a persistent shallow chamber, or from trauma with partial or complete iris prolapse. The approach to treatment depends on the location and extent of the adhesions.

Limited synechiae extending directly to the graft wound, especially when the chamber angle is spared, have only a limited effect on graft survival, although on occasion they can be a source of vascularization and graft rejection (Fig. 52.11).[49,50] It may be possible to free these adhesions pharmacologically, especially if there is no significant tissue incarceration. On the third or fourth postoperative day, when the fibrin begins to break down, the pupil should be aggressively dilated with a phenylephrine hydrochloride-cyclopentolate series and, if this is not effective, constricted with pilocarpine. Long-acting cycloplegics, such as atropine or scopalamine, should not be used after surgery to preserve this pupillary capacity. If unsuccessful and the intraocular pressure remains under control, these synechiae are probably best left alone. When surgery is indicated, use of a viscoelastic agent to assist in sweeping iris adhesions from the back of the cornea helps to prevent irreversible damage to the graft endothelium.[51]

More extensive anterior synechiae, with broad contact between the iris and the back of the cornea threatening the filtration angle, usually develop in eyes that have been operated on in the inflamed state. Although the potential to develop severe glaucoma exists, surgical intervention includes risks of bleeding and increasing inflammation. The use of intensive topical steroids (prednisolone 1% every hour) and occasionally systemic steroids for a few days may control the inflammation and allow the iris to drop back. At this point, pharmacologic manipulation of the pupil may be helpful.

Iris prolapse usually occurs as a result of trauma and should be repaired immediately (Fig. 52.12). Depending on the extent of wound disruption, topical or general anesthesia can be used. If the iris tissue prolapse is limited in both extent and duration and if the

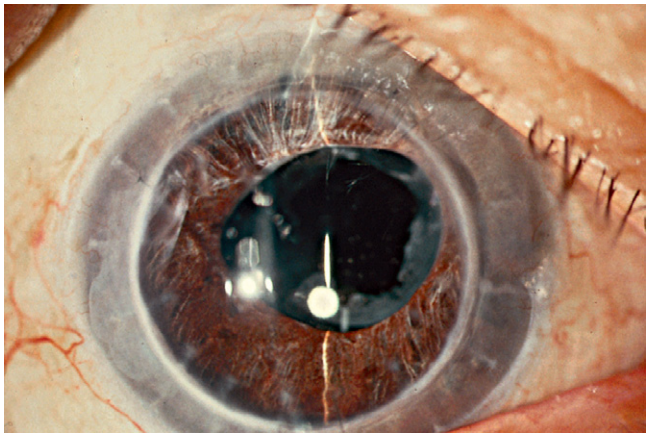

Figure 52.13. Total angle closure from progressive anterior synechiae formation developed in this patient with marked postoperative inflammation. The graft has remained clear, and the intraocular pressure has been controlled with medication.

tissue appears viable, it can be reposited directly. Exposed, nonviable iris tissue should be excised before repositing the portion of iris incarcerated in the wound. The wound usually requires repair with additional interrupted sutures until a watertight closure is obtained. These cases should be considered potentially contaminated, and appropriate antibiotic coverage should be administered.

Anterior synechiae can, on occasion, cause a progressive zippering of the chamber angle (Fig. 52.13). This situation most commonly develops in patients with active inflammation at the time of keratoplasty, particularly if there are pre-existing adhesions. These adhesions may have been lysed at surgery, such that the chamber initially seems of good depth. Then several weeks into the postoperative period, broad peripheral anterior synechiae begin to appear. At first these are localized, but gradually and relentlessly, the synechiae progress. Over a period of weeks the angle becomes 'zippered' up. Occasionally, the process stops at a large peripheral iridectomy, which has caused some surgeons to recommend performing an iridectomy in advance of the zippering process in hopes of halting it. Frequently, however, the process will 'jump' across the iridectomy until all or nearly all of the angle is closed. As may be expected, there is a gradual elevation of the intraocular pressure until a secondary glaucoma develops, which is very difficult to control medically. At times an anterior chamber lens holds the angle open, at least grossly, in the region of the foot plates so that the associated glaucoma may not be quite as difficult to control. There is no proven way to abort this process after it begins other than attempting to suppress the associated inflammation.[52] Surgical intervention is fraught with potential complications. Possible ways to control the glaucoma in these cases are discussed separately.

HYPHEMA

Blood in the anterior chamber after surgery is unusual. Even with very vascularized corneas, the vessels are tamponaded by the pressure created by the corneal sutures. When a hyphema does occur, it is usually the result of bleeding from the angle occurring when an anterior chamber lens foot process is being removed, from a vascularized synechia that is lysed during anterior chamber reconstruction, or from generalized oozing from the surface of a highly inflamed iris. Usually, these bleeding points can be managed at the time of surgery using a viscoelastic to tamponade them or a fine retinal cautery needle for direct cautery.[53] Alternatively, the use of thrombin 1 : 100 or epinephrine 1 : 1000 may be helpful. A small hyphema after surgery can be ignored and spontaneously absorbs in a few days if there is no further bleeding. A large hyphema that is causing uncontrollable glaucoma requires surgical evacuation.

EXCESSIVE IRITIS

All corneal transplant patients experience a variable degree of anterior chamber reaction immediately after surgery; its extent depends on factors such as the degree of iris manipulation and the condition of the eye before surgery. Excessive inflammation may be encountered after surgery and can include fibrin clot formation and a hypopyon in the anterior chamber. Clinical judgment must be exercised in deciding whether this is a sterile inflammatory reaction or whether an infection must be actively ruled out. The presence of excessive white blood cells in contact with the new endothelium can be damaging to the graft, as evidenced by the stromal edema and thickening that these grafts demonstrate.[54] If infection is believed to be unlikely, intensive steroid therapy is warranted. Prednisolone acetate 1% can be administered as often as one drop every hour. A short course of systemic steroids may be needed. A short-acting cycloplegic agent should be given to help prevent posterior synechiae and pupillary block.

If the fibrin clot does not respond to intensive steroid therapy and there is a risk of both pupillary block from a secluded or occluded pupil and damage to the graft endothelium, the use of tissue plasminogen activator can be considered. A 25 μg dose of tissue plasminogen activator given intracamerally has been described.[55] This drug causes complete resolution of the fibrin clot over several hours and appears to be nontoxic to the endothelium.[56] This drug can also result in intraocular bleeding, and therefore its use in any patient who has experienced intraoperative hemorrhage should be carefully considered. The possibility of infection must be considered in any eye that does not respond to treatment.

PUPILLARY BLOCK

With the development of pupillary block, aqueous is obstructed in its movement from the posterior to the anterior chamber, the anterior chamber shallows as the iris bulges anteriorly, and the angle is thus obstructed, with an elevation in intraocular pressure. The incidence of pupillary block is very low after surgery using modern corneal transplantation techniques. Air, which can be trapped behind the pupil at the time of surgery, has largely been replaced as a tissue separator by various viscoelastic agents.[38] Vitreous, which can adhere to and block the pupil, is either removed by an adequate anterior vitrectomy or held back by an intact posterior capsule or posterior chamber intraocular lens. Pupillary block can arise when an eye is left aphakic or a secondary anterior chamber or sewn-in posterior chamber lens is used. If no iridectomy has been performed or has been blocked with peripheral vitreous, pupillary block may ensue. In a phakic eye, marked inflammation can occlude the pupil with posterior synechiae. The elevated intraocular pressure usually will differentiate a shallow chamber because of pupillary block from a shallow chamber secondary to a wound leak. Vigorous dilation of the pupil with several drops of cyclocyl 1% alternating with neosynephrine 2.5% often relieves the situation. In situations where dilation is ineffectual or where the block recurs, a peripheral iridectomy is indicated. This can usually be done with a laser, but where the peripheral iris cannot be approached through the cornea,

perhaps because of a lack of clarity, a surgical iridectomy is warranted. This condition should be aggressively treated to avoid the formation of permanent peripheral anterior synechiae.

GLAUCOMA

Glaucoma after corneal transplantation can be difficult both to diagnose and to treat. It develops in approximately one-third of patients[57] and is unusual in uncomplicated phakic grafts but quite common in pseudophakic or aphakic grafts,[58] especially when there are associated anterior segment abnormalities. The most frequent association with postkeratoplasty glaucoma is the presence of preexisting glaucoma.[58] Because the inability to control intraocular pressure successfully after surgery is frequently associated with graft failure,[59] preoperative pressure control is mandatory. Diagnosing glaucoma before surgery can be difficult because of the problem of accurately measuring intraocular pressure in the presence of a scarred, irregular, or edematous cornea. Corneal opacification can also interfere with visualization of the chamber angle and optic nerve in addition to interfering with obtaining an accurate visual field. Patients whose pressures are controlled, but only on maximally tolerated medication, should be considered for possible glaucoma surgery before keratoplasty because pressure control will most likely be lost after corneal transplantation. Combining glaucoma surgery and keratoplasty has been reported.[60,61] This approach is risky because, if the glaucoma procedure fails, the surgeon must deal with the difficult problem of uncontrolled intraocular pressure in a patient with a fresh graft.

Measuring intraocular pressure after surgery presents a technical problem. The limited area of smooth surface contour of the cornea in the immediate postkeratoplasty period limits the ability to use applanation tonometry. Makay Marg electronic tonometry,[62] pneumatic tonometry,[63] and the newer Tono-Pen[64] give more accurate measurements under these circumstances, but even these instruments can, on occasion, be misleading. A very thin and clear corneal transplant on the first postoperative day raises the possibility of elevated intraocular pressure.[65] The high pressure compresses the stroma, but, because there is no epithelium or only a thin layer of epithelium present, the epithelial barrier is not functioning, and therefore epithelial edema is not seen. The presence of synechiae or the presence of blood, fibrin, or both in the anterior chamber should increase the suspicion of pressure problems. The knowledge of preoperative risk factors or intraoperative problems allows for the anticipation of postoperative glaucoma.

On the first postoperative day, elevated intraocular pressure is common.[66] An oral carbonic anhydrase inhibitor, such as acetazolamide 250 mg four times per day and topical agents such as timolol 0.5%, apraclonidine 0.5%,[67] and latanoprost may prove helpful.[68] Aggressive management of any associated pupillary block, synechiae, or excessive inflammation is appropriate. Elevated intraocular pressure from the presence of a retained viscoelastic agent usually clears spontaneously in 24–48 h.[6] In the rare instance where the pressure is so high that acute damage to the optic nerve is feared, a hyperosmotic agent can be given orally for 1 or 2 days. Such an approach can only be considered a temporizing measure until more definitive therapy is instituted.

On a more chronic basis, if elevated intraocular persists, it may be possible to change to a topical carbonic anhydrase inhibitor. A miotic, such as pilocarpine or carbachol, although initially contraindicated because of its effect on the blood aqueous barrier, can be added as soon as the postoperative inflammation is brought under control. Topical epinephrine or dipivefrin has only a limited use because of its known propensity to cause macular edema in the aphakic or pseudophakic patient. As pointed out previously, these agents and their preservatives may adversely affect the status of the corneal epithelium on the surface of the new graft, and this consideration must be taken into account in treating glaucoma.

The possibility that the use of a topical steroid is playing either a primary or a contributing role in the development of a patient's pressure elevation should be considered, particularly when this elevation develops 1 or 2 weeks after steroid administration is started. In addition to keeping the use of steroids to the minimal dosage necessary, switching to a steroid with less propensity to pressure elevation, such as fluoromethalone or loteprednol etabonate,[69] is warranted.

If patients fail to respond to medical therapy, the presence of a corneal transplant makes surgical intervention more risky because of the possibility of causing graft failure. The simplest and safest surgical approach is argon laser trabeculoplasty.[70] Most patients are not suitable for this procedure because they are either aphakic or pseudophakic, or because visualization of their angle is poor or much of their angle is closed. For many of the same reasons, a classic trabeculectomy has a low success rate.[71] Adding an antimetabolite, such as mitomycin C or 5-fluorouracil, may increase the risk of graft failure.[72] In the recent past, the best option available for most of these eyes was a cyclodestructive procedure. Originally, cyclocryotherapy was the procedure of choice for intractable glaucoma[73] and it still has a place in the therapeutic armamentarium when access to other treatment methods is unavailable.[52] Significant complications are associated with this treatment including iritis, hemorrhage, macular edema, graft failure, decreased vision, and especially late-term phthisis bulbi (Fig. 52.14).[74,75] For this reason a graded approach to treatment is indicated. Initially 180° of the ciliary body is treated using three applications in each quadrant for 60 s at 60–80°C. Depending on the response achieved, additional treatment applications can be added, one or two at a time, in the previously untreated quadrants of the globe. This approach is challenging because the difference in aqueous production between a high pressure and phthisis may be minimal in eyes with severely impaired outflow. Trans-scleral neodymium:yttrium aluminum garnet (Nd:YAG) photocoagulation, either contact[76] or noncontact,[77] has largely supplanted cryotherapy as a means of destroying the ciliary processes and decreasing aqueous production because

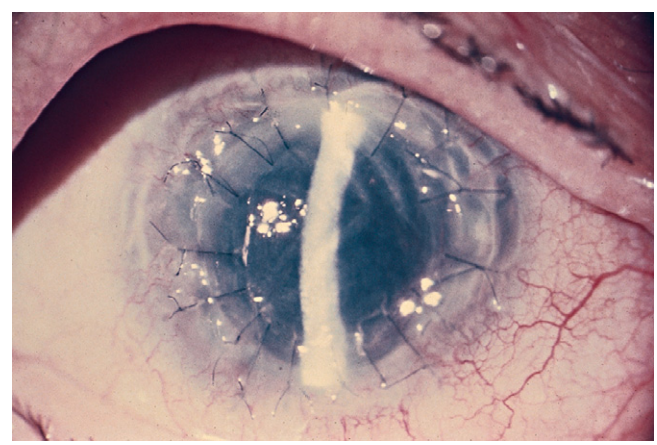

Figure 52.14. Graft failure after cyclocryotherapy.

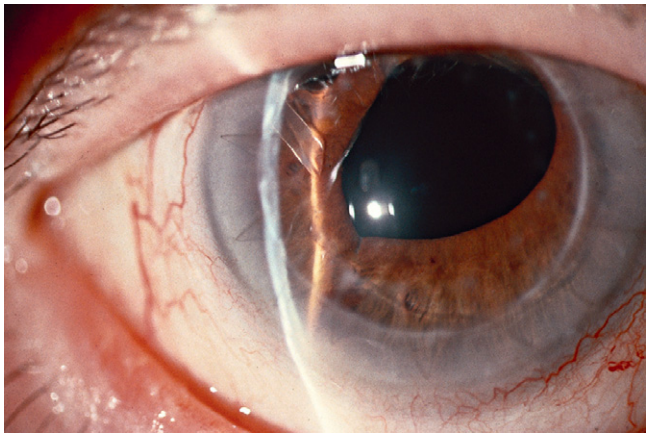

Figure 52.15. Note that the position of the tube from this valve is well away from the back of the graft.

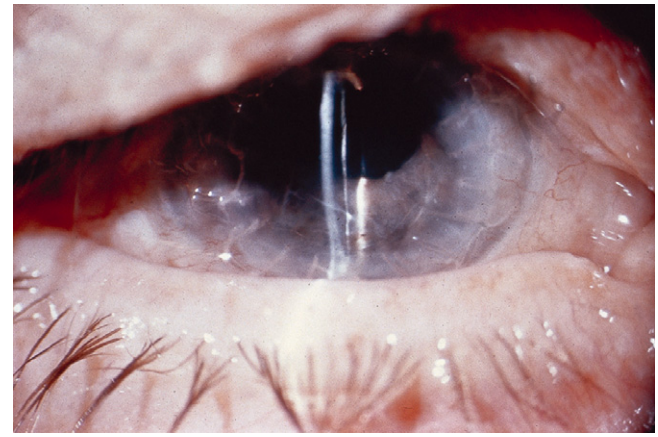

Figure 52.16. Retained Descemet's membrane as a thin, clear, wavy membrane separated by a false anterior chamber from a clear corneal transplant.

the associated complication rate appears to be less. A graded approach is used; the risk of graft failure increases with multiple treatment sessions. Whether other laser glaucoma procedures, such as transpupil[78] or endoscopic[79] argon laser cyclophotocoagulation, will have a place in the treatment of postkeratoplasty glaucoma remains to be seen.

Valves, such as the Ahmed,[80] Baerveldt,[81] or Molteno valve,[82] appear to give the best chance for long-term pressure control with little or no medication. The surgical approach is the same as in the nontransplanted patient. The drainage tube can be placed in the anterior chamber or, where none is present, in the posterior chamber after an adequate vitrectomy. With anterior chamber placement, particular care must be given to the length, position, and angle of the tube to avoid touching the back of the graft (Fig. 52.15). A significant incidence of graft failure and hypotony after surgery only underscores the difficulty of treating glaucoma in the postkeratoplasty patient.[83]

VASCULARIZATION

Vascularization of the graft bed greatly influences the incidence of graft rejection.[49] The most important sources of blood vessels extending up to and into a corneal transplant are pre-existing corneal vascularization, loose sutures and exposed corneal knots, corneal ulcers, and bandage soft contact lenses, especially when used on an extended-wear basis.

Unfortunately, there is usually no way to remove pre-existing vessels from the corneal bed. Rarely a single-feeder vessel, if it originates from the surface of the sclera, can be cauterized outside the limbus or is amenable to laser photocoagulation. A fibrovascular pannus can be stripped off the cornea at the time of surgery. Often removal of the diseased recipient button removes the impetus to vascular ingrowth, and the active vessels present before surgery regress after surgery.

Treatment of corneal vascularization involves the suppression of vessel growth by the appropriate use of topical steroids,[84] recipient-side focal subconjunctival triamcinolone injection (personal communication, Fred Brightbill, MD), removing loose sutures and exposed knots, aggressively treating corneal infections, and limiting the use of bandage lenses. Timing of suture removal plays a large role in preventing the complications of corneal vascularization. If the donor graft is healthy, pre-existing vessels or vessels approaching the host–graft junction tend to grow along the junction and not enter the graft. As soon as this has happened, the wound in this area has usually healed sufficiently to allow suture removal. If interrupted sutures have been used, the suture at this location should be removed. The flexibility of interrupted sutures in this situation is an indication for their use where pre-existing corneal vessels are present. If a running suture has been used, management is more difficult. If the rest of the wound has not sufficiently healed, suture removal can lead to wound dehiscence. The options then are to increase the dose of topical steroids, keeping in mind that this slows healing in the rest of the wound, or to remove a section of the running suture. After a section has been removed, the running suture tends to continue loosening, a loop at a time, because of the action of the eyelids. If this happens, the suture can be stabilized by the placement of a bandage soft contact lens, but the presence of the latter may cause further progression of the vascularization. Superficial vessels crossing the graft–host junction do not indicate wound healing but fortunately do not carry an increased risk of rejection. On occasion, however, superficial vessels, on reaching the junction, can dip down, enter the stroma of the graft, and thereby pose a risk of rejection.

RETAINED DESCEMET'S MEMBRANE

Finding a wavy, diaphanous membrane in the anterior chamber that creates a false chamber behind a graft on the first postoperative visit indicates that Descemet's membrane has been left behind at the time the recipient button was removed (Fig. 52.16). Retention of Descemet's membrane occurs most commonly in an edematous cornea where, after partial trephination, an opening is made into the anterior chamber and curved corneal scissors are introduced. By accident, the lower blade is not placed into the anterior chamber, but rather anterior to Descemet's membrane, stripping the latter from the corneal stroma. On completion of the excision of the recipient button, the button is lifted from the eye, leaving the central portion of Descemet's membrane behind. Descemet's membrane then settles down over the iris, where it is remarkably difficult to see.

A retained Descemet's membrane eventually leads to loss of graft clarity by clouding or by coming into contact with the graft endothelium. Several approaches to dealing with this problem are available. If the membrane has been mostly cut free at the time of surgery leaving only a small area of connection, its excision can be completed under a viscoelastic agent either through a limbal excision

or through the corneal wound. A technique using the Nd : YAG laser to make a central opening in the membrane has been described.[85] The long-term outcome of this procedure has not been reported. A long-term solution to this problem is to repeat the keratoplasty.

PRIMARY GRAFT FAILURE

Primary graft failure refers to the situation where the donor cornea is thick and edematous from the first postoperative day and never clears.[86,87] Technically, the term 'primary' would imply that the transplanted tissue itself was not healthy. This occurrence should be very rare if the tissue is harvested and used under current rigorous protocols. Usually, graft failure in this circumstance is secondary to intraoperative problems. Primary graft failure is best handled by graft replacement with a new donor before wound healing.[88] In this circumstance, the sutures can be cut and the failed graft removed without the need for trephining. Haste in making this decision is, however, not warranted because almost all grafts can be easily removed up to 1 month or more after surgery.

53 Post keratoplasty infections

Namrata Sharma, Gaurav Prakash, Rasik B. Vajpayee

INTRODUCTION

Graft infection is a particularly devastating complication following corneal transplant surgery and may cause graft failure if not managed promptly and appropriately. The immunity of the ocular surface of a corneal graft is suboptimal due to altered tear film dynamics, loss of corneal sensations, and frequent instillation of topical corticosteroids in the early postoperative period, and a range of risk factors may predispose to infectious keratitis in a corneal graft. The important predisposing factors that may cause infectious keratitis in a corneal graft include donor tissue contamination, ocular surface diseases, and suture-related problems. In most instances, infection in a corneal graft is associated with poor visual outcome.

INCIDENCE

Graft infections are known to occur more commonly in developing countries, and the incidence has been reported to be as high as 11.9%.[1] In developed countries, the incidence of infectious keratitis after corneal transplantation surgery varies from 1.7 to 7.4%.[2–5] The incidence of infectious keratitis following lamellar keratoplasty has been reported to be 11.11%.[6] Most infections present in the first year of corneal transplantation surgery.[2–4] A higher occurrence of graft infection in developing countries is related to type of indications vis-à-vis primary corneal pathology, suboptimal quality of health-care services, and noncompliance of follow-up schedule due to socioeconomic reasons.

PREDISPOSING FACTORS

Various factors that can predispose to infection in corneal graft include type of corneal pathology of the recipient, donor tissue contamination, and ocular surface problems. In some instances, systemic diseases and socioeconomic status of the patient may be responsible for the occurrence of graft infection.

INDICATIONS FOR KERATOPLASTY

There are certain types of corneal pathologies that predispose to infections following penetrating keratoplasty. Corneal grafts performed for bullous keratopathy[7] and corneoiridic scars[8] carry a higher risk of infection as compared to corneal grafts done for cases like keratoconus, early Fuchs' endothelial dystrophy, and stromal corneal dystrophies.

CONTAMINATION OF DONOR TISSUE

Certain causes of donor death like malignancy, cardiac diseases, and septicemia are more frequently associated with graft infection.[9] Also, at times the preservation media for tissue storage may be a potential source of graft infection due to inadvertent contamination during the processing and storage of the donor tissue.[10]

PRE-EXISTING INFECTIONS

Pre-existing infections in the ocular adenexa like dacryocystitis, meibominitis, and blepharitis if not recognized and appropriately treated preoperatively, may predispose to infectious keratitis in an otherwise clear and healthy corneal graft.

RECURRENCE OF HOST INFECTION

Recurrence of infection is usually seen when there is an incomplete excision of infected tissue of the host cornea in cases of therapeutic grafts. While performing therapeutic keratoplasty, the surgeon should make sure that the host trephination encompasses the entire diseased tissue along with a 1.0 mm healthy rim. In cases where transplantation is performed for herpes simplex keratitis, recurrence is common and may occur in 23% cases of transplanted corneas.[4]

PERSISTENT EPITHELIAL DEFECT

A persistent epithelial defect compromises the mechanical barrier of corneal protection against entry of microbes and increases the

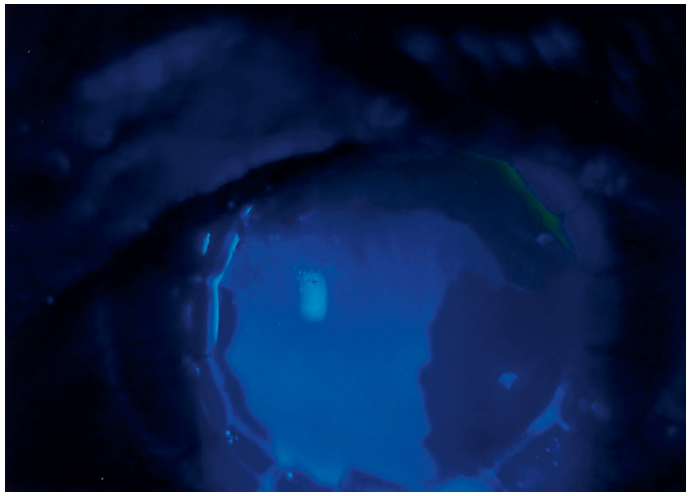

Figure 53.1. Persistent epithelial defect.

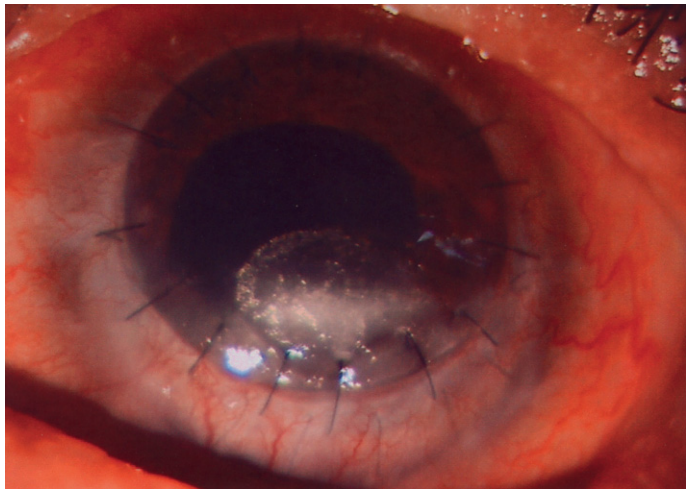

Figure 53.2. Tight suture with persistent epithelial defect with graft infection.

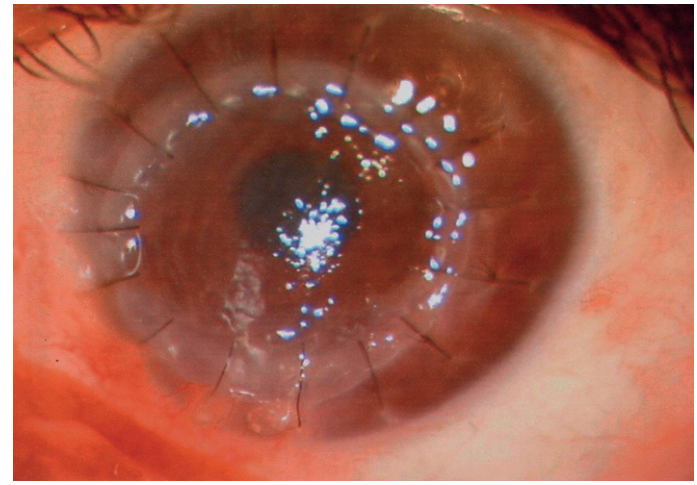

Figure 53.4. Loose suture with mucin deposits.

chances of occurrence of microbial keratitis in a graft (Fig. 53.1). Lid abnormalities like trichiasis, poor quality and inadvertent damage of the donor tissue, tight suturing (Fig. 53.2), loose suturing (Fig. 53.3), and toxicity of the preservative present in topical drops can delay the epithelialization of the corneal graft, leading to the occurrence of persistent epithelial defects. Epithelial defects as the inciting factors of infectious keratitis after corneal transplantation have been implicated in 14–74% cases in various series.[1,4,6,8]

CONTACT LENS

Bandage contact lenses are commonly used to manage persistent epithelial defects following corneal transplantation surgery. These lenses prevent microtrauma to the loose epithelium due to lid movement and thus promote healing of the epithelial defect. However, lenses also induce corneal hypoxia, reduce local immunity, and can cause increased microbial adherence and a subsequent keratitis.[7] In one study, lenses were implicated in 45% of cases of microbial keratitis after corneal transplantation.[11] It is unclear whether the contact lens itself or the persistent epithelial defect is responsible for causation of microbial keratitis in such cases.

DRY EYE AND OCULAR SURFACE PROBLEMS

Ocular surface disorders like dry eye and dellen result in altered tear-film dynamics and decreased tear-film coating. The tear film has antimicrobial substances like lysozymes, which act as the first line of defense. The tears also wash off the debris and microbes from the ocular surface. A compromised tear film increases the chances of adherence of the microbes to the transplanted corneas, thus causing microbial keratitis. A compromised ocular surface has been reported as a cause of postkeratoplasty infection in 33–66% of the cases.[1,4,6]

SUTURE-RELATED PROBLEMS

Suture-related problems are the most important predisposing factors for graft infection.[6,12–15] Loose, broken, and exposed sutures attract mucin (Fig. 53.4) and act as a nidus for microbial invasion and proliferation that can cause graft infection. A continuous suture (Fig. 53.5) has a higher chance of predisposing a graft to the occurrence of infection as compared to interrupted sutures. Unlike continuous sutures, interrupted sutures can be easily and selectively removed if there is a suture-related problem or at the first sign of a suture-related infection.[8]

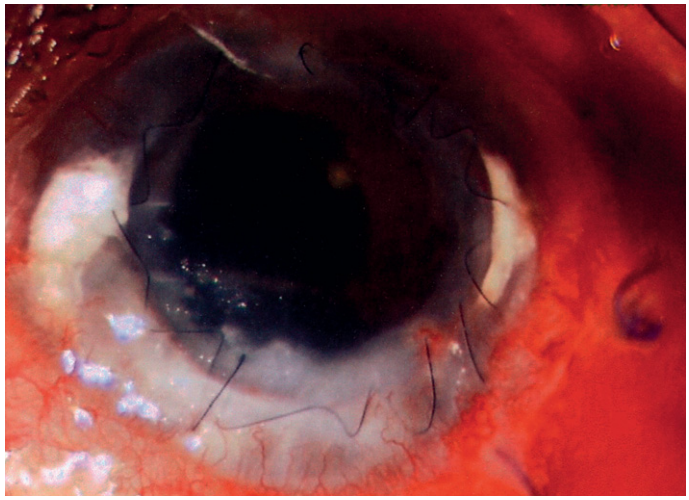

Figure 53.5. Loose continuous suture with graft infection.

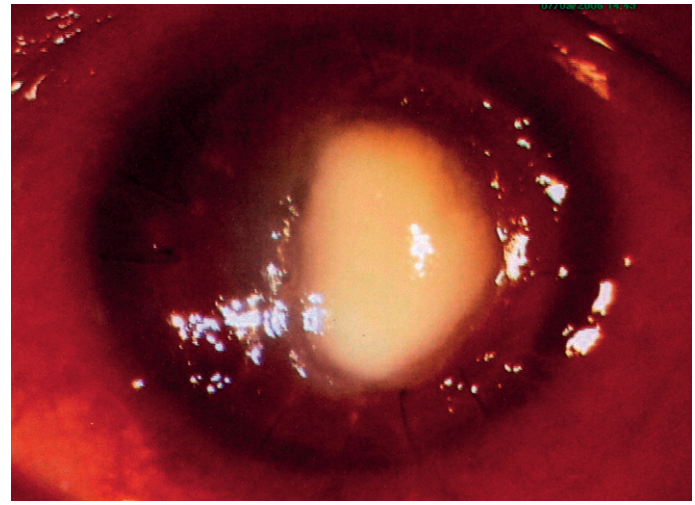

Figure 53.6. Fungal keratitis after keratoplasty.

A loose or broken suture or the recent removal of a suture may be associated with infectious keratitis in 14–60% cases.[3,4,6,8,15] Suture abscesses have been reported in 2–3.3% cases of penetrating keratoplasty.[14,15]

Systemic and other associations

Patients with diabetes mellitus reportedly have higher chances of developing graft infection.[7,8] In developing countries, graft infection is associated with low socioeconomic status of the patient.[8,16,17] In one study there was 2.5 times higher chances of infection in the lower socioeconomic group of patients compared to those in the higher strata; the difference was attributed to poor living conditions and inadequate hygiene.[16]

MICROBIOLOGY OF GRAFT INFECTION

The most common cause of graft infection is herpes simplex virus followed by bacterial organisms. More cases with Gram-positive cocci (coagulase-negative staphylococci, *Streptococcus pneumoniae*, and *Staphylococcus aureus*)[1,2,18] have been reported as compared to Gram-negative organisms (*Pseudomonas aeruginosa*, and *Serratia marcescens*). Mycotic keratitis after corneal transplantation has also been known to occur, and fungi of *Aspergillus* and *Mucoraceae* species[19] are most commonly isolated fungal organisms from these cases (Fig. 53.6).

CLINICAL FEATURES

A patient with graft infection usually presents with reduced vision and discharge from the eye. If the infection is related to a defective suture or if it is in the form of a localized dendritic keratitis, the vision may not be reduced much in early stages.

TIME OF PRESENTATION

Most cases of graft infections have been reported to occur within a year of the corneal transplantation surgery.[2–4,6] Infections caused by contaminated donor tissue and recurrence of the host infection usually occur during the early postoperative period. However, herpetic reinfections demonstrate a variable pattern and may occur years after the keratoplasty[20–22] (Fig. 53.7).

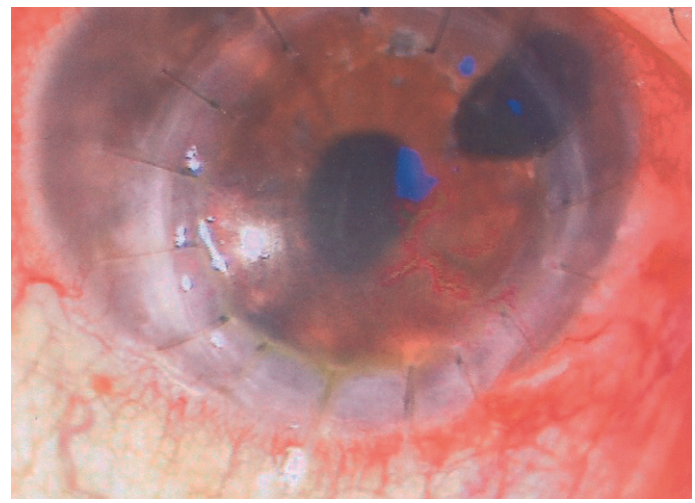

Figure 53.7. Herpetic infection in graft. Rose bengal staining shows dendritic pattern.

Symptoms and signs

Patients with graft infection in the early postoperative period commonly present with non-specific symptoms of redness, photophobia, foreign body sensation, and purulent discharge. There may be a sudden or gradual decrease in the visual acuity depending on the location of the lesion. Some patients with infection at the graft–host junction or with infection localized to the periphery of the graft may present with a normal visual acuity.

There may be a delay in diagnosis of infection in lamellar grafts, especially in the early stages, because an infiltrate may develop in the interface and may remain unnoticed.[6]

The ulcer should be examined with the biomicroscope and documented with a careful detailed drawing and photographs (if possible). The size of the epithelial defect, infiltrate, and hypopyon (if present) should be measured and documented at all visits (Fig. 53.8).

The ulcers in the grafted cornea may be either peripheral or central in location. Peripheral ulcers are usually associated with suture-related problems.[2] Centrally located ulcers suggest exposure and tear-film abnormalities. Advanced cases may present with frank graft dehiscence or melting.

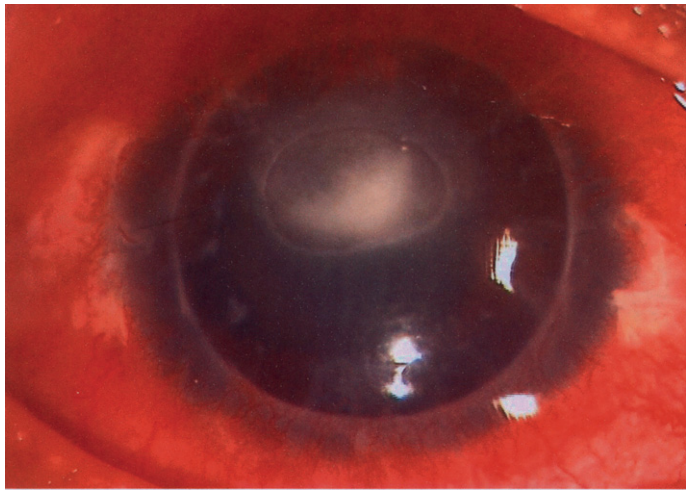

Figure 53.8. Bacterial keratitis after keratoplasty.

INVESTIGATIONS

Most corneal transplant surgeons prefer to culture swabs taken from the donor corneoscleral rim and the media. These may be of help in identifying the causative microbe, especially if the infection has occurred in the early postoperative period.

All cases of graft infection should be subjected to a detailed microbiological workup, which includes scraping of the ulcerated area, preparation of smears, and inoculation of the material obtained on appropriate culture media.

The corneal scraping should be done under topical anesthesia using a slit-lamp biomicroscope. Smears for Gram's stain and potassium hydroxide (KOH) wet mount should be prepared. In cases of suture-related problems, the offending suture should be removed and sent for bacterial and fungal culture examinations. If a contact lens is in place, it should be removed and placed on a separate culture plate. Initially the cultures should be done on blood agar, chocolate agar, and Sabouraud dextrose agar. Special culture media like Lowenstein–Jensen media, non-nutrient agar with *Escherichia coli*, and thyoglycolate broth should be used if there is clinical suspicion of infection by unusual pathogens.

If the infiltrate is deep within the graft and not accessible to superficial scraping, then a multifilamentous silk suture can be passed through the lesion and placed in culture media in an effort to recover the pathogen.

MANAGEMENT

Corneal graft infection requires a prompt and judicious management, which depends on a good clinical judgment and an early microbiological diagnosis of the ulcer.

MEDICAL MANAGEMENT

We prefer to hospitalize all cases with corneal graft infection. This helps us to optimize and monitor the therapeutic approaches applied, particularly in cases from poor socioeconomic backgrounds. In all cases of suppurative infectious keratitis of the corneal graft, topical corticosteroids should be stopped immediately (or rapidly tapered if there is the possibility of a *Pseudomonas* infection) and an intensive regimen of broad-spectrum combination therapy with fortified cefazolin 50 mg/mL and fortified tobramycin 14 mg/mL should be instituted every 30 min round the clock in the first 24 h. Alternatively, fortified cefazolin 50 mg/mL and gatifloxacin 3 mg/mL may be started in the same frequency. Monotherapy with fluoroquinolone antibiotic eye drops may also be instituted, although increasing instances of resistance of *S. aureus* and coagulase-negative *Staphylococcus* and *Streptococcus* to these agents have been reported.[22]

If there is microbiological evidence of fungus (on Gram's smear, KOH wet mount, or culture examination), 5% Natamycin eye drops every hour during the day and every 2 h at night are begun. Supportive topical medical therapy is given in the form of cycloplegics (preferably short acting such as tropicamide eye drops), lubricants, and antiglaucoma medications (if required). Topical corticosteroid therapy may be restarted in cases of bacterial infections only if the offending organism has been identified and there is a significant positive response to the antimicrobial therapy. Systemic antibiotics are indicated in cases with frank/impending scleral involvement, graft melting, perforation, or dehiscence.

The medical management is modified on the basis of clinical response and microbiological reports. The patient should be examined daily to monitor the clinical response of the ulcer. The signs of healing include a decrease in the size of the epithelial defect, infiltrate, anterior chamber reaction, and hypopyon, if present. The signs of worsening include increase in size of epithelial defect, stromal infiltrate, anterior chamber reaction, hypopyon, stromal thinning, and perforation. At every visit the graft–host junction should be carefully examined for wound dehiscence. Once the clinical improvement occurs, the topical medications should be tapered.

However, if the medical management fails, surgical options for the management of postkeratoplasty infections should be employed. If the cultures are negative and the keratitis worsens despite medical therapy, a diagnostic biopsy may be undertaken.

SURGICAL MANAGEMENT

Management of suture-related problems

If a loose suture is noted in the early postoperative period, it should be removed and replaced immediately, taking care that the exposed part of the suture does not traverse the corneal stroma. If a suture is the cause of infection during the late postoperative period, i.e. after 3 months, it should immediately be removed and sent for cultures. During the late postoperative period, removal of a single interrupted suture does not adversely affect the wound stability. However, if infection occurs due to a loose continuous suture, it should immediately be removed and replaced with interrupted sutures.

Emergency therapeutic keratoplasty or graft exchange

The indications for a graft exchange include nonresolving graft ulcers, deep-seated abscess nonresponsive to treatment, wound dehiscence, perforation, or graft melting. A graft exchange using the same-size graft as the one used in the prior surgery may be done in cases where the infection has not spread to the host cornea or a larger-sized graft may be used in cases where the infection spreads to the host cornea.

SPECIFIC ENTITIES

HERPETIC CORNEAL GRAFT KERATITIS

Herpes simplex virus keratitis may recur in cases of penetrating keratoplasty performed for herpetic scars or may develop following

keratoplasty without a clinical history of herpes keratitis in the host.[23] The incidence of recurrence of herpetic infection after penetrating keratoplasty varies from 10 to 25% during the first year of follow-up.[23,24] Most cases of herpetic keratitis are thought to represent reactivation from the virus putatively dormant in the neuronal ganglia. Herpetic keratitis of a corneal graft may have a variable presentation. It may present as a classic dendritic ulcer, persistent epithelial defect, graft rejection, or a herpetic stromal infiltration of the graft.[25] Distinguishing a geographical herpetic ulcer from a neurotrophic ulcer may be a challenge, but is achieved using slit-lamp biomicroscopy with rose bengal staining. The risk of recurrence of herpetic infection increases if corticosteroids are used without an antiviral agent after penetrating keratoplasty. A prophylactic dose of systemic acyclovir 800 mg per day is recommended for up to a year in cases of penetrating keratoplasty done for herpetic scars.[24–26]

INFECTIOUS CRYSTALLINE KERATOPATHY

Infectious crystalline keratopathy is an indolent corneal infection in which needle-like, branching crystalline opacities are seen underneath an intact epithelium within the corneal stroma, in the absence of appreciable corneal or anterior segment inflammation.[27,28] This has been reported to occur most frequently after penetrating keratoplasty and has been attributed to the chronic use of topical corticosteroids. Long-term use of topical corticosteroids, a routine therapy for cases of corneal transplantation, causes relative immunosuppression, allowing infection to develop with little or no inflammation in the cornea. The biofilm or the bacterial glycocalyx protects the organisms from penetration of antibiotics and interferes with phagocytosis of the organisms.[27] The most commonly reported organism includes *Streptococcus viridans*, but other organisms such as *S. pneumoniae*, coagulase-negative *Staphylococcus*, *P. aeruginosa*, and *Candida* species have also been implicated.[28] The lamellar architecture of the corneal stroma allows the organisms to spread laterally in a crystalline manner.

ASSOCIATED ENDOPHTHALMITIS

Endophthalmitis may occur early or late after penetrating keratoplasty, often with disastrous consequences. It may occur in 4–13% of the cases of graft infection.[2,3,8,13] The sources of infection are contaminated donor tissue or corneal storage media or irrigating solutions. Ulcerative keratitis at the graft–junction may progress to perforation and subsequent endophthalmitis. Anterior vitrectomy performed at the time of penetrating keratoplasty may increase the chance of endophthalmitis by 1.5 times.[29] In cases of corneal graft infection associated with endophthalmitis, intravitreal injection of vancomycin 1 mg in 0.1 mL and ceftazidime 2.25 mg in 0.1 mL should be given along with topical therapy for corneal ulcer.

GRAFT SURVIVAL AND VISUAL OUTCOME

Visual prognosis in eyes with postkeratoplasty graft infection is poor even after successful medical therapy due to corneal scarring after resolution of keratitis and a high rate of graft decompensation. A repeat keratoplasty is required in almost half of the cases.[2,8] Clear grafts following graft infection has been reported in 23–67% cases in various studies.[3,4,13,18] A best-corrected visual acuity (BCVA) of better than 6/60 on Snellen's acuity chart is seen in only 14–30% of the eyes, and only 6% of patients achieved a BCVA of ≥6/18 at the final follow-up in one study.[8] Infections after lamellar keratoplasty are associated with grave prognosis and may not be amenable to antimicrobial therapy.[6] This may necessitate the removal of the graft or a therapeutic penetrating keratoplasty.[6]

CONCLUSION

Microbial keratitis after corneal transplantation represents a serious vision-threatening complication and may lead to visual loss due to corneal scarring, graft failure, or endophthalmitis. It is difficult to restore useful vision with treatment and most of these cases require a regraft; hence, an early diagnosis and appropriate medical or surgical intervention are mandatory in such cases.

54 Glaucoma

Catherine Newton, Linda L. Burk

One of the major causes of graft failure is inadequate control of elevated intraocular pressure (IOP). Although the endothelium may tolerate modest elevations of IOP, as seen in chronic open-angle glaucoma,[1] Bigar and Witmer[2] have shown that significant endothelial cell loss occurs as a result of acute and greatly elevated IOP. It is imperative to recognize and manage glaucoma after keratoplasty so that graft clarity is preserved.

DIAGNOSIS

Glaucoma is defined as elevated IOP sufficient to cause injury to the optic nerve, as evidenced by characteristic loss of the visual field or glaucomatous cupping of the optic nerve disc. Often it is not possible to assess adequately the optic nerve and visual field before surgery or in the immediate postoperative period because of preoperative media opacification and postoperative corneal distortion. The IOP, however, can and must be determined.

In a landmark article by Irvine and Kaufman,[3] attention was called to the association of elevated IOP associated with penetrating keratoplasty and the need for the accurate assessment of the post-keratoplasty IOP. The most accurate commercially available instrument for measurement of the IOP in the early postoperative period is the Tono-Pen.[4] The Tono-Pen reading must be correlated with corneal thicknesses.[5–7]

INCIDENCE

The incidence of moderately to greatly elevated IOP after penetrating keratoplasty is yet unknown. There are reported ranges of 12–27%.[8,9] Pre-existing glaucoma and anterior chamber dysgenesis are the highest risks for development of postkeratoplasty glaucoma.[10] Combined cataract with an artificial lens implant, anterior vitrectomy, and anterior segment reconstruction increase the overall incidence of postoperative glaucoma.[8–10]

PATHOGENESIS

In addition to pre-existing glaucoma, new onset of postoperative glaucoma may develop as a result of any number of mechanical problems, including sequelae of inflammatory conditions, wound closure technique, and paraoperative pharmacologic agents.

BOX 54.1 CAUSES OF ELEVATED IOP AFTER PENETRATING KERATOPLASTY

Inflammatory sequelae
- Fibrinous iritis
- Peripheral anterior synechiae
- Posterior synechiae

Suturing technique
- Compression of angle
- Trabecular meshwork collapse
- Wound leak with loss of anterior chamber volume
- Posterior wound gape with iridocorneal adhesions

Drug-induced elevation
- Corticosteroid
- Viscoelastic substances

Other
- Pupillary block secondary to intracameral air in endothelial keratoplasty
- Ghost-cell glaucoma
- Misdirected aqueous or ciliary block (malignant) glaucoma
- Preoperative angle recession
- Preoperative glaucoma

Bourne et al[11] corroborated the findings of Zimmerman and coworkers[12] by showing that using a 0.5 mm larger donor (punched from the endothelial side) resulted in significant decrease in the incidence of postoperative glaucoma in aphakic patients. The need for disparate-sized grafting is predicated on the use of tight wound closure with resultant tissue compression. Femtosecond laser preparation of the corneal donor button and the recipient bed increases the amount of lineal wound apposition and may accelerate the healing process as well as lessen the need for tight sutures leading to angle compression.[13] In a clinical study comparing the effects of Viscoat (3.8% sodium chondroitin sulfate and 3% sodium hyaluronate) and Healon (1% sodium hyaluronate), 4 of 24 eyes had pressures of 50 mmHg or more despite the surgeon's attempted removal

of the viscoelastic substance at the conclusion of the operation.[14] These pressures occurred at 24 h or less after surgery and there was no difference for either drug. Unacceptably high pressures may be sustained for several hours if no treatment is given.

MANAGEMENT

PREVENTIVE MEASURES

Thoft et al[15] as well as most corneal surgeons advocate the liberal use of topical corticosteroids in the early postoperative period to prevent the sequelae of severe ocular inflammation. François[16] and Goldmann[17] have demonstrated that long-term use of corticosteroids can cause glaucoma in susceptible patients. Therefore, consideration should be given to using fluorometholone-like drugs, including rimexolone (Vexol), loteprednol etabonate 0.5% (Lotemax), or 0.2% (Alrex) in patients at risk of steroid-responsive glaucoma.

MEDICAL TREATMENT

Depending on the cause of the elevated IOP after keratoplasty, medical management in the form of topical β-adrenergic blocking agents, α-adrenergic agonist agents, prostaglandin analogs, miotics, and carbonic anhydrase inhibitors may be useful. Shrader et al[18] found that 45% of the patients over 65 years of age treated with systemic acetazolamide experienced a malaise symptom complex consisting of fatigue, depression, anorexia, and weight loss. Hypokalemia and development of renal calculi are also known risks associated with systemic carbonic anhydrase inhibitors. Therefore, systemic carbonic anhydrase inhibitors must be used with great caution in the elderly keratoplasty patient population.

Topical β blockers are contraindicated in patients with congestive heart failure and obstructive pulmonary disease.

Apraclonidine hydrochloride (Iopidine) and brimonidine tartrate (Alphagan) are relatively selective, α_2-adrenergic agonists. They can be used in the paraoperative period. Suggested dosing would be 1 h before surgery and 12 h after surgery.[19] Although α_2-adrenergic agents have been shown to be effective over the short term, many patients sustain long-term benefits as well.[20] Ocular hypersensitivity to these drugs is a known problem, with the incidence of allergic reaction to apraclonidine being 48%[21] and that of brimonidine 25.7%[22]; however, in patients previously allergic to apraclonidine, only about 23% of those patients will develop an allergic reaction to brimonidine.[23]

The prostaglandin analogs, most notably latanoprost (Xalatan), bimatoprost (Lumigan), and travoprost (Travatan), have been shown to be effective in reducing IOPs by as much as 27–30%, with a single evening dose.[24] Caution, however, must be used in conjunction with corneal transplantation, as the mechanism of action of the prostaglandin analogs may be that of mediating inflammation. Indeed, conjunctival hyperemia is seen in approximately 30% of patients using these medications.[25]

Miotics are known to dilate the ocular blood vessels and break down the blood–aqueous barrier, and they may induce chronic iridocyclitis. Therefore, they are used with caution in eyes that are already inflamed.

Topical carbonic anhydrase inhibitors, dorzolamide (Trusopt) and brinzolamide (Azopt), can lower the IOPs in 17 and 25%, respectively.[26] There have been reports of irreversible corneal decompensation in patients who have had compromised endothelium.[27] Other studies have shown that the long-term effects on the corneal endothelium of dorzolamide are comparable to the β blockers.[28]

LASER TRABECULOPLASTY

Argon laser trabeculoplasty should be considered now that the transient increases in post-treatment IOP have greatly decreased in number with the introduction of apraclonidine (Iopidine).[19] The amount of trabecular meshwork available for treatment may be limited by peripheral anterior synechiae and anterior-chamber intraocular lens haptics. Studies have shown that argon laser trabeculoplasty and selective laser trabeculoplasty have similar 1 year results.[29] Long-term results show a diminishing effect with laser trabeculoplasty.[30]

MISDIRECTED AQUEOUS, CILIOVITREAL BLOCK, OR MALIGNANT GLAUCOMA

In cases of misdirected aqueous resulting in ciliovitreal block, or so-called *malignant glaucoma*, Epstein et al[31] have advocated neodymium: yttrium aluminum garnet (Nd:YAG) laser therapy to the intact hyaloid face. The theory is that the pathogenesis of ciliovitreal block is total obliteration of the posterior chamber by the vitreous body, which comes forward into apposition with the posterior surface of the iris and ciliary body because aqueous humor filters behind the vitreous body. In this situation, a peripheral iridectomy is of no help. They have reported successful therapy with rupture of the hyaloid face using the Nd:YAG laser. Indeed misdirected aqueous may occur even in the presence of a posterior chamber lens and intact posterior capsule. Tomey and coworkers[32] described the use of the Nd:YAG laser with 3–10 mW energy for a total of as much as 375 mJ.

PUPILLARY BLOCK

Pupillary block can occur with air in the anterior chamber following Descemet's automated endothelial keratoplasty procedures.[33] This problem can be addressed by relieving excess air by means of a paracentesis. In some cases, it may be necessary to perform an Nd:YAG laser peripheral iridotomy to relieve this condition.

CYCLODESTRUCTIVE PROCEDURES

Cohen et al[34] reported IOP control in 67% of patients at 1 year after Nd:YAG laser photocoagulation for postkeratoplasty glaucoma. Multiple treatments were required in 13 eyes (46%). Of the 14 eyes with clear pretreatment grafts, 6 (43%) became edematous during follow-up observation. All the failed grafts had multiple treatments. It is difficult to ascertain whether these grafts failed as a result of endothelial damage secondary to previously elevated IOP, inflammation caused by the cyclophotocoagulation, or endothelial rejection. No graft demonstrated classic signs of endothelial rejection.

Endoscopic cyclophotocoagulation has been performed in conjunction with phacoemulsification of a cataract with insertion of an intraocular lens, as well as in conjunction with penetrating keratoplasty via an open-sky approach.[35] Preliminary results are encouraging. The advantage of direct visualization of the ciliary process is touted by reports of successful endoscopic cyclophotocoagulation following previous attempts of trans-scleral diode laser treatments.[36]

SETON SURGERY

Modern seton devices have shown promise in the treatment of refractory glaucoma. While long-term results of keratoplasty in eyes

with glaucoma drainage devices have shown that the glaucoma is well controlled in 74% of eyes the first year and 63% of eyes the second year, the graft survival is not nearly as good. The grafts remaining clear after the drainage devices at 1 year were about 58% and at 2 years about 26%.[37] The main complication of these shunt devices is overfiltration in the early postoperative period, leading to prolonged hypotony, suprachoroidal hemorrhage, and choroidal effusion. Other complications include obstruction of the tube by vitreous or uveal tissue and implant exposure. Temporary tube ligation, anterior vitrectomy, and scleral patch graft have decreased the incidence of these complications.

A study by Arroyave et al concluded that the graft decompensation is significantly less a problem when the tube is placed in the posterior chamber following an extensive pars plana vitrectomy.[38] Increased inflammation may result from the presence of an implanted foreign body. Kirkness et al[39] suggested that inflammatory cells may transverse the altered blood–ocular barrier into the anterior chamber from the area surrounding the subconjunctival seton, causing increased rate of graft rejection and failure.

CONVENTIONAL SURGICAL INTERVENTION

Scarring of the conjunctiva from previous surgery may limit the successful formation of an avascular filtering bleb.[40] In a study of 35 eyes undergoing trabeculectomy for postkeratoplasty glaucoma, Gilvarry and coworkers[41] reported that 70% of eyes were controlled at 9 months and only 50% were controlled at 2 years, and 83% of the successful eyes required additional glaucoma medication to achieve IOP control. Combined penetrating keratoplasty and trabeculectomy with mitomycin-C have been studied in small numbers of patients with variable results. Wu Dunn et al found a relatively high risk of bleb failure within the first 3 months,[42] while Chowers and Ticho[43] found that 85% of eyes undergoing the combined procedure remained with pressures well controlled and clear corneal grafts at an average of 16.5 months follow-up. Adverse prognostic factors included multiple grafts and synechial closure of the angle.

Gilvarry and coworkers[41] considered trabeculectomy in eyes with little conjunctival scarring because there is a relatively low rate of complication. The use of adjunctive 5-fluorouracil with trabeculectomy has been widely investigated. It is known to produce large and persistent epithelial defects, which predispose the patient to microbial keratitis and stromal scarring and thinning.[44] It should be used with caution in the recently grafted eye. The occurrence of postoperative flat chamber has been decreased with the use of delayed argon laser suture lysis of the scleral flap.[45]

SUMMARY

Inadequate control of IOP after penetrating keratoplasty is one of the leading causes of graft failure. For avoidance of this complication it is mandatory that IOP be assessed accurately, early, and often. Careful paraoperative evaluation of the keratoplasty patient, keeping in mind risk factors such as inflammation, mechanical problems, and drug-induced side effects, will lead to better management. Glaucoma is a final outcome, but its pathogenesis is multifactorial. It is incumbent upon the keratoplasty surgeon to attempt to elucidate the pathogenesis of the postoperative glaucoma so that one or more appropriate therapies can be instituted to remedy the problem.

Surgical intervention is often necessary, although significant risks to the graft exist with any proposed procedure. Laser trabeculoplasty may be considered in eyes where a dramatic improvement in IOP is not necessary. Trabeculectomy with or without antimetabolites when the conjunctiva is mobile and not heavily scarred may be indicated. Seton devices are successful, but the rates of graft failure and complications are significant and placement location may be a factor. Endoscopic cyclophotocoagulation may be more precise than trans-scleral Nd:YAG laser cyclophotocoagulation. Ongoing study is needed to determine which of the available treatments will be the surgical procedure of choice in postkeratoplasty glaucoma.

55 Suture removal

Frederick S. Brightbill, Edward L. Shaw

The decision to remove a corneal transplant suture is complex, yet it is critical to final visual outcome and is based primarily on sound clinical judgment.

CRITERIA FOR SUTURE REMOVAL

A crystal-clear corneal transplant with high astigmatism and poor vision does not constitute a successful case. Almost any well-prepared ophthalmologist can tie a nylon suture and close a wound, but the expertise comes in knowing when to remove the suture. Several criteria for considering suture removal appear in Box 55.1.

When the graft–host interface shows a visible, fine wound scar or there is obvious vascularization around a suture, removal is necessary. A loose suture that was not seen previously usually reflects scar formation with wound contracture and should be removed. Otherwise, mucus and debris may become trapped around the suture and provoke a foreign body reaction or act as a nidus of infection. This can also act as an immunologic stimulus leading to graft rejection. Numerous problems may be caused by loose sutures or exposed knots (Box 55.2).[1,2]

A loose suture may cause severe pain, photophobia, blepharospasm, and even blepharoptosis.[3,4] Upper tarsal conjunctival ulcers and giant papillary hypertrophy[5] may occur from loose or irritating sutures and, if conjunctival injection and corneal epithelial trauma continue, iritis may follow, leading to graft rejection and possible failure.

If a suture is too tight, severe corneal flattening occurs in the same meridian as the interrupted suture. Extreme flattening of the center of the cornea in a plateau configuration can be seen with a tight running suture. The impression of a tight suture may be easily confirmed by slit-lamp examination. One may see stress lines in the deep stroma and Descemet's membrane and a 'cheesewiring' effect as the suture cuts through the corneal tissue. The keratometer and corneal topography further confirm the astigmatic effect and irregular corneal surface.

If the knot of an interrupted suture has a long end causing significant foreign body symptoms but the suture cannot be removed because of inadequate wound healing, either cutting or cauterization of the suture end using a low-temperature disposable cautery is warranted. With slit-lamp observation, the tip of the cautery is brought to the immediate vicinity of the suture end and activated momentarily. After release of the 'on' button, the tip is touched to the suture end, melting it into a small, smooth ball. Care must be taken not to burn too closely to the epithelium because corneal ulceration or melting of the suture can occur.

Cutting the exposed suture end is also possible by using one hand to grasp the suture with a jeweler's forceps and the other hand to cut it, using a disposable knife blade. This can be accomplished under slit-lamp control using a lid speculum or with an assistant holding the eyelids open.

WOUND HEALING

Today most grafted corneas heal without obvious vascularization of the graft–host interface. The practice of burying suture knots either on the donor or on the recipient side of the wound has limited the growth of limbal vessels into the donor and resulted in white, quiet eyes with minimal irritation. Transplants with buried sutures require less corticosteroid than in earlier times when surface knots stimulated vascular ingrowth to the graft–host interface and threatened rejection. The object of corticosteroid treatment should be to use as low a dose as possible to limit iritis and vascularization but not interfere with wound healing. After the first few weeks of treatment, that may be as little as one or two drops daily of 1% prednisolone acetate.

Although corneal vascularization is usually a definitive sign of wound healing and an indication for suture removal, it may not be a foolproof sign. In fact, one may often be misled if vascularization alone is used as the sole measure of healing. One must be sure that, in cases of corneal scarring and edema, keratoconus with wound-thickness disparity, and chemical burns, adequate time has elapsed for full wound healing and maximal wound tensile strength.[6,7] This is especially true when one is administering antibiotics, topical and systemic steroids, antivirals, and bandage contact lenses, all of which may significantly alter wound healing while modifying the vascular response. It is well documented that some antibiotics prolong epithelial repair, which is known to be essential for proper

BOX 55.1 CRITERIA FOR SUTURE REMOVAL

A loose suture
A tight suture
Vascularization of the suture tract
Vascularization of the recipient or donor stroma
Pronounced inflammation or infiltration around a suture
Contraction of the graft–host wound
A thin, fibrous 'healed' graft–host wound scar

BOX 55.2 COMPLICATIONS OF LOOSE SUTURES OR EXPOSED KNOTS

Foreign body sensation and pain
Epithelial erosions and ulcers
Corneal vascularization
Dellen
Conjunctival injection
Tarsal ulcers
Giant papillary hypertrophy, conjunctivitis, or both
Blepharospasm, blepharoptosis, or both
Photophobia
Iritis
Infection
Graft failure

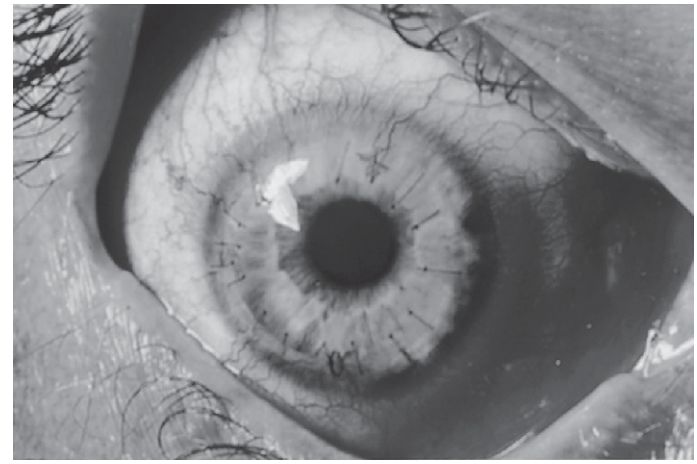

Figure 55.1. A 40-year-old woman with long history of herpes simplex keratitis with pronounced vascularization. Three months after surgery there is exuberant vessel growth over and through suture tracts. Note single 9-0 silk suture needed at time of surgery because of persistent leaking through needle tracts. Six sutures have already been removed.

wound healing. Idoxuridine, trifluorothymidine, and arabinoside monophosphate (the monophosphate ester of vidarabine) cause toxic changes in regenerating epithelium. Interestingly, only the last actually retards closure of corneal wounds while increasing stromal wound strength.[8–10] The first two antivirals reduce tensile wound strength by 50%.[10,11]

Corticosteroids have been implicated both clinically and experimentally in delayed corneal wound healing and in decreased tensile strength.[12–14] This effect is believed to be attributable to the direct reduction in fibroblastic activity at the wound edge. These fibroblasts are derived from the stromal keratocytes, which migrate from the limbal area.[15] The steroid effect, studied with DNA synthesis inhibition techniques, showed 73–82% reduction of cells incorporating isotopes and a 50% reduction in the area of healing.[16,17]

The use of a bandage soft contact lens after keratoplasty to treat an epithelial defect, ameliorate poor surface wetting, or alleviate suture irritation may lead to superficial vascularization, which may give the impression of deep wound edge vascularization. This effect would be very much like that seen when conjunctiva covers a poorly apposed cataract wound. If sutures are removed too soon, wound dehiscence may occur. However, a thick bandage lens or a lens fitting too tightly can cause deep vascularization and provoke graft rejections.[2]

The ultimate dilemma therefore occurs in the treatment of flagrant vascularization of the suture tract (Fig. 55.1). Graft rejection is of great concern and requires an increased dosage of corticosteroids. With more steroid use, wound healing is slowed. If the sutures seem to be provoking vascularization, one may need to remove them, keeping in mind the possibility of wound separation. If maintenance of the vascularized suture is imperative, injection of depot corticosteroid (such as triamcinolone 20 mg) subconjunctivally around the area of donor–recipient vascularization may solve both problems by causing regression of vessels and allowing suture retention. The intraocular pressure must be carefully monitored during this critical time.

The use of an argon laser specifically to close a particularly large vessel leading to an obvious area of the graft or to a suture has been advocated and may be helpful in preventing secondary lipid keratopathy or potential rejection. One of the authors (ELS) has had better success with conjunctival recession and cautery than with the laser. Using either method, the offending vessels have either remained inactive or slowly returned, but with far less aggressiveness.

NYLON SUTURES

Since its introduction in 1968, the 10-0 monofilament nylon (22 μm) suture has become the overwhelming choice of transplant surgeons. Some authorities advocate the use of 11-0 monofilament nylon (16–18 μm) suture combined with the 10-0 nylon,[14,15,18] and 8-0 white silk anchoring sutures are still used, but by only a few surgeons.

The development of this extremely fine, consistent, elastic, and minimally tissue-reactive suture has revolutionized corneal transplantation. The rate of corneal rejection has dropped because of diminished inflammation and vascularization of the wound. The negative side effect of controlled healing is that significantly more time is needed to achieve complete wound healing. Whereas silk sutures require only a few weeks to a few months for wound healing, nylon sutures take months and often a year to achieve the same effect. Wound over-ride and late wound dehiscence may still occur[19,20] but with diminished frequency, because most transplant surgeons now wait 7–12 months to remove the final nylon sutures. This contrasts with studies of wound dehiscence reported in the early and middle 1970s when experience was first being gained in their use.[4,18,19,21–23]

In an attempt to decrease postoperative astigmatism and achieve faster visual correction, the use of multiple interrupted, single, or double continuous sutures or a combination of these methods was developed. These suture closure styles have permitted variations on

the usual timing of suture removal. Development of selective interrupted suture removal and running suture adjustment techniques followed.[24–29]

These early suture removal or adjustment proponents all make the assumption that the manipulation of the wound and hence the corneal curvature in the first months after surgery will ultimately yield lower astigmatism and more stable faster vision. Although it is self-evident that removing a particularly tight suture tends to lower the astigmatism in the offending meridian, there is still no evidence that final vision or suture out astigmatism is affected.

The use of biomicroscopy, careful manifest refraction, keratometry, and topography all aid in the analysis of the offending tight suture. Recent studies have shown, however, that even with the most sophisticated topographic analysis, vector forces can still confound the appropriate axis of astigmatism. It has also been shown that if one were to decide to remove interrupted sutures early, one should remove only one suture at a time to control results better.[29] Consequently, surgeons are committed to conducting sequential additional postoperative visits for suture removal without real documentation of added success. Fortunately, there is only a small risk of complications such as wound gape, excessive meridian steepening and, rarely, wound leak.

Intraoperative adjustment of a single or double continuous suture has never been shown to be reliable because of the forces exerted by intraocular pressure, wound edema, a sutured scleral ring, or the lid speculum. Postoperative continuous suture slit-lamp adjustment should take place after epithelial healing and corneal thinning. The technique requires acquired skill and a gentle touch, usually using sterile tying forceps. The forceps are then used to break through the epithelium and Bowman's membrane, taking care to grasp gently but not pinch the suture. The continuous suture is then pulled, in a rotating fashion, loop by loop from the flatter meridian toward the steeper one. Great care is necessary to avoid twisting or torque to the suture during this maneuver. If the suture appears too tight or does not move easily, then the adjustment should be aborted. Obviously with the double continuous suture technique one usually adjusts the tighter, deeper suture, leaving the more superficial suture alone.

Both authors are still not convinced that the risk-to-reward ratio is acceptable in this problematic maneuver. There is no evidence that the risk of suture breakage and the need for urgent repair justifies the possible, but yet not proven, lowered postoperative astigmatism. Furthermore, it has been shown that the immediate positive results can be quite transient and can regress back to the original measurements.

Other complications related to suture removal[23,30,31] are summarized in Box 55.3.

THE TIMING OF SUTURE REMOVAL

Given the effect of factors such as recipient age, method of suturing, and medication on graft wound healing, an exact timetable for suture removal is of limited value, and only general guidelines follow:

1. In clear, nonvascularized grafts with buried, well-approximated sutures and good visual acuity, there is no need for suture removal.
2. In grafts sutured with both interrupted and running sutures, the usual sequence for removal of the cardinal (anchoring) 9-0 or 10-0 nylon sutures (if not removed at the end of surgery) begins around the fourth to sixth postoperative week.
3. When 16–20 10-0 nylon suture in interrupted fashion alone is used, suture removal is initiated at approximately 3 months and completed between 6 and 12 months.
4. For 10-0 nylon running suture alone, in most cases it is left in place for 7–12 months.
5. When 11-0 nylon suture is used (double running technique), the ophthalmologist has several choices: (1) The 10-0 running nylon suture may be removed between 2 and 4 months and the 11-0 suture left in place indefinitely.[13,32,33] (2) Both sutures may be left in place indefinitely if spectacle refraction provides good vision. (3) When scar formation is noted (6–12 months), either the 10-0 or the 11-0 suture is removed while retaining the other, and refraction is performed 4–6 weeks later.
6. Remove all broken or loose sutures protruding through or above the epithelium (except when no healing has occurred) to prevent induced infection, chronic irritation (which may lead to rejection), and frequent return visits for removal of suture remnants.

In infants and children, where wound healing may occur rapidly (weeks to just a few months), the timing of suture removal becomes extremely critical. Rapid new vessel formation, wound contraction, and loosening of suture[34] may lead to rejection at a much earlier time than in the adult eye. Parents should be encouraged to inspect the eye frequently for increased injection, discharge, or accumulation of mucus around loosened sutures. Often weekly visits are needed so that suture removal can be carried out and inflammation leading to rejection can be avoided.

TECHNIQUE

Many instruments and techniques can be used to remove sutures. Frequently used instruments are listed in Box 55.4.

BOX 55.3 COMPLICATIONS RELATED TO SUTURE REMOVAL

Wound gape
Wound over-ride
High astigmatism
Rapid graft edema
Graft rejection or failure
Endophthalmitis
Glaucoma
Hyphema with vitreous hemorrhage
Retinal detachment
Epithelial downgrowth

BOX 55.4 INSTRUMENTS USED FOR CORNEAL SUTURE REMOVAL

Vannas scissors
Westcott (sharp points) or fine stitch scissors
Razor blade knife (blade breaker)
Beaver blade no. 75
20-gauge needle
Argon or yttrium–aluminum–garnet (YAG) laser
Jeweler's forceps
Tying forceps

Topical anesthesia is used with either 0.5% proparacaine hydrochloride or 0.5% tetracaine hydrochloride given in both eyes. Suture removal may be carried out with the patient seated at the slit lamp, or a microscope may be used with the patient reclined in the office chair. In the former method, an assistant holds the upper eyelid against the supraorbital rim with a sterile cotton swab so that no pressure is exerted against the eye. A razor blade knife is used to cut the sutures in host tissue (when knots are buried in the donor cornea), and a jeweler's forceps removes the sutures by grasping the exposed suture end. The grasped suture is rotated so that the force is directed toward the periphery. This protects against the graft from being pulled away from the host. For recipient-buried suture knots, the opposite technique is performed.

The authors' preferred technique is to cut sutures at the bend or 'V' of the suture and then use the blade of the knife to tease the suture free of epithelium so that there is a long piece of suture to grasp with a jeweler's forceps. A 45° Alcon I-Knife or a no. 75 Beaver microsharp blade, originally used at surgery and then resterilized for one or two more uses, usually suffices.

With running 10-0 nylon sutures, every other loop in the host cornea is first cut, leaving an intact loop that is also grasped in the host tissue and pulled peripherally. Antibiotic prophylaxis, such as neomycin/bacitracin ointment, twice daily for 3 days after suture removal is recommended. Patients are instructed to contact the office if there is pain, excessive redness, decreased visual acuity, or photophobia. Significant change in vision is very common after suture removal, and patients must be forewarned of this possibility. Most patients are then examined 24–48 h after suture removal for epithelial defects, wound override, or dehiscence.

Children or patients with severe photophobia or blepharospasm may need general anesthesia, mask-assisted oxygen with deep intravenous sedation, or peribulbar blocks to facilitate wound inspection and suture removal.

COMPLICATIONS OF SUTURE REMOVAL

The four most commonly encountered problems after suture removal are (1) retained suture material, (2) infection, (3) wound dehiscence, and (4) induced astigmatism.

RETAINED SUTURE MATERIAL

Chronic low-grade inflammation, visual fluctuation caused by changes in astigmatism, and late suture erosion through the graft surface may occur with retained nylon sutures (Fig. 55.2). With running suture wound closure, this is usually not a problem except at the position of the buried knot (usually the 12 o'clock position). With multiple interrupted buried suture knots, however, suture breakage in attempted knot removal may occur, especially if the knot has not been placed close to the graft surface or if a significant amount of stromal fibrosis has occurred around the knot.

Bourne and Maguire[35] have suggested using an argon laser to cut the knot free of the suture in cases where the bulky knot and trailing suture cannot be removed with the usual technique. They use a laser setting of 300–500 mW, 50 μm spot size and a 0.2 s duration pulse. Although this technique seems like overkill, it may serve unique situations and should be considered.

INFECTION

Harris and coworkers[36] reported a large series of 108 bacterial and fungal ulcers in patients who underwent penetrating keratoplasties

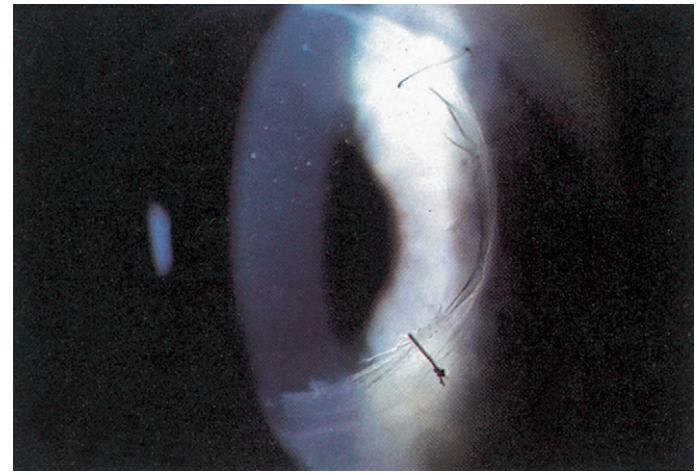

Figure 55.2. White, active keratitic precipitates (KP) in eye with retained, broken, buried 10-0 nylon sutures 8 months after penetrating keratoplasty for keratoconus.

1–72 months before 'an exposed suture having been noted and/or removed.' Thirty-three eyes (31% of total number of infections) had an infection within 10 days of suture removal. Most infections (89%) occurred in eyes receiving corticosteroids and maintenance antibiotics.

It is apparent clinically that the act of suture removal is a potentially dangerous time.[37,38] This is the case presumably because the epithelial surface is broken and mucoid debris and bacterial organisms are introduced into the graft as the nylon suture is rotated out of the stroma. The surgeon must show particular care when cutting and removing loose sutures so as to avoid introducing debris into the graft. Immediately after suture removal, an antibiotic ointment is placed in the eye, and topical antibiotics are instilled for several days thereafter.

WOUND DEHISCENCE

In the event of wound dehiscence, wound over-ride, or wound rupture (Fig. 55.3, *A* and *B*), the patient is scheduled for immediate surgical repair. Most adult patients treated by one of the authors (ELS) undergo repair under topical anesthesia to minimize the chance of further wound separation or even periorbital hemorrhage. The other author (FSB) prefers peribulbar injection before repair. A small percentage of patients (usually children) undergo intravenous sedation or anesthesia standby, or both. If there is only anterior wound dehiscence, interrupted 10-0 nylon sutures are placed in the center of the wound and past the obvious limits of poor wound healing to prevent further wound separation (Fig. 55.3, *B* and *C*). One should take care to pass the needle through the apparently intact wound without touching the wound edges, thereby lessening the chances of further dehiscence. As many sutures as needed are used. If there have been inordinate amounts of wound edema, instead of 10-0 nylon, one author (ELS) uses 9-0 polypropylene, or rarely 8-0 silk, for wound approximation. If there is a broken running suture, it is spliced to a new 10-0 nylon after the graft is aligned with interrupted 10-0 nylon sutures (see Figs 55.3, *B* and 55.4). In cases of complete wound dehiscence or rupture when there is a flat chamber, the anterior chamber is redeepened with air or sodium hyaluronate to separate the iris from the wound during suturing. Subconjunctival cephazolin sodium 100 mg and Celestone (Schering, Kenilworth, NJ) 6 mg are

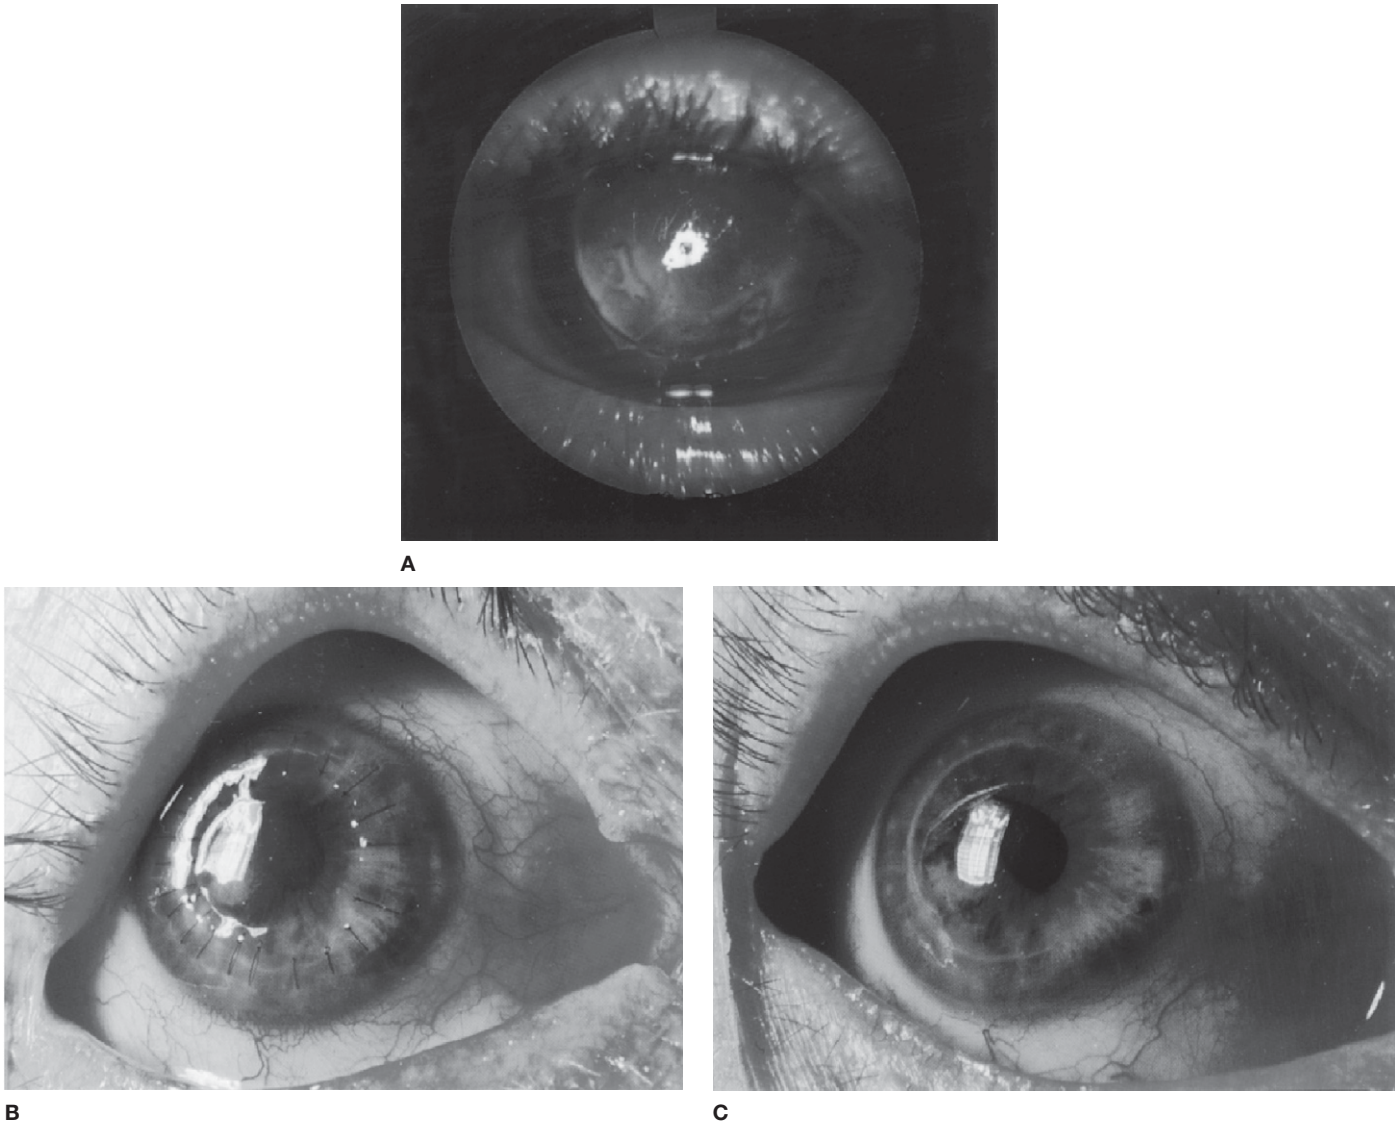

Figure 55.3. *A*, Wound dehiscence at the temporal half 4 days after running 10-0 nylon suture removal 9.5 months after surgery in a 72-year-old man. *B*, Appearance of the same patient 4 months after wound revision and placement of interrupted sutures. Note that nasal sutures are placed in an apparently healed wound as a precaution to further wound separation. *C*, The same patient 13 months after wound revision with vision corrected to 20/40 with a +8.50 +2.00 × 120 aphakic spectacle.

used by one author (FSB). The new sutures are considered as if they were initially placed, and wound healing is judged as previously described.

The overall incidence of wound dehiscence has been estimated at 2–9%.[16,20,21,32] Some cases in earlier reports occurred in the first months after surgery and were attributable to poor healing or necrotic recipient tissue and were not directly related to suture removal. Graft failure rates of 50% after wound dehiscence were reported in the older literature but have declined significantly in the authors' experience in recent years.

INDUCED ASTIGMATISM

Nylon sutures may induce wound compression when tightened because of their inherent elasticity and the need to achieve watertight wound closure at surgery. Many grafted eyes before suture removal have flatter K readings and become steeper (that is, more myopic) after suture removal. Significant changes in astigmatism (either greater or less) may also accompany suture removal.

A word of caution is advisable. Some corneal surgeons advocate observation rather than suture removal in quiet grafted eyes that are without progressive vascularization and have minimal postoperative astigmatism (less than 3.5 D). Many grafted eyes, particularly when the knots are buried, when individual sutures are selectively removed, or when the double running technique is used, have regular mires on keratometry and very acceptable distance and near visual acuity at the 20/30 level. Too many corneal surgeons have shared the unnerving experience of inducing large amounts of astigmatism and patient annoyance by removing compressive sutures in low astigmatic grafts. An evolving concept regarding suture removal in an otherwise quiet eye that is refractable using a spectacle or a contact lens to an acceptable level of vision is to allow the wound to heal as it is with the suture in place.

The trade-offs resulting in some eyes where suture retention is the decided course of action seem to be chronic changes in refractive error (that is, a mildly unstable wound) and very subtle inflammation, particularly surrounding the retained suture with subepithelial fibrosis, and, ultimately in many eyes, late suture breakage with accompanying inflammation (Fig. 55.5).

56 Astigmatism preoperative and operative factors

Sheraz M. Daya, Marcela Espinosa-Lagana

Since the goal of penetrating keratoplasty (PKP) in most cases is visual rehabilitation, maintenance of a clear graft in the long term is only one consideration. The other is to provide a good optical outcome by minimizing astigmatism and refractive error. Understandably there are a number of variables that influence astigmatism; however, standardization of technique and attention to several preoperative and operative factors can be very useful in reducing astigmatism in the long term.

DONOR CORNEA

Pre-existing donor astigmatism and orientation of the donor in relation to the host have been speculated to affect astigmatic outcome. The influence on astigmatism by orientation of the donor in a similar meridian to the host, as in suturing the 12 o'clock point of the donor to the 12 o'clock position in the host, as well as lateralizing for instance right donor eye to right host, was the subject of a multicentric investigation, the OWL (Orientation with Lateralization) study in the UK. The study was inconclusive and not published.[1] Another study, however, demonstrated that donor astigmatism could influence the axis and magnitude of astigmatism, and this could be influenced by orientation of the graft.[2]

HOST DISEASE

Host diagnosis as well as morphology can affect postoperative outcome. In keratoconus, removal of all visible diseased tissue encompassed by the Fleischer ring provides some reassurance that the rim will be thick enough for the donor and continued ectasia in the rim will be avoided. However, there have been reports of continued inferior ectasia and elevation 10–15 years postoperatively, with induced astigmatism successfully treated by wedge resection.[3,4] There are several possible mechanisms of this progressive astigmatism, including progressive corneal thinning of the host cornea, progressive misalignment of the graft–host interface over time, and recurrence of keratoconus in the graft. With newer imaging tools for the cornea, including corneal tomography and particularly ocular coherence tomography, it will be easier in the future to determine the true cause of progressive inferior steepening (Fig. 56.1).

Inflammatory disease such as *Herpes simplex* may result in a thin vascularized rim, which can affect outcome as well as the postoperative course. Sectoral vascularization can lead to differential healing, again making the astigmatic outcome unpredictable. Selective early suture removal in these instances may minimize the effect of wound healing and lends support to the use of interrupted sutures in these instances.

HOST TREPHINATION

This is felt by many to be one of the greatest influences in astigmatism, and the objective of predictably reproducing a similar cut from one case to the next has influenced the production of numerous devices and approaches. The goal of host trephination is to cut the cornea as vertically as possible.[5] Most trephination methods commonly used, including freehand and the Hessburg–Barron, result in cutting outward with a larger opening on the endothelial side compared with the epithelium. The pressure exerted on the cornea while trephining, the intraocular pressure, as well as the method of suction fixation (whether to the sclera or cornea) all influence the degree of outward sloping. Low intraocular pressure can be elevated by injection of viscoelastic through a limbal stab incision prior to trephination. Corneal fixation by the Hessburg–Barron trephine is felt to increase the overcut by drawing the peripheral cornea into the outer ring. The Barron trephine works on similar lines; however, it has 16 compartments to minimize the displacement of peripheral cornea. The more sophisticated Hanna- and Krumeich-guided trephine systems both attempt to minimize overcutting posteriorly and provide suction fixation onto the sclera. Both systems are excellent; however, they are complex and can be expensive.[6] An alternative system that appeared to be promising was the Asmatome.[7] This is a motorized system that uses vacuum fixation on the central portion of the cornea and draws the cornea (both host and donor) into a rotating motorized trephine. A comparative study did not demonstrate any convincing evidence of the benefit of this system over other similar trephination systems.[8]

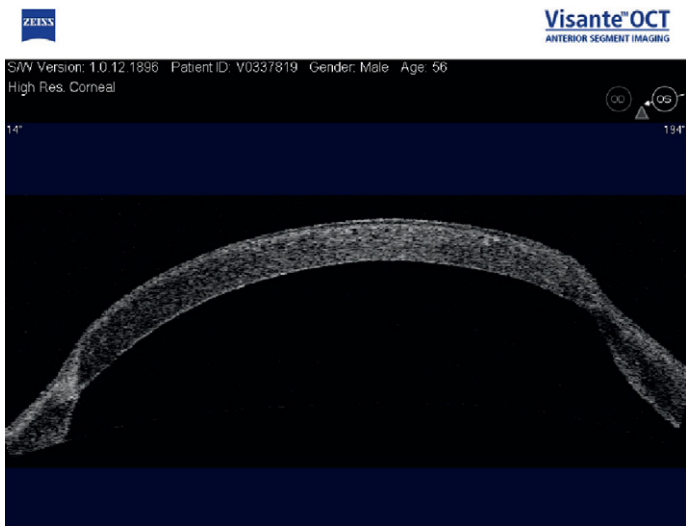

Figure 56.1. Visante (Courtesy of Zeiss-Meditec) ocular coherence tomography (OCT) image of the left eye of a patient who received a corneal graft 26 years earlier for keratoconus. The image demonstrates peripheral corneal thinning outside the corneal graft accounting for graft tilt and inferior steepening with high astigmatism.

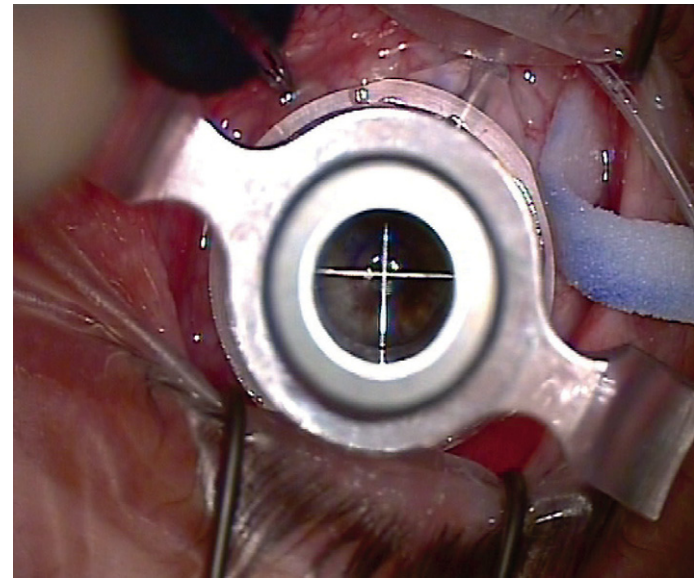

Figure 56.2. Daya Disposable Recipient Trephine System (Courtesy of Network Medical, UK), which uses scleral vacuum fixation to accurately guide an ultrasharp trephine.

Eccentric trephination on the host can induce astigmatism.[9] Centration is best ensured by carefully marking the center of the cornea. The correct location can be confirmed using calipers. Using a 3 mm optic zone marker around the central mark also provides a further point of reference during trephination.

TREPHINE QUALITY

Trephine quality in terms of sharpness can have considerable influence on cut quality. Newer developments in nanotechnology, including ion-forging of trephines, in combination with nanostructured carbon coatings can produce high-quality cutting edges, which are more stable with diamond-like properties.[10] With improvements in sharpness there is a reduction in the necessary force and consequent corneal deformation, resulting in a better cut with less posterior overcutting. However, sharp trephines are less forgiving and a guided mechanism is helpful in avoiding decentered and tilted cuts, and contributing to a more vertical cut (Fig. 56.2).

POSTERIOR LEDGE

The surgical technique of leaving a posterior ledge compensates for the overcutting and assists in producing a self-sealing incision. The ledge is created by trephination to over 90% of the cornea depth, preferably to Descemet's membrane, and then cutting the host button out with beveled corneal scissors. If performed correctly with a thin and narrow lip, the possibility of graft tilt is minimized and closure can be accomplished with loose sutures without the danger of a wound leak (Fig. 56.3). Excessive compressive forces of sutures to ensure closure are avoided, thereby minimizing astigmatism. On the other hand, a thick or irregular posterior lip can lead to graft over-ride and potentially increase astigmatism. The posterior lip is best examined after removal of the button to ensure that it is equally thin for 360°. If not, it is best removed entirely with curved corneal or Vannas scissors. Another technique to prevent graft over-ride is to make radial cuts in the ledge, decrease resistance from the ledge, and minimize over-ride, and still accomplishing the goal of wound security.

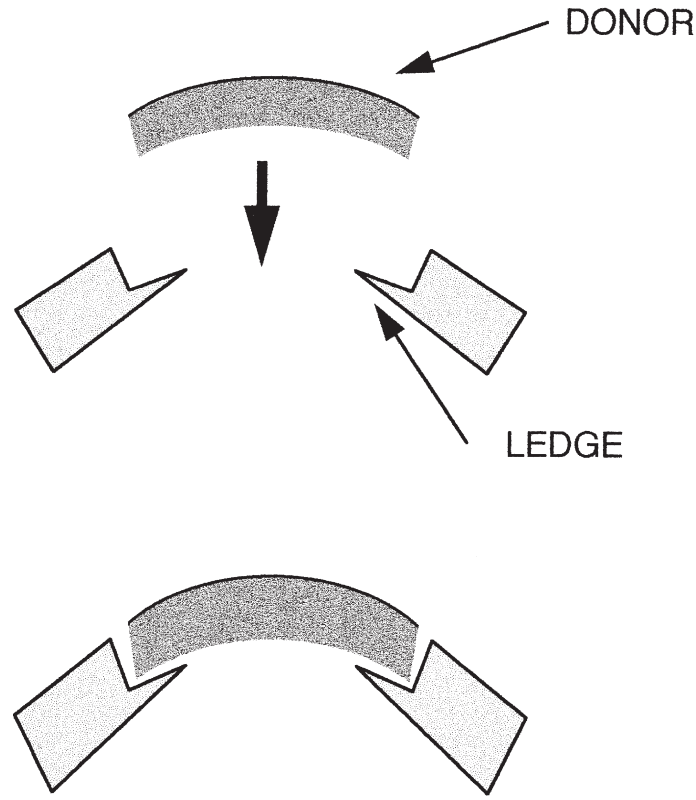

Figure 56.3. Schematic to demonstrate the benefit of a recipient ledge in preventing wound leaks and permitting loose suture closure. The posterior lip avoids tilt and acts as two-step incision, decreasing leakage and chamber flattening during surgery.

DONOR TREPHINATION

Most commonly, donor trephination is performed by cutting from the endothelial side to the epithelium. The rational basis for this is

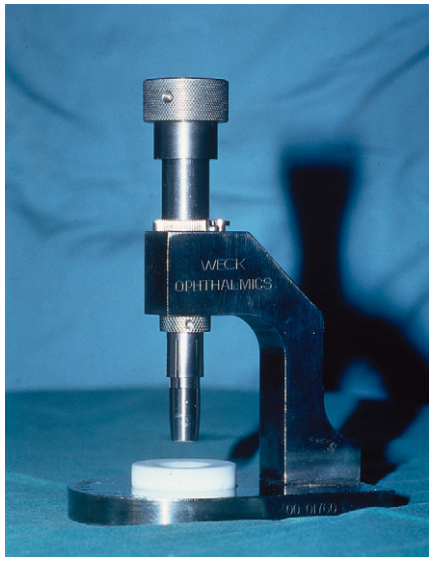

Figure 56.4. The Iowa Press (Courtesy of Bausch & Lomb Storz, Rochester, NY, USA), for donor creation cutting from the endothelial side to the epithelium.

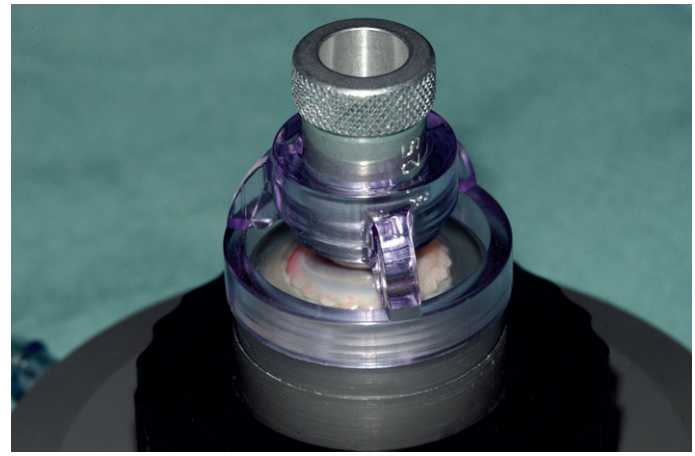

Figure 56.5. Donor preparation cutting from anterior to posterior using a disposable anterior chamber (Courtesy of Coronet Network Medical, UK).

to protect the endothelial surface and it is best accomplished by a vertical punch such as the Iowa Press (Fig. 56.4) or the Barron disposable donor punch. Centration as well as good apposition of the donor on the donor block helps to ensure a vertical and round cut. Compound curved donor Teflon wells with centration circles help to achieve these goals. Oversizing the donor by 0.25–0.5 mm compensates for the overcutting that generally occurs in host trephination. In high myopic cases such as keratoconus, the use of the same-size donor in effect undersizes the donor[11,12] in relation to the host, producing corneal flattening with reduction of myopia.[13]

Another approach that has become more popular has been to create an artificial anterior chamber and cut the cornea from the epithelial side in the same manner as the host using the same-size trephine. This is accomplished using nondisposable systems such as the Krumeich-guided trephine and Hanna systems. Disposable systems such as the Coronet (Network Medical, UK) are now available (Fig. 56.5). Theoretically the wound configuration in the host and donor will be identical if same-size trephines are used and the pressure of the artificial anterior chamber is similar to the recipient eye. Use of this approach has not been shown to minimize astigmatism.[14]

LASER TREPHINATION

Excimer laser trephination has been advocated by Naumann, who has suggested that high astigmatic change following suture removal can be decreased using this technique.[15] The technique, however, has not become popular partially because of limited access to this costly technology. Additionally, excimer laser trephination with existing lasers does take considerable time to accomplish complete trephination. Femtosecond laser technology has been used to perform trephination and is currently under investigation. This will be discussed briefly below under 'Future Directions.'

EXTERNAL COMPRESSION

An oval opening in the host will produce astigmatism. A speculum that places force on the fornices and globe can contribute to ovalization. The use of a three-dimensional speculum with rotatable blades like the Schott speculum (Katena Instruments, Denville, NJ) with rests placed on the forehead and cheek removes pressure from the globe. Decreasing the aperture size also reduces pressure on the globe but at the same time can reduce access to the eye.

The Flieringa ring is useful in maintaining scleral support and ensuring a circular opening when used in aphakic cases; however, when sutured in place improperly, it can produce an oval or distorted opening.

An oval opening sometimes cannot be avoided, for instance in keratoconus eyes, where the host rim has a tendency to retract, especially inferiorly. Compensation for an irregular opening can be made by careful placement of cardinal sutures and further interrupted sutures.

CARDINAL SUTURES

This is probably one of the most important operative factors in minimizing astigmatism. These sutures influence correct placement of the donor within the host and must be placed symmetrically. Placing 8- and 12-blade radial keratotomy markers on the host prior to trephination provides useful reference marks for symmetric suture placement. The second suture is considered the most important and is placed at the point where the donor cornea is bisected by toothed grasping forceps. A useful tip is to let go of the needle when it has been passed through the donor and into the host. The cornea is inspected to ensure that it is symmetrically placed without over-riding on either side (Fig. 56.6). If the needle is incorrectly placed, it can be withdrawn from the host and repositioned. A similar maneuver can be used for the 3 and 9 o'clock sutures.

SUTURING

There are many methods of suturing the cornea to minimize astigmatism, and each method has its own supporters. Whichever method is used, sutures should be passed as vertically as possible into the donor cornea to 90% depth and passed through just above Descemet's membrane. The needle should pass through the host at the same level and up vertically.[16] Depressing the posterior ledge and leveling the needle so that it appears that it is going 'downhill' is a good method to ensure maximal depth on the host. Because of the vector forces created, a shallow and sloped bite on the donor

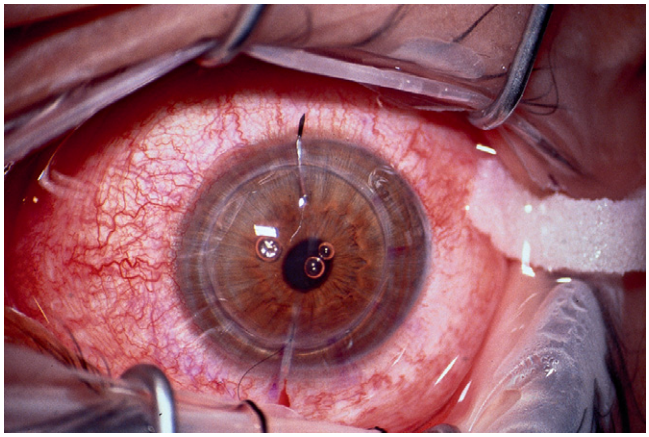

Figure 56.6. Graft alignment checked by releasing needle from the needle holder prior to complete passage.

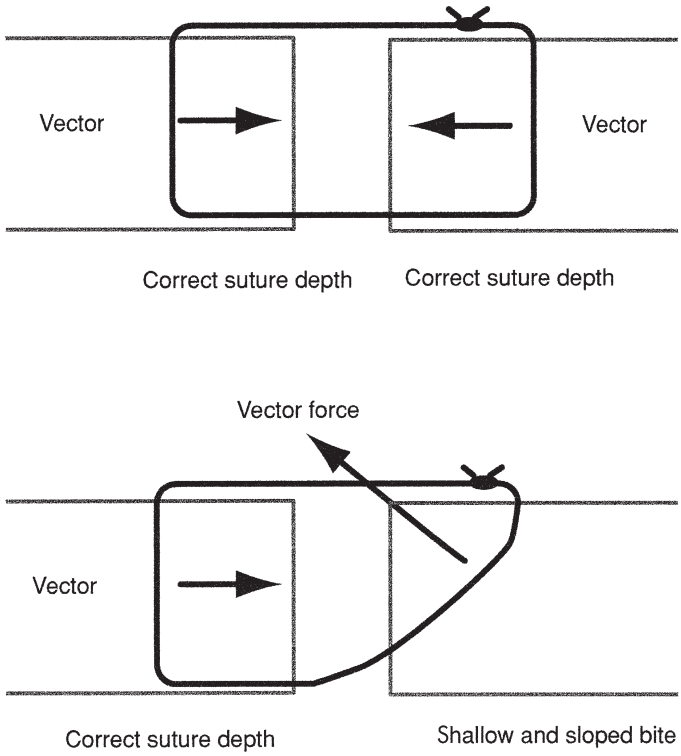

Figure 56.7. Schematic comparing the vector forces induced in a correctly placed suture compared with a sloped and shallow bite on the donor.

can lead to an over-ride, and a similar pass on the host can lead to an under-ride on the donor, both contributing to astigmatism (Fig. 56.7). Compound curved needles such as the CU8 needle (Alcon, Fort Worth, TX) help considerably in attaining short deep bites on the donor and host. Deep bites on both donor and host are easier to achieve using interrupted sutures.

Sixteen interrupted sutures provide excellent graft–host apposition; however, selective suture removal for early visual rehabilitation cannot be performed without risking graft dehiscence. More recently, because of improved graft stability derived from interrupted sutures, many corneal surgeons have been using 22 and 24 interrupted sutures and, although able to, find less need to selectively remove sutures during the early postoperative period. A 24-bite running suture is favored by many, as this suture can be adjusted operatively and postoperatively.[17,18] The Hoffmann double running suture is favored by many surgeons in some parts of Europe; however, it has not been demonstrated to be of any particular advantage in terms of astigmatism.[19] A combined 12 interrupted and 12-bite running suture combines the best of both worlds, but takes longer to perform.

On completion of suturing, qualitative measurements using reflective devices such as the Maloney ring can be used to adjust sutures to ensure that a circular mire is obtained. Surgical quantitative keratometers such as the Smirmaul or Varidot can be used, although a clear advantage has yet to be demonstrated.

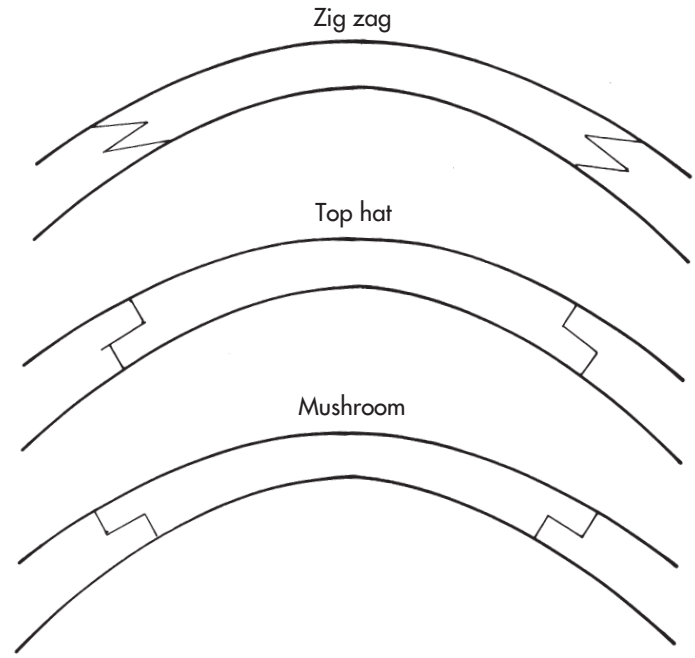

Figure 56.8. Schematic of the Steinert 'zig-zag' geometric configuration using the Intralase Femtosecond Laser (Courtesy of Intralase Inc., Irvine, CA).

FUTURE DIRECTIONS

FEMTOSECOND LASER TREPHINATION

The femtosecond laser approved for making cuts within the cornea has been popularized in refractive surgery and has become increasingly popular in flap creation. It has the advantage of being able to perform formed cuts in the cornea on both donor and recipient. A variety of geometric patterns including a top-hat, mushroom, and several 'tongue and groove' patterns have been developed, and preliminary evidence suggests that this results in better graft–host apposition with reduced astigmatism (Fig. 56.8). Experimental evidence has already demonstrated improved mechanical stability using the top-hat configuration.[20]

INTRACORNEAL RING (KRUMEICH)

A novel concept of incorporating an alloy ring (8 mm cobalt–molybdenum–titanium) in the graft–host wound has been pioneered by Krumeich and demonstrated to not only reduce astigmatism but also allow for postoperative manipulation to reduce astigmatism

further by intentional shape deformation. Recent evidence presented suggests that the ring not only arrests vascularization of the donor corneal button but also reduces the risk of graft rejection. The mechanism for this is unclear.[21]

SUMMARY

There are a number of pre- and postoperative factors that influence astigmatism. The more important aspects are preparation of both donor and host, as well as suture placement and proper wound apposition. Adherence to many of the concepts described above certainly minimizes astigmatism in both the long and the short terms. In spite of new technology, including improved trephination, basic principles and methods to minimize astigmatism are essentially unchanged.

Neither author has proprietary or financial interests in any of the products or materials described.

57 Contact lens fitting after penetrating keratoplasty

Christine W. Sindt

Contact lenses fitted after penetrating keratoplasty (PKP) are usually provided either for therapeutic reasons, for example a soft lens used to treat a persistent epithelial defect or to correct residual refractive error, especially astigmatism.[1]

THERAPEUTIC FITTING

Hydrogel (soft) contact lenses have a long and well-accepted history of therapeutic applications. In PKP patients, these are primarily used for relief of pain, mechanical protection for a denuded or eroded corneal epithelium, maintenance of corneal hydration, barrier protection from the action of the lids or lashes, retention of medication in the eye during the few days after surgery, and the general promotion of ocular healing.

In the past, most practitioners have utilized conventional disposable HEMA-based (hydroxy-ethyl-methyl-methacrylate) hydrogels for these therapeutic purposes. HEMA lenses have widespread availability and low or negligible costs. HEMA lenses are commonly available in mid-to-high water content polymers. Ultrathin disposable hydrogel lenses should be avoided, as they may wrinkle and not provide adequate splinting function. While HEMA lenses may appear to move satisfactorily during the first few minutes of lens evaluation, their dehydration on the eye after 30 min or longer may make them behave in a much tighter fashion. As such, it is important to evaluate these lenses after at least 20–30 min on the eye, as well as in follow-up visits.

Penetrating keratoplasties often require regular use and overnight wear for several days to re-establish a barrier to infection and to prevent subepithelial scarring. Silicone hydrogel lenses are superior in this regard as they provide increased oxygen flux compared to conventional hydrogel lenses. Additionally, the risks of secondary microbial infection, while not entirely eliminated, are greatly reduced with the use of a silicone hydrogel (SiHy) lens.[1–4] SiHy lenses do have a stiffer modulus, which will translate into occasional lens awareness for some patients, although this settles quickly. The overall pain relief that it provides is far greater than any minor issues relating to modulus awareness, so this rarely is a problem.

Some disposable lenses are only available in one base curve and thus may potentially gape or move excessively and further aggravate a fragile or damaged epithelium (Fig. 57.1). Conversely, the lens may be too tight, preventing tear and cellular debris exchange (Fig. 57.2). The use of a steeper fitting lens with less movement may be more appropriate in cases involving pain relief or in splinting of the corneal surface. A lens that provides more visible movement is preferred, however, in cases of a corneal epithelium that is eroded, damaged, or absent.

FITTING METHOD

Centration with complete covering of the graft–host sutured junction, comfort, and slight movement on the blink are key signs to achieve satisfactory fitting. The patient is instructed to wear the contact lens until follow-up, which may be as soon as 1 day or as late as 1 week, depending on the physician's level of comfort and expectations of the problem being addressed. Treatment with an antibiotic, cycloplegic, and nonsuspension corticosteroid drop is given in the usual doses after keratoplasty.

When no underlying recipient cause exists for epithelial breakdown in the donor (such as exposure, dryness, or graft–host wound disparity), a therapeutic lens usually achieves healing in 1–2 weeks. Artificial tears such as 0.5 and 1% methylcellulose, guar-based agents like the Systane® (Alcon Laboratories, Fort Worth, TX) line of products, or thicker agents such as Refresh PM or Lacri-Lube (Allergan, Irvine, CA) should be used to maintain wetting of the corneal graft surface. Preservative-free products are preferred, when possible, to avoid a toxic keratopathy.

OPTICAL FITTING TO CORRECT REFRACTIVE ERROR

Among the most significant factors in the determination of final transplant astigmatism are the donor cornea, recipient disease, external compression factors and intraocular pressure (IOP) during trephination, graft centration, donor button to recipient bed size, tissue malapposition, suture placement, wound healing, and suture removal. Since no one surgical technique has eliminated the problem of astigmatism, the surgeon must be prepared to manage the frequent complications of both irregular and high corneal graft

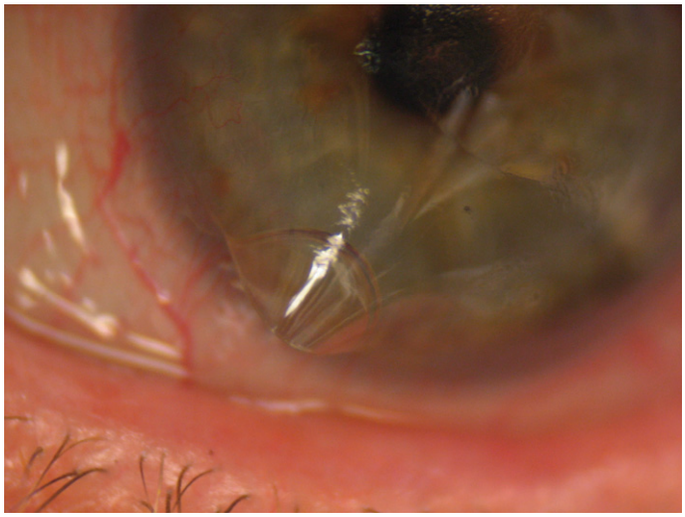

Figure 57.1. Highly irregular or steep corneas will prevent proper draping of soft contact lenses.

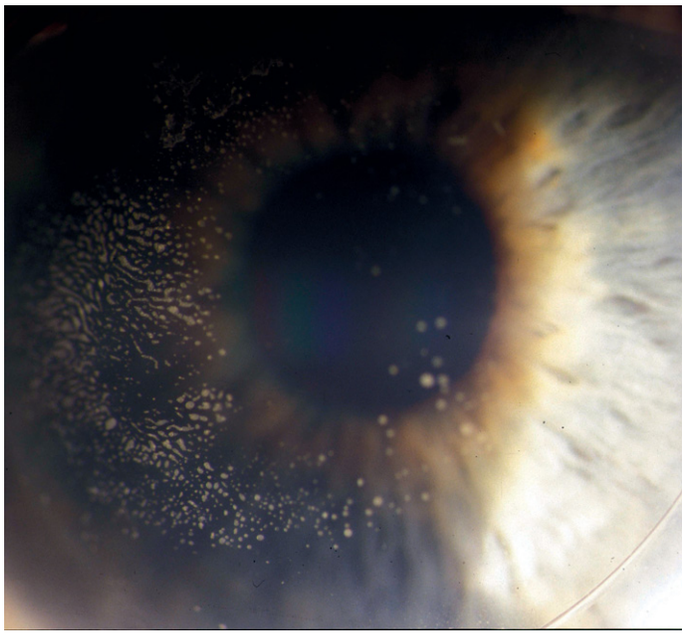

Figure 57.2. Mucus debris under a lens with poor tear exchange.

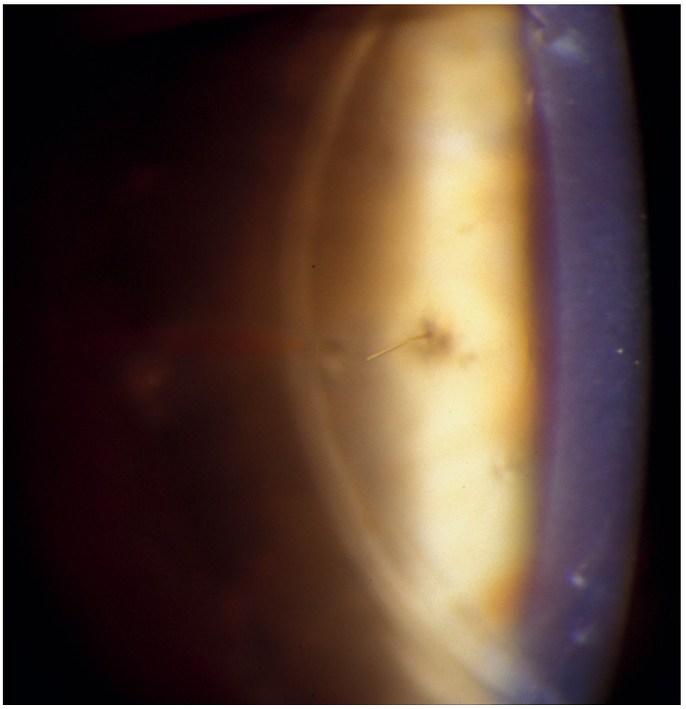

Figure 57.3. Loose or broken sutures must be removed to avoid discomfort and decrease risk of infection or inflammation.

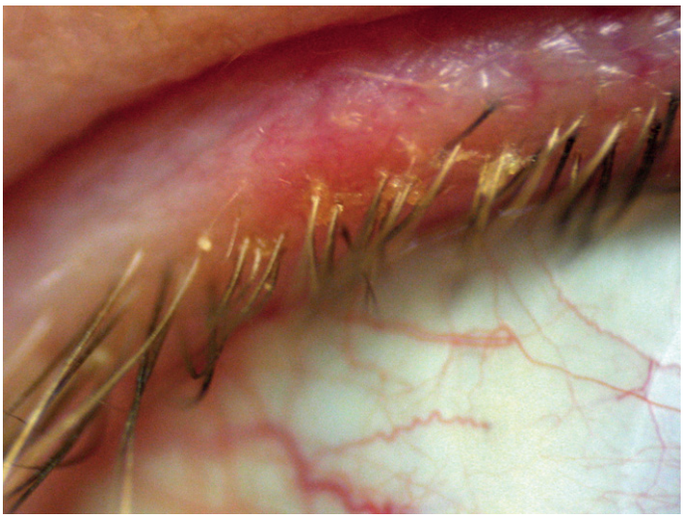

Figure 57.4. Post penetrating keratoplasty patients are wary of touching the eye area. Lack of lid hygiene may exacerbate lid disease, complicating contact lens fitting.

astigmatism.[3,4] Anisometropia is also common following PKP, especially if cataract surgery is concomitantly performed or if the patient had particularly high pre-existing refractive error. Contact lenses have been traditionally implemented to improve visual performance of optical errors after PKP.

The percentage of PKP eyes receiving contact lenses will vary, depending on the surgical technique, the surgeon's amicability toward contact lenses, and the relationship between the contact lens fitter and the referring physician.

TIME OF FITTING

A contact lens may be fitted anytime after the wound has healed and if there is intact epithelium over the corneal sutures. To avoid frequent and costly changes, it is best to wait until selective suture removal has been performed to the surgeon's satisfaction and the corneal topography is stable. Contraindications for optical contact lens fitting include persistent epithelial defects, inflammation, loose sutures, corneal infiltrates, and lid disease (Figs 57.3 and 57.4).

CONTACT LENS OPTIONS

Both soft and gas-permeable (GP) lenses have been used for post-PKP optical correction. Soft lenses have limited ability to correct irregular astigmatism; they also have a higher risk of infection and inflammation. In some cases, soft lenses may be useful to piggyback a GP lens; however, we will primarily limit our optical correction discussions to the use of GP lenses.

Hard versus soft lenses

The author's bias is toward GP lens fitting in grafts, for the following reasons:

1. The average refractive graft astigmatism requiring contact lens fitting is between 4 and 9 D. This precludes sharp visual acuity with most soft lenses.
2. Decreased corneal graft sensation allows for moderate comfort with GP wear compared with the cosmetically fit eye.
3. GP lenses are more durable, more easily verified, easier to clean, have high oxygen transmission, and are less likely to spoil.

GP LENS DESIGN

GP lenses can be classified into (1) corneal designs, (2) scleral designs, and (3) hybrid designs.

All GP lens designs are fitted using fluorescein to determine alignment. Areas of paracentral lens–graft touch and strange astigmatic patterns are invariably seen. The objectives of fitting are to limit this touch and to design a peripheral curve system that allows for adequate tear exchange. It is important to evaluate the fluorescein pattern before the lens is dispensed since small changes in lens design will have a large effect on the overall sagittal depth of the contact lens and will result in a significantly different-looking lens fit (Fig. 57.5, *A–D*). Peripheral curve and edge modification can be done in the office; however, with today's materials and computer-driven lathe technology, it is best to have the lens remade through the laboratory; this ensures repeatability on remakes and decreases future chair time.

As soon as the lens has been examined on the eye and found to be satisfactory, the lens can be dispensed. Dispensing includes practicing insertion and removal of the lens under technician observation and thorough instructions in the cleaning and care of the lens. Wearing schedules are comparable with those in cosmetically GP fit eyes, with all-day wear by 1 week (Table 57.1). The patient is instructed to return to the office immediately if redness, secretions, visual blurring, or pain (RSVP) should occur.

The patient is followed at 2 weeks after the initial dispensing, 1 month after that, and then at 6-month intervals. At each visit, the lens fit is evaluated, the lens is removed to check for graft complications, and the lens itself is verified to make sure that the parameters have not changed (and to make sure that the patient has the correct lenses in the correct eyes).

Corneal designs

Corneal designs include spherical, front toric, back toric, bitoric, larger or smaller diameters, and rotationally asymmetric and reverse geometry. In general, it is best to start with spherical lenses of varying diameters before trying to work with an alternative design.

A lens centered directly over the graft is in the ideal position. Perfect centration, however, rarely occurs in grafts with high or irregular astigmatism, a decentered button, or a peripheral wound irregularity. In difficult cases, even after many lens trials and modifications, the best lens fit may still have the patient apparently looking through the edge of the lens. If the patient sees well and has good comfort and the graft health is not compromised, a decentered fit is acceptable (Fig. 57.6).

Scleral designs

Scleral lenses primarily fit the sclera and vault the irregularity of the cornea (Fig. 57.7 *A* and *B*). These lenses offer superior comfort and handling compared to other lens types. New lens materials supply adequate oxygen transmission, however, in this author's experience, scleral lenses should not be fitted on eyes with endothelial cell counts of less than 1000 (Fig. 57.8) to avoid edema. Around 800 cells seem to be where problems arise, so 1000 leaves a margin of safety.

Scleral lenses are fitted based on sagittal depth as opposed to keratometric readings. While there are formulas to calculate the sagittal depth of the eye, a fitting set is the easiest way to determine necessary vault. The amount of sagittal depth of the eye is determined by the horizontal visible iris diameter, the corneal curvature, and the eccentricity value of the peripheral cornea.

The diameter of the scleral lens will determine the fitting technique, and the manufacturer should be consulted on the subtleties of a particular lens. In general, the lens should exhibit alignment with the sclera, without impingement of blood vessels (Fig. 57.9, *A* and *B*). There should be pooling in the limbal area and either complete vaulting or gracing touch over the central cornea. Notches can be cut in the periphery of scleral lenses to prevent impingement of pinguecula blood flow (Fig. 57.10).

Larger (18 mm or greater) lenses will create a suction on the eye. It is necessary to break the suction before removal. This is easily done by pressing on the eye and does not seem to be a deterrent to patient compliance or health of the graft (Fig. 57.11). Fenestration holes may be added in the limbal pooling area to relieve the suction effect and aid with removal of scleral lenses smaller than 18 mm. Larger lenses, however, cannot have fenestration holes due to pooling of air in the optical zone.

Hybrid designs

Hybrid lenses (rigid center and soft skirt) aid in the centration and comfort of the contact lens. The Synergeyes® (SynergEyes Inc, Carlsbad, CA) lens has a central GP lens with a Dk (oxygen transmission) of 100 and a 31% water low Dk skirt. These lenses are not intuitive to fit; they are fit much steeper than expected and, if the lens exhibits tightening, the lens fit must be made steeper yet. The lens should move vertically with the blink, like a standard soft contact lens.

The GP portion of the Synergeyes® lens is 8.2 mm, which is the average size of the donor button. One must watch the lens cornea junction to avoid corneal erosions. High cylinder corneas will induce flexure of the lens, and over-refractive cylinder will be demonstrated.

GP LENS MATERIALS

GP lenses are available in a variety of oxygen transmissibility, surface wettability, and button diameters. It is best to discuss the specific needs with the laboratory when selecting a material.

MEASURING THE CORNEAL CURVATURE

Topography is most helpful when analyzing a cornea for a contact lens fit. Elevation data are significantly more useful than axial images. Tangential maps, while having limited use in diagnosis, are of no value in contact lens fitting.

Axial maps describe rate of change. The axial map may be useful in selecting an initial base curve of the contact lens; however, it does not give information on how the lens will perform on the eye.

The elevation map, however, depicts the highs and lows of the cornea. This map is particularly useful in discerning where the lens

will ride (always over the highest elevation, unless the eyelid forces are particularly strong) and where problematic areas of erosions may occur.

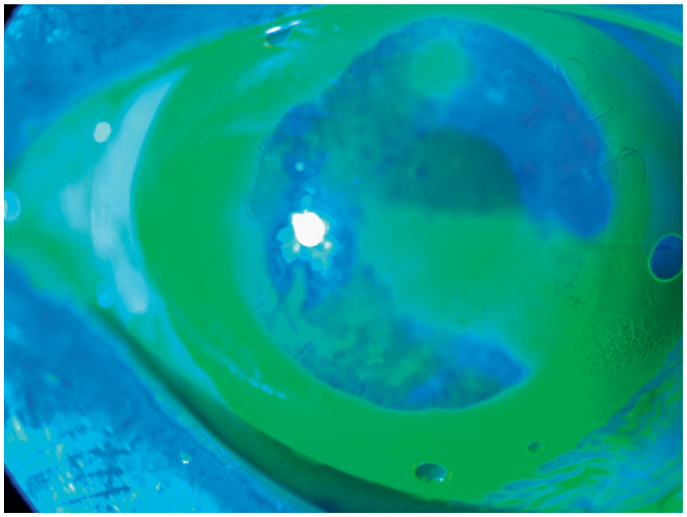
The fluorescein evaluation of a contact lens will correspond to the elevation map. Areas of touch correspond to the red or elevated areas on the elevation map, whereas on the axial map the red areas simply refer to the areas of greatest curvature, which could either represent an elevation or a dip in the cornea.

POST PENETRATING KERATOPLASTY TOPOGRAPHY AFFECTING THE CONTACT LENS FIT

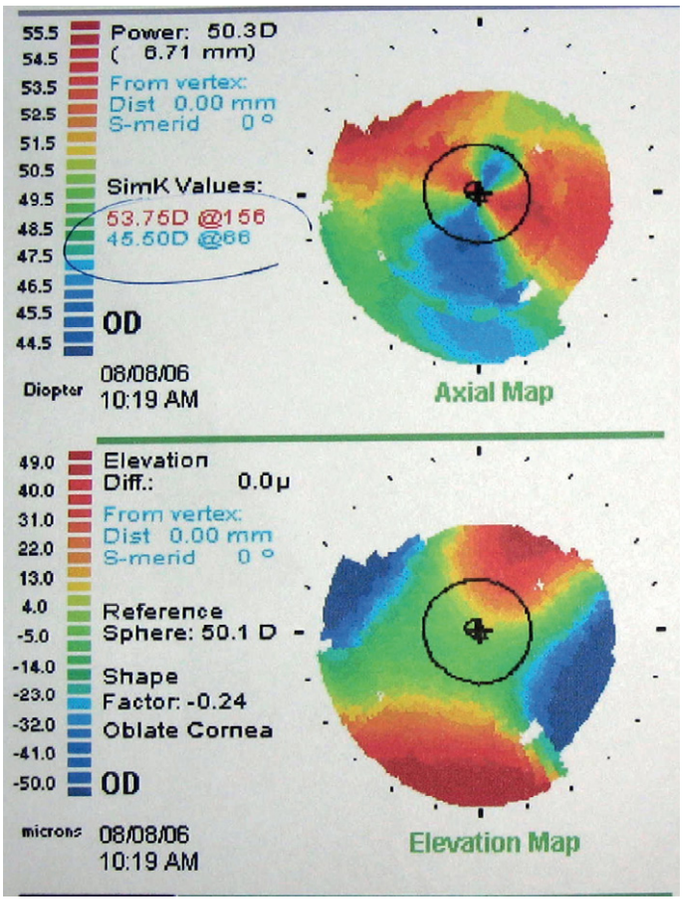
Lens design and selection is based on the topography of the eye.

The plateau graft

A plateau graft, also commonly called a drum head graft, has a relatively flat center and steeper periphery (Fig. 57.12). A plateau graft may result from several factors, including tight stitches, low IOP at the time of surgery, or a button that is less than 0.5 mm larger than the host. A relatively small button is frequently used in patients with keratoconus in order to reduce myopia. Therefore, a plateau graft is relatively common in this setting.



A



B

Figure 57.7. *A,* Scleral lenses align in the periphery and mask the irregularity of the cornea. *B,* The corneal toricity of the topographer corresponds to the fluorescein pattern of the contact lens.

This type of graft is arguably one of the most difficult to fit with a contact lens. It is also difficult to surgically correct and is best to avoid it at the time of surgery. Postsurgical correction includes resuturing or removal of the running suture.

A standard designed GP, such as typical 9.0 mm lens, is a very bad option for a plateau graft. The lens will decenter and align over the graft–host junction. Air bubbles will be trapped under the

Figure 57.9. *A,*Tight peripheral curves will indent the sclera and impinge blood flow. *B,* Removing the lens will cause rebound hyperemia and inflammation.

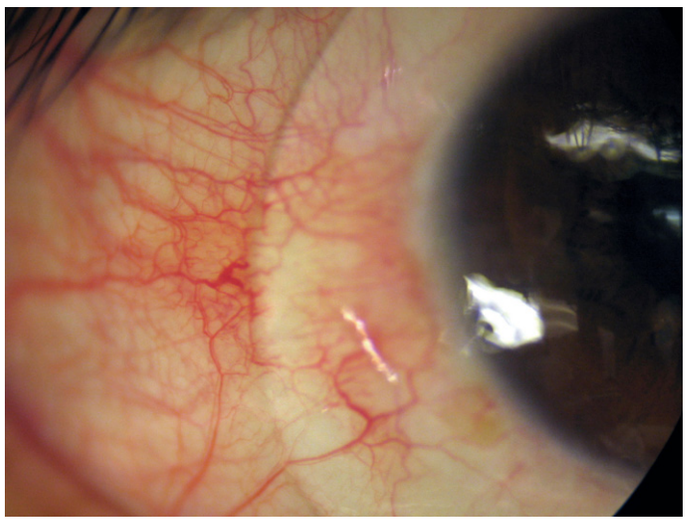

Figure 57.10. Local blood vessel impingement may occur over pinguecula causing inflamed pinguecula and subsequent lens intolerance. Notches can be cut out of the lens to relieve impingement.

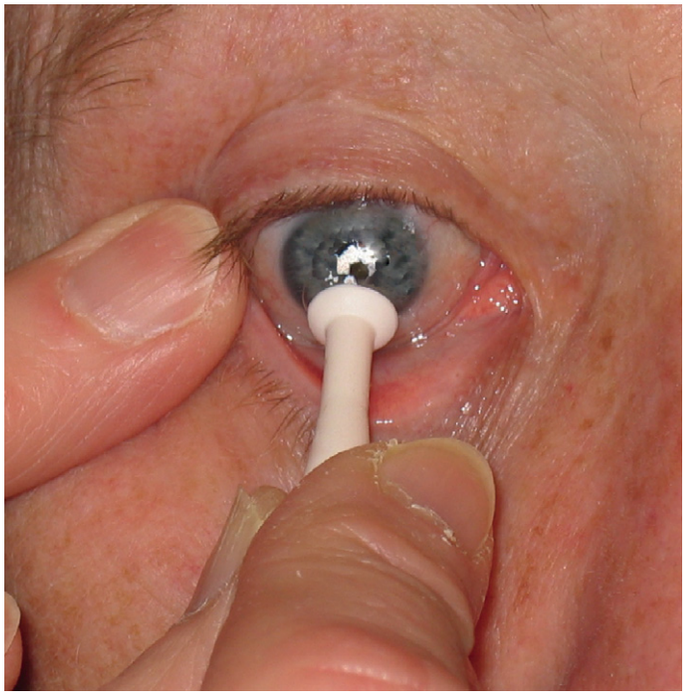

Figure 57.11. Suction must be released before removing lens. Place plunger in inferior one-third of lens. While lifting up on the plunger, push in on the globe to break the seal.

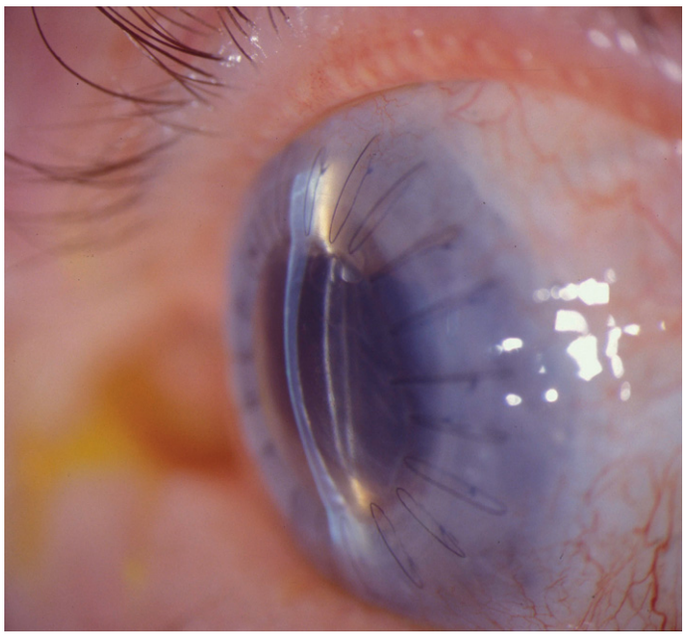

Figure 57.12. Centrally flat plateau grafts are often the most challenging to fit.

lens and/or there will be inferior edge lift off. Small, flat lenses, designed to align with the center graft, will ride very high (Fig. 57.13). A large-diameter reverse geometry or a scleral lens is the best option (Fig. 57.14). To fit a large-diameter lens to a plateau graft, select a lens that aligns in the periphery, and then select another lens that aligns centrally (usually with some coaxing of the lids to hold it in place). The laboratory will easily be able to take these two measurements and integrate them together in a reverse geometry design.

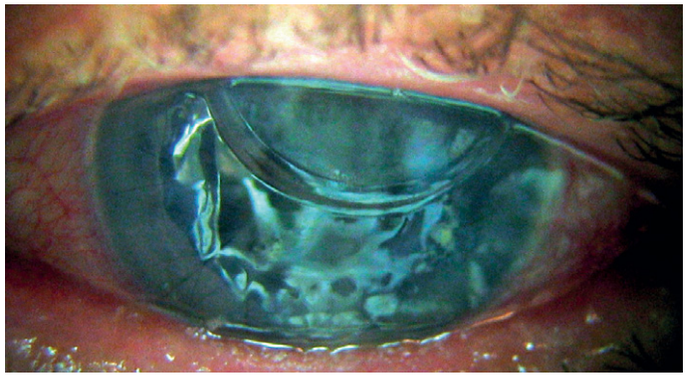

Figure 57.13. Contact lens fit in alignment to a 30.00 D graft rides high and does not cover the pupil.

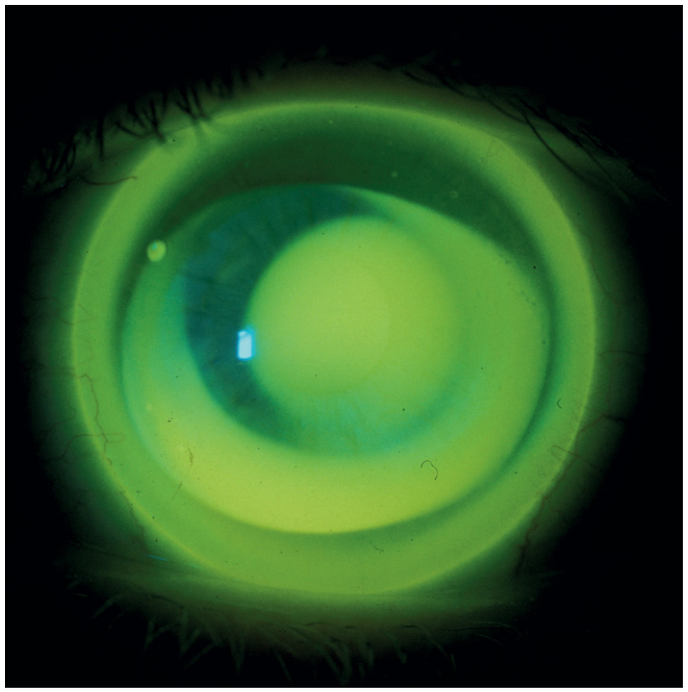

Figure 57.14. Large-diameter, reverse-geometry lenses are often the most effective lens on a plateau graft.

The proud graft

The proud graft has a steep center with significant flattening into the periphery (Fig. 57.15). In this case, the graft is evenly elevated above the host. The proud graft results from a small recipient bed or a large donor button. The result is a pseudo-cone effect. Surgical correction options for a proud graft include resuturing, repeat PKP, photorefractive keratectomy (PRK) for anisometropia (surface ablation recommended rather than LASIK due to concern about graft avulsion during flap creation), and epikeratophakia.

These grafts are fitted with the same principles as with keratoconus. The base curve radius needs to be steepened, while the peripheral curves need to be flattened. These corneas are more difficult to fit because, unlike the extreme prolate corneas of keratoconus, these corneas need a larger optical zone and there are few fitting sets that meet this requirement. If the optic zone is not steep enough or of sufficient diameter, the contact lens will rock on the apex of the cornea and exhibit inferior lift off as the upper lid holds the superior lens edge against the eye (Fig. 57.16).

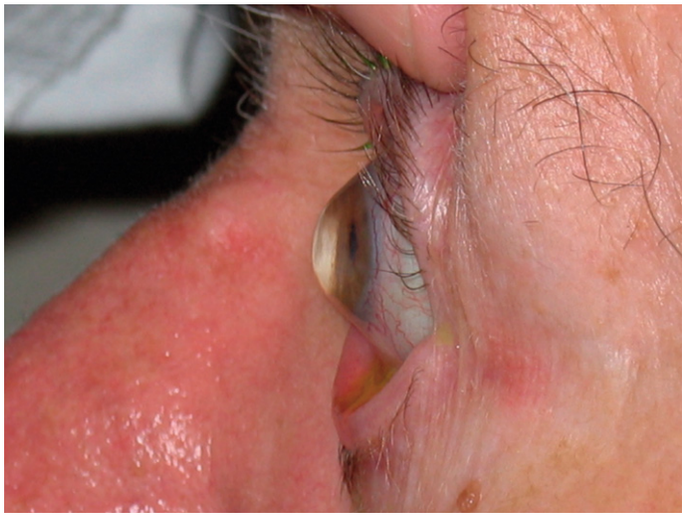

Figure 57.15. Pseudokeratoconus grafts require contact lenses with significant sagittal depth.

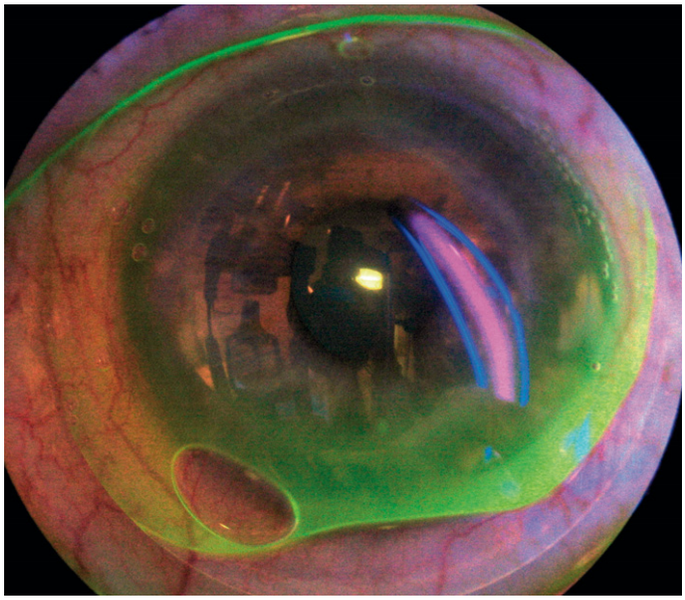

Figure 57.16. Inferior edge lift off on a proud graft caused by insufficient sagittal depth with resulting tipping of the lens.

The tilted graft

Graft tilt can happen anywhere on the graft but is usually seen inferiorly (Fig. 57.17). It is common in patients suffering from keratoconus or pellucid marginal degeneration when the entire ectatic area was not removed during surgery, often being called recurrence of keratoconus. Graft tilt is also trephine dependent and results from undercutting of the tissue. Wound dehiscence, tissue malapposition, improper suture placement, and unequal suture tension will also result in tilting of the graft. Surgical methods to correct graft tilt include selective suture removal, placing new sutures, wedge resections, and wound revision.

Lens fitting on a tilted graft takes a good bit of creativity. Lenses commonly used involve large-diameter corneal or scleral lenses, small lenses that are held up by the upper lid and avoid inferior lift off, keratoconus designs if there is an isolated point of elevation, or asymmetrical lenses that have different curves in different quadrants of the lens.

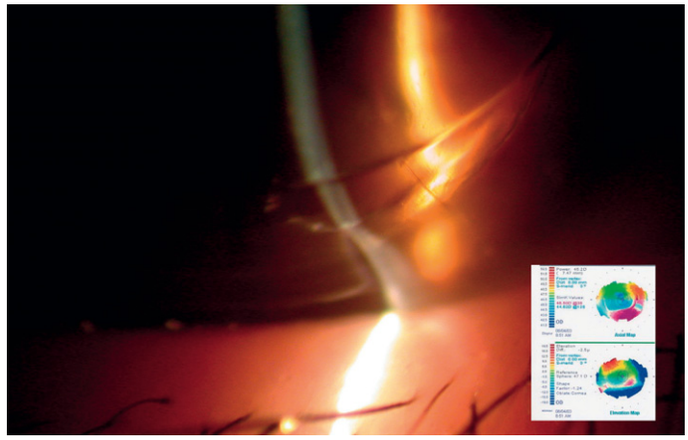

Figure 57.17. Graft tilt after a cornea transplant for pellucid marginal degeneration.

The high cylinder graft

A high cylinder graft results from an elliptical opening or improper cardinal suture placement or tension. While 5–6 D of astigmatism is common, fitting difficulties begin when there is an excess of this amount. Surgical correction of high cylinders includes selective suture removal, resuture, corneal relaxing incisions (with or without compression sutures), refractive procedures, wedge resection, repeat PKP, or refractive implants. Toric intraocular lenses are not advisable, in this author's opinion, because if a contact lens fit will be necessary anyway, all the lenticular (IOL) cylinder will show through the contact lens, equal and opposite in power to the original corneal cylinder.

Fitting high cylinder corneas with contact lenses is highly dependent on the extent and location of the cylinder. Contact lens options include spherical GP lenses, bitoric/back toric lenses, and large-diameter/scleral lenses.

On a graft, the cylinder can be located just on the graft (creating high refractive astigmatism), just on the host (creating difficulty with centration), or across the entire eye (Fig. 57.18.)

Always try a spherical lens first. On a graft where the majority of the astigmatism is centrally located, or if there is with-the-rule astigmatism, the lens will generally center nicely and the patient will have good visual acuity (often preferring the vision compared to better aligned by fluorescein evaluation) toric lenses (Fig. 57.19).

A cylinder wholly located on the host tissue will cause decentration of the contact lens, since the corneal contact lens will ride over the highest elevation on the cornea.

SUTURE REMOVAL

Contact lens fitting can take place approximately 2 weeks post suture removal. This time allows for healing of epithelial defects and stabilization of corneal topography. Topography of the graft immediately after suture removal, however, will show the approximate shape of the graft (Fig. 57.20). Approximate curvature readings can be reviewed immediately post suture removal to determine if special fitting requirements will be needed; however, it is preferable to wait 2 weeks to allow for smoothing and stabilization.

PIGGYBACKING

Using a silicone hydrogel lens to piggyback a GP lens will increase comfort and can protect the fragile epithelium of the graft. It can

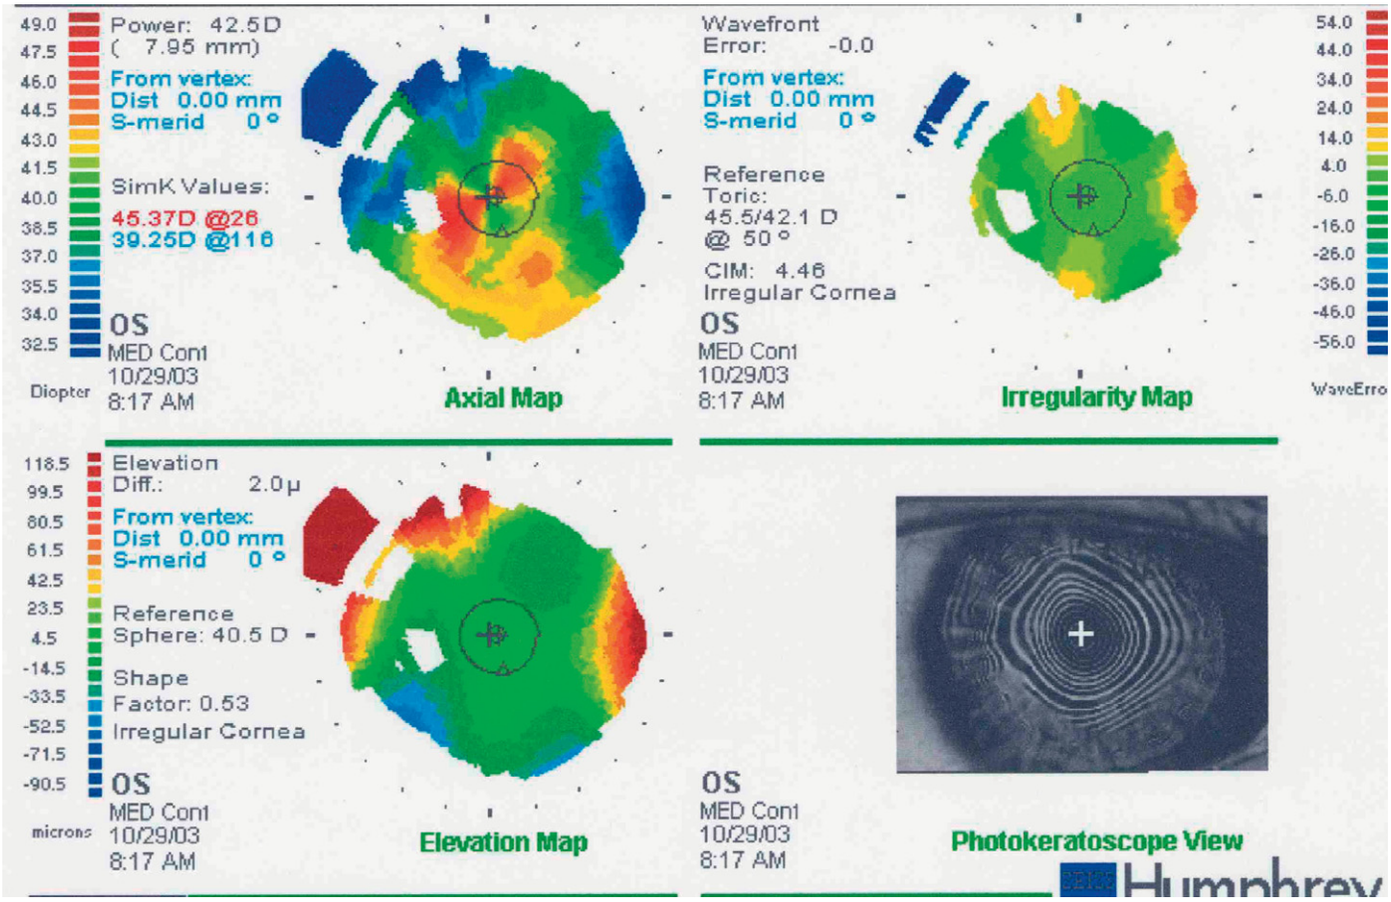

Figure 57.18. Cylinder located wholly on the graft tissue should be fitted with a spherical lens.

also reduce mucus buildup between the contact lens and the cornea. Cost and convenience are considerations, as some people have difficulty handling a two lens system or cannot afford additional lenses. Piggybacking does not reduce lid sensations and can increase risk of inflammation in people with chronic lid disease, so it should be used judiciously.

Selection of a piggyback lens not only includes material selection, but also power. In cases where a practitioner is using a Focus Night & Day® (CIBA Vision, Duluth, GA) lens as a bandage lens under a thick, complex-design GP lens, patient comfort may be less than one would expect. Using a lower modulus lens with better draping of the periphery, such as Acuvue Oasys (Vistakon, Jacksonville, FL) Air Optix (CIBA Vision) will increase comfort (Table 57.2).

The power of the piggyback lens, and subsequent lens configuration, can be used to alter the curvature of the eye. A plus lens can be used on a plateau (oblate) graft to create a more prolate surface. Corneal topography can be performed over the piggyback lens to determine the new surface shape. Similarly, minus lenses can be used on a proud graft (prolate) to create a more oblate shape, although this tends not to make quite as dramatic a difference.

SUMMARY

Fitting a corneal graft with a contact lens is inherently challenging, but quite rewarding.

Skills in conventional rigid lens fitting are a necessary prerequisite, as is a good supply of trial lenses. Additionally, a willingness to be creative and innovative in lens selection, and persistence in lens modification, increases the chance of a successful fit.

The expectation of what is a good fit on a graft cannot be based solely on criteria used for conventional contact lens fitting. Good visual acuity, lens stability, and patient comfort without any sign of superficial punctate keratitis or neovascularization may be present in a lens that looks like it does not fit well.

Corneal surgeons continue to strive for the ideal keratoplasty result, but until the time when low astigmatism is as predictable as graft clarity is now, a need will exist for postoperative visual correction with a contact lens.

58 Control of postkeratoplasty astigmatism

Woodford S. Van Meter

After penetrating keratoplasty (PKP), a clear graft is almost always expected with current eye banking techniques, microsurgical instrumentation, and knowledgeable postoperative care. However, even with a clear graft, ametropia, which includes spherical errors and astigmatism, is the leading cause of decreased visual acuity after surgery.[1–4] Astigmatism limits best-corrected acuity after surgery, impairs visual rehabilitation, and can make contact lens wear difficult. A highly myopic patient with a clear graft is significantly disadvantaged even without astigmatism. A patient loses 0.2 lines of vision with every diopter of refraction error from plano, so the closer a cornea is to emmetropia after surgery, the better the patient's potential visual acuity will be.[5] This chapter is devoted to the control of astigmatism after keratoplasty.

Postkeratoplasty astigmatism can be treated either with sutures in place or after they have been removed. Ultimately all sutures have to be removed, and so treatment with sutures in place may lose effectiveness once sutures are removed. Manipulating sutures to control astigmatism while the sutures are in place is determined by the specific suturing techniques used and suturing was discussed in a previous chapter. For example, removal of interrupted sutures can flatten the steep meridian but will not steepen a flat meridian. Adjustment of a continuous suture can flatten a steep meridian, steepen a flat meridian, or both, but will not address residual spherical refractive error. If astigmatism has been reduced to acceptable levels with sutures in place, a contact lens may be used over the cornea for visual rehabilitation and the sutures may be left in place indefinitely, excepting any suture complications.

After all sutures have been removed, visual rehabilitation should be attempted with glasses or contact lenses. Reduction of existing astigmatism requires surgical intervention to alter corneal topography to flatten the steep meridian, steepen the flat meridian, or both. Surgical techniques may include refractive surgery, such as laser-assisted in situ keratomileusis (LASIK), or photorefractive keratectomy (PRK) discussed elsewhere, or incisional surgery to alter the existing graft–host junction, discussed in the following pages. Relaxing incisions to flatten a steep meridian and compression sutures with or without a wedge resection to steepen a flat meridian are examples of incisional surgery. T-cuts and arcuate keratotomy serve the same function as relaxing incisions. Excimer laser procedures for astigmatism, including photorefractive keratectomy and laser in situ keratomileusis, are discussed in subsequent chapters.

The topography of the donor cornea is generally not stable until 2–6 weeks after surgery. Glycosaminoglycans in the corneal storage medium have higher osmolarity than the normal corneal stroma and cause an increase in thickness in the donor button immediately after surgery due to influx of aqueous fluid. Resolution of corneal edema is necessary to allow the postoperative suture tension to stabilize. The corneal epithelium should heal sufficiently to permit an accurate measurement of corneal shape, especially with reflection-based imaging systems. Corneal edema, epithelial irregularity, and subsequent fixation errors may all affect imaging and consequently intervention. Decisions concerning suture removal should be made only after reproducible topographic images have been achieved and, ideally, confirmed on consecutive visits.

The amount of residual astigmatism that can be tolerated depends on a number of factors, including the patient's age, occupation, fellow eye, binocularity, visual acuity, temperament, and expectations. A large amount of astigmatism may be tolerated in a patient with poor vision and minimal occupational visual requirements, whereas a low level of astigmatism may not be tolerated in a patient who is emmetropic in the other eye and must see fine print. The effort that a surgeon should put into astigmatism reduction depends on the experience of the surgeon and the patient's needs and expectations. Patient needs and surgical skill may be fixed and unalterable, but patient expectations can be tempered by frank discussion of corneal astigmatism before keratoplasty.

Visual rehabilitation following PKP has three stages: glasses, contact lenses, and surgical intervention. Surgical intervention should not be used until all sutures are cut. Rarely following a PKP does a patient achieve emmetropia. Glasses and/or contact lenses can be utilized for vision several months postoperatively, but frequently, some modification of the graft topography by the surgeon is necessary for the patients to achieve their best potential vision. Such intervention includes suture manipulation and surgical intervention.

BOX 58.1 CHRONOLOGIC EVENTS TO CONTROL ASTIGMATISM

1. Care in cutting donor and host, care in suturing
2. Suture adjustment
3. Removal of all sutures after wound is healed
4. Surgical intervention with relaxing incisions or wedge resection
5. Photoastigmatic refractive keratectomy with or without LASIK
6. Regrafting

The feasibility of glasses and contact lenses should be considered after each step.

CONTROL OF ASTIGMATISM

Postkeratoplasty astigmatism may be the result of a number of factors, including suturing techniques, wound morphologic characteristics, trephination of the donor or host tissue, or localized pathologic condition in the host (or donor) cornea. Specific suturing techniques are frequently dictated by the expertise of the surgeon and the presence or absence of localized structural abnormalities observed in the cornea, such as vascularization or scarring. The steps to control astigmatism are listed in Box 58.1.

All suturing techniques lend themselves to adjustment in one way or another even if the adjustment is only removal of the sutures. Suture manipulation can effectively reduce astigmatism if the astigmatism is caused by the suture. Suture adjustment does not completely overcome astigmatism resulting from other factors, such as uneven wound morphology, asymmetric or uneven graft–host fit, or wound abnormalities that result from irregularly placed cardinal sutures.

If suture adjustment achieves adequate control of astigmatism, then sutures should be left in place indefinitely. If suture manipulation does not adequately control astigmatism, then one must wait until all sutures can be removed safely. Sometimes removal of all sutures results in improvement in topography. If astigmatism is unacceptable after all sutures are out, surgical intervention using a relaxing incision or a wedge resection may be timed to make the cornea more spherical. Often minimal adjustments to a cornea with irregular astigmatism can drastically improve contact lens wear. If surgical intervention fails, then regrafting may be necessary to achieve an optically useful cornea.

ADJUSTMENT OF KERATOPLASTY SUTURES

Suture adjustment is an integral part of postoperative visual rehabilitation after keratoplasty. The adjustment may involve partial suture removal, removal of all sutures, or adjustment in the tension of existing (continuous) sutures. Sutures should remain in place once corneal astigmatism is satisfactory and until there is some indication for removal. Indications for removal are scarring or vascularization that increases the risk of graft rejection, suture breakage that may cause patient discomfort and serve as a nidus of infection or inflammation, infiltrate, stromal melting, or residual astigmatism that causes decreased vision.

Attention to several issues intraoperatively can be attempted to preserve the option of leaving sutures in place as long as possible. At the time of suture placement, surgeons should avoid excessive trauma to the nylon sutures when handling the suture. Bites should be placed at 90% depth to permit wound approximation without distortion. Minimal tissue trauma while handling wound edges, preserving the suture, and avoiding vascularization that may already be present improve the chances of postoperative suture adjustment, which effectively reduces astigmatism.

SINGLE INTERRUPTED SUTURES

The only adjustment possible with interrupted sutures is removal of one or more sutures. In the early days of corneal transplantation, silk sutures were used and of necessity had to be removed early to prevent inflammation and vascularization. Early removal reduced the effect of the suture on astigmatism; sutures were less likely to induce astigmatism after removal, but clear grafts were not as common with silk as with the less reactive sutures available today. There is a narrow therapeutic window of opportunity for effectively removing an interrupted nylon suture; early removal can cause wound dehiscence, but waiting too long can mean that no effect is realized from suture removal. Loose interrupted sutures provide no structural support and should be removed to avoid infection. With this idea in mind, the surgeon should not risk losing a 'good' result trying for a 'perfect' result. Tight interrupted sutures steepen the cornea, and removal of an excessively tight suture will flatten the steep meridian and may cause a little steepening of the flat meridian.[6] Little in general can be done to steepen a meridian that is already too flat except for resuturing the wound.

Qualitative adjustment of topography by removing interrupted sutures is problematic because there are only a finite number of sutures present and flattening is the primary outcome. As soon as an interrupted suture is removed, if too little or too much flattening is obtained, nothing else can be attempted in that axis using suture manipulation. Tight interrupted sutures can be removed earlier (for example, with 16 interrupted sutures, one suture could be removed as early as 2–3 months if it is too tight, although no two adjacent sutures should be removed before 6 months). Occasionally, earlier suture removal may be indicated at the discretion of the surgeon as long as it can be reliably determined that the wound is sufficiently healed to withstand suture removal without wound slippage or dehiscence.

As soon as the suture or sutures to be removed have been identified by topography, a drop of topical antibiotic and a drop of topical anesthetic should be placed in the eye. Cut the suture with a straight blade (Microsharp or Beaver no. 75 blade) and remove with tying forceps (Fig. 58.1). A sudden jerk to remove the suture, like tearing toilet paper with one hand, is more effective than slower, less forceful pressure. Buried knots are not a problem, but exposed loose ends can cause patient discomfort and infectious keratitis and should therefore be removed with moderate urgency. The eye should be patched for 18–24 h with a topical antibiotic ointment. Topical corticosteroid drops may be resumed on the following day or should be started if the patient was not taking drops before suture removal, because removal of sutures can incite inflammation that can potentiate a graft rejection. Re-evaluate the eye in 2–3 weeks and repeat the procedure until satisfactory corneal topography has been achieved or until there are no more sutures to remove in the steep axis.

Results

The effect of removing a single suture cannot be easily predicted. Photokeratoscopy or topography can be used to help determine

which interrupted sutures should be removed (Fig. 58.2, *A* and *B*) but do not precisely correlate with the amount of tension in the tight suture. Removal of a tight interrupted suture may result in anywhere from 0 to 10 D of change, depending on the tightness of the suture, the length of the suture, and specific details of the wound in the vicinity of the suture. When a single interrupted suture is removed, average anticipated astigmatic change is approximately 2–3 D. When no interrupted sutures remain in the steep axis, no additional sutures should be removed and the effect of suture removal is complete.

COMBINED CONTINUOUS AND INTERRUPTED SUTURES

The combined continuous and interrupted suture (CCIS) technique has both the advantages and the disadvantages of a continuous suture and interrupted sutures.[7] This technique is especially advantageous for surgeons learning the continuous suture technique. The continuous suture provides extra security when interrupted sutures are removed early for astigmatism control, and the interrupted sutures provide safety in the event of irregular bites or early breakage of the continuous suture.

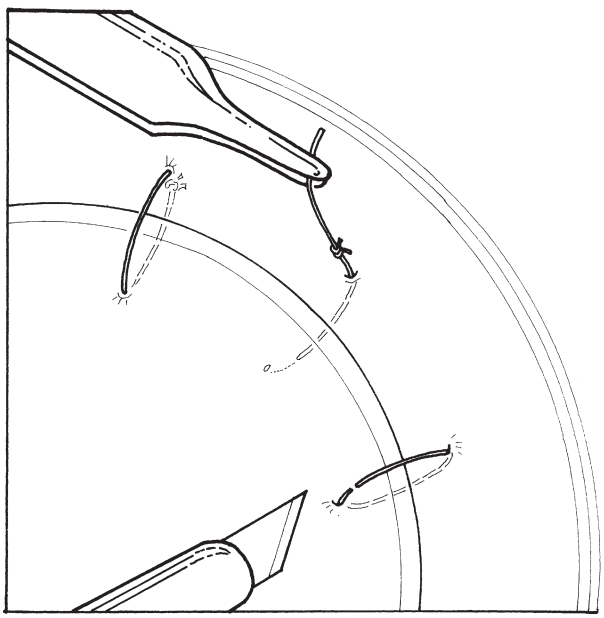

Figure 58.1. Interrupted suture with knot buried on recipient side of graft junction is cut on donor side. Loose suture segment is then pulled with a snap to remove knot from recipient, which puts less stress on wound than pulling knot from donor side.

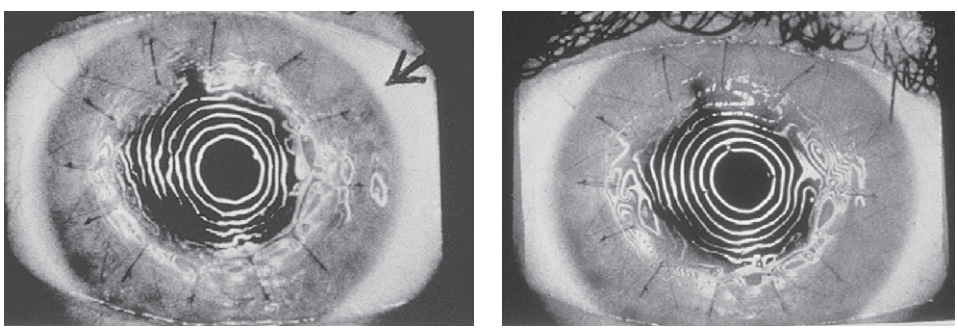
Technique

At approximately 3–4 weeks after keratoplasty surgery, corneal topography should be evaluated. A tight interrupted suture is identified with keratometry, photokeratoscopy (see Fig. 58.2), or videokeratography and then removed.[8] Two or three weeks later, corneal topography should be remeasured to assess changes in the patient's cornea resulting from removal of the suture and to assess whether additional suture removal is indicated. Subsequent sutures are removed as indicated until corneal astigmatism is reduced to an acceptable level, generally 3 D or less, or until there are no more interrupted sutures to remove in the tight meridian.[9–13]

One limitation of CCIS suture adjustment is that, like single interrupted sutures, only the tight suture can be removed and only the curvature in the steep axis can be reduced. A cornea that is excessively flat in one axis cannot be steepened by removing sutures. If removal of sutures in the tight meridian does not reduce corneal cylinder or there are no more sutures to remove, adjustment is not effective, and the patient and physician must then wait until all sutures can be removed before addressing corneal astigmatism or surgical methods. A second disadvantage of the CCIS technique is that interrupted sutures are very difficult to remove after several years. Sutures that are partially eroded, loose, or broken several years after surgery may be very difficult to remove because of fibrosis around buried, knotted segments. Loose suture segments over time can cause patient discomfort, infectious keratitis, or graft rejection.[14–17] Once acceptable corneal astigmatism is achieved, the suture should be left in place until there is an indication for removal.[18–20]

Results

Patients in whom the CCIS technique is used experience a reduction in corneal astigmatism from an average of 7.5 to 2.6 D at 1 year with sutures in place.[20] The ability to adjust astigmatism one suture at a time titrates the astigmatism reduction in small increments and is more controlled than the removal of all sutures. Average astigmatism when all sutures are out regresses to approximately 4 D in most series.[2,11]



A **B**

Figure 58.2. *A*, Photokeratoscopy (placido disc projection topography) is used to identify tight suture, causing steep meridian at 2 o'clock (black arrow). *B*, Same eye with suture out 2 months after surgery with 2.5 D of corneal astigmatism.

SINGLE CONTINUOUS SUTURE

The single continuous suture (SCS) technique is also effective for keratoplasty wound closure. The SCS technique requires less time than interrupted sutures but is technically more demanding and less forgiving than multiple interrupted sutures. Adjustment of an SCS can change corneal topography to reduce astigmatism with the suture still in place to support the wound,[21] and McNeill[22] and Wessels[23] described adjustment of an SCS to reduce postkeratoplasty astigmatism in 1988 and multiple surgeons have confirmed the effectiveness of this technique.[24–26]

The SCS can be adjusted using sterile tying forceps. The surgeons should first apply drops of topical antibiotic and anesthetic to the eye and carefully measure corneal topography. A keratometer is the most useful instrument to use for suture adjustment because reflection of central corneal topography in the mires permits measurement of both the quality and the quantity of astigmatism. Repeated glimpses of corneal topography are helpful during the adjustment procedure. One edge of the forceps can be used to carefully divide Bowman's layer with the tip of the forceps in the wound. The forceps are gently passed through Bowman's layer into the anterior corneal stroma, with care taken not to advance the tips beyond 50% of corneal depth or to traumatize the continuous suture. Division of Bowman's layer relaxes the wound to facilitate alterations in corneal topography with adjustment of suture tension and makes it easier to pick up the suture with the forceps. The suture can then be carefully advanced from the flat to the steep meridian, simultaneously flattening the steep meridian and steepening the flat meridian (Fig. 58.3). Laxity in the sutures advances loop by loop, with the goal of adjustment to distribute suture tension equally 360° around the wound. If the suture is tied too tightly, adjustment should not be pursued because attempts to move a very tight suture forcefully can result in suture breakage. If the suture is tied too tightly to move, adjustment should then be deferred, and attempts to resolve astigmatism should follow suture removal.

Suture adjustment in a theoretic cornea with K readings of $40.00 \times 180/50.00 \times 90$ is demonstrated in Figure 58.4. The suture in each quadrant is advanced from the flat meridian toward the steep meridian, resulting in a more spherical cornea as the flat meridian becomes steeper and the steep meridian becomes flatter. Regression of the measured astigmatism generally occurs, and a slight overcorrection in the adjustment end point for regression may be helpful.

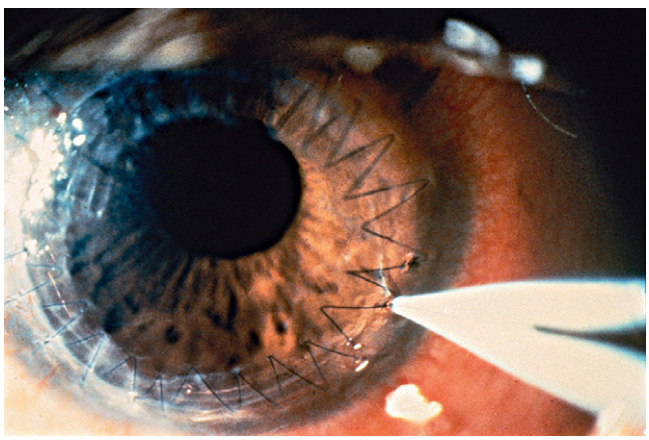


Figure 58.3. After Bowman's layer is broken, grasp the suture and advance from flat meridian toward steep meridian, taking care not to twist or cut the suture on the edge of the tying platform.

Corneal mires can be changed from an elliptic reflex on a toric cornea to a circular reflex on a spherical cornea, as shown in Figure 58.5, *A*. Figure 58.5, *B* shows adjustment from a D-shaped pattern, and Figure 58.5, *C* shows adjustment of a teardrop pattern.

Care must be taken to prevent suture breakage during the adjustment procedure because the wound itself is not stable enough to remain intact without suture support in the first weeks or months following keratoplasty. During the early postoperative period, when suture adjustment is most effective, suture breakage can result in wound dehiscence and requires immediate repair in the operating room. Consequently, adjustment of a continuous suture should not be attempted unless the surgeon has an oper-

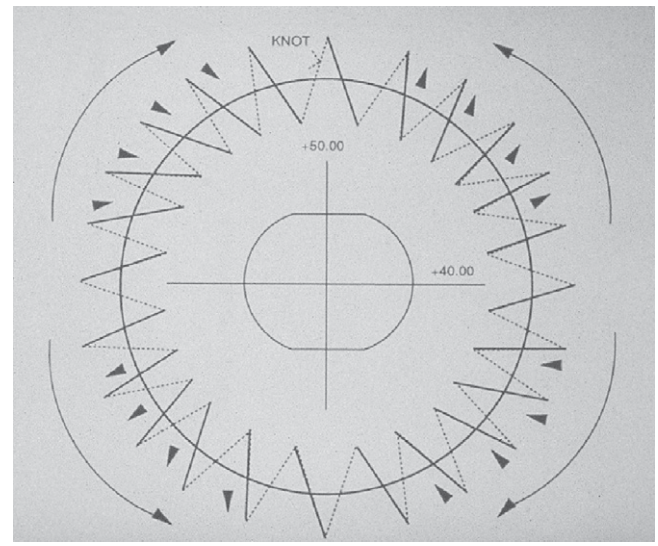

Figure 58.4. Suture is advanced from the flat meridian, steepening the flat meridian by increasing suture tension to the steep meridian, where a looser suture allows meridian to flatten.

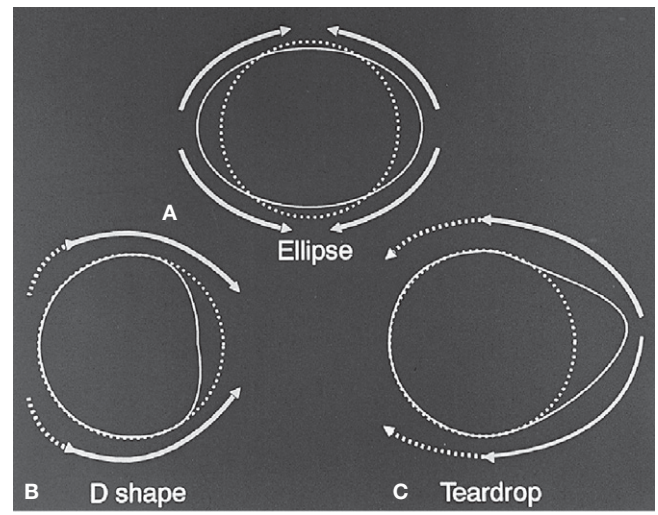

Figure 58.5. *A*, Adjustment of suture in astigmatic cornea with elliptical mires requires symmetric suture manipulation in four quadrants, advancing the suture from the flat to steep region. *B*, D-shaped pattern results from suture with excessive tension in one meridian. Suture tension is gathered from wound and used to loosen the wound at flat side of D and equalize the tension 360°. *C*, A teardrop pattern results from suture with less tension in one area. Adjustment of teardrop pattern is accomplished by taking up tension where suture is loose (at point of teardrop) and redistributing tension evenly around the wound to achieve spherical mires.

ating room available should more elaborate surgical intervention be necessary.

Regression after the second or third suture adjustment is a poor prognostic sign and rarely does repeat adjustment help when the first or second attempt does not change corneal astigmatism. Because residual postkeratoplasty astigmatism is multifactorial, other factors that cause astigmatism, such as wound morphologic characteristics, gross misplacement of sutures, or uneven wound trephination may prevent any suture adjustment from effectively reducing corneal astigmatism. If suture adjustment is not effective, the patient may be fitted with glasses or contact lenses when possible and await final suture removal as soon as the wound has stabilized. After suture removal, other invasive procedures, such as relaxing incision or wedge resection, may be indicated. These procedures are discussed later in this chapter.

Removal of a continuous suture is best accomplished by cutting the suture on the host side of the cornea in alternate loops and then loosening the center of the 'W' with a bent 30-gauge needle or the dull side of a no. 75 Beaver blade. The loosened loop can then be removed with tying forceps (Fig. 58.6). The eye should be patched overnight with a topical polymyxin and bacitracin ophthalmic ointment. Re-evaluation of topography to determine the effect of suture removal can be completed within 2–3 weeks.

Results

The results of an SCS in one study showed an average reduction from 6.5 to 1.5 D after adjustment, regression of 2.5 D when optically stable, and final average astigmatism of 3.5 D at 2 years with sutures still in place.[23] However, an SCS without adjustment had 2.5 of regression in a comparable population, suggesting that inherent wound stability may exist with a continuous suture closure. Sutures-out astigmatism in those patients with sufficient astigmatism to require adjustment was approximately 4 D, comparable to that with a CCIS technique.[20] However, astigmatism with sutures in was significantly less with SCS than with CCIS and was achieved in shorter postoperative time than CCIS, patients' satisfaction with the quality of vision being reported to be higher with CCIS than with SCS.[27]

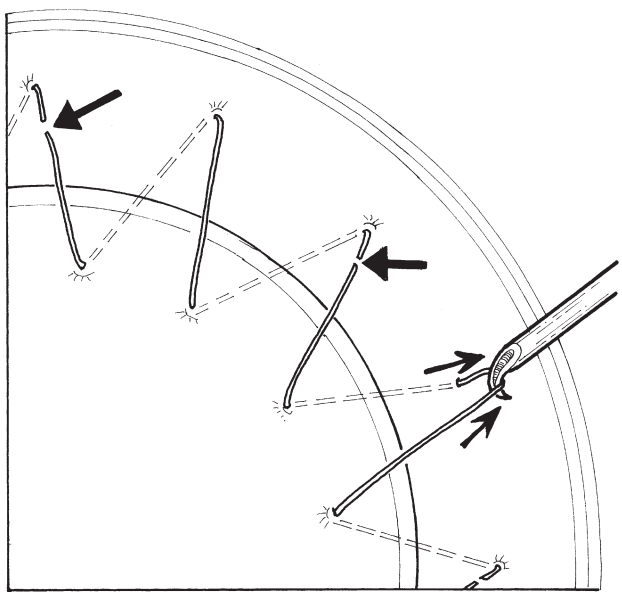

Figure 58.6. Continuous suture is removed by cutting alternate recipient side loops, then pulling from apex of the W to remove two-bite segment. Bent 30-gauge needle can pull suture bite to loosen.

DOUBLE CONTINUOUS SUTURE

Adjustment of the double continuous suture initially was reported using two 10-0 nylon sutures with early removal of one of the two sutures.[28] This technique was modified using a 10-0 and an 11-0 nylon suture with removal of the 10-0 nylon suture at 2 or 3 months, leaving the 11-0 suture in place for 12 months.[29] Removal of the deeper, tighter, 10-0 nylon suture reduced astigmatism, and the 11-0 nylon suture remained secured in place and the wound in place preventing wound dehiscence without placing untoward suture compression on the wound.

A double running suture with two 10-0 nylon sutures, which secure the wound with 12 bites each, has been shown effective, eliminating the technical intricacy of running an 11-0 nylon suture.[30] The deeper, tighter, 10-0 nylon suture is removed to reduce the suture effect on corneal topography, leaving the shallower suture in place as a safety net. Both sutures can be left in place after surgery if the patient is optically stable with acceptable visual acuity. If the patient requires suture adjustment, the deeper, tighter, 10-0 nylon suture can be adjusted in the same manner as an SCS to reduce corneal astigmatism. The second 10-0 nylon suture remains in place if the original suture is divided or if the deeper suture needs to be removed because of unacceptable astigmatism. After adjustment, both sutures remain in place until removal is indicated.

FINAL CONSIDERATIONS

Three important points should be impressed on keratoplasty surgeons regarding suture adjustment. First, corneal astigmatism is multifactorial and suture adjustment can only correct astigmatism that is the result of uneven suture tension in a reasonably well-approximated wound or if cardinal sutures are not evenly placed. If the wound is unevenly approximated, adjustment of suture tension may help to reduce astigmatism with sutures in place but will not reduce astigmatism after sutures are out. Wound astigmatism, at best, may be masked by an adjusted suture until such time as the suture is removed.

Second, as soon as the suture or sutures have been adjusted to achieve suitable topography, the suture should be left in place until such time as it has to be removed.[14–16] Patients may be well advised to 'take their sutures to the grave' if visual acuity is acceptable and there are no signs of suture intolerance. Some fibrosis can be expected around the suture tract, but fibrosis alone is usually not an indication for suture removal. The most common indication for removal of an SCS is suture breakage, which most frequently occurs around the 12 o'clock meridian because of the constant movement of the lids over the suture with blinking.

Third, after several years, continuous sutures are much easier to remove than interrupted sutures. The continuous suture causes less inflammation in the cornea than interrupted sutures, suture segments without knots are removed easier than buried knots, and there is less likelihood of residual buried suture remnants from broken segments attached to buried knots that cannot be removed.

CONTROL OF ASTIGMATISM WITH SUTURES OUT

If satisfactory corneal topography is not achieved by suture adjustment, then suture removal is indicated as soon as wound stability and safety factors permit. After all corneal sutures have been removed, careful measurement of corneal topography by qualitative

and quantitative methods should be repeated over a period of at least 2 weeks to establish stability. Videokeratography is most helpful, but important information can be obtained from combined use of keratometry and photokeratoscopy. The plan for astigmatism reduction is based on which areas of the cornea are steep and which are flat. Understandably, reduction in astigmatism with sutures out is more effective without wound interface abnormalities causing radial asymmetry.

Once astigmatism is quantified, visual rehabilitation can proceed. Visual correction means rehabilitation initially with spectacles. Contact lenses should be tried next if spectacles do not provide adequate vision and finally surgical intervention if contact lenses are not suitable (due to inadequate vision, inadequate comfort, inability to handle, or expense). Repeat keratoplasty may be the most reasonable option if surgical intervention does not provide adequate vision. Contact lenses and lamellar refractive procedures are discussed elsewhere in this volume.

Refraction should be performed postoperatively by someone experienced in low vision refraction techniques because patients with high astigmatism, irregular corneal astigmatism, or maculopathy may not appreciate 0.25 D steps in refraction, and 0.50 or 1.00 D increments may be necessary. Generally, the manifest refractive astigmatism is ⅔ to ¾ of the measured keratometric astigmatism.[30a]

Contact lens fitting is necessary in approximately half of PKP patients to achieve adequate useable vision. An experienced contact lens artisan, either on site or near by, dramatically improves results compared to distant contact lens services. Patients with keratoconus or high refractive error preoperatively who are used to wearing contact lenses will enjoy rapid visual rehabilitation because they are already used to wearing contact lenses. High DK (DK value is the oxygen permiability of a contact lens) rigid gas permeable (RGP) contact lenses are the lens of choice. Some patients who cannot tolerate RGP contact lens may be comfortable with a hybrid lens with RGP center and hydrogel carrier (Synergeyes, Carlsbad, CA).

Surgical techniques for astigmatism control, which include refractive surgical techniques to alter corneal astigmatism after suture removal, fall into two categories: relaxation (to flatten a steep meridian) and compression (to steepen a flat meridian). A steep meridian can be flattened with a relaxing incision (including arcuate incisions, transverse incisions, trapezoidal incisions, and incisions within the wound). A flat corneal meridian can be steepened with compression sutures, a wedge resection, or both. Both relaxing incisions and wedge resections affect the opposite meridian and the meridian of intent, but conceptually they are discussed as primary procedures that either flatten or steepen. Either or both of these techniques can be used to reduce postoperative astigmatism after all sutures have been removed.

RELAXING INCISIONS

Incisional keratotomy for astigmatism has been in use for over a century. Snellen[31] initially described relaxing incisions made in the cornea in 1869. Lans[32] confirmed the flattening effects of this technique, and Sato[33] used relaxing incisions in the posterior cornea in his well-publicized preradial incisional keratotomy.

Relaxing incisions with modern microsurgical techniques were described by Troutman and Swinger[34] as arcuate keratotomy in 1980. Relaxing incisions are placed in the steep meridian and act by directly flattening the central cornea in the meridian of the incision (Fig. 58.7, *A* and *B*). Up to 16 D of vector change in corneal astigmatism have been observed, although modifications in technique have made the procedure more titratable now.[35–37] The ratio of flattening in steep meridian to steepening in the flat meridian is approximately 0.975, so one expects the same amount of steepening in the perpendicular meridian as there is flattening in the meridian of the incision.[37] In the average patient, a relaxing incision is capable of correcting 4–5 D of astigmatism.

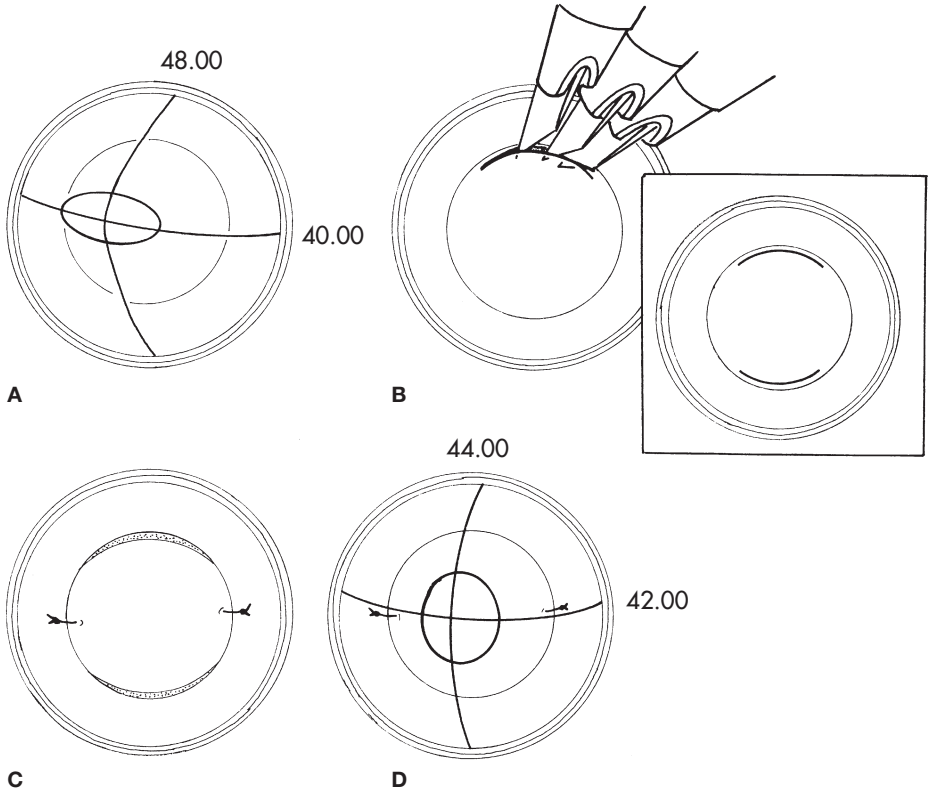

Figure 58.7. *A*, Eight diopters of with-the-rule astigmatism. *B*, Relaxing arcuate incision made at the graft–host junction in the scar with no. 75 blade at the slit lamp. *B* (inset), Alternative incision just inside the graft–host junction. *C*, Compression sutures alone or in combination with relaxing incisions. *D*, Effective reduction of astigmatism.

As the perpendicular meridian steepens, the total power of the spherical equivalent of the cornea does not significantly change after the procedure. The amount of correction obtained is influenced by the depth and length of the incisions and the proximity of the incisions to the optical axis.[35] Incisions are most effective when placed just inside the graft–host junction (Fig. 58.7, *B*). The keratoplasty wound generally makes significant astigmatism reduction refractory to incisions outside the corneal wound.

There are several advantages of relaxing incisions over wedge resections: there is generally a more rapid return of vision, sutures are not required, and the procedure can be performed under topical anesthetic at the slit lamp in the physician's office.

The technique for relaxing incision involves the placement of several drops of topical anesthetic and antibiotic in the eye. At the slit lamp under direct visualization, a no. 75 blade or a faceted (flat-edge) diamond blade is used to make an incision through Bowman's layer either at the graft–host scar or just inside the donor wound, in the steep meridian identified by topographical analysis. Slow and careful deepening of the incision is performed through the stroma, observing for and limiting wound gape. If perforation occurs with significant chamber loss, resuturing is necessary. The incisions may be made in one or both meridians and may be made in two irregular meridians (i.e. meridians not 180° apart).[38] Relaxing incisions are most effective if there are localized areas of wound compression, that is the host wound over-rides the donor (see Fig. 58.5, *B*, 'D' pattern) and if they are carried out within 3 months after suture removal. Relaxing incisions are less effective if there is smooth wound approximation, and the astigmatism is minimal and symmetrical, and if they are carried out more than 6 months after suture removal.

The Ruiz procedure, which makes multiple linear cuts in a trapezoidal shape, has been unpredictable in most reports from the USA. Transverse keratotomy, or T-cut, is a modification of the Ruiz procedure. These procedures do not show any advantage over arcuate keratotomy in or near the corneal wound.[39,40]

COMPRESSION SUTURES

Compression sutures using 9-0 or 10-0 nylon or 10-0 or 11-0 polypropylene or braided nylon (Mersilene, Ethicon, Somerville, NJ) may be placed across the graft–host junction to steepen the flat meridian.[41] Compression sutures alone may make only minimal changes in corneal topography, and the effect tends to regress over time. Placement of alternate 10-0 and 9-0 nylon sutures to achieve overcorrection, along with removing the 9-0 sutures to titrate the effect, and leaving the 10-0 nylon sutures, may provide some adjustability to the procedure. The sutures should be tied tight enough to achieve a slight overcorrection, and the compression sutures subsequently can be removed one by one several months later if overcorrection persists.

Compression sutures can also be helpful in the opposite meridian to accentuate the effect of relaxing incisions (Fig. 58.7, *C* and *D*).[42] Compression sutures may help open the tissue in the relaxing incision and may provide more steepening in the opposite meridian than relaxing incisions alone provide. In general, compression sutures are left in place permanently unless persistent overcorrection occurs, at which point selective removal may be beneficial.

WEDGE RESECTION

Corneal wedge resections were initially described by Poyales and Actas in 1953.[43] The corneal wedge resection with an operating microscope, microsurgical instruments was developed by Troutman in 1972.[44] A 95%-thickness wedge of tissue in a crescent shape is excised in the flat meridian of the wound (Fig. 58.8, *A–D*). The wedge can be removed from either the donor or the host cornea, with one of the two incisions made in the original wound and portions of the tissue resected from either the graft or the host side of the wound. Because wedge resections average 10 D of correction for each 1 mm in thickness of wedge tissue removed, these are usually reserved for eyes with more than 7–8 D of astigmatism, and

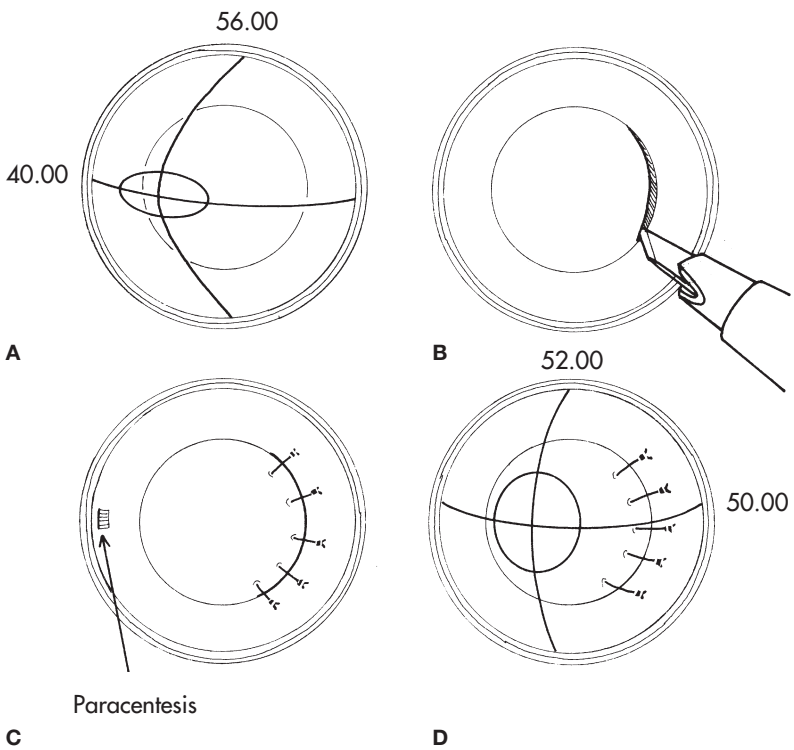

Figure 58.8. *A*, Sixteen diopters of with-the-rule astigmatism in sutures-out graft. *B*, Wedge resection performed in flattest meridian demonstrated on topography. *C*, Paracentesis may facilitate wound closure. *D*, Suture knots buried and astigmatic reduction achieved with cylinder modification in both axes.

therefore resections of 0.5–1.0 mm of tissue are performed. There is generally a flattening of the steep meridian in the perpendicular axis that is up to 50% of the steepening obtained in the flat meridian of the axis of the wedge resection. For example, to eliminate 9 D of astigmatism, one may try to achieve 6 D of steepening with the wedge resection in the flat meridian and expect 50% of the amount, or 3 D, of flattening in the steep meridian to make 9 D total correction.[45–47]

Wedge resections should be performed in the operating room because surgical instrumentation is required. There is risk of perforation, and the procedure can inadvertently lead to intraocular exposure. Occasionally, paracentesis of the anterior chamber is necessary to compress the wound fully with sutures placed in the wedge resection (Fig. 58.8, *C*). The postoperative course is more protracted than a simple relaxing incision because of slower wound healing, and the surgeon is cautioned against early suture removal, which may negate the procedure by the return of pre-wedge high astigmatism. Often wedge sutures are left in place indefinitely when astigmatic reduction is satisfactory.

FINAL CONSIDERATION

If surgical intervention with relaxing incision or wedge resection does not provide satisfactory reduction of astigmatism or if these procedures are outside the comfort zone of the operating surgeon, then regrafting may be indicated. The patient, after all, had a corneal transplant in the first place because of decreased vision. LASIK, LASEK (laser-assisted epithelial keratomileusis), and PRK have provided varying degrees of success in relieving postkeratoplasty astigmatism, but reports of improved astigmatism by cutting a microkeratome flap and then replacing the cap without laser suggest that cutting the flap alone can be helpful. All of these options will be discussed elsewhere in this volume.

59 Refractive surgery following penetrating keratoplasty

Renée Solomon, Eric D. Donnenfeld

Over 45 000 penetrating keratoplasties (PKPs) are performed annually.[1,2] Although significant improvements in microsurgical techniques have resulted in PKP becoming more successful and more common, postoperative refractive errors are common following anatomically successful PKPs. Most patients will not tolerate more than 3 D of anisometropia, due to image size disparity or astigmatism of greater than 1½–3 D.[3,4] Refractive unpredictability following PKP is extremely common, due to the inherent imprecision of the operation, with most series documenting mean cylinders of 4–5 D and significant anisometropia.[5–11] The residual refractive error may be due to surgical technique, wound healing, and donor tissue variables and is often further complicated by implantation of an intraocular lens. Refractive anisometropia and high postoperative astigmatism can compromise the patient's return to normal binocular function. Anisometropia may result in headache, photophobia, burning, tearing, diplopia, and blurred vision.[3] Binder reported in a series of patients following corneal transplant and cataract extraction that only 21 out of 43 eyes achieved refractive errors within 2 D of emmetropia.[12] Davis et al evaluated patients having combined cataract extraction with PKP. Only 75% of patients fell between −4.00 and +2.00, when emmetropia was the goal.[13] Flowers et al evaluated intraocular lens power calculation in combined corneal transplant and cataract extraction and reported that only 39% of patients had a refractive error within 2 D of emmetropia. The range of ametropia was from −9.75 to +12.88 D, with 65% of the patients having myopic errors.[6]

Many of these patients who cannot be rehabilitated with spectacle correction can be aided by contact lenses. Contact lenses are vital to the rehabilitation of the postkeratoplasty patient. Ten to thirty per cent of patients who undergo PKP wear contact lenses for visual rehabilitation. The incidence of contact lens wear following PKP for keratoconus is 25–50%.[14,15] Both soft and gas-permeable contact lenses are extremely effective and remain the primary technique of visual rehabilitation following PKP for patients who cannot tolerate spectacles.[14–16] Their use is successful in 80–90% of cases.[14] For myopia with low degrees of astigmatism, soft contact lenses are highly effective. Fitting with a gas-permeable contact lens may be required for patients with greater levels of regular astigmatism and any level of irregular astigmatism.

Contact lens wear is not successful in many patients requiring visual correction following PKP. The topographic abnormalities created by the PKP wound can limit contact lens wear. In addition, contact lens intolerance may be caused by ocular, occupational, and systemic factors. Patients with dry eyes, blepharitis, lid abnormalities, and corneal neovascularization may not tolerate contact lenses. Occupational concerns include exposure to environmental factors such as wind, water, smoke, and poor sanitary conditions. Patients with poor manual dexterity, tremors, arthritis, or decreased visual acuity may be unable to manipulate a contact lens. Finally, unmotivated patients and patients unwilling or unable to practice good contact lens hygiene will be contact lens failures. In these patients, surgical alternatives may be the only option.

PHOTOREFRACTIVE KERATECTOMY FOLLOWING PENETRATING KERATOPLASTY

Given the success of the excimer laser in treating myopia and astigmatism,[17–19] photorefractive keratectomy (PRK) has been studied and used to treat post-PKP refractive errors.[20–32] However, the use of PRK in PKP patients is less predictable and less effective than for naturally occurring astigmatism and myopia.[20,21,33] A previously transplanted cornea may respond differently to PRK because corneal wound healing in a grafted cornea may differ from the normal wound-healing response of a patient's own cornea.[20] Post-PKP PRK is also associated with increased incidence of irregular astigmatism,[34,35] significant regression, and late-developing corneal haze, which limit the effectiveness of PRK after PKP.[20,23,24,31,36] Maloney et al, in a multicenter trial, reported a 29% rate of two lines or more visual acuity loss in patients treated with a PRK following prior ocular surgery.[27] Two case reports have documented allograft rejection following surface excimer laser photoablation.[37,38]

Recently, topography-modulated PRK after PKP has been investigated to treat irregular astigmatism.[39,40] The software program, corneal interactive programmed topographic ablation (LIGI, Taranto, Italy), has been shown to be extremely effective for the treatment of irregular astigmatism after PKP.[39] This software

program, by transferring programmed ablation from the corneal topography to a flying-spot excimer laser, is able to provide customized laser ablation to correct post-PKP astigmatism. There was improvement in uncorrected and best-corrected visual acuity in all 10 eyes studied. During the mean follow-up of 8.4 months, no haze or regression was observed. The authors attribute their good results to the nature of the localized abnormality seen with irregular astigmatism. Ablating this localized abnormality requires less tissue removal than that required to correct a similar amount of regular astigmatism. Alessio et al believe that this sparing of corneal tissue allows treatment of high levels of irregular astigmatism, achieving at the same time a regular and smooth surface.[39] Hjortdal and Ehlers have also studied astigmatism in postkeratoplasty eyes with customized laser ablation and have concluded that topography-guided PRK of highly astigmatic corneal grafts can improve best-corrected visual acuity and decrease corneal wavefront aberrations.[40]

While PRK is effective in reducing spherical equivalent to improve uncorrected and best-corrected visual acuity as well as refractive and keratometric astigmatism, there is frequently a decrease in best spectacle-corrected visual acuity (BSCVA) of at least one line. Visually significant haze, which develops from 3 to 12 months postoperatively, is the primary cause of the reduced BSCVA. More postoperative visually significant haze develops in PRK patients who have undergone prior keratoplasty, and a tendency for haze formation correlates positively with ablation depth.[20,23,34] In addition to reducing BSCVA, dense haze may also induce regression and irregular astigmatism and cause visual symptoms, including haloes, blurred vision, and glare. Many techniques have been tried that have had either little or no success in reducing postoperative haze or which produced severe side effects, including postoperative steroids,[41,42] corneal cooling and rehydration during PRK,[43] synthetic inhibitor of metalloproteinase and cyclosporin A,[44] and topical antitransforming growth factor-beta and topical interferon alpha 2b.[45,46] More recently, mitomycin C (MMC), an antibiotic with alkylating properties, has been shown to be effective in treating post-PRK haze by preventing the proliferation of keratocytes,[47–51] and MMC has been shown to decrease corneal light scattering after phototherapeutic keratectomy.[52] MMC inhibits DNA synthesis, preferentially affecting rapidly dividing cells, is fast acting, and demonstrates long-lasting suppression of keratocyte activity after only a single dose.[51] Typically only prolonged use of higher concentrations of MMC lead to significant complications.[53,54] Transient toxic side effects such as hyperemia, pain, and blepharospasm have been reported with 0.02% MMC but resolved with cessation of the drug.[47] Majmudar et al[49] used MMC in eight eyes of five patients who had undergone RK or PRK and demonstrated an improvement in corneal clarity and BSCVA in each eye. The technique described by Majmudar et al[49] and Raviv et al[55] is as follows. A no. 64 Beaver blade was used to remove the patient's corneal epithelium and as much fibrosis as possible. Then a 6 mm circular sponge soaked in MMC (0.02%) was applied to the central corneal surface for 2 min. After removal of the sponge, the ocular surface was irrigated with 30 mL of balanced salt solution. The eye was then covered with antibiotic-steroid ointment and covered with a contact lens or patch. In one of the eight eyes described by Majmudar et al[49] they used MMC to treat central haze in a PRK patient post-PKP. A 44-year-old patient, who underwent PRK post-PKP 18 years prior, developed corneal haze, which limited the BSCVA to 20/30. The described procedure resulted in a clear cornea and BSCVA of 20/20. Azar and Jain[56] emphasize that based on the data by Majmudar et al[50] it may be justified to use MMC to treat pre-existing corneal scarring; however, they caution against the use of MMC for the prevention of corneal scarring. Azar and Jain propose that, if MMC is used prophylactically, the use of annular application may be more beneficial than use of MMC-soaked discs.[56,57] They hypothesize that the beneficial effect of MMC may be due to the inhibition of keratocytes under the annular zone of application, thus decreasing the centripetal migration of activated keratocytes and subsequent collagen deposition. They also believe that the annular method may be beneficial in decreasing corneal toxicity and the contact of MMC with the central 3 mm of the cornea. We have applied 0.02% MMC for 30 s to nine patients undergoing PRK following PKP for keratoconus, with no loss of BSCVA, corneal haze, or adverse reactions to the corneal button. Solomon et al[58] presented a case of a 43-year-old male with a refraction of +7.00 -4.75×125 in the right eye who underwent PRK 10 months following PKP for keratoconus. A hyperopic ablation was performed ablating 72 µm of tissue in a 522-µm-thick cornea with a 6.0 mm optical zone and 9.0 mm ablation zone. After photoablation, 0.02% MMC was applied to the corneal stromal bed for 2 min with a sponge and then irrigated copiously with balanced salt solution. Six months postoperatively, the patient's uncorrected visual acuity (UCVA) was 20/30, and the BSCVA improved to 20/20 with a refraction of -0.25 -0.25×164. No corneal haze was reported postoperatively. Additional studies have been performed by the authors of this chapter to examine the effectiveness of PRK post PKP with MMC, and only one patient has experienced corneal haze, which was safely removed with a lamellar keratectomy.[48] When applied as described by Majumdar et al[49] MMC appears to be a safe and effective method for treating postoperative haze following PRK and may improve the efficacy of PRK following PKP.

Laser-assisted subepithelial keratectomy (LASEK) has also been evaluated in the management of ametropia and irregular astigmatism after keratoplasty. In a pilot study, 16 eyes of 15 patients who were intolerant of spectacle and contact lens correction due to astigmatic anisometropia after keratoplasty (15 penetrating and 1 lamellar) had topography-assisted customized excimer laser treatments. All eyes had LASEK using 15% alcohol with a 20–30 s application. Four eyes received an application of mitomycin-C (MMC) 0.2 mg/mL for 1 min after stromal ablation. The mean preoperative spherical equivalent (SE) was -3.50 ± 3.97 D (SD) (range +1.625 to −9.25 D). The preoperative cylindrical error was −7.2 D (range −2.75 to −13.5 D). The programmed laser correction was −3.14 D (range +1.62 to −9 D) with a maximum attempted cylindrical correction of −7 D. At the final follow-up visit of 18 months, the mean postoperative SE was -1.08 ± 1.85 D (range +3 to −4.78 D). Ten eyes (62.5%) were within ±1 D of the intended correction. The mean postoperative cylindrical error was −2.72 D (range −0.5 to −6.5 D). Analysis of higher-order aberrations using a 6.0 mm pupil size demonstrated a significant reduction of higher-order root mean square (RMS), trefoil, and fourth-order spherical aberration at 18 months compared with preoperative values. Uncorrected visual acuity improved in all eyes. Best spectacle-corrected visual acuity was unchanged or improved in 13 eyes (81%) and worse in 2 eyes by 1 line; 1 eye lost 3 lines due to an increase in preexisting cataract. In eyes that did not receive MMC, corneal haze (grades II–IV) was encountered in three eyes (27%). One eye

required phototherapeutic keratectomy with MMC application at 12 months. Of the four eyes treated with MMC, one had trace haze and three had no detectable haze. There were no other complications reported. A significant improvement of both lower- and higher-order aberrations was obtained with good refractive stability for over 18 months. Iatrogenic haze typically occurred but appeared to be minimized with adjunctive use of intraoperative MMC.[59]

LASIK FOLLOWING PENETRATING KERATOPLASTY

LASIK offers several advantages over PRK in the treatment of myopia and astigmatism. These advantages include, but are not limited to, rapid visual rehabilitation, decreased stromal scarring, less irregular astigmatism, minimal regression, and the ability to treat a greater range of refractive disorders.[17,60–63] The major disadvantage of laser in situ keratomileusis (LASIK) is the risk of complications related to the creation of the lamellar flap. There have been several reports demonstrating efficacy and safety of LASIK following PKP.[64–76]

PATIENT SELECTION AND PREOPERATIVE EVALUATION

LASIK following PKP is subject to the same constraints as conventional LASIK. Monocular patients or patients with limited visual potential in the fellow eye are not good candidates. In addition, patients with wound healing disorders, significant dry eye, and collagen vascular disease should be offered other options. Finally, patients should have realistic expectations for their rehabilitation following LASIK for PKP. The accuracy of the procedure is not as precise as conventional LASIK and patients should expect to require spectacles for residual refractive error. The goal of LASIK following PKP is the return of spectacle-corrected binocularity.

TIME INTERVAL BETWEEN PKP AND LASIK

The time frame between performing the PKP and the LASIK procedure has not been firmly established. However, all corneal sutures must be removed prior to the LASIK as they will induce astigmatism. The time frame for suture removal varies greatly depending on the variables of patient age, corneal vascularization, corticosteroid use, physical examination of the graft–wound interface, and surgeon preference. Following suture removal there are two variables, which dictate whether the eye is ready for LASIK: a stable refraction and a well-healed wound, which will withstand the increased intraocular pressure, created during the LASIK procedure. Conventional wisdom is that following gas-permeable contact lens wear, the lens should be removed for a month for every decade of contact lens wear. Following suture removal, the cornea should also be allowed to return to a stable configuration. Lam and colleagues[77] have recommended that the wound be examined for whitening and scarification, while the refraction and corneal topography should be stable on serial evaluation. Some authors recommend waiting for 2–3 years,[65,68] while others recommend for as little as 8 months[67] to perform LASIK following the PKP procedure. Of note, there have been no documented cases of wound dehiscence following LASIK for PKP refractive errors. We therefore recommend waiting a minimum of 3 months following suture removal and until serial topographies are stable to perform LASIK following PKP. We always perform monocular surgery.

PREOPERATIVE EVALUATION

The preoperative examination should be comprehensive and should include a thorough retinal evaluation. The ocular surface should be carefully evaluated, as patients following PKP will have decreased corneal sensation and may have accompanying tear-film abnormalities. The anticipated LASIK procedure will often cause a neurotrophic keratitis and worsen the dry eye condition.[78] Patients with preoperative lid disease should be treated with lid hygiene, antibiotic and/or steroid application to the lid margin as indicated, and oral tetracycline family antibiotics as indicated. Patients with aqueous deficiency dry eye should be treated with tear supplementation, ointments, and punctal occlusion when needed. The corneal graft should be carefully evaluated. Any sign of allograft rejection or intraocular inflammation is a contraindication to the procedure and should be treated. Areas of pannus should be noted, as they may cause significant bleeding during the LASIK procedure. In addition, the graft–host interface should be examined for adequate wound healing and particularly for signs of poor wound apposition. Patients with high astigmatism may have an unstable wound with over-ride of the wound, which would increase the risk of wound dehiscence. Typically, patients with wound over-ride will have marked hemimeridional flattening in the axis of the over-ride. These patients should have their wound reapproximated in the aberrant region and then resutured prior to considering LASIK. The corneal clarity and pachymetry should be evaluated and, when in doubt, specular microscopy should be performed. Patients with poor endothelial reserve may have an increased risk of flap slippage due to decreased endothelial pump function holding the flap in place. Patients with a history of keratoconus should have their topography examined carefully for signs of recurrent disease. When the topography is equivocal or additional information is needed, new technology, such as the Orbscan (Orbtek, Inc., Salt Lake City, UT) or high-frequency ultrasound may provide additional information regarding anterior corneal curvature, posterior corneal curvature, and corneal pachymetry. Patients with previous relaxing incisions should have the axis of the incisions carefully documented. The corneal hinge should be positioned away from the relaxing incision to decrease the incidence of free flaps. For example, a patient with a superior relaxing incision should have a nasal hinged flap.

The status of the lens should also be carefully evaluated. Following PKP there is an increased incidence of cataract formation. LASIK is contraindicated in these patients who would most benefit from cataract extraction and intraocular lens implantation to help correct spherical refractive errors. In patients with a history of previous cataract extraction and intraocular lens implantation the status of the implant should be evaluated. In general patients with posterior chamber lenses do very well with LASIK. On the other hand, LASIK is usually contraindicated in patients with an anterior-chamber intraocular lens, unless the anterior chamber is very deep. These patients are at risk of endothelial touch against the intraocular lens when the cornea is compressed during the microkeratome pass.

The most common indication in the USA for PKP is pseudophakic bullous keratopathy (PBK).[79–81] There is a high incidence of macular pathology following PKP for PBK. Patients whose final visual rehabilitation is limited by macular pathology are often less motivated to wear contact lenses. Chronic cystoid macular edema is seen in

42–50% of cases of PBK,[82,83] and there is a 6–24% incidence of involutional macular degeneration following PKP,[84,85] both of which can severely limit visual rehabilitation. These patients may have a best-corrected visual acuity ranging from 20/25 to count fingers, with the majority having visual acuities of 20/40 or less.[15] Price et al reported that only 50% of patients with grafts for PBK achieved a visual acuity of 20/40 or better,[15] while Zaidman and Goldman[86] reported 31% and Speaker et al[87] a 22% incidence of visual acuity of 20/40 or better following PKP for PBK.

Pseudophakic bullous keratopathy occurs overwhelmingly in an elderly population. Assuming that these patients have good visual acuity in their fellow eye, there may be little motivation for an elderly individual, with no possibility of visual rehabilitation to the level of the fellow eye, to wear a soft or gas-permeable contact lens. These patients have had previous cataract surgery, PKP, approximately 1 year of postoperative visits prior to suture removal and, often, a vitreoretinal consultation. When they are ready for their visual rehabilitation, they are told that they cannot be improved with spectacles due to significant anisometropia. Even though their central visual acuity may be diminished, these patients would benefit greatly from the expanded peripheral visual field. These patients are excellent candidates for post-PKP LASIK, which can offer permanent rehabilitation of their refractive error.

Recently Mann et al studied patients who have had bilateral PKP. They determined that patients who have undergone bilateral PKPs with good postoperative vision and low levels of myopia, astigmatism, and minimal wound over-ride are good candidates for bilateral nonsimultaneous LASIK.[88]

Surgical technique

There are several alterations of our normal LASIK technique when treating myopia and/or astigmatism following PKP. As in all LASIK, preservation of the epithelium is extremely important to reduce the risk of flap slippage, epithelial ingrowth, and flap melts. Following a PKP these concerns are even more important. The surgeon should optimize the ocular surface preoperatively as discussed earlier and at the time of surgery minimize the use of topical anesthetics with the first drop of topical anesthesia given immediately prior to the surgical procedure. The ocular surface should be irrigated immediately following surface marking with gentian violet to reduce toxicity but maintain the marking in the event of a free flap. Perioperatively, toxic medications such as the aminoglycoside antibiotics should be avoided, and, if a nonsteroidal anti-inflammatory is employed, we prefer nonpreserved ketorolac tromethamine (Acular LS, Allergan, Irvine, CA). Intraoperatively, following flap repositioning, we place a drop of carboxymethylcellulose 1% (Celluvisc, Allergan, Irvine, CA) directly on the center of the flap after approximately 30 s to lubricate and protect the ocular surface.[89] After repositioning of the corneal flap, we generally wait 2 min for the flap to adhere to the underlying stromal bed in conventional LASIK. In LASIK after PKP, we wait 5 min for flap adherence before removing the speculum. We carefully perform a striae test for flap adherence and, if the flap is not tightly apposed to the stromal bed or if there is an epithelial defect, we place a bandage contact lens. Immediately after exiting the surgical suite the patient is asked to gently keep their eyes closed for 30 min, and the flap is re-evaluated carefully by slit-lamp biomicroscopy. Any flap irregularity is dealt with, and we do not allow the patient to leave until we are fully satisfied that the flap is in good position. The patients are then asked to return home and keep their eyes closed for 2–3 h. The patient uses nonpreserved tears transiently or for a week and wears a shield for a week as well. We are also more liberal with our use of postoperative corticosteroids than in our normal LASIK patients. In LASIK following PKP, we use prednisolone acetate 1% four times daily for 1 week tapering to once daily for 2 weeks. We feel that the additional use of corticosteroids is indicated due to the potential risk of graft rejection following any surgical procedure on a PKP. For antibiotic prophylaxis we use gatifloxacin 0.3% (Zymar, Allergan, Irvine, CA) four times a day beginning the day prior to surgery and continuing 5 days postoperatively.

We also alter our perioperative management for specific indications. Patients with corneal neovascularization are given one drop of 1% epinephrine 30 s prior to the microkeratome pass to reduce intraoperative bleeding. Patients with a history of herpes simplex or herpes zoster should be evaluated carefully for corneal sensation. Patients with a history of herpes simplex are treated preoperatively with oral antiviral therapy, which is then continued for a minimum of 10 days postoperatively to reduce the risk of recurrent viral disease induced by surgical trauma.

The LASIK surgeon must maintain a high degree of concern for the possibility of flap instability and slippage in any postkeratoplasty eye, especially during the perioperative period. Solomon et al[90] presented three cases of flap slippage in postkeratoplasty LASIK eyes. The main risk for flap slippage was corneal edema. All three patients had PKB as the indication for PKP, and all had peripheral corneal edema at the time of flap slippage, which occurred at a mean of 7 days postoperatively (range, 3–10 days). The final results of treatment for flap slippage were mixed. One patient had a lift and smooth procedure with a one-line improvement in BSCVA to 20/40; one patient had a two-line loss of BSCVA and underwent removal of the surgical flap, with UCVA of 20/50 and no loss of BSCVA of 20/30. The third patient had a three-line loss of BSCVA following a lift and smooth procedure and underwent a repeat PKP for irregular astigmatism. This small case series highlights the importance of the endothelial pump function in maintaining the adherence of the LASIK flap. Any sign of corneal edema is an indication that the endothelial pump function has been overwhelmed and that the flap is at increased risk of slippage.

Corneal grafts are at higher risk of corneal edema because of their lower numbers of endothelial cells. The mean human endothelial cell density starts at around 4000 cells/mm^2 in the first decade of life, declining gradually to a plateau of around 2600 cells/mm^2 by the age of 40 years.[91] While the average cell density of donor corneas is around 2665 cells/mm^2,[92] grafts undergo a more rapid and continual decline in endothelial cell count than do normal corneas, with cell loss of 7.8% per year for the first 5 postoperative years, followed by a 4.7% annual decline for years 5–10, according to a Mayo clinic study.[93] This compares to a 0.5% per year decline in normal controls.[94]

Even if a graft is clear and nonedematous before LASIK, the surgeon must decide whether there is a possibility of endothelial compromise from LASIK itself. On the one hand, current studies have found no long-term endothelial effects of LASIK. Jones et al found no effect on the endothelium in 98 eyes that were followed up to 12 weeks postoperatively,[95] and Pérez-Santonja et al, who followed patients up to 6 months, found that endothelial parameters in contact lens wearers actually improved after LASIK because of the discontinuation of contact lens wear.[96] One study of four patients who underwent LASIK after PKP and were followed for 12 months found no change in the endothelium.[97] On the other hand, changes in endothelial cell morphology, probably related to transient corneal edema, were noted at 15 min postoperatively by Kim et al.[98]

Although these changes resolved by the first postoperative day, they could compromise endothelial pump function in postkeratoplasty eyes.

As part of the LASIK evaluation in postkeratoplasty eyes, we recommend a careful examination of the corneal graft for evidence of corneal edema. Pachymetry should be reviewed not only for adequate post-LASIK bed thickness but also for evidence of edema. Specular microscopy may be performed if there is clinical suspicion of low endothelial cell density.

In most cases of LASIK, especially in patients with a history of a dry eye, we recommend a nasal-hinged flap, which helps to retain corneal sensation. We maintain this recommendation in postkeratoplasty eyes because maintaining corneal sensation is vital to long-term success of a corneal graft. However, in the case of LASIK performed on a postkeratoplasty eye with Fuchs' dystrophy or PBK, or any postkeratoplasty eye in which the endothelial function may be marginal, we instead recommend an 8.5 mm-diameter superior hinge flap, particularly when the peripheral host bed has frank edema. If the peripheral cornea is edematous and the pump function of the endothelium is decreased, it is more likely that the peripheral flap will elevate and dislocate following a blink, compared to a superior-hinged flap. The smaller-diameter flap has less tissue overlying the edematous peripheral bed and is also less likely to elevate. We also recommend that patients with endothelial compromise who undergo LASIK wear protective shields for a longer than normal period and be followed closely to reduce the risk of flap slippage.

At the time of surgery we use our standard LASIK procedure altered only to avoid initiating the incision at the corneal transplant graft–host interface. The patient's donor corneas generally range in size from 7.75– 8.5 mm in diameter. The flap diameter created by most microkeratomes is approximately 8.5–9.5 mm. Therefore, the flap is almost exactly the same size as the donor cornea. We avoid initiating the flap temporally or inferiorly at the graft–host interface, while attempting to center the flap over the pupil. This allows the flap to drape over the wound. We believe that this creates better wound apposition of the flap to the recipient bed. The corneal scar tissue at the PKP wound tends to be less pliable than normal corneal tissue. In addition, initiating the LASIK incision away from the wound prevents applying additional pressure directly to the corneal transplant incision and may decrease the risk of wound dehiscence. We also avoid placing the hinge over corneal relaxing incisions.

ONE-STEP VERSUS TWO-STEP LASIK FOLLOWING PENETRATING KERATOPLASTY

When planning to perform LASIK on an eye with a previous corneal transplant, the surgeon must address the issue of whether to perform LASIK as a one- or a two-step procedure. In the two-step procedure, as described by Vajpayee and Dada,[99] the surgeon cuts and replaces the flap and then follows the corneal topography, keratometry, and refraction for a variable span of time (weeks to months). Once the measurements have stabilized, the flap is lifted and ablation is performed to correct any residual refractive error.

The main argument for performing a two-step procedure is that some corneal remodeling may occur following the creation of the microkeratome cut alone. This cut may change the biomechanics of the post-transplant cornea, which depends to a great extent on the dynamics at the host–graft interface. Changes in corneal shape following the creation of a flap, and prior to laser ablation, has been noted by Roberts.[100] Anecdotally, Vajpayee and Dada reported treating several of their patients successfully with the two-step procedure. Busin et al[101] sought to take advantage of the change in astigmatic power and/or axis that occurs following the creation of a lamellar cut. In a series of nine eyes, all of which were at least 22 months post-transplant, creation of lamellar flaps alone resulted in a mean reduction of 1.6 D of cylindrical error and 1.0 D mean reduction of myopia 3 months postoperatively, without laser ablation. Alio and colleagues[102] compared the correction of postkeratoplasty astigmatism using LASIK in a one-step (11 patients) versus a two-step (11 patients) procedure. The authors suggested that a two-step approach may lead to a more precise and better refractive outcome in PKP eyes. Mularoni and colleagues examined a two-step LASIK procedure using topography-guided ablation to correct astigmatism after PKP. In the first step, a flap was created using the Hansatome microkeratome. In the second step, topography-guided ablation using the LaserSight LSX was planned with interactive software (CIPTA) once topographical and refractive stabilization had been obtained. Uncorrected visual acuity improved in all 15 (100%) eyes. Mean postoperative astigmatism was −1.67 (range: −3.5 to 0; SD: 1.26). No patient lost Snellen lines of BSCVA.[103]

There are a few arguments for performing a one-step LASIK procedure in a postkeratoplasty eye. First, it is likely that most of the instability of the refractive error following flap formation (with or without stromal ablation) is due to a change in flap position rather than to changes in corneal biomechanics. Good flap position may be difficult to obtain even in normal corneas, and flap instability is especially problematic in postkeratoplasty eyes, in part because of the compromised pump function of the graft endothelium, and in part because of the irregularity of the bed and the graft–host junction. It is possible that the changes in refraction and topography, seen over the weeks to months following the creation of a corneal flap in a postkeratoplasty eye, are due to continued slippage of the flap. If this is the case, then performing a two-step procedure simply increases the uncertainty about the final flap position because the flap must be laid down twice. In addition, performing a two-step procedure gives rise to an additional episode of possible flap complications, including infection and allograft rejection. The adherence of the flap over some areas of the graft–host interface can be much more tenacious than is seen in normal corneas, making it more difficult for the surgeon to re-lift the flap without complications. Epithelial ingrowth becomes a higher likelihood with the irregular flap border that can occur in these situations.

Although the refraction in postkeratoplasty eyes seems to fluctuate more than in normal eyes, the results of the one-step procedure produce a considerable and immediate improvement in visual function that will be delayed with the two-step procedure and that is not achieved with the creation of a lamellar flap alone. Nirankari produced a 74% reduction in myopia with the one-step method, and Solomon et al achieved a 90% reduction in myopia in 22 patients (with an average improvement of 6.8 D at 3 months).[90] In contrast, Busin et al saw a reduction of myopia by 19% in eyes treated with a lamellar cut alone.[101] The cylindrical correction was also better with the one-step method (a 65% reduction in cylinder documented by Nirankari, and 59% by Solomon et al[90]) compared to the lamellar-flap-only method (32% reduction in cylinder).[101]

COMPLICATIONS OF LASIK AFTER PENETRATING KERATOPLASTY

Any complication reported following LASIK for visual rehabilitation of myopia, hyperopia, or astigmatism may occur following LASIK for postkeratoplasty refractive error. The complications cited in the

literature include intraoperative paracentral flap perforation,[68] flap dislocations requiring placement of a suture,[68,70] buttonhole flap,[71] hemorrhage in the stromal bed,[64] obstruction of the microkeratome path by graft sutures,[64] consecutive irregular astigmatism,[66] photoablation decentration,[94] corneal perforation concurrent with astigmatic keratotomy performed under the flap,[69] peripheral interface epithelial ingrowth not requiring treatment,[74] one case of severe epithelial ingrowth treated without success for 6 months at which time eye had irregular astigmatism and moderate stromal melt,[75] and three cases of diffuse lamellar keratitis, one of which caused a decrease in BSCVA.[76] We have additionally seen flap striae, epithelial ingrowth, and flap melts following LASIK in patients with previous PKPs (Figs 59.1–59.4).

In LASIK the intraocular pressure is elevated to over 65 mmHg, and there is a very small but very real risk of wound dehiscence. We recommend LASIK following PKP be performed by experienced LASIK surgeons who can minimize the suction time needed during surgery. A careful slit-lamp examination on the day of surgery is extremely important, as improper wound alignment may lead to wound dehiscence, epithelial ingrowth, poor flap adherence, and ectasia.[70]

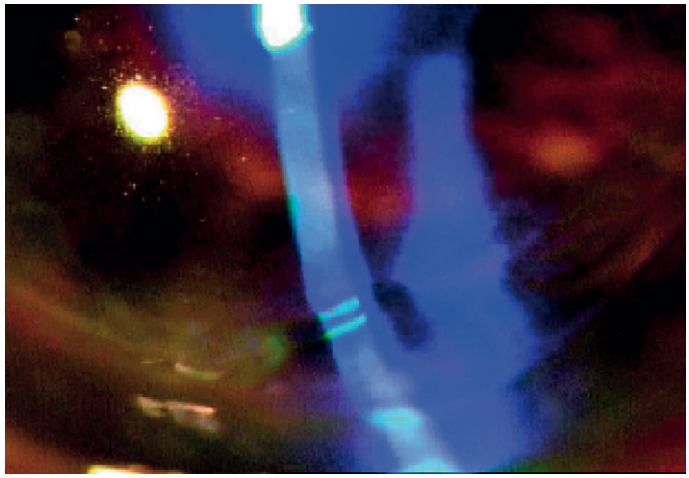

Figure 59.1. Epithelial ingrowth following LASIK in a patient with previous PKP.

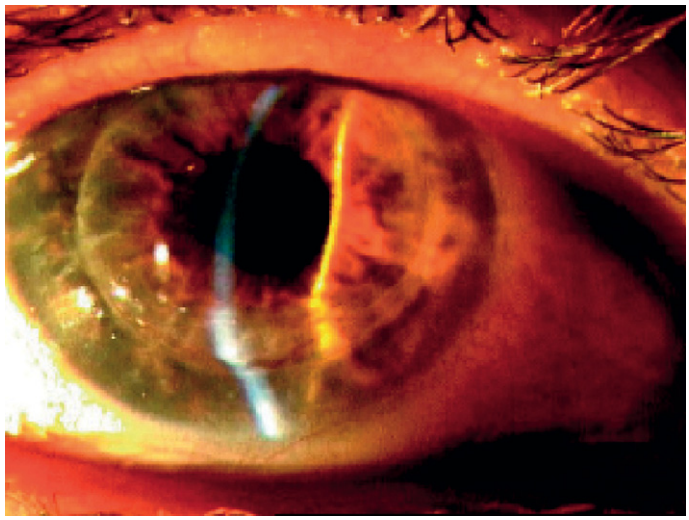

Figure 59.2. Flap melt in a patient with epithelial ingrowth following LASIK after PKP for residual refractive error.

If the placement of a flap on an eye post PKP needs to be adjusted, it is extremely important to carefully debride that epithelium, which rapidly grows over the exposed stromal bed. Flap stabilization with 10-0 nylon interrupted sutures should be considered if the flap does not properly adhere. It is important to bury the knots outside the flap to prevent epithelial defects on the flap and epithelial seeding at the stromal interface. Furthermore, burying the knots under the peripheral epithelium helps to prevent flap dislocation from suture tension caused by the resistance to sliding of the knot through the flap at the time of surgical removal.[70]

CLINICAL RESULTS

The first case reports by Arenas and Maglione,[64] Arenas and Garcia,[73] Zaldivar and associates,[65] as well as Parisi et al[67] in 1997 documented the efficacy of LASIK following PKP. In these case reports, all the patients were treated for residual myopia or myopic astigmatism following PKP for keratoconus.

The first large series of LASIK following PKP was presented by Donnenfeld and associates at the American Academy of Ophthalmology in 1998 and published in 1999 (Table 59.1).[66] The most common indication for the PKP was keratoconus (13 eyes), followed by PBK (5 eyes), Fuchs' endothelial dystrophy with combined cataract extraction (3 eyes), herpes simplex keratitis (1 eye), and herpes

Buzard et al	26	92.9	60.9	86
Hardten et al	57	85.4	58.5	43

[a]Fourteen patients also received arcuate keratotomies in the stromal bed at the time of surgery.

LASIK, laser in situ keratomileusis; UCVA, uncorrected visual acuity.

zoster keratitis (1 eye). Fifteen eyes were phakic and eight eyes were pseudophakic. Three patients had undergone corneal relaxing incisions for high cylinder following PKP and antecedent to their LASIK surgery. Two patients underwent enhancements. Sixteen eyes were followed for 6 months, and seven eyes were followed for 12 months. The mean spherical equivalent preoperatively was −7.58 ± 4.42 D, which was reduced to −1.09 ± 2.01, −0.79 ± 1.84, −0.77 ± 1.25, and −1.57 ± 1.20 D, respectively, 1, 3, 6, and 12 months following LASIK. The mean cylinder preoperatively was 3.64 ± 1.72 D, which was reduced to 1.98 ± 1.15, 1.64 ± 1.14, 1.48 ± 0.92, and 1.29 ± 1.04 D, respectively, at 1, 3, 6, and 12 months following LASIK. Spherical equivalent anisometropia was reduced from a mean of 6.88 ± 4.4 to 1.42 ± 1.05 D at the final examination. Best-corrected visual acuity remained the same or improved in 21 of 23 eyes and decreased by one line in a patient who developed a nuclear sclerotic cataract and three lines in a patient who developed irregular astigmatism. Endothelial cell counts measured in nine patients preoperatively and at 3 months postoperatively demonstrated no statistically significant loss. There were no surgical flap or corneal transplant complications.

RESULTS AND VISUAL OUTCOME

There have been several other studies of comparably large series examining LASIK after PKP whose results are summarized in Table 59.1. Preschel and colleagues[70] examined 25 eyes treated with LASIK for astigmatism and myopia following PKP. Two eyes were enhanced with additional LASIK, but the authors did not include these postenhancement results in their analysis. Fifteen patients were followed for at least 6 months and five of those were followed for 1 year. The mean follow-up time was 5.52 months with a range of 1 day to 12 months. The mean preoperative spherical equivalent of −4.70 ± 2.98 D was decreased to −0.95 ± 1.45 D postoperatively. The mean cylinder preoperatively was −4.58 ± 2.12 D, which was reduced postoperatively to 1.60 ± 1.19 D. For this series, the UCVA was available in only 16 eyes at the last examination. Prior to LASIK, the UCVA was worse than 20/40 in all the eyes. After LASIK, 31.81% of the eyes demonstrated an UCVA of equal to or better than 20/40. Best spectacle-corrected visual acuity remained the same or improved in 16 of 23 eyes. Four eyes lost one line of BSCVA and three eyes lost two lines of BSCVA, one of which only had 1 day of post-LASIK follow-up. Another one of these eyes had a dislocated flap on the first postoperative day and had a BSCVA of 20/30 but gained four lines of UCVA. A third eye of this group had a postoperative BSCVA of 20/40 but gained eight lines of UCVA from 20/800 to 20/50. The complications in this series were two displaced flaps that were treated with 10-0 nylon interrupted sutures to stabilize the flaps after repositioning.

Guell and coworkers[74] performed LASIK in 87 eyes of which 20 had undergone prior PKP. The authors presented a pooled analysis of the results of LASIK after PKP and after other surgical procedures including RK, PRK, and cataract surgery. A distinct analysis of post-PKP results was not offered. They did note that the predictability in treating astigmatism in post-PKP eyes was comparable to that for eyes with no prior surgery. The authors reported that when examining stability of post-LASIK refraction for the entire group, a change of ±0.5 D was observed for 94.3% of patients. They point out that an important exception was one case of LASIK after a PKP, which regressed 2.00 D of cylinder. Guell et al also noted that for 45% of the eyes (9 out of 20 eyes) that were treated with LASIK post PKP, enhancements were necessary to treat undercorrections. Although not included in the studied series, Guell and coworkers mentioned that they perform relaxing incisions in post-PKP eyes with more than 6 D of cylinder and wait until the refraction is stable to treat the residual error with LASIK.

Webber and associates[69] studied 26 eyes and reported results of LASIK in 25 eyes with post-PKP ametropia. One eye was excluded from the analysis as it sustained a corneal perforation. The most common indication for PKP in the Webber et al study was keratoconus (23 eyes). The three other grafts were performed for PKB, childhood trauma, and *Acanthamoeba* keratitis. Four eyes had a history of ocular surgery after the PKP. One eye underwent a cataract extraction with intraocular lens implantation, one eye had a resuture of the graft–host junction, and two eyes had incisional refractive keratectomies. Fourteen eyes received arcuate cuts in the stromal bed at the time of surgery. Eighteen eyes were followed for 6 months or more and seven eyes were followed for 12 months. The mean preoperative spherical equivalent of −5.20 ± 2.31 D was reduced to −1.31 ± 1.63 D at the final follow-up. The mean cylinder preoperatively was −8.67 ± 3.22 D, which was decreased postoperatively to 2.92 ± 1.71 D. The patients who received arcuate cuts concurrent with the LASIK demonstrated greater target-induced

astigmatism, surgically induced astigmatism, and astigmatism correction index than those eyes, which did not. Three eyes showed a decreased BSCVA by one line and all eyes were unchanged or showed improvement in up to six lines of UCVA.

In their case series, Forseto and colleagues[68] studied the efficacy of LASIK in 22 eyes post keratoplasty. Eighteen eyes had a history of prior PKP, while four eyes underwent lamellar keratoplasty. The most common indication for PKP in the Forseto et al study was keratoconus (20 eyes). The two other grafts were performed for leukoma from herpes and irregular astigmatism after LASIK. The eyes were followed for an average of 10.09 months with 11 patients being followed for 1 year. Spherical equivalent demonstrated a mean reduction from –4.55 ± 3.66 D preoperatively to –0.67 ± 1.24 D postoperatively. Cylinder demonstrated a mean reduction from –4.24 ± 2.29 D preoperatively to –1.79 ± 1.12 D postoperatively. In 17 eyes the BSCVA was unchanged or improved. Of the five eyes not showing improvement, two lost two lines and three showed a decrease in one line of BSCVA. Stability of the refractive results was noticed between 1 and 6 months post-LASIK. At their final examination, 16 eyes (72.7%) demonstrated a refractive error within ±1.00 D of emmetropia. In 11 eyes it was determined that the mean endothelial cell count did not show any statistically significant loss. There were complications in two eyes, one eye had an intraoperative paracentral flap perforation and the other eye had a flap dislocation, which required stabilization with sutures.

In a series of 27 cases, Lima and colleagues[75] reported results of LASIK to correct ametropia after PKP for keratoconus for 26 of the eyes. One eye was excluded from the analysis because of an inability to obtain an exact postoperative refraction. The patient was treated for severe epithelial ingrowth for 6 months at which point the patient developed irregular astigmatism and moderate stromal melt. The average length of follow-up was 9.52 months for 23 myopic eyes and 5.75 months for 4 hyperopic eyes. Prior to LASIK, the mean refractive spherical equivalent in the myopic eyes was –5.27 ± 1.91 D and –0.45 ± 1.68 D at the final follow-up. Mean spherical equivalent for hyperopic eyes decreased from +5.18 ± 1.46 to +1.18 ± 0.94 D post-LASIK. In all of the hyperopic eyes and 18 (78%) myopic eyes, postoperative UCVA was 20/40 or better. Postoperative BSCVA was better than 20/25 in all of the hyperopic eyes and 22 (95.7%) of the myopic eyes. One eye lost one line of BSCVA. The significant complication was that one eye lost six lines secondary to refractory epithelial ingrowth, which resulted in irregular astigmatism and stromal melt.

Malecha and Holland[76] examined LASIK in 20 eyes following PKP. One eye was excluded from the analysis because of a severe traumatic injury post LASIK. In the majority of eyes (73.7%) keratoconus was the indication for PKP. Other causes included corneal scar secondary to injury (two eyes), corneal scar secondary to HSV keratitis (one eye), and corneal thinning (one eye). One eye received an accurate incision in the graft to reduce astigmatism. The average length of post-LASIK follow-up was 5 months (range 1–14 months). UCVA was 20/400 or worse in 73.7% of eyes before LASIK and improved to 20/40 or better post LASIK in 73.7% of eyes. The mean preoperative refractive spherical equivalent was reduced by 3.39 D (80.0%) from 4.24 ± 2.81 D preoperatively to 0.85 ± 0.84 D at the final follow-up. The mean cylinder was reduced by 2.83 D (69.9%) from 4.05 ± 1.71 to 1.22 ± 1.14 D. Seventeen of the nineteen eyes achieved a BSCVA of 30/40 or better. Myopic degeneration was responsible for the decreased BSCVA in one eye with BSCVA of 20/50 and DLK was noted in one eye with a BSCVA of 20/150. A total of three eyes developed DLK and were treated with steroids. Two of the cases resolved promptly with no decrease in BSCVA. In the third case, grade 2 DLK persisted, causing stromal haze and decreased BSCVA in a patient with a history of systemic lupus erythematosus.

Buzard and colleagues[104] evaluated 26 eyes that had LASIK at least 1 year after PKP. All eyes were followed for at least 6 months after LASIK; 22 eyes were followed for 12 months. Sutures were removed at a mean of 13 months post PKP. Before LASIK, the mean spherical equivalent (SE) was –4.94 ± 2.79 D and the mean astigmatism was 2.71 ± 2.33 D. At the last follow-up at 12 months, the mean postoperative UCVA was 20/30, the mean SE was –0.35 ± 0.65 D, and the mean residual astigmatism was 1.06 ± 0.67 D. Eighty-six percent of patients had an SE within ±1.00 D of emmetropia and a UCVA of 20/40 or better. Ten eyes (39%) had one or more enhancements, which were performed a mean of 6 months after the primary LASIK. The authors noted that significant complications such as wound dehiscence, epithelial ingrowth, and corneal decompensation did not occur. At the last follow-up, 18% of patients lost one line of best-corrected visual acuity and 27% gained one line.

Hardten and coworkers[105] performed a retrospective review of 57 eyes of 48 patients with anisometropia or high astigmatism who were unable to wear glasses or a contact lens after PK and who underwent LASIK for visual rehabilitation. UCVA, BCVA, and corneal transplant integrity were recorded before surgery as well as up to 60 months after LASIK. The mean follow-up after the LASIK was 21.4 ± 14.2 months (range 3–60 months). Mean preoperative SE was –4.19 ± 3.38 D. The mean preoperative astigmatism was 4.67 ± 2.18 D. Preoperative BCVA was 20/40 or better in 42 eyes (74%). At 2 years the mean SE was –0.61 ± 1.81 D, and mean astigmatism was 1.94 ± 1.35 D for the 28 eyes with follow-up. UCVA was 20/40 or better in 12 eyes (43%), and BCVA was 20/40 or better in 24 eyes (86%) at 2 years. A gain in BCVA of one line or more was seen in eight eyes (29%). Two eyes (7%) had loss of two or more lines of BCVA at 2 years. There were nine eyes (16%) that developed epithelial ingrowth and five eyes (9%) in this series had repeat corneal transplants.

SURGICAL ALTERNATIVES TO LASIK FOLLOWING PENETRATING KERATOPLASTY

The surgical alternatives for correction of postkeratoplasty astigmatism include corneal relaxing incisions and wedge resections.[106–108] Kirkness et al reported a series of 201 corneal transplants for keratoconus and found that 18% of patients required refractive surgery for the correction of astigmatism.[109] These procedures can significantly decrease corneal cylinder and are highly effective procedures. However, they have minimal effect on spherical equivalent. In addition, they can be unpredictable and may destabilize the graft–host wound.

Radial keratotomy can decrease low to intermediate levels of myopia. In a large clinical trial, radial keratotomy has been shown to be effective but is associated with glare, significant inaccuracy, refractive instability, increased risk of traumatic ruptured globe, and progressive hyperopia.[110] Most series document poor visual rehabilitation with radial keratotomy for postkeratoplasty myopia; therefore, radial keratotomy is not considered effective in its treatment.[111]

Pseudophakic patients with significant anisometropia can consider an intraocular lens exchange or a piggy-back intraocular lens.

Unfortunately, these patients have already often undergone a significant number of intraocular procedures. This alternative requires an additional intraocular procedure, which increases the risk of endothelial decompensation and glaucoma and may incite a graft rejection.[112]

CONCLUSION

The goal of therapeutic LASIK for visual rehabilitation following PKP is not necessarily the same as LASIK for the correction of myopia and/or astigmatism. The primary goal of LASIK following PKP is resolution of sufficient myopia and astigmatism to allow spectacle correction of the residual refractive error. Uncorrected visual acuity remains a secondary goal with LASIK following PKP, whereas UCVA is clearly the primary objective of cosmetic LASIK. For this reason, return to binocularity and optimized best-corrected visual acuity with spectacles is the true end-point for success with LASIK following PKP.

Unfortunately, irregular as well as regular astigmatism is a common finding after PKP. A potential advantage of LASIK is that there is evidence that the flap in LASIK creates a more regular ocular surface than occurs in PRK.[17] While irregular astigmatism can be a significant problem following LASIK for visual rehabilitation following PKP, we feel that there is less irregular astigmatism as compared to PRK.

Many patients following PKP will have irregular astigmatism, which, although not amenable to spectacle correction, can be rehabilitated with a gas-permeable contact lens. We discourage these patients, if they are at all contact lens tolerant, from having LASIK performed, as the excimer laser is currently not successful in treating irregular astigmatism. We anticipate that the development of customized corneal ablations guided by corneal topography or wavefront analysis will successfully treat some forms of irregular astigmatism in the next several years. This will allow even more accurate treatment of post-PKP refractive errors. While we only treated myopia and myopic astigmatism, LASIK may also be effective in the treatment of hyperopia and hyperopic astigmatism, although their larger peripheral ablations may impact directly on the corneal transplant wound.

In conclusion, LASIK is successful in treating postkeratoplasty myopia and astigmatism in most patients. Patients are overwhelmingly able to resolve their anisometropia and achieve binocular function. LASIK following PKP is more effective in treating residual myopia than astigmatism. We advocate a conservative approach to treating refractive errors following PKP with LASIK. Contact lenses remain the standard of care and are to be encouraged whenever feasible. When contact lens use is not possible, we suggest slightly undercorrecting the myopia, especially when the fellow eye is myopic. In addition, LASIK offers the advantage of allowing enhancements at a later date for residual refractive errors. LASIK offers the corneal surgeon an exciting new tool in the visual rehabilitation of the corneal transplant patient.

60 LASIK and surface ablation

Eric D. Donnenfeld, Steven I. Rosenfeld, Renée Solomon

The era of modern refractive surgery began with the advent of excimer laser photoablation when the 193 nm argon–fluoride excimer laser was introduced. The field of refractive surgery was radically altered because this laser provided highly accurate ablations of the anterior corneal stroma to obtain a new range of curvature that facilitated innovative new surgical techniques.

In the early days of excimer laser refractive surgery, after first debriding the epithelium, surgeons performed photorefractive keratectomy (PRK) (Fig. 60.1) by ablating the cornea using the excimer laser. As the field progressed and laser in situ keratomileusis (LASIK) (Fig. 60.2) was introduced, the corneal stroma was ablated with the same excimer laser after creation of a lamellar flap made with a microkeratome.

Initially, IBM developed the excimer laser to photo-etch computer chips. The phrase excimer laser, contracted from *ex*cited d*imer*, reflects the events that occur in the excimer laser cavity, that is the argon and fluorine gas molecules are mixed. Usually, argon and fluorine are stable under normal physiologic conditions. However, that changes when the gas molecules are exposed to a transient high-voltage electrical charge. The result is molecular excitation to a higher energy state, and on return to the resting state the molecules emit the 193 nm excimer laser wavelength.

The excimer laser offers a number of benefits for ophthalmologic use. The instrument can precisely remove corneal tissue, and focal corneal edema develops in the tissue adjacent to the ablated area. This allows accurate shaping of the corneal tissue during refractive surgical techniques. This accuracy is possible because the cornea has an extremely high absorption coefficient at the 193-nm wavelength, where only one photon of excimer laser energy has the ability to break the carbon–carbon and carbon–nitrogen bonds that form the collagen molecules in the cornea. Discrete fragments of corneal tissue are released as the molecular bonds are broken, and the adjacent tissue remains undamaged. Specifically, the desired tissue is removed or excised, and this is accomplished with minimal damage.

The US Food and Drug Association (FDA) began studying PRK in the late 1980s and after completing the requisite studies in animals, Marguerite McDonald, MD,[1] performed the first procedure in a human eye in 1988. PRK was a successful and highly regarded technique; however, as with all surgeries, there were associated complications, the most important of which was delayed epithelial healing that spanned several days and was characterized by pain and photophobia. Other complications included corneal haze and scarring.

In 1990, Ioannis Pallikaris, MD, combined the techniques of lamellar corneal surgery (e.g. keratomileusis) and PRK, and performed the first LASIK procedure when he used the excimer laser to sculpt the corneal stroma beneath a corneal flap, fashioned with a microkeratome. The microkeratome was not new to ophthalmology; it had been designed and used by Jose Barraquer[2] for frozen tissue keratomileusis, and had undergone several subsequent modifications by other surgeons. The excimer laser produced better optical results than previous generations of lamellar corneal surgery because it ablated tissue with submicron accuracy and created larger optical zones.

With the introduction of LASIK, PRK lost a great deal of its acclaim. The advantages of LASIK over PRK are that following LASIK there is significantly less pain, the eye heals more rapidly, the vision returns more rapidly, and enhancement procedures to fine tune patient's vision can be performed sooner. Interestingly though, PRK has recently begun to regain its initial popularity, in part because of the recognition that the development of postoperative ectasia may be less likely to occur following PRK than LASIK.[3,4] In addition, surface ablation may allow for better fidelity with the customized wavefront patterns now utilized by the newer excimer lasers.

Surface ablation may be preferable to LASIK in patients with epithelial basement membrane disease and in those with thin corneas. PRK and the newer procedures of epi-LASIK and laser subepithelial keratomileusis (LASEK) avoid the increased higher order aberrations associated with creation of a LASIK flap. In addition, surface ablations remove the risk of flap complications such as incomplete flaps, buttonholes, and striae. These factors have resulted in increased use of surface ablation over the past few years.

Surface ablation consists of three main procedures, which are variations of one another: PRK, LASEK, and epi-LASIK. In the evolution of PRK, methods were developed to promote easier epithelial debridement, including the use of dilute topical alcohol. The

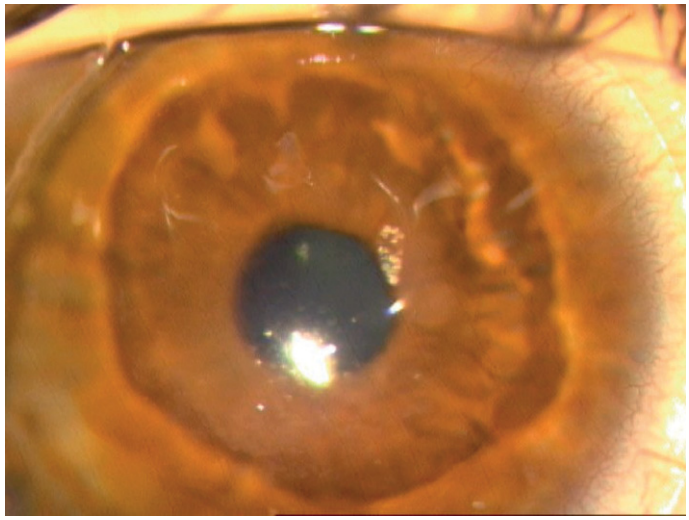

Figure 60.1. Central corneal epithelium has been removed in this eye undergoing photorefractive keratectomy.

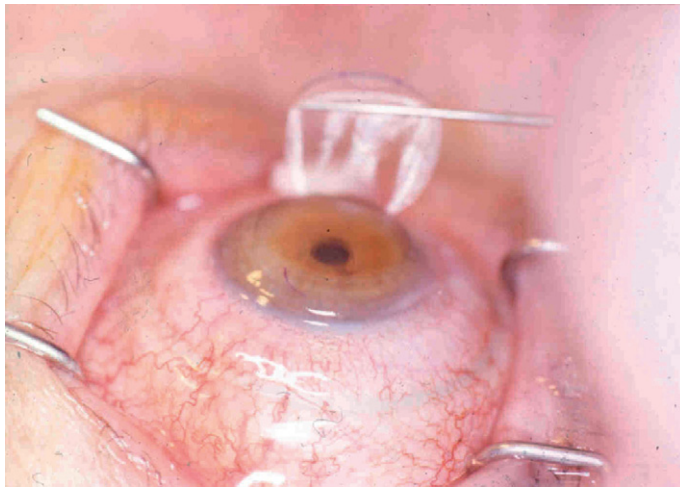

Figure 60.2. Image of elevated corneal flap during a LASIK procedure.

technique of LASEK developed when some surgeons thought that preservation of the epithelium would be beneficial. Alcohol was used to loosen the epithelium, which was then retracted manually. After photoablation was performed, the epithelium was replaced. In epi-LASIK, a microkeratome is used to mechanically create an epithelial flap using a modified dull blade and a thin applanation plate without using substances that are toxic to the epithelium, such as alcohol. The epithelial flap may be replaced over the ablation site or excised, depending on the surgeon's preference. Both epi-LASIK and LASEK are similar to PRK in that the epithelium is removed and the photoablation is performed directly on Bowman's membrane. The visual results seem comparable with all three procedures.

PATIENT SELECTION

The most important factor in determining appropriate candidates for PRK, the other surface ablation procedure, and LASIK is the capacity for healing. Patients who heal well tend to do well after corneal ablative refractive surgery and, conversely, patients with healing abnormalities should be considered carefully or denied surface ablation and LASIK. Generally, the major contraindication to surface ablation is a history of connective tissue disease, such as rheumatoid arthritis or systemic lupus erythematosus, thyroid disease, Sjögren's syndrome, or Wegener's granulomatosis, because these diseases are associated with less predictable wound healing and the potential for development of corneal melting and severe dry eye. However, patients whose diseases are well managed may achieve excellent outcomes after refractive surgery.[5]

Keloid formation initially was considered a contraindication to PRK; however, recent investigations have determined that that is no longer the case. Patients who have anesthetic or neurotrophic corneas, such as those with herpes simplex, herpes zoster, or trigeminal ganglion problems, are not candidates for LASIK because of problems with neurotrophic healing. Those with milder neurotrophic corneas, such as may be found in patients with diabetes, can be considered for refractive surgery; however, individuals with substantial diabetic maculopathy or corneal anesthesia are not candidates.

Another subgroup of patients who are not candidates for refractive surgery are monocular patients with significant loss of vision in their fellow eye. Refractive surgery is associated with a small, but real, risk of visually significant complications. If the patient were to lose vision in the good eye, and could not adequately function with the vision in their bad eye, they should not undergo refractive surgery.

A careful preoperative ocular examination is essential before any refractive procedure. Performing LASIK properly may be impeded by eyes that are deep set, by large brows, and by small interpalpebral fissures because these anatomic variations may reduce the ocular exposure needed for successful LASIK. A surface ablation procedure may be more suitable.

During the preoperative examination, the surgeon should closely examine the cornea for signs of pathology, including neovascularization, nodules, scarring, and corneal ectasia. The surgical plan may be altered or the hinge location changed in order to avoid areas of neovascularization or nodules. The best method to evaluate the cornea is with the red reflex through a dilated pupil. Although a thorough slit-lamp examination can reveal most corneal irregularities, corneal topography is a more sensitive method to look for subtle irregularities such as forme fruste keratoconus and pellucid marginal degeneration. Refractive surgery should generally be avoided in these latter two conditions because of the unpredictable outcomes and increased risks for postoperative ectasia.

Before refractive surgery, the size of the pupil under scotopic conditions should be determined. Even though it is controversial whether pupil size impacts night vision disturbances and visual outcomes after refractive surgery, patients with larger pupils preoperatively should be counseled that they may be at greater risk for postoperative night vision complaints. Recent studies by Schallhorn[6] revealed that preoperative pupil size had no significant effect on the incidence of glare, halos, and other night vision complaints. Rather, they found that the degree of preoperative myopia and ablation depth correlated more closely with these postoperative symptoms. The higher aberrations that were induced in the corneal periphery as a result of an interaction between the pupil size and the ablation zone were responsible for the resultant decreased visual acuity in the early days of excimer laser photoablation or sharp transition to unablated cornea) that was the cause of the complaints.

Figure 60.3. Conjunctival lissamine green staining in an eye with dry eye disease.

Another important part of the refractive evaluation is careful evaluation of the manifest and cycloplegic refractions. If the difference between the manifest and cycloplegic refractions exceeds 0.50 D, a post-cycloplegic refraction might be of benefit, attempting to 'push as much plus' as possible. Cyclopentolate 1% generally is used for younger patients and tropicamide 1% for older patients. The refraction must be stable prior to embarking on refractive surgery. Many surgeons require a 0.50 D change in refraction over the previous 6 months. If the interim change is greater, surgery should be postponed until stability is achieved.

Candidates for refractive surgery should also be evaluated for signs and symptoms of a dry eye syndrome, which may include assessment of the patient's history, the tear meniscus, Schirmer's testing, and supravital corneal and conjunctival staining with fluorescein, and lissamine green (Fig. 60.3) or rose bengal to identify early cases of dry eye. Dry eye can be a complication of LASIK more so than PRK, and the presence of dry eye preoperatively is a risk factor for dry eye postoperatively. If a dry eye is diagnosed, treatment should be instituted preoperatively with intensive lubrication including artificial tears and ointments, immunomodulating drugs (such as topical corticosteroids or cyclosporin), oral doxycycline, punctal occlusion, or all of these to limit postoperative keratopathy that can lead to flap irregularities, delayed healing, and even regression or under correction. Recently, patients have been reported to achieve better visual outcomes with less need for an enhancement procedure when the tear film and ocular surface are more stable.[7]

When evaluating the cornea before LASIK, it is of particular importance to look for signs of an anterior basement membrane dystrophy that could predispose the patient to epithelial defects with the microkeratome pass. These patients are usually best served by having PRK, depending on the refractive error.

Surgeons should use a preoperative stepwise checklist in which both the surgeon and the technician confirm the patient's name, the refraction, and the eye undergoing surgery. Some laser models require that the surgeon enter the size of the optical zone and whether or not a blend of the ablation zone (defined as an area of peripheral asphericity that reduces the possible undesirable effects of an abrupt transition from the optical zone to the untreated cornea) is to be performed. In the presence of sufficient corneal tissue, an ablation zone larger than the scotopic pupil size is usually selected.

SURGICAL PROCEDURES

Topical antibiotic prophylaxis is sometimes used preoperatively before the refractive procedure. Five to 10% povidone–iodine (Betadine) or alcohol wipes can be used to prep the skin before or after entering the laser suite, and 5% povidone–iodine drops can be applied to the ocular surface and then irrigated for further antisepsis. There is no consensus about the efficacy of these practices.

Before the actual laser treatment, the patient should be counseled about what to expect during the surgery, and the sounds and smell of the laser. Patients who are anxious can be given an oral sedative such as diazepam.

In patients with a high degree of astigmatism, some surgeons mark the horizontal or vertical corneal axis while the patient is sitting upright to ensure accurate alignment when the patient is positioned under the laser. The marks compensate for any cyclotorsion that commonly occurs when the patient moves from sitting to a supine or reclining position. A 15° offset in the treatment axis can decrease the effective cylinder power by 50% and result in a substantial axis shift.

A sterile drape can be placed over the skin and eyelashes based on surgeon preference after the patient is positioned under the laser. Topical tetracaine anesthetic drops, proparacaine anesthetic drops, or both, are applied to the eye. The drops should not be applied too early because they can cause a punctuate keratitis and substantial loosening of the epithelium. An eyelid speculum is placed in the eye to be treated, and an opaque patch is placed over the fellow eye to eliminate cross fixation. A gauze pad can be taped over the patient's temple between the operative eye and the ear to absorb the flow of excess eye drops and irrigating fluid. The patient is instructed to maintain fixation on the blinking red fixation light, while the surgeon focuses and centers the laser. For most patients, line-of-sight fixation during LASIK or surface ablation results in more accurate centration than globe immobilization.

Because corneal haze is a major complication associated with PRK, a soaked pledget of mitomycin (usually 0.02% or 0.2 mg/mL) can be placed on the ablated surface for anywhere from 12 s to 2 min at the end of the laser treatment. The length of time that the pledget is in place depends on surgeon preference. Recent studies seem to indicate that shorter application times are equally effective in primary surface ablations, hence the trend to 12-s applications. This treatment decreases the chances of the development of postoperative corneal haze after various procedures such as previous corneal surgery such as PRK, LASIK flap creation, penetrating keratoplasty, or radial keratotomy. Many surgeons also use mitomycin during PRK to treat moderate to high refractive errors. Irrigation of the corneal surface with copious amounts of chilled balanced salt solution (15–30 mL) to remove the excess mitomycin and minimize the toxicity is crucial. To avoid damaging limbal stem cells, the surgeon should avoid exposing the limbus or conjunctiva to the mitomycin. Human confocal microscopy studies have reported a reduced keratocyte population and less haze in eyes treated with mitomycin. However, the downside is that vision-threatening complications associated with the drug have been reported after glaucoma and pterygium surgeries, and they tend to occur many years later. There currently is no ideal topical wound-healing

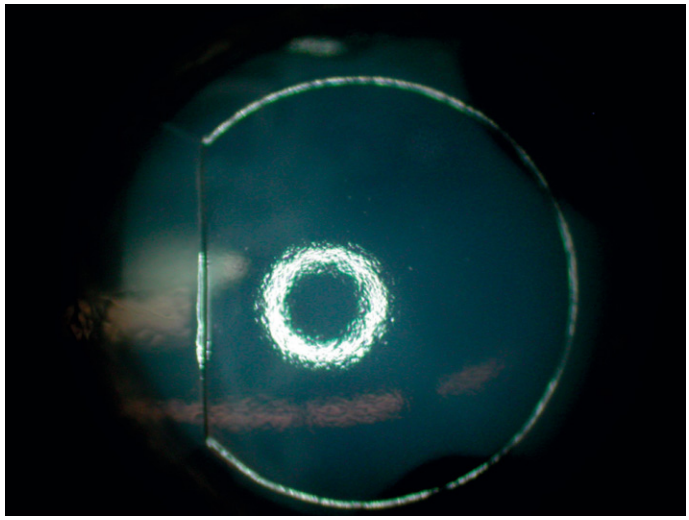

Figure 60.4. Stromal bed (in the center) and an elevated epithelial flap (on the left) during an epi-LASIK procedure.

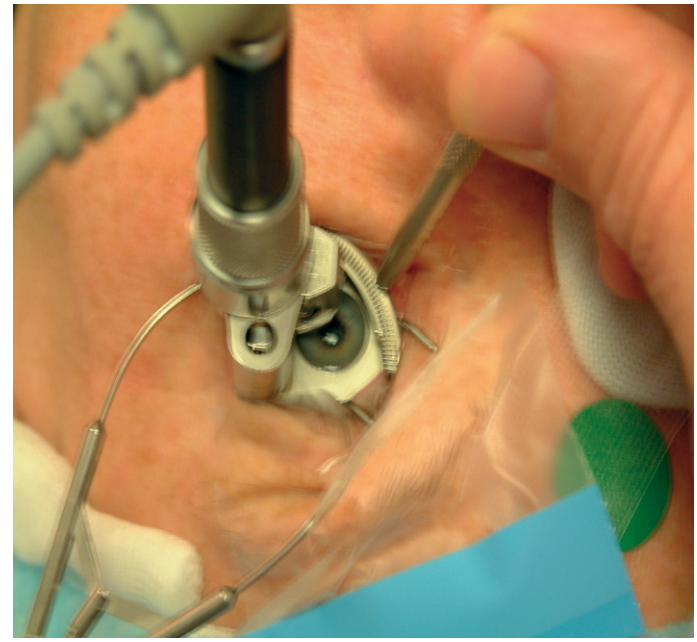

Figure 60.5. Microkeratome on the cornea being used to cut a corneal flap in a LASIK procedure.

modulator with high specificity for inhibiting collagen synthesis without toxic side-effects.

Epi-LASIK, which preserves the epithelium, has mostly replaced LASEK (Fig. 60.4). Epi-LASIK utilizes the special microkeratome to create an epithelial flap that preserves more viable epithelial cells which may improve epithelial flap adherence, reduce postoperative discomfort, and improve the visual outcomes compared to LASEK. Some surgeons perform epi-LASIK and deliberately excise the epithelial flap, claiming faster healing and visual recovery compared to preserving and replacing the flap. The primary disadvantages associated with these procedures are the degree of postoperative patient discomfort, the extended recovery time needed for visual rehabilitation, and the increased corneal haze in patients with higher refractive errors. There is also an increased risk of infectious keratitis with any surface ablation procedure compared to LASIK due to the extended healing time.

CONVENTIONAL AND WAVEFRONT-GUIDED ABLATIONS

Conventional excimer laser ablation can address lower order or spherocylindrical aberrations such as myopia, hyperopia, and astigmatism, which make up roughly 90% of all aberrations. Higher order aberrations, which make up the remainder, cannot be corrected with spectacles but may not adversely affect vision in small degrees. Their effects on the normal population recently have been reported. Higher order aberrations that develop after excimer laser ablation cause loss of contrast sensitivity and night-time halos and glare that result in lower quality of vision. Spherical aberration is most commonly associated with these visual complaints.

Wavefront-guided ablation creates customized ablation profiles for individuals to reduce both preexisting aberrations and reduce the induction of new aberrations. Wavefront-guided treatments can correct the spherical error and astigmatism and higher order aberrations, and thus can offer better visual quality. Wavefront-guided ablations seem to provide better contrast acuity and less induction of postoperative higher order aberrations compared with conventional ablations. However, most customized ablations do induce varying amounts of higher order aberrations. Advances in aberrometry and registration systems have resulted in improved outcomes with wavefront-guided ablations.

THE MICROKERATOME

Stopping the microkeratome pass just short of creating a free cap was an improvement that resulted in better outcomes. A hinge on the corneal tissue allows the flap to be lifted for the laser ablation and precisely returned to its original position. The flap adheres to the underlying stromal bed because of the corneal endothelial pump function. Flap repositioning eliminates suture-induced distortion and reduces irregular astigmatism.

The two basic components of the microkeratome are a suction ring and cutting head. The suction ring adheres to the globe to provide a stable platform for the microkeratome cutting head, and to raise the intraocular pressure (IOP) and stiffen the cornea to prevent movement away from the blade during flap creation. The dimensions of the suction ring determine the flap diameter and the size of the stabilizing hinge. The suction ring is connected to a vacuum pump, which typically is controlled by an on–off foot pedal.

The cutting head comprises a highly sharpened cutting blade, which is discarded after either each eye is treated or after a bilateral treatment, and the applanation head, or plate, which flattens the cornea as the cutting blade advances (Fig. 60.5). The length of the blade that extends beyond the applanation plate and the thickness of the applanation plate primarily determine the flap thickness. Another component of the cutting head is the electric or gas-driven turbine motor that oscillates the blade between 6000 and 15 000 cycles per minute. The same motor or a second motor mechanically advances the cutting head across the suction ring over the cornea. This is known as translation. In several models, the surgeon may manually advance the cutting head.

The actual flap thickness varies from the nominal flap thickness depending on the type of microkeratome, patient age, the preoperative corneal thickness, the preoperative keratometry, the preoperative astigmatism, the corneal diameter, and the speed of translation

of the microkeratome pass. In general, the faster the translation speed across the cornea, the thinner the flap that will be created. Maintaining a steady speed of translation avoids the creation of bumps in the stromal bed.

The flap diameter is determined based on the refractive error (hyperopic corrections and wavefront-guided treatments require a larger flap because of the larger ablation diameter), the corneal curvature and dimensions of the microkeratome suction ring (flatter corneas result in a smaller flap for the same size ring), patient's anatomy (peripheral corneal blood vessels and corneal diameter), and the surgeon's preference. Depending on the manufacturer, the suction ring is usually centered over the entrance pupil but if a suction ring creates a flap with a diameter under 9.5 mm, some surgeons prefer to skew it toward the hinge to ensure that the hinge will not be in the laser optical zone.

Thinner flaps leave more stromal bed thickness for the ablation and possible enhancements. However, thicker flaps have a lower risk of buttonholes and flap folds and may be more stable. Each type of microkeratome characteristically creates a flap with a range of thicknesses of which the surgeon must be aware and include them in the surgical plan to make sure there is an adequate residual stromal bed. The surgeon cannot predict the flap thickness based solely on the labeling of the microkeratome head.

Once the suction ring is properly positioned and the suction activated, the IOP should be measured, because low IOP can result in a poor-quality, thin, or incomplete flap. Excellent ocular exposure facilitates free movement of the microkeratome and proper suction ring fixation. Blockage of the suction ports from eyelashes under the suction ring or from redundant or scarred conjunctiva may result in inadequate suction. To avoid pseudosuction, the true suction can be ascertained by observing that the eye moves when the suction ring is gently moved, the pupil is mildly dilated, and the patient cannot see the fixation light. The IOP can be measured by using the Barraquer plastic applanator, a pneumotonometer, or palpating the eye. Novice surgeons should use an objective rather than a subjective method to measure the IOP.

Before making the lamellar cut, the cornea is moistened with proparacaine containing glycerin or with nonpreserved artificial tears. Balanced salt solution is not used because there is potential to create mineral deposits within the microkeratome that can interfere with its proper function. The microkeratome is placed on the suction ring, its path is checked for obstacles, and the microkeratome is activated and passed over the cornea until halted by the hinge-creating stopper, and then reversed off the cornea. Some surgeons believe that epithelial defects can be reduced by lowering the vacuum or discontinuing the suction during reversal; other models require the vacuum to remain at full pressure during reversal. Improvements in microkeratomes have decreased the incidence of epithelial defects. If an epithelial defect occurs in one eye during a microkeratome pass, an epithelial defect is highly likely to develop in the second eye, regardless of changes in the vacuum level, implying the presence of a subclinical epitheliopathy such as epithelial basement membrane disease that is made manifest by the microkeratome pass.

PEARLS TO PROTECT THE STROMAL BED THICKNESS AND FLAP

Most surgeons follow the guideline of 250 µm as the minimum residual corneal bed thickness. However, this thickness is anecdotal and not based on laboratory-based investigations or controlled prospective studies; 250 µm of tissue in the stromal bed after ablation does not guarantee that postoperative corneal ectasia will not develop. A retrospective study of 10 eyes of seven patients who developed corneal ectasia after LASIK showed that 30% had a residual stromal bed thickness of 250 µm or more. In that group of patients, 88% had previously undiagnosed forme fruste keratoconus. The actual LASIK flap created may be thinner or thicker than desired, despite the labeling of the microkeratome head. A thicker flap will leave a thinner stromal bed than anticipated after the ablation, which may result in a stromal bed thinner than 250 µm. Intraoperative pachymetry allows one to measure the flap thickness and stromal bed prior to the ablation. Subtracting the amount of tissue to be ablated from the pretreatment stromal bed measurement allows the surgeon to calculate the postoperative stromal bed thickness prior to the ablation. Intraoperative pachymetry is most helpful in patients with high myopia, thin corneas, and when doing enhancements.[8–10]

FEMTOSECOND LASER

In addition to a mechanical microkeratome, surgeons are increasingly using the femtosecond laser (IntraLase) to create flaps (Fig. 60.6, *A* and *B*, Fig. 60.7).[11,12] The laser also requires the use of a suction ring, with the accompanying elevation in IOP and potential for optic nerve damage, although the femtosecond laser requires a more prolonged period of suction and elevated IOP than does the conventional microkeratome. Proper centration of the suction ring is critical and as such is performed under a separate microscope. The suction ring is centered over the pupil, and suction is applied. The docking procedure is initiated under the femtosecond laser's microscope, with the patient's chin and forehead level and the suction ring parallel to the eye. The applanation lens is centered over the suction ring and lowered into place using a joystick; the suction ring then is unclipped to complete the attachment to the docking device.

Complete applanation of the cornea must be achieved or an incomplete flap or incomplete side cut may result. Once centration is confirmed by the laser's computer, the surgeon applies the femtosecond laser emission. In contrast to a mechanical keratectomy, the femtosecond laser creates an opaque bubble layer, which results from the cavitation bubbles produced by the interaction between the laser and the corneal tissue. The vacuum is released, the suction ring is removed, and the patient is repositioned under the excimer laser. One of several spatulas with a semi-sharp edge may be used to identify and score the flap edge near the hinge. The instrument is passed across the flap along the base of the superior hinge, and the flap is lifted by sweeping inferiorly and separating the flap interface, dissecting one-third of the flap at a time, which decreases the risk of tearing the flap. If bilateral LASIK surgery is planned, the flap in the second eye can be created before performing the excimer ablations.

The femtosecond laser works by causing photodisruption of the corneal collagen. When thousands of contiguous pulses are scanned across the cornea in a controlled pattern, the result is a lamellar flap. A computer controls the flap diameter and depth, and the hinge location and size. The advantages of the femtosecond laser are the potential for more reliable and reproducible flap thickness, lessening or avoiding complications such as buttonhole perforations, and precise control of flap dimensions and hinge location. In addition, some investigators have reported that using the femtosecond laser results in less induced astigmatism, and less epithelial

injury compared to mechanical microkeratomes. Other studies showed better uncorrected visual acuity and manifest refractive outcomes with the femtosecond laser.

The femtosecond laser has been gaining in popularity because it allows the surgeon to adjust for the variables involved in flap creation, including the thickness and diameter, hinge location and angle, bed energy, and spot separation. Hyperopic and wavefront-guided treatments usually require creation of a flap with a larger diameter. The femtosecond laser creates a planar flap while mechanical microkeratomes create a meniscus flap. The corneal morphology or curvature does not affect the flap thickness with the femtosecond laser.

Other postoperative complications, such as DLK, may be more likely to occur with the femtosecond laser and they have been reported to occur more commonly during the first cases performed by a surgeon, until the laser energy is reduced. Some surgeons use more intensive and prolonged topical steroid therapy with the femtosecond laser to reduce the risk of DLK.

COMPLICATIONS OF REFRACTIVE SURGERY

PROCEDURE LIMITATIONS

Despite the greater popularity of LASIK it has limitations. The procedure is generally not preferred for treating myopia exceeding −12.0 D or hyperopia exceeding +5.0 D because of poorer predictability and an increased potential for complications.

Interestingly, the visual outcomes after LASIK and PRK are similar. In one study of myopic patients with refractive errors ranging from −1.0 to −9.5 D, the refractive outcomes were equal. In another study of myopic patients with refractive errors between −6.0 and −15.0 D, the incidence of postoperative optical symptoms after LASIK was slightly decreased compared with PRK. In contrast, almost twice as many patients with refractive errors ranging from −2.5 to 8.0 D who underwent LASIK in one eye were highly satisfied with their results compared with the results in the fellow eye treated with PRK 1 year after treatment. The LASIK-treated eyes in these highly satisfied patients experienced less postoperative pain, more rapid visual recovery, were more likely to achieve an uncorrected visual acuity of 20/20 or better, and had a lower incidence of postoperative topographic irregularities.

The incidence of visually significant complications in LASIK is small and estimated to be less than 1%. As with most surgical procedures, the incidence of complications decreases with surgeon experience, and when complications do arise, rapid recognition and treatment can help to minimize their effect.

A brief list of LASIK complications includes button holes, incomplete flaps, free caps, epithelial erosions, macrostriae, microstriae, dislocated flaps, dry eye syndrome, DLK, infectious keratitis, epithelial ingrowth, interface debris, corneal ectasia, decentered ablations, and irregular astigmatism. The visual complications include night vision disturbances (glare and halos), reduced contrast sensitivity, loss of best corrected visual acuity, monocular or binocular diplopia, and, rarely, blindness.

Advances in technology continue to improve the visual outcomes. The planar flap and smooth stromal beds obtained with the femtosecond laser seem to improve the visual outcomes. Wavefront-guided laser ablation offers the potential for improved visual quality by reducing the incidence of laser induced higher order aberrations. PRK is increasing in popularity in conjunction with the wavefront-guided lasers because surface ablation avoids the higher order aberrations induced by the corneal flap in LASIK. The newer generation lasers provide smoother ablations, which when combined with immune modulating agents like mitomycin C seem to reduce the incidence of corneal haze following any surface ablation treatment. There is no substitute for randomized prospective studies to determine if any of these newer techniques or modalities are superior to their predecessors, despite what seem to be theoretical advantages. Interestingly, a recent review of the literature failed to demonstrate that wavefront-guided refractive surgery outperformed conventional LASIK with newer technologic refinements such as broad ablation zones, smoothing to the periphery, and eye-trackers. Currently, there is no treatment for irregular astigmatism, but the research into true custom ablation may eventually solve this condition.

61 Rejection: clinical forms, diagnosis, and treatment

Matthew A. Dahlgren, Jay H. Krachmer

Allograft rejection is the most common cause of corneal graft failure after an initial period of graft clarity.[1] Surprisingly, the lifetime chance for a rejection episode is about 25%, but with timely diagnosis and treatment the majority of these rejection episodes can be reversed to prevent graft demise. Numerous prospective, retrospective, and case series have reported that rejection complicates 4–20% of routine low-risk penetrating keratoplasty surgeries.[2–10] The considerable range probably reflects different patient populations, host characteristics, postoperative management, and diagnostic criteria. Certain host factors increase the risk of allograft rejection episodes to about 50% in the first year and 65% in the first 3 years following surgery (Table 61.1).[10,11]

The first corneal transplant was performed by Edward Zirm in 1905,[12] but the rejection reaction was not described until 1948. Paufique, Sourdille, and Offret hypothesized that transplanted tissue contained unfamiliar proteins which could cause allograft clouding after initial clarity.[13] They coined the term *maladie du greffon* (graft sickness) to describe this pathology. Khodadoust and Silverstein first clinically illustrated in their 1969 paper that the allograft epithelium, stroma, and endothelium can all suffer a rejection reaction separately or together.[14] Early work on the pathophysiology of corneal rejection was done in rabbits by Maumenee in 1951[15] and in human subjects by Polack and Kanai in 1972,[16] in which they demonstrated sensitization of the host to the donor tissue as the primary cause of rejection.

With our current understanding of immunology, a rejection cannot occur unless three different principal elements transpire.[17] First, the antigens from the donor cornea must be carried by host antigen-presenting cells (APC) to a local lymph node or other nearby lymphatic tissue. While at the lymphatic site, the APCs must initiate and amplify an immune response causing host sensitization. Finally, helper T cells, cytotoxic T cells, B cells, and antibodies need to travel back to the allograft site. Here these and other effector components exert their inflammatory and destructive effect. Many of the known risk factors for rejection promote one or more of these principal elements.

The presence of ocular inflammation is perhaps the highest risk factor for a rejection reaction.[18] When preoperative inflammation is present, the host recipient bed will have a marked increase of APCs, escalating the chance of rejection.[19,20] Inflammation also increases endothelial growth factor, which promotes the growth of new vessels and stimulates lymphangiogenesis.[21] Major histocompatibility complex (MHC) antigens, both class I and II, are increased in an inflamed eye, enabling the immune response.[22] Finally, inflammation causes a breakdown in the blood–aqueous barrier, disrupting the immune privilege of the anterior chamber.[23,24] Suture abscess, recurrent herpes simplex virus infection, persistent epithelial defect, and uveitis are a few major causes of postoperative inflammatory incitement. If possible, corneal transplantation surgery should be delayed until inflammation is properly treated. Likewise, postoperative inflammation should be treated aggressively.

Preoperative deep stromal vascularization of the host cornea is a major risk factor for allograft rejection. Usually sequelae from inflammation, these blood vessels provide afferent outflow of APC and an efferent highway to the graft. Lymphatic channels are also coupled with the vascularization, which contributes to the afferent immune reflex arc. Intraoperatively, efforts should be made to free up anterior synechiae to minimize contact of the vascular iris with the endothelium.[9] Postoperative vessel ingrowth of the graft should be recognized early and treated to retain immune privilege.

Other known risk factors for a rejection reaction are repeat corneal transplantation, prior rejection episodes, larger grafts, and recipients under the age of 40. Up to 40% of patients exhibit an episode of rejection when there are two or more previous grafts.[25] Larger corneal grafts are closer to the limbus, predisposing patients to a higher risk of rejection. This is because the peripheral cornea and limbus are the natural habitat of Langerhans cells (LC). These cells are a type of APC that can trigger the immune cascade. Many retrospective studies have shown that younger patients exhibit a higher rate of rejection episodes.[26,27] The immune system in younger patients may be more prone to sensitization and capable of generating an aggressive response as compared to older donor recipients.

It is critically important that patients and their families be repeatedly educated in the postoperative period about corneal graft rejection. The three most common symptoms of redness, pain, and decreased vision should be reviewed with the patient at each office visit. If these symptoms persist more than 24 h, the patient should be instructed to call the clinic for evaluation. The four commonly

accepted forms of allograft rejection—epithelial, subepithelial, stromal, and endothelial—may all cause one or more of the three principal symptoms. Endothelial rejection is the most common type seen clinically, which causes permanent donor endothelial cell injury and can lead to subsequent graft failure.

EPITHELIAL REJECTION

The average onset of an epithelial rejection reaction is 3 months, and the cumulative risk is 10–14%.[9,10] It usually occurs after 1 month of surgery, but within the first year after transplantation.[10] It is more commonly seen in patients under 50 years of age. The true incidence may be underreported as the event is usually asymptomatic and discovered on routine postoperative examination.

Slit-lamp examination reveals an elevated thin rejection line in the epithelium that starts peripherally near the graft–host junction. The rejection line stains with fluorescein or rose bengal due to the destruction of the donor epithelial cells. Over the course of a few days, this line will migrate centrally across the entire donor tissue. The donor epithelium central to the line is irregular, but the host epithelium which follows the line is clear (Fig. 61.1). Minimal if any clinical inflammation is present.

During this episode, the host epithelium is thought to replace the donor epithelium. There is no correlation with vascularization of the graft. Graft failure from epithelial rejection is uncommon; however, epithelial rejection often forecasts or accompanies overt endothelial rejection.

SUBEPITHELIAL INFILTRATES

A subepithelial infiltrate (SEI) rejection reaction was initially described in 1978.[28] This phenomenon occurs in 10–15% of penetrating keratoplasty cases with an average onset of 10 months.[9,10] Similar to epithelial rejection, SEI rejection can be seen in isolation or concomitantly with other types of rejection. However, these patients are more likely to have ocular symptoms, notably redness and photosensitivity.

The subepithelial infiltrates are 0.2–0.5 mm hazy white lesions located in the anterior stroma (Fig. 61.2). They are most easily identified with a broad oblique beam or sclerotic scatter at the slit-lamp biomicroscope. SEIs are exclusively located in the allograft, characteristically in a central random distribution. Their appearance is identical to those of epidemic keratoconjunctivitis (EKC), but in EKC the infiltrates are located in both the donor and host tissue. The infiltrates represent areas of cellular infiltration, and topical corticosteroids will often make the SEIs quickly disappear. In isolation they will not cause any permanent graft harm or scarring, but their presence may portend an impending fulminant endothelial rejection.

Figure 61.1. Epithelial rejection line. Irregular donor epithelium (1), clear host epithelium (2), and epithelial rejection line (3) are demonstrated. (Figure is taken from Krachmer JH, Palay DA. Cornea Atlas, 2nd edn. © Elsevier; 2006.)

STROMAL REJECTION

Stromal rejection is very uncommon; however, its sequelae can cause permanent allograft opacity and failure. Typically, a mid to deep stromal infiltrate is seen in the graft associated with pain and intraocular inflammation (Fig. 61.3). Deep stromal vessels may invade the graft bringing additional inflammatory mediators and depositing lipid exudates. In rare instances, the graft stroma may become necrotic and perforation may ensue.

ENDOTHELIAL REJECTION

Endothelial rejection is by far the most common type of allograft rejection. This type of reaction is of utmost importance to recognize early in order to prevent graft failure. The average onset for endothelial rejection is 8 months.[10] It occurs after at least a 2-week period of graft clarity, but can happen as late as 20 years after penetrating keratoplasty.[10] Patients notice decrease in vision, redness, pain, and light sensitivity.

During this presentation, fine keratic precipitates are observed on the allograft endothelium in a random distribution or in an undulating line. This line, known as the Khodadoust line, begins in the periphery of the graft and processes centrally (Figs 61.4 and 61.5). Careful observation may reveal the rejection line originating near a focus of neovascularization. The graft behind the line often

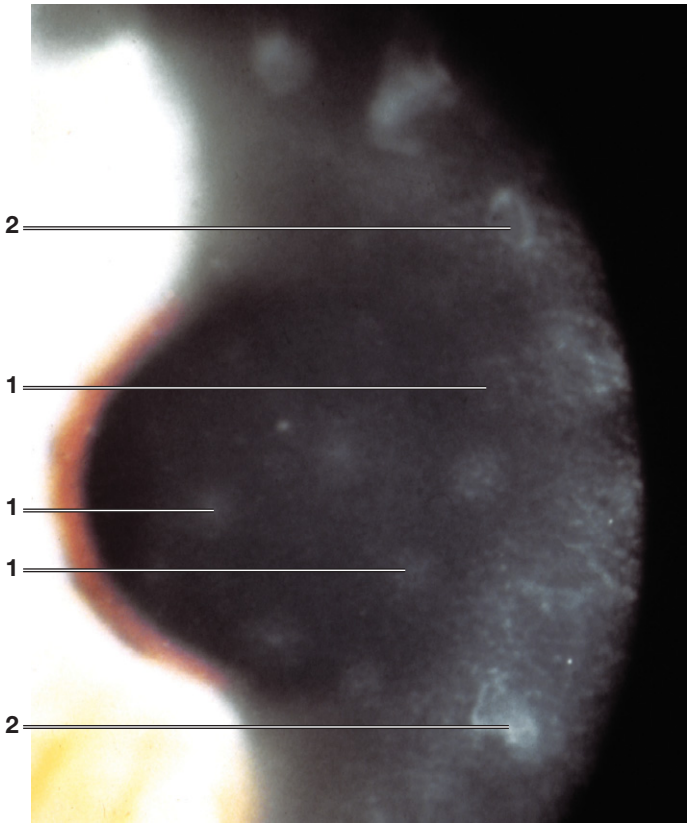

Figure 61.2. Subepithelial infiltrates. Hazy white subepithelial infiltrates (1) and corneal suture scars (2) are shown. (Figure is taken from Krachmer JH, Palay DA. Cornea Atlas, 2nd edn. © Elsevier; 2006.)

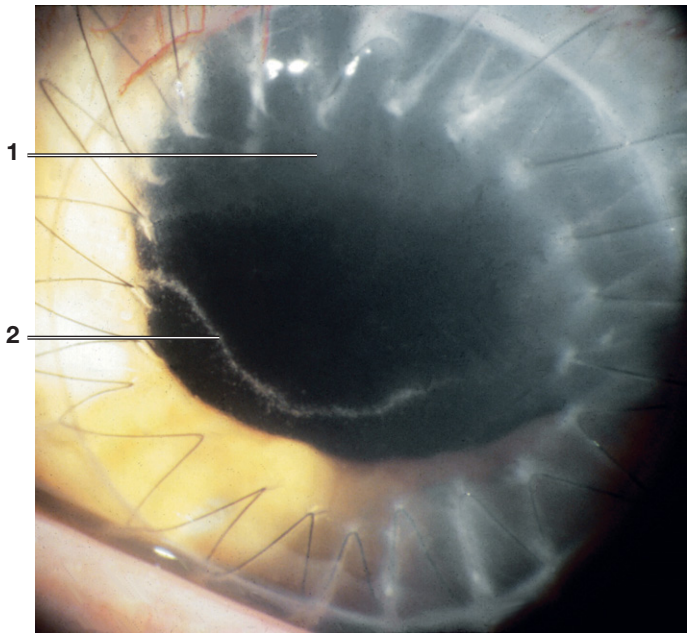

Figure 61.3. Stromal rejection. Superior mid-stromal infiltrate (1) with nearby stromal vascularization is present. An epithelial rejection line (2) is also seen. (Figure is taken from Krachmer JH, Palay DA. Cornea Atlas, 2nd edn. © Elsevier; 2006.)

exhibits stromal and epithelial edema due to the stress on the local endothelial cells. If the keratic precipitates are randomly spread out over the endothelium, diffuse stromal edema with folds in Descemet's membrane will occur (Figs 61.6 and 61.7). Invariably, some element of conjunctival injection is present, especially around the limbus ('ciliary flush'). A mild to moderate anterior chamber cellular reaction with aqueous flare accompanies the rejection episode. The inflammation may also induce endothelial cell polymegathism.

DIFFERENTIAL DIAGNOSIS

It is often difficult to distinguish between endothelial rejection and inflammation caused by herpes simplex virus (HSV). Herpes simplex keratitis is a common indication for corneal transplantation, and the viral infection may recur anytime postoperatively. Patients may also acquire HSV in the postoperative period. HSV keratouveitis causes symptoms similar to graft rejection, and findings also include conjunctival hyperemia, anterior chamber reaction, and fine endothelial keratic precipitates. In this situation, the host endothelium should be carefully inspected for keratic precipitates. Host precipitates are more commonly seen in HSV, whereas precipitates from endothelial rejection are confined to the donor button. Stromal edema can make this task difficult, so often the two entities cannot be clinically distinguished. Oral acyclovir in a therapeutic dose should be co-administered if uncertainty is present.

Over time, cornea allografts may fail due to progressive endothelial cell decompensation unrelated to acute graft rejection. These grafts exhibit stromal thickening with Descemet's folds, microcystic epithelial edema, and occasionally frank bullous keratopathy. The picture may become obscured if old endothelial pigment is misinterpreted as being active keratic precipitates. However, late graft failure is not accompanied by inflammation. If doubt exists, treatment with corticosteroids should begin. If no improvement is observed in one week, then permanent endothelial dysfunction is present.

Epithelial ingrowth through the graft–host junction often advances across the endothelium in a chainlike pattern mimicking the Khodadoust rejection line. The line caused by epithelial ingrowth has more of a scalloped edge and, unlike rejection, it can also grow across the host endothelium, angle, and iris. Application of argon laser to an area of involved iris will produce a whitening effect. Angle involvement may produce a refractory glaucoma. The ingrowth usually can be traced back to a current or prior area of poor wound closure. Often large clumps of epithelial cells can be seen floating in the anterior chamber. These cells along with the epithelial line do not respond to corticosteroid treatment. Management can be extremely difficult.

Finally, low-virulent infectious endophthalmitis can cause signs similar to endothelial rejection. In these situations, the anterior chamber reaction may persist or worsen with corticosteroid treatment. Hypopyon and vitreous cell may be present, which are not seen in allograft rejection. If the patient is pseudophakic, the intraocular lens implant and capsule should be carefully examined for infiltrates caused by *Propionibacterium acnes* and *Staphylococcus epidermidis*. If suspected, aqueous and vitreous cultures should be obtained.

TREATMENT

Corticosteroids are the primary treatment for acute cornea allograft rejection reaction.[29] The initial treatment with these drugs should be prompt and aggressive, especially for endothelial rejection. In

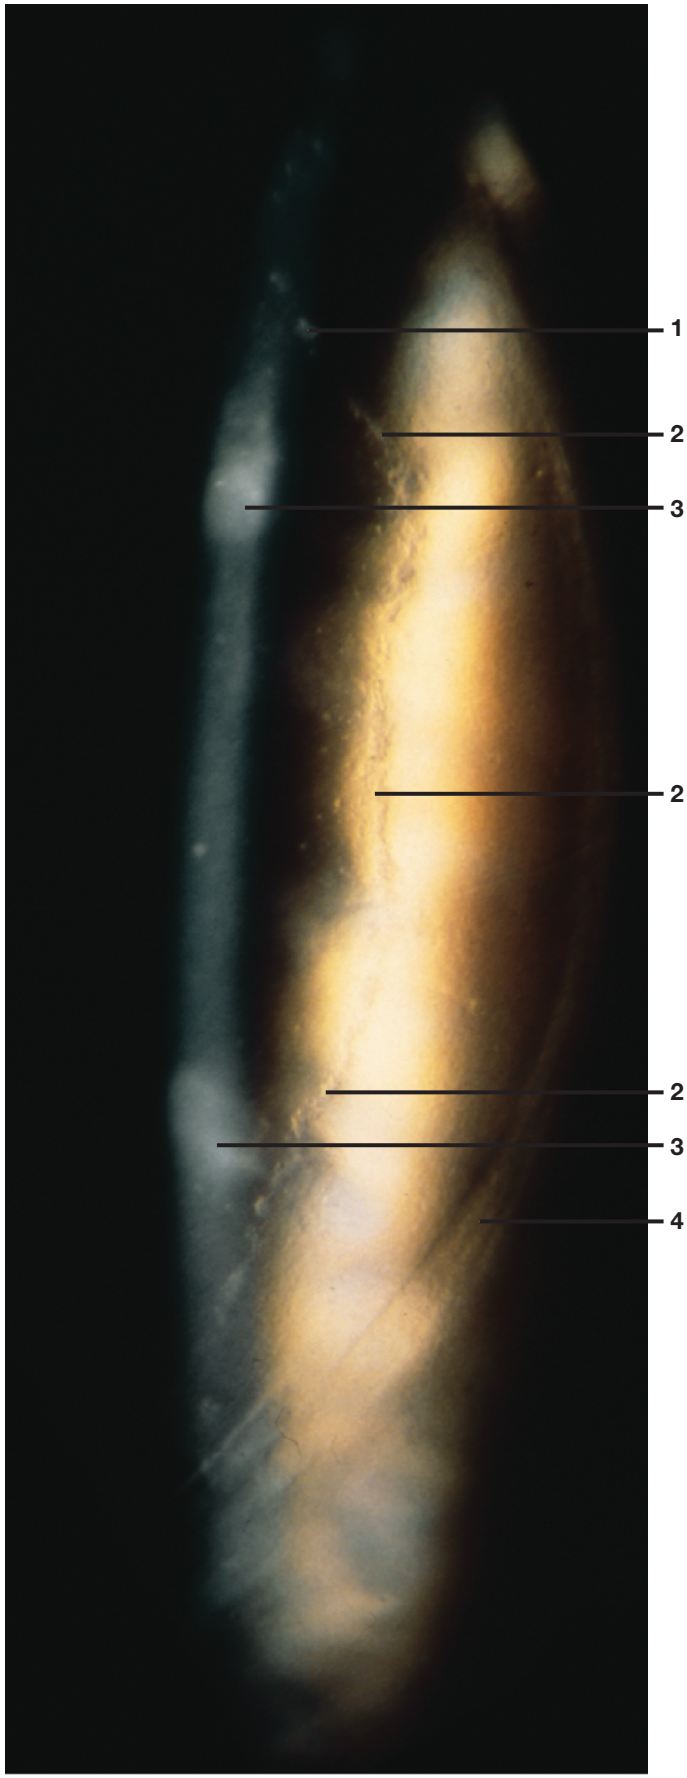

Figure 61.4. Endothelial rejection line. The undulating rejection line is white in direct light (1) but translucent in indirect light (2). Suture tract scars (3) and the graft host junction (4) are seen. (Figure is taken from Krachmer JH, Palay DA. Cornea Atlas, 2nd edn. © Elsevier; 2006.)

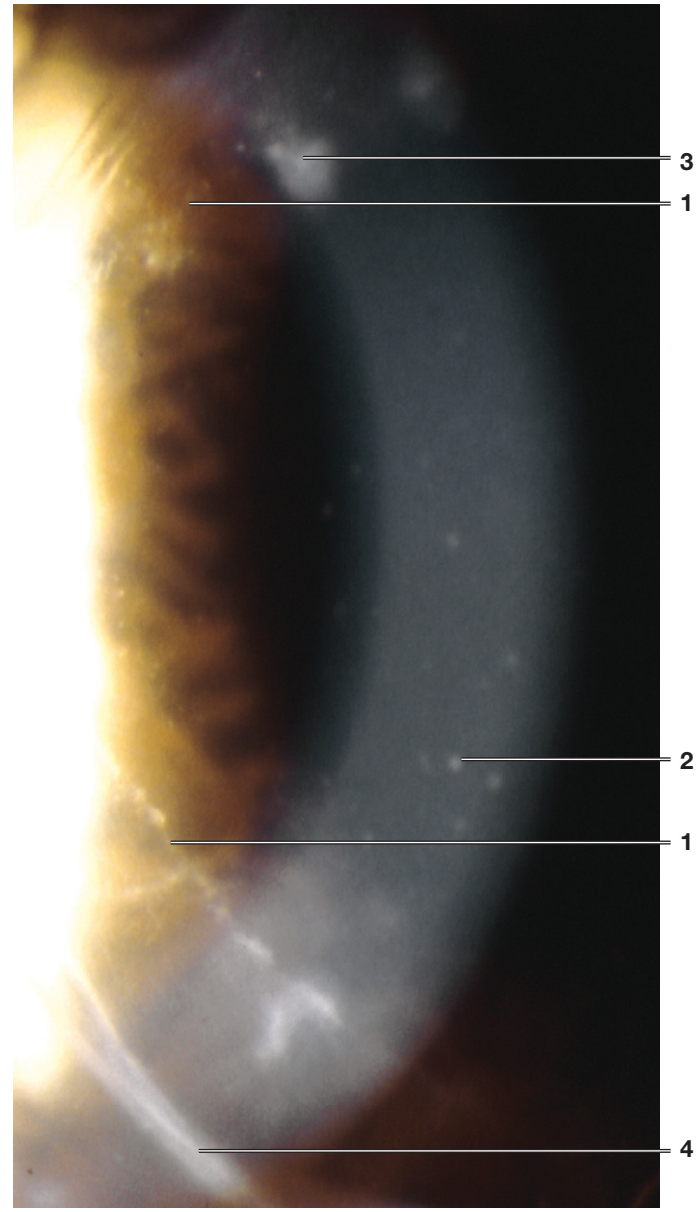

Figure 61.5. Endothelial rejection. The endothelial rejection line (1) and diffuse keratic precipitates (2) are shown. Suture tract scars (3) and the graft host junction (4) are seen. (Figure is taken from Krachmer JH, Palay DA. Cornea Atlas, 2nd edn. © Elsevier; 2006.)

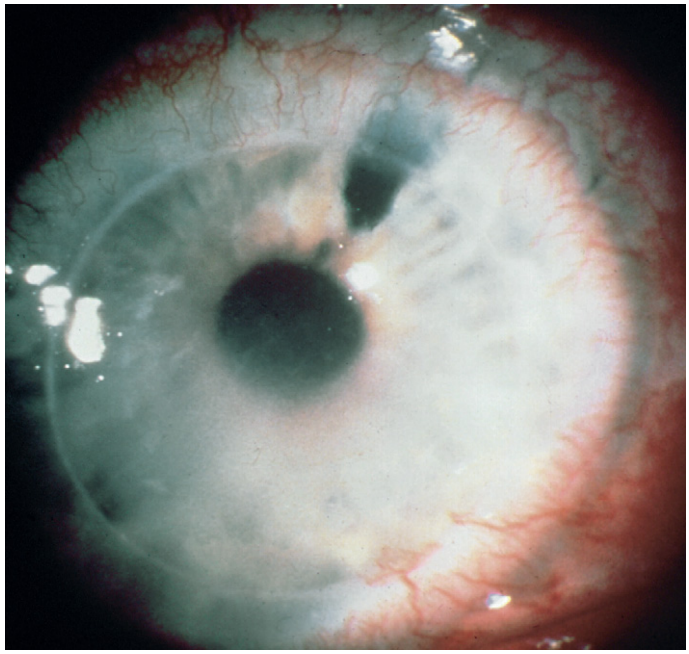

Figure 61.6. Endothelial rejection. There is diffuse inferior corneal edema from endothelial rejection. (Figure is taken from Krachmer JH, Palay DA. Cornea Atlas, 2nd edn. © Elsevier; 2006.)

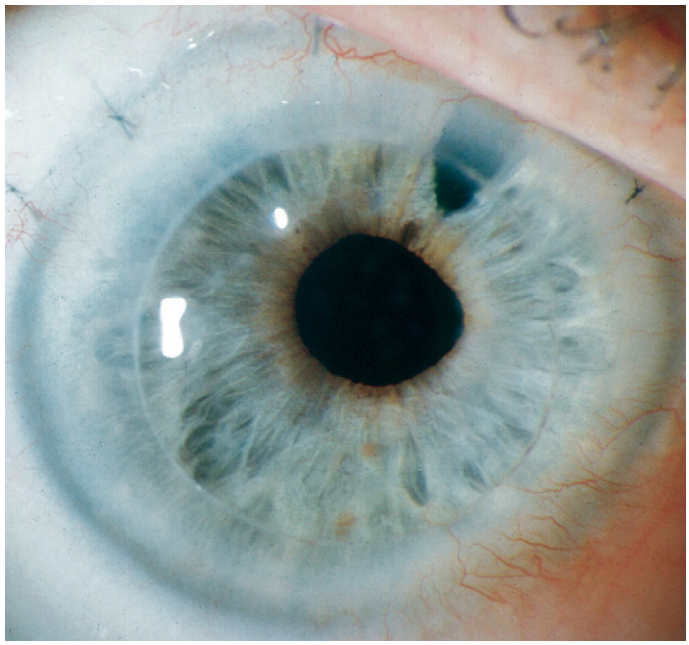

Figure 61.7. Same patient as Figure 61.6. Graft clarity is restored after aggressive treatment with topical and systemic corticosteroids. (Figure is taken from Krachmer JH, Palay DA. Cornea Atlas, 2nd edn. © Elsevier; 2006.)

the majority of cases, graft rejection can be reversed with swift and proper treatment. Patient response should be monitored frequently and carefully. Glaucoma and cataract are frequent ocular complications of steroid treatment, and may need to be managed concurrently to save the graft. Common side effects of short-term systemic steroid treatment include hyperglycemia, weight gain, hypertension, heartburn, insomnia, adrenal suppression, psychosis, and delirium. There are no large randomized controlled trials that show the definitive optimal route and dosage of steroids.

Epithelial and subepithelial rejection reactions usually can be handled with topical prednisolone 1% every 2–3 h while awake. The patient should be seen in follow-up in 5–7 days to ensure adequate response and to look for any signs of consequent endothelial rejection. If regression is seen, the topical medication can be slowly tapered down to a baseline level.

Endothelial rejection can be treated with topical, periocular, and/or systemic corticosteroids. In the event of a mild endothelial reaction, topical prednisolone acetate 1% should be used every hour while awake, and a steroid ointment should be placed at night. Cycloplegia with atropine or scopolamine should be considered. A 2006 survey showed that about 10% of respondent members of The Cornea Society also use topical cyclosporin for acute endothelial rejection.[29] The patient should return in 3–5 days, and the treatment may be slowly tapered if improvement is noted.

Severe endothelial rejection reactions, noncompliant individuals, and high-risk grafts should receive the same initial topical regimen with periocular and/or systemic steroids. Subconjunctival or sub-Tenon's injection of dexamethasone 12–24 mg (short acting) or triamcinolone 4–8 mg (long acting) can easily be done in the office under topical anesthesia. Periocular steroids are particularly advantageous in poorly controlled diabetics and elderly individuals to avoid systemic steroid-induced hyperglycemia and psychosis, respectively.

Intravenous methylprednisolone 3–5 mg/kg followed by oral prednisone 1 mg/kg/day or oral prednisone alone are also very rapid and successful methods to treat graft rejection. One small prospective randomized trial by Hill et al demonstrated that treatment with a single 500 mg IV dose of methylprednisolone combined with topical steroid was more effective and better tolerated than daily high dose oral prednisone with topical steroid, but the difference was not statistically significant.[30] Hill et al also showed in a later study that a second treatment with IV methylprednisolone in the following 24–48 h offered no additional advantage over a single dose.[31]

If oral steroids are administered and the patient has shown marked clinical improvement of the rejection episode within 5–7 days, they can be abruptly discontinued. Adequate topical therapy must continue. However, if the inflammation has only partially receded, oral steroid treatment should be prolonged until further resolution. A steroid taper regimen should be implemented if therapy is planned beyond 10 days. If no response in the first week is seen with high dose systemic steroids, it is doubtful that they will succeed in improving the reaction. They should be discontinued to prevent unwanted side effects.

PREVENTION

Grafts at high risk for rejection require judicious tapering of topical corticosteroids after transplant surgery. While low-risk patients may be able to discontinue topical steroids several months after surgery, high-risk individuals should continue use indefinitely. In 2004, additional prophylaxis with topical cyclosporin 2% in high-risk patients was routinely used by 50% of respondent members of The Cornea Society.[29] Retrospective evidence has established that topical cyclosporin 2% administered two to four times a day reduces the risk of allograft rejection.[32–34]

Systemic immunosuppression may be beneficial in grafts at high risk for rejection, but is not often used. No large randomized

controlled trials exist to demonstrate an advantage, and toxicity is worrisome. Favorable results of decreased allograft rejection for highly vascularized corneas and limbal grafts have been published regarding oral cyclosporin.[35–37] Other studies have shown no benefit.[38,39] The initial dose of cyclosporin is 2–5 mg/kg/day divided equally twice a day, and treatment is continued for about one year. Its mechanism of action includes selectively inhibiting T-helper and T-suppressor lymphocytes. Blood levels of the drug must be monitored because it is metabolized through the cytochrome P450 system, which can be altered by various medications. Toxicity can lead to nephrotoxicity and severe hypertension. Other important side effects include hepatotoxicity, gingival hyperplasia, and hirsutism.

Systemic tacrolimus (FK506) and mycophenolate mofetil also show promise in preventing allograft rejection in high-risk patients.[40,41] Tacrolimus also inhibits T-lymphocytes, but through a different mechanism than cyclosporin. Its side effects are similar to cyclosporin, but nephrotoxicity and hypertension occur less frequently. Mycophenolate disrupts de novo guanosine synthesis, which in turn selectively inhibits the production of T- and B-lymphocytes. Gastrointestinal symptoms are the most common side effects, but myelosuppression can also occur. Frequent monitoring of blood counts, electrolytes, kidney and liver function are required for both these medications.

The value of matching histocompatibility antigens between donor and recipient, especially in patients with risk factors for rejection, has long been debated. All nucleated cells express major histocompatibility class I (MHC-I) antigens. These HLA class I antigens, detected on corneal epithelial cells and keratocytes,[42] have been shown to elicit a host cytotoxic T cell immune response.[43] Class II antigens, found on donor epithelial APCs, can activate host helper T cells by causing a delayed hypersensitivity immune reaction.[44]

Outcomes in Canada and northern Europe have shown a benefit from HLA typing and matching.[44–46] However, the large multicenter prospective randomized double-blinded American Collaborative Corneal Transplant Study (CCTS) showed that there was no advantage in matching HLA class I and II antigen for high-risk corneal transplantation.[11] This same study did show that matching ABO antigens produced a significant decrease in rate of rejection and graft failure. HLA typing and matching on every patient would generate more initial cost, but it could save future expenditure if graft failure rates were less. A major drawback would be patients potentially spending months to years on waiting lists for a compatible donor, especially in heterogeneous populations like the USA.

Specific immunopharmacologic drugs may provide transplant surgeons future options for preventing and reversing allograft rejection reactions.[18] Local treatment with synthesized antibody fragments targeted at different arms of the immune casade may disrupt APCs, cytokines, immune effector cells, and other mediators. Gene therapy may also be used to modulate the immune response or restore function to the corneal endothelium.

SUMMARY

Acute cornea allograft rejection is the most common cause of postoperative graft failure. Patient education regarding symptoms is important to prevent delays in treatment. All types of rejection should be treated with topical corticosteroids, but severe rejection and high-risk patients should be administered a more aggressive regimen. Further prospective randomized clinical trials are necessary to determine if systemic immunosuppression should be employed in high-risk patients.

62 Immunosuppression in high-risk keratoplasty

Ali R. Djalilian, Nariman Nassiri, Janet A. Lee, Edward J. Holland

The high success rate of corneal transplants can be attributed largely to the unique avascular structure of the cornea, absence of corneal lymphatics, low expression of major histocompatibility antigens, and expression of immune inhibitory factors such as CD95 (Fas) ligand, α-melanocyte stimulating hormone (α-MSH), and transforming growth factor (TGF)-β.[1,2] These features allow the graft to remain somewhat isolated from the immune system and effectively provide an immunologically privileged status. Nonetheless, immune-mediated rejection remains one of the leading causes of graft failure.[3,4] Up to 30% of penetrating keratoplasty patients will have at least one episode of rejection,[5] with 2.6–7% of all grafts eventually failing because of rejection.[4,6] The success rate of uncomplicated first grafts performed in nonvascularized 'low-risk' beds is as high as 90%. However, the success of corneal grafts placed in 'high-risk' beds is significantly lower with rejection rates of up to 50–70%.

Several host factors have been shown to increase the risk of immune-mediated rejection. The most important factor appears to be the degree of corneal neovascularization.[3,5] In vascularized corneas, the recipient's immune system can recognize and attack the donor tissue much more readily. Other factors that can increase the risk of immune-mediated rejection include repeat grafts, large grafts, bilateral grafts, past or present inflammatory eye disease, past or present elevated intraocular pressure, history of previous anterior segment surgery, younger age, ocular surface disease, and quadrants of anterior synechiae.[3,7,8] The term 'high risk' has been used to refer to those grafts that have a higher likelihood of rejection. Most authors consider patients to be high risk if they have two or more quadrants of neovascularization or have a history of graft failure resulting from rejection.

The management of high-risk keratoplasty continues to be a significant challenge, with the incidence of rejection reportedly between 50 and 90%, depending on the definition of high risk.[3,9–11] In general, two approaches can be taken to prevent immune-mediated rejection in high-risk corneal transplantation: (1) making the donor tissue less antigenic and (2) suppressing the host immune response. This chapter primarily addresses the latter approach.

MECHANISM OF REJECTION

The primary antigens that are recognized by the immune system as foreign include the major histocompatibility antigens (human lymphocyte antigens [HLA]) and ABO antigens, which are a subset of the minor histocompatibility antigens. Major antigens are further divided into class I and II antigens. Class I HLA antigens (HLA-A, -B, and -C) are expressed by all nucleated cells in the body and are found on the corneal epithelium, stromal keratocytes, and endothelial cells, whereas class II antigens (HLA-DR, -DQ, and -DP) are present mainly on antigen presenting cells (APCs) such as macrophages, dendritic cells, and Langerhans cells.[12] It has recently been demonstrated that Langerhans cells reside throughout the central and peripheral corneal epithelium,[13] and dendritic cells are present in the anterior stroma.[14,15] Under the influence of interferon-γ, both epithelial and endothelial cells have been shown to also express class II antigens. ABO antigens have been detected primarily on epithelial cells. However, some reports indicate that endothelial cells may also express these antigens.[16]

Corneal graft rejection involves an induction phase, called the afferent arm, and an expression phase called the efferent arm. During the afferent arm of the immune response, antigen recognition occurs by two pathways. In the direct pathway, donor APCs present donor MHC II antigens to T cells, thus directly sensitizing the host. The indirect pathway involves host APCs processing donor antigens, which are then presented to naïve T cells. The exact location of antigen presentation is under debate, but may occur in the cornea, uvea, conjunctiva-associated lymphoid tissue, or draining lymph nodes.[7]

The efferent arm of the allograft response is the destructive phase, incurring damage primarily via a cell-mediated process. CD4+ Th1 cells are the main mediators of the efferent phase. The secretion of IL-2 by CD4+ T cells activates other T and B cells, while IFN-γ activates macrophages and induces antigen expression in the donor tissue. The role of CD8+ cytotoxic T cells in the graft immune response remains controversial. Though they can contribute to tissue damage, graft rejection can occur in their absence.[17]

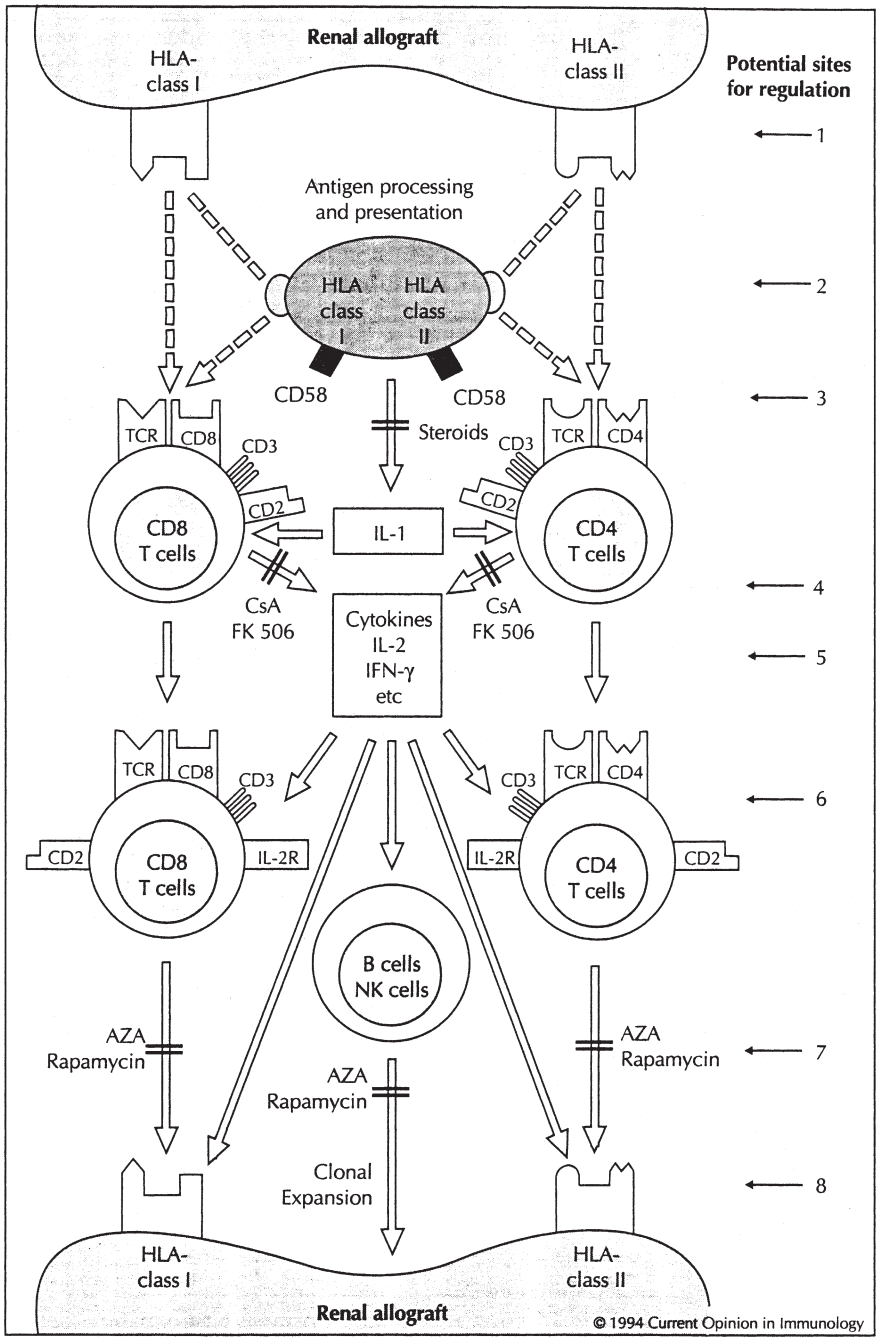

Figure 62.1. Schematic representation of the antiallograft response showing human lymphocyte antigen (HLA), which is the primary stimulus for the initiation of the antiallograft response, the cell surface proteins participating in antigenic recognition and signal transduction, the contribution of cytokines and cell types to the immune response, and the potential sites for the regulation of the antiallograft response. Potential sites for regulation are shown on the right. Site 1, histoincompatibility between the recipient and the donor can be minimized (e.g. HLA matching); site 2, monokine production by antigen presenting cells can be prevented (e.g. by corticosteroids); site 3, antigen recognition can be blocked (e.g. by OKT3 monoclonal antibodies); site 4, T-cell cytokine production can be inhibited (e.g. by cyclosporin A); site 5, cytokine activity can be inhibited (e.g. by anti-interleukin-2 antibody); site 6, cell cycle progression can be inhibited (e.g. by anti-interleukin-2 receptor antibody); site 7, clonal expansion can be inhibited (e.g. by azathioprine); site 8, allograft damage can be prevented by masking target antigen molecules (e.g. by antibodies directed at adhesion molecule sites). (Reproduced with permission from Sharma VK, Li B, Khanna A, et al. Which way for drug-mediated immunosuppression? Curr Opin Immunol 1994; 6: 784–790 © 1994 with permission from Elsevier.)

The anti-allograft response can be manipulated at a number of different levels. The potential sites for regulation of this process are shown in Figure 62.1 and are further discussed below.

REDUCING DONOR ANTIGENICITY

Several strategies have been used to reduce the antigenic load of the donor. Removal of the donor epithelium was also believed to decrease the risk of rejection because the epithelium is a source of class I and class II antigens. However, a prospective randomized study found no difference in rejection rate regardless of whether the donor epithelium was removed.[18] Donor tissue pretreatments have been successful in reducing its antigenicity in experimental conditions, such as exposure to ultraviolet light, hyperbaric oxygen, heterologous antibodies, and storage in organ culture.[19–22] However, none of these techniques has been shown to be clinically significant.

Tissue matching has been studied extensively as another strategy for reducing donor antigenicity in high-risk corneal transplantation. The American Collaborative Corneal Transplant Study (CCTS) reported no benefit from HLA class I and class II matching in high-risk corneal transplantation.[23] On the other hand, studies from other areas of the world have reported a benefit in HLA matching.[24–27] This discrepancy may be attributed to various factors, including errors in tissue matching, the heterogeneous patient population in the USA, differences in intensity of topical immunosuppression, and inclusion of patients with limbal stem cell deficiency in the CCTS. ABO compatibility was found to prolong graft survival in the CCTS, although this finding has also been met with controversy in comparison to other studies.[28,29] At this time, there is not enough

evidence to support routine HLA matching in high-risk keratoplasty. ABO matching is less expensive and has a higher likelihood of finding a match, making its use more practical in selected high-risk cases.

SUPPRESSING THE IMMUNE RESPONSE

Currently, pharmacologic suppression of the host immune response remains the mainstay of preventing corneal allograft rejection. Although corticosteroids continue to be the gold standard of ocular immunosuppressants, promising newer agents may provide a safe and effective adjunct for immunosuppressive therapy in high-risk corneal transplantation.

GLUCOCORTICOSTEROIDS

Corticosteroids are currently the most effective ocular immunosuppressants available. Their immunomodulatory actions are due to inhibition of the activity of transcription factors, such as activator protein-1 (AP-1) and nuclear factor kappa B (NF-kappa B), that are involved in activation of pro-inflammatory genes. They suppress the production and effects of cytokines involved in the inflammatory response, inhibit leukocyte adhesion and migration to the sites of inflammation, and interfere with the functions of endothelial cells, leukocytes, and fibroblasts. When given systemically, steroids also reduce the number of circulating T cells and inhibit their proliferation.

Corticosteroids are most commonly administered by topical application, which provides good ocular penetration and effective immunosuppression. In high-risk patients, topical steroids are started early in the perioperative period and applied frequently, followed by long-term indefinite use when no contraindications exist. A typical regimen involves 1% prednisolone acetate applied every 2 h for the first few weeks with a gradual decrease over the following several months. Because high-risk patients often require higher doses of topical steroids for prolonged periods, they are more prone to experiencing complications such as cataracts, glaucoma, and delayed wound healing.

Systemic steroids can be used as an adjunct to topical therapy, particularly in high-risk cases where topical steroids alone may be insufficient in preventing rejection. Patients may receive large systemic doses (methylprednisolone 125–250 mg intravenously) at the time of surgery followed by prednisone 1 mg/kg per day. The prednisone is then slowly tapered over 3–6 months. Unfortunately, systemic therapy with steroids has been associated with many adverse effects including osteoporosis, peptic ulcer disease, glucose intolerance, and weight gain.

Mild graft rejection is often reversible by reinstituting or increasing the dose of topical steroids. Severe rejections that involve the endothelium require more aggressive treatment. Initially, methylprednisolone 125–250 mg is given by intravenous bolus, followed by intensive topical therapy (every hour) and oral prednisone 1 mg/kg/day. A subconjunctival injection of steroids may also be given as an adjunct (triamcinolone 10–40 mg).

Although topical corticosteroids remain the mainstay of achieving corneal graft immunosuppression, rejections still occur in many high-risk patients receiving steroids. Except when indicated for severe post-op anterior segment inflammation (e.g. atopic patients), systemic steroids as a single agent are not likely to provide significant benefit over topical steroids in preventing rejection over the long term. Thus, newer immunosuppressive agents (as discussed below) are needed for long-term maintenance therapy in very high-risk cases.

CYCLOSPORIN A

Cyclosporin A (CsA) represents a newer generation of specific immunosuppressive agents that selectively interfere with immunocompetent cells without causing generalized cytotoxic effects. Structurally, CsA is a hydrophobic, cyclic undecapeptide derived from the fungus *Tolypocladium inflatumgans*. It works mainly on T cells by binding to an intracellular peptide known as cyclophilin. By inhibiting cyclophilin activity, CsA blocks the transcription and production of IL-2, thus limiting the activation of CD4+ and CD8+ T cells. In addition, CsA blocks the production of other lymphokines such as interferon-γ and inhibits the expression of high-affinity IL-2 receptors.

TOPICAL CYCLOSPORIN A

The topical absorption of CsA is hindered by its hydrophobic structure, which cannot penetrate the hydrophilic stroma. To enhance its ocular absorption, a number of lipid vehicles have been used. In this regard, an emulsion formulation of 0.05% was approved for the treatment of keratoconjunctivitis sicca.[30] Most studies have indicated very low penetration of CsA into the anterior chamber regardless of the vehicle or formulation, suggesting that the effects of topical CsA are mostly mediated through the ocular surface.

Several studies have demonstrated the efficacy of CsA as a topical immunosuppressant in high-risk keratoplasty. In a study of 11 high-risk keratoplasty patients treated with 2% CsA in olive oil, 10 corneas remained clear after a mean follow-up of 16 months.[31] Holland et al[32] reported the use of topical CsA to treat 43 patients with a variety of anterior segment inflammatory conditions, including 11 high-risk keratoplasty patients for whom topical corticosteroid therapy had failed. Zhao and Jin[33] used 0.5% CsA to treat 16 patients with refractory corneal graft rejection and achieved a complete cure in nine eyes and marked improvement in another six eyes. To prevent recurrence, they advocated continuing CsA for at least 12 months after graft rejection is reversed. Inoue et al retrospectively compared 86 high-risk penetrating keratoplasties treated with 2% CsA to 97 control eyes. The rejection-free graft survival rate was 70% in the CsA group and 45% in the control group. However, the long-term graft survival rate appeared to be similar in the two groups.[34]

Topical CsA when used alone appears to be effective for both treatment and prevention of corneal graft rejection. However, when used in conjunction with topical steroids, studies have shown mixed results. A large trial by Bouchard and Cavanagh[35] failed to demonstrate any improvement in graft survival when CsA 2% ointment was applied twice daily in high-risk patients receiving topical steroids four times a day. This study has been criticized for using patients who were not truly high risk, and for using a higher dose of topical steroid that may have masked the effect of CsA. In contrast, other studies have demonstrated an additive effect of topical CsA when used in conjunction with topical steroids.[36]

Topical CsA is well tolerated. Studies have demonstrated a self-limiting transient epithelial keratitis in some patients, even with frequent dosing. In the 43 patients reported by Holland et al,[32] only two experienced severe ocular discomfort. The remaining patients

tolerated the medication well, including several receiving hourly application. In the phase III safety evaluation of CsA 0.1% emulsion over 1–3 years, burning, stinging, and conjunctival hyperemia were the most common adverse events with twice daily dosing, but were severe in only 2 out of 412 patients for each.[37] The commercially available CsA 0.05% is considered to be at least as safe and well tolerated as the higher concentration, with side effects being mild to moderate and transient.

An investigation concerning the systemic absorption of topical CsA has demonstrated negligible systemic CsA levels.[30] Thus, monitoring of blood CsA levels does not seem necessary for patients using topical CsA.

SYSTEMIC CYCLOSPORIN A

Systemic CsA has played an important role in the success of many solid organ transplants, but its use in corneal transplantation has been limited primarily to monocular high-risk patients due to its significant side effects. Several studies have demonstrated that systemic CsA can be effective in preventing corneal graft rejection in high-risk keratoplasty.[38–40] Hill et al[38] demonstrated that high-risk patients receiving systemic CsA in conjunction with topical steroids had a significant improvement in graft survival compared to patients receiving topical steroids alone or in combination with systemic steroids. The maximum benefit was achieved in patients who had received CsA for 12 months, although a beneficial effect was noted in those treated for 4 and 6 months as well. More recent studies have demonstrated limited beneficial effect of CsA as a single agent in reducing graft rejection. Rumelt et al[39] studied oral CsA use for an average of 12 months in 28 repeated corneal grafts with four quadrants of vascularization. They found a rejection rate of 32% in treated versus 42% in controls. Poon et al[40] studied 49 patients with various high-risk keratoplasty characteristics who were treated with oral CsA for 1 year. Though a trend toward reduced rejection and failure in treated patients was observed compared to controls, this did not reach statistical significance. These groups have concluded that while systemic CsA has a limited beneficial effect, its role in high-risk keratoplasty needs further evaluation, given its significant cost and side effects.

Systemic CsA is associated with a number of side effects, including nephrotoxicity, hepatotoxicity, and hypertension. In the 43 patients treated by Hill et al,[38] 4 patients developed elevation of serum creatinine which reverted to normal with CsA dose reduction, and one became mildly hypertensive, requiring treatment.

To minimize the risk of adverse effects, the blood CsA level should be closely monitored and kept within the therapeutic range. A target trough level between 130 and 170 ng/mL has been suggested using the specific whole blood method (monoclonal antibody), though levels as high as 200 ng/mL may be necessary in some patients. A typical dosing regimen is 3 mg/kg per day. While there are no studies indicating the optimum duration of therapy, systemic CsA is considered a long-term strategy. Hill has demonstrated that 12 months of treatment is superior to 4 months, with maintenance of the benefit even after stopping treatment.[9,38] Short-term use is not likely to be as beneficial in preventing rejection. All patients require monthly monitoring of blood pressure, serum creatinine, liver enzymes, and blood counts while taking CsA. With appropriate screening and monitoring, systemic CsA can be a useful tool in restoring vision in many high-risk patients. Additionally, CsA may be considered especially for high-risk cases secondary to atopic dermatitis.[41]

TACROLIMUS

Tacrolimus (FK-506, Prograf) is a calcineurin inhibitor derived from the fungus *Streptomyces tsukubaensis*, with a mechanism of action very similar to CsA, but with 10–100 times more immunosuppressive potential in vitro. It binds to an immunophilin known as FK-506 binding protein, which then blocks the transcription of several lymphokines, including IL-2. This, in turn, inhibits T cell activation.

Tacrolimus has been shown to prolong corneal graft survival in animals following topical, subconjunctival, intraperitoneal, and systemic administration, including a high-risk keratoplasty model.[42,43] Additionally, tacrolimus-treated animals were found to have less corneal vascularization than controls.[44]

Topical tacrolimus, when used in combination with lamellar keratoplasty, was found to be effective in treating Mooren's ulcer.[45] A study by Wang et al[46] showed lower rates of rejection with topical tacrolimus 0.05% compared to topical CsA 0.1%. Out of 28 high-risk patients using tacrolimus, 64% experienced rejection compared to 95% in patients that were using CsA 0.1% topically.

In a study by Reinhard et al[47] on the use of topical tacrolimus in normal-risk keratoplasty patients, they observed local side effects including superficial punctate keratitis, burning, conjunctival injection, an erosion that persisted over 10 days, and development of a superficial opacity. These events all resolved with discontinuation of the medication and treatment with topical steroids. In the 20 patients on tacrolimus, there were no detectable levels of tacrolimus in whole blood samples.

Systemic tacrolimus has been used successfully in human kidney and liver transplantation. Sloper et al[48] treated 17 high-risk keratoplasty patients (23 grafts) with oral tacrolimus, including six patients who also required limbal transplantation, for a mean follow-up period of 24 months. Three cases of reversible rejection occurred, all of which were associated with low levels of tacrolimus, and no cases of failure occurred while on tacrolimus. This was significant in contrast to 12 out of 18 cases without tacrolimus that failed secondary to rejection. Four patients stopped treatment without any problems, but two patients experienced reversible rejection episodes shortly after cessation of at least a year of therapy, suggesting the need for long-term treatment in some cases.

Side effects of systemic tacrolimus are similar to CsA, including nephrotoxicity and hypertension. Sloper et al[48] reported onset of hypertension in 4 out of 17 patients, with two others experiencing an exacerbation of pre-existing hypertension requiring additional medication. Renal toxicity was seen in two patients, with three others showing small increases in serum creatinine. This elevation was reversible in three patients with a tacrolimus dose reduction, but remained slightly elevated in the remaining two. In a separate report, two patients experiencing renal toxicity due to tacrolimus eventually experienced graft failure after dose reduction.[49]

Tacrolimus has been used increasingly as an alternative to CsA in organ transplantation. Its efficacy and safety in high-risk human corneal transplantation compared to CsA remains to be studied. The recommended starting dose is 1 mg twice daily with incremental 1 mg increases up to 4 mg twice daily to maintain a trough level

of 5–8 ng/mL. Monthly monitoring of blood pressure, serum creatinine, tacrolimus trough levels, and electrolytes is necessary. Though optimal duration of therapy is not yet known, tacrolimus likely requires a long-term strategy for prevention of graft rejection and failure.

AZATHIOPRINE

Azathioprine is a cytotoxic agent that is converted to 6-mercaptopurine, which competitively inhibits purine synthesis. To effectively block DNA synthesis, the targeted cells must be actively dividing. Thus, azathioprine must be given early in the rejection process to effectively block T cell proliferation.

Clinical studies have demonstrated the efficacy of azathioprine in preventing and treating early corneal graft rejection.[50,51] However, its role in high-risk keratoplasty is limited to resistant or monocular cases, where systemic therapy is used in combination with a calcineurin inhibitor such as CsA or tacrolimus. It is no longer considered as a single agent in corneal transplantation.

Azathioprine is associated with a number of cytotoxic side effects, including bone marrow suppression, gastrointestinal toxicity, and alopecia. In a case reported by Sudhir et al,[52] aplastic anemia with associated bilateral pre-retinal macular hemorrhages and gastrointestinal bleeding occurred in a man treated with azathioprine 2 mg/kg after high-risk keratoplasty. Anemia and bone marrow suppression are usually dose related and reversible after dose reduction or cessation of treatment. Monitoring of blood and platelet counts as well as liver function is recommended weekly for the first month, bi-monthly for the next two months, and monthly thereafter.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (MMF) is an anti-metabolite that blocks the proliferation of T and B cells by inhibiting guanosine synthesis in T- and B-lymphocytes. It has been used extensively in organ transplantation as an alternative to azathioprine, often in combination with a calcineurin inhibitor.

MMF has demonstrated efficacy in reducing graft rejection in high-risk keratoplasty in humans. Reinhard et al[53] reported the preliminary results of a prospective, randomized control study comparing oral MMF to controls in high-risk keratoplasty. The MMF group received 1 g twice daily for 6 months, while all patients received oral and topical steroids postoperatively. A total of 89% of grafts in the MMF groups did not experience immune reactions, compared to 67% of controls, which was statistically significant. None of the MMF grafts experienced irreversible rejection, while three control grafts failed. They concluded that MMF considerably reduces the proportion of immune reactions in high-risk keratoplasty, but that long-term survival and optimal treatment duration remain uncertain.[53]

Compared to oral CsA, MMF appears to be equally efficacious in preventing rejection in high-risk keratoplasty. Reinhard et al[54] have reported the 3-year results of a randomized prospective trial comparing MMF to oral CsA in high-risk patients. MMF 1 g twice daily and oral CsA titrated to a trough of 120–150 ng/mL were given for 6 months. At 3 years, 74% of grafts in the MMF group remained clear, compared to 69% in the CsA group.

Overall, MMF appears to be a safe and effective immunosuppressant. Administration at a fixed dose of 500–1000 mg twice daily is the standard regimen. Monitoring blood levels of MMF is not required, which simplifies the management. The most commonly reported side effects of MMF include bone marrow suppression, gastrointestinal symptoms, and hepatotoxicity, all of which are reversible with cessation of treatment. The authors currently recommend MMF as an adjunct to CsA or tacrolimus in the management of high-risk patients, who are dependent on a clear graft for functional vision.

RAPAMYCIN

Rapamycin (sirolimus, Rapamune) is a bacterial macrolide with antifungal and immunosuppressant properties. It inhibits growth factor-stimulated cell proliferation, including inhibition of IL-2-stimulated T-lymphocyte proliferation. Rapamycin and its derivatives do not interfere with the calcineurin system, decreasing the potential for nephrotoxicity. This is in contrast to cyclosporin A and tacrolimus, which are both calcineurin inhibitors and are known for their nephrotoxic side effects.

A prospective pilot study in humans demonstrated similar efficacy between rapamycin and MMF in preventing immune reactions after high-risk keratoplasty.[55] Ten patients on oral rapamycin were compared to 24 patients on MMF, both treated for 6 months postoperatively with a 2 week taper. No immune reactions were observed in either group during the treatment period. Two reversible immune reactions occurred in the rapamycin group and five in the MMF group during a 2-year follow-up, showing no statistically significant difference between groups. No irreversible immune reactions occurred in either group.

All patients on rapamycin experienced side effects in this study, including dyslipidemia, furunculosis, exanthema, and gastrointestinal disturbance. Other reported side effects include thrombocytopenia, anemia, peripheral edema, urogenital tract infections, and arthralgia. One case of nephrotoxicity was reported associated with the combination of tacrolimus and rapamycin.[49] The use of rapamycin theoretically has a decreased potential for nephrotoxicity as monotherapy, which makes it an attractive alternative to cyclosporin A and tacrolimus, but its own side effect profile may be significant in certain patients.[56,57]

Dosing of rapamycin in renal transplantation is adjusted according to blood trough levels, with a target of 4–12 ng/mL in the early postoperative period when in combination with cyclosporin A. In the Birnbaum study, their target blood trough level was 4–10 ng/mL with a mean level of 5.5 + 2.0 ng/mL. Recently, a new intraocular drug delivery system using a glycolide-co-lactide-co-caprolactone copolymer (PGLC)-implant containing rapamycin was shown to prolong high-risk corneal allograft survival in rabbits.[58] More work is needed to determine appropriate methods of dosing and duration of treatment for rapamycin therapy in penetrating keratoplasty.

MONOCLONAL ANTIBODIES

Monoclonal antibodies directed against T cell antigens have been used extensively to reverse acute graft rejection in solid organ transplantation. However, topical therapy with antibodies has been generally ineffective due to poor absorption across the cornea. Ippoliti and Frontere first reported that intracameral injection of anti-CD3 or anti-CD6 monoclonal antibodies can reverse acute corneal allograft rejection.[59] Later on, a study in humans has shown

successful reversal of corneal graft rejection after treatment with topical anti-IFN-γ antibodies in 10 of 13 patients.[60]

Basiliximab is a new humanized monoclonal antibody with high binding specificity for the IL-2 receptor of activated T-cells. In a pilot study by Schmitz et al, use of basiliximab with cyclosporin A in seven patients undergoing high-risk keratoplasty demonstrated no immune reactions during a 14–25 month follow-up period.[61]

Campath-1H is a humanized anti-lymphocyte monoclonal antibody directed against the pan-lymphocyte antigen CD-52. It has been used for induction therapy after transplantation, followed by other immunosuppressive agents for long-term maintenance. Use of systemic Campath-1H has been reported in two cases of recurrent corneal graft rejection. One patient with rheumatoid arthritis and rejection of nine previous grafts was treated with Campath-1H and retained a clear graft for 24 months before developing proteus keratitis resulting in enucleation. A second patient with recurrent graft rejection had maintained a clear graft at 25 months after treatment with Campath-1H.[62,63]

Blockade of the CD40-CD154 co-stimulatory pathway has also been a recent target for therapy. T-cell activation requires interaction of the T-cell receptor with the MHC complex on antigen presenting cells (APC) as well as co-stimulatory signals from APCs. A major co-stimulatory signaling pathway is mediated by CD40 binding to CD40-ligand, also known as CD154. This interaction stimulates differentiation of CD4+ T helper 1 cells, which are the primary mediators in corneal allograft rejection.

Systemic administration of CTLA4-Ig and anti-CD154 monoclonal antibody has been shown to be beneficial in the survival of corneal transplantation,[64,65] but some reports of thromboembolic complications associated with systemic treatment in non-ocular transplantation may limit the clinical usefulness of this therapy in keratoplasty patients.[66] Qian et al have investigated subconjunctival anti-CD154 mAb in normal and high-risk murine keratoplasty.[67] Both normal and high-risk grafts had significantly increased rates of survival with treatment, though high-risk grafts required twice the dose and frequency of anti-CD154 mAb to achieve significance. Additionally, these benefits were largely lost after termination of treatment, suggesting that this mode of therapy would require combination with other agents, especially after cessation of anti-CD154.

Until now, the use of monoclonal antibodies in the treatment regimen of high-risk keratoplasty has remained limited, in part due to ineffective delivery methods and side effects of systemic therapy. However, with the evolution of safer humanized antibodies and more efficacious delivery systems, both systemic and local administration will gain more attention.

CONCLUSIONS

The management of high-risk keratoplasty continues to be a significant clinical challenge. The authors currently recommend indefinite use of topical steroids and topical CsA in all high-risk grafts. In patients with multiple graft failures who are dependent on graft clarity for functional vision a multi-drug regimen consisting of (1) oral steroids (on a tapering dose), (2) CsA or tacrolimus, and (3) azathioprine, MMF, or rapamycin may be considered. The patients will need careful monitoring for the potential side effects. With continuing advances in molecular biology and immunology, the development of safer and more specific immunosuppressive agents as well as strategies for the immunomodulation of the corneal graft before transplantation can be expected. Until then, early recognition and immunosuppression will continue to be the most important factors in preventing graft failure.

63 Outcomes of penetrating keratoplasty

Douglas J. Coster, Keryn A. Williams

Corneal transplantation is usually performed to improve vision and to decrease visual disability, thereby improving quality of life. This being so, the most appropriate outcome measures are graft survival, the extent of postoperative visual disability, and the degree of patient satisfaction with the procedure.

CHOICE OF OUTCOME MEASURES

The relatively high rate of corneal graft failure, approximately 40% of all grafts at 10 years,[1] indicates that graft failure is a relevant measure of outcome. Furthermore graft function or failure is a simple call. The difference between a thin, transparent graft and a thick opaque graft is obvious, with little argument or disagreement amongst clinicians about the functional status of a graft, although there can be considerable contention about the cause of a graft failure. Invariably, those with failed grafts have poor vision. However, an analysis of corneal transplantation based solely on graft survival tells nothing about the relative success of the surviving grafts. Measuring the impact of a successful, functioning corneal graft is a complicated matter. Not all patients with a clear and functioning graft see well, and not all of those who see well are satisfied with the outcome.

Visual disability is the most common indication for corneal transplantation: the predominance of those having grafts do so to see better. The results of corneal transplantation should therefore be judged by the reduction in visual disability that is achieved. There are few studies employing this outcome measure. More often a surrogate measure is used, such as visual acuity in the grafted eye. While visual acuity may be a convenient measure, the link between visual acuity and visual disability can be tenuous. Inconsistencies between charts and lighting conditions, the impact of optical correction, and the influence of the other eye, all affect the integrity of the relationship.

There are few studies of the impact of corneal transplantation on patient well-being. In an early report, patient satisfaction was found to correlate with the acquisition and maintenance of a clear graft, of not needing a contact lens, and of achieving better vision in the operated eye than the contralateral eye.[2] Not surprisingly, patients with a nonfunctioning graft were dissatisfied.

ASSESSMENT OF LONG-TERM CORNEAL GRAFT OUTCOMES

The long-term outcome of corneal transplantation is relevant for at least two reasons. First, many graft recipients are young and have long-term expectations for their graft. Furthermore, successive grafts tend to have a decreasing prognosis for success. The aim must be to get a patient through life with as few corneal grafts as possible. Second, the impact of surgical variations and methods of processing corneal tissues for surgery may only show up after decades of observation. Data on corneal graft outcomes can be collected in various ways. Much of what is reported is in the form of retrospective case series, usually with short follow-up. There are a few randomized controlled clinical trials, and where they do exist the follow-up is short, usually no more than a year or two.

CORNEAL GRAFT REGISTRIES

Some of the most useful data are held in an increasing number of corneal graft registries.[1,3–5] These registries collect information on large numbers of patients receiving corneal transplants who have been followed for prolonged periods of time, in some cases decades. Such data are important in that they are collected from the real world of clinical practice, rather than the more contrived world of the academic medical center where most trials are conducted. A large number of surgeons contribute records, so that it is possible to consider the impact of a wide range of approaches. Appropriate statistical analysis can accommodate the inevitable losses to follow-up. As in other areas of clinical transplantation,[6] graft registries have proved to be a useful source of information about the long-term results of corneal transplantation.

The Australian Corneal Graft Registry was the first large-scale corneal graft registry.[3] It was established in 1985 to provide data on the long-term results of corneal transplantation and to identify factors influencing graft survival.[7] It now holds records of more than 20 000 grafts, some of which have been followed for over 20 years.[1] More than 200 surgeons contribute data to the registry and 400 other clinicians contribute to the follow-up. A number of

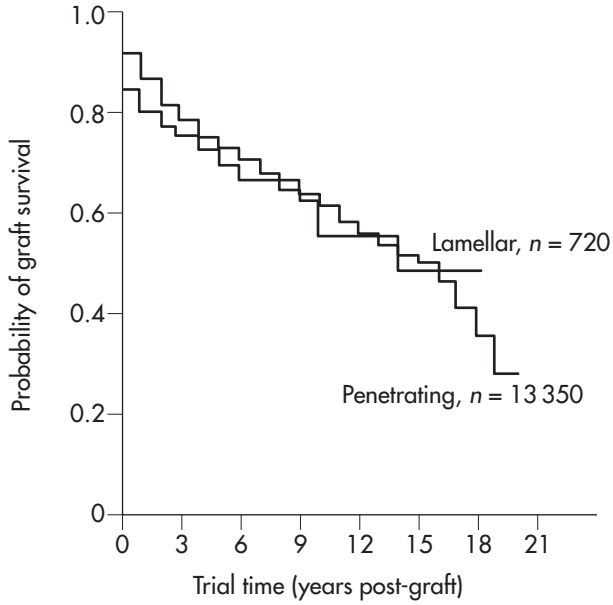

Figure 63.1. Kaplan–Meier survival of penetrating and lamellar corneal grafts. For each curve, *n* indicates the number of grafts initially at risk. Data reproduced with permission from the Australian Corneal Graft Registry, http://hdl.handle.net/2328/1002.

registries have been established elsewhere and work along similar lines, including the British register based in Bristol,[4] and a register in Sweden.[5] There is remarkable consistency in the results reported from the various registries.

Table 63.1 Factors influencing penetrating corneal graft survival in multivariate analysis (Cox proportional hazards regression analysis) to a significant extent

Variable	Range of Hazard Ratios
Surgeon identity	0.30–2.55
Donor age (each additional 10 years)	1.05
Indication for graft	1.00–2.60
Each additional ipsilateral graft	1.18
Lens status (phakic, pseudophakic, aphakic)	1.00–2.02
History of inflammation in grafted eye	1.00–3.14
Corneal vascularization at graft	0.83–1.67
History of raised intraocular pressure	0.64–3.87
Need for anterior vitrectomy at graft	1.00–1.29
Graft diameter	0.56–1.15
Early removal of graft sutures	0.38–1.00
Graft neovascularization	1.00–1.97
Postgraft raised intraocular pressure	1.00–2.24
Occurrence of graft rejection episode	1.00–3.41

LONG-TERM CORNEAL GRAFT SURVIVAL

The 10 year survival of penetrating corneal transplants followed in the Australian Corneal Graft Register is 62% (Fig. 63.1). At 15 years, graft survival has reduced to 55%. This is similar to survival rates observed in other corneal graft registries. The extended rate of attrition is notable: there are few early graft failures but steady loss continues over many years. The survival curve fails to flatten out. The overall graft survival rate for corneal allografts is less than that of solid vascularized organs,[8] a result not widely appreciated.

In recent years there has been a renewed enthusiasm for lamellar transplantation. The premise has been to avoid transplanting corneal endothelium by performing lamellar surgery wherever possible, so as to avoid an allograft response directed at the irreplaceable corneal endothelium. Perhaps it is surprising that the survival of lamellar grafts is no better than for penetrating procedures, approximately 60% at 10 years (Fig. 63.1).

The collective results of all corneal transplants encompass a wide range of clinical factors related to graft outcomes. The procedure is carried out for an extensive range of conditions, under varying circumstances, by a large number of surgeons who employ a range of surgical approaches and diverse sources of corneal donors. The large number of patients followed in registries permits identification of some of the independent variables that affect graft survival (Table 63.1).

GRAFT SURVIVAL FOR MAJOR INDICATIONS

Keratoconus

Keratoconus is a common indication for corneal transplantation, accounting for 25–30% of cases in most developed countries. Patients with keratoconus have an excellent chance of achieving successful engraftment. The survival of penetrating corneal grafts performed for keratoconus is 97% at 1 year, 95% at 5 years, 90% at 10 years, and 82% at 15 years (Fig. 63.2, *A*). Survival is slightly reduced in patients with keratoconus who had hydrops at the time of surgery, and in those with intellectual disability.

Pseudophakic bullous keratopathy

Pseudophakic bullous keratopathy is another common indication for corneal transplantation, accounting for 25% of cases in a number of studies. The results of corneal transplantation are inferior to those observed in patients with keratoconus. Graft survival is 83% at 1 year, 60% at 5 years, 45% at 10 years, and 40% at 15 years (Fig. 63.2, B).

Previous failed corneal graft

Corneal transplantation is often performed to replace a previous graft that has failed. The survival of a first graft is 67% at 10 years and the estimated median survival is approximately 20 years (Fig. 63.2, *C*). Survival of successive ipsilateral grafts is reduced with every graft. For fifth and subsequent grafts analyzed together, survival is 1% at 10 years and the estimated median survival is 1 year.

Corneal dystrophy

Corneal dystrophies are also treated with penetrating keratoplasty. The most common indication for transplantation within this category is Fuchs' dystrophy, which is approximately five times more frequent than other dystrophies. Grafts for stromal dystrophies survive a little better than do grafts for Fuchs' dystrophy

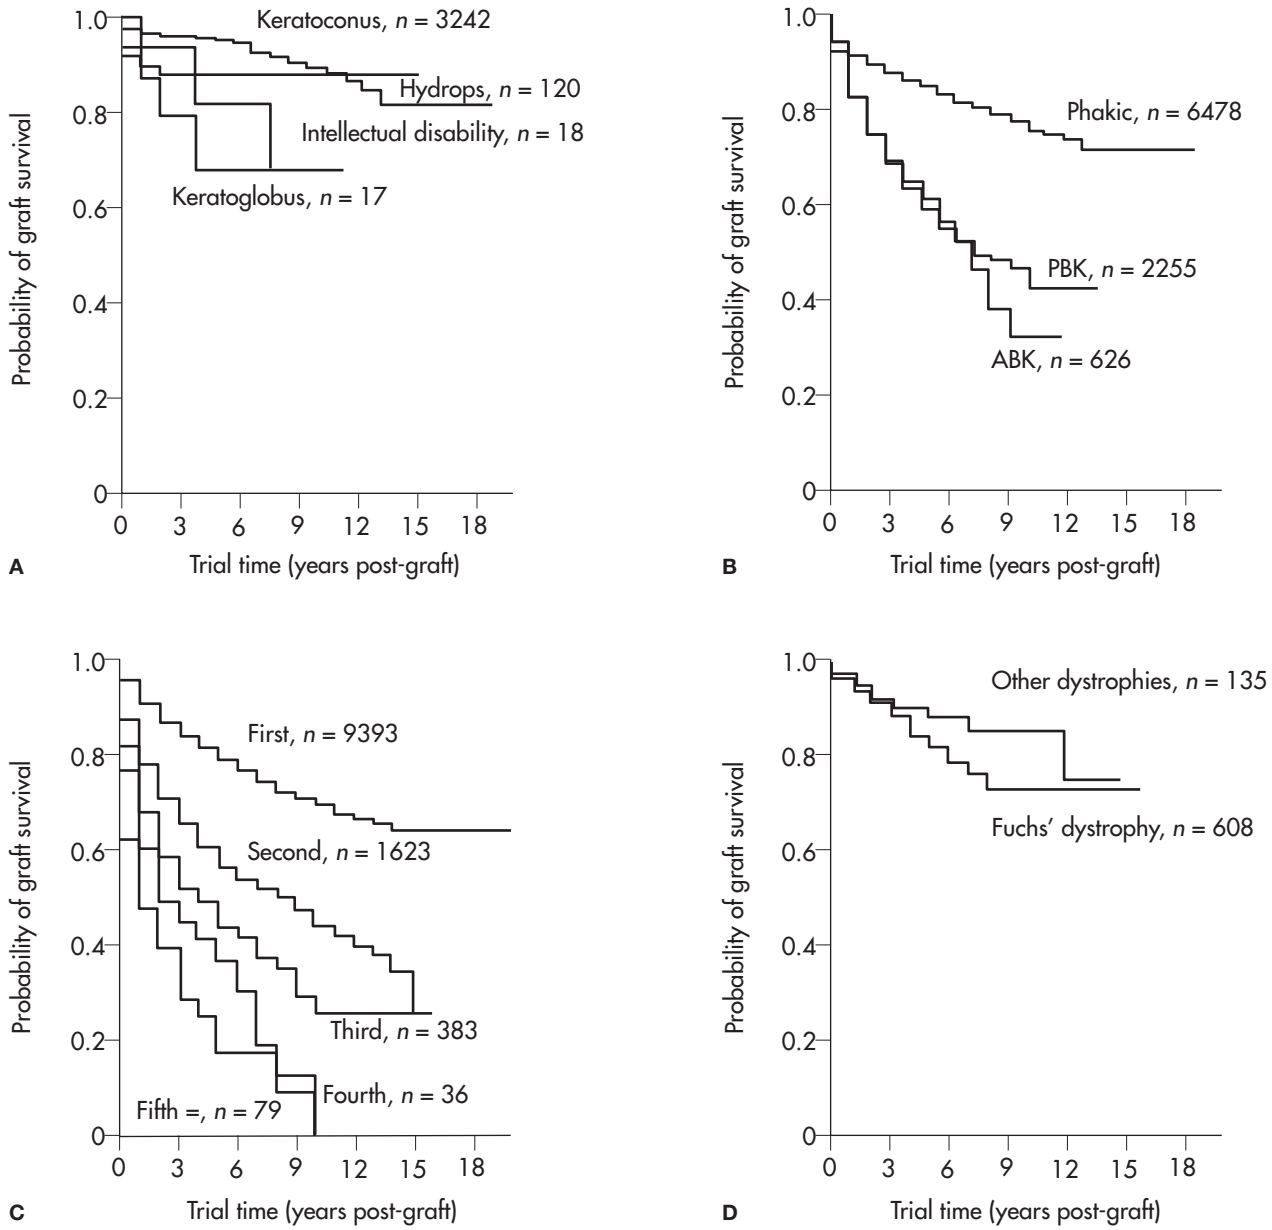

Figure 63.2. Kaplan–Meier survival of penetrating corneal grafts performed for common indications for graft. *A*, Survival of first ipsilateral grafts for keratoconus, keratoconus with hydrops, keratoconus in patients with an intellectual disability, and keratoglobus. *B*, Survival of first ipsilateral grafts in phakic eyes, in eyes with pseudophakic bullous keratopathy (PBK), and in eyes with aphakic bullous keratopathy (ABK). *C*, Survival of first, second, third, fourth, and subsequent ipsilateral corneal grafts. *D*, Survival of first ipsilateral grafts for Fuchs' dystrophy or for other corneal dystrophies. For each curve, *n* indicates the number of grafts initially at risk. Data reproduced with permission from the Australian Corneal Graft Registry, http://hdl.handle.net/2328/1002.

(Fig. 63.2, *D*). Graft survival for Fuchs' dystrophy is 95% at 1 year, 82% at 5 years, and 73% at 10 years. The corresponding figures for stromal dystrophies are 94%, 88%, and 85% at 1, 5, and 10 years, respectively.

Infective processes

At times corneal transplantation is required to control infective processes. Herpes simplex virus infections can cause sight-threatening corneal pathology. Chronic disease often results in scarring which can adversely affect vision; acute fulminating herpetic disease can threaten the survival of the cornea and lead to the loss of the eye. Where a corneal graft is performed for herpetic scarring, the 10 year graft survival is 68% (Fig. 63.3, *A*). In instances where the recipient cornea is inflamed due to active herpetic disease at the time of transplantation, the 10 year graft survival falls to 32%.

Corneal grafts for other infective conditions have a similarly poor prognosis. For example, the survival of grafts performed for nonherpetic perforations, the majority of which are likely to be due to microbial infection, is 59% at 1 year and 35% at 5 years, with an estimated median survival of 5 years. For those with a corneal abscess but not perforation the corresponding figures are 76% and 46%, with an estimated median survival of 6 years. For grafts performed for fungal keratitis the survival is poorer again: 52% at 1 year and 42% at 5 years, with a median survival of 2 years.

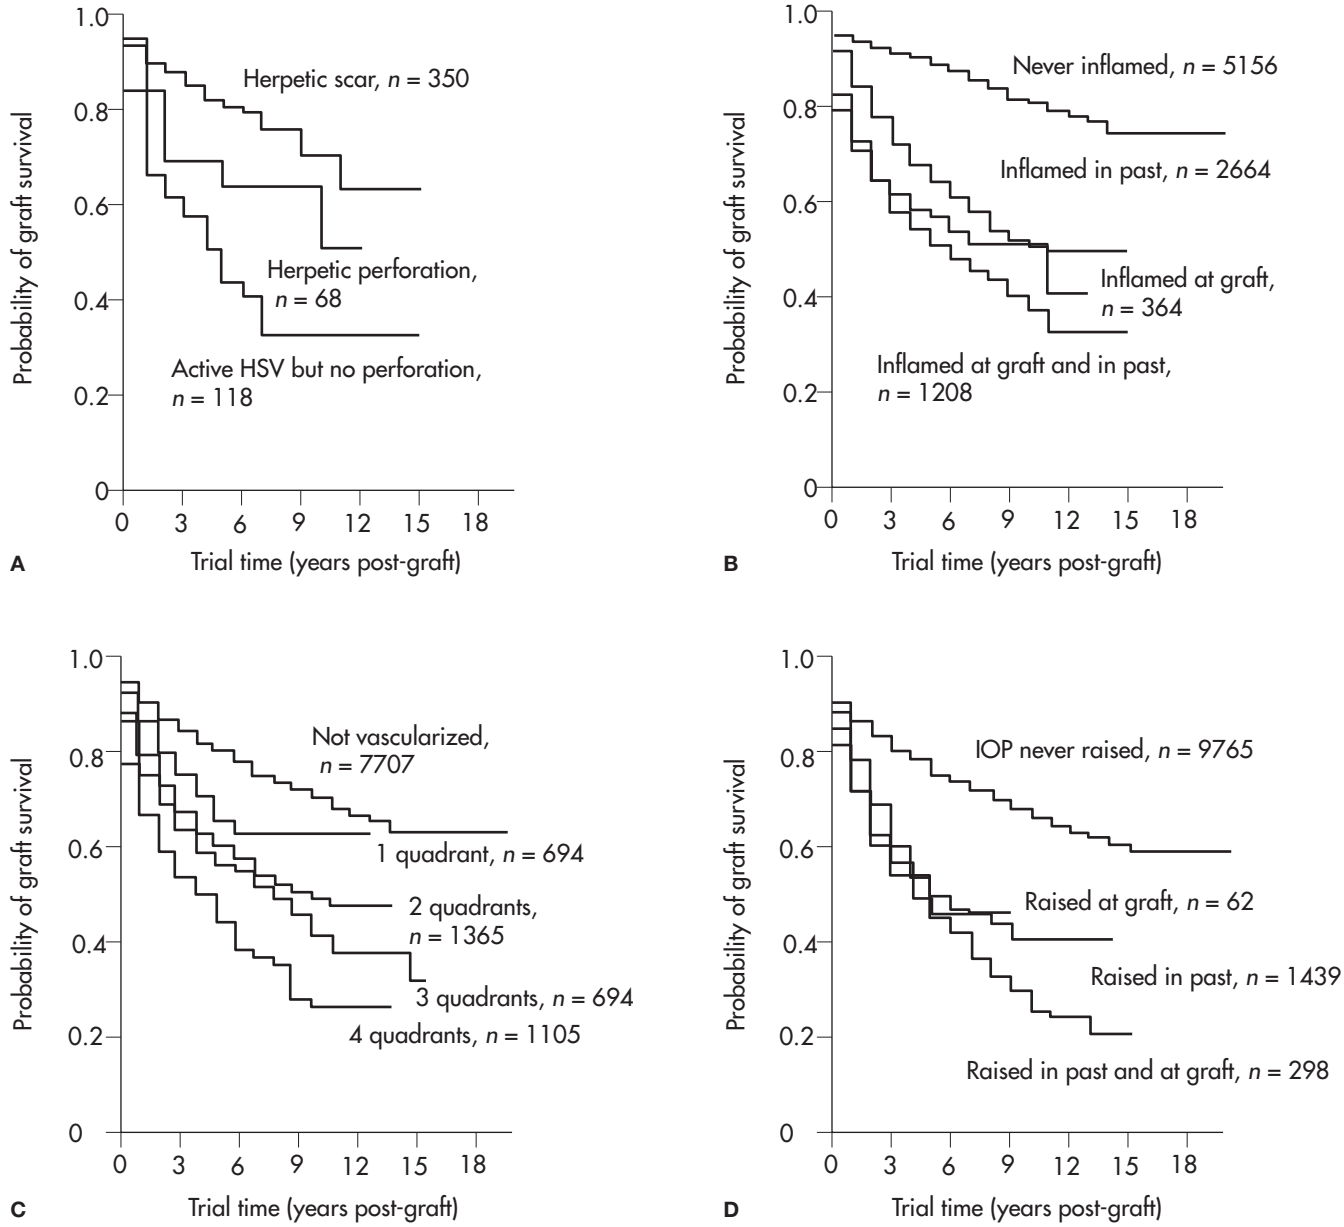

Figure 63.3. Kaplan–Meier survival of penetrating corneal grafts. *A*, Survival of first ipsilateral grafts for herpes simplex virus (HSV) infection. *B*, Influence of a history of ocular inflammation on subsequent graft survival. *C*, Influence of recipient corneal neovascularization, present at the time of corneal transplantation, on subsequent graft survival. *D*, Influence of a history of raised intraocular pressure (IOP) on subsequent graft survival. For each curve, *n* indicates the number of grafts initially at risk. Data reproduced with permission from the Australian Corneal Graft Registry, http://hdl.handle.net/2328/1002.

THE IMPACT OF INFLAMMATION ON CORNEAL ALLOGRAFT REJECTION

An obvious pattern emerges to explain the different survival rates for corneal grafts performed for different indications. Grafts for conditions where there is no history of corneal inflammation, such as keratoconus and stromal dystrophy, do better than those performed for acquired inflammatory conditions. If the etiological agent tends to persist after the graft, as is the case in herpetic keratitis and fungal keratitis, the outcomes are worse again. Those with active inflammation at the time of surgery have the poorest prognosis, but a history of inflammation prior to the graft, decades previously, is also associated with reduced survival rates (Fig. 63.3, *B*). The common path to graft failure in these cases is through allograft rejection.[9] Inflammation erodes graft privilege[10–12] and predisposes to corneal neovascularization, which has a well-established association with reduced graft survival (Fig. 63.3, *C*).

ELEVATED INTRAOCULAR PRESSURE

Elevated intraocular pressure at the time of the graft or at any time prior to the graft reduces graft survival (Fig. 63.3, *D*). Raised intraocular pressure in patients with corneal disease is almost always a

secondary phenomenon, rather than the result of primary glaucoma. Inflammation can reduce the functional reserve capacity of the aqueous drainage mechanisms and in this respect, elevated intraocular pressure may be a marker of previous or active inflammation.

SURGICAL FACTORS INFLUENCING CORNEAL GRAFT OUTCOME

The supposed improvement in the outcome of corneal transplantation over the last 100 years is often attributed to changes in surgical practice. The development of new surgical materials such as monofilament nylon, and the evolution of ocular microsurgery accompanying the widespread use of the operating microscope, have undoubtedly impacted strongly on corneal transplantation. However, it can only be assumed that these surgical developments improved surgical outcomes, because so little information on the outcomes of corneal transplantation prior to the 1950s is available.

In the past, personal opinion, case reports, personal series, uncontrolled studies and the like were used to justify the introduction of variations in surgical technique. With the emergence of the evidence-based medicine movement, there has been increasing interest in the quality of research evidence. As the evolution of surgical techniques continues, so too do the preferred methods of evaluating the impact of therapeutic advances. The gold standard is to compare the proposed advance with the existing therapy through a randomized, controlled clinical trial (RCT). Unfortunately, there are relatively few RCTs of surgical techniques in corneal transplantation, as is the case across most of surgery.

The evidence base for surgical techniques in corneal transplantation was recently reviewed.[13] Looking at the effectiveness of various surgical interventions, 26 trials were identified. Methodological problems were widespread—less than optimal outcome measures, small numbers and therefore low power, and short follow-up were common issues. None of the studies used patient-centered outcomes as the outcome measure, few used graft survival, most used refractive measurements (often keratometry), and a few used intraocular pressure.

Ocular refractive measures in response to intervention tend to be convenient but have limited meaning in terms of patient satisfaction and quality of life. The issue of astigmatism demonstrates this. It is convenient to measure keratometric astigmatism: small variations can be measured and almost any corneal surgery, however trivial, will alter the measurement. The usefulness of this approach in a clinical setting is limited because it only deals with the regular component of astigmatism, and the irregular component may have a profound effect on vision. In addition, keratometric astigmatism is not the same as the refractive astigmatism, which may be more important to the patient.

Despite the limitations of the reported studies, there is evidence of benefit being derived from some surgical approaches. Shrinking the apex of a cone prior to surgery reduces postoperative myopia.[14] There is some support for the use of an excimer laser to cut the donor and host cornea, compared with conventional trephination.[15,16] In addition, there is evidence that graft–host size disparity improves results. Oversizing has a beneficial effect on postoperative intraocular pressure in aphakic or combined cases.[17] Oversizing also increases keratometric readings, with corresponding changes in refraction.[18,19] The use of a viscoelastic agent has been shown to reduce endothelial cell loss to a statistically significant degree.[20] Whether this reduction is clinically significant is another issue, given that it does not improve the graft failure rate.[21,22] It was proposed a decade or two ago that removing the donor epithelium would improve graft survival by reducing allosensitization, and an early trial supported this notion.[23] A larger, more recent trial failed to identify any beneficial effect.[24] There has been much conjecture over the years about whether any particular suture pattern provides a better result by reducing postoperative astigmatism. There is no evidence from clinical trials that suture technique significantly influences the final 'sutures-out' astigmatism.

FACTORS RELATED TO THE DONOR CORNEA

The donor cornea is a key element in the corneal transplantation process. Eye banking has become a sophisticated enterprise and is rigorously regulated in most jurisdictions. Eye banking is aimed at eliminating, as far as is possible, the risk of transferring infectious diseases with the graft, and at providing a cornea with the maximal functional reserve capacity. Although it is not possible to eliminate completely the possibility of transfer of a communicable disease in a donor cornea, the measures that are currently employed ensure that this is a very rare event. So too is primary graft failure, although this does occur from time to time. Subtle variations in the functional reserve capacity of the donor cornea which might affect the long-term survival of the graft are difficult to identify, and evidence of diminished endothelial cell function might not emerge for decades, until the graft fails.

Donor age

Corneal surgeons commonly believe that younger donors provide better corneas. So widely held is the belief that donor age adversely affects graft survival, that surgeons often seek young donors for their young patients and accept old donors only for older recipients. Examination of long-term registry data shows that donor age does influence graft survival significantly in both univariate (Fig. 63.4)

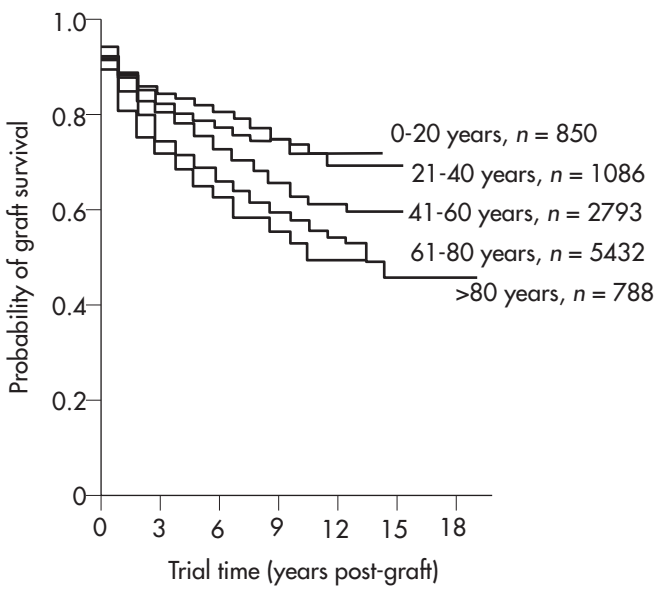

Figure 63.4. Kaplan–Meier survival of penetrating corneal grafts. Influence of donor age on graft survival. For each curve, *n* indicates the number of grafts initially at risk. Data reproduced with permission from the Australian Corneal Graft Registry, http://hdl.handle.net/2328/1002.

and multivariate analysis (Table 63.1), but that observations need to be maintained over decades to detect differences, and that the effect is extremely small. This is an important issue, because were the use of older donors to become more acceptable, the donor pool (a scarce resource in many parts of the world) could be expanded considerably.

HISTOCOMPATIBILITY MATCHING

With the prognosis for corneal transplantation in high-risk patients remaining poor, and the clinical context of corneal transplantation precluding the widespread use of approaches that have contributed to the striking improvements in survival of essential organ allografts, the impact of histocompatibility matching on corneal graft survival is of increasing interest. Better matching may be the only currently available method to improve the results of corneal transplantation, since systemic immunosuppression is not an option for most corneal recipients and there is no prospect of using living-related donors, two of the major approaches associated with the improvement of renal transplant survival over the past 25 years.

The results of the American Collaborative Corneal Transplantation Study (CCTS), a carefully conducted randomized clinical trial, indicated that HLA class I and class II histocompatibility matching had no influence on the survival of corneal transplants in patients at high risk of graft failure.[25] However, there are data from other sources (although not randomized controlled clinical trials) indicating that matching is helpful in prolonging corneal graft survival.[26–28] Histocompatibility matching has progressed to being more reliable and more reproducible with the development of modern molecular techniques for typing. A high error rate in the typing of patients in the CCTS trial was reported by the investigators soon after the study was completed,[29] and the impact of this error rate was subsequently assessed as being likely to have affected the reliability of the results.[30] Various groups, principally from Europe, have more recently reported substantial benefits of matching.[31] The most recent data and perhaps the most striking come from Berlin,[28] in which it was found that HLA matching improves the survival of corneal grafts by 40% at 3 years in high-risk patients. Perhaps it is time to reconsider the effect of matching on the results of corneal transplantation.

VISUAL OUTCOME AFTER CORNEAL TRANSPLANTATION

Graft survival tells the story of gross success or failure. It does not say anything about the degree of visual rehabilitation achieved by those with a clear graft. An assessment of visual performance is required to do this. Visual acuity is the conventional way of measuring vision in the clinical context. Snellen acuity, in the original form or modified to facilitate statistical analysis using logMAR charts, is the approach used in most countries and is the outcome measure most frequently employed in studies looking at the visual results of corneal transplantation.[5] However, there is significant variation in the way vision is measured from center to center.

The evaluation of visual acuity, often open to criticism in clinical assessment, is particularly problematic after corneal transplantation. A meaningful assessment cannot be made until after sutures are out and the final refraction is established. This is almost always at least a year after surgery and the very best acuity may not be achieved until into the third postoperative year. There is also the issue of the optical correction. Most patients will need to wear spectacles to achieve their best vision, and some will need a contact lens. Whatever the patient requires for best-corrected vision may not be tolerable or acceptable in every day life. It should be remembered that even patients very disabled by corneal disease can be expected to see the bottom line of an acuity chart with the aid of a pinhole and a chart lit by an atomic flash. Anisometropia may be a problem for some; others prefer to accept less than best-corrected vision rather than suffer the inconvenience of spectacles or a contact lens. For these reasons, it has been suggested that the acuity of patients with corneal grafts should be measured with their 'socially acceptable' correction.

Binocular acuity is related to visual acuity. How much a person can do with his or her vision depends on how well the better eye sees, not on how poor the worst eye is. Failure to recognize the importance of binocular acuity in corneal transplantation can result in patients having surgery which is complicated, resource-consuming, and hazardous to the patient if immunosuppression is used, without the prospect of reduced disability even if a functioning graft is achieved.

Within the Australian Corneal Graft Registry, Snellen acuity after corneal transplantation is found to be 6/12 or better in 40% of the patient cohort in whom the visual acuity has been measured (Fig. 63.5). The visual results for patients grafted for keratoconus are much better, with 71% achieving 6/12 or better and 89% recording at least one line of improvement on the Snellen chart following corneal transplantation. Several studies—all retrospective patient series–reveal remarkably consistent results, with 90% of patients achieving 6/12 or better.[32–34]

VISUAL DISABILITY AFTER CORNEAL TRANSPLANTATION

Patient-centered outcomes are seldom used in the evaluation of corneal transplantation. Although visual acuity and keratometric readings are convenient measures, they provide little information about the impact of the procedure on the patient. For example, there is a tendency to express the results of corneal transplantation in terms of corneal astigmatism. It is more convenient to measure the keratometric astigmatism rather the spectacle astigmatism. This approach is likely to provide solid numbers: keratometry is objective, and there is a subjective element to refractive astigmatism. However, the refractive astigmatism may relate more closely to the patient's visual performance. This general approach assumes that corneal astigmatism is a major factor limiting visual acuity, and that acuity in turn is the major factor influencing visual disability. In reality, not all individuals with good Snellen acuity consider themselves to see well: some patients with very high levels of acuity are quite frustrated by their vision. Visual acuity is only one domain of visual function, and other aspects of visual performance are also important. For example, good contrast sensitivity is necessary for everyday functioning. Subnormal contrast sensitivity has been reported after corneal transplantation for keratoconus.[35] There are also some studies which demonstrate increased wavefront aberrations in patients with corneal grafts.[36,37]

CONCLUSIONS

Paradoxically, corneal transplantation is both successful and unsuccessful. For patients with dystrophic conditions such as keratoconus or the corneal dystrophies, the results are excellent, at least when considered from the perspective of successful engraftment. Graft

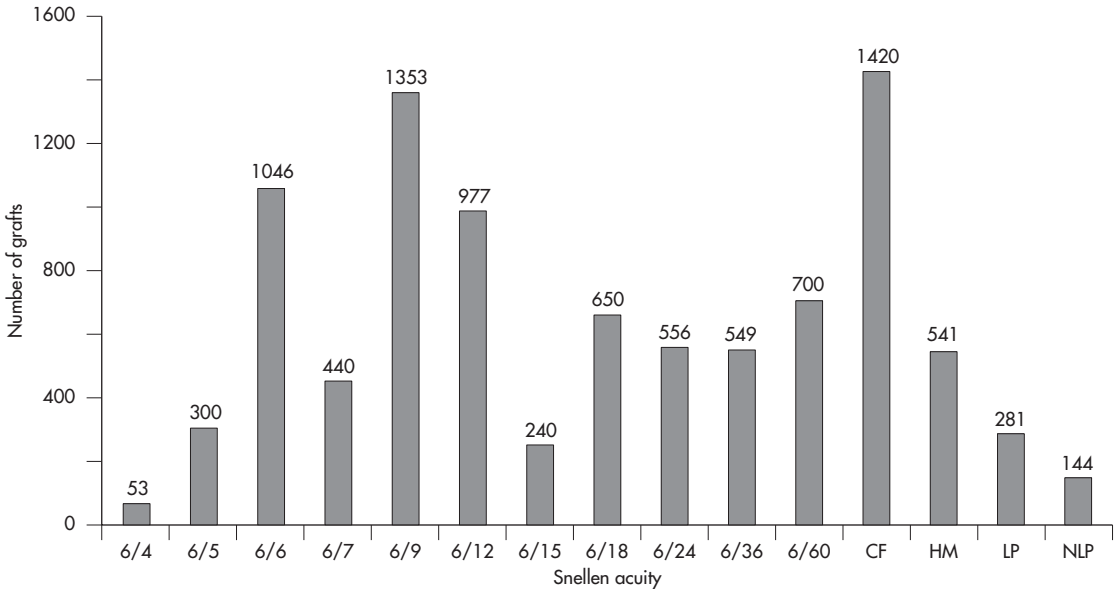

Figure 63.5. Snellen acuity recorded in the grafted eye at the time of most recent follow-up. CF, count fingers at 3 m; HM, hand movements; LP, perception of light; NLP, no perception of light. survival in this group of patients is high. Unfortunately, acquired corneal diseases causing blindness are common around the world. For the group of patients with inflammation or corneal scarring, the results of corneal transplantation are less impressive, so unimpressive that many patients are not considered for surgery. The developments that have improved the outcomes of allotransplantation for vascularized organs are generally not applicable to corneal transplantation. To develop alternative management strategies to improve the outcome of corneal transplantation will require extensive research. For this research to be applicable to clinical corneal transplantation, more needs to be known about the long-term clinical course and the factors influencing outcomes, and there are surprising gaps in our knowledge. Examples include the relationship of corneal endothelial cell count to graft survival, the relationship of eye banking procedures to graft survival, and the incidence of transfer of slow virus and prion infections through corneal transplantation. One way to fill these gaps is through surveillance programs or registries. As regulation of transplantation programs increases, it may become obligatory to keep long-term data on the outcomes of transplantation. This has already been threatened in some jurisdictions, and it is difficult to envisage any other way of elucidating the long-term outcomes. Following patients over the long-term is necessary to answer important questions about corneal transplantation. There is also a need for more clinical trials. The only way to evaluate clinical interventions is with prospective, randomized clinical trials. Few have been performed in the area of clinical corneal transplantation and the approach deserves further encouragement.

64 Surgical technique for DSAEK—Descemet's stripping automated endothelial keratoplasty

Mark S. Gorovoy

INTRODUCTION

The technique of Descemet's Stripping Automated Endothelial Keratoplasty (DSAEK) for endothelial failure is explained with clinical pearls to facilitate its use. DSAEK is a novel procedure that replaces penetrating keratoplasty (PKP) for endothelial disease.[1] The visual results of DSAEK exceed those of PKP.

HISTORICAL PERSPECTIVE

PKP has been the standard of care for corneal transplantation for over 50 years. Modern microsurgical techniques and improved eye banking have resulted in a very highly successful operation, especially if the measure of outcome is a clear cornea. PKP is a full-thickness procedure and applicable for a large range of disease including corneal decompensation from endothelial failure, stromal scars, and ectatic disease. However, visual results with PKP are highly variable, unpredictable, and visual recovery may be delayed. Unacceptable astigmatism, both regular and irregular, may limit spectacle correction. Full thickness trephinations and longterm sutures contribute to the refractive dilemmas and surface disease. The susceptibility to traumatic wound dehiscence and loss of vision remains permanent.

Clearly, a procedure that not only improves the anatomy (i.e. corneal clarity), but also consistently improves the function (i.e. visual acuity as measured by best corrected spectacle visual acuity—BCSVA) is highly desirable. DSAEK, by avoiding full thickness trephinations and long-term sutures, avoids the functional shortcomings of PKP and results in a rapid high-quality visual recovery. DSAEK is a focused surgery for endothelial diseases, such as Fuchs', pseudophakic, or aphakic bullous keratopathy (P/ABK), prior PKP endothelial graft failure or iridocorneal endothelial (ICE) syndrome. Is it not applicable for stromal scars or ectatic disease?

The origins of DSAEK stem from the work of Dr Gerritt Melles.[2–5] His original technique of posterior lamellar keratoplasty (PLK) involved a large limbal incision and deep manual lamellar corneal dissections with excision and transplantation of a similarly dissected donor disk. Next evolved a smaller (5 mm) clear cornea temporal incision and a taco-fold donor insertion. Dr Mark Terry renamed the procedure Deep Lamellar Endothelial Keratoplasty (DLEK) and has been instrumental in promoting the superior outcomes of DLEK.[6–9] PLK (DLEK) requires extensive surgeon skill to master the arduous lamellar dissections of both the patient and donor (performed on an artificial chamber).

The next evolution by Melles was the substitution of the patient dissection with Descemet's stripping.[10] This pivotal change gave birth to Descemet's Stripping Endo Keratoplasty (DSEK). Descemet's stripping eliminated the manual dissection of the patient and my adaptation of the Moria ALTK system eliminated the manual dissection of the donor and gave rise to DSAEK. The elimination of all manual lamellar dissections has resulted in a more consistent and reproducible surgical outcome. Visual recovery is hastened by the two smooth lamellar surfaces.

TECHNIQUE

DSAEK is this author's procedure of choice for all patients requiring corneal transplantation due to endothelial disease. DSAEK surgery is totally dissimilar to PKP surgery and because it is a relatively new procedure, the aim is to continue to modify technique to improve patient outcomes.

The Achilles heel of DSAEK is donor dislocation and most changes to the procedure are in an effort to reduce the risk of this complication. In the following sections the author's present surgical technique and postoperative maneuvers are described in detail.

PATIENT SELECTION

DSAEK is indicated for corneal endothelial disease. Fuchs' dystrophy comprises the largest cohort followed by P/ABK and prior graft endothelial failure. The technique is essentially the same for all diagnoses. All patients must be pseudophakic with a posterior chamber intraocular lens (IOL). It is preferred to do DSAEK as a stand-alone procedure, not combined with other procedures.

All phakic patients are rendered pseudophakic even if it requires a clear lensectomy. The only exception is a cornea too opaque for phaco. This approach deepens the anterior chamber for donor

unfolding and avoids future cataract surgery that is almost inevitable—thereby avoiding phaco-induced endothelial cell loss.

All anterior chamber IOLs are replaced with sutured scleral IOLs. Glaucoma must be well controlled and if necessary filtering or shunt surgery is performed pre-DSAEK. These staged procedures are completed approximately 4–6 weeks apart.

PREOPERATIVE TREATMENT

A fourth generation fluoroquinolone antibiotic is started q.i.d. the day prior to surgery. Topical anesthesia using 2% xylocaine jelly and i.v. sedation as needed are utilized. The pupil is left unaltered, i.e. no miosis or mydriasis.

In the operating room, 10% betadine solution preparation to the skin and lids is performed with direct instillation onto the globe. A nasal speculum is placed after the lid margin and lashes are draped with tegaderm. The author sits laterally with the microscope and marks the corneal surface with a 9 mm trephination marker inked with a marking pen. This allows the size of the donor tissue trephination to be judged. A 9 mm donor is used unless this marking approaches 2 mm to the limbus, indicating a smaller donor size is preferable such as 8.5 or 8.75 mm. It is important to avoid the donor lenticule from impinging too close to the angle. The patient's eye is left open with the speculum in situ and while attention is turned to the donor tissue preparation. This 'air drying' allows a swollen, edematous cornea to deturgesce and improves the operative visibility.

DONOR

Attention is then turned to the donor tissue. The donor cap is placed on the ALTK system and cut with a 300 keratome head as shown in Figure 64.1. Air is used to inflate the donor cap. A very firm corneal dome is verified with finger ballottment. The donor rim must be a consistent 16 mm rim size, without any divots. The local eye bank must be made aware that a large rim size is required. The anterior cap is removed from the keratome head and the remaining posterior lamellar donor tissue is removed from the ALTK 'hat' and placed on a cutting block and trephined endothelial side up. When lifting up the hat, simultaneous forced air pressure prevents the donor tissue from collapsing on the ALTK stage.

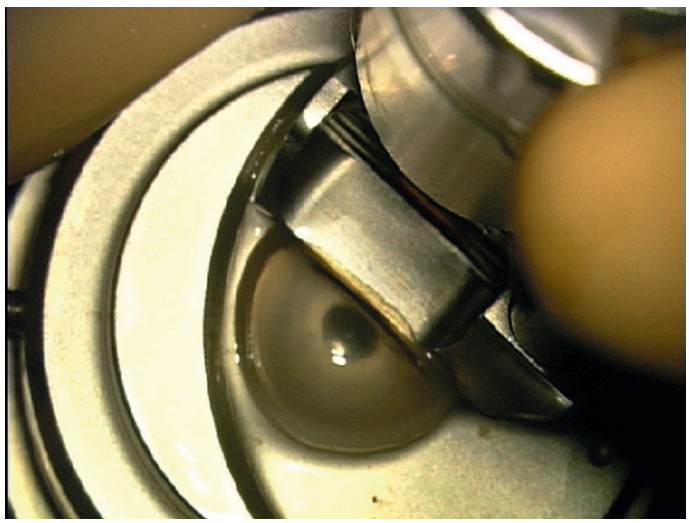

Figure 64.1. Tissue being cut on the Moria ALTK system.

Centration of the donor tissue on the cutting block is essential to avoid a decentered cut and a full thickness donor disk edge. If that occurs, recenter the tissue and recut it to remove the full thickness section. A perfectly round donor tissue is not required and causes no optical problems. A drop of transplant media is placed on the donor and attention is returned to the patient.

The 1 mm, diamond blade cut, vertical limbal paracentesis are made superiorly, inferiorly, and nasally. A clear cornea 2.75 mm keratome incision is made temporally. Through the right-handed paracentesis, the irrigating Descemet's stripper (Harvey Instruments) is introduced into the anterior chamber and Descemet's is scored along the surface trephination mark for close to 360° as shown in Figure 64.2. Descemet's membrane is then stripped 2–3 mm for several clock hours. The irrigation and aspiration 4 mm port hand piece (Bausch & Lomb millennium) is introduced through the keratome incision and the loose Descemet's edge is aspirated and dragged out of the wound (Fig. 64.3). This may take several passes to remove all of Descemet's membrane within the scored area. Three full thickness stabs using the same diamond paracentesis blade are made equidistant in the mid-periphery for future interface fluid drainage as previously described by Dr Frances Price. The temporal incision is enlarged to 5 mm.

DONOR INSERTION

The donor tissue in its cutting block is placed under the microscope and excessive fluid is removed with a sponge. Several drops of

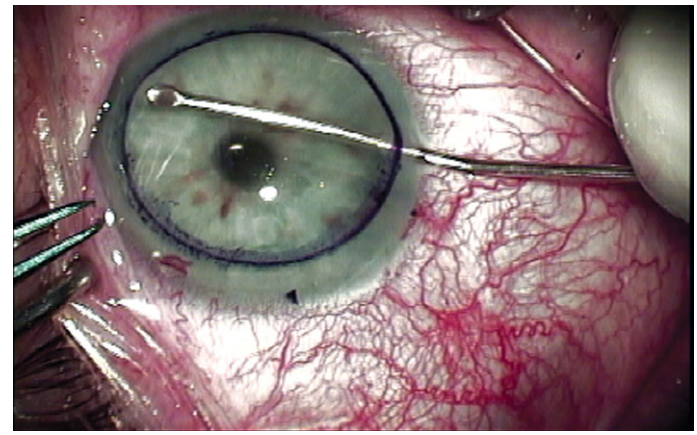

Figure 64.2. Stripper scoring Descemet's membrane.

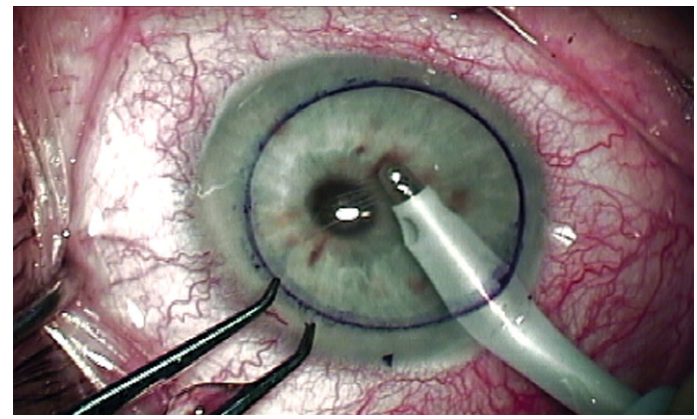

Figure 64.3. Irrigation and aspiration stripping of Descemet's membrane.

Healon (AMO) are placed on the donor tissue which is then folded over like a taco in a 60/40 fold. It is grabbed with Goosey inserter forceps (Moria) and inserted into the anterior chamber (Fig. 64.4). One 10-0 nylon is applied to partially close the incision and BSS solution is used to deepen the anterior chamber. The donor may unfold spontaneously. If not, the irrigation and aspiration hand piece is used to deepen the anterior chamber and grab the underside of the 'taco' and unfold it.

A final wound suture is placed and the tissue is centered to the limbus. This is accomplished by reforming the anterior chamber about 50% depth and balloting the limbus with any device, even your finger. The tissue will move away from the spot the limbus is 'smacked.' Once the tissue is centered a full air bubble fills the anterior chamber outlining the donor disk edge as demonstrated in Figure 64.5. If the donor decenters during this step the air is removed and the tissue is recentered. The mid-peripheral stab incisions are then probed with a spatula or cannula and interface fluid is visually expressed out. Dilating drops are applied and the patient is left supine for 1 h in the holding area. After 1 h, a slit lamp examination verifies the position of the donor and air is 'burped' out through the paracentesis or wound site until the lower air bubble meniscus is above the inferior pupil edge. This insures absolutely no chance for a pupillary block. A shield is applied. Drops of antibiotics q.i.d. and prednisone are started with office follow-up the next day.

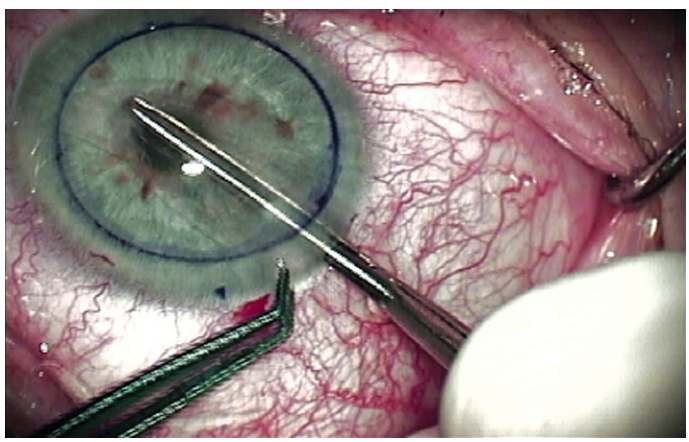

Figure 64.4. Folded donor inserted into the anterior chamber.

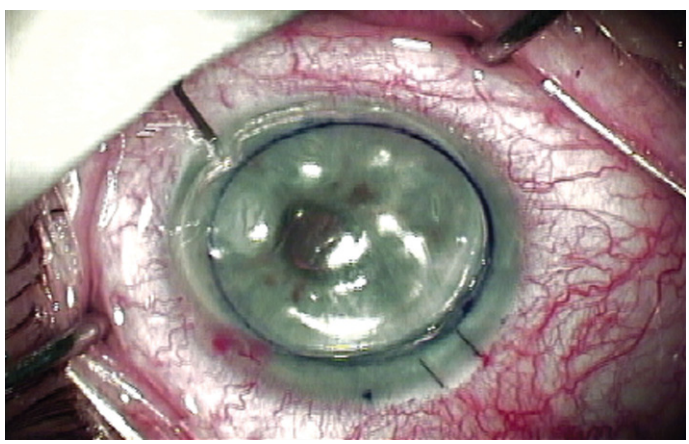

Figure 64.5. Full anterior chamber bubble.

POSTOPERATIVE DAY 1

Slit lamp examination confirms the appropriate position of the donor tissue. The two key questions at this stage are: is the cornea grossly edematous or has the donor disk slipped inferiorly? If the answer is yes to these two questions, donor dislocation if likely (Fig. 64.6). Careful slit-lamp examination can identify very tiny gaps in adhesion, even with +4 corneal edema. In these situations, repeat air bubbling is done in the minor operating room under the microscope and the supine positioning and air bubble burping is repeated just as in the original operating room procedure (Fig. 64.7).

In several DSAEK patients three bubbles have had to be placed. There is no harm to the 'loose' donor disk as the aqueous provides endothelial nourishment independent of stromal attachment. Interestingly, one patient had delayed donor adhesion for 7 weeks and yet has a perfect result with an excellent endothelial cell count. The surgical goal is to achieve a donor dislocation of less than 5%.

The postoperative drop regime is 1 week of antibiotic drops and prednisone drops q.i.d. for 3 months then tapered to once a day by month 6. Steroid responders may need accelerated tapering and even a switch to Lotemax (Bausch & Lomb BID) or topical

cyclosporin , plus glaucoma agents. Best spectacle corrected visual acuity (BSCVA) is obtained between 6 and 12 weeks at which time a new spectacle script can be provided. Figure 64.8 shows a clear DSAEK at 6 weeks postsurgery. Limbal sutures can be removed after 6 weeks for astigmatism control.

DISCUSSION

DSAEK has revolutionized the way this author approaches and treats endothelial corneal failure. This paradigm shift has given the confidence to be appropriately aggressive when counseling patients about the risks and options of corneal transplant surgery without concomitant retinal disease. A BSCVA of 20/40 by 6 weeks in over 80% of patients is generally expected. This improves to 20/40 in over 90% of eyes by week 12 and BSCVA of 20/20 is reached in 16% by 6–12 months. Typically, there are no significant refractive surprises. Price has published a large series of DSAEK outcomes, confirming the excellent postoperative visual results.[11]

Patients with bilateral disease are requesting second eye surgery by 3 months. However, appropriate patient counseling must never ignore the risks of any corneal transplant surgery: infection, primary failure, rejection, and glaucoma.

This author's enthusiasm for DSAEK has resulted in offering monthly courses for corneal surgeons. Their positive feedback is infectious. I no longer recommend DSAEK as an alternative to PKP. It has replaced PKP as my standard of care for endothelial disease and I anticipate it will be the universal standard of care in the very near future.

65 Posterior lamellar keratoplasty and deep lamellar endothelial keratoplasty

Neda Shamie, Edwin S. Chen, Mark A. Terry

BACKGROUND AND HISTORY

Corneal endothelial dysfunction accounts for most of the nearly 40 000 penetrating keratoplasties (PKP) performed in the USA annually.[1] This is despite the clear understanding of the pathophysiology of endothelial keratopathies such as Fuchs' endothelial keratopathy as well as pseudophakic bullous keratopathy in which the stromal and the epithelial layers are at least initially healthy and that primarily the endothelial layer and the posterior corneal layers are diseased.[2–4] With that understanding, many scientists and corneal surgeons have been intensely studying a more selective approach to the surgical treatment of corneal endothelial dysfunction for many years. As a result of their efforts, selective endothelial keratoplasty (EK) has now reached mainstream practice with increasing number of corneal surgeons performing EK for their patients with corneal endothelial dysfunction. This is thought to be due to the many improvements and simplifications of the surgical techniques and clearly proven excellent clinical results.[5–20]

Drs Polack, Barraquer and others initially introduced endothelial keratoplasty ca. 1965, with a technique that involved creating a hinged corneal flap which would then be retracted for trephination and transplantation of the posterior stroma and endothelium.[21,22] This required suturing of the hinged flap at the very least. The technique was clearly more selective than penetrating keratoplasty in treating endothelial dysfunction as it replaced only the posterior stromal and endothelial layers. Despite its selective approach, it did not address the many problems associated with surface sutures and penetrating corneal wounds such as irregular astigmatism, delayed visual recovery, and a potentially unstable globe. To address these problems, in 1993 Ko et al presented results from laboratory experiments on rabbits in which they performed endothelial keratoplasty through a scleral limbal approach.[23] This led to a resurgence of interest in the subject and intense examination of EK as a valuable surgical option.

Gerrit Melles of the Netherlands performed the first human scleral limbal approach to EK in 1998 through a 9.0 mm incision.[24] He named the procedure posterior lamellar keratoplasty (PLK), the same name used by many surgeons performing endothelial keratoplasty under a hinged flap.[18–20,25,26] The Melles' PLK technique utilized air for both resection of the recipient tissue and stabilization of the donor tissue after insertion. This technique obviated the need for the use of any corneal sutures. Melles' PLK procedure proved to be extremely technically difficult but his contribution to the field indeed led to the accelerated movement toward further improvements in EK techniques.[20]

In 1999, Mark Terry of Portland, Oregon, began intensive laboratory experimentation in pursuit of simplifying the technique's approach while maintaining or improving its results. He utilized the cohesive viscoelastic agent Healon (Pfizer, New York, NY) in the laboratory and through prospective clinical studies has shown that Healon can be safely used in stabilizing the anterior chamber and thus simplifying the procedure. The cohesive nature of Healon allows it to be easily removed in its entirety without residual coating of tissue and without hindering donor graft adhesion.[27,28] Terry renamed the procedure deep lamellar endothelial keratoplasty (DLEK) to differentiate it from the hinged procedure originally named PLK and to emphasize the endothelial transplantation involved in this procedure.[6,26] A prospective randomized study of EK under the approval of Institutional Review Board (IRB) was begun and Terry performed the first human case of DLEK in the USA in March 2000.[27] Since then, surgeons have performed the procedure in the appropriate patients and have heralded its many benefits over PKP for their patients with corneal endothelial dysfunction.[12]

The many benefits of this procedure compared to penetrating keratoplasty stem from its preservation of the normal corneal surface as it does not require penetrating corneal wounds and thus avoids the need for surface sutures. The tensile strength of the scleral tunnel wound of EK is also much greater than the PKP wound and allows for more rapid wound healing. The lack of surface sutures inherently lowers the risk of suture-related complications such as irregular astigmatism, unpredictable corneal curvature, suture-related graft rejection, and infections. Also, there is no need for rigorous and prolonged postoperative follow-up with the need for selective suture removal.

Despite proven benefits over PKP, DLEK/PLK poses a number of challenges to the corneal surgeon. First and foremost, the difficulty

in performing the surgery limits its utility on a large scale as many surgeons may avoid adding these procedures to their surgical armamentarium. Another concern stems from the creation of the deep lamellar dissection in the recipient as well as the donor cornea; it is postulated that this deep stroma to stroma interface limits the final visual potential in the DLEK/PLK eyes.[9,12,29,30]

Descemet's stripping endothelial keratoplasty (DSEK) and Descemet's stripping automated endothelial keratoplasty (DSAEK) are modifications of Melles' PLK which circumvent the need for a manual lamellar stromal dissection of the recipient cornea by selectively removing the endothelial layer through a Descemetorhexis, a technique originally described by Melles.[31,32] Since their introduction, DSEK and DSAEK have quickly replaced DLEK/PLK in popularity given the simplified surgical steps and better visual outcomes.[13,15,17] However, the skills and the techniques involved in performing DLEK such as the deep manual lamellar dissection of the recipient cornea should be maintained as there still remain indications for performing DLEK or PLK in patients at high risk for the complications unique to Descemet's stripping surgery.

The Descemetorhexis step in DSEK and DSAEK leaves the recipient corneal bed extremely smooth as demonstrated on electron microscopy.[33] This is thought to explain the higher rates of graft dislocation in DSEK/DSAEK as compared to DLEK in which the recipient stromal bed's roughened properties are thought to create better adherence.[13,16] Many steps have been proposed to lower this rate of graft dislocation in the DSEK/DSAEK cases with the use of prolonged intraocular air in the anterior chamber for continued stabilization of the graft the most commonly advocated.[16,33] Therefore, any condition in which retention of this air bubble in the anterior chamber is in question would preclude DSEK/DSAEK and lead to DLEK as the procedure of choice in that patient. Examples of these include a stable anterior chamber intraocular lens (IOL) that is deemed unnecessary to be explanted or exchanged, aphakia in a patient who is to be left aphakic (i.e. a very high axial myopia) and significant irreparable iris defects. In these and similar cases, there is no hindrance to the movement of the anterior chamber air bubble to the posterior pole. With the posterior migration of the air bubble, the risk of graft dislocation can potentially increase as the benefits of the air bubble acting to hold the donor graft in place is lost. The posterior migration of the air bubble can also result in pupillary block or secondary angle closure with increased postoperative intraocular pressures. Although the current indications for DLEK may seem limited, it continues to be an excellent option for the appropriate candidate and thus the lamellar corneal surgeon must continue to know the skills involved in performing this form of EK.

PREOPERATIVE CONSIDERATIONS

SURGICAL PLANNING

In the preoperative evaluation when the decision is made to proceed with EK, attention needs to be paid to several other factors to help in planning the surgical approach as well as to offer the patient the most realistic expectations. These could include the status of the lens (crystalline or previously implanted IOL), any evidence of vitreous prolapse, presence of anterior segment abnormalities (e.g. iris synechiae), and evidence of retinal or macular pathology. One can then better plan the surgical approach in case, for example, a scleral fixated IOL, anterior vitrectomy, or anterior segment reconstruction may be needed.

INFORMED CONSENT

An informed consent is obtained with a clear representation of outcomes expected. The patient should be informed of the risk of graft failure as well as dislocations requiring further surgery. There is the high risk for developing cataract in the cases in which the patient is to be left phakic. If, with further discussion, the patient and the surgeon do in fact decide to proceed with crystalline lens extraction to avoid secondary cataract extraction, the patient needs to understand the expected loss of accommodation. There is also the possible limitation of visual potential secondary to the surgical interface.[7] Additionally, the patient should be made aware of other risks associated with intraocular surgery per se such as developing glaucoma, retinal detachment, endophthalmitis, etc.

INTRAOCULAR LENS POWER CALCULATIONS

One great benefit of EK over PKP is the preservation of surface corneal curvature.[5,7,8] This simplifies the calculation of the power of the IOL to be implanted as one can simply use the preoperative average keratometry readings of the virgin (original) cornea in the calculations. This of course is very different from the scenario in PKP patients in whom the average keratometry readings change drastically due to the vertical wounds and the surface sutures of PKP.[34–37] If epithelial edema of the surgical eye prohibits accurate keratometry readings, then keratometry readings from the fellow eye can be used. If both corneas are edematous and prohibit accurate keratometry readings, then the EK can be performed first and the cataract extraction with IOL implantation performed 3 months later when more accurate measurements can be performed. If combined EK surgery with cataract extraction and IOL implantation is to be done the target postoperative refraction should be approximately −1.0 diopters using standard IOL calculation. This is to compensate for the myopic shape of the microkeratome prepared donor lenticule which results in a 0.5–1.0 diopters of hyperopic shift.[38].

PREOPERATIVE MEDICATIONS

In the case of patients requiring cataract extraction with IOL implantation or exchange of an IOL with possible scleral fixated IOL in conjunction with endothelial keratoplasty, the usual preoperative dilating drops are used as per surgeon's protocol. Preoperative antibiotic eye drops are also used per the surgeon's preference. Apraclonidine 0.5% drops are also instilled in the operative eye to lower the intraocular pressure and to minimize conjunctival injection. The eye is prepped and draped in the usual sterile ophthalmic manner with the use of povidone-iodine solution.

In the case where the patient undergoing EK is to be left phakic or has stable implanted IOL, the pupil is constricted using G. pilocarpine.

ANESTHESIA

DLEK surgery is usually done under retrobulbar block anesthesia with a seventh nerve (orbicularis) block to obtain, not only sufficient anesthesia, but also akinesia of the lids. General anesthesia (either endotracheal or laryngeal mask airway technique) may be considered in patients who may not be cooperative or in whom posterior pressure needs to be minimized (e.g. an eye with a shallow chamber). It is even possible to perform DLEK surgery on selected

high-risk patients under topical anesthesia, but this is not recommended for the initial cases of the novice surgeon as lack of akinesia can potentially increase intraoperative complications.

TECHNIQUES AND INTRAOPERATIVE CONSIDERATIONS FOR DLEK SURGERY

MANAGEMENT OF THE PHAKIC, APHAKIC, OR PSEUDOPHAKIC PATIENT

When cataract extraction is to be performed, the procedure is done prior to the DLEK and possibly after epithelial scraping to improve visualization if significant surface haze is present. Dispersive viscoelastic agents such as Viscoat (Alcon, Fort Worth, TX) should be avoided during any and all portions of the surgery as they can adhere to the stromal interface and prevent donor disk adherence to the bare recipient stromal bed. It is also recommended to perform the cataract surgery through a separate scleral limbal incision. This small cataract wound is sutured tightly prior to creation of the stromal pocket of DLEK.

An anterior chamber intraocular lens (ACIOL) need not be exchanged for a posterior chamber lens in all cases. The decision should depend on the stability of the anterior chamber lens and the type of lens. If the ACIOL is of the more modern flexible open looped type and seems to be nicely sized and positioned in the angle, it can be left in place. Otherwise, it may be prudent to replace the ACIOL with a posterior chamber lens (i.e. a sulcus or a scleral-fixated PCIOL) to decrease chance of endothelial damage.

In the case of the aphakic patient, if the posterior capsule is intact, a PCIOL can be safely placed in the capsular bag or the sulcus. Otherwise, the decision must be made to scleral fixate a PCIOL or leave the patient aphakic (i.e. in the high axial myopic patient or the rare patient with no visual potential undergoing surgery only for symptom relief).

PREPARATION OF THE RECIPIENT CORNEA

Surgery is usually performed from the temporal side for ease of access. An 8.0-, 8.5-, or 9.0-mm diameter circular corneal marker (depending on the size of recipient cornea) is used to imprint a circular mark onto the corneal surface. When the centration of the mark meets the surgeon's approval, the circular indentation is then accentuated with dotted marks using a sterile marker. This mark will act as the template to performing the posterior lamellar resection later in the procedure.

Prior to creating the scleral incisions, two clear corneal limbal stab incisions (about 1 mm diameter) are placed about 5 clock hours apart, to be used as access points to the anterior chamber later in the operation. A 1 mm diamond knife can create a better paracentesis wound with greater ease of anterior chamber entry as compared to a metal blade. For ease of identification and reentry, these ports can also be marked with a sterile marker. Additionally, great attention must be paid to creating the paracentesis ports in an angle that does not interfere with the edge of the 8.0-, 8.5-, or 9.0-mm lamellar graft (i.e. entry should be at a sharper angle than one is accustomed to in ports created for cataract extraction). Through one of the stab incisions, the cohesive viscoelastic Healon is placed into the anterior chamber to replace the aqueous fully and to maintain normal pressure.

Conjunctival peritomy is performed to allow for the 5.0-mm temporal scleral tunnel. Hemostasis is obtained using cautery. A 5.0-mm length incision at 350 μm depth is created parallel to, and 1 mm posterior to, the limbus temporally using a trifaceted, guarded diamond knife. Using a crescent blade, a deep lamellar pocket is dissected at about 80% depth into approximately 1 mm of clear cornea. Straight and curved stromal dissectors (e.g. Devers Dissectors, Bausch & Lomb, St Louis, MO or Melles Dissectors, DORC, Netherlands) are used to extend the lamellar pocket through and beyond the pupillary axis, from limbus to limbus. The most difficult aspect of creating the lamellar dissection is finding the right plane and making sure not to perforate anteriorly or posteriorly. The Devers dissectors used in creating this lamellar interface have semi-sharp tips with blunted sides which if advanced without significant force should maintain a plane and not perforate through the cornea. Melles has proposed performing this step of the surgery with air in the anterior chamber to create an 'air-to-endothelium interface' and thus an optical surface to help delineate the depth of dissection.[39] After the stromal pocket has been created limbus-to-limbus, additional Healon should be used to fill the chamber in preparation for resection of the recipient tissue.

After a satisfactory deep stromal pocket is created, a 2.8-mm keratome is used to enter the anterior chamber through the scleral tunnel at the proximal mark of the corneal circular template mark. Intracorneal, low profile, highly curved microscissors of surgeon's choice (i.e. Cindy scissors, Bausch & Lomb, St Louis, MO) are used to excise a posterior disk of the recipient cornea using the circular mark made on the corneal surface as a guide. The wound is extended to the full 5.0 mm. Utrata forceps are then used to remove the lamellar disk that is subsequently inspected for thickness and diameter. After the posterior disk has been removed, 10-0 nylon, interrupted, sutures are placed in the corneal wound to help maintain the anterior chamber while allowing a 3.0-mm opening. Using an irrigation/aspiration handpiece inserted through this opening, meticulous aspiration of all of the Healon viscoelastic is completed. Thereafter, the chamber is deepened and maintained using balanced saline solution (BSS) (Alcon laboratories, Dallax, TX.) and attention is turned to preparing the donor tissue.

It is also worth noting that nowhere in the procedure should Viscoat or other dispersive viscoelastic materials be used. The real concern is that complete removal of dispersive viscoelastic agents is very difficult and that any remaining viscoelastic in the anterior chamber, prior to inserting the donor disk, can adhere to the interface between the donor and the recipient cornea and result in non-adherence and subsequent dislocation of the graft. Healon or cohesive viscoelastics on the other hand are easily removed from the anterior chamber with careful and thorough irrigation and aspiration and have not contributed to any dislocations in the largest prospective study of DLEK.[11,12] The use of cohesive viscoelastic has in fact simplified many of the steps in all forms of EK surgery.[11,12,30,31]

PREPARATION OF THE DONOR CORNEA

We currently use donor tissue that has been precut with an automated microkeratome by a technician at the Lions Eye Bank of Oregon (Portland, OR). We have found that results have been comparable with surgeon-prepared tissue.[39] If a surgeon cuts the donor tissue himself, an artificial anterior chamber system such as the Moria ALTK artificial anterior chamber equipped with a microkeratome (Moria/Microtech Inc., Doylestown, PA) can be used to prepare the donor lamellar graft. The chamber is initially primed by injecting Optisol-GS (Chiron Vision, Irvine, CA) until a meniscus is

formed on the post. The standard corneal-scleral cap tissue received from an eye bank is coated with Healon on the endothelial side and placed onto the post of the artificial anterior chamber endothelial side down. Others have suggested placing the donor cornea epithelial side down onto the artificial anterior chamber to avoid compromising the endothelial cells;[41] this is not common practice in the large centers performing endothelial keratoplasty. The donor tissue is capped into place and more Optisol-GS injected into the artificial anterior chamber until a desired pressure is obtained. Using the sterile marker, a mark is made centrally onto the cornea as well as peripherally at the horizontal meridian.

In the case that manual lamellar dissection is to be performed, random and scattered marks can be made on the surface to be used as reference points to help in visualizing the depth of dissection. A Barron suction recipient trephine (Katena Products, Denville, NJ) of 0.5 mm larger diameter than the desired donor graft size is placed over the donor tissue, suction applied and trephination is carried out at approximately 60% depth. For example, if the original circular surface mark on the recipient cornea was 8.0 mm with the posterior disk of the same size resected, an 8.5-mm trephine should be used for this step. After the trephine is removed, the depth of the cut should be inspected. The crescent blade and stromal dissectors described above are then used to dissect a lamellar pocket at approximately 80% depth through the donor tissue. The lamellar dissection can also be initiated by using the trifaceted diamond knife set at 350 μm in the same fashion as described in preparing the recipient cornea.

In the case that an automated microkeratome (i.e. Moria, CBm, 300 μm) is to be used, the artificial anterior chamber should be pressurized by injecting Optisol. The pressure is verified to be at least 65 mmHg using a Barraquer tonometer (Ocular Instruments, Bellevue, WA). The epithelium is then removed using a Merocel surgical sponge (Medtronics Ophthalmics, Jacksonville, FL). The microkeratome is inserted onto its gear tract without the stopper in order to create a free cap. The corneal surface is then painted with a Merocel sponge soaked in Optisol, and the microkeratome cut made smoothly across the cornea.

After the lamellar cut is made with a microkeratome, the cut cap is inspected for the completion of the cut as well as for thickness. Its diameter is also measured to ensure that it is at least 1.0 mm larger than the planned graft size and thus allow for a 0.5-mm margin for error in centration of the punch (i.e. for an 8.0-mm graft, the cap should ideally be at least 9.0 mm in diameter). If the cap is not adequate in size, the surgeon can manually extend the lamellar dissection beyond the outer edge of the cut stroma using stromal dissectors. The circular outer edge of the exposed stromal bed of the donor cornea is accentuated with small dotted marks; this allows for better centration of the trephine in a later step. The stromal bed is dried using Merocel sponges, and the free cap replaced in the correct orientation using the horizontal mark as a guide. In the case where manual dissection of the donor graft is performed, the dissection should extend as far as the metal cap of the artificial anterior chamber that once more ensures a large enough margin of error for unplanned decentration.

The pedestal of the anterior chamber is slowly lowered while paying close attention to the contour of the cornea; to avoid trauma to the endothelial cells, the natural contour of the cornea must be maintained during this step of the surgery by gently injecting Optisol into the artificial anterior chamber as the pedestal is being lowered and the chamber depressurized. Once there is adequate separation between the pedestal and the metal cap, the edges of the tissue need to be freed from the artificial anterior chamber's metal cap with gentle nudging using the tip of closed forceps. Freeing of the cornea from the artificial anterior chamber is verified by ensuring no movement of the corneal-scleral tissue while the metal cap is rotated and then removed. The tissue is then gently and slowly removed from the pedestal allowing the cohesive Healon to fall away in one mass. Any residual Healon on the endothelial side of the donor cornea is carefully and gently washed off using Optisol. If Eyebank "precut" tissue is used, the donor cornea is placed endothelial-side down onto a sterile, lint-free surface vaulted on its scleral rim. The peripheral gutter of the microkeratome prepared cap is then accentuated using a sterile marking pen to aid in centering the trephination. The tissue is then placed endothelial side up onto a standard punch trephine block and a same size donor button is punched making sure to center the trephination using the earlier marks made on the donor cornea as a reference. A small linear ribbon of Healon is then injected onto the horizontal meridian of the donor tissue. Thereafter the tissue is folded, with the endothelial surface on the inside, into an asymmetric 'taco' shape being vigilant not to damage the endothelium—the fold should be asymmetric with the anterior lip of the folded donor button 40% of the full diameter and the posterior lip 60%.

DONOR GRAFT INSERTION AND ATTACHMENT

Any sutures previously placed in the 5.0-mm tunneled wound should be removed. The folded donor tissue is grasped using specialized forceps (i.e. Charlie insertion forceps) that are non-coopting to avoid crushing the tissue centrally. The tissue is then inserted into the anterior chamber with the 60% side of the 'taco' facing up. The insertion is accomplished in one swift move, placing the distal tip of the Charlie forceps all the way across the anterior chamber and with unremitting surveillance of the unfolding of the graft. It is not unusual for the anterior chamber to partially collapse as the forceps exit the wound. If this occurs, BSS should be injected through the paracentesis ports to deepen the chamber. In order to normalize the chamber depth, the scleral wound may need to be closed using interrupted 10-0 nylon sutures. At this juncture, the tissue typically opens partially with the 60% stromal side of the 'taco' already adhering to the recipient bed and the remaining 40% unfolding perpendicular to the iris plane. An air bubble can then be injected into the anterior chamber, between the two sides of the unfolding 'taco,' to aid in the opening and the self-adhesion of the donor button. Final positioning of the donor disk is done with a reverse Sinskey hook or equivalent instrument if necessary. The reverse Sinskey hook is inserted into the anterior chamber through one of the side-ports furthest away from the direction toward which the graft needs to be shifted. The hook is passed across the midline and engaged in the periphery of the graft while gently pushing the graft into position trying to avoid causing striae. This is more easily done if the anterior chamber is only partially filled with air as a complete air bubble hinders mobility of the graft. When the graft is positioned in the desired location, the anterior chamber is completely filled with a large air bubble and any interface fluid is swept out using a Cindy sweeper (Bausch & Lomb, St Louis, MO) or similar instrument of surgeon's choice to indent the surface cornea and sweep from centrally to peripherally in all quadrants. Using the reverse Sinskey hook or a similar instrument, the edges of the donor graft

are tucked under the peripheral flap of the recipient's uncut outer posterior corneal edge. This is done by gently pushing back the recipient posterior corneal lip and allowing the donor graft edge to fall into the gap created by the lamellar plane of the recipient cornea which extends beyond the cut circular diameter.

CONCLUSION OF THE PROCEDURE

After the wound is fully closed, knots buried, and conjunctiva is closed, the air bubble is fully removed and replaced with BSS. It is believed that when the air bubble is replaced by BSS, the natural endothelial pump function of the donor disk allows for adherence to the stromal bed. A collagen shield soaked in cefazolin, moxifloxacin, and dexamethasone is placed over the eye. Detailed description of the procedure can be found in original papers by Terry et al.[9,11,27]

SUMMARY

Over the last decade, the techniques used in endothelial keratoplasty have improved and evolved with many modifications simplifying and advancing EK surgery to be more widely accepted and utilized. This evolution has led to DSEK/DSAEK in which the easier approach to preparing the recipient cornea has helped catapult this technique to the forefront of EK surgery. However, DLEK/PLK remain excellent options for the patients who are at high risk for complications of DSEK/DSAEK surgery. With this in mind, it is important for the corneal surgeon treating patients with endothelial keratopathy to know and maintain the skills needed in performing DLEK/PLK and more importantly recognize the circumstances in which it is the preferred procedure in treating endothelial keratopathy.

66 Descemet's stripping with endothelial keratoplasty (DSEK)

Marianne O. Price, Francis W. Price

INTRODUCTION

Descemet's stripping with endothelial keratoplasty (DSEK) has been one of the most important breakthroughs in transplant surgery in the last 30 years. Earlier iterations of endothelial keratoplasty, including Melles original posterior lamellar keratoplasty (PLK) technique and the closely related deep lamellar endothelial keratoplasty (DLEK) technique, simply did not provide as rapid visual recovery and were so technically difficult that few corneal surgeons were willing to perform them.[1] DSEK provides so many advantages compared with penetrating keratoplasty (PK) that the authors believe that all corneal surgeons should be performing it and patients are even demanding it.[1,2]

The most challenging aspects of the earlier PLK/DLEK technique were the manual recipient lamellar dissection and the excision of the posterior recipient stromal button using small curved scissors and trephine.[3] Melles greatly simplified his earlier procedure by describing a Descemetorhexis technique that merely involved stripping Descemet's membrane and dysfunctional endothelium from the host cornea.[4] The basic DSEK procedure can be further facilitated by employing a microkeratome to perform the donor lamellar dissection, a variation known as Descemet's stripping with automated endothelial keratoplasty (DSAEK).[2,5,6] Several eye banks now provide microkeratome pre-dissected donor tissue for DSEK.

SURGICAL TECHNIQUE

Surgical instruments to facilitate DSEK are available from multiple sources, including DORC International (Zuidland, the Netherlands), Moria (France), and Bausch & Lomb Surgical (St Louis, MO). Beginning the case with preparation of the donor tissue allows the surgeon to make sure the donor tissue is suitable for transplantation before opening the patient's eye.

DONOR TISSUE PREPARATION

Lamellar dissection of the donor tissue can be performed manually or with a microkeratome, or the donor tissue can be pre-dissected by the eye bank. In the USA it is difficult to obtain donor tissue less than 48 h from death to use because of required testing, so whole globes can seldom be used. Corneal/scleral rims should have a diameter of 16–17 mm to ensure firm and air-tight fixation on an artificial anterior chamber during dissection. Artificial anterior chambers are available from Bausch & Lomb, Moria, and Katena.

The donor tissue should be examined carefully to ensure there are no divots or cuts through the peripheral cornea to the limbus that might allow the tissue to slip or depressurize during the dissection. After mounting the donor tissue on an artificial anterior chamber, the center of the cornea should be marked with gentian violet to facilitate centering the tissue on the trephine block after the dissection.

Estimating the dissection depth can be a challenge with manual dissections. Melles found that filling the anterior chamber with air creates a reflection that helps the surgeon gauge the dissection depth.[7] Some surgeons utilize this technique, while others prefer to use tissue storage solution, balanced salt solution, or viscoelastic in the artificial anterior chamber to help protect the corneal endothelium.[8] However, use of anything other than air makes it harder to judge the dissection depth, because the depth can only be estimated by direct visualization of the anterior tissue, without direct feedback on the amount of residual tissue under the dissecting blade. If viscoelastic is used, it should be thoroughly removed prior to autoclaving the artificial anterior chamber, because byproducts can form that could be transferred to the next donor cornea and cause toxic anterior segment syndrome in subsequent cases.

Manual dissections can be performed in several ways. A small one-third depth incision can be made in the peripheral cornea and a series of curved dissecting blades of increasing length can be used to extend the dissection plane across the cornea (Fig. 66.1).

Some surgeons place a Barron suction recipient trephine over the donor tissue for trephination to approximately 60% depth and then extend a dissection plane across the tissue. With either method the surgeon should aim for approximately 80% dissection depth. If the posterior donor button is too thin it will be difficult to manipulate and more prone to develop wrinkles that can be difficult to remove when applanated against the recipient cornea. Also, extremely deep donor dissections are more likely to damage the endothelium.

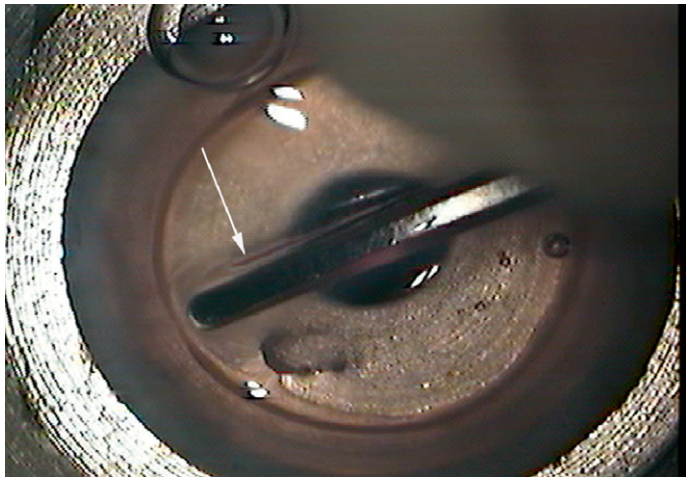

Figure 66.1. Manual lamellar dissection of a donor corneal/scleral rim mounted on an artificial anterior chamber. A series of three curved blades of increasing length are used to extend the dissection plane across the donor cornea. Air in the anterior chamber creates a reflection (arrow) that helps indicate the depth of the dissection.

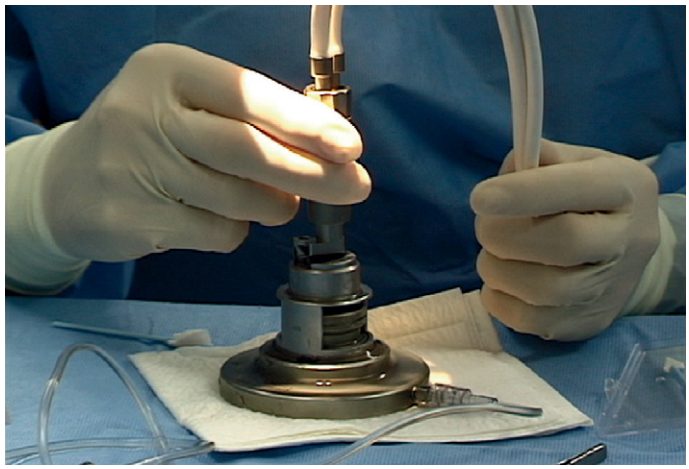

Figure 66.2. Microkeratome dissection of a donor corneal/scleral rim mounted on an artificial anterior chamber.

With microkeratome dissection (Fig. 66.2), the surgeon should aim for posterior donor button thickness of 0.10–0.18 mm. Depth plates (head sizes) are available that provide nominal dissection depths of 250, 300, 350, and 400 µm. To guide selection of an appropriate dissection depth, the donor thickness can be measured using ultrasonic pachymetry if the artificial anterior chamber is pressurized with viscoelastic, balanced salt solution, or tissue storage solution. Donor tissue thicknesses vary substantially, but typically range from 0.45 to 0.70 mm after epithelial removal for donor corneas stored in tissue storage solution, as provided by USA eye banks. Posterior thicknesses of less than 0.10 mm after dissection should be avoided because vital staining indicates that the endothelium can be damaged by extremely deep dissections (Craig Fowler, personal communication).

After dissection, the donor tissue is carefully removed from the artificial anterior chamber and placed endothelial side up on a standard punch trephine block, where it is punched to a diameter that has been selected based on the width of the recipient's cornea. The donor tissue can be covered with tissue storage solution while the recipient's eye is being prepared.

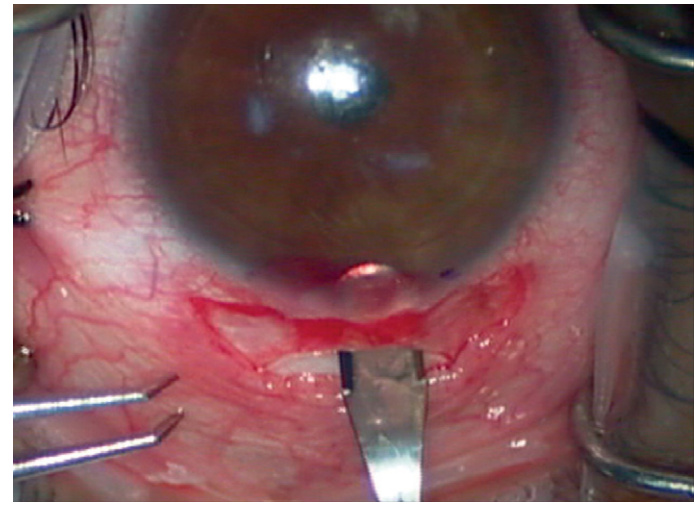

Figure 66.3. Temporal scleral tunnel incision in the recipient eye.

RECIPIENT PREPARATION

DSEK is often performed with topical anesthesia and monitored intravenous sedation. Topical anesthesia may consist of proparacaine hydrochloride eye drops and application of pledgets soaked in 2% xylocaine to the conjunctiva at the site where the incision will be made. However, local anesthesia (retrobulbar or peribulbar block) is generally preferable for the surgeon's first several cases. With local anesthesia it is important to apply a pressure device, such as a Honan balloon (the Lebanon Corporation, Lebanon, IN), to soften the eye prior to surgery, because back pressure from periorbital swelling can lead to forceful shallowing of the anterior chamber while the donor tissue is being inserted. In some cases backpressure can even push the donor tissue back out of the eye.

With the patient in a supine position, the horizontal corneal diameter of the recipient eye is measured with calipers to guide the selection of an appropriate donor tissue diameter. Placement of traction sutures can help stabilize the eye during surgery.

A 5-mm temporal clear corneal or scleral tunnel incision is made in the recipient eye (Fig. 66.3). A properly constructed scleral tunnel incision can form a watertight seal, allowing the surgery to be performed without the use of any sutures, and it provides an extra margin of safety because it can be closed quickly if the patient coughs or develops a suprachoroidal hemorrhage during the procedure. Temporal placement of the incision facilitates donor tissue insertion because the corneal diameter is longest in the horizontal direction. In addition, temporal placement preserves the superior conjunctiva for future glaucoma surgery, should that ever become necessary.

If the recipient epithelium is hazy or scarred it can be removed, and this will usually improve the view into the eye. The trephine used to punch the donor button can also be used to lightly mark the surface of the recipient cornea to delineate the area for Descemet's membrane removal. Descemet's membrane is then scored in a circular pattern along the perimeter of the area to be removed, using a modified Sinskey hook (Fig. 66.4). The recipient endothelium should only be stripped from the area that will be covered by donor tissue, because any stripped areas not covered with donor tissue will become edematous. To prevent this from happening, some surgeons score an area somewhat smaller than the planned donor diameter. Trypan blue can be introduced into the anterior

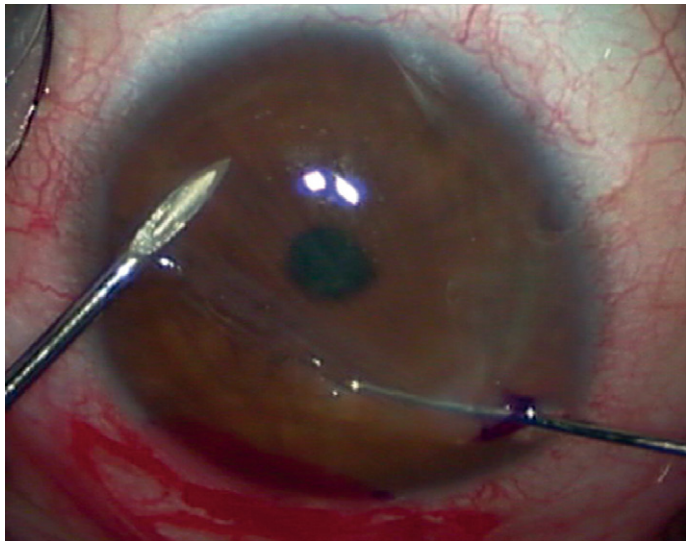

Figure 66.4. Scoring of Descemet's membrane, with continuous infusion of balanced salt solution to maintain the anterior chamber.

chamber to improve membrane visualization during the stripping procedure. It preferentially stains exposed membrane.

The far edge of Descemet's membrane is grasped with a stripping instrument (Fig. 66.5, *A*) or infusion/aspiration tip (Fig. 66.5, *B*) and carefully peeled off and removed from the eye. The membrane can be spread on the eye to determine whether removal was complete. Sometimes the membrane fragments must be removed in pieces. During the scoring and stripping steps, the anterior chamber can remain formed by injecting viscoelastic or by intermittent or continuous infusion of balanced salt solution or air. If viscoelastic is used, it must all be completely removed before inserting the donor button because residual viscoelastic will impair donor adherence.

DONOR IMPLANTATION

A small drop of cohesive viscoelastic is placed in the center of the donor button on the endothelial side, and the posterior tissue is gently lifted away from the anterior tissue. The posterior button can be folded over on itself like a taco, with the endothelial side inward (Fig. 66.6). Most surgeons overfold the tissue with approximately 60% on the anterior side and 40% posterior. Although this exposes some peripheral endothelium to potential damage during insertion, it makes it easier for the posterior side to sweep across and unfold in the correct orientation after placement in the eye. This is particularly important when the anterior chamber is relatively shallow. The folded donor taco is gently grasped with forceps and inserted into the recipient eye (Fig. 66.7). Several companies make forceps that only compress the tissue at the tip, which should help minimize endothelial damage.

Another way to insert the donor tissue is to pull the folded tissue into the eye from an incision 180° away using a suture.[9] The tissue can also be laid endothelial side upward on a funnel glide which curls the tissue into a cylindrical shape as it is pulled into the eye with a small forceps.[10] An advantage of the latter two methods is that the tissue automatically unfolds stromal side up as it enters the anterior chamber. After the donor tissue is inserted, the anterior chamber is inflated by injecting air or balanced salt solution, which allows the posterior portion of the donor taco to unfold (Fig. 66.8). The anterior chamber is then completely filled with air to firmly press the donor tissue up against the recipient cornea.

While the anterior chamber is filled with air, the surface of the recipient cornea is massaged to help center the donor button and move any entrapped fluid out of the donor–recipient interface (Fig. 66.9). A variety of instruments have been utilized for this maneuver, but use of a Lindstrom LASIK roller is recommended to help minimize damage to the recipient epithelium.[6] Four small incisions can be made in the recipient cornea down to the graft interface to help drain any residual fluid trapped between the donor and recipient (Fig. 66.10).[6] Most surgeons remove some of the air after 8–10 min to prevent pupillary block,[6] although some leave the anterior chamber completely filled for 1–2 h.[5] A residual air bubble approximately the same diameter as the donor button can then be left in the eye. At the end of surgery, antibiotics, steroids, and nonsteroidal anti-inflammatory (NSAID) medications are applied to the treated eye. Some surgeons have the patient lie face-up in the recovery area for 30–60 min after the procedure and/or instruct them to lie

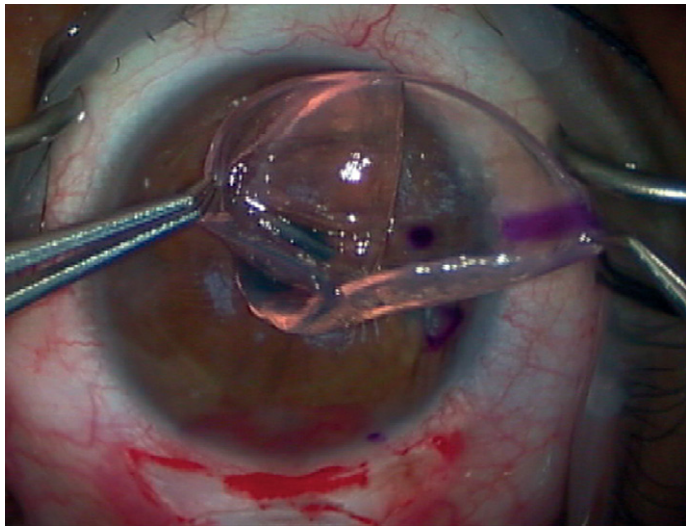

Figure 66.6. Separation of the posterior donor tissue from the anterior tissue, and folding it over a drop of viscoelastic into a taco configuration.

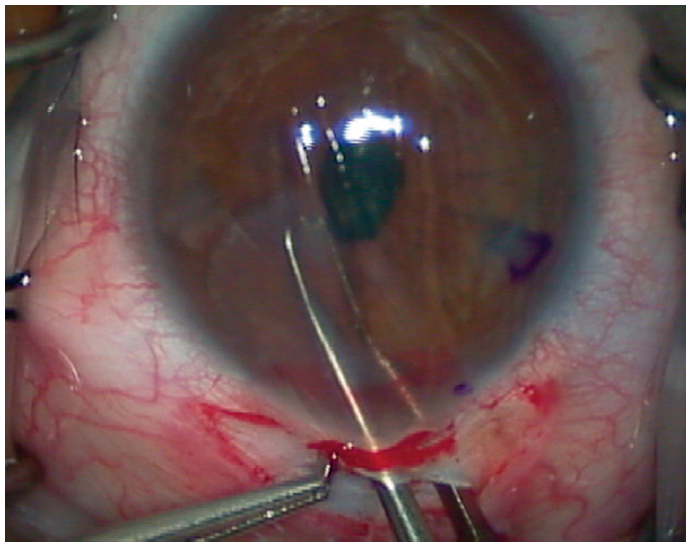

Figure 66.7. Insertion of the folded donor tissue into the recipient eye using forceps that only compress the tissue at the tip.

face-up as much as possible for the first postoperative day so that the residual air bubble can continue to press the donor tissue against the recipient cornea.

MODIFIED TECHNIQUE FOR ANIRIDIC APHAKIC EYES

Eyes lacking lens and iris tissue pose a special challenge because there is no barrier to prevent donor or recipient tissue from falling back onto the retina. If no guttata are present, the recipient Descemet's membrane and endothelium can simply be left in place, rather than run the risk of dropping any pieces back into the posterior segment.[11] Also, the donor tissue should be secured at all times. During donor insertion, the trailing end of the donor taco can be held in the scleral tunnel incision while an anchor suture is placed in the anterior portion of the donor taco, to secure it to the recipient cornea (Fig. 66.11).[11] The anchor suture can be removed after the eye is totally filled with air. There is no need to remove

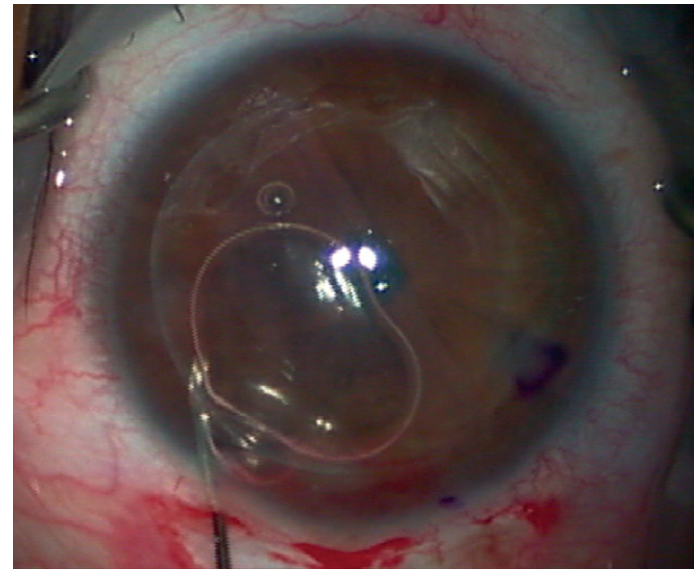

Figure 66.8. Injecting air into the anterior chamber to unfold the donor taco and press it firmly against the recipient cornea.

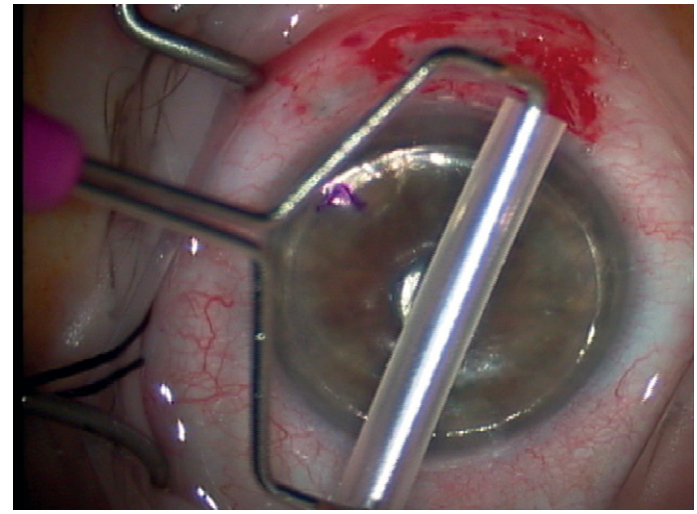

Figure 66.9. Massaging the surface of the recipient cornea with a Lindstrom roller to help center the donor tissue and remove fluid from the donor–recipient interface, with the anterior chamber completely filled with air.

some of the air to prevent pupillary block in eyes with congenital or traumatic aniridia.

MODIFIED TECHNIQUE TO RESTORE CLARITY TO FAILED PENETRATING GRAFTS

DSEK can restore clarity to a penetrating graft that has failed from endothelial decompensation and it will usually provide an easier postoperative course for the patient compared with a PK regraft.[12] In a healed PK wound, the principal areas of strength are the scarring that occurs at Bowman's and at Descemet's membrane. To preserve as much of the wound strength as possible, Descemet's stripping can be omitted, if the surgeon is sure there are no guttata or other abnormalities present that might impair postoperative visual acuity. Otherwise, the procedure is similar to performing DSEK on a virgin eye.

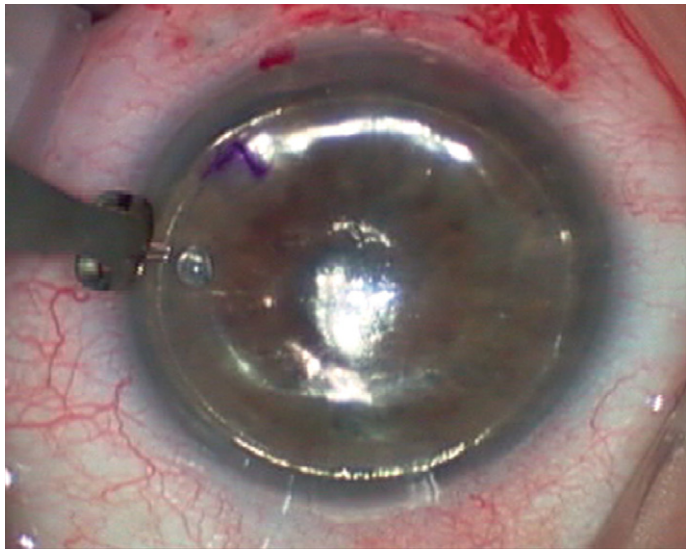

Figure 66.10. Making small peripheral corneal incisions to release any residual fluid entrapped at the graft–recipient interface, while the anterior chamber is completely filled with air.

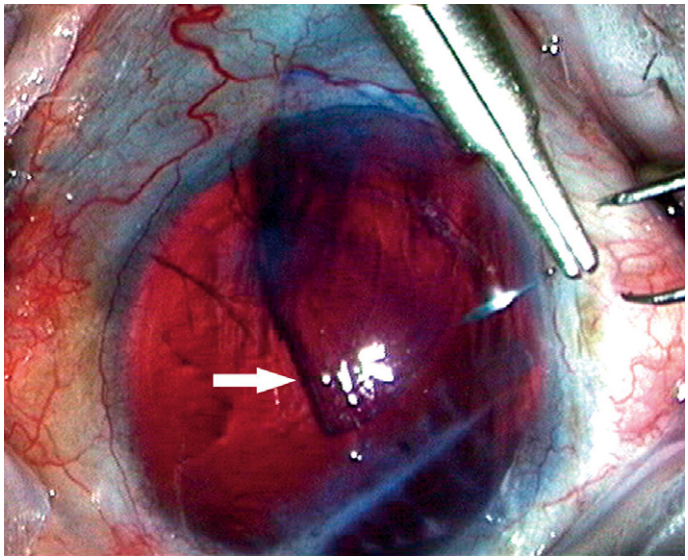

Figure 66.11. Securing the peripheral anterior edge of the folded donor tissue to the recipient cornea with a temporary anchor suture in an eye that was aniridic and aphakic following traumatic injury.

COMBINED PROCEDURES

Other intraocular surgeries, such as phacoemulsification, intraocular lens (IOL) implantation, IOL exchange, secondary IOL implantation, pars plana vitrectomy, or anterior vitrectomy can be combined with DSEK.[6] However, it is often preferable to perform these other procedures beforehand as a separate procedure. In particular, performing cataract extraction and IOL implantation prior to DSEK helps deepen the anterior chamber and facilitates unfolding the donor taco. With standard PK, the opposite sequence is usually preferable—cataract extraction and IOL implantation are typically delayed until after the final refractive outcome has been determined because refractive outcomes are so unpredictable after PK. DSEK has the advantage of being more refractive-neutral.[1]

WHAT TO EXPECT AFTER DSEK/DSAEK?

Patients typically instill topical antibiotics for a week and topical corticosteroids four times daily for several months. Although corticosteroids delay wound healing, this is of minimal concern with the small DSEK incision, so many surgeons maintain pseudophakic DSEK eyes on once or twice daily dosing with topical corticosteroids indefinitely to prevent graft rejection, unless the patient is a steroid-responder.

The most frequent postoperative complication with DSEK/DSAEK is that sometimes the donor tissue detaches in the early postoperative period (usually 1 day to 1 week after surgery). If this happens, air can be injected into the anterior chamber to again firmly press the donor tissue against the recipient cornea.[6] A complete air fill is often maintained for 1–2 h when the donor tissue needs to be reattached.

DSEK/DSAEK requires much less manipulation of the recipient cornea and anterior chamber, compared with the earlier PLK/DLEK procedure, and this helps minimize intraoperative and postoperative complications. For example, we found that PLK/DLEK could cause cataracts when performed in phakic eyes.[2,13] Also, the two hand-dissections required in PLK/DLEK provide more opportunity for graft–recipient interface haze or other problems to interfere with visual recovery.[14–16] Wrinkles in the graft can also be a problem and are potentially more likely with PLK/DLEK, because the graft tissue can become compressed if the hand-cut recipient bed is somewhat undersized or the graft is not well-centered in the bed.[17] Finally, perforation of the recipient cornea sometimes occurs during the PLK/DLEK lamellar dissection, requiring intraoperative conversion to PK.[8] This is not an issue with DSEK/DSAEK because the recipient cornea is not dissected.

A major advantage of the DSEK/DSAEK technique is that it does not significantly alter corneal topography and is essentially a refractive neutral transplant procedure. For example, in a series of 100 consecutive DSEK cases and a similar series of 100 consecutive DSAEK procedures, mean refractive cylinder was 1.5 D both before and 6 months after surgery.[2] Mean spherical equivalent refraction also changed less than 0.5 D after DSEK/DSAEK.[2] In contrast, mean refractive cylinder of 4 D is common after PK,[18,19] and 10–15% of PK patients usually require hard contact lenses for best vision. Unfortunately, hard lenses can be difficult to manage, especially for older patients.[20] Subsequent surgical interventions, such as relaxing incisions to correct astigmatic errors, are frequently performed after PK,[21,22] but rarely needed after DSEK or DSAEK.

Visual recovery is relatively rapid and predictable after EK compared with PK, and seems to be faster with DSAEK compared with DLEK or DSEK, probably because it produces the smoothest donor and recipient interfaces. For example, one month after surgery, mean visual acuity was approximately 1 line better in a series of 100 DSAEK eyes compared with a series of 100 consecutive DSEK eyes.[2] By 3 months after surgery, mean visual acuity was equivalent for the DSEK and DSAEK procedures.[2] By 6 months after surgery, 69–77% of DSAEK eyes achieved 20/40 vision in two case series.[2,5] By comparison, visual recovery after DLEK is somewhat slower, taking 12–18 months.[23] In a series of 100 consecutive DLEK cases, 49% of the eyes achieved 20/40 vision within 6 months of surgery.[8]

The average patient age is around 70 years in most DSAEK, DSEK, and DLEK series, so retinal problems limit some patients' visual

potential.[2,5,8] When eyes with documented preoperative retinal or amblyopia problems were excluded from the analysis, 80% of DSAEK eyes achieved 20/40 visual acuity within 6 months of surgery and none had vision worse than 20/80.[2] In contrast, after PK, anisometropia can prevent 10–20% of the treated eyes from achieving functional vision.[21] Younger DSEK/DSAEK recipients were significantly more likely to achieve better postoperative visual acuity than older recipients even after eyes with documented retinal problems were excluded ($p = 0.001$).[2] Interestingly, although DSEK/DSAEK increases central corneal thickness because some donor stroma is implanted without removal of any recipient stroma, corneal thickness does not have a statistically significant correlation with postoperative Snellen acuity as measured using a Snellen chart in a darkened room.[2]

DSEK and DSAEK provide significant advantages for the patient compared with PK. Perhaps the most significant advantage of an EK procedure is that it reduces the risk of losing the eye. Whereas the eye is completely open for part of the PK procedure, EK can be performed through a small scleral tunnel incision, which can be easily closed should the patient cough or develop a suprachoroidal hemorrhage. Also, a healed PK eye never fully regains the strength of a virgin eye and remains at increased risk of loss from traumatic injury for the remainder of the patient's life.[24,25] In contrast, EK maintains most of the structural integrity of the eye.

EK should also minimize if not eliminate the risk that ocular surface complications will interfere with recovery. In a series of over 1800 PK surgeries, ocular surface complications were responsible for 25% of the graft failures in the first 5 years after surgery.[26] PK severs the corneal nerves leaving the central cornea neurotrophic and susceptible to dryness, epithelial defects, and infection. PK also requires prolonged presence of corneal sutures, which can provide a path for infection as they loosen. In contrast, EK preserves most central corneal innervation and does not require any sutures.[6] These features make EK particularly well suited for regions of the world where sanitation challenges increase the risk of infection and where transportation challenges make it difficult for patients to return quickly if they develop a loose suture.

The risk of graft rejection also seems to be lower with EK procedures compared with PK and this may be related to the fact that EK patients are often maintained indefinitely on low dose topical steroids.[27] Whereas PK patients are often taken off topical steroids to help accelerate wound healing and prevent cataract formation, rapid wound healing is less of a concern with EK because the incision is relatively small. Also, most EK patients are pseudophakic, so that eliminates the concern that long-term topical steroids can induce cataract formation.

DSEK/DSAEK has improved the risk/benefit ratio of corneal transplants so substantially that increasing numbers of potential candidates are now choosing to have a transplant. When PK was the only option, some patients who had experienced the lengthy PK recovery period in one eye never wanted to have it done in their second eye. Also, many patients preferred to postpone a PK until after retirement because the lengthy recovery would severely impair their ability to work. In contrast, in the authors' experience, many DSAEK patients request to have their second eye treated within a month of having DSAEK performed on the first eye, and many Fuchs' patients are choosing to have DSAEK performed before the glare and visual impairment become so disabling. In fact, many Fuchs' patients are choosing to have DSAEK one or even two decades sooner than they would have had PK, and this is increasing the demand for donor corneas.

HOW CAN THE TECHNIQUE BE IMPROVED?

Endothelial keratoplasty techniques continue to evolve, with efforts being directed toward achieving a smaller host incision, smoother donor interface, and ex vivo generation of corneal endothelium.

Various methods of inserting the donor tissue through a smaller incision are being evaluated. The effect of incisions smaller than 5 mm on long-term endothelial cell survival remains to be determined.

Regardless of the method used to perform the donor lamellar dissection, the donor interface is not as smooth as the recipient stromal surface exposed after stripping Descemet's membrane. Work is underway to optimize femtosecond laser parameters to produce smoother posterior lamellar dissections.[28,29] The precision and flexibility of the femtosecond laser should potentially allow more accurate control of donor thickness and provide the ability to match the contour of the donor dissection to the posterior corneal curvature of the recipient. An alternative approach to achieve a smoother donor interface is to remove donor Descemet's membrane with attached endothelium for implantation into the recipient eye.[30] The principal challenge is that the membrane and single cell layer are fragile and can be easily torn or damaged. Also, the thin membrane can develop intractable wrinkles when pressed against the recipient cornea. Innovative techniques and insertion instruments are being developed to address these challenges.[31–33]

Ex vivo generation of corneal endothelium could bypass the need for better donor dissection techniques and allow more patients to benefit from a transplant despite the chronic worldwide shortage of donor corneas.[34,35] Cultured endothelium has been successfully derived from endothelial cells harvested from donor corneas. Eventually, it may be possible to generate autologous corneal endothelium from recipient adult stem cells. Autologous endothelium would eliminate graft rejection concerns and the need for prolonged corticosteroid therapy to prevent rejection.

CONCLUSION

DSEK/DSAEK has significantly increased the benefits and reduced the risks of transplantation for patients with endothelial dysfunction. The relatively rapid and predictable visual recovery and minimal postoperative restrictions are increasing the demand for corneal transplants.[36] Our next challenge is to find ways to increase the supply of high-quality donor tissue and accelerate development of ex vivo derived sources to meet this need.

67 Microkeratome-assisted posterior lamellar keratoplasty

Suy Anne R. Martins, Guillermo E. Noguera, Ashley Behrens

Corneal endothelial cell failure is one of the leading causes of corneal visual loss in the USA and other industrialized countries of the world.[1–3] This fact may be of importance in the selection of the procedure to be performed, in developed and developing countries, to correct the endothelial cell failure.

Since the 1930s, penetrating keratoplasty (PK) has been the procedure of choice to manage corneal disorders. Despite the advantages of a lamellar procedure—i.e. less risk of intraocular complications and allograft rejection—penetrating keratoplasty has proved to be a technique preferred by most surgeons around the world, and for many years has been the only treatment for visual impairment resulting from corneal endothelial cell decompensation. Endothelial cell loss, pleomorphism, and polymegethism may progress following PK and result in late graft corneal failure.[4] Lamellar keratoplasty (LK) may avoid many of these problems, but it is limited by delayed epithelialization, persistent epithelial defects, difficult surgical technique, and graft–host interface haze and vascularization.[5] However, in the 1960s, Malbran described the 'peeling-off' technique, in which the recipient cornea of patients with keratoconus was removed by applying traction to the partially dissected cornea overlying the cone.[6–8] Other authors describe a surgical technique for LK that consists of a partial trephination of the anterior corneal stroma, and a single plane dissection of the recipient stroma. It is often demanding to meticulously dissect the recipient stroma and by performing a PK, one is able to avoid the challenges of a lamellar dissection.[9]

The concept of deep LK is not new. Previous published reports have confirmed the advantages and limitations of LK.[5,10–16] and it has been the focus of intense study over the past decade, with an acceleration of technique modifications over the past 4 years. Since at least 1998, there have been two separate approaches to deep LK. Several surgeons resurrected a technique described long ago by Polack and others,[17] whereby an anterior flap was created either manually or with a microkeratome, the flap was retracted, and the posterior recipient stroma was trephined out. The tissue was replaced with a donor posterior lamellar button and the overlying flap was sutured into place.[18–21] This approach is attractive to the corneal surgeon because it required only familiar surgical skills and promised a smooth stromal interface by means of a microkeratome cut.

PENETRATING KERATOPLASTY

Penetrating keratoplasty (PK) is the most common and successful tissue transplantation worldwide. For over 100 years, it has been the standard of care for certain corneal diseases that cause visual impairment.[22,23] The total number of cases of corneal transplants with reported recipient diagnoses in the USA in the year 2000 was 31 532. Likewise, the leading indications for PK have changed over the years. Before the mid-1970s, keratoconus and regrafts were the primary indications for corneal transplants,[24,25] whereas bullous keratopathy has become the leading cause for PK, with the advent of cataract extraction and placement of intraocular lenses (IOLs).[26–31] Fuchs' dystrophy, keratoconus, corneal scarring, failed graft, and aphakic bullous keratopathy followed pseudophakic bullous keratopathy as the other major indications for PK.[31] Remarkable progress has been achieved in corneal surgery during the last century that include surgical techniques, tissue storage, and immunosuppression.[1,32]

PK has become a safe and effective procedure but it is sometimes complicated by high and/or irregular astigmatism,[1,33,34] insufficient wound healing,[34,35] prolonged recovery time, and tissue rejection.[36,37] Ing et al[4] showed a decline in endothelial cell count after PK in a large-scale study, from mean cell counts of 2467 cells/mm^2 at 2 months, to 1958 cells/mm^2 at 1 year and 960 cells/mm^2 at 10 years. This endothelial cell data is comparable to that found in other studies.[1,4,38–41] Furthermore, risk of suture-related problems,[42] and other interface complications[43] are associated with PK.

The major clinical complication between 10 and 15 years after keratoplasty is graft failure, predominantly caused by late endothelial failure.[44] Graft failure after PK can be defined as an irreversible loss of graft clarity due to endothelial cell failure.[45] By 2000–2001, Kang et al reported that failed grafts were the leading indication for PK.[31] This trend has also been observed in other centers and Sugar reported that failed grafts surpassed other indications for PK

at both of their institutions for the last 100 cases that they each performed in the 1990s.[46]

Each year, the Eye Bank Association of America (EBAA) reports statistics on corneal transplant activity in the USA. Statistics from the past decade indicate that there were fewer corneal transplants performed in the USA in 2000 (33 260) than in 1990 (36 037).[47] The decrease in the number of corneal transplants performed in the USA today, compared with 10 years ago, invites the question of what factors are affecting the demand. Has the need (or clinical indications) for corneal transplantation decreased, e.g. less traumatic techniques of phacoemulsification with a resulting decline in the prevalence of pseudophakic corneal edema or a transition to posterior lamellar keratoplasty techniques?

CLASSIFICATION OF CORNEAL TRANSPLANTATION ACCORDING TO THE REPLACED STRUCTURE

The popularity of lamellar procedures has been increasing in recent years as highlighted in the preceding chapters. One of the factors is the development of better instrumentation for the surgery: easier to use and safer microkeratomes, and the introduction of femtosecond lasers for lamellar dissection. In parallel to these advances, new variants of corneal transplantation have been proposed, several lamellar keratoplasty surgical techniques have been developed, modified or improved, including microkeratome-assisted anterior and posterior lamellar keratoplasty,[20,21,48,49] anterior lamellar keratoplasty using air-dissection or visco-dissection,[14,16] sutureless posterior lamellar keratoplasty,[48,50,51] LASIK for post-keratoplasty astigmatism,[52] and excimer laser-assisted keratophakia for keratoconus or to manage complications after LASIK.[53]

We summarize below some popular types of lamellar corneal transplantation according to the replaced structure:

1. Anterior lamellar keratoplasty (ALK): In this procedure the superficial corneal layers are removed leaving intermediate and posterior stroma intact.[12,49–53]
2. Deep lamellar keratoplasty (DLK): Resection of the corneal stroma, leaving either minimal or no residual posterior stroma—only Descemet's membrane.[10,11,14–16]
3. Posterior lamellar keratoplasty (PLK): Consists of removing posterior stroma, Descemet's membrane, and the damaged endothelial cell layer leaving superficial corneal layers including anterior stroma intact.

In PLK a graft comprising posterior stroma, Descemet's membrane and a healthy endothelial cell layer of suitable dimensions is placed in the recipient bed of the cornea. Several approaches have been reported to achieve this form of transplantation. Deep lamellar endothelial keratoplasty (DLEK), and a variation of this technique called Descemet's stripping endothelial keratoplasty (DSEK) are currently the most popular techniques.[9,13,48,50]

POSTERIOR LAMELLAR KERATOPLASTY (PLK)

The PLK technique for endothelial keratoplasty (EK) was first introduced by Tillet several decades ago.[54] However, starting from this concept, two separate PLK techniques evolved: one which comprises his original open-sky, hinged flap approach and another which changed the approach such that the recipient's anterior chamber is entered from a smaller curvilinear incision. The former is commonly named microkeratome-assisted PLK (MAPLK, also called endokeratoplasty or endothelial lamellar keratoplasty) while the latter is designated deep lamellar endothelial keratoplasty (DLEK).

Recently, PLK has undergone some modifications, and published reports on several small series suggest advantages over standard PK.[55–58] In this surgical procedure there is a selective corneal endothelial cell layer replacement that reduces or eliminates surface incisions or sutures.[55,56] In addition, rejection episodes may be lower.

Lamellar keratoplasty approaches have been successful in the treatment of anterior corneal pathology for over 100 years.[59–61] However, only relatively recently have these lamellar techniques been applied to the replacement of the posterior stroma and the endothelium and gained renewed widespread interest.[4,10,11,13–16,48,50,55–58]

The concept of a scleral-limbal approach to endothelial keratoplasty was first described by Ko et al[57] in 1993. Melles et al brought selective endothelial keratoplasty to fruition with the first human limbal approach in 1998.[62] Melles had the insight to solve the problems associated with corneal sutures in transplantation by substituting intraocular air to support the tissue.[12] This critical breakthrough began the transformation of modern endothelial surgery. The procedure was named posterior lamellar keratoplasty (PLK), and this was a name that was also being used by many surgeons using the 'flap' technique of endothelial replacement surgery.[63]

SCLERAL-POCKET INCISION APPROACH

As outlined in earlier chapters, the initial technique of Melles et al[55] involved a 9-mm superior incision and use of an air bubble for recipient tissue dissections and resections, as well as donor placement and attachment. However, in the absence of viscoelastic use, the PLK procedure was technically difficult to the extreme.[12,62,64–66]

Terry and Ousley established a USA prospective study of endothelial keratoplasty to broaden its scientific validity with a large prospective database.[56] They performed the first USA endothelial keratoplasty in March 2000, using a highly cohesive viscoelastic to stabilize the anterior segment and make the surgery easier. They renamed this procedure as deep lamellar endothelial keratoplasty (DLEK). The essential surgical steps in this procedure have been fully outlined in a preceding chapter.

In 2002, Melles and associates further developed a modified approach for a small-incision PLK technique.[50] They were able to reduce the incision size to 5 mm by folding the tissue before insertion. Their single case report showed proof of concept for a folded graft to clear the cornea, but the resultant endothelial cell count was considerably less than his prior large-incision series. A 5.0-mm scleral tunnel incision was made, and a stromal pocket was dissected across the cornea, just above Descemet's membrane, at a visually controlled depth.[65] Then, trypan blue 0.06% (VisionBlue, DORC International, Zuidland, The Netherlands) was diluted 1:6 with balanced salt solution and injected into the stromal pocket to stain the stromal interface. With an 8.5-mm punch trephine, an indentation was made in the corneal surface epithelium to outline the size of the posterior lamellar disk that was to be excised. Custom-made curved microscissors were used to excise an 8.5-mm diameter recipient posterior lamellar disk. In a whole donor globe, obtained less than 48 h after death, a deep corneal pocket was dissected at 80% of stromal depth.[65] The corneoscleral rim was excised from the globe, and an 8.5-mm diameter posterior lamellar

disk was trephined (endothelium to epithelium). After covering the donor endothelial surface with a viscoelastic material, the posterior lamellar disk was folded with the endothelium at the inside, using a custom-made inserter. After removing all air from the eye, the donor posterior disk was positioned into the recipient anterior chamber. After unfolding the posterior lamellar disk, it was positioned in the recipient posterior opening without suture fixation. The anterior chamber was then completely filled with air, and after 5 min all air was exchanged by balanced salt solution. The disk was found to keep its position by the adherence of the stromal tissue at the donor-to-host interface, and/or the negative stromal pressure created by the donor endothelial pump. Because no sutures are used and the tissue is transplanted through a scleral tunnel incision, the surgically induced astigmatism may be minimized, suture-related complications eliminated, and the risk of wound dehiscence reduced.

However, due to the high level of skills to perform these surgeries, DLEK has been the subject of several investigations and modifications over the past 6 years. Several corneal surgeons have performed large numbers of DLEK procedures and sufficient data is available. On average, best corrected visual acuity (BCVA) is 20/48 at maximum 2-year follow-up.[55,67–69] Melles et al reported that all patients operated on with the initial PLK procedure who did not have concomitant ocular disease had a BCVA of 20/30 or better; and several had 20/20 (Netherlands Institute for Innovative Ocular Surgery, unpublished data). Similarly, these same studies also showed that DLEK yields minimal postoperative astigmatism, on average, of 1.46 D. One study showed an average postoperative spherical equivalent of –0.369 D at 1 year.[55] Postoperative endothelial cell density averages 1790.5 cells/mm^2 at 36 months at a maximum of 3 years postoperatively.[55,67–69] Clearly, DLEK specifically has potential benefits, mostly due to its lack of corneal incisions and suture use.

However, some possible pitfalls are also incurred specifically with DLEK, which largely lie in its steep surgical learning curve. The accuracy (and thus success) of this technique is strongly dependent on the surgeon's abilities, making the procedure complex to reproduce.

More recently, Seitz et al have demonstrated in a laboratory model the feasibility of using the femtosecond laser for DLEK to create both the opening incision as well as the stromal dissection, which may allow a more straightforward surgical procedure.[70] Other authors have also corroborated this with further experimental studies.[71–73] This technique may become popular in the near future with the expansion of the femtosecond laser market for corneal surgery.

MICROKERATOME-ASSISTED PLK (MAPLK)

The advent of new microkeratomes (both manual and automated) has allowed therapeutic lamellar keratoplasty to be readily performed in a reproducible manner. These instruments are predominantly adopted from those available for laser in-situ keratomileusis (LASIK). In addition, artificial anterior chambers have been developed for use with corneoscleral buttons when whole eyes are not available. Therapeutic automated lamellar keratoplasty can be used both for anterior stromal pathology and endothelial dysfunction, but here we will only describe the MAPLK surgical approach.

In MAPLK, a hinged anterior stromal flap of approximately 350 μm (200–450 μm) in thickness is first cut in the host cornea, and the diseased posterior cornea is trephined (the trephine size used depends on the diameter of the flap and hinge width obtained). The donor cornea is prepared using the same microkeratome parameters to cut the anterior corneal disk. The residual posterior stroma and endothelium are trephined to the same size. The donor is transplanted and may be sutured on the recipient bed, although most surgeons (including the authors) do not find it necessary to suture the posterior lamellar button.[48] Finally, the anterior flap is repositioned and sutured.

The creation of a flap by means of a microkeratome to perform a PLK is easier and faster than the manually dissected sclerocorneal approach, and the risk of damaging the endothelial cells may be lower. In short follow-up series, 50% of patients had a BCVA of 20/60 or better (range: 20/30–20/200) at a maximum of 1 year of follow up.[19,74] One study reported a 1 month average spherical equivalent of –1.25 D.[19] At 12 months, Ehlers et al[74] found that the endothelial cell density was in the range of 1200–2300 cells/mm^2. None of these studies reported episodes of graft rejection or wound dehiscence.

However, in the corneal flap technique, a minimal number of sutures are still required to secure the corneal flap and the transplanted corneal disk, which remains a potential drawback. Corneal sutures have been associated with several problems, particularly following PK, indeed, a 5-year retrospective study of 361 grafts (1993–94) reported erosions over the nylon sutures in 10.8% of cases, infiltrates at suture entrance site in 9.4%, and infectious keratitis in 3.3%.[41] Similarly, the use of sutures may induce some astigmatism, although in MAPLK significantly lower and for a shorter period than in classic PK.[75]

In 2002, we described an experimental laboratory model for posterior lamellar keratoplasty using an artificial anterior chamber.[21] Thirty-six human eye bank corneas (18 donors and 18 recipients) were mounted on an artificial anterior chamber, and a manual microkeratome was used to create a hinged anterior lamellar keratectomy. A 7.0-mm diameter posterior lamellar disk (posterior stroma, Descemet's membrane, and endothelium) was then trephined from the recipient cornea. Three different sizes (7.0, 7.25, and 7.5 mm) of donor buttons were compared. They were sutured into the recipient bed with a running 10-0 nylon suture and covered by the host corneal flap. The flap was replaced without sutures. The resulting corneal surface was analyzed by computerized videokeratography and graft stability studied by resistance to high intraocular pressures. Regular and minimal postoperative astigmatism was present in all cases. There was an average change in astigmatism of 1.47 D (SD 1.49) postoperatively. The grafts and flaps maintained watertight seals with average bursting pressures of 66.9 mmHg (SD 46.4). Although donor buttons oversized by 0.5 mm had the least change in average keratometry, those oversized by 0.25 mm had the best stability at higher pressures. With this model, it was possible to evaluate the effects of many variables such as flap thickness, flap diameter, donor button diameter, and number of sutures and technique of suturing. This comparison was also performed with a running suture and a sutureless hinged anterior lamellar corneal flap.

To compare postoperative astigmatic change and graft stability, we used two different donor button diameters in endothelial lamellar keratoplasty to treat corneal endothelial failure. They showed that average intraocular pressures of up to 88 mmHg could be resisted in laboratory human eyes when a 200-μm flap is used for the MAPLK procedure. This laboratory model system should be useful in evaluating different mechanical factors that contribute to graft success.

An important principle of lamellar refractive and LASIK surgery is that in order to preserve the tectonic integrity of the cornea, a minimum of half or more of residual corneal tissue must remain after the creation of a flap to prevent refractive instability. However, in our clinical series, the thickness of the transplanted posterior stroma appears to have a somewhat different contribution to corneal stability compared to that in LASIK patients. Even when the transplanted disks are thinner than half of the cornea, these corneas appear to remain stable over time avoiding ectasia. Wound healing after this type of approach may be different as compared to LASIK, and the circumferential cut perpendicular to the orientation of collagen fibers may increase the strength of the wound and the posterior cornea.

One of the possible advantages of the microkeratome approach, compared to manual dissection, is related to the optical properties of corneal flaps with smoother cut surfaces. Interface scarring is almost absent after microkeratome dissection in LASIK. When compared with manual dissection, microkeratomes create a smoother donor–recipient interface and a more consistent depth than manual dissection. However, similar to other lamellar approaches including hand-dissection, there seems to be a limit of improvement in visual acuity close to 20/30–20/40 in regards to the maximum best average Snellen visual acuity achieved in the clinical series of MAPLK.

Based on information collected from clinical observations of keratorefractive surgery and various types of keratoplasty, we have postulated a hypothesis that may provide some explanation to the limited optical results observed in MAPLK. These are the facts:

1. LASIK has demonstrated that corneal dissection performed by means of a microkeratome can easily achieve an optical quality compatible with 20/20 or better vision. However, when a corneal free-cap is accidentally obtained, it is necessary to be replaced in exactly the same orientation it had before the cut to avoid visual problems after the surgery. Mismatch may create reduction in best-corrected visual acuity.
2. Anterior lamellar keratoplasty and former classic keratomileusis procedures with donor tissue have traditionally provided a limited best corrected visual acuity.
3. Deep anterior lamellar keratoplasty down to Descemet's membrane provides potential best-corrected visual acuities of 20/20 or better.

From these three facts, we believe that the different orientation of collagen fibers in the interface between two corneas may create optical distortions not currently measurable by available methods and with potential to affect the resulting visual acuity. Even in cases of using the same cornea (LASIK), this orientation of structural fibers is very particular for each individual (resembling a fingerprint), and a simple rotational mismatch induces optical distortions. Therefore, a perfect match is essentially impossible when two different corneas are used and a stroma–stroma interface exists, which is perhaps the major limitation of any procedure involving stroma–stroma interface.

Some other possible pitfalls of MAPLK have also been observed. This procedure induces a shift in postoperative average corneal power and astigmatism similar to a stromal flattening of the corneal surface in LASIK. In MAPLK there is a donut effect of donor–recipient interface due to sutures, which is transmitted to the surface flap. Surface sutures may also contribute to this astigmatism and high absolute power. As with LASIK, flap complications may also occur; epithelial ingrowth in the flap–graft interface can decrease the BCVA and it has been reported in clinical cases of MAPLK.[76] Similarly, it is suspected that corneal melting and micro/macrostriae are also possible adverse outcomes of MAPLK.

MODIFIED MICROKERATOME-ASSISTED POSTERIOR LAMELLAR KERATECTOMY (MMAPLK)

The modified microkeratome-assisted posterior lamellar keratoplasty (MMAPLK) is essentially similar to previously microkeratome-assisted techniques.[19,21,48,54] However, Pirouzmanesh et al, in an attempt to reproduce a more stable postoperative cornea and reduce the dependence on sutures, proposed a wider flap hinge in the recipient cornea as a result of a partial flap cut up to the pupillary margin.[77] A 300-µm-thick partial flap keratectomy was performed in human donor corneoscleral rims using an artificial anterior chamber and a manual microkeratome (Fig. 67.1).

The flap was stopped at the left central opening border, providing a wide hinge to add stability. Differing from previously published techniques, this approach attempts to obtain a wide flap hinge with relatively less likelihood of flap slippage, to provide more stability to the corneal flap and reduce the overall corneal opening to preserve corneal integrity.[20,21,48] After flap reflection, undermining the cornea at the level of the hinge allows for the trephine to be expanded underneath the hinge (Fig. 67.2). A 6.25-mm trephination was performed to obtain a disk of posterior stroma, Descemet's membrane, and endothelium (Figs 67.3 and 67.4). The disk was subsequently positioned in a sutureless fashion, and the flap secured with either five interrupted sutures or a chondroitin-sulfate-aldehyde-based adhesive (Fig. 67.5). Increasing intrachamber pressures were created to detect graft stability. Videokeratographic data were recorded to evaluate astigmatic change. The mean (SD) astigmatic change was 3.08 (0.84) D in the sutured group and 1.13 (0.55) D in the corneal adhesive group ($p = 0.008$). Mean (SD) resisted pressures were 95.68 (27.38) mmHg and 82.45 (18.40) mmHg in the sutured and glued groups, respectively ($p = 0.97$), which is significantly higher than the numbers observed with standard MAPLK using the same setting.

Sutures remain the gold standard for corneal incisions and wound repair because of the efficiency and strength of the closure. However, sutures may not be the ideal method for wound closure, especially in the cornea: many corneal surgeons recognize that sutures can be

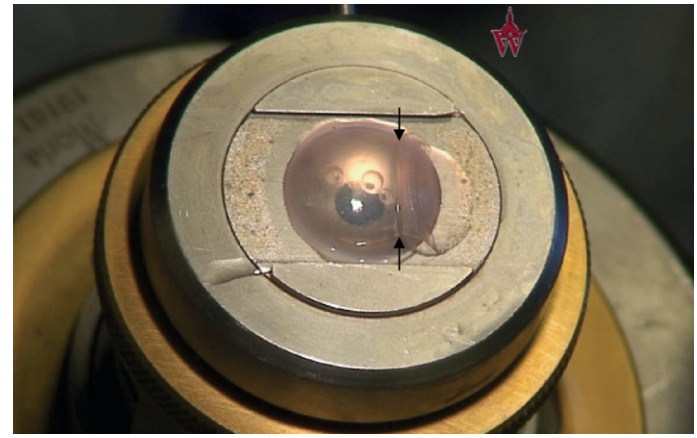

Figure 67.1. Simulation, in an artificial anterior chamber, of a partial flap in the recipient. Flap with a large hinge (arrows) at the pupillary margin. This allows more stability of the flap and the cornea as a whole.

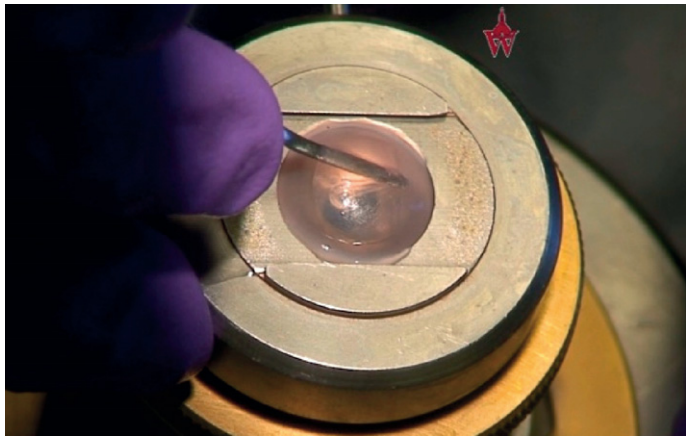

Figure 67.2. Flap hinge dissection. The spatula is inserted underneath the flap hinge and a pocket is created to allow the trephine blade to create an opening in the stromal bed.

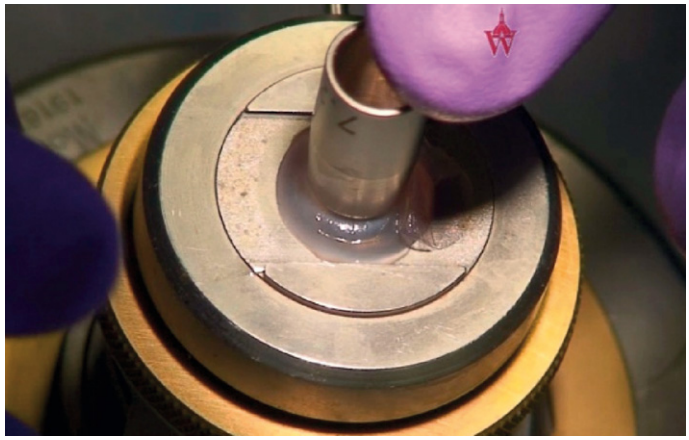

Figure 67.3. After flap reflection, a freehand trephine is centered on the stromal bed surface, avoiding the cut of the flap hinge.

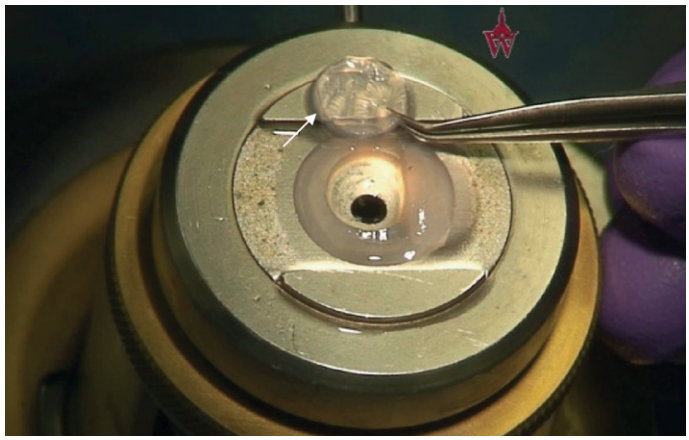

Figure 67.4. A disk is obtained with diseased endothelium (arrow), which is to be replaced with a disk obtained in similar fashion from a donor.

a source of potential problems. The use of tissue adhesive in this study produced less astigmatism than other reports of MAPLK.[20,21,48] Furthermore, the absence of sutures made the technique more simple and considerably less time-consuming.

DONOR TISSUE PREPARATION

Donor corneal tissue can be obtained from a fresh globe or a preserved corneoscleral button. When a button is used, an artificial anterior chamber is required to perform the microkeratome cut.[78]

For both the MAPLK and DLEK methods, donor tissue is prepared a few different ways using an artificial anterior chamber. In one method, the donor corneoscleral button is mounted on the artificial chamber endothelial side down and a lamellar pocket is dissected similar to the DLEK recipient procedure. Then the button is turned epithelial side down on a punch and trephined at a diameter that is dependent on the measured diameter of the recipient posterior lamellar disk. The donor posterior disk is then separated from its anterior corneal layers and used as indicated in the respective procedures. Another method may use a microkeratome for the lamellar dissection. In 2002, Behrens et al[79] evaluated the safety and accuracy of a manual microkeratome and an artificial anterior chamber to harvest corneal lenticules for lamellar keratoplasty. They found that the system was reproducible for harvesting corneal lenticules for lamellar keratoplasty. Its ease of use and high accuracy under controlled conditions may warrant its use for the lamellar dissection part of the donor preparation, following the trephination of the posterior stromal lenticule as previously described.

Another technique for harvesting donor tissue for posterior lamellar keratoplasty was described by Suwan-apichon and associates,[80] in which a corneoscleral button is mounted onto an artificial anterior chamber endothelial side up and the stromal dissection is accomplished with a simple blunt spatula. The planarity and endothelial cell loss associated with the harvest appear comparable to previously described techniques.[81] This modified method is advantageous in that a standard reusable blunt corneal dissector is employed without the added complexity and cost associated with sharp, disposable three knife sets. Furthermore, the orientation of the endothelium up on the anterior chamber allows greater surgeon control during the harvest.

The concerns with donor preparation techniques lie in ensuring endothelial cell survival and technical ease. All procedures have shown comparable endothelial cell survival and no particular method is favored over the other (Figs. 67.6–67.9).

DESCEMET'S STRIPPING WITH ENDOTHELIAL KERATOPLASTY (DSEK)

As highlighted in the preceding chapters, a revolutionary refinement of the DLEK procedure was performed when Melles et al[82] proposed the stripping of Descemet's membrane from the recipient's stromal bed so as to create a smooth recipient surface, without the incision or dissection of the corneal stroma. The technique enables the surgeon to consistently excise Descemet's membrane, to significantly reduce the surgical time required to perform the entire transplantation, i.e. the preparation of the recipient bed and the implantation of the donor posterior lamellar button, and to use a 'closed system' by performing the transplantation through a small tunnel incision. However, other surgeons working on pure Descemet's membrane replacement have found that Descemet's membrane is quite fragile and manipulations of donor tissue, which are reasonably well tolerated in the current endothelial keratoplasty techniques, result in wrinkles, folds, tears, and unacceptable endothelial cell loss. Various modifications of carriers have been used in an attempt to overcome these challenges.[83,84]

FUTURE DIRECTIONS OF PLK

In summary, four techniques for PLK may be distinguished, although various modifications may exist: (1) PLK through a 9.0-mm scleral incision using a spoon-shaped glide for insertion of a 7.5-mm donor,[13,55] made popular in the USA as DLEK;[58] (2) PLK through a 5.0-mm self-sealing scleral incision using a 9.0-mm folded donor,[50] made popular as small-incision DLEK;[85] (3) MAPLK and MMAPLK, which attempt to achieve a smoother surface that may lead to a better surgical outcome with a clearer interface;[20,21,77] and (4) PLK by stripping Descemet's membrane and the insertion of a 9.0-mm folded donor, now referred to as DSEK,[86] or Descemet-stripping automated endothelial keratoplasty (DSAEK), when a microkeratome is used for preparation of the donor tissue. Compared with a penetrating keratoplasty, all these techniques may produce minimal change in refractive power of the transplanted cornea, minimal induced astigmatism, elimination of long-term suture-induced complications, elimination of late wound dehiscence, faster visual rehabilitation, and a lesser demand of postoperative care.[51]

Further development in endothelial keratoplasty will be directed at eliminating the stroma–stroma interface to achieve cases with 20/20 vision. However, neither microkeratomes nor femtosecond lasers are currently capable of deep stromal dissections that are as smooth as the Descemet's-stripped recipient interface side.[87,88]

Melles et al presented the first published report of a successful pure Descemet's membrane transplantation through a small 3.5-mm corneal incision, and have extended the endothelial keratoplasty lexicon to 'Descemet's membrane endothelial keratoplasty' (DMEK).[86] While the visual recovery in this one case was rapid and complete due to the exquisitely smooth surface now on both sides of the interface, what was most astonishing in this single case report was the early donor endothelial cell survival measured at 2350 cells/mm^2 and 1 week postoperative best corrected visual acuity of 20/20.

The current work with in situ human corneal endothelial cell regeneration is exciting and complementary to the evolution of the surgical techniques of endothelial transplantation. Azar's group in Boston (ARVO, 2006) has recently shown success in amplification of human endothelium in the laboratory with good hexagonal morphology. This technique has the potential of taking the recipient's peripheral endothelial cells, increasing the cell density in the laboratory and re-transplanting them back to the recipient central cornea, thus circumventing any issues of immune-mediated graft rejection.[89] If we can extrapolate these laboratory models to the

clinical realm, endothelial keratoplasty as we know may be completely transformed. Ultimately, it may be possible in the future to prevent the need for endothelial transplant by directly stimulating the patient's remaining endothelial cells to regenerate, using viral vectors to transfer genetic material that induces and controls endothelial mitosis.[90]

For all of these newer procedures, long-term follow-up data is needed to determine whether these techniques will become safe and effective alternatives to penetrating keratoplasty in years to come.

68 Descemet's stripping automated endothelial keratoplasty: avoiding complications

James Rowsey, Jason A. Evangelista, John Williams, Bradley D. Fouraker

Corneal transplantation is fraught with numerous surgical and postoperative complications,[1–5] which may be avoided by the newer techniques of endothelial replacement alone. Melles, Culbertson, Terry, and Price have developed a coterie of techniques to allow replacement of either the posterior stroma and adjacent endothelium or Descemet's membrane with attached endothelium to avoid many of these complications.[6–15] These newer techniques, however, are associated with their own unique complications that can confound the visual recovery with these modalities. Terry has reviewed the early deep lamellar endothelial keratoplasty (DLEK) complications including:[15]

1. Intraoperative conversion to penetrating keratoplasty (PK)
2. Uneven recipient or donor bed thickness
3. Excessive posterior pressure from the vitreous or lid speculum
4. Iris prolapse
5. Bleeding from the scleral wound into the interface
6. Dislocation or decentration of the donor disk
7. Early postoperative disk dislocation
8. Graft rejection
9. Late endothelial graft failure
10. Cataract formation requiring cataract removal
11. Steroid or surgical induced glaucoma
12. Persistent epithelial or surface irregularities requiring debridement.

We review the current Descemet's stripping automated endothelial keratoplasty (DSAEK) technique with the attendant complications from this procedure modification and the methods to minimize these and additional complications by approaching the surgical procedure in a stepwise fashion. Each surgical maneuver may induce new or cumulative complications (Table 68.1) that can cause graft failure or poor postoperative visual acuity recovery.

PREOPERATIVE DECISION MAKING

We initially avoided patients with anterior chamber intraocular lenses as the narrow chamber angle makes unfolding the donor material in the anterior chamber more difficult causing endothelial cell loss (Table 68.1). In addition, an anterior chamber intraocular lens may be a harbinger of previous surgical frustration. Vitreous strands may remain in the anterior segment precluding good coadaptation or positioning of the donor material. We also prefer eyes with no prior sector iridectomy as the air injection performed at the conclusion of the case may not be held in the anterior chamber when the patient is upright. If the air proceeds to the posterior chamber it causes anterior displacement of the iris, peripheral corneal touch, and donor dislocation centrally as the iris is repositioned upon air removal. Furthermore, the need for repeated repositioning of the donor material appears to be associated with increasing endothelial cell loss.

AVOIDING OPERATIVE COMPLICATIONS

Two drops of 100% glycerin are placed on the recipient cornea prior to prepping the patient to allow for maximum deturgescence of the corneal stromal preoperatively. This allows better visualization of the anterior segment and a thinner stroma, which is vital when phacoemulsification is anticipated. Deturgescing the corneal stroma also increases the osmotic pressure of the stroma, decreasing the propensity for donor dislocation. The diameter of the recipient cornea is measured with calipers. A cornea of 10 mm or less makes it exceedingly difficult to unfold the standard 8 mm donor in the anterior chamber. We use a smaller donor if the anterior chamber is shallow, in the presence of an anterior chamber intraocular lens, or with a smaller cornea.

DONOR PREPARATION

Inspect the donor to insure that it is of adequate size with the scleral rim to fit the artificial anterior chamber. If the donor is too small in one quadrant, inadequate adhesion in the anterior chamber will occur. Leakage of the anterior chamber at the time of the pass causes an uneven cut. Remove iris from the posterior surface of the donor material and excess conjunctiva. Excess conjunctiva may prolapse onto the surface of the cornea and produce an irregular cut or cause the anterior chamber to collapse with inadequate pressure during the microkeratome pass. Pay careful attention to placing the donor material over viscoelastic on the base of the artificial anterior

Table 68.1 Successful Descemet's stripping automated endothelial keratoplasty (DSAEK) surgery

Avoid Surgical Problems Process Steps	**Postop Complications Observed**	→

AC = anterior chamber.

ACIOL = anterior chamber intraocular lens.

RK = radial keratotomy.

chamber to avoid slippage of the cornea with the endothelium touching the adjacent steel producing endothelial cell loss.

After the cornea donor is secured on the artificial chamber, remove the donor epithelium with a #15 blade and Weckcell sponges until a clear Bowman's membrane is observed. This avoids the potential smearing of epithelium under the cap during the microkeratome pass and production of epithelial ingrowth. Maintenance of the artificial anterior chamber pressure by an assistant is useful at this time. Cut the microkeratome pass smoothly with no skittering, which produces an uneven cut. Be certain that the microkeratome head is well seated before the pass is attempted or an unduly thick donor material will be provided, with loss of best potential vision.

Mark the center of the cut stromal bed with a gentian violet 'S' after drying. This avoids initially placing the donor material in the anterior chamber upside down which requires further manipulation and possible endothelial cells loss. While still on the artificial anterior chamber, undermine the edge of the donor material with a 2.2 mm sharp point crescent blade from the edge of the microkeratome cut to the limbus for 360°. The undermining of the donor corneal incision to 12 mm prevents excessive donor thickness on one side when the cornea is subsequently punched. This avoids uneven donor thickness and subsequent astigmatism or a hyperopic shift from a thickened cornea in the periphery. Mark the stromal side of the donor at the cut edge in four quadrants with gentian violet to assist in producing a centered cut with the trephine when the donor material is inverted on the cutting block.

Increase the fluid flow in the artificial anterior chamber during removal of the donor material to avoid anterior chamber collapse and loss of the endothelium. Irrigate all remaining viscoelastic from the endothelial surface to avoid excess in the anterior chamber during donor insertion, since this could result in poor co-aptation and donor dislocation.

Dry the stromal side of the donor and place it on a dry, cooled cutting block. The hole in the center of a wet cutting block may act as a piston during the cutting procedure jettisoning the donor material forward with excessive trauma to the donor and producing endothelial cell loss. Observe the donor through the 8-mm trephine during the cutting for adequate centration to avoid a decentered cut (Fig. 68.1).

Gently dry the stromal edges of the donor with a Weckcell sponge to avoid excessive Optisol hydration of the donor. A thinner donor decreases the chances of subsequent donor dislocation. Protect the donor under Optisol on the back table while addressing the recipient bed. Cover the donor material on the back table but preclude touching the donor endothelium with any covering that is utilized, to prevent endothelial cell loss.

RECIPIENT PREPARATION

Examine the recipient bed for any surface scars or secondary Cogan's map-dot-fingerprint dystrophy from recurrent corneal edema. A decision must be made to either debride the recipient epithelium with a Weckcell because of the common preoperative subepithelial fibrosis in Fuchs' dystrophy patients or to wait for this debridement in the postoperative period. The advantages of removing the epithelium at the time of surgery are better visualization of the cornea and anterior chamber and a second surgical encounter is avoided. The disadvantages of removing the epithelium at the time of the initial surgical procedure is that epithelial removal leads to keratocyte apoptosis which itself leads to a slower re-epithelialization. In addition, the slower re-epithelialization allows for excess stromal hydration from the tear film decreasing the inhibition pressure of the stroma, leading to potential donor dislocation.

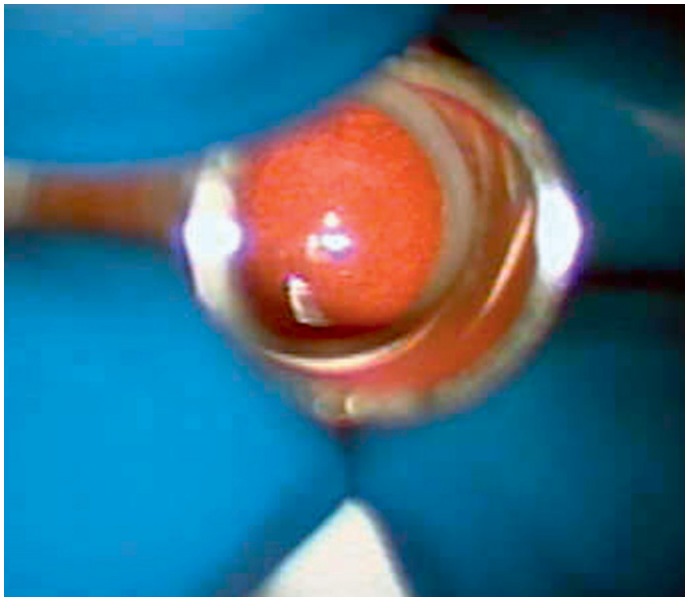

Figure 68.1. Cutting the donor with a hand-held trephine.

Mark the center of the host cornea with a Sinskey hook and the edge of the proposed endothelial resection site with an 8-mm trephine. Avoid excessive pressure or scarring of the recipient bed with the trephine.

Provide a limbal incision 500 μm deep, two clock hours in length (6 mm) in the temporal cornea. Place 1-mm limbal stab incisions at the 12 o'clock, 6 o'clock and 11 o'clock positions for infusion port placement and subsequent unfolding of the donor, as required. Advance the temporal incision 2 mm as a corneal tunnel, avoiding bleeding into the interface. If bleeding occurs, cauterize the bed to insure that the bed will be dry and bleeding will not occur either in the interface between the donor and the stroma or into the anterior chamber. Bleeding in the subsequent interface produces loss of best vision. Place an infusion port in one of the limbal incisions where unfolding of the donor material is anticipated. The infusion port itself can be used quite judiciously to assist in unfolding the donor material even without an air bubble.

Enter the anterior chamber by a 1-mm incision through the original temporal stromal dissection plane (Fig. 68.2). Utilizing the Asico–Price Sinskey hook, scribe the outline of the proposed Descemet's dissection area (Fig. 68.3). This scribing should be slightly smaller than the 8-mm overlying epithelial mark of the trephine. Making the recipient bed slightly smaller than the donor avoids recipient peripheral stromal edema and subsequent postoperative discomfort from bullae over denuded stroma. Bullae formation is exacerbated if all of Descemet's is removed or a significantly larger area of Descemet's is removed than the donor material can clear adequately, giving a foreign body sensation until the cornea deturgesces. At the completion of the scribing technique, the infusion line is turned off and the anterior chamber is filled with Trypan blue. The edges of the bed are now stained allowing for better visualization of the Descemet's lifting off the stroma. The Trypan blue is then irrigated out of the anterior chamber and from behind the iris when infusion is resumed. The Asico–Price Sinskey hook is utilized to gently peel Descemet's membrane from the posterior

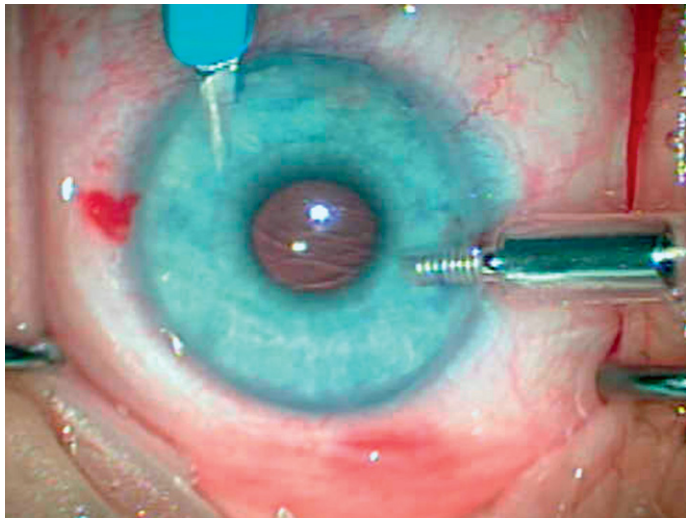

Figure 68.2. Entering the anterior chamber through a 1-mm portion of the temporal corneal tunnel.

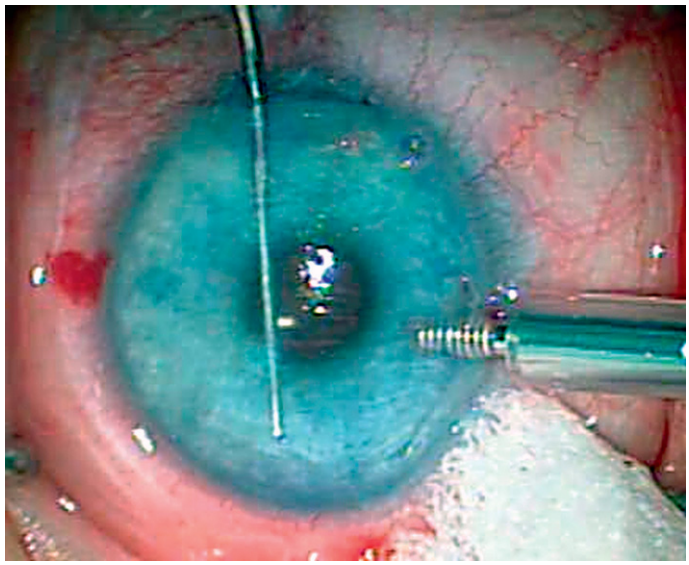

Figure 68.3. Reverse Sinskey scoring Descemet's membrane and endothelium.

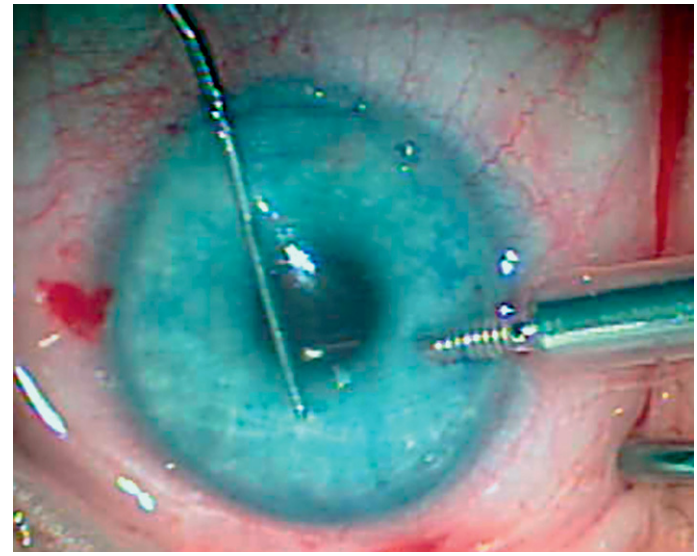

Figure 68.4. Reverse Sinskey pulling Descemet's membrane from overlying stroma.

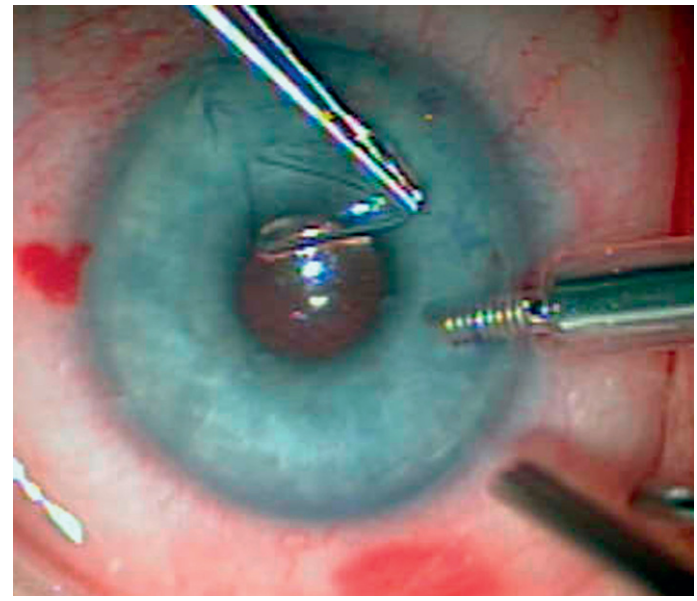

Figure 68.5. Removed Descemet's membrane and endothelium.

stroma (Fig. 68.4). This procedure requires an exceedingly gentle touch. Excessive pressure causes perforation and dehiscence of the delicate posterior stromal fibers with a subsequent scar in the stroma. We have found that utilizing a light pipe with the microscope light turned off during the Descemet's stripping technique is helpful with scleral scatter from the limbus to see the relucency of the dislocated Descemet's membrane. Both Trypan blue and the light pipe are advantageous with very edematous corneas to determine the Descemet's has been stripped to avoid any residual Descemet's pieces at the edge of the recipient bed. It is possible to either pull Descemet's off the stroma or push it off with the Sinskey hook. The infusion port will normally assist in lifting the edge adjacent to the infusion port but will blow Descemet's back onto the stroma 180° away. Others routinely utilize the irrigation–aspiration (I/A) tip to assist in Descemet's stripping and we have found this technique advantageous during a triple phacoemulsification-intraocular lens implantation-DSAEK when the I/A tip is already prepared.

Enlarge the internal opening of the limbal incision to the full 2 clock hours, watching for any bleeding. Remove the freed Descemet's with forceps (Fig. 68.5). Drape the Descemet's sheet over the host cornea to ensure the removal was complete. Utilize the Terry scraper to remove any remaining Descemet's membrane and provide a roughened surface for 360° just inside the 8-mm optical zone for subsequent adherence of the donor material. Do not scrape in the visual axis as this could cause stromal scarring and loss of best corrected vision. Do not enlarge the Descemet's stripping outside of the proposed donor coverage for this will cause an edematous recipient rim.

Under the operating microscope fold the donor in a 60/40% taco configuration with a viscoelastic bead in the fold (Fig. 68.6). Utilize enough Optisol on the block that the folded donor endothelium does not touch the block during this step (Fig. 68.7), producing loss of the endothelium.

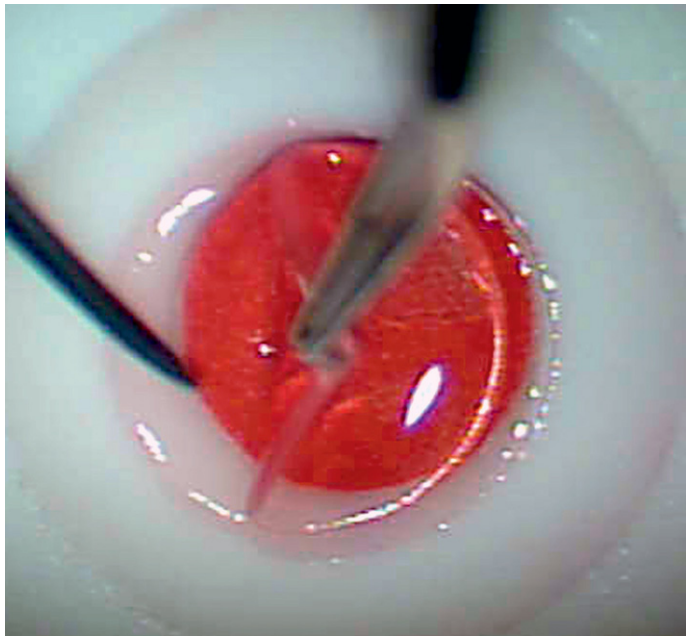

Figure 68.6. Folding of posterior donor cornea.

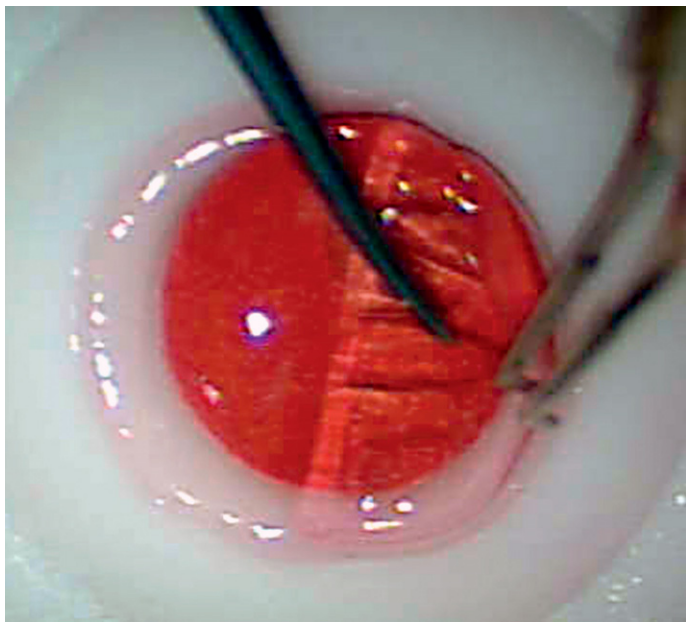

Figure 68.7. Folded donor cornea.

DONOR INSERTION

Grasp the donor 1 mm from the fold with the Charlie forceps (Fig. 68.8), and insert the donor quickly into the anterior chamber to the opposite limbus (Fig. 68.9). Gently release the donor material near the infusion port. The infusion port assists in the unfolding procedure. Do not touch the infusion port as this can cause endothelial cell loss. Be careful that the pressure of the infusion port is not excessive, which will prolapse the iris or donor back out of the anterior chamber onto the surgical drape causing endothelial cell loss. Place a single 10-0 nylon suture through the incision to maintain the anterior chamber.

Unfolding may occur spontaneously when the anterior chamber is filled. If the unfolding is inadequate there are two options. Grasping the edge of the donor material at the limbus through the limbal ports with a Sinskey hook can manipulate the edges in place (Fig. 68.10). Use the infusion line or air to assist the unfolding. It may be necessary to place an additional suture in the limbus to maintain the anterior chamber since collapse produces endothelial cell loss. Another alternative is filling the anterior chamber with air. Place a second suture in the limbus, and use a 30-gauge needle on a tuberculin syringe placed obliquely through a new limbus site and inject air between the donor edges. Avoid air in front of the donor material as this can prolapse the donor onto the iris or intraocular lens producing endothelial cell loss. It is convenient to place the 30-gauge needle through a new insertion site that can preclude air evacuation spontaneously through a previously used limbal incision. Longer scleral tunnels with the original DLEK procedure avoided this air extrusion. However, the larger tunnels require more attention to avoid bleeding. Limbal incisions allow more frequent prolapse of air especially during a manipulation procedure.

When the donor is in place, close the main wound with sutures and completely fill the anterior chamber with air to an intraocular pressure of 50 for 8 min. This procedure avoids donor dehiscence. Place four full-thickness 1-mm radial keratotomy incisions at the

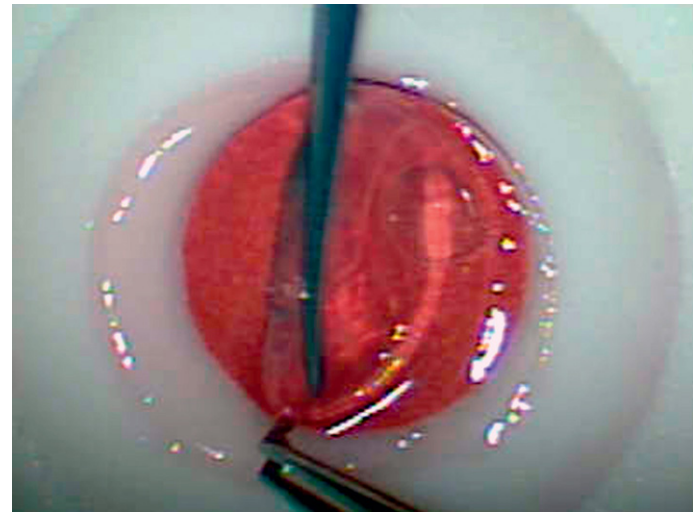

Figure 68.8. Grasping folded edge with Charlie forceps.

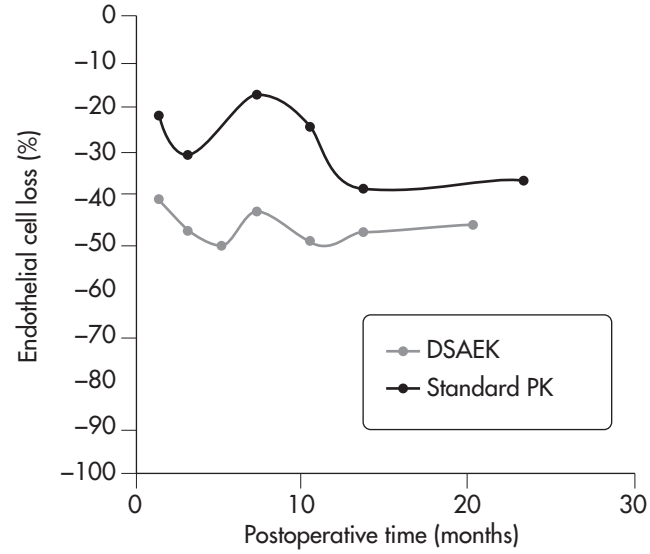

Figure 68.11. Percentage of postoperative endothelial cell loss of Descemet's stripping automated endothelial keratoplasty (DSAEK) versus standard penetrating keratoplasty (PK).

6-mm optical zone with a diamond blade to allow for fluid egress from the donor recipient interface. This is done over air and it is easy to observe when excess fluid is removed. If longer incisions are placed, excessive flattening of the cornea can occur with subsequent hyperopia.

Roll the recipient's epithelium with an iris spatula to move the donor material to a final position, avoiding decentration. This roll is accomplished with approximately 50 strokes of the iris spatula from the center of the cornea to the periphery with fluid or viscoelastic on the surface to avoid damaging the epithelium. Remove half of the air leaving an air bubble the size of the donor material. This procedure avoids donor dehiscence.

Apply two drops of 1% atropine solution and topical glycerine at the end of the procedure. The atropine allows for the pupil dilation and avoids subsequent pupillary block with air. Pupillary block causes the iris to adhere to the donor material with subsequent donor dislocation during the postoperative care. Lightly patch the eye over dexamethasone/tobramycin (0.1%/0.3%) ophthalmic ointment. A tight or indenting patch can produce donor dehiscence. On the first postoperative day prescribe the above ointment six times a day and inspect for donor adherence. In one week, ointment is changed to prednisolone acetate ophthalmic 1% suspension six times a day for 1 month to avoid graft rejection. The limbal sutures are removed at 1 month to decrease corneal astigmatism.

POSTOPERATIVE COMPLICATIONS

At 1 h postoperatively verify that the air in the anterior chamber has been adequate to provide good adherence of the donor material to the stroma. Glycerin is re-applied at the examination to allow for further stromal drying and better donor adherence avoiding donor dislocation. Additional air is placed in the anterior chamber if any donor dislocation is noted. A Povidone iodine re-prep is required as inadequate sterilization may produce endophthalmitis. Any fluid in the interface is removed through one of the previous radial incisions with a Sinskey hook and a 31-gauge needle is also useful to aspirate this fluid if it persists in the interface. Further manipulation can produce endothelial cell loss. Vitreous in the anterior chamber with entanglement of the donor material may produce corneal donor dehiscence.

A primary donor failure may be observed. This donor failure is normally seen in approximately 1 in 400 cases; however, it is unlikely without excessive surgeon manipulation. The donor material can be replaced through the same or an additional limbal incision. At 1 week, if the donor is dislocated we add air to the anterior chamber. This may produce further endothelial cell loss. At 2 weeks, if the donor remains off, we add air to the anterior chamber and suture the donor in four quadrants with a mattress suture from the recipient into the anterior chamber. This can also be associated with endothelial cell loss. If the donor is off at 2 months we replace it through the same limbal incision. Additional surgical procedures may be associated with cystoid macular edema.

We have found long-term endothelial cell loss to be greater when compared to standard PK (unpublished data). We compared preoperative endothelial cell counts obtained from the reference eye bank and the postoperative specular microscope data (Fig. 68.11). These differences were statistically significant until the 15-month postoperative period. Long-term differences are still being analyzed. In the 143 eyes with prolonged follow-up, we have observed nine cases (6.3%) of primary graft failure and, of those that survived, nine cases (6.7%) of late graft failure.

Graft rejection has been observed in two patients, one who discontinued their steroids, and one who was transferred off Pred Forte to generic prednisone acetate 1%. Although these drugs are 'pharmaceutically' equivalent they do not appear to be physiologically equivalent when rejection is the defining criteria.

In summary, the newer techniques of the Descemet's stripping endothelial keratoplasty provide excellent opportunities to avoid surface sutures, incisions, and irregular astigmatism and especially fragile wounds that may rupture. The complications for these new procedures are being demonstrated with prolonged follow-up. However, the rapid visual recovery, reduced astigmatism, wounds resistant to traumatic rupture, and negligible suture-related strife make this new advance advantageous to both the patient and surgeon.

69 The future of keratoplasty

Omar Ahmad, Shahzad Mian, Alan Sugar

INTRODUCTION

In the 100 years since Eduard Zirm performed the first successful penetrating keratoplasty, corneal transplantation has progressed through the application of innovative technology and surgical technique to become arguably the most successful type of tissue transplantation.[1,2] Despite the advances that have been made in keratoplasty outcomes, graft survival remains a major concern, particularly in patients with repeat keratoplasty and inflammatory conditions.[3] The primary goal of successful keratoplasty is preservation of a clear graft and optimal rehabilitation of visual function, assessed by factors such as postoperative visual acuity, astigmatism, and time to recovery. This chapter focuses on new trephination techniques, sutureless adhesion technology, and alternatives to human cadaveric cornea transplantation, including keratoprostheses and bioengineered corneas. These are areas of development which we feel will dramatically improve the art and science of keratoplasty over the next decade.

TREPHINATION TECHNIQUES

Trephines that are currently used to incise the donor graft button and remove the recipient diseased cornea include handheld, suction, and automated devices. Skilled trephination technique is needed to avoid irregular and decentered cuts, which can lead to astigmatism and refractive error postoperatively.[4] Optimal outcome with both handheld and automated trephination systems is dependent on a centered perpendicular cut, use of a sharp blade edge, and a well-matched donor button and recipient bed.[5] Advances in manual trephination and the development of laser trephination devices can lead to improvement intraoperatively and postoperatively.

MANUAL TREPHINES

Manual trephination remains the most common incision technique because of ease of use, availability, and prohibitive aspects of laser trephination such as increased operative time and surgical cost. The development of suction and automated systems has improved reliability and reproducibility of corneal cuts. Sharp blade edges can reduce tangential and axial contact forces when cutting corneal tissue.[6] Nanotechnology, such as carbon coating of conventional trephine blades, can confer diamond-like cutting properties. While this is an improvement on current manual trephines, laser trephination can provide superior performance.[6]

LASER TREPHINATION

The use of lasers for trephination in keratoplasty was proposed over 15 years ago.[7] The theoretical advantages of nonmechanical trephination include elimination of axial and tangential contact forces, reduction of cut edge disparity with subsequent topographic distortions, and minimal trauma to intraocular tissue. The first laser trephination system to be used in penetrating keratoplasty was the excimer laser, which can create noncircular (i.e. elliptical) cuts through the application of variably shaped hardware masks.[8] Techniques such as positional spikes and orientation teeth can be used for the precise placement of the donor button in the recipient bed and as a visual aid for the placement of cardinal and secondary sutures (Fig. 69.1, *A–C*).[9] In a prospective, randomized, single center study, Seitz et al demonstrated an improvement in postoperative astigmatism, corneal topography, and best corrected visual acuity using excimer laser trephination compared to mechanical trephination in penetrating keratoplasty.[10,11] Astigmatism in the excimer trephination group was 3.0 D ± 2.1 D compared to the control group astigmatism of 6.1 D ± 2.7 D. While the control group astigmatism was significantly higher than most other previously published results using manual trephination, the laser trephination still produced slightly less astigmatism than most previously published studies. The results of the excimer laser series are important because they represent the largest and best-studied series of laser trephination keratoplasty.

FEMTOSECOND LASER KERATOPLASTY

The limitations of excimer laser keratoplasty include increased surgical time and cost associated with need for bulky machinery. To address some of these concerns, lower cost mid-infrared lasers such

as the hydrogen fluoride laser and erbium:YAG laser are being evaluated.[12,13] Most recently, the femtosecond laser is being investigated for lamellar and penetrating keratoplasty.[14–17]

The femtosecond laser is currently used in the USA for making anterior corneal flaps in LASIK surgery. It is a focusable infrared laser, similar to the more familiar neodymium-YAG laser, but utilizes instead ultrafast pulses in the hundred femtosecond (100×10–15 s) duration range. With the energy and firing pattern controlled by a computer, the femtosecond laser is capable of cutting tissue at various depths and patterns, producing very minimal inflammation and collateral tissue damage.[15–19] Thermal damage to adjacent tissue in the cornea has been measured to be in the order of 1 μm.[20] The laser essentially vaporizes small volumes of tissue by photodisruption, producing a plasma, shock wave, cavitation, and gas (CO_2 and H_2O) bubble generation. Unlike lasers employing visible wavelengths, the ability of the femtosecond laser to cut cornea is less hampered by optical haze, making it more useful in treating edematous corneas. The laser-control software may be programmed to produce intrastromal lamellar, axial, or pocket cuts at any depth or diameter. The laser spots may be fired in a spiral pattern or a zigzag (raster) pattern to achieve lamellar cuts. During treatment, the cornea is flattened with a suction-applanating lens to help immobilize the eye and to allow treatment of a geometrically simpler planar cornea. The femtosecond laser uses low energy coupled with higher power pulses to achieve a more rapid trephination. The laser-control software is also customizable to achieve different graft geometric configurations, potentially allowing for sutureless, self-adhesive keratoplasty, which will be discussed in greater detail later.[18,19]

FEMTOSECOND LASER-ASSISTED POSTERIOR LAMELLAR KERATOPLASTY

Femtosecond laser-assisted posterior lamellar keratoplasty has been performed with the laser control parameters, including energy, depth, and treatment diameter, programmed on the clinical femtosecond laser (FS-Laser, Intralase Corp., Irvine, CA) in both human eye bank eyes and an in vivo rabbit model (Fig. 69.2). Short applanating interface lenses (100–150 μm shorter in axial length than the standard LASIK lenses) are employed to allow the deep corneal treatment. The posterior trephination energy is higher (6.0–8.8 μJ) with trephination diameters of 6.0–7.0 mm diameter to assure complete detachment of the peripheral edges in deep stroma. The laser firing sequence for the trephination begins in the anterior chamber and moves progressively forward through endothelium, Descemet's membrane, and posterior stroma. Following completion of posterior trephination, the laser parameters are reset to cut the lamellar interface at a depth of 150–200 μm anterior to the endothelial surface with the energy set at 6.0–8.7 μJ. The diameter of the lamellar cut is oversized 1–2 mm larger than the trephination diameter in order to assure that the two cuts intersect. A limbal corneal paracentesis is made. The femtosecond laser or a blade may be used to create a 4-mm tunnel incision in the peripheral cornea in order to enter the lamellar interface plane. The interface is swept with a Barraquer iris sweep to release the posterior corneal disk, which is then removed from the eye through the incision with Utrata capsulotomy forceps.

The donor tissue is prepared by mounting the corneoscleral buttons in an artificial anterior chamber device. The laser treatment is rendered through the applanating lens in the same manner as with the globes and the corneoscleral button is removed from the artificial anterior chamber and placed on a Teflon block endothelial-

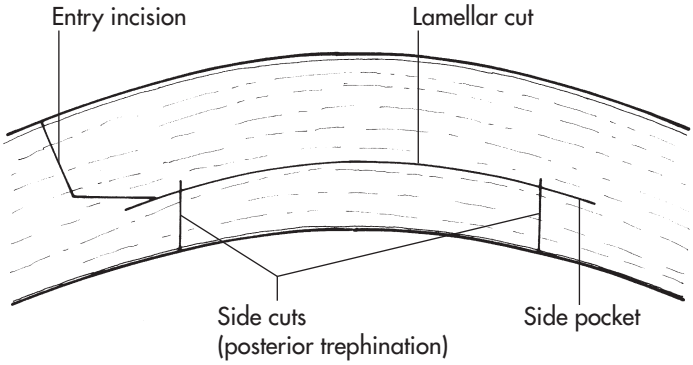

Figure 69.2. Femtosecond laser posterior lamellar keratoplasty: schematic cross-sectional view of lamellar and trephination cuts. Lamellar bed is oversized peripherally to assure intersection of cuts and to create side pocket to secure donor disk edge. Laser spot firing sequence begins in anterior chamber, just posterior to endothelium, and progresses in anterior direction into stroma. Peripheral corneal incision is made manually from anterior corneal surface with crescent blade and connects to lamellar interface. (Reprinted with permission from Soong HK, Mian S, Abbasi O, Juhasz T. Femtosecond laser-assisted posterior lamellar keratoplasty: initial studies of surgical technique in eye bank eyes. Ophthalmology 2005; 112(1): 44–49, © Elsevier 2005.)

side up. Grasping an edge of the posterior corneal disk with Utrata forceps and an edge of the parent corneoscleral button with Harms forceps, the disk is gently peeled apart from the button. The posterior corneal disk is then folded taco-style, with the endothelial surface inside, protected by a thin coat of viscoelastic material. The folded disk is held with Utrata forceps and inserted into the posterior stromal bed through the incision.

SUTURELESS CORNEAL ADHESION

Sutures are currently the gold standard for the adhesion of the corneal graft to the recipient bed. Sutures play a particularly vital role in penetrating keratoplasty, where they may remain for over a year to allow full support during tissue healing. However, astigmatism is the major flaw of sutures as a fastening agent.[20] Numerous suture techniques have been developed in attempts to reduce astigmatism.[21–23] Significant interest remains in sutureless techniques that could theoretically reduce this undesirable surgical outcome. Sutureless adhesion techniques can possibly reduce surgical time and epithelial growth beneath flaps/grafts, decrease postoperative follow-up, and eliminate a possible source of irritation, inflammation, graft rejection, and infection.

GLUE

Glues have been used previously in ophthalmology, particularly for treating corneal perforations. Glues commonly used in ophthalmology can be subdivided into synthetic adhesives (e.g. cyanoacrylate derivatives) and bioadhesives (e.g. fibrin glues). Cyanoacrylates are not suitable for use as a tissue adhesive in penetrating keratoplasty because they behave as a foreign body that is impermeable to fluids and metabolites. Bioadhesives, on the other hand, disappear over time but still provide the necessary tensile strength for successful closure of the adhesive surface.

The use of glues as a corneal surgical aid is still being explored. Kang et al described the successful use of two novel biodendrimer tissue adhesives in the closure of laser in situ keratomileusis (LASIK) flaps in human eye bank eyes.[24] The authors postulated that the use of these adhesives in surgeries that involve stromal flap creation, such as lamellar keratoplasty, can reduce the incidence of epithelial ingrowth. Pirouzmanesh et al developed an experimental model for microkeratome-assisted posterior lamellar keratoplasty comparing the tensile strength provided by a chondroitin-sulfate-aldehyde adhesive versus five interrupted sutures. They found that the mean pressure at which leakage occurred were slightly lower for the bioadhesive but not by a statistically significant amount (95.68 for sutures vs 82.45 for the adhesive). In addition to this, there was a significant decrease in the amount of astigmatism as recorded by videokeratoscopy (3.08 D for sutures vs 1.13 D for adhesive).[25] Kaufman et al successfully used fibrin glue in a small series of sutureless lamellar keratoplasties.[26] While these surgeries were successful, the authors concluded that further improvements would need to be made before the fibrin glue could gain widespread use.

LASER TISSUE WELDING

Tissue welding has been extensively studied in vascular surgery using low energy laser beams. Laser tissue welding is defined here as the attempt to produce full-thickness, continuous adhesion of ocular tissue without the aid of photosensitizing dyes or chromophores. Several animal models have studied the application of lasers such as hydrogen fluoride and CO_2 for corneal tissue welding.[27,28] A porcine model of keratoplasty using a near infrared (NIR) laser has been used to form full length welds of corneal tissue with high tensile strength.[29] Initial results from this study suggest that laser tissue welding may be used as an adjunct for sutureless closure in corneal surgeries since the welding creates minimal tissue disruption, resulting in minimal corneal opacification or change in surface contour. Ultimately, the mean tensile strength of the laser-welded tissue was only one-tenth of sutured tissue, likely limiting its use as an independent corneal tissue adhesive.

KERATODESMOS

Photochemical keratodesmos (PKD) is a method of producing sutureless adhesions by applying a photosensitizer to wound surfaces followed by low energy laser irradiation. The laser promotes cross-linkage between collagen molecules on opposing surfaces to produce a tight seal without inducing thermal damage to the adjacent tissue. A specific PKD model which utilizes rose bengal dye activated by low-energy laser irradiation with argon ion laser at wavelength of 514 nm has been studied in rabbit models in the setting of lamellar incisions, corneal incisions, and PKP models.[30–32] An initial ex vivo model using enucleated rabbit eyes demonstrated that the intraocular pressure needed to produce leakage from a lamellar wound sealed with PKD was similar to that seen with radial 10-0 nylon sutures. An in vivo study looking at the closure produced by PKD for a 3.5-mm non-self sealing corneal wound 2 mm anterior to the limbus in New Zealand white rabbits demonstrated strong closure up to 14 days after surgery. This same PKD system was ultimately tested for penetrating keratoplasty in New Zealand white rabbits (Fig. 69.3). One eye received both 16 interrupted sutures and rose bengal PKD with 2 min of irradiation at 532 nm. The other eye, with only 16 interrupted sutures, served as the control group. The wound leakage began at 250 mmHg of intraocular pressure in the control group and 410 mmHg in the treated eye group ($p < 0.05$, paired t-test). The authors concluded that photochemical keratodesmos may be a useful adjunct to sutures in the immediate postoperative period.

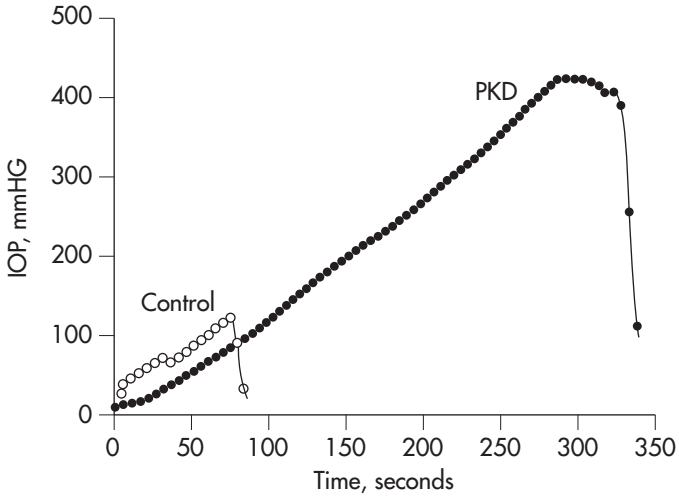

Figure 69.3. Photochemical keratodesmos (PKD) with penetrating keratoplasty: The intraocular pressure (IOP) in the PKD-treated eye (•) is significantly higher when compared to the control eye (◦) of the same rabbit. (From Proano CE, Azar DT, Mocan MC, Redmond RW, Kochevar LE.[30] © 2004 with permission from Elsevier.)

Clinical confirmation that PKD can be used was demonstrated by Pini et al, who successfully utilized diode laser radiation (805 nm) at low power in conjunction with the chromophore indocyanine cardio-green (ICG).[33] This system was used for the successful closure of three penetrating keratoplasties in conjunction with placement of eight sutures.

CUT AND PASTE KERATOPLASTY

Traditional penetrating keratoplasty relies on preparation of a circular donor button to fit into a matched recipient bed. The wound in routine penetrating keratoplasty utilizes vertical, edge-to-edge wound healing where fairly tight sutures are needed to secure the donor button. A fundamental change in shape of the donor button and recipient bed in order to produce an inherently stable corneal graft may reduce the need for sutures or allow for sutureless adhesion.

SURGICAL CUT AND PASTE

Busin has described a 'nut and bolt' or inverse mushroom configuration surgical technique for penetrating keratoplasty.[34] The technique as described by Busin attempts to create a corneal donor button that closely matches the recipient bed. Shaped keratoplasty is a two-level keratoplasty characterized by a different size of the anterior and posterior layers of the cornea. The donor button is prepared using a 7.0-mm Barron suction trephine to make a circular, 0.3-mm incision in the corneal bed from the epithelial side. Next, a bevel up stromal lamellar dissection is performed with a knife out to the limbus. Finally, the cornea is placed endothelial-side up in a Barron suction punch and a 9.0-mm donor button is punched out. Similarly, the recipient bed is prepared using a 7.0-mm Barron suction trephine to make a 0.3-mm deep incision. A bevel up knife dissection is done 1.0 mm peripherally in the lamellar stroma. Finally, corneal scissors are used to complete the excision of the corneal button from the peripheral end of the posterior lamellar stroma. The corneal graft is then placed in the recipient bed and secured with a loose running 10-0 nylon suture. The sutures are removed as early as 3 months, thus, significantly reducing the dependency on sutures to hold the edges firmly together. The ability to remove all sutures as early as 3 months in Busin's series implies that there may be improved stability of this graft configuration.

LASER CUT AND PASTE KERATOPLASTY

Laser techniques are well suited for carrying out the steps of cut and paste keratoplasty. Both the excimer laser and Er:YAG lasers are able to create divergent cut angles that produce conical incisions with wider endothelium diameter than epithelial diameter.[35,36] The advantages of this configuration include use of intraocular pressure to push the corneal graft into the recipient bed, increase in wound surface, and increase in number of endothelial cells transplanted, especially important in disorders with endothelial cell dysfunction (e.g. Fuchs' dystrophy).

Ex vivo animal cornea studies looking at the femtosecond laser and the use of alternative incisions such as 'inverse mushroom' and conical incisions have yielded interesting results. Animal models have shown the feasibility of using the femtosecond laser to create conical corneal incisions that range from 0 to 60° from the sagittal axis, as well as the addition of positional orientation spikes.[19] Taking this one step further, a femtosecond laser was used to create 'top hat' configurations out of both polymethylmethacrylate (PMMA) and porcine corneas.[18] A laboratory model showed that the 'top hat' configuration created by the femtosecond laser was slightly more mechanically stable than that of traditional penetrating keratoplasty.[37]

ALTERNATIVES TO HUMAN TISSUE KERATOPLASTY

There has been great interest in the development of alternatives to human tissue keratoplasty due to risk of graft failure and rejection, limited supply of human tissue, and risk of transmission of infections. Graft failure remains a significant concern, especially in high-risk groups like herpes simplex keratitis, repeat keratoplasty, and Stevens–Johnson syndrome. In addition, rates of graft survival vary greatly amongst different clinical series, with geographic region being one major variable. The rate of graft rejection in these high-risk groups can range from 30 to 50%.[38] When viewing blindness secondary to corneal pathology in a worldwide perspective, there is even more motivation to develop alternatives to cadaveric corneas. For example, while there is currently no waiting list for corneal transplantation in the USA, in developed countries such as Japan there is much less cadaveric tissue available. This shortage will likely only continue to increase as factors such as refractive surgery continue to reduce the potential tissue supply. On a global level, there are currently over 10 million cases of blindness secondary to corneal opacification, with infectious and ocular surface disease causing scarring being quite common in underdeveloped countries.[39] The potential advantages of artificial corneas include eliminating the risk of graft rejection and reducing the need for long-term follow-up. We will examine three possible alternatives to human donor tissue keratoplasty: new corneal replacements, which can be subdivided into keratoprosthesis and tissue-engineered corneal equivalents; stem cell and endothelial cell transplantation.

KERATOPROSTHESIS

Numerous keratoprosthetic devices are already available such as the Boston (Dohlman-Doane) (Chapters 78, 79), osteo-odonto, Alpha-

Cor, and BIOKOP prostheses. However, all of these prostheses have features that can be improved upon such as biocompatibility of materials and long-term complications including inflammation, infection, and glaucoma. An ideal synthetic keratoprosthesis must perform all of the basic functions of a native cornea. These include but are not limited to (1) transparency, (2) barrier functions, (3) permeability to oxygen and nutrients, (4) avoid toxic, immune, and inflammatory responses, (5) biocompatibility and integration into the surrounding tissue.[40] Current research aims to improve keratoprosthetic materials and growth of a corneal epithelial cell layer over the anterior surface of the keratoprosthesis.

Both PMMA (polymethylmethacrylate) and pHEMA (poly-2-hydroxyethyl methacrylate) are being evaluated to optimize keratoprosthesis function as assessed by all five native cornea functions. While the use of pHEMA in the AlphaCor prosthesis has improved biointegration, there continues to be a lack of epithelialization of the anterior surface and inferior mechanical strength. Tensile strength is an important characteristic for the skirt portion of the core-and-skirt model because it anchors the prosthesis to the eye. Research is being carried out to strengthen pHEMA by copolymerization and altering the cross-linking agents.[41] PDMS (polydimethylsiloxane), PDMS-poly (*N*-isopropyl acrylamide), and perfluoropolyether-based products are being developed in hopes of creating even better keratoprosthetic materials. For example, PDMS-poly (*N*-isopropyl acrylamide) shows improved glucose permeability levels over previous materials.[42]

The ability to maintain an epithelial surface is important as it provides a barrier of protection from the tear film, proteinases, and inflammatory cells. Properties of the implant surface such as hydrophilicity, porosity, topography, adhesiveness, and permeability to nutrients are vital to an implant's epithelialization ability. For example, pore sizes of less than 1 μm promote epithelial cell proliferation.[43] In an attempt to liken the implant surface to that of the epithelial basement membrane, extracellular matrix proteins (collagen, laminin, etc.) and fibronectin have been coated over implant surfaces and have been shown in in vitro studies to increase epithelial cell adhesion and proliferation. Growth factors are another promising way of both promoting epithelialization on the anterior surface of implants and avoiding retroprosthetic membrane formation. Epidermal growth factor (EGF) is being studied as a promoter of epithelium on the anterior surface of PDMS, while coating TGF-beta on surfaces results in a downregulation of cell adherence.[44,45]

ARTIFICIAL CORNEAS

Tissue engineered corneal equivalents have the same basic goal as keratoprostheses; however, they are made of the same central collagen layer and cell types (epithelial cells, keratocytes, endothelial cells) that are found in the cornea. These corneal alternatives aim to improve integration into the eye while retaining important functions of the cornea such as wound healing and sensitivity (if nerve innervation can be achieved).

There are several artificial cornea models that have been proposed including the French LOEX model, the University of Minnesota collagen sponge model, and the University of Ottawa composite model. The University of Ottawa composite model developed by Griffith et al may represent the closest of these models to a system that would be practical for human use. This artificial cornea model has been shown to resemble the human cornea optically while at the same time being mechanically strong enough to be successfully sutured onto human corneal limbal rings and rabbit eyes.[46,47]

Preliminary results demonstrate that tissue-engineered corneas can reproduce some of the desirable features of the cornea. For example, in an in vitro study using collagen scaffold cross-linked with *N*-isopropyl-acrylamide, acrylic acid, and acryloxysuccinamide, neurite ingrowth was demonstrated in the collagen hydrogel with the application of nerve growth factor (NGF) and Tyr-Ile-Gly-Ser-Arg (YIGSR) peptide.[48,49] These reconstructed corneas regained some touch sensitivity 7–14 days after surgery and demonstrated epithelial growth with nerve ingrowth.

There still remain significant issues to be addressed before tissue-engineered corneas can be considered for human use. The corneal scaffolds developed to date lack the requisite strength to be considered for long-term use in humans. The strength of these collagen hydrogels has been improved by increasing collagen concentrations as well as cross-linking the collagen with different agents.[50] Further in vivo studies will be needed to determine how close artificial tissue-engineered corneas are to becoming a feasible alternative in humans.

EPITHELIAL CELL TRANSPLANTATION

The corneal epithelium is replenished by a population of stem cells located in the basal epithelium at the corneoscleral limbus. This population of cells is particularly important in keratoplasty as conditions lacking epithelial stem cells, such as aniridia and severe chemical burns, are much more difficult to successfully treat with PKP. It has been shown that the renewal of this stem cell population by either autologous or homologous transplantation of limbal stem cells can help to maintain a healthy ocular surface in these conditions.[51,52]

While the successful transplantation of corneal epithelial stem cells has already been achieved, two exciting areas of future improvement are the better identification of the stem cells using cellular markers and the application of cultured epithelial stem cells. The identification of stem cell cellular markers is an area of keen interest as better identification of these cells could allow for more effective cell transplantation. Determining which markers most effectively distinguish true epithelial limbal stem cells from their early progeny has proven difficult because there are conflicting data on several of the most promising markers, including the p63 transcription family, ATP binding cassette transporter G2, and different cytoskeletal proteins.[53–55] Another interesting application of better identification of stem cells is that stem cells from tissue other than the corneoscleral limbus may be a potential source of cells, such as the conjunctiva.[56]

ENDOTHELIAL CELL TRANSPLANTATION

Endothelial dysfunction (Fuchs' dystrophy, post-cataract surgery endothelial cell loss, etc.) is a major indication for keratoplasty currently, particularly in developed countries. Optimal treatment involves endothelial cell transplantation alone, with the transfer of either primary or transfected human corneal endothelial cells (HCEC) into a patient's eye. Research into this promising field currently focuses on two major areas: the preparation of appropriate cultured HCEC that can be functional after transplantation and the development of an appropriate carrier for the cells.

The challenge in establishing a functional pool of cultured HCEC is to ensure that the cells have enough proliferative capability to maintain a sufficient cell density in the transplanted cornea but at

the same time to control the proliferation so that the proliferation stops after the establishment of a close monolayer. An immortalized line of HCEC that has been transfected with the large and small antigen of the SV-40 virus shows the necessary regenerative capacity, however they continue to divide after establishing a monolayer.[57] For transfected cell lines like these to be effective, the vector system that exerts its proliferative influence would have to shut down after the successful establishment of a monolayer with sufficient cells.[58] Alternatively, manipulation of external influences on the endothelial cells such as growth factors can be used. Different cell transport systems include gelatin membranes, coated hydrogels, and amniotic membrane with all of these systems showing potential for facilitating cell transportation.[59–61]

SUMMARY

In summary, techniques for keratoplasty are continuing to evolve with technological advances such as the femtosecond laser. Laser trephination may help improve visual outcomes with improved wound apposition and reduced astigmatism. Sutureless or near sutureless keratoplasty may also further improve visual outcomes and reduce rates of neovascularization, rejection, and infection secondary to sutures. Finally, alternatives to human tissue keratoplasty may not only allow for optimal visual outcomes and reduced complications but reduce dependency on donor tissue availability.

70 Chemical injuries of the eye

Roswell R. Pfister, Daryl A. Pfister

Concentrated chemicals splashed into the eye produce severe and prolonged ocular complications. The result can be devastating, with major medical, surgical, personal, social, and economic ramifications. When the injury is bilateral, the patient's world collapses, forcing family, and ultimately society, to bear the brunt of personal and financial needs. Although these events are fortunately not very frequent, the magnitude of the problem and the benefits of reestablishing vision have forced a major effort to uncover the best management protocol for control of complications and to determine optimal treatments to regain vision. To this end, a generation of research has significantly improved the prognosis and made visual rehabilitation a realizable goal.

EPIDEMIOLOGY

Chemical injuries are sustained in the workplace, in home environments, or as a method of assault. Only in large industrial workplaces can safety engineers control the incidence of injury through education and minimizing risk from dangerous equipment or areas. Despite such programs, the storage and use of powerful alkalis, sometimes under extreme pressure and high temperature, continue to pose serious threats even to the properly attired worker wearing protective clothing and goggles. Unprepared farmers using liquid ammonia as fertilizer and homeowners using powerful cleansing agents often do so without eye protection.

The most common cause of a severe alkali injury of the eye in USA has been an assault. Data gathered from a large urban hospital show that young black men are at greatest risk, usually in a domestic setting, where there is low income, high-density housing, and a record of alcoholism and prior assaults.[1] In the industrial sector, approximately 10% of 52 142 cases of ocular trauma reported from 16 states were chemical injuries (1.6% acid, 0.6% alkali).

Of 221 chemical injuries reported in 180 patients at the Croyden Eye Unit, UK, almost half were caused by alkali in males (75.6%) between the ages of 16 and 25.[2] Accidental injuries accounted for 89.4%; the remainder assaults. Work-related accidents numbered 63%, 33% occurred at home and 3% at school.

Two large series of chemical injuries were reported by Kuckelkorn and colleagues in Aachen, Germany in 1990–1991.[3,4] In the first report, 236 injuries occurred in 171 patients of whom 70% were males. Industrial accidents numbered 61%, 37% were household and 2% unknown. Most injuries were classified as mild (88%). In their second series, they evaluated 42 patients sustaining severe alkali injuries occurring over a 7-year period. The industrial sector contributed 73.8% while the rest were sustained at home.

Certain types of automobile airbags, upon deployment, can release sodium hydroxide as part of the chemically driven rapid inflation process, causing corneal abrasions and mild alkali injuries. Although these cases make up 21.6% of eye injury cases caused by airbags, in most cases they heal readily.[5]

The type of chemical injury can be acidic, alkaline, or toxic. Strong acid injuries include sulfuric, hydrochloric, muriatic, etc. Alkalis causing eye injury include ammonium hydroxide, sodium hydroxide, potassium hydroxide, magnesium hydroxide, and calcium hydroxide. Toxic agents include a huge variety of chemicals which are destructive to biological tissues, but which are not particularly acidic or alkaline. Table 70.1 summarizes the possible source and relevant comments pertaining to the commonest types of acid and alkali injury. Wagoner presents a comprehensive review of chemical injuries.[6]

MAJOR CHEMICAL DIFFERENCES BETWEEN ALKALI, ACID, AND TOXIC INJURIES OF THE EYE

ALKALINE

The pain, lacrimation, and blepharospasm following an ocular alkali injury result from direct injury of free nerve endings located in the epithelium of the cornea, conjunctiva, and eyelids. Ammonium ions penetrate the eye almost instantaneously but a delay of 3 to 5 min occurs after sodium hydroxide.[7] Depending on the severity of the injury, a wave of hydroxyl ions rapidly advance through ocular tissues, causing saponification of cellular membranes with massive cell death and extensive hydrolysis of the corneal matrix consisting of glycosaminoglycans and collagen. Lye injuries (i.e. sodium hydroxide (NaOH), caustic soda, sodium hydrate) occur most often when it is used as a drain cleaner. Potassium hydroxide

Table 70.1 Common causes of chemical injury

Class	Compound	Common Sources and Uses	Comments
Alkali	Ammonia [NH_3]	1. Fertilizers 2. Refrigerants 3. Cleaning agents (7% solution)	1. Combines with water to form NH_4OH fumes 2. Very rapid penetration
	Lye [NaOH]	Drain cleaners	Penetrates almost as rapidly as ammonia
	Potassium hydroxide [KOH]	Caustic potash	Severity similar to that of lye
	Magnesium hydroxide [$Mg(OH)_2$]	Sparklers	Produces combined thermal and alkali injury
	Lime [$Ca(OH)_2$]	1. Plaster 2. Mortar 3. Cement 4. Whitewash	1. Most common cause of chemical injury in workplace 2. Poor penetration 3. Toxicity increased by retained particulate matter
Acid	Sulfuric acid [H_2SO_4]	1. Industrial cleaner 2. Battery acid	1. Combines with water to produce corneal thermal injury 2. May have associated foreign body or laceration from battery acid
	Sulfurous acid [H_2SO_3]	1. Formed from sulfur dioxide (SO_2) by combination with corneal water 2. Fruit and vegetable preservative 3. Bleach 4. Refrigerant	Penetrates more easily than other acids
	Hydrofluoric acid [HF]	1. Glass polishing 2. Glass frosting 3. Mineral refining 4. Gasoline alkylation 5. Silicone production	1. Penetrates easily 2. Produces severe injury
	Acetic acid [CH_3COOH]	1. Vinegar—4–10% 2. Essence of vinegar—80% 3. Glacial acetic acid—90%	1. Mild injury with less than 10% concentration 2. Severe injury with higher concentration
	Chromic acid [Cr_2O_3]	Used in the chrome plating industry	Chronic exposure produces chronic conjunctivitis with brown discoloration
	Hydrochloric acid [HCl]	Used as a 32–38% solution	Severe injury only with high concentration and prolonged exposure

Adapted from McCulley JP. Chemical injuries. In: Smolin G, Thoft RA, eds. The Cornea: Scientific Foundations and Clinical Practice. 2nd edn. Boston: Little Brown; 1987.

(KOH, caustic potash) and magnesium hydroxide ($Mg(OH)_2$) are encountered infrequently as causes of chemical injuries of the eye. Magnesium hydroxide is found in sparklers and flares; the combination of thermal and chemical injury accounts for more severe injury.

Lime ($Ca(OH)_2$), fresh lime, quicklime ($CaO + H_2O = Ca(OH)_2$), calcium hydrate, slaked lime, hydrated lime, plaster, mortar, cement, and whitewash are some of the more commonly encountered substances producing ocular burns.

ACIDIC

Weak acidic compounds on contact with the outer eye precipitate proteins within the corneal and conjunctival epithelium, thus acting as a partial barrier to further ingress of the chemical. In its wake is left a grayish white epithelium, which often obscures all tissues, posterior to it. Stripping off this opacified epithelial layer often reveals an underlying clear corneal stroma. As long as the corneal stem cells ringing the cornea are not damaged

then epithelial recovery is likely with relatively little or no stromal cloudiness.

Very strong acids, however, overcome this precipitated proteineous obstacle handily and progress through tissue much as alkali. The end result of a very severe acidic injury is often indistinguishable from that of an alkaline injury. For that reason this chapter will deal with alkaline and acid injuries as one, unless otherwise specified.

TOXIC

Hydrofluoric acid, used for centuries in industry, has found a new use in the semiconductor industry where it is essential technology in the manufacture of silicon chips for computers and other devices controlled by digital technology. It is so highly toxic that as little as 7 mL, or 2.5% burn of the body is sufficient to cause death from uncontrolled hypocalcemia.[8]

For the subgroup comprising mustard gas injuries occurring during military campaigns, the reader is referred to a comprehensive review.[9]

NATURAL CLINICAL HISTORY

The immediate pain, lacrimation, and blepharospasm following an ocular alkali injury result from direct stimulation and destruction of pain receptor nerve endings located in the epithelium of the cornea, conjunctiva, and eyelids. Pain is also associated with severe burns of cornea and sclera where there is a sudden, spiking rise in the intraocular pressure, lasting about 10 min, caused primarily by shrinkage of the collagenous envelope of the eye. A more prolonged rise in pressure quickly follows, secondary to prostaglandin release.[10] Strong alkali rapidly penetrates into the eye and remains unneutralized, overcoming the poor buffering capacity of the aqueous humor and anterior segment tissues. In much less than 1 min the aqueous humor pH rises to greater than 12, causing saponification of plasma membranes with lysis of corneal cells as well as those lining and adjacent to the anterior chamber. The blood–aqueous barrier is destroyed, removing the physiologic cellular pumping mechanisms and releasing necrotic cellular debris into the aqueous humor. A severe fibrinous inflammatory reaction supervenes in the entire anterior segment of the eye.

Glaucoma may ensue from necrotic and inflammatory debris accumulating in the aqueous humor and chamber angle obstructing outflow, later promoting anterior synechial closure, especially inferiorly. The trabeculum and ciliary body might be injured directly by the penetration of alkali through the sclera or by contact with alkalotic aqueous humor percolating through the meshwork. Ocular hypertension, hypotension, or both may occur at different time periods, depending on the predominance of one or more factors. Chemical injury to iris, crystalline lens, and ciliary body may produce mydriasis, cataract, and even phthisis bulbi, respectively. Externally, this inflammatory reaction may be so profound as to lead to extensive symblephara and even ankyloblepharon from the apposition of raw conjunctival surfaces.

WOUND HEALING

Repair of the chemically damaged eye is a complex process unique to each tissue and involving each cellular and extracellular tissue layer, including the eyelids, corneal and conjunctival epithelium, fibroblasts and collagen, endothelium, and all other tissues contiguous to the anterior chamber.

Epithelium

Destruction of the corneal epithelium alone in a mild injury might lead to nebular superficial scarring or to recurrent corneal erosions, resulting from injury to basal lamina and anterior corneal stroma. When the injury to cornea is more intense, but limited to the cornea and leaving the epithelial stem cell population intact, then epithelial healing is likely to proceed unimpeded. On the other hand, a very severe experimental alkali injury of 12 mm in rabbits, which does not destroy the limbal stem cells, showed substantial epithelial adhesion problems leading to persistent epithelial defects.[11,12] In this animal model, epithelial movement initially proceeds at a rate similar to that occurring after an abrasion, but stops at 84 h at the time when the leading epithelial edge loses its adherence to the stroma and then subsequently peels back as a sheet at 96 h. Thereafter a persistent epithelial defect is maintained. It has been suggested that this loss of epithelial adhesion might result from accelerated degradation of the fibronectin surface coating by plasminogen activator, a substance probably secreted in excessive amounts by the basal epithelial cells in the alkali-injured eye.[13] Therefore, in the chemically injured cornea, the presence of a normal corneal stem cell population does not necessarily imply that epithelial healing is assured. In fact, some of these persistent epithelial defects might issue from the consequences of a severely degraded stromal matrix. Clearly, epithelial–stromal interaction plays an important role in the adhesion of epithelium to stroma.

When a portion of the limbal stem cells is destroyed, the remaining stem cell population heals by centrifugal propagation of pluripotential epithelial stem cells around the corneal periphery combined with centripetal ingrowth of transient amplifying and terminally differentiated cells on to the denuded cornea. If the injury destroys the entire limbal palisades of Vogt containing stem cells, then the phenotypic source of corneal epithelium is lost and the cornea remains denuded for months, finally resurfaced by the spread of viable conjunctival epithelial cells over a blanket of vascularized scar tissue (pannus).

Stroma

Healing of the corneal stroma in a timely manner is the key to avoidance of ulceration and perforation of the globe. Two events proceed simultaneously in the repair process: (1) degradation and removal of necrotic debris, and (2) replacement of portions of the fixed cells, collagenous matrix, and glycosaminoglycans. Concentrated alkali strips the cornea of its vital cells and glycosaminoglycans, leaving behind much of the skeletal framework of the collagen in a denatured form. Alkali degradation of cellular and extracellular proteins yields inflammatory mediators, which are chemotactic to neutrophils.[14] At high concentrations, these simple tripeptides, consisting of acetylated or methylated proline–glycine–proline tripeptides, constitute powerful attractive agents, appearing to initiate and promote neutrophilic invasion of the cornea. This might represent one of the signals from the wound inducing the secretion of adhesion molecules from the vascular endothelium (*E*-selectin) and the intravascular leukocytes (L-selection) to incite leukocyte rolling leading to adhesion to the vascular endothelium.

Once neutrophils accumulate, their release of leukotrienes, and in the presence of interleukin-1 alpha and 6, serves to recruit successive waves of inflammatory cells resulting in a downward spiraling cascade of tissue destructive events. These inflammatory

components serve to perpetuate surface inflammation, with continued release of a variety of degradative enzymes including *N*-acetylglucosaminidase and Cathepsin-D into the tissues and tear film. The positive side of neutrophil presence is the finding that they seem to stimulate epithelial proliferation when examined by its proliferative cellular nuclear expression.[15] In this study, neutrophils appear to act as the initiating messenger promoting the process of corneal vascularization.

Alkali injury of collagen also releases a second inflammatory mediator which metabolically stimulates the local neutrophils to undergo a respiratory burst. Prodigious oxygen use by the stimulated neutrophils results in the by-product superoxide radicals, an unstable form of oxygen that is highly destructive of tissues. When the mediator is present in excess there is also extreme stimulation, causing polymorphonuclear leukocyte (PMN) lysis with the release of granules containing a wide variety of enzymes. The release and activation of degrader enzymes from the specific and azurophilic granules of PMNs act to destroy tissue by cleaving proteins and other molecular species. These responses serve to promote dissolution of the remaining degraded corneal stroma, tipping the scales toward corneal ulceration and perforation.

Fibroblasts invading the cornea after severe alkali injuries are immature, with their polysomal systems in disarray. Collagen produced from these cells is underhydroxylated, preventing it from winding into the triple helical structure of normal collagen. These individual strands of amino acids are highly vulnerable to enzymatic lysis. These tissue characteristics are the sine qua non of localized tissue scorbutus.[16] As a result of this ascorbate deficiency, the repair process is faulty, with the destruction–repair equation shifted in the direction of tissue disappearance and hence corneal ulceration. In very severe injuries, fibroblasts invade the cornea slowly or not at all, resulting in rapid conversion of stroma to a necrotic sequestrum.

Endothelium

In mild injuries, penetration of alkali is minimal and the endothelium is undamaged. Moderate injuries probably cause some endothelial cell death but mostly interfere with the pump mechanism, leading to a variable degree of reversible corneal edema. Severe injuries will destroy endothelium, leading to severe corneal thickening. Alternately, the simultaneous loss of glycosaminoglycans, which bind water in the cornea, might result in less significant net gain or loss of thickness during the early stages; only an opaque cornea.

CLASSIFICATION OF ALKALI INJURIES

Understanding and documenting the salient findings in an alkali injury of the eye permit proper classification so that appropriate immediate treatment can be initiated and accurate prognostication adduced. Documentation of the following physical data is recommended in the form of a labeled drawing:

1. Epithelial defect: Instill fluorescein and measure the size and draw the shape of the defect. Include any conjunctival epithelial defects, especially as they relate to the perilimbal conjunctiva (stem cells).
2. Stromal opacity: Gradations are made on the basis of a penlight examination. Grade 0 represents clear cornea; grade 1, mild corneal haze; grade 2, mild to moderate opacity; grade 3, moderate opacity; grade 4, moderate to severe opacity, in which details of iris trabeculae cannot be seen but the pupil is visible; grade 5, severe corneal opacity, in which the pupil is not visible with a penlight.
3. Perilimbal ischemia: Document the clock hours at which the conjunctiva is whitened. In these areas, the conjunctiva and episclera are devoid of blood vessels. This whitening is not to be confused with less severe injury in which there is chemosis and thrombosed blood vessels but the conjunctiva is still pink.
4. Adnexa: The blinking pattern, exposure, or lagophthalmos should be measured and documented.

These measurements and findings can then be applied to the classification of alkali injuries as described by Hughes[17] and modified by Pfister and Koski[18] (Figs 70.1–70.5). This classification, with accompanying drawings, represents the span of damage encountered after alkali injury. The accuracy of early assessment becomes very important in subsequent evaluation and treatment plans.

Regarding terminology, the literature is replete with allusions to alkali burns, potentially confusing the alkali injury terminology with a thermal component that might or might not exist. This

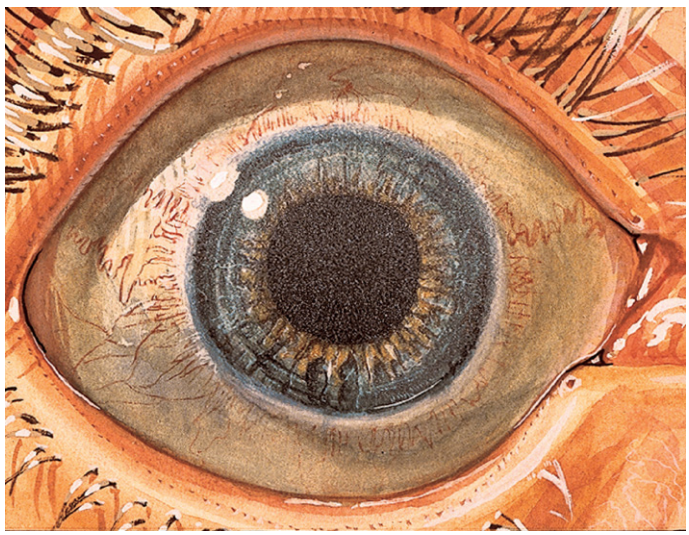

Figure 70.1. Classification of alkali-burned eyes—mild (1-a): Corneal epithelial erosion, faint anterior stromal haziness, no ischemic necrosis of perilimbal conjunctiva and sclera. Prognosis: healing with little or no corneal scarring; visual loss usually no greater than one or two lines.

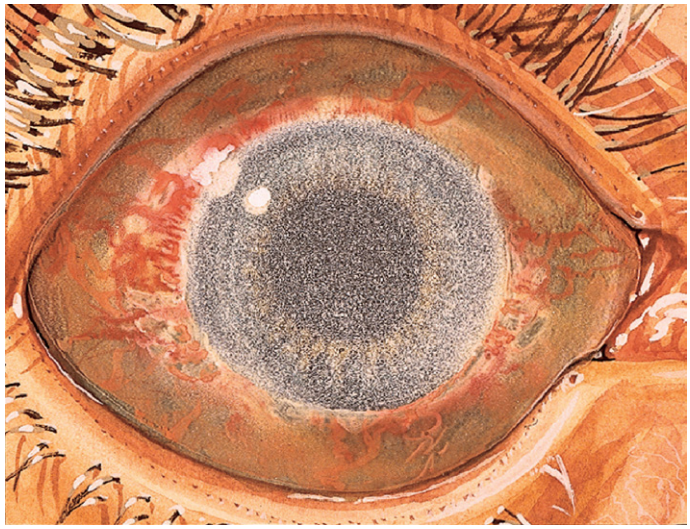

Figure 70.2. Classification of alkali-burned eyes—moderate (1-b): Moderate corneal opacity, little or no significant ischemic necrosis of perilimbal conjunctiva. Prognosis: slow healing of epithelium with moderate scarring, peripheral corneal vascularization, and visual loss of two to seven lines.

Figure 70.3. Classification of alkali-burned eyes—moderate to severe (1-c): Corneal opacity blurring iris details, ischemic necrosis of conjunctiva limited to less than one-third of perilimbal conjunctiva. Prognosis: prolonged corneal healing with significant corneal vascularization and scarring; vision usually limited to 20/200 or less.

Figure 70.4. Classification of alkali-burned eyes—severe (1-d): Blurring of papillary outline, ischemia of approximately one-third to two-thirds of perilimbal conjunctiva, cornea often marbleized. Prognosis: very prolonged corneal healing with inflammation and high incidence of corneal ulceration and perforation. In the best cases, severe corneal vascularization and scarring with counting-fingers vision.

Figure 70.5. Classification of alkali-burned eyes—very severe (1-e): Pupil not visible; more than two-thirds ischemia of perilimbal conjunctiva, cornea often marbleized. Prognosis: very prolonged corneal healing with inflammation and high incidence of corneal ulceration and perforation. In the best cases, severe corneal vascularization and scarring with counting-fingers vision. (Courtesy Pfister R, Koski J. The pathophysiology and treatment of the alkali burned eye. South Med J 1982; 75: 417–422.)

chapter designates alkali injury or acid injury of the eye to distinguish chemical from true thermal burns. When both injuries occur simultaneously, then alkali–thermal injury or thermal–alkali injury might be used, with what is thought to be the most prominent injurious agent stated first. Acid injuries should be referred to in a similar way.

EMERGENCY TREATMENT

The harm caused by alkali injury is predicated on the concentration of the cation, the duration of exposure, and the pH of the solution. To remove the source of the caustic agent from the external eye, immediate irrigation of the eye at the scene of the accident and for 1–2 h thereafter is mandatory. Using this technique alone to reduce the alkali concentration in the corneal stroma and aqueous humor after a severe alkali injury is open to question. Studies on the effect of 90 min of external irrigation on intraocular pH in an animal model of a severe alkali injury has shown only a 1.5 pH unit reduction of the elevated pH.[19] It is necessary to lavage the external eye, but relatively little progress can be made to end the intraocular cauterization by alkali using this technique alone. However, in a noncontrolled clinical study copious irrigation of 49 eyes with milder alkali injuries resulted in grade 1 injury, while no irrigation of 17 eyes resulted in grade 2 injury.[20] Removal of the aqueous by paracentesis lowers the pH by 1.5 pH units. Reformation of the aqueous humor with buffered phosphate solution lowers the pH by an additional 1.5 pH units. It is premature to suggest that all severe alkali injuries should undergo paracentesis. However, in the absence of strict scientific information, it is reasonable to suggest that, in severe injuries occurring 1–2 h previously, paracentesis and removal of an aliquot of aqueous humor be performed when facilities permit. This approach can be accomplished at the slit lamp or in the minor operating room suite. Under topical anesthesia, a razor blade fragment or commercially available super-sharp blade can create a partial-thickness, self-sealing tunnel at the limbus down which a 25-gauge needle is inserted, finally penetrating into the anterior chamber. If available, it is preferable to replace the aqueous humor with a buffered phosphate solution or balanced salt solution to reduce the intraocular pH to near normal levels.

Several chemical injuries require special treatment. For example, the pultaceous character of lime used in cement compounds clings to the conjunctiva. The bulk of material can be removed with a cotton-tipped applicator, but the sticky paste in contact with the conjunctiva can be released from the tissue with greater ease by irrigation with a solution of ethylenediamine tetraacetic acid (EDTA) 0.01 mg/mL. Removal of this alkaline paste or powder from the cul-de-sacs is mandatory.

The intraocular pressure rise after alkali injury can usually be treated by topical α- or β-blockers topically and/or systemically administered carbonic anhydrase inhibitors. If the pressure is extremely high and/or fails to respond, temporary control can be achieved by paracentesis at the limbus, under topical anesthesia, followed by periodic release of aqueous humor through a beveled incision made at the slit lamp or in the minor surgical suite. This approach also releases debris from the eye and buys time in the initial phases until the pressure dissipates spontaneously or glaucoma medications gain control of the intraocular pressure.

The presence of necrotic tissue in the external eye gives rise to inflammatory mediators, attracting PMN into the damaged cornea and stimulating release of the full range of PMN enzyme and metabolic products destructive to even the remaining normal tissues. To avert some of these devastating consequences, careful excision of necrotic tissues might be carried out early to reduce the mediator load encouraging this process.

Eyelid function must be assessed after alkali injury since it is critical to the healing process in the cornea. The greater the failure of lid function the more likely corneal healing will be incomplete. Chronic ocular exposure and/or trichiasis will usually worsen the ocular prognosis by encouraging the development of persistent epithelial defects. The consequence of these defects can be ulceration and perforation of the globe. Attention to lid malfunction might be as minimal as the use of ointment or more aggressively with a plastic bubble or wrap to minimize air exposure.

Alkali destruction of conjunctival epithelium, in combination with the inflammatory response, causes fibrinous adhesions which must be opened periodically under topical anesthesia. When extensive damage of conjunctiva has occurred, fibrous proliferation in the subconjunctival tissues shrinks the linear surface of conjunctiva and promotes the formation of symblephara, particularly by contact between the raw surfaces of naturally apposed conjunctiva. In the most severe cases, the eyelids become scarred to the globe (ankyloblepharon), either permanently closing the eye or causing the exposed cornea to dry, with resulting epithelial defects, leading to further PMN infiltration, ulceration, and eventually perforation.

Prophylactic approaches to maintain eyelid mobility and limit conjunctival and fornical contracture might be helpful but are of unproven value. These approaches consist of lining the palpebral conjunctiva with a thin plastic wrap, which is secured by sutures passing through the upper and lower fornices. When lid mobility has already been compromised by scarring, surgical incisions to recreate tissue planes can seldom be covered by rearrangement of existing conjunctiva. Coverage of these raw areas with mucus membrane obtained from the mouth might have a better chance of remaining open. Amniotic membrane has been found to have powerful anti-inflammatory properties and a suitable substrate for epithelial expansion on to the conjunctival surface and improving eyelid function. When total ankyloblepharon is present, any known effort to reconstitute a semblance of the natural conjunctival environment, for the purpose of preparation for corneal transplantation, is very likely to be unsuccessful.

Pain management during this stage of the disease is not complicated. The pain at the time of injury can be excruciating, but usually short-lived. Pain receptors are destroyed by the alkali; hence, they do not continue to transmit a pain response. When necessary, pain control might be required for several days; rarely greater than 1 week. Photophobia can, however, be extreme, creating a painful environment that can be improved only with UV protective dark wraparound sunglasses, or occasionally complete exclusion of ambient light.

TRANSITIONAL STAGE TREATMENT

The transitional stage treatment of the alkali-injured eye begins as early as 1 to 2 weeks in milder injuries and as late as 1 to 2 months in more severe cases. Problems such as epithelial defects, inflammation and ulceration, glaucoma, symblephara, and eyelid dysfunction might appear or continue from the acute stage through the subacute to the chronic stage imperceptibly and without interruption.

Epithelium

The healing of a corneal epithelial defect after alkali injury is largely predicated upon the severity of the injury and the extent of perilimbal injury. Part of the significance of perilimbal injury is the finding that the stem cell phenotype for corneal epithelial cells resides deep within a narrow band of cells located on, and partially straddling, the limbus. Loss of some portion of the stem cells requires that corneal epithelium be repopulated from the geographically distant remaining stem cells. If all corneal stem cells have been destroyed, then corneal re-epithelialization proceeds from the viable edge of the conjunctival epithelium with cells phenotypic for conjunctiva. If the conjunctival stem cells, located in the fornices, are also destroyed, then extensive symblephara are likely, including ankyloblepharon. At this time, there are no data regarding conjunctival stem cell replacement.

The formulation and frequency of applied medications used during this period can be toxic to fresh epithelium covering the alkali-injured cornea. Preservatives such a benzylalkonium chloride and ointments, especially those containing lanolin, can perpetuate or create epithelial defects. It is wise to avoid topical treatment with multiple medications in the hope of preventing corneal ulceration when there is no clear-cut indication to do so. At most, initial treatment with an antibiotic four times a day and a mydriatic and cycloplegic twice a day is indicated.

Inflammation and corneal ulceration

Alkali injury of the cornea has been shown to trigger the release of inflammatory mediators, which are believed to be responsible for chemoattraction and subsequent activation of PMNs within the corneal stroma. The density of the PMN infiltrate appears to be directly related to the severity of the injury and to the likelihood of subsequent ulceration. Although all cells of the cornea have been shown to be capable of releasing a broad spectrum of enzymes destructive of collagen and glycosaminoglycans, the presence of enormous numbers of PMNs and absence of any other cells in significant numbers point to PMNs and their products as the major cellular elements causally related to ulceration.

Historically, treatment of ulcers resulting from alkali injuries has been directed at inhibition of collagenase production by PMNs and corneal cells. Although controversy still exists, acetylcysteine, L-cysteine, and EDTA all have been reported to inhibit mammalian collagenase in vitro and significantly reduce the incidence of ulceration in animal corneas after alkali injuries. In contrast, one study in extreme alkali-injured animal eyes showed no favorable effect of acetylcysteine when compared to control eyes (81% versus 75%).[21] In an open clinical study, L-cysteine (0.2 mg solution) was begun on the seventh day after a 'total' alkali injury in 33 human eyes and only one perforated eye.[22] An alkali injury study including 28 human eyes substantiated the favorable effect of L-cysteine in the acute stage, in the presence of an ulcer, and before or after corneal transplantation. In 35 patients with corneal ulceration (diseases unspecified) treated with 0.2 mg EDTA, 86% healed or remained unchanged compared to 46% of the 26 control eyes.[23] Cysteine and acetylcysteine are both effective inhibitors of collagenase, but the latter has the advantage of greater stability and ready availability in the marketplace. Although it is suspected that acetylcysteine has a favorable effect in some human alkali-injured corneas, this effect has not been proven by clinical trial. If desired, acetylcysteine or L-cysteine drops should commence as soon as possible after the injury.

The use of topical corticosteroids after chemical injury is very controversial. If used for the first 7 days after injury, it may decrease the inflammatory reaction of the entire anterior segment, possibly reducing some of the late side effects, such as glaucoma. If used for longer than 7 days, topical corticosteroids interfere with the repair process and may result in corneal ulceration and perforation. It seems most reasonable to avoid topical corticosteroids if possible, but especially later than 7 to 10 days after the injury.

A surgical emergency arises when a leaking descemetocele or frank perforation supervene. If the perforation is smaller than

1.0 mm in diameter (the ulcer itself is usually much larger) and relatively free of blood vessels, then adhesive closure with isobutylcyanoacrylate is the least invasive and the most effective way of reestablishing the integrity of the eye.[24] A soft contact lens diminishes the discomfort of the adhesive. The adhesive remains in place for 2 to 10 weeks after which it falls off, or is loosened enough to be picked off with jewelers' forceps. Larger corneal ulcerations and perforations require a fresh corneal patch graft to replace tissue lost from ulceration. The ulcer bed and edges are cleaned of epithelium and inflammatory debris. Necrotic tissue is excised from the edges and base to create a viable bed of stroma into which the transplanted tissue is positioned. The donor patch graft is trephined about 0.5 mm larger than the greatest diameter of the recipient bed, trimmed during the suturing procedure to fit the contours of the ulcer bed, and fastened to the edges of the ulcer with interrupted sutures of 10-0 nylon with their knots buried into the stroma.[25]

Glaucoma

Any caustic agent might damage the trabecular meshwork directly, or necrotic and inflammatory debris can clog the outflow channels. Organization of this inflammatory sediment results in fibroproliferation, collagen retraction, and the formation of extensive anterior synechiae, further impeding outflow facility.

Treatment of this type of glaucoma consists mainly of diminishing aqueous production. Oral and topical carbonic anhydrase inhibitors and topical α and β-blockers are the major agents of intraocular pressure control. Prostaglandin-derived drugs are likely to be beneficial but an awareness of a possible stimulation of inflammation must be kept in mind. Severe scarring of the perilimbal conjunctiva and bulbar conjunctiva, combined with foreshortening of the fornices, makes filtration surgery much less successful. Cautious use of wound modifying agents such as mitomycin-C can improve success significantly. If one or more filtration surgeries fail, the use of translimbal intraocular setons, linked to equatorial filtration plates, offers an effective way to syphon aqueous from a severely glaucomatous eye.

VISUAL REHABILITATION

The application of new methods issuing from research has changed the formerly dismal outlook for the chemically injured eye. A substantial degree of success has been achieved by diligent attention to creating an intraocular and extraocular milieu favorable to corneal transplantation. Success in any type of restorative surgery will be governed by (1) lid globe congruity with normal blinking and the absence of corneal exposure; (2) sufficient resurfacing tear film layer to which a transplanted cornea can adapt; (3) the presence of epithelial stem cells phenotypic for cornea; (4) the absence of any inflammation, current ulceration or uncontrolled glaucoma; (5) flawless surgical technique; (6) fresh corneal transplant tissue; and (7) mental stability and cooperation of the patient to withstand occasional setbacks.

Preparatory procedures to lyse symblephara, expand cul-de-sacs, and eliminate lagophthalmos are often required to reestablish normal lid physiology and anatomy. Secondary glaucoma must also be controlled with medications, cyclocryothermy, or filtration surgery. Laser of large feeder vessels at the limbus may be done to control bleeding at the time of surgery.

Alkali-injured eyes and anterior segment necrosis share a similar fate of vascular insufficiency. To improve vascular support of the anterior segment in alkali-injured eyes, Reim and coworkers have popularized excision of necrotic conjunctiva and advancement of viable tenons capsule, the latter obtained by careful dissection to preserve the posterior vascular supply.[26] The procedure, referred to as tenon-plasty, prevented or arrested corneal ulceration in 24 eyes of 21 patients sustaining severe alkali injury.

Amniotic membrane sutured over the injured cornea and conjunctiva has proven to be of immense value in suppressing inflammation and providing a new substrate over which epithelium readily grows. Although amniotic membrane alone is insufficient to maintain an intact epithlelial layer on the cornea devoid of a stem cell source, it is of exceptional value when combined with corneal stem cell transplantation. Its fate after transplantation is unclear, but it is of inestimable value as an immediate prelude to corneal stem cell transplantation. The technique of amniotic membrane transplantation is covered in another chapter.

Replacement of the corneal stem cells lost from disease or injury is a new and exciting surgical procedure.[27,28] If the injury is monocular, then autotransplantation of corneal limbal stem cells from the uninjured eye offers an opportunity to replenish the stem cell supply autogenously. When the injury is bilateral, research by Pfister indicated that allografted limbal tissue was capable of restoring the stem cell population from an unrelated donor. Replacement of the entire cornea and adjacent stem cells by penetrating keratoplasty has been performed successfully and reported in two different series.[29,30] Kukelkorn replaced the entire cornea in sterile ulcerating, alkali-injured eyes, preserving an intact epithelium and absence of ulceration over a 1-year period. Redbrake reported nine eyes operated this way, preserving the epithelium but only maintaining clarity in two. Nevertheless, under the circumstances, these results should be considered a successful outcome. One potential danger might be that such large transplants might interfere with the trabecular outflow channels and hence increase the likelihood of glaucoma. The use of a 12 or 13 mm lamellar corneal transplant, including the limbal epithelial stem cell population, managed to restore the epithelial integrity, without complications, in an average of 5.2 days.[31] The latter approach, performed an average of 29.5 months after injury, might gain all the advantages of replacement of the cornea and associated stem cells but reduce the chance of consequent glaucoma. An alternative approach in the case of deep corneal ulceration, descemetocele or frank corneal perforation would be to suture a piece of cornea into the ulcerated bed to reestablish integrity of the globe.

The optimal medical and surgical conditions necessary to promote allografted corneal stem cell growth and to protect them from the immune process are currently in discovery. It is clear, however, that immunosuppression, of some type, is required to sustain the vitality of these allografted tissues. As an adjunct, amniotic membrane stretched over the alkali-injured cornea has proved to be useful when transplanting corneal stem cells by replacing the abnormal surface of the cornea with a new surface tending to quiet the inflammatory process.[32,33] Amniotic membrane alone does not substitute for corneal stem cells in a severe alkali injury where there is a stem cell deficiency or loss. The advent of in vitro techniques to culture and expand corneal stem cells might soon provide a new and immunologically more suitable source of corneal stem cells.[34]

If corneal surgery is delayed 18 months to 2 years after a chemical burn, it increases the chances of success, especially in the absence of preexisting ulceration, perforation, or glaucoma.[35] Corneal surgery is indicated for the worst eye in bilateral burns

when serviceable vision is not available. If the injury is monocular, restorative corneal surgery is still an option, given that the overall status is favorable as noted above.

There are some patients with severe monocular injuries in whom a definite need for binocularity does not exist and in whom all presurgical conditions are not met. Corneal transplantation might not be advised in these patients because transplantation in chemically burned eyes is fraught with numerous potential complications.

If it is elected to perform corneal transplantation, it is important to pay meticulous attention to the rigorous protocol of this difficult surgery. A few points of importance will be mentioned. Trephination with a vacuum cutter and a vertical section of the remaining attachments with scissors improves the quality of the wound architecture. If suction cannot be achieved because of surface irregularity, layering a ring of viscoelastic on the cornea usually assists vacuum adherence. Unless bleeding is severe, it is wisest to avoid cautery of wound vessels. Most bleeding can be controlled by absorbing fresh blood from the wound edges with sponges and simple pinching of bleeding vessels with forceps before the wound is fully opened.

When cataract is present, it is usually wisest to remove the cataract at the time of corneal surgery. Cataract surgery should follow modern techniques with special emphasis on the approach to the open eye. If preoperative pressure devices reduce the vitreous volume such that the crystalline lens has no tendency to prolapse forward, then a capsulorrhexis can be performed. Efforts to create a capsulorrhexis in the presence of positive vitreous pressure can result in a radial tear, zonular dehiscence, and possibly vitreous loss. If positive vitreous pressure is noted, a 'can opener' technique should be used. In either case, hydrodissection of the lens usually prolapses the lens nucleus for easy removal. Cortical clean-up with irrigation and aspiration and intracapsular placement of an intraocular lens can then be accomplished. Choice of the intraocular lens should be dictated by haptic design, namely torsional strength, easy collapsibility, and null antero-posterior movement on linear contraction of the haptics. These requirements are met with the Bausch & Lomb model #122 dualens.

The donor cornea should be fresh, with intact epithelium, and cut 0.50 to 0.75 mm larger than the recipient bed. Retraction of the recipient tissue opening requires a larger donor diameter to avoid tension on the wound. Donor tissue is age matched but human leukocyte antigen or blood typing is not usually done for the first transplant. A continuous 10-0 nylon suture may be used if the recipient corneal tissue is sufficiently firm and of near normal thickness. It is occasionally necessary to use interrupted sutures, especially for more extensively vascularized or thin corneas. The knots must be buried to avoid epithelial defects and as a portal for infection. For the same reasons it is critical to remove loose or broken sutures as soon as possible.

If epithelial defects are noted, an assessment of the reasons behind the problem is necessary. Eyelid congruity, exposure keratitis, tear abnormalities, corneal stem cell population, corneal matrix deficiency, and topical drug preservatives can be responsible for initiating and perpetuating persistent epithelial defects of the cornea. In addition to correcting these abnormalities an old but effective concept of using the patients' own serum, applied as topical drops every 3 h, has been revived. Occasionally, a soft contact lens might be fitted for continuous wear on a temporary basis.

In the most severe cases, implantation of a keratoprosthesis might afford the only means by which vision can be restored. Corneas exhibiting exuberant vascularity, repeated failures of freshly transplanted corneal tissue, and the inability to restore normal lid anatomy are potential indications for this procedure. The operation is only advisable in those with severe bilateral injuries in whom serviceable vision is not present in either eye. All currently available devices are investigational and are difficult to implant. A surprising degree of success has been achieved, but this success must be balanced against the sometimes serious and untreatable complications that can occur.[36]

NEW RESEARCH DIRECTIONS

Pathophysiologic understanding of chemical injuries of the eye has been refined by basic biochemical, physiologic, and anatomic studies. This refinement has been driven by the evolution of the disciplines of molecular biology and biochemistry as applied to ocular disease. As a result, ophthalmologists are now able to use orthomolecular approaches to supplement traditional treatment.

EXPERIMENTAL TREATMENT MODALITIES

The ascorbic acid level is depressed to one-third of normal in an animal model of severe alkali injury to the eye. Topical or subcutaneously administered ascorbate (10%) significantly decreases the incidence of corneal ulcerations and perforations if the aqueous humor ascorbate level can be elevated to 15 mg/dL. Light and electron microscopy and radioactive tracer experiments show that the mechanism of action is replenishment of ascorbic acid to the scorbutic fibroblasts of the cornea. Ascorbic acid is a powerful reducing agent required by fibroblasts to synthesize collagen, thereby promoting healing of damaged corneal tissues.

Neutrophils (PMNs) play a central role in corneal ulceration developing as a consequence of alkali injury. Topically applied citrate has been shown to be extremely effective in decreasing the incidence of corneal ulceration after alkali injury of the animal eye.[37] Citrate is a chelator of extracellular calcium; necessary for all activities of the PMNs by acting as an important intracellular second messenger within the cell. Inhibition of the PMNs through calcium depletion may be caused by interference with calcium–calmodulin microfilament or microtubule interfaces in the plasma membrane. Hence, topical treatment with citrate can entirely halt PMN activities. Citrate also inhibits the efferent leg of the inflammatory response by interfering with the adherence of PMNs to vascular endothelium. This effect decreases the migration of PMNs into the damaged cornea, thus diminishing the discharge of hydrolytic enzymes into the corneal stroma.

Ascorbate and citrate reduce the incidence of corneal ulceration in alkali-injured eyes by different mechanisms, accounting for the substantial further reduction in corneal ulceration in alkali-injured animals when these foodstuffs are used together. Corneal ulcers decreased from an untreated incidence of 80% to a transitory 4.6% when citrate and ascorbate eye drops were alternated concurrently throughout the day.[38]

Using the Roper–Hall modification of Hughes classification of alkali injuries, Brodovsky showed that grade III injuries treated with a combination of ascorbate, citrate, and FML attained vision of 20/40 or better in the treated group including 27 of 29 eyes, (93%) compared to 3 of 6 eyes (50%) in the control group.[39] There was also a trend toward shorter hospital stays in the treatment group. Specific topical treatment consisted of 10% ascorbate, 10% citrate and fluoromethalone every 2 h, day and night, and 1% atropine t.

i.d. and chloramphenicol q.i.d. To this was added 500 mg ascorbate q.i.d. and 4 g of a proprietary urinary alkalinizer containing 720 mg of citric acid anhydrous and 620 mg of sodium citrate anhydrous t.i.d. In none of the other groups is there any statistical differences between the treated and control groups.

Other putative treatments to prevent corneal ulceration in severe alkali injury, such as oral tetracycline, subconjunctival progesterone, intramuscular nortestosterone, and thiol dipeptides, have all shown favorable effects in animal models of alkali injuries. However, a clinical trial will be needed before any of these approaches can be considered for routine human use.

OTHER POSSIBLE CHEMICAL THERAPIES

Fibronectin has been implicated as a key element in wound healing for its involvement in cell-to-cell and cell-to-matrix adhesion and cell spreading. Eye trauma causes exudation of large proteins such as fibrinogen from conjunctival blood vessels, reaching the bare basement membrane where polymerization and deposition take place. Epithelial defects occurring in herpetic keratitis, in trophic corneal ulcers, and after cataract surgery have responded to fibronectin drops when used in an open-labeled study. However, albumin eye drops were as effective as fibronectin in the treatment of persistent epithelial defects after alkali injuries in rabbits.[40] This finding suggests a nonspecific response. The determination of the value of fibronectin in persistent epithelial defects again can only be gleaned from a prospective, randomized clinical trial.

Epidermal growth factor enhances the rate of healing and induces hyperplasia in corneal epithelium.[41,42] Epidermal growth factor stimulated complete epithelial healing after alkali injury in two studies, but in each instance recurrent erosions re-established the defect.[43,44] This epithelial proliferation is clearly stimulated by epidermal growth factor, but its usefulness in corneal diseases is unknown.

71 Corneal and scleral ruptures and lacerations*

Constance A. Cox, William J. Dupps, Jr., Geoffrey J. Brent, David M. Meisler

The overall goals of treating the patient with a corneal or scleral rupture or lacerations include: (1) preventing further injury to the eye before surgery; (2) triaging and treating associated injuries; (3) expediting preoperative evaluation and anesthesia clearance, if needed; (4) obtaining infection-control cultures and providing systemic antibiotics, if indicated, as well as tetanus prophylaxis; (5) documenting medical records meticulously; and (6) engaging in comprehensive and honest discussion with the patient and family members.

When a patient with ocular trauma presents, a quick global assessment of the patient's overall condition should be done before a complete ocular examination is performed. Life-threatening trauma must be treated before all else. Additionally, severe pain or nausea should be treated as soon as possible to minimize lid squeezing and Valsalva effects, which could lead to the loss of intraocular contents. If at all possible, surgical consent should be obtained prior to the patient receiving narcotics or other drugs that could affect the sensorium. If it is obvious that the patient has an open or unstable globe, a rigid eyeshield should be secured in place until definitive eye care can be administered. The use of a plastic rather than a metal shield allows it to remain in place during most radiographic imaging studies. Computerized tomography (CT) scanning may be necessary for foreign body assessment; requesting 1 mm cuts through the orbits will increase the sensitivity of the imaging. Gentle, non-contact ultrasound may be useful to verify the integrity of the posterior segment if there is suspicion of posterior globe laceration.

HISTORY AND PHYSICAL EXAMINATION

The mechanism of injury should be determined to assess the likelihood of a retained intraocular or orbital foreign body and to identify its likely composition. For medico-legal reasons, the time of the injury, use of protective eyewear, alcohol and/or drug involvement (especially in the setting of transportation-related injuries), any history of previous eye disease, injury or surgery, and any history of treatment for the present injury should be recorded.[1] Although gross disruption of the globe is obvious, one should always be suspicious of occult injury. Searching for a hidden ocular perforation is essential in the treatment of high-risk injuries involving sharp, slender objects (e.g. darts, ice picks, wire, knives, glass shards, and Taser dart electrodes[2]) or high-speed projectiles produced by machinery or metal-on-metal contact, which can leave small, self-sealing ocular wounds. Air guns are another significant source of injury and account for approximately 1200 ocular injuries per year, predominantly in young males.[3] Lacerations to the eyelids or brow should raise the suspicion of an associated occult perforating eye injury. Relevant history and salient aspects of the examination are summarized in Box 71.1.

RUPTURE IN EYES WITH PREVIOUS OCULAR SURGERY

Any ocular surgery involving a penetrating wound or focal thinning of the corneoscleral shell could increase the risk of rupture or dehiscence at the site of the wound. When a history of the previous surgery is obtained or is suggested by the examination, the ophthalmologist should maintain a high index of suspicion for tissue disruption at the pertinent wound locations. The structural integrity of the globe with prior surgery is affected by the length, location, and shape of the wound, with the longest incisions having the greatest adverse effect, and a 3-mm scleral pocket yielding less disruption of globe structure.[4] Therefore, large limbal wounds associated with extracapsular cataract surgery are a more significant risk factor for traumatic wound dehiscence than the beveled wounds of a small scleral tunnel or small clear corneal incision. In the same setting, shearing forces can lead to pseudophacodonesis, iridodonesis, and corneal edema from endothelial injury.[5]

In the setting of blunt trauma, a rapid increase in intraocular pressure leads to a transient increase in stress throughout the

BOX 71.1 HISTORY AND PHYSICAL SUMMARY OF THE OCULAR TRAUMA PATIENT

I. History

A. Events of current injury

1. Mechanism of injury
2. Activity at time of injury
3. Time elapsed since injury
4. Use of protective equipment/eyewear
5. Previous treatment
6. Time since last food ingestion

B. Ocular history: routine, plus—

1. Previous trauma and surgery
2. Level of visual acuity in involved eye before injury

C. Medical history: routine, plus—

1. Use of anticoagulant medications—especially over-the-counter medications, which often contain aspirin
2. Status of tetanus prophylaxis
3. Any difficulties with previous anesthesia or surgery
4. Recent alcohol or drug use to assess need for delirium tremens prophylaxis

II. Physical examination

A. Visual acuity

1. Best corrected (ideal)
2. Pinhole

B. External assessment

1. Associated life-threatening injuries—consult appropriate personnel
2. Associated orbital and facial injuries—oculoplastic, ear, nose, and throat, neurosurgical or oral-maxillofacial surgeons
3. Gross inspection of involved eye (exerting minimal pressure)
4. Evidence of visible foreign body on adenexa, skin

C. Motility—omit if globe is, or may be, lacerated

D. Confrontational visual fields

E. Pupils—use as dim a light as possible to minimize patient squeezing

1. Relative afferent pupillary defect (RAPD)—if efferent abnormality is present in injured eye, RAPD assessed by observing the unaffected eye's consensual response during illumination of the injured eye
2. Distortion/peaking toward limbus?

F. Slit-lamp examination: routine, plus—

1. Presence of conjunctival laceration/hemorrhage—risk of underlying scleral laceration or foreign body
2. Scleral laceration
3. Corneal laceration or foreign body
4. Presence of extruded intraocular contents
5. Seidel test, if indicated
6. Gonioscopy to look for anterior chamber foreign body and angle damage ONLY if globe is intact
7. Note iris irregularities
8. Iridodenesis, phacodonesis or pseudophacodonesis
9. Intraocular pressure ONLY if globe is intact

G. Dilated fundus examination: routine, plus—

1. Rule out vitreous hemorrhage, intraocular foreign body
2. Retinal dialysis, tears, detachments, commotion
3. Choroidal or scleral rupture
4. Optic nerve head edema, avulsion
5. Depressed examination ONLY if globe is intact and no hyphema

H. Additional testing

1. Ultrasound—noncontact or GENTLE pressure
2. Imaging study—computed tomography is safest in the acute setting
3. Preoperative testing as indicated

corneoscleral shell. Wherever stress is more highly concentrated, a marked increase in risk of mechanical failure exists. Wound strength is only partially restored by the wound healing process and a focal deficit in wound integrity presents a lifetime risk for future dehiscence.[6]

For the same reasons, the wound of a full-thickness penetrating keratoplasty presents a considerable risk of dehiscence with blunt trauma.[7] In one case series, wound dehiscence occurred with inanimate objects, a fist, eyeglasses, fingers, eye rubbing, accidental fall, an eye-drop bottle, and unknown causes.[7] This risk is likely compounded by inhomogeneous healing of the graft–host junction, which leads to the development of focal areas of weakness prone to dehiscence at lower pressure loads than other regions.[8]

Ocular rupture due to blunt trauma after refractive surgery has been reported, but the risk relative to nonoperated eyes has not been well characterized in vivo. In eyes with a history of prior incisional refractive surgery, rupture most frequently occurs at an incisional site.[9,10] Ex vivo studies of excimer laser photorefractive keratectomy (PRK) and phototherapeutic keratectomy (PTK) suggest that myopic PRK, up to 10 D, does not significantly affect ocular integrity.[10] However, a lower bursting strength with rupture occurring at the edge of the ablation zone was observed with PTK ablations greater than 40% of central corneal thickness.[10]

PATIENT COUNSELING AND PROGNOSIS

Frank counseling of the patient and family before surgical repair regarding the extent of the injuries and the prognosis for visual recovery is time well spent. Ensuring that all involved have realistic goals and expectations eases future discussions about visual potential, the need for additional surgeries, and the possibility of enucleation. From a medico-legal perspective, this is critical. The clinician should approach these discussions with honesty and 'guarded optimism', if appropriate, but must stress that the full extent of the injury often cannot be discerned until the time of surgery, and that the primary goal is to save the eye. Restoring vision is an important but secondary goal. By taking time to answer questions, the clinician can assess the patient's level of understanding of these essential issues and can clarify areas of misunderstanding as time allows.

The National Eye Trauma System Registry recorded data from 48 centers in 28 states from 2939 patients over 6 years (1985–1991) and found the majority of injuries occurred in the home (28%) and involved males (83%) under the age of 40 (78%). Projectiles accounted for 40% of penetrating injuries overall, with 24% arising from sharp objects (most commonly metal, glass, and plastic) and 19% from blunt objects. Alcohol use was identified as a significant risk factor for injury, and non-polycarbonate lenses were found to add to the injury in some cases. The majority of cases involved the anterior segment with or without posterior segment involvement, and 21% of patients ended up with 'no light perception' vision.[1] A realistic picture should be painted regarding the guarded prospect of good visual outcome.

Advances in microsurgical techniques have improved the overall visual prognosis in penetrating ocular trauma, but in many cases the guarded prognosis for useful vision and/or saving the eye persists. On presentation, factors that are associated with a 'better' prognosis include visual acuity of count fingers or better, isolated corneal lacerations (less than 8 mm), absence of vitreous or uveal prolapse, and absence of vitreous hemorrhage.[11,12] Vitreous hemorrhage in children may resolve quickly without surgical intervention.[13] Therefore, it may be prudent to observe vitreous hemorrhage in children for a time before proceeding to surgery. There is a slightly better prognosis with penetrating injury caused by a sharp object than with disruption of the globe resulting from blunt injury.[12]

NONSURGICAL MANAGEMENT

Corneal injuries should be examined carefully at the slit lamp for evidence of ocular penetration. Under high magnification, one should scrutinize the integrity of Descemet's membrane and look for evidence of microtrauma to the lens capsule and iris. A Seidel test should be performed by painting the injured surface with fluorescein-impregnated strips to look for any leak of aqueous fluid. If no obvious leak is seen, gentle pressure should be applied through the upper or lower eyelid to reveal any self-sealing injury or 'slow' leaks. The treatment principles for self-sealing or partial-thickness wounds are (1) to stabilize the wound to promote healing and (2) to prevent infection.

A simple partial-thickness corneal wound that maintains good tissue approximation may be managed medically with a broad-spectrum antibiotic ointment or drop. Cycloplegic drops may provide comfort. A self-sealing puncture wound or short laceration may be treated by applying a bandage soft contact lens. With a small corneal laceration (2 or 3 mm) that maintains good tissue approximation and a formed anterior chamber, a bandage contact lens (in conjunction with a topical antibiotic) may be effective in splinting the wound, thus obviating the need for sutures. A slightly thicker soft contact lens provides more corneal support. The patient must be followed closely to monitor for infection and ensure that the anterior chamber remains formed.

For small lacerations, puncture wounds, wounds with minimal tissue loss, or wounds with slow but persistent aqueous leakage, cyanoacrylate tissue adhesive may be useful. The tissue bed must be dry and free of epithelial cells at the time of adhesive application. A thin film of adhesive is applied using a small-gauge disposable needle, a microcapillary applicator, or the broken wooden end of a sterile cotton-tipped applicator. Alternatively, a drop of adhesive can be placed in the center of a cut-out piece of sterile plastic surgical drape that is placed on the wound as a 'patch'. Following the application, adhesive should be given several minutes to dry before any further manipulation is performed. A bandage contact lens is fitted to keep the adhesive from prematurely dislodging and to minimize irritation to the tarsal conjunctiva. The adhesive dislodges on its own as re-epithelialization occurs. While the contact lens remains in place, prophylactic antibiotic drops and a cycloplegic agent are recommended; a topical nonsteroidal anti-inflammatory drop may prove helpful for increasing patient comfort for the short term. Prolonged use of topical nonsteroidal anti-inflammatory drops should be avoided due to their propensity for a corneal melt. In poorly cooperative patients (e.g. children, demented, or intellectually impaired) or in those with questionable compliance, a definitive surgical closure may be more appropriate.

If there is evidence of ocular penetration, even in the presence of a self-sealing wound, the patient is at increased risk for developing endophthalmitis. Such patients require close observation; treatment with intravenous antibiotics may be considered, although the efficacy of this approach remains unproved. Children should be followed closely for the development of amblyopia.

SURGICAL MANAGEMENT

FORMATION OF A SURGICAL THERAPEUTIC STRATEGY

The ophthalmologist must integrate information gathered in the history and physical examination and prepare a rational approach to repair of the traumatized ocular tissue. The goals of ocular trauma repair are to (1) restore the integrity of the globe, (2) restore normal anatomic relationships, and (3) minimize the risk of complications either at the time of initial surgery or during subsequent surgical procedures. These goals are oriented toward preserving the eye and restoring useful vision. To this end, the ophthalmologist must reform a watertight globe, remove any disrupted lens fragments and/or vitreous, reposition viable uvea, excise necrotic uvea, and remove any intraocular foreign body.

General anesthesia is preferred for a patient with a ruptured globe because any peribulbar or retrobulbar injections would increase orbital pressure, which could lead to further loss of intraocular contents. A nondepolarizing muscle relaxant such as vecuronium prevents the associated increase in intraocular pressure that is caused by contraction of the extraocular muscles, thereby decreasing the risk of expulsion of intraocular contents. In a patient with extensive facial trauma and a difficult airway, succinylcholine may be appropriate.[14] The eye then is prepped carefully—with as little pressure on the globe as possible. Direct topical exposure of betadine solution to an obviously open wound is to be avoided. Exposure can be obtained by carefully inserting a lid speculum that exerts minimal pressure on the globe, by passing 4-0 silk traction sutures through the tarsus of the upper and lower lids, or by using Steri-Strips to retract the lids to the cheek and to the brow. All movements and manipulations of the globe should be performed in such a way so as to avoid undue pressure on the globe, at least until a watertight closure is achieved, thus reducing the risk of additional prolapse of intraocular contents.

SIMPLE CORNEAL LACERATIONS

The traditional teaching regarding wound closure is to align first the limbus and any angled aspects of the laceration. Any pigmented lesions or scars also can be used to aid in alignment. The remaining wound(s) then are bisected continually using successive suture bites. This method assures that the lateral aspects of the wound return to their original relationship, thus providing a straightforward approach to the restoration of normal anatomic relationships and ensuring a watertight closure.

Some basic keratorefractive principles can be applied in the initial repair to minimize distortion of corneal topography. The cornea tends to flatten over any laceration or sutured wound (Fig. 71.1), and lacerations that are longer or closer to the visual axis induce greater flattening.[15,16] To counteract these effects, large compressive sutures are used to close the peripheral aspects of the corneal laceration, which flattens the peripheral cornea and steepens the central cornea (Fig. 71.2). The central aspect of the laceration then is closed using smaller and looser suture bites to approximate wound edges without causing excessive distortion. To aid accurate wound closure, a temporary suture may be placed that bisects the length of the wound to minimize lateral displacement of wound edges during closure. Sutures across the visual axis may be required to achieve adequate closure—the surgeon's first priority—but are avoided if possible due to the risk of visually significant fibrosis.

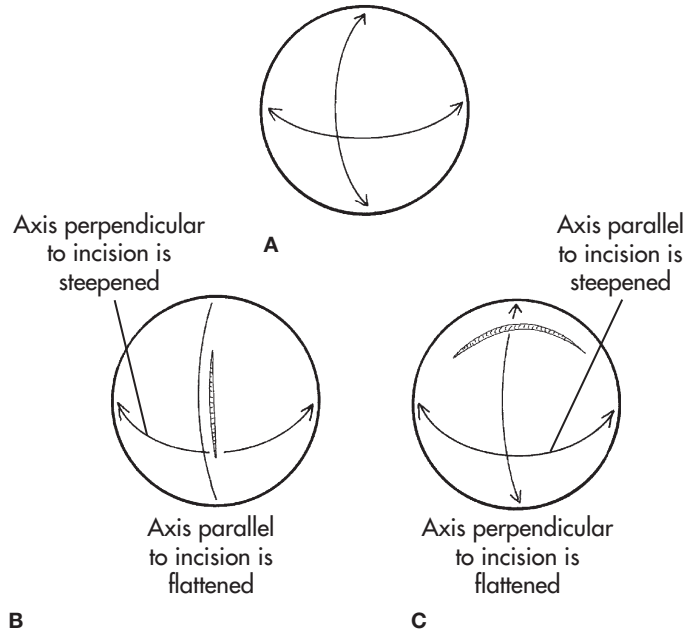

Figure 71.1. *A*, Normal symmetric (astigmatic) cornea radii of curvature. *B*, Effect of a radial incision on axes perpendicular and parallel to the incision. *C*, Effect of a circumferential incision on axes parallel and perpendicular to the incision.

Certain high-risk, full-thickness, self-sealing wounds that involve longer lacerations (>3 or 4 mm) and wounds occurring in uncooperative patients are managed best by primary surgical closure. In cases of a self-sealing wound that maintains a formed anterior chamber, the wound may be closed directly with minimal manipulation to avoid distortion of the wound. Gentle fixation of the sclera at the limbus is attempted using a toothed forceps (Fig. 71.3). A one-handed technique then is used to pass the corneal sutures. The needle is directed into the cornea at a 90° angle and is passed through the stroma following the curve of the needle. This technique avoids manipulation of the wound edge, thereby minimizing leakage of aqueous fluid and keeping the anterior chamber formed. This minimal touch technique also is advantageous when suturing is done near the visual axis as it minimizes iatrogenic tissue trauma from fixation forceps.

In general, monofilament suture (nylon or polypropylene) should be selected: 10-0 suture for clear cornea and 9-0 suture near the limbus. One should consider using 11-0 suture near or in the visual axis to help minimize scarring. A spatulated needle is preferred because it facilitates the maintenance of suture passes at partial stromal thickness. Suture passes should be approximately 1.5 to 2.0 mm total in length. Slightly longer passes may be needed if the wound margin is edematous or macerated, to ensure the incorporation of healthy tissue by the suture. The suture should be approximately 85 to 95% of stromal thickness, incorporating an equal depth of tissue on each side of the wound. Sutures that are too shallow allow the internal aspect of the wound to gape, and sutures that are too deep (full thickness) may act as a conduit, enabling microorganisms or epithelial cells to enter the eye and aqueous to leak out. Suture bites should be oriented perpendicularly to the path of the wound. Obliquely placed sutures exert a shearing force along the length of the wound that can lead to lateral displacement of the wound margins.

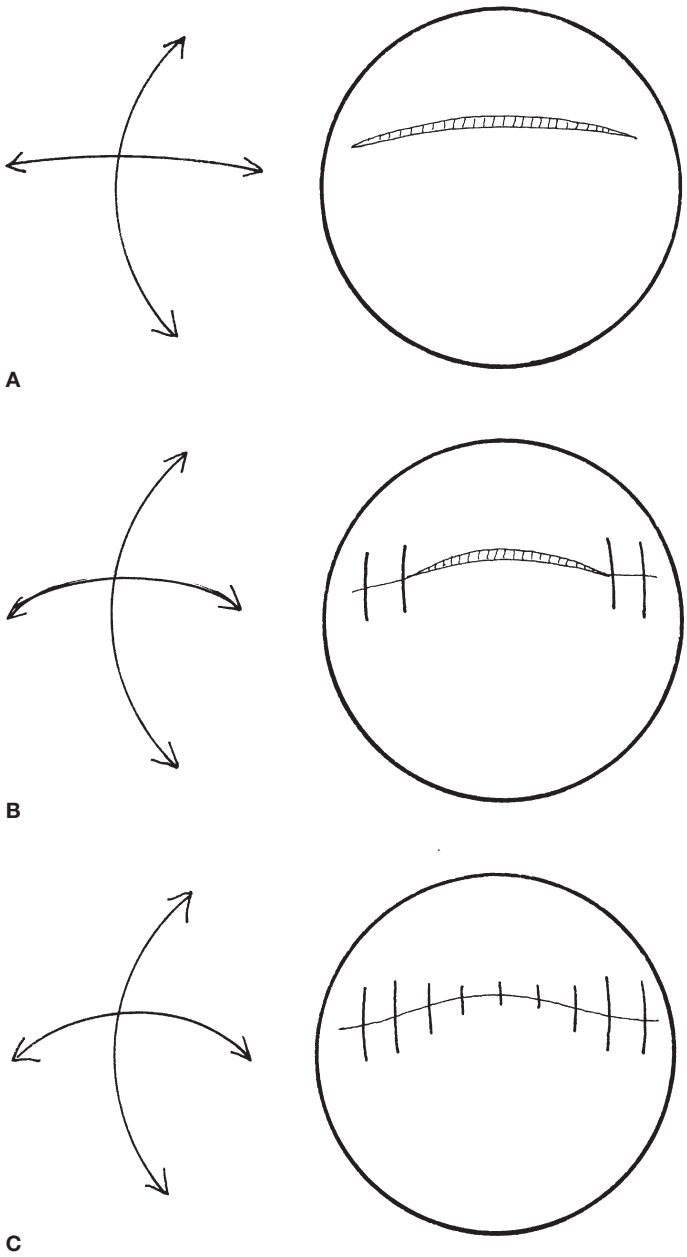

Figure 71.2. *A*, Cornea flattened in axis perpendicular to the laceration. *B*, Longer peripheral compression sutures act to steepen the central curvature. *C*, Shorter central sutures reappose the cornea while limiting flattening.

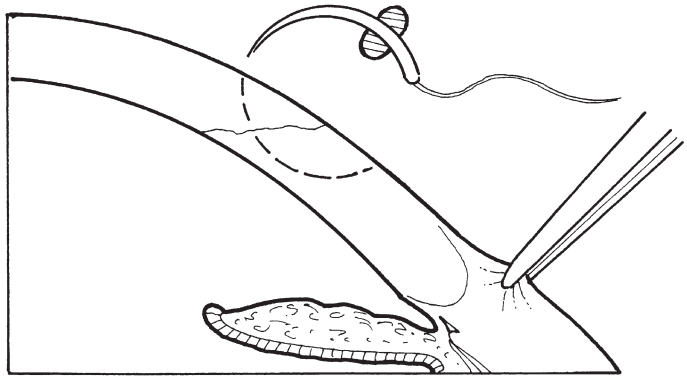

Figure 71.3. Demonstrates minimal touch of the needle and suture to avoid disruption of self-sealing corneal wound.

A running suture may allow for normalization of suture tension across a wound, which may decrease induced astigmatism; however, unless the wound is perfectly straight, it can cause lateral displacement of the wound margins, leading to irregular closure and wound gape. Closure with a running stitch places the integrity of the entire wound on a single suture and knot, which may pose a safety risk. The use of simple interrupted sutures facilitates a more anatomic repair and simplifies both postoperative management of loose sutures and selective suture removal.

A simple suture exerts a zone of tissue compression along the axis of the wound that is approximately the same length as the suture. These compression zones must just overlap for a watertight repair to be constructed. Longer suture bites allow a greater distance between sutures, and smaller bites require more closely spaced sutures. Excessive overlap of compression zones can lead to excessive scarring and tissue flattening.

Suture knots should be tied with either slipknots or square knots (3-1-1 or 2-1-1 throws), and the loose ends cut short with suture scissors or a sharp blade. The knots then should be buried away from the visual axis, and the cut suture ends should be directed away from the corneal surface to facilitate future suture removal.

The architecture of a beveled corneal laceration or incision provides it with a self-sealing mechanism (the basis for shelved cataract incisions, Fig. 71.4). A full-thickness, perpendicularly oriented laceration or incision is prone to leak because any pressure (interior or exterior) serves to displace the wound edges. Therefore, all perpendicular aspects of the laceration should be repaired first to allow a more rapid watertight closure, thus facilitating reformation of the anterior chamber. Passage of temporary sutures may be needed to form a watertight closure, which allows the anterior chamber to be reformed and better-placed 'permanent' sutures.

It is often difficult to obtain a watertight closure with stellate corneal lacerations, especially when they involve tissue avulsion. When there is no tissue loss and the apices are well formed, simple suture closure with the aid of bridging sutures may be helpful. With tissue loss, or apices that approximate poorly, the purse-string technique proposed by Eisner[17] may provide closure (Fig. 71.5). A diamond blade set at half stromal thickness is used to make a small incision in the normal cornea between the base and the apex of each pedicle. A continuous 10-0 nylon suture is passed from incision to incision in a purse-string fashion and is tied. The knot is buried. If there is persistent leakage from the wound, tissue adhesive and a bandage soft contact lens may be used. A conjunctival flap does not stop a persistent corneal wound leak, and it obscures the view of the anterior chamber, making follow-up more difficult. Additionally, conjunctival flaps are visually and cosmetically inferior to direct surgical repair.

If an avulsed piece of corneal tissue is present, it should be sutured back into place. The apices of the avulsed tissue should be secured first, and then additional sutures should be added as needed to reapproximate the wound.

A flat or shallow anterior chamber must be reformed with balanced salt solution, an air bubble, or a viscoelastic. Balanced salt solution or air should be tried first because, if it adequately maintains the chamber, viscoelastics can be avoided. Viscoelastics can complicate matters by mimicking vitreous, thus making tissue and suture manipulation more difficult, and they require removal from the eye to prevent intraocular pressure spikes. The chamber may be

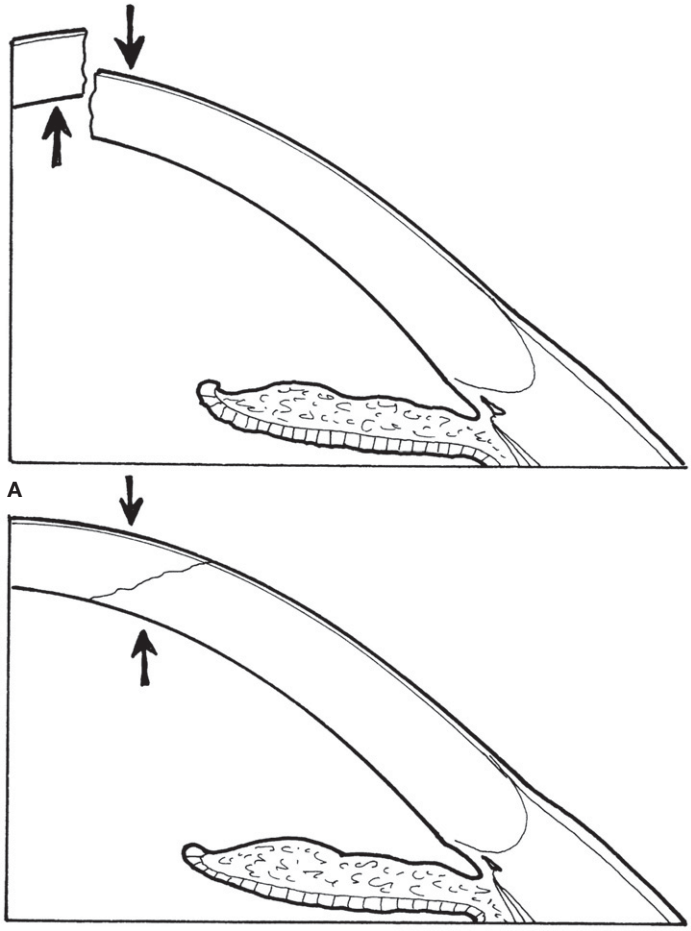

Figure 71.4. *A*, Perpendicular corneal wounds subjected to compressive forces tend to disrupt more easily than *B*, beveled wounds.

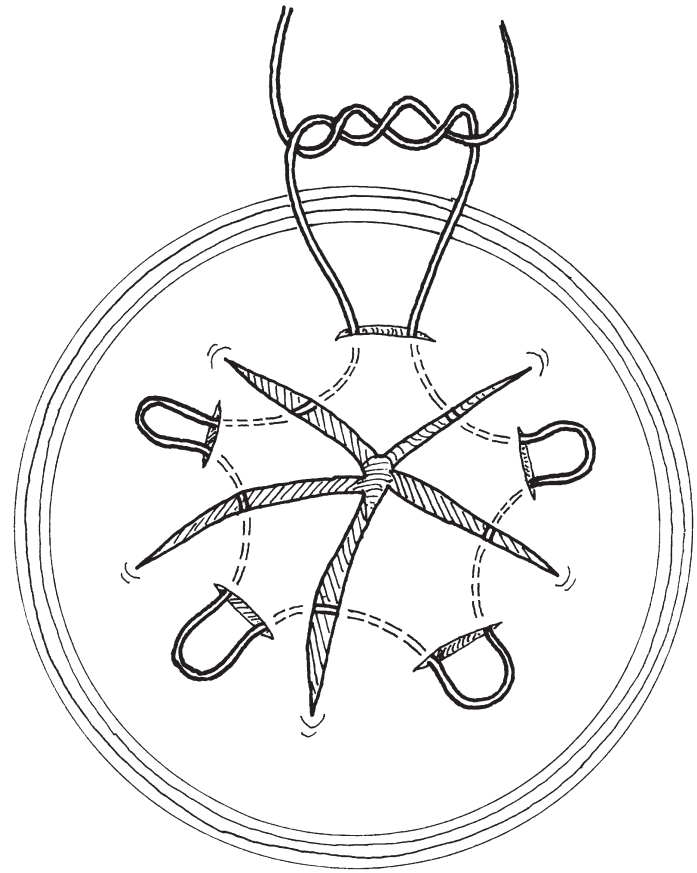

Figure 71.5. Eisner's method of wound closure for a stellate laceration.

reformed either through the original wound or through a separate limbus-based paracentesis positioned away from the wound. A separate paracentesis, although difficult to perform in a hypotonous eye, is advantageous because it is self-sealing and avoids further manipulation of the wound margin. A diamond rather than a metal blade may better facilitate formation of the paracentesis. All wounds should be checked for watertight closure using a dry cellulose sponge.

TREATMENT OF IRIS PROLAPSE

Patients with larger and more peripheral corneal lacerations or flattening of the anterior chamber are prone to iris incarceration in the wound or iris prolapse. To minimize postoperative complications such as refractive problems secondary to excess light scatter, peripheral anterior synechiae formation, and undesirable cosmetic appearance caused by the missing iris, prolapsed tissue should be repositioned and the repaired wound freed of incarcerated tissue. In general, tissue that is exposed for less than 24 to 36 h is probably safe to reposition if it appears healthy. However, prolapsed iris tissue that is obviously necrotic, macerated, or contaminated should be excised to avoid the increased risk of infection and inflammation that is associated with repositioning the tissue. If any sign of surface epithelialization exists, it is better to excise the tissue so that epithelial cells are not introduced into the anterior chamber. To excise prolapsed tissue, one must grasp gently the edge of the exposed iris with smooth forceps, exerting minimal traction; then the tissue can be cut flush with the cornea using Vannas or Castroviejo scissors. The surgeon must preserve as much viable-appearing iris tissue as possible to facilitate reconstruction of the iris diaphragm.

Pharmacologic manipulation may suffice for repositioning the iris in patients with minimal incarceration and a formed anterior chamber. A dilating agent (intraocular epinephrine 1:10000) may free iris that is entrapped in the central aspect of a corneal laceration. Conversely, a miotic agent (acetylcholine or carbachol) may free iris that is entrapped in the peripheral aspect of a corneal laceration.

If the anterior chamber is at least partially formed, further deepening the chamber with intraocular saline or viscoelastic may relieve iris incarceration. A viscoelastic that is injected between the iris and the peripheral cornea can be used to push or 'steamroll' the iris out of the wound. An instrument such as a cyclodialysis or iris spatula, or a blunt irrigating cannula, may be used to sweep the iris from the wound. While avoiding the corneal endothelium and the lens, the surgeon must try to 'tease' the iris from the wound. Working from the center toward the periphery minimizes tension on the iris root, thereby reducing the risk of creating an iridodialysis cleft or tearing the iris root, which can cause additional bleeding.[18]

With a flat anterior chamber, the corneal wound must be closed. It may be necessary to place shallow temporary suture bites to avoid impaling iris tissue while allowing a watertight closure so that the anterior chamber can be reformed (Fig. 71.6). Through a paracentesis site, injected viscoelastic or a mechanical iris sweep separates

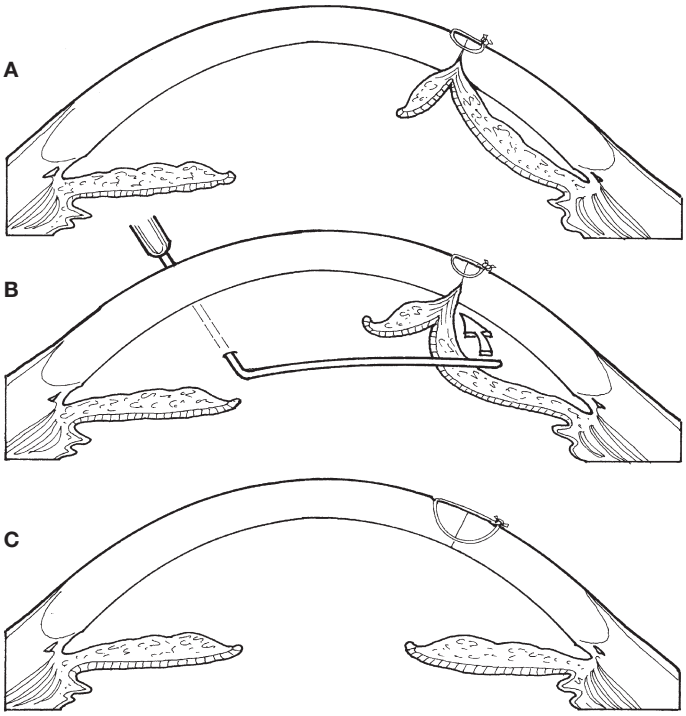

Figure 71.6. *A*, Corneal laceration with a flat anterior chamber. Initial shallow suture bites are passed to reform the chamber and avoid capturing the iris. Viscoelastic through the wound may be used initially to move the prolapsed iris posteriorly. *B*, Once the anterior chamber is reformed, a cyclodialysis spatula and/or viscoelastic is used through the paracentesis site to pull the iris free from the posterior aspect of the wound. *C*, Deeper sutures (pre-Descemet's level) are passed and shallow temporary sutures are removed.

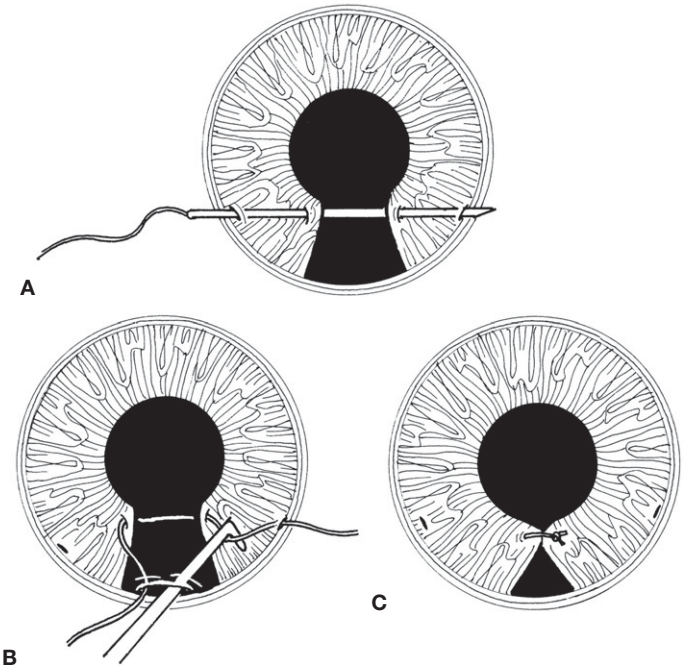

Figure 71.7. *A*, McCannel suture technique for the repair of iris trauma. A straight needle is passed through each side of the iris. *B*, The needle is removed and a Sinskey hook is used to retract the suture end through a third incision. *C*, The suture is tied and cut short, and the iris is reposited in the anterior chamber.

the incarcerated iris from the posterior aspect of the wound. The temporary sutures then can be replaced with deeper, more appropriate sutures.

Before the prolapsed peripheral iris is excised, or when one is treating lacerations near the limbus, the involved uveal tissue must be inspected carefully to ensure that the ciliary body is not involved; any unnecessary manipulation can cause bleeding. If significant iris bleeding is encountered during surgical repair, viscoelastic can be used as a tamponade. If the globe is watertight, gentle pressure may be applied to the globe, or infusion pressure may be increased if an infusion line is in use. Additionally, intraocular epinephrine 1 : 10 000 can be injected for its vasoconstrictive effect. A surgical peripheral iridectomy should be performed in an area in which peripheral iris incarceration was relieved to minimize the risk of peripheral anterior synechiae formation.

ASSOCIATED IRIS TRAUMA

An iris laceration is repaired to maintain a tight iris diaphragm, which decreases the risk of peripheral anterior synechiae and iris–corneal adhesions. Restoring pupil shape is important for refractive and cosmetic reasons. Repair of the iris defect can be accomplished either primarily or secondarily. At the primary surgery, a 10-0 Prolene suture on a vascular needle can be used to close the iris defect. The cut suture ends must be kept short to avoid contact with nearby tissues. Alternatively, iris laceration may be repaired using the McCannel suture technique (Fig. 71.7). A similar technique can be used to repair an area of iridodialysis.

ANTERIOR SEGMENT TRAUMA WITH ASSOCIATED LENS DAMAGE

Once a projectile or foreign body breeches the cornea, there is little to prevent it from disrupting the crystalline lens as well. A thorough preoperative and intraoperative evaluation of the lens is often difficult owing to poor visibility from corneal edema and anterior chamber blood and/or fibrin. Depending on the type and extent of the corneal wound, a meticulous evaluation may be accomplished most accurately before wound closure. In patients with poor pupillary dilation, it may be necessary to use a Graether collar-button or cyclodialysis spatula to push or retract the iris, thereby enabling the lens to be inspected thoroughly. A fibrinous anterior chamber reaction, which deposits across an intact anterior lens capsule, may obscure the lens or appear as a dense cataract. After the anterior chamber is restored, adequate visibility of the lens may not be achieved secondary to corneal edema; in these instances, it is better to wait and let the eye settle, reevaluate, and possibly do a secondary cataract extraction, if indicated. Further, a small breech of the lens capsule (such as occurs after a penetrating injury from a wire or a small in-and-out projectile) may seal spontaneously and cause only a localized opacity of the lens that is not visually significant and that may be observed.

In patients with a dense cataract and an adequate view after complete repair of the corneal laceration a primary lensectomy may be carried out.[19] This allows for a more accurate examination of the fundus, prevents additional phacogenic inflammation, and may obviate the need for additional ocular surgery. The use of flexible iris hooks that are inserted through multiple paracentesis incisions may aid in expanding the pupil. When there appears to be minimal capsular disruption, good zonular support, and an intact posterior capsule, a standard extracapsular or phacoemulsification technique

may be used. A limbus or temporally based incision is constructed, and surgery is carried out according to standard technique. The surgeon should be vigilant for significant amounts of zonular dehiscence and must be prepared to use capsular tension rings or to convert the surgical technique for lens delivery, if necessary. In cases with extensive zonular dehiscence, an intracapsular cataract extraction technique can be employed if the lens is accessible from a limbal incision.

If the lens is severely subluxated, disrupted, or dislocated with vitreous prolapse into the anterior chamber, then vitrectomy instrumentation should be used to perform a lensectomy and vitrectomy. Every attempt should be made to preserve as much capsule as possible so that a posterior chamber intraocular lens (PC-IOL) may be placed either in the bag or in the sulcus, primarily or secondarily. The vitrectomy-cutting instrument and irrigation are introduced through the limbus or the pars plana, depending on the surgeon's preference and the type of injury, to remove vitreous and liberated lens material from the anterior chamber. An anterior capsular rent can be trimmed and if possible converted to a capsulotomy or possibly a continuous capsulorrhexis. The remaining lens material may be removed using aspiration and cutting. Very hard nuclear material may be removed by nuclear expression or phacofragmentation. If necessary, a thorough anterior vitrectomy is performed. The anterior chamber is evaluated carefully to ensure that there is no vitreous remaining that could become incarcerated in the wound and lead to postoperative vitreous traction, inflammation, or retinal traction. Also, such incarcerated vitreous could act as a 'vitreous wick', causing wound leakage and increasing the risk of infection.

The insertion of an IOL at the time of primary surgery remains controversial. A primary IOL implant could save the patient from additional surgery, yet the selection of proper IOL power, the correct anatomic placement, and the risks associated with implanting a prosthetic device in the face of potential intraocular infection are of concern. A secondary IOL implantation has the advantage of using more reliable IOL power calculations based on actual keratometry readings. In eyes with an adequate view through the cornea after repair and with no gross wound contamination or evidence of infection, a primary IOL implantation may be a reasonable choice.[20–22] In eyes that have adequate anterior or posterior capsular support a PC-IOL should be considered. If the capsular bag is intact, an IOL may be implanted in the bag; if not, a sulcus-fixation PC-IOL may be appropriate. Without capsular support, a PC-IOL may be sutured trans-sclerally or an anterior chamber lens inserted if the iris and angle structure are preserved.

Lens power determination can be sufficiently accurate when keratometry and axial length measurements of the fellow healthy eye are used.[20,21] Even if this calculation is inaccurate, it could be reasoned that it would be better to be a 4 or 5 D ametrope than an aphake. Children in the amblyogenic age range may experience rapid visual rehabilitation, and therefore may avoid the difficulties of an arduous contact lens fit atop corneal scarring or sutures. Patients may need to wear a rigid contact lens to neutralize irregular astigmatism after corneal laceration.

CORNEOSCLERAL LACERATIONS WITHOUT LOSS OF TISSUE

A localized peritomy is made to improve visibility of the wound that is being repaired. Excessive manipulation of the globe and extensive exploration should be avoided until all visible wounds are closed. If the wound edges are separated significantly, regrasping the needle after passage through the first wound edge facilitates closure. Well-delineated corneoscleral lacerations or small, isolated, scleral lacerations from sharp penetrating injury may be repaired primarily and may not require extensive exploration. Extremely posterior lacerations and those associated with severe blunt trauma require exploration of all quadrants of the globe to look for scleral disruption. Smaller scleral lacerations may be repaired using non-absorbable 8-0 nylon suture or absorbable 7-0 polyglactin (Vicryl). For larger corneoscleral lacerations, it is best to start by approximating the limbus using non-absorbable 8-0 or 9-0 nylon suture. One must proceed posteriorly with the repair using simple interrupted sutures and closing the wound as it is exposed ('zippered' closure).[18] In lacerations that extend far posteriorly, the use of a half-round needle makes suture passes easier when work is being done in a deep 'hole'. If exposure of the posterior aspect of the wound is difficult owing to orbital tissue prolapse, a small malleable retractor or a pediatric nasal speculum can be used to improve visibility, with care taken not to exert pressure on the globe.

Prolapsed vitreous should be engaged with a dry cellulose sponge and cut flush with the wound using Wescott scissors; alternatively, a vitreous cutting device may be used. Care should be taken to minimize unnecessary traction on the vitreous. Prolapsed uveal tissue should be repositioned before wound closure is completed. Ideally, there should be no vitreous or uveal tissue incarcerated in the wound. Every attempt must be made to preserve prolapsed uveal tissue. Repositioning of prolapsed uveal tissue may be facilitated if an assistant gently pushes the prolapsed tissue back into the wound using a smooth flat spatula as the surgeon passes the sutures. The wound edges also may be raised gently with a forceps while passing suture bites to keep uveal tissue from being impaled by the suture needle. Uveal tissue is handled with extra care because it can bleed easily and profusely. If it is necessary for uveal tissue to be removed, pre-cauterizing helps to control bleeding. Wounds with extensive uveal prolapse have a worse visual prognosis.[11] Viscoelastics should not be injected into the subretinal space to reposition uveal tissue because they are absorbed poorly and may cause excessive inflammation and increase the risk of retinal detachment.

Once all visible wounds are closed, a 360° peritomy is made, and all four quadrants are opened through Tenon's capsule and explored. Placement of one or more bridle sutures of 4-0 silk under an extraocular muscle or tendon, or through the limbus, may be useful for rotating the globe to aid in exploration. Particular attention is directed to the anatomically thinnest area of the sclera, which is posterior to the insertions of the extraocular muscles, to inspect for occult scleral rupture.[23] If lacerations extend through, or under, extraocular muscles, an assistant can retract the muscle gently using a muscle hook to aid in exposure. If more exposure is needed, the muscle tendon can be secured using a double-armed polyglactin (Vicryl) suture with a spatulated needle; then it can be severed from its insertion and reattached after the laceration is repaired.

It may not be possible to close a scleral wound surgically that extends far posteriorly, near the optic nerve. Prolapsed vitreous and uveal tissues are also more difficult to manage in far posterior lacerations. In these cases, it is better to leave the posterior aspect of the wound open than to cause additional damage and further tissue prolapse with extreme manipulations.

An isolated posterior scleral laceration or rupture from blunt trauma, a projectile injury, or a perforating wound of the globe may occur without associated corneal injury. This should be suspected when the history is appropriate and the examination demonstrates decreased visual acuity, focal subconjunctival hemorrhage and che-

mosis, conjunctival laceration, uveal 'show' under the conjunctiva, decreased intraocular pressure, hyphema, vitreous hemorrhage, pupillary irregularity, or a shallow or excessively deep anterior chamber.[18] These injuries are repaired, as are anterior scleral lacerations, by using a 360° peritomy with exploration of all four quadrants and wound closure as the wound(s) are uncovered. An isolated posterior scleral wound near the optic nerve can be seen in penetrating trauma of the globe and may be managed best without primary surgical closure for the same reasons cited above. In these cases, the orbital tissue serves to tamponade the wound as it heals.

CORNEOSCLERAL LACERATIONS WITH ASSOCIATED TISSUE LOSS

Every attempt should be made to find and reposition any avulsed corneal or scleral tissue. Injuries involving loss of a small tissue area may be closed using tight sutures, although this can lead to significant amounts of tissue distortion and wound tension, which may impede healing and complicate visual rehabilitation. Tissue adhesive may aid in closure. Avulsion of larger tissue areas requires replacement with either fresh or preserved donor corneal and/or scleral tissue. It is best to remove frankly necrotic or infected-appearing tissue before a graft is placed. Devitalized or irregular margins then are trimmed using scissors or a sharp blade to form a smooth circular recipient bed. Care should be taken to avoid further injury to underlying uveal tissue. Alternatively, a partial-thickness trephination may be performed and the remaining tissue removed with scissors or a sharp blade, as in penetrating keratoplasty. Trephination of an open, hypotonous globe is technically more difficult to perform. A suction trephine may accomplish incision in these cases. Alternatively, the trephine blade may be inked and used as a marker to define a distinct border that can be excised with a free-hand technique using blades and/or scissors. This makes it easier to fit a watertight patch. Depending on the wound architecture, either partial-thickness (lamellar) or full-thickness grafts may be used.

A full-thickness or penetrating graft requires a recipient bed with a well-defined rim of healthy tissue to suture to. The patch is cut approximately 0.25 to 0.5 mm larger than the recipient bed and is secured into place using simple, interrupted, 10-0 nylon sutures for a corneal patch and 8-0 nylon for a scleral patch. First, four cardinal sutures should be placed at the 3, 6, 9, and 12 o'clock positions to secure and align the graft and make watertight closure easier. The anterior chamber then can be reformed and the wound integrity checked.

A lamellar graft is indicated for areas of tissue loss that have irregular, macerated, or thin stromal margins. Partial-thickness corneal lacerations may be managed with therapeutic deep anterior lamellar keratoplasty,[24] and residual superficial scars may be amenable to PTK.[25]

Lamellar grafting is begun by creating a partial-thickness incision around the wound using a trephine or a sharp blade. A partial-thickness recipient bed then is formed. The lamellar graft is fashioned to be slightly larger than and similar in thickness to the recipient bed. If the recipient bed is trephined, the patch may be trephined 0.25 to 0.5 mm larger; if the recipient bed is irregular, the patch can be hand-fashioned. The patch is laid into place and secured using 10-0 nylon sutures. The sutures should exit from the donor material at approximately 90 to 95% thickness and enter the deepest portion of the recipient shelf. The knots are trimmed and buried.

Penetrating keratoplasty is rarely performed for repair of acute trauma. Graft survival is guarded owing to the added inflammation associated with acute trauma.[26–28] For short-term repair, a patch graft may be used until full-thickness keratoplasty can be performed secondarily. In the setting of extensive tissue loss, a penetrating keratoplasty may be appropriate.

The peri-operative medication regimen for corneoscleral lacerations with associated tissue loss may include systemic antibiotics as well as postoperative topical antimicrobials and steroids. In cases of extensive inflammation, systemic steroids may also be warranted.

IRREPARABLE TISSUE INJURY

With extensive tissue loss or severe disruption of the globe with loss of intraocular contents, primary surgical repair may be impractical. Every attempt should be made to restore the integrity of the globe to allow time for patient and family acceptance of imminent enucleation. If primary repair is not possible, and primary enucleation has been discussed and consent has been obtained preoperatively, enucleation can be performed at the initial surgery. This saves the patient the time and risk of a second surgery under general anesthesia, and it reduces the risk of sympathetic ophthalmia.

72 Epithelial downgrowth, pearl tumors, and fibrous ingrowth

Albert S. Jun, Elizabeth C. L. Vito, Julia A. Haller, Walter J. Stark

INTRODUCTION

Ophthalmologists have long recognized the ability of ectopic ocular surface cells to proliferate in the anterior segment of the eye as epithelial downgrowth and fibrous ingrowth. MacKenzie first described an epithelial cyst in 1832.[1] Collins and Cross[2] were the first to describe the clinical and histologic features of epithelialization of the anterior chamber. Though rare, these disorders can be devastating sequelae of trauma or anterior segment surgery and must be considered in the differential diagnosis of postoperative complications. Despite increased awareness among ophthalmologists and improvements in anterior segment surgical techniques, these entities remain a diagnostic and therapeutic challenge.

TYPES OF EPITHELIAL PROLIFERATION

In 1937, Perera[3] divided epithelial proliferation into three separate categories based on prognosis and treatment: (1) 'pearl' tumors of the iris, (2) epithelial cysts, or (3) epithelial ingrowth or downgrowth. Most authors still follow Perera's classification scheme. In recent years, however, the term 'epithelial ingrowth' has been used to describe complications resulting from lamellar refractive laser surgery to the cornea, while 'epithelial downgrowth' denotes complications arising from intraocular surgery or penetrating trauma.

EPITHELIAL CYSTS AND SHEET-LIKE EPITHELIAL DOWNGROWTH

CLINICAL/DIAGNOSTIC FEATURES

Risk factors and incidence

The conditions leading to epithelial cysts and sheet-like epithelial downgrowth are the same. Both disorders are preceded by intraocular surgery or penetrating trauma, especially if the healing process was prolonged or complicated. The time from surgery or trauma to presentation can be days to years,[4] with the longest such reported interval being 52 years.[5] It should be noted that the incidence of epithelial downgrowth in its various forms has never been clear. Large studies of this entity are usually histopathologic in nature.[6,7] Clinical studies of epithelial downgrowth usually encompass many decades over which knowledge and surgical techniques have changed substantially.

Chen and Pineda's 2002 literature review ranked the relative risk of epithelial downgrowth in descending order as cataract extraction, penetrating injury, and penetrating keratoplasty.[8] However, it requires mention that none of the case series they cite are limited to modern surgical techniques. Although rigorous studies are lacking, it is generally assumed that the risk of epithelial cysts and downgrowth has decreased in recent decades with the advent of improved microsurgical instruments and techniques. In 1993, Holliday and coworkers[9] reported the first case of epithelial downgrowth after a sutureless cataract operation using phacoemulsification. Since then, two additional cases have been reported by Vargas et al.[10]

Presenting signs and diagnostic features

A patient with an epithelial cyst may present with pupillary distortion, iridocyclitis, glaucoma, or occlusion of the visual axis (Fig. 72.1). The clinician will see a translucent or gray cyst that commonly connects with the surgical or traumatic wound. Epithelial cysts discontinuous with the wound are thought to arise from surface cells implanted by intraocular instruments.[11–13] In Weiner et al's 30-year review of 124 cases, the most common presenting signs of epithelial downgrowth included a retrocorneal membrane (45%), glaucoma (43%), a positive Seidel test (23%), and corneal edema (21%).[7] According to Solomon et al, hypotony is also present in approximately one-third of cases.[13]

Early detection and treatment of epithelial downgrowth are important for a favorable outcome. Unfortunately, epithelial downgrowth is rare and may be mistaken for more common conditions such as keratoplasty rejection, corticosteroid-induced glaucoma, or iritis.[14] In a review of 207 histopathologically proven cases of epithelial downgrowth at a major referral center, it was found that 36% of the cases were clinically misdiagnosed.[6] In addition, 50% of cases were not clinically suspected until the pathology report

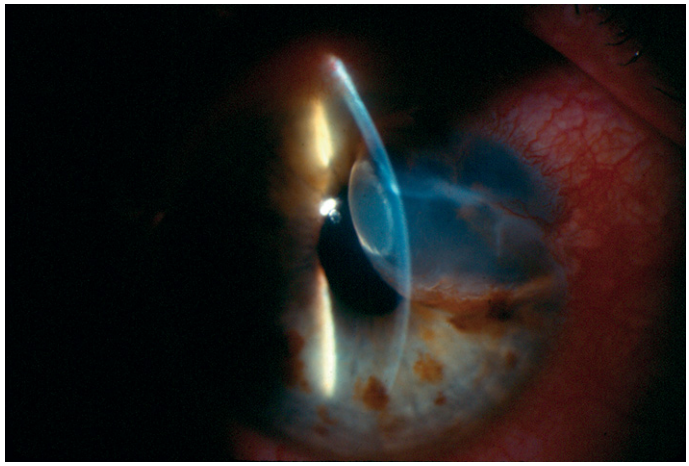

Figure 72.1. Slit-lamp biomicroscopy of an anterior chamber epithelial cyst extending into the visual axis. Note the healed, traumatic corneal laceration overlying the cyst and extending to the limbus.

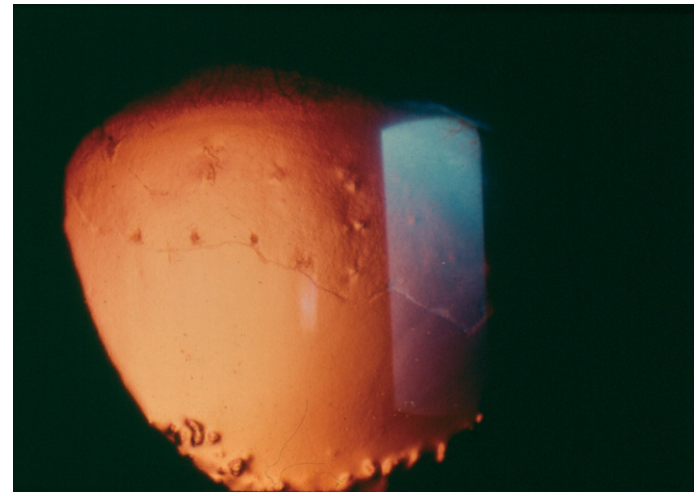

Figure 72.2. Retroillumination of a translucent retrocorneal membrane extending across the superior half of the cornea. Note the typical scalloped profile of the membrane's central border. Reproduced with permission from Stark WJ, Michels RG, Maumenee AE, et al. Surgical management of epithelial ingrowth. Am J Ophthalmol 1978; 85: 772–780.

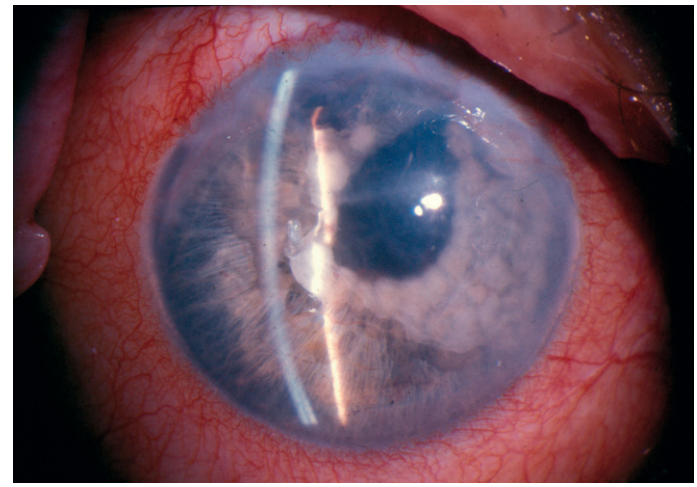

Figure 72.3. Epithelial downgrowth appearing as a whitish membrane on the iris surface extending to the right of the slit beam. Note the peaked pupil indicating incarceration of iris tissue into the superior limbal wound. Reproduced with permission from Stark WJ, Michels RG, Maumenee AE, et al. Surgical management of epithelial ingrowth. Am J Ophthalmol 1978; 85: 772–780.

became available. Therefore, the clinician should have a high index of suspicion for epithelial downgrowth and consider the following diagnostic features/maneuvers:

(1) Retrocorneal membrane as clearly visualized in retroillumination (Fig. 72.2). A scalloped leading edge is typical in most cases of sheet-like epithelial downgrowth.
(2) Epithelialization of the angle on gonioscopy. Glycerin 50% can be used to clear the edematous cornea before gonioscopic examination.
(3) Wound-incarcerated tissue such as iris, lens cortex or capsule, or vitreous (Fig. 72.3).[13]
(4) Abnormal eye pressure (high or low). Although estimates of prevalence vary widely, sheet-like epithelial downgrowth can cause glaucoma via obstruction of the trabecular meshwork. Furthermore, fistulous tracts can produce hypotony in these patients.
(5) Misshapen pupil.
(6) Corneal or iris neovascularization. These vessels are proposed to nourish the ingrowth, and are found in approximately 50% of cases.[13]
(7) Seidel test positive fistula or bleb.
(8) Confocal or specular microscopy. Studies may disclose cells with epithelial morphology on the posterior corneal surface.
(9) Vitreous biopsy. Cytopathology of vitreous specimens may disclose epithelial cells.[15]
(10) Argon laser photocoagulation of the iris. Blanching of epithelial cells on the iris after photocoagulation can be used to diagnose downgrowth or delineate treatment areas (Fig. 72.4).

MANAGEMENT

Epithelial cysts

The treatment of epithelial cysts varies according to the presenting findings and progression. When cysts remain small and stable, periodic observation is sufficient. If the cyst enlarges, medications or eventually surgery may be required to prevent or treat complications such as loss of vision, pupillary distortion, secondary glaucoma, iridocyclitis, corneal edema, and pain.[16]

As reviewed by Solomon et al,[13] epithelial cysts have been treated in prior decades with diathermy, electrolysis, repeated aspiration, aspiration then diathermy, and irrigation of the cyst with radioactive, corrosive, and desiccating agents. While apparently successful in isolated cases with limited follow-up, they have all since been abandoned as unreliable or unsafe.

Photocoagulation has gained popularity as a method to puncture and shrink epithelial cysts. Although minimally invasive, this approach has been reported to require multiple applications to achieve lasting clinical success.[13] Furthermore, photocoagulation may show limited benefit in situations where the cyst shows minimal pigmentation, is firmly adherent to cornea or vitreous, or is present in the posterior chamber. In addition, puncturing the cyst without removing it may lead to conversion into sheet-like epithelial downgrowth.

A variety of techniques have been proposed for surgical excision of epithelial cystic downgrowth. The overarching caveat is to avoid

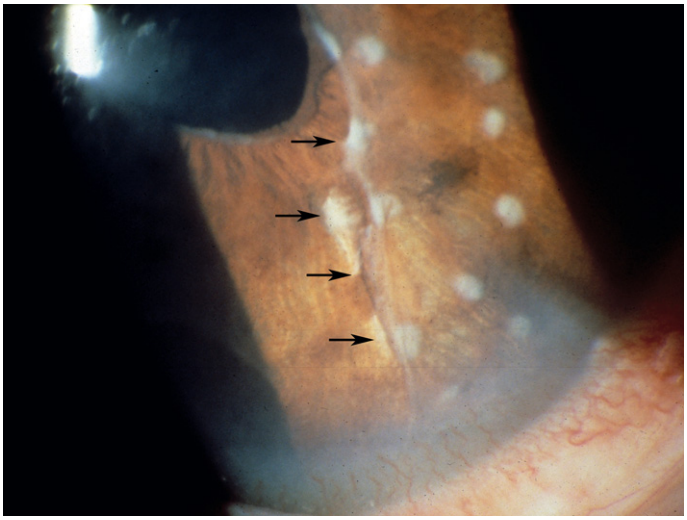

Figure 72.4. Argon laser photocoagulation of sheet-like epithelial downgrowth on the iris; 500 μm spot size is used. Epithelial cells turn white in response to laser energy compared with iris tissue, which turns brown. This method is used to delineate the border between affected and unaffected iris tissue (arrows).

turning the more manageable epithelial cyst into the much more invasive sheet-like epithelial downgrowth via intervention.

Haller et al[16] advocate a conservative approach which begins with viscodissection of the cyst away from adjacent intraocular structures (Fig. 72.5). A 30-gauge needle is used to puncture the apex of the cyst and aspirate its contents. An endolaser probe is then used to collapse and destroy the cyst wall with photocoagulation (Fig. 72.5). Haller et al report the successful use of this technique in four eyes with postoperative visual acuity ranging from 20/20 to 20/40.[16] Such a conservative approach with sparing of the iris, lens, and other ocular structures has obvious benefit and may be particularly helpful in children where amblyopia management can be an issue.

A second, more aggressive approach for treating epithelial cysts includes surgical excision and devitalization of the epithelial tissues, including vitrectomy, lensectomy, fluid-air exchange, and cryoablation of residual cells in the affected area.[17] Corneal edema may occur after cyst excision and freezing; penetrating keratoplasty has been performed to improve visual acuity in some of these cases.[17] One potential drawback to this method, however, includes conversion of the cyst into the more difficult to manage sheet-like epithelial downgrowth.[16] In addition, removal of the lens and iris may contribute to amblyopia in children.[16]

Some contemporary authors promote an even more radical en bloc resectioning procedure[18,19] consisting of simultaneous removal of epithelial downgrowth together with adjacent iris, pars plicata of the ciliary body, and cornea and sclera in full-thickness. This method is promoted as a way to avoid turning epithelial cysts into epithelial downgrowth. Corneal endothelial decompensation and vitreous hemorrhage occurred in more than 20% of cases in a single, large series of 51 patients, and median visual acuity showed a decrease from 20/60 to 20/100.[18]

Mitomycin C (MMC) is a more recent treatment adjunct for epithelial cysts. Two case reports[20,21] have been published in which an epithelial cyst was first aspirated, then injected with MMC, and finally rinsed with balanced salt solution. Neither recurrence nor complications were reported at follow-up of 18 months and 1 year, respectively. Although promising, this approach should be undertaken with caution as MMC is toxic to the corneal endothelium and could potentially cause corneal endothelial failure.

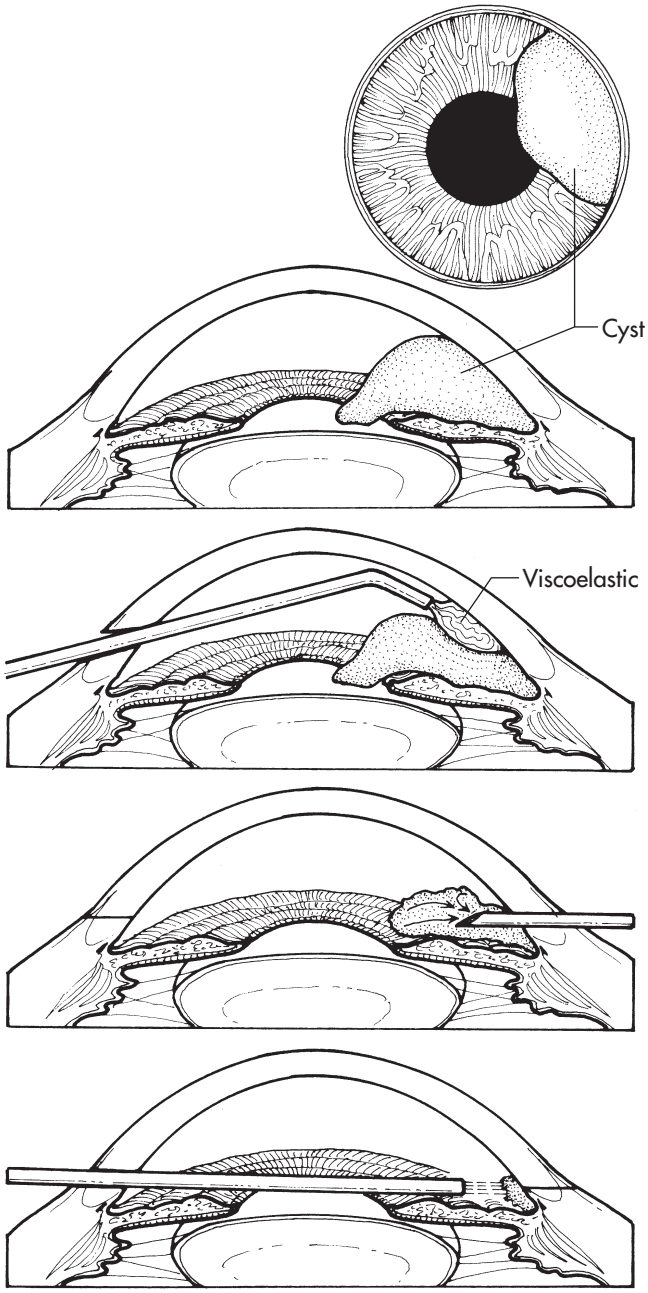

Figure 72.5. Conservative surgical management of epithelial cysts including viscodissection, aspiration, and endolaser photocoagulation. Reproduced with permission from Haller JA, Stark WJ, Azab A, et al. Surgical management of anterior chamber epithelial cysts. Am J Ophthalmol 2003; 135(3): 309–313.

One important caveat to surgical excision of epithelial cysts is potential conversion to the more difficult to treat sheet-like epithelial downgrowth. Furthermore, in light of the unpredictable natural history of epithelial cysts, larger series of cases with longer follow-up would be beneficial for determining optimal approaches to therapy including observation, photocoagulation, excision, or pharmacologic agents.

Sheet-like epithelial downgrowth

Over the years, ophthalmologists have vigorously attempted to eradicate sheet-like epithelial downgrowth in a variety of ways,

knowing that if left untreated, this condition frequently leads to severe loss of vision and enucleation due to intractable glaucoma, pain, and other complications. Previous management techniques for treating epithelial downgrowth included X-rays, freezing, and photocoagulation.[13] These approaches have since been discontinued in favor of Stark's and Michels' modification of Maumenee's original surgical technique.[17,22]

Preoperatively, argon laser photocoagulation is applied to the iris surface in order to outline the extent of epithelial growth (Fig. 72.4). Photocoagulation spots are applied along the advancing edge of the epithelial sheet in such a way that one half of each spot turns white, corresponding to the presence of epithelial cells, and the other half turns brown, corresponding to uninvolved iris tissue.

The procedure begins with the placement of traction sutures under each rectus muscle. A conjunctival peritomy is constructed to expose the superior corneoscleral limbus. If a fistula is present, a partial thickness scleral flap is reflected over the opening and sutured to the peripheral cornea as described by Maumenee.[22]

A sclerotomy is performed 4 mm posterior and parallel to the corneoscleral limbus in the superotemporal quadrant. A vitrectomy instrument, equipped with an overlying fiberoptic sleeve, is inserted into the pupillary space. Areas of involved iris and vitreous are excised. Hemostasis is achieved by increasing the intraocular pressure or by applying bipolar diathermy.[23]

After excising the involved iris and vitreous tissue, any vitreous gel remaining in the anterior half of the vitreous cavity is removed. The vitrectomy instrument is then withdrawn and the sclerotomy site closed with sutures. The fundus is examined with indirect ophthalmoscopy with scleral depression. Any retinal tears are treated with cryotherapy and their position marked on the sclera. A scleral buckle can be placed beneath any retinal breaks.

The anterior half of the eye is filled with sterile air by fluid–gas exchange. Cryotherapy is applied in a transcorneal and transscleral fashion to devitalize remaining epithelium on the posterior surface of the cornea, the anterior chamber angle, and the ciliary body (Fig. 72.6). The air bubble in the anterior chamber allows advancement of the full-thickness freeze from the corneoscleral limbus onto the cornea with considerable precision. Cryotherapy is extended onto the cornea to just beyond the edge of the epithelial sheet as visualized pre-operatively or intraoperatively (Fig. 72.7). If no retinal breaks are present, the air bubble is replaced by balanced salt solution at the conclusion of surgery. If retinal breaks are present, positioning of the patient can be used to achieve gas tamponade. Topical corticosteroids are used postoperatively with frequency and duration determined by the extent of postoperative inflammation. Remaining intraocular epithelium in the treated area typically sloughs during the first few postoperative days.

Using this approach, Stark et al reported visual improvement in eight of ten consecutive cases, and better than 20/50 vision in four eyes.[17] Penetrating keratoplasty for endothelial decompensation after transcorneal cryotherapy can be performed with good results.[24]

Some surgeons advocate en bloc excision of the cornea, sclera, iris, ciliary body, and vitreous.[18,19,25] Using this method for sheet-like epithelial downgrowth, a recurrence rate of 0% was reported in a total of 69 cases. However, this approach is associated with transient intraocular pressure rise and uveitis, decrease in median visual acuity, and postoperative astigmatism.[18,19,25] Lai and Haller described the use of 5-fluorouracil (5-FU) as an adjunctive therapy for sheet-like epithelial downgrowth.[26] Two injections of 500 μg of 5-FU were placed into the anterior chamber of a monocular patient with extensive involvement of epithelial downgrowth. Eight months after the second 5-FU injection, the treated eye showed complete resolution of the epithelial downgrowth. Although limited to a single case report to date, this approach is promising and deserves further evaluation for safety and efficacy. It may have particular value in cases of extensive involvement in which more conservative initial therapy is warranted.[26]

HISTOPATHOLOGY

Epithelial cysts and downgrowth disclose identical histopathologic features including one or more layers of nonkeratinized, stratified squamous cells (Fig. 72.8, *A* and *B*).[27] When goblet cells are present, the source of the downgrowth or cyst is believed to be conjunctival; when goblet cells are absent (the more common scenario), the source of the downgrowth or cyst is believed to be corneal.[28] Immunohis-

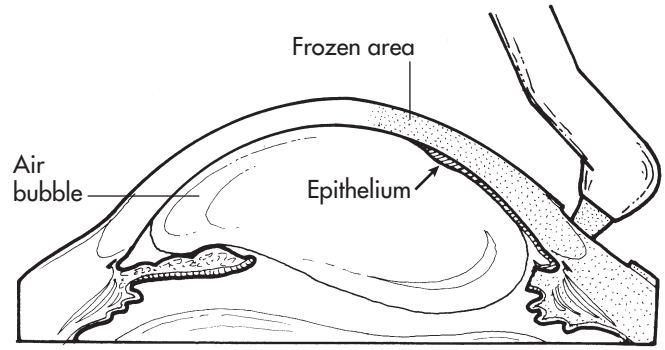

Figure 72.7. Full thickness cryotherapy for sheet-like epithelial downgrowth is applied to a point just beyond the borders of the involved area on the posterior cornea. The anterior chamber remains filled with air during cryotherapy and is replaced with balanced salt solution at the end of the procedure. The de-vitalized epithelial tissue sloughs into the anterior chamber during the first 24–48 h after treatment.

Hematoxylin and eosin staining of cystic (*A*) and sheet-like (*B*) epithelial downgrowth (original magnification = 200X). *A*, Note the cyst wall consisting of a nonkeratinized, stratified, squamous epithelium (arrow). *B*, In the sheet-like epithelial downgrowth, a histologically similar epithelium is seen extending continuously from the posterior cornea, over the anterior chamber angle (arrow), and around the iris margin into the posterior chamber.

tochemical staining using monoclonal antibodies to keratin (e.g. in the microvillus processes and hemidesmosomes) can also be used to determine the conjunctival or corneal origin of growths in the eye.[29]

Surface epithelium can be seen extending deep into the surgical wound, and careful sectioning may reveal its continuity with epithelium lining the anterior chamber.[6] The intraocular tissue such as iris, lens capsule, or vitreous may be incarcerated in the wound.[6] Several authors have noted that the corneal endothelium is missing[30] or has undergone epithelial metaplasia[31] in areas of posterior corneal epithelialization.

EXPERIMENTAL STUDIES

Despite our understanding of risk factors (difficult surgery, slowly healing wounds, postoperative hypotony, etc.) the underlying mechanisms leading to epithelial downgrowth remain poorly understood. A limited number of experimental attempts to reproduce the clinical spectrum of epithelial downgrowth have met with modest success. In the 1930s, investigators succeeded in producing epithelial downgrowth when they implanted epithelium continuous with its surface origin in hypotonous, inflamed eyes.[13] The most successful of these experiments placed the conjunctival or corneal epithelium in contact with the iris (thought to play a nutritive role), and maintained the eye in hypotony by placing vitreous, lens capsule, or celluloid in the wound.[13]

Theoretically, the breakdown of the blood–aqueous barrier in hypotonous, inflamed eyes provides serum-borne growth factors needed by proliferating epithelium.[32] These factors are not normally present in uninflamed aqueous humor which though sufficient to maintain viable epithelium,[13,33,34] is insufficient to induce proliferation. Clinical and experimental studies suggest that healthy endothelial cells inhibit the advance of ectopic epithelium[35,36] and, conversely, that damaged or missing endothelium poses an increased risk of epithelialization.[13]

In the mid-1980s, Burris et al reported the development of a cat model of epithelial downgrowth which exhibited strong morphologic and ultrastructural similarities to the human disease.[31] Such a model could be used to test the safety and efficacy of potential antiproliferative agents for the treatment of epithelial downgrowth such as the antitransferrin receptor immunotoxin,[37] 5-FU, or MMC.

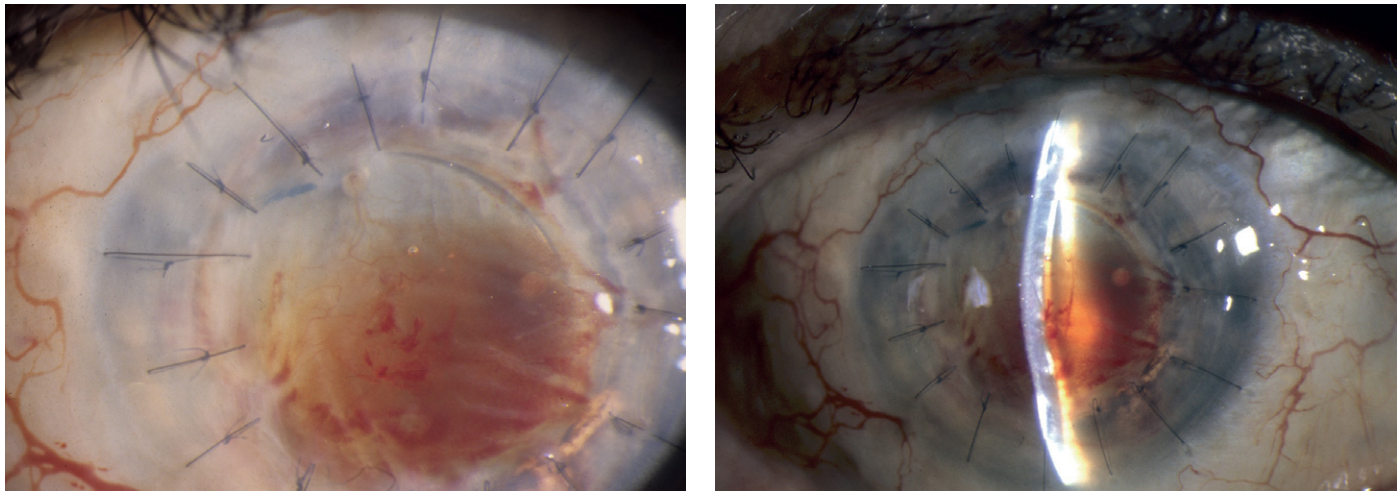
Pearl tumors

These lesions are extremely rare and appear as solid pearly tumors or opaque cysts implanted on the iris surface. Unlike epithelial cysts, which generally appear more translucent, pearl tumors do not show a connection with the entrance wound as they result from traumatic implantation of skin or hair follicles. Pearl tumors are usually small and may not enlarge substantially. Growth occurs slowly, and in extremely rare cases these lesions will reach a clinically significant size or extend posteriorly behind the iris.[38] Mild iridocyclitis may be present. Histopathologically, these tumors disclose encapsulated stratified or cuboidal epithelium surrounding keratinized cells or necrotic debris. Cholesterol, fat, hair follicles, or foreign bodies may be present within the core. If the tumor is small, does not affect vision, and is not growing, it may simply be monitored. If the tumor enlarges or recalcitrant iridocyclitis develops, total excision is indicated, generally with good results.

FIBROUS INGROWTH

CLINICAL/DIAGNOSTIC FEATURES

Ernst Fuchs first described fibrous ingrowth in 1901.[13,39] This entity appears as projections or sheets of fibrous, collagenous tissue interposed between Descemet's membrane and the corneal endothelium (Fig. 72.9, *A* and *B*).[40] Vascularization is sometimes present. In advanced cases, the cornea will appear cloudy and edematous.[41] Fibrous ingrowth often occurs in the setting of elevated intraocular pressure and has been reported to be present in 38 to 55% of epithelial downgrowth cases.[7] The risk factors for fibrous ingrowth-penetrating trauma and surgery are the same as those of epithelial downgrowth.



A B

Figure 72.9. Slit-lamp biomicroscopy of fibrous ingrowth. *A*, Note the opaque, fibrovascular membrane extending across the corneal graft. *B*, A slit-beam indicates the location of the membrane on the posterior corneal surface.

PATHOPHYSIOLOGY AND HISTOPATHOLOGY

Fibrous ingrowth is essentially a healing process—fibroplasia—gone awry. Factors that potentially contribute to this process include prolonged inflammation, poor wound apposition, or a damaged corneal endothelium.[40] The source of the aberrant fibroblasts is unclear. Competing hypotheses postulate that the fibroblastic cells arise from a stromal scarring process; metaplastic corneal endothelium; subepithelial connective tissue; or blood mononuclear cells.[40,41] The theory that retrocorneal fibrous membranes originate from metaplastic corneal endothelial cells was supported by experiments done in 1972 in which rabbit endothelial cells were repeatedly damaged via freezing, but Descemet's membrane was left intact as a barrier for corneal stromal cells.[41] However, these experiments do not rule out the possibility that under different circumstances fibrous ingrowth can arise from other sources such as keratocytes or subconjunctival fibroblasts. Histopathologic analysis discloses the presence of spindle-shaped, fibroblastic cells within a fibrous membrane.[42,43] These cells can be seen within vitreous strands (if present),[43] and the fibrous membrane may contain blood vessels.[42] Ultrastructural analysis discloses fibroblastic cells containing 20 nm fibrils indicating new collagen synthesis.[43]

MANAGEMENT

Unlike epithelial downgrowth, fibrous downgrowth is more amenable to conservative management due to the generally slow growth rate of the aberrant fibrous tissue. Initial treatment approaches can focus on the clinical complications that may be apparent at the time of presentation, in particular glaucoma and corneal decompensation. The former can be treated with varying success using intraocular pressure lowering medications or filtering/drainage device surgery. A more aggressive approach includes membranectomy using a combination of sharp and blunt dissection depending on the degree of tissue thickness and adherence to anterior segment structures.[42] Penetrating keratoplasty can be performed if corneal decompensation is already present or develops subsequently. Such a procedure would be considered at high risk for premature graft rejection or failure. However, results can be quite satisfactory as Bloomfield et al report 20/30 visual acuity with 1-year followup after penetrating keratoplasty for fibrous ingrowth in a single eye.[42]

CONCLUSIONS

Epithelial downgrowth, pearl tumors, and fibrous ingrowth are rare complications of anterior segment surgery or penetrating trauma. Although the incidence of these entities is difficult to estimate, they have become less common with the advent of modern microsurgical techniques. Epithelial cysts, pearl tumors, and fibrous ingrowth can be relatively indolent and may not require intervention. Sheet-like epithelial downgrowth in particular can grow extensively, leading to severe sequelae. Thus, some authors recommend aggressive treatment with cryotherapy or en bloc excision. A relatively small number of reports suggest the value of more conservative treatments such as laser photocoagulation or intraocular agents such as 5-FU or MMC. Despite increased awareness among ophthalmologists, these disorders remain diagnostic and therapeutic challenges. As early diagnosis and initiation of therapy may be beneficial for final outcome, these entities should be considered with vigilance in the settings of postoperative complications and penetrating trauma.

73 Traumatic cataract, vitreous prolapse, and loose zonules

Michael L. Nordlund, Robert Cionni

INTRODUCTION

Cataract surgery is a common, safe, and highly efficacious procedure with which most ophthalmologists develop proficiency and comfort. In eyes with zonular instability, however, the procedure becomes significantly more challenging and complex. This chapter discusses these challenges and describes methods for managing these difficult surgeries. The procedures detailed in this chapter relate to cataract extraction through a small incision approach. Triple procedures involving corneal transplantation in combination with cataract extraction and intraocular lens (IOL) placement are detailed in chapter 43.

The human lens is an anatomical marvel. It is composed primarily of crystalline proteins encapsulated in a membrane primarily composed of collagen and suspended from the ciliary body by the radial zonules of Zinn[1,2] (Fig. 73.1). Lens zonules are composed primarily of fibrillins. Fibrillins are large proteins that form extracellular microfibril suprastructures ubiquitously found in elastic and non-elastic tissues.[3] Microfibrils appear to have dual roles. Mechanically they confer stability and limited elasticity to tissues and physiologically they modulate the activity of growth factors of the transforming growth factor beta (TGF-β) superfamily. Studies of human lens zonules confirm the remarkable elasticity conferred by their microfibril composition. In fact, human zonules can stretch four times their resting length.[2] In contrast, the importance of TGF-β regulation in zonular function or development has not yet been determined. Despite the remarkable elasticity of lens zonules, these structures provide impressive stability to the crystalline lens. This dual character of stability and elasticity contributes to the accommodative function of the lens and facilitates the surgeon's ability to perform cataract surgery.

The function of the lens zonules can be compromised by trauma or disease. Blunt force, perforating trauma, and iatrogenic events can result in zonular disruption. Most commonly, these etiologies cause localized or segmental breaks in the zonular apparatus.[4,5] Alternatively, disease states such as Marfan's syndrome, homocysteinuria, and pseudoexfoliation can cause diffuse weakening of the entire zonular apparatus.[6–8] While these patients will often present with spontaneous lens dislocation resulting from localized breaks in the zonules, the stability of all the zonules is often compromised.

Compromised zonular function greatly complicates cataract extraction and IOL placement. Firstly, zonular weakness or loss can allow for marked posterior displacement of the crystalline lens when the patient is placed supine and the anterior chamber is inflated with viscoelastics or balanced salt solutions. In cases of traumatic zonular loss, disruption of the anterior hyaloid and vitreous prolapse into the anterior chamber may be present. Secondly, zonular instability can significantly reduce the resistance of the lens to the radial forces applied during creation of the capsulorrhexis, phacoemulsification of the nucleus, or stripping of cortical material from the capsular bag. Postoperative centration of the IOL can also be compromised in the presence of zonular instability. Finally, zonular instability resulting from systemic conditions is commonly accompanied by other co-morbid conditions such as axial myopia, reduced scleral rigidity, vascular fragility, and iris and corneal abnormalities which can significantly increase the unpredictability of the surgery. As a result, the surgeon must be prepared to handle the expected unique challenges of zonular instability as well as the unexpected challenges that may occur during the procedure.

EVALUATING THE PATIENT WITH ZONULAR INSTABILITY

As with all patients being considered for cataract surgery, patients with zonular instability need a complete eye exam to determine the nature of the cataract and assess its impact on visual function. Additionally, the visual potential of the eye needs to be assessed in order for surgeons to provide patients with realistic expectations of their visual recovery. In addition to the standard evaluation, however, patients with zonular instability need to be assessed for additional specific characteristics. First and foremost, the extent and type of zonular instability needs to be assessed. Obtaining a thorough patient history is the first step in this analysis. Soliciting information such as a history of Marfan's syndrome, homocysteinuria, or other systemic disease that may affect zonule integrity suggests the presence of diffuse and more severe zonular disease. In patients with a history of trauma, the nature and severity of trauma can be useful in predicting the extent and location of

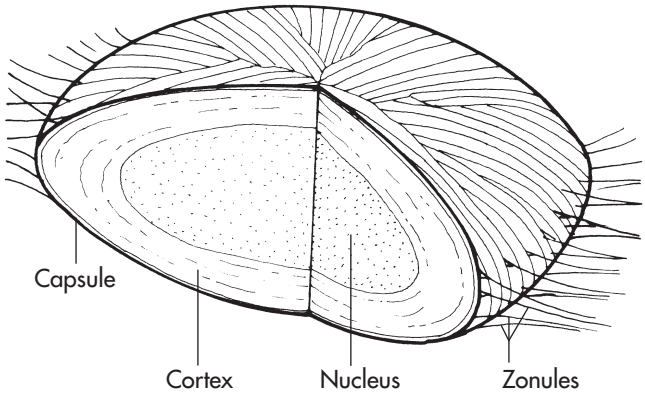

Figure 73.1. Zonule anatomy: The schematic demonstrates the extensive network of zonules that support the lens. While individual zonules are quite elastic and capable of stretching four times their resting length, the arrangement and large number of zonules provides robust support for the lens in the normal eye. Disease and trauma can dramatically impact the integrity of the zonular complex.

zonular loss. For example, severe blunt trauma will often have more widespread effects on the zonules than a perforating injury created by sharp objects. Reviewing the nature of the patient's visual symptoms can also be informative. Complaints of a 'wiggle' or 'shimmer' quality to their vision suggest moderate to severe phacodonosis. Similarly a complaint of the vision changing significantly with head position is consistent with severe phacodonosis. In patients with previous ocular surgery, the type and timing of the surgery should be evaluated and operative reports can be reviewed for evidence of zonular laxity or loss.

Examination of patients with zonular instability begins with gross external examination of the globe and orbit. The orbit should be assessed for its depth and size in order to gauge accessibility of the globe and plan incision placement. Evaluation of the globe for evidence of trauma can often reveal the location of previous trauma and alert the surgeon to potential areas of zonular weakness or loss. Gross analysis of the shape, size, and function of the pupil can further help isolate potential areas of zonular damage.

On slit-lamp examination, the clarity of the cornea and presence of scars should be assessed to determine if there will be limitations in visualization. Scar locations can also help predict areas of zonular weakness. The presence of vitreous in the anterior chamber indicates likely zonular loss. Pigment deposits on the anterior capsule and corneal endothelium are suggestive of significant trauma and pseudoexfoliative material on the anterior capsule indicates potential zonular instability associated with pseudoexfoliation syndrome. In patients with a history of trauma, gonioscopy can help localize areas of potential angle recession that may correspond to areas of zonular trauma. The iris should be evaluated for iridodenesis, iridodialysis, and transillumination defects that provide clues to the nature and location of areas of potential zonular abnormalities. Segmental dysfunction of the pupillary sphincter can help localize areas of potential zonular trauma. Poor dilation is common in eyes with trauma and pseudoexfoliation and may further complicate visualization of the lens during surgery. Finally, the integrity of the lens capsule and lens zonules must be evaluated. Phacodonosis or decentration of the crystalline lens is indicative of more severe zonular loss. Phacodonosis is more evident prior to dilation as the dilated pupil and ciliary body tends to tamponade a loose lens. After dilation, the position of the lens with the patient supine and face up can be assessed with a direct ophthalmoscope or portable slit lamp. Posterior dislocation of the lens during this maneuver suggests severe zonular loss.

Typically, obtaining axial length and keratometric measurements is not difficult in these patients unless there is significant scarring in the cornea. Predicting postoperative anterior chamber depth in these patients can be difficult, however. In general, patients with significant zonular weakness or loss will have deeper anterior chambers than predicted postoperatively. Thus, when choosing a lens power, we aim for a little more myopia than usual. This hedge minimizes the chance for a postoperative hyperopic result.

PLANNING THE SURGERY

Unpredictability is a cardinal feature of cataract surgery in patients with zonular instability. Thus, the surgeries are often more involved and longer than expected preoperatively. Therefore, it is prudent to use long-acting anesthetics such as peribulbar or retrobulbar anesthesia. In young or particularly anxious patients, general anesthesia is sometimes required to ensure patient cooperation. Patients with pseudoexfoliation syndrome and no other abnormality on exam are an exception to this rule and can safely undergo cataract surgery using topical anesthesia. However, if there is any concern that vitrectomy or suturing of a capsular tension ring or lens may be required, regional anesthesia will greatly facilitate the surgery and provide additional comfort to the patient.

Preoperative preparation of the eye with zonular instability is not different from routine cataract surgery. The eye is dilated with 2.5% phenylephrine and either 1% tropicamide or 1% cyclopentolate. A topical nonsteroidal anti-inflammatory is helpful in preserving mydriasis and may minimize cystoid macular edema. Topical fluoroquinolones and 5% betadine may be instilled into the cul-de-sac preoperatively to reduce levels of microbial flora.

In planning surgery for patients with zonular instability, we find it useful to preoperatively stage patients into one of three categories.

Type I zonular stability is characterized by mild generalized zonular weakness or with localized zonular loss. Examples of patients in this group are those with pseudoexfoliation syndrome or localized trauma. On examination, the pseudoexfoliation patient will typically have pseudoexfoliative deposits on the anterior chamber, small pupils even with dilation, and iris transillumination defects. In the eye with a small area of localized trauma, there is often vitreous prolapse and iris trauma in the area of zonular loss. However, no phacodonosis or lens decentration is present preoperatively. These patients represent the mildest form of zonular instability.

Type II zonular instability is characterized by those eyes with marked regional zonular loss but with apparent retained zonular integrity in at least one quadrant. These patients typically have had significant trauma or systemic conditions such as Marfan's syndrome, homocysteinuria, congenital ectopia lentis, and Weil–Marchesani syndrome. On examination there is usually obvious evidence of zonular compromise. There may be associated iris abnormalities such as an iridodialysis. Vitreous prolapse into the anterior chamber is common. Posterior or anterior displacement of the lens in the area of zonular loss is common and there may be phacodonosis with eye movements. The lens is typically decentered and may tilt posteriorly when the patient is supine. Despite these findings, the eye appears to have at least one quadrant where the lens zonules appear intact.

Type III zonular instability includes those patients with diffuse and severe zonular weakness or with near total or total zonular loss. Patients in this group can include patients with advanced systemic conditions or severe trauma.

TYPE I INSTABILITY

The expectation for patients with minimal zonular instability is that the cataract can be removed with little deviation from the standard cataract surgery. The defining feature of these patients is that the lens is well stabilized and can tolerate the stresses of a gentle cataract surgery. The zonular deficiencies in these patients, however, can result in decentration of the posterior chamber IOL. Thus, the primary surgical deviation in most of these cases consists of placement of a standard capsular tension ring (CTR) to stabilize the capsular bag. The patient with segmental zonular loss may also require vitrectomy.

Capsular tension rings were first described in rabbits by Hara and Yamada in 1991,[9] in patients by Legler and Witshcel (1993), and in human cadaver eyes by Nagamoto and Bissen-Miyajima in 1994. The current standard CTR is a flexible, circular, open ring segment composed of polymethylmethacrylate with eyelets at each end (Fig. 73.2, *A*). When inserted into the capsular bag, CTRs are compressed to the size of the capsule and provide centripetal force to the equator of the capsular bag. This distention helps maintain the normal shape of the capsular bag allowing for centration of the IOL within the capsular bag. Additionally, the tension created by the CTR provides rigidity to the capsule. Thus, stability provided by areas of strong zonule integrity is transferred via the inherent rigidity of the compressed CTR to areas with less stability. Capsular tension rings work best in eyes with less than approximately 120° of consecutive zonular loss.

In eyes with more than 120° of consecutive zonular loss, there is often insufficient support in the axis of loss to prevent decentration of the capsule and thus a sutured or modified CTR or capsular tension segment (CTS) may be required. Modified CTRs were developed by Cionni and are similar to standard CTRs with the exception that they have suture eyelets that extend anteriorly around the anterior capsule and allow suturing of the CTR to the sclera without having to pierce the capsule with a needle (Fig. 73.2, *B–D*). The CTS is a similar device developed by Ahmed in that it contains an anteriorly displaced eyelet for suturing of the device to the sclera, but differs in that it extends only 120°[10] (Fig. 73.2, *E*). These devices are discussed in more detail in the discussion of type II stability.

Standard capsular tension rings are currently produced by two manufacturers: Morcher GmbH (Stuttgart, Germany) and Ophtec (Groningen, The Netherlands). CTRs are available in different sizes and are packaged according to the diameter of the CTR in its uncompressed state. When selecting a standard CTR, it is preferred that the length and diameter of the CTR be greater than the circumference and diameter of the capsular bag to ensure enough expansile force to expand and stabilize the capsular bag. Axial length and white to white measurements can be used to approximate the capsular bag diameter, and thus may be helpful in selecting the appropriate size CTR.[10,11] However, with the exception of very small eyes, it is difficult for the CTR to be too long. Thus, we typically use the longest CTR, which is 14.5 mm in diameter in the uncompressed state. Other authors also prefer routinely using larger-sized CTRs.[10] The only downside to using the largest CTR in each case is the largest CTR is also the stiffest and one needs to be more careful during insertion to avoid damaging zonules further.

Incision placement is an important consideration in planning surgery in these patients and can greatly facilitate or hinder the surgery. In patients with pseudoexfoliation and no other abnormalities on examination, we use a standard temporal clear corneal incision. In those eyes with segmental zonular loss, we find it helpful to place the clear corneal incision 90–180° from the area of loss. The advantage of this incision placement is that it facilitates suturing of a capsular tension ring in the area of loss if it becomes necessary to do so. Suturing a ring adjacent to or below the incision can be difficult. However, it is also important to pay attention to the anatomy of the patient's orbit. Deep and small orbits can interfere with access to the incision. Thus, in these patients it is helpful to keep the incision in the temporal cornea.

In type I zonular instability, the creation of the capsulorrhexis, phacoemulsification, and cortical removal can typically be performed using standard cataract surgery techniques. There are a few potential modifications that may simplify the surgery, however. First, in eyes with zonular loss, vitreous tends to follow the flow of fluid. We recommend placing a generous amount of a dispersive viscoelastic agent over the area of zonular loss to help prevent vitreous prolapse. Additionally, it is important to avoid collapse of the anterior chamber in these cases. When pressure in the anterior chamber decreases, a posterior to anterior pressure gradient develops which can promote anterior displacement of vitreous. This situation occurs most commonly with withdrawal of large instruments from the main incision. Thus, simultaneous introduction of viscoelastic or balanced salt solution through a paracentesis each time instruments are removed from the main incision will help maintain a formed anterior chamber and minimize the chance of vitreous advancing forward. Slow motion phacoemulsification using lower bottle heights and aspiration and vacuum settings can also be useful in preventing sudden pressure changes that contribute to chamber collapse and instability.[12] The management of vitreous in the anterior chamber is discussed below. Careful but thorough hydrodissection to separate the lens from the capsule will minimize stress during manipulation of the nucleus and cortical stripping.[13,14] In dense nuclear cataracts, higher ultrasound power can increase the cutting power of the phacoemulsification tip, and therefore reduce lateral force on the lens and zonules. Finally, careful cortical stripping in the area of zonular dehiscence is required to prevent additional disruption of the intact zonules adjacent to the area of loss. The surgeon should consider cortical viscodissection to decrease the zonular stress during cortex removal (Fig. 73.3). In cases where the zonular loss is sufficient to interfere with gentle cortical stripping, a CTR can be placed to help stabilize the bag for cortical removal. While the ring may trap some cortical material, viscodissection prior to CTR placement will limit entrapped cortex. This maneuver is not commonly required in eyes with type I zonular instability, but is often necessary in more severe cases.

In eyes with zonular loss, vitreous may prolapse into the anterior chamber. If vitreous is not present at the beginning of the case, the use of dispersive viscoelastics to tamponade the area of loss can prevent vitreous prolapse. The tamponade may need to be reapplied during the case if some of the viscoelastic is accidentally removed during phacoemulsification or cortical removal. If the tamponade fails or if vitreous is present at the beginning of the case, a vitrectomy must be performed. Vitrectomy is best performed using a bimanual technique through either an anterior chamber approach or through a pars plana approach. It is commonly recognized that bimanual vitrectomy with an irrigating cannula placed through a paracentesis and a vitrector inserted through a pars plana

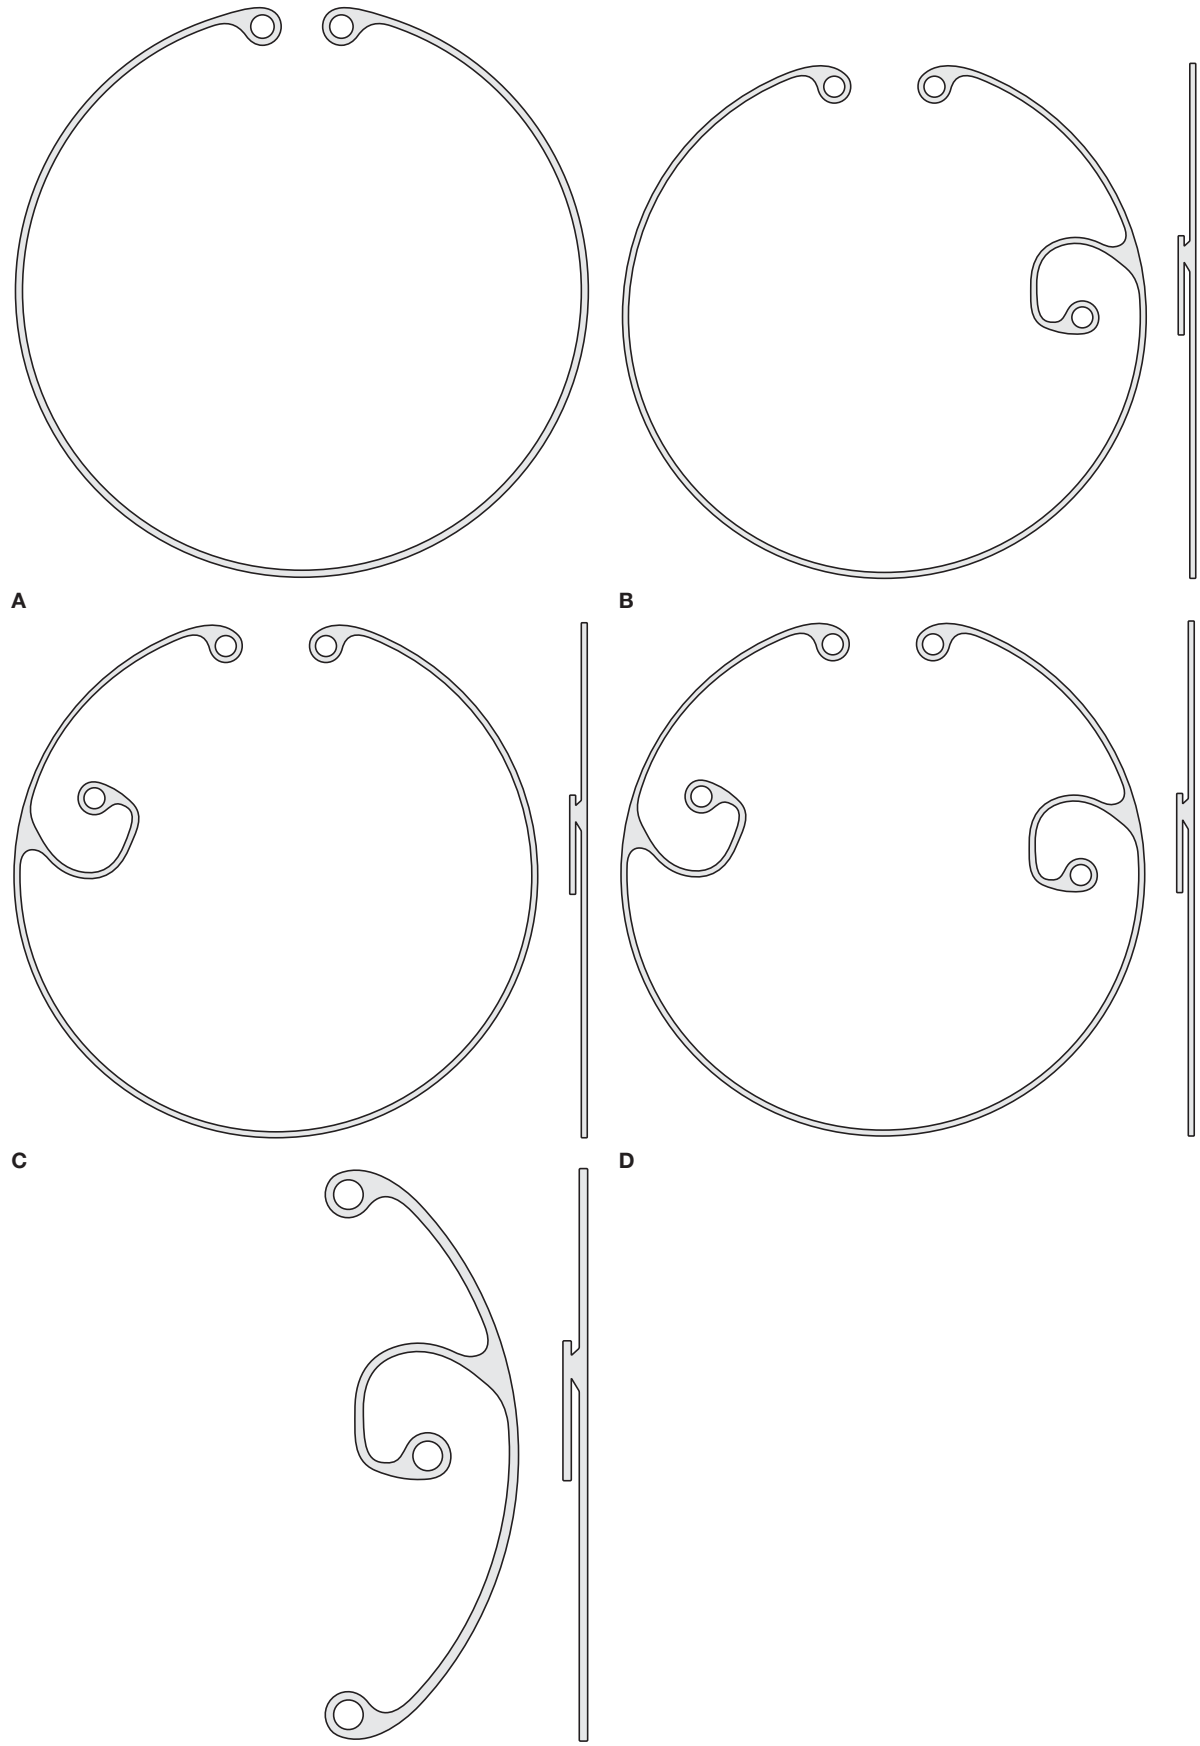

Figure 73.2. Capsular support devices. *A*, The appearance of the standard capsular tension ring (CTR). *B*, *C*, and *D*, Modified capsular tension rings (MCTRs). These devices possess an anteriorly displaced suture fixation eyelet to allow for suturing of the device to the scleral wall without having to compromise the integrity of the capsule. The MCTR in *D* has two fixation eyelets for eyes with little or no zonular support. *E*, The capsular tension segment.

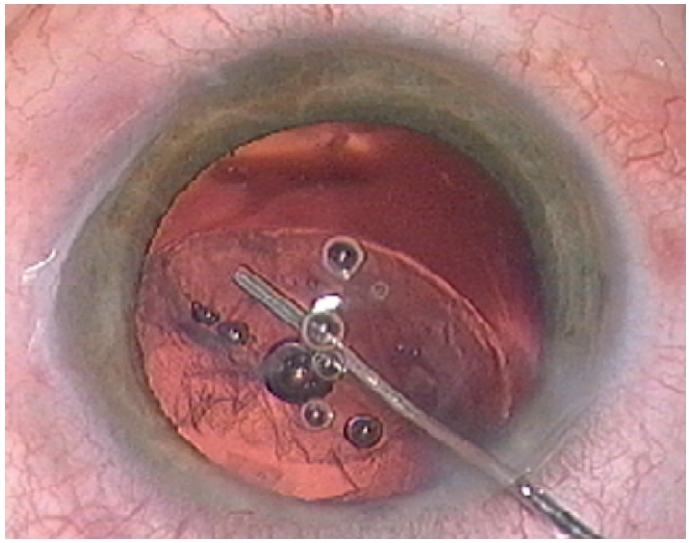

Figure 73.3. Viscodissection of lenticular cortex is achieved by gentle injection of a dispersive viscoelastic between the capsule and the lens cortex. This procedure greatly reduces adhesion of the cortex to the capsule and thus facilitates subsequent cortical removal. Viscodissection is particularly useful when a CTR must be placed prior to cortical removal. In these cases viscodissection is performed prior to placing the CTR and can significantly reduce the chance of equatorial cortical material being entrapped between the CTR and capsule.

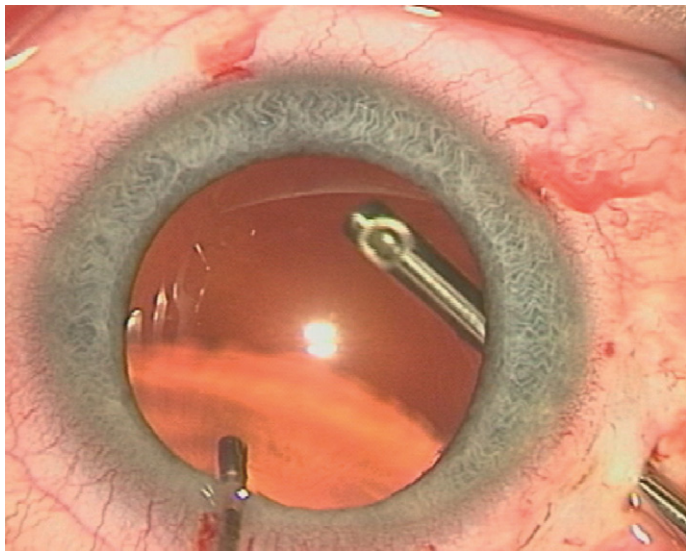

Figure 73.4. The photograph demonstrates bimanual vitrectomy in a patient with lens subluxation and vitreous prolapse into the anterior chamber. An irrigating cannula is inserted through a paracentesis. The vitrector is then inserted through a pars plana sclerotomy and can be visualized posterior to the lens. The bimanual approach greatly facilitates vitreous removal.

sclerotomy is generally the most efficient approach.[15,16] The advantage of this approach is that the flow of fluid is from the anterior chamber to the posterior chamber, and thus, vitreous is swept out of the anterior chamber. We typically use a 20 gauge vitrector and make a sclerotomy 3.0–3.5 mm posterior to the limbus directly below the main corneal incision (Fig. 73.4). With the main incision 90–180° from the area of zonular loss, this location facilitates placement of the end of the vitrector in the affected area while maintaining visualization of the instrument through the pupil. Often, only

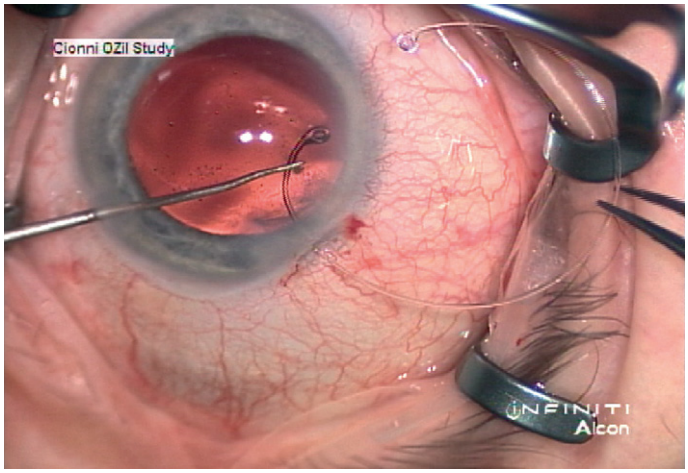

Figure 73.5. Placement of a standard CTR is achieved with the inserter or with a bimanual technique using standard instrumentation. In this photograph, the CTR is being inserted with a forceps. Once the leading edge is in the capsule, it is advanced by gently pushing the trailing end using the forceps. A second instrument, such as a y-hook, can be inserted through a paracentesis and used as a guide if necessary. The trailing end can be dialed into the capsule using either the forceps or y-hook.

a small, localized vitrectomy is required to clear the anterior chamber using this technique. Another significant advance in the management of vitreous prolapse into the anterior chamber is the use of purified intracameral triamcinolone acetonide to stain the vitreous.[17] Identification of the vitreous in this manner greatly facilitates vitreous removal by allowing the surgeon to properly direct the vitrector and visualize when the normally transparent vitreous is gone. Upon completion of the case, the sclerotomy and the conjunctiva are closed with a suture of choice. Newer 25 or 23 gauge vitrectomy probes can be used in conjunction with transconjunctivally placed trocars and typically do not require scleral and conjunctiva closure.[18] Specifics regarding the settings for the various vitrectomy methods differ depending on the equipment used and are beyond the scope of this chapter. Details are best obtained from surgeons or company representatives familiar with the specific equipment in question.

Following cortical removal we typically place a standard CTR in eyes with type I zonular instability. An important prerequisite, however, is that the posterior capsule and the capsulorrhexis be intact. CTRs exert radial tension on the equator of the capsular bag, which can promote extension of tears and can result in migration of the CTR into the posterior chamber.[19–21] If the capsule is torn, a posterior chamber IOL will likely need to be sutured in order to achieve stability and centration or an anterior chamber lens must be placed. Methods for suturing of IOLs are discussed in the section of type III zonular instability. With an intact capsule, a CTR can be placed using specially designed inserters or using standard instrumentation. To place the ring, the capsular bag and anterior chamber are inflated with viscoelastic and one end of the ring is inserted through the main incision and into the bag (Fig. 73.5). The ring is slowly advanced with the inserter or a forceps with one hand and gently guided in the proper direction with a second instrument through a paracentesis. The second instrument helps minimize tension on the edge of the capsulorrhexis and lateral displacement of the capsular bag. When the trailing end approaches the main incision, a y-hook or the inserter engaged in the trailing eye hook

is used to advance the ring until the trailing end is under the edge of the capsulorrhexis and the eyelet is released. If one encounters difficulty 'feeding' the CTR along the capsular bag equator, a 10.0 nylon suture can be looped through the leading eyelet, left trailing out the incision and gently tugged during ring insertion to help guide the leading eyelet circumferentially. If it is unclear whether a suture will be required to maintain centration of the IOL, a modified CTR can be placed instead of a standard CTR. If it is subsequently determined that a suture is not required, the fixation hook of the MCTR can be placed posterior to the capsulorrhexis edge, inside the capsular bag and the MCTR will perform as a standard CTR. It is important in these situations, however, that the suture loop be placed into the capsular bag to avoid the risk of postoperative iris capture in the loop.

After placement of the CTR, the IOL is inserted into the bag. Viscoelastic can then be removed with automated irrigation and aspiration. If vitrectomy has been performed or if there is an area of zonular loss, reduced aspiration and vacuum settings may help prevent forward displacement of vitreous into the anterior chamber. It is also advisable to leave some dispersive viscoelastic in the area of the dehiscence to prevent late intraoperative vitreous prolapse. Postoperative elevations of intraocular pressure are typically transient and can be managed with topical or oral medications if necessary.

The safety and effectiveness of CTRs in patients with type I zonular instability has been well documented. Gimbel et al published a retrospective review of 14 cases in which the CTR was used for mild zonular laxity or loss.[22] He concluded that the use of CTRs in these patients helped prevent capsular bag collapse and vitreous loss and maintain centration of the IOL. Byraktar et al published a prospective randomized trial of 78 eyes with pseudoexfoliation. In the study, half of the patients received a CTR and half did not. In the eyes without a CTR, five developed zonular loss and three had a posterior capsule rupture. In contrast, no eyes in the CTR group had zonular loss and only two eyes suffered a posterior capsule rupture. Additionally, IOL centration was better in the group that received the CTR.[23] Finally, Price et al published interim results of a multicenter trial using the Ophtec CTR.[24] In this paper, 255 eyes with weakened or broken zonules comprising one-third or less of the circumference of the lens capsule received a CTR. At 1 year following surgery, only 4 of 172 eyes had decentration of the IOL. Complications during surgery were rare and included posterior capsular rupture in 3 eyes and vitreous loss in 6 eyes. The authors concluded that the use of the CTR in these patients was safe and provided capsular support during and after cataract surgery.

TYPE II INSTABILITY

Eyes with type II instability present additional challenges. These eyes are characterized by significant zonular loss and nearly all phases of the surgery become more difficult. In these patients, the surgical objective is to remove the cataract while maintaining an intact capsule and provide long term, in-the-bag, support for a posterior chamber IOL (PCIOL) by securing the capsule with a sutured capsular tension ring or segment. Since suturing is likely to be required, selection of incision site is particularly important. Again, our preference is to have the incision 90–180° from the location, the suture will likely be required, in deep obstructed orbits, somewhere in the temporal aspect of the eye. Some of these cases may have vitreous prolapse in the anterior chamber and thus require vitrectomy early in the case. Vitreous provides significant support to the lens, however. Thus, if the vitreous does not interfere with access to the lens, it is typically easier to perform the capsulorrhexis and stabilize the capsule with hooks or a CTS prior to the vitrectomy (Fig. 73.6) Our approach to vitrectomy in these patients is described in the previous section on type I instability. The use of triamcinolone acetonide resuspended in balanced salt solution (BSS) to label the vitreous is particularly helpful in these cases since it allows the surgeon to visualize the removal of vitreous, and therefore remove as little vitreous as required.

The capsulorrhexis in eyes with marked zonular loss can be very challenging. First, the lens may have a tendency to drift posterior while trying to grasp or penetrate the anterior capsule. For this reason, it is best to begin the capsulorrhexis in an area of maximum fixation and tear away from this area. If there is too little support to begin the capsulorrhexis, it is often helpful to support the lens with a blunt second instrument passed through a pars plana sclerotomy. A capsulorrhexis forceps may perform better than a cystotome in these patients since the forceps can grasp the capsule and pull tangentially without any downward force on the lens. In fact, gentle anterior elevation can be applied with the forceps during the creation of the capsulorrhexis to further help stabilize the lens. Care must be taken not to pull too anteriorly, however, or it is likely the advancing tear of the capsulorrhexis will extend radially. The second difficulty in performing the capsulorrhexis in these eyes is that during the tearing of the capsulorrhexis the lens will tend to decenter as the tear is directed away from the area of zonular loss. One method of addressing this problem is to use a second instrument to stabilize the capsule while completing the capsulorrhexis. Iris hooks or a CTS can be used to secure the edge of the anterior capsule in an area where the capsulorrhexis has been performed[10,25–27] (Fig. 73.6). This additional fixation will provide the necessary counter traction to stabilize the capsule while tearing away from this area. Additional hooks or a second CTS can be

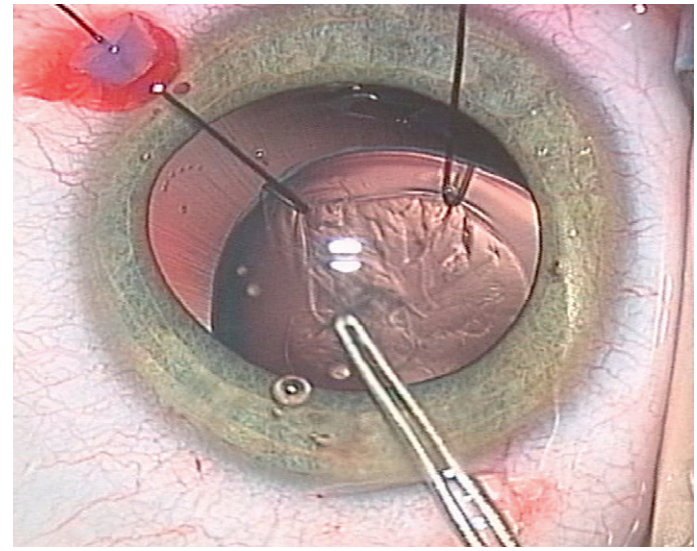

Figure 73.6. Nylon iris hooks are utilized to stabilize the capsular bag during creation of the capsulorrhexis. The capsulorrhexis is started in an area of zonular integrity and the tear is directed away from this area. As the tear advances into areas of less integrity, there may be insufficient counter traction to control the advancing tear. In these situations iris hooks can be used to secure the edge of the capsulorrhexis. The hooks provide the needed capsular stability to resist the forces of the advancing tear during completion of the capsulorrhexis.

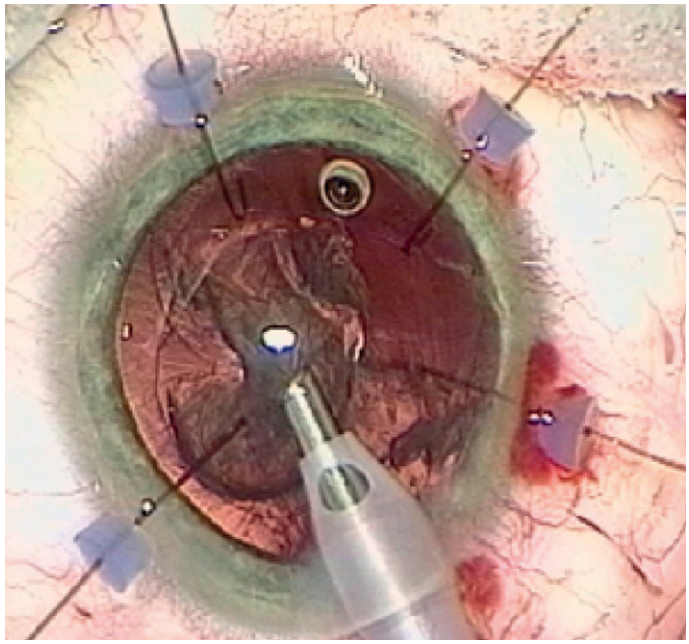

Figure 73.7. Four iris hooks have been used to secure the edge of the capsulorrhexis. The hooks provide marked capsular support which prevents posterior and lateral displacement of the capsule during phacoemulsification and cortical removal.

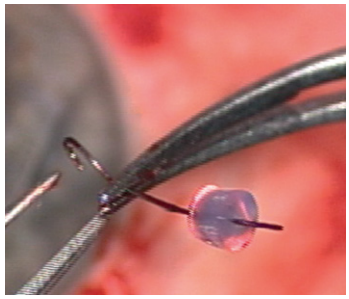

Figure 73.8. When placing iris hooks to secure the capsule, the ideal positioning is to have the bend in the hook engage the capsulorrhexis edge and apply a primarily lateral force. In eyes with deep anterior chambers, iris hooks inserted at the limbus must course posteriorly to reach the capsule which can result in the ends of the hooks exerting more anterior force on the capsule. This positioning increases the risk of capsular tears. To prevent this from happening, the shaft of the iris hook can be bent to change the orientation of the hook relative to the shaft. In this photograph, two forceps are used to bend the shaft to the desired position where it is held for 10–15 s.

placed if needed as the capsulorrhexis is created. It is not always possible to achieve a centered capsulorrhexis of ideal size (5–6 mm) in these eyes. It is better to have a decentered intact capsulorrhexis than a radial tear. If the capsulorrhexis edge is in the visual axis and symptomatic, it can be enlarged with the YAG laser, but no sooner than 2 months post-op.

In some eyes an intact capsulorrhexis may not be possible. The CTS can often be used to provide intraoperative and long-term stability in these cases. Unlike the modified CTR, the CTS has a short intracapsular segment that does not exert radial tension on the equator of the capsule. Rather it slips under capsule edge to provide localized stability of the anterior capsule. Like the modified ring, it has an anteriorly located fixation eyelet to facilitate suturing of the device to the sclera for permanent fixation. These unique features allow the CTS to be used in cases with radial tears of the anterior capsule or posterior capsular rupture.[10]

Once the capsulorrhexis is completed, it is helpful to stabilize and center the capsule in preparation for cataract removal. Iris hooks or the CTS are ideal for this purpose[10,25–27] (Fig. 73.7). The hooks are inserted through limbal stab incisions and the edge of the capsulorrhexis engaged in the areas of zonular loss. Bending a disposable nylon iris retractor back on itself and holding it in that bent position for 10–15 s will allow it to maintain a more usable configuration throughout the procedure (Fig. 73.8). Depending on the amount of instability, one to four hooks can be placed. As mentioned earlier, multiple capsular tension segments can also be placed if necessary to stabilize the capsule.[10] While it is prudent to use caution, an intact capsulorrhexis can typically withstand significant tangential pressure. Stabilization and centration of the capsule greatly facilitates subsequent phacoemulsification of the nucleus and cortical removal. Prior to cataract removal, however, all vitreous should be removed from the anterior chamber. The anterior chamber can be inspected for additional vitreous with triamcinolone acetonide suspended in balanced salt solution as previously described. Once the anterior chamber is clear of vitreous, tamponade of the area with zonular loss should be performed with a copious amount of dispersive viscoelastic. Typically, phacoemulsification can then be performed as previously described for type I instability. Cortical removal can then be attempted. The loss of zonular support across large areas of the lens, however, often results in inadequate stability of the equatorial capsule. Thus, as cortex is stripped centrally, the equatorial capsule migrates centrally with the cortical material and further stress and damage may occur to adjacent intact zonules. When this occurs, cortical stripping can be greatly facilitated by placing a modified CTR prior to cortical removal. As mentioned above, viscodissection will also help immensely. In patients where the surgeon has placed a CTS to stabilize the capsule, it is important to realize that the CTS does not provide equatorial stability to the capsule. If the capsule is intact, a standard CTR can be placed in these patients to assist with cortical stripping and IOL centration.[10]

Patients with type II instability require suture fixation to maintain centration of the IOL. To achieve centration and maintain an intact capsule, a modified CTR or a CTS is required. The modified CTRs come in left- and right-handed versions which differ in the axial orientation of the suture loops relative to the curvature of the leading edge of the ring. When placing the modified CTR, it is important that the suture loop project anteriorly to capture the edge of the anterior capsule. Thus, left-handed rings are passed in clockwise and right-handed loops are inserted counterclockwise.

When suturing the modified ring with two fixation hooks (Model 2-L), suture the eyelets at whatever axes achieve centration. This may not necessarily be 180° apart and depends on the diameter of the capsular bag. Prior to placing the ring, one end of a double armed 9-0 prolene suture or 8.0 gortex suture with long needles such as CIF-4 or CTC-6 needles, is passed through the suture fixation eyelet (Fig. 73.9). Other suture types can be used and are discussed below. An inserter can be used for Model 2-C or standard instruments can be used to place any of the MCTRs which are inserted as described previously. Once the ring is in the capsule, it must be rotated to orient the fixation hook in the area of zonular loss.

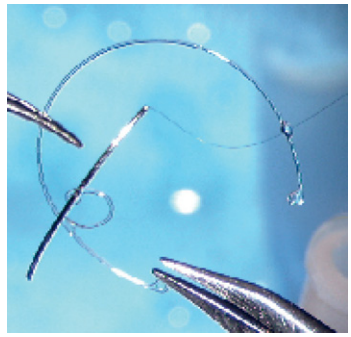

Figure 73.9. This photograph demonstrates placement of the MCTR. A 9-0 prolene suture is passed through the fixation eyelet. The MCTR is then placed in the capsule as described. Specially designed inserters allow for one-handed insertion. Alternatively, bimanual insertion can be performed using standard instrumentation such as forceps and y-hook.

Once the desired positioning is achieved, the sutures are placed. We typically perform an ab interno suturing technique. A conjunctival peritomy approximately 2–3 clock hours in length and a small conjunctival relaxing incision are performed in the area the sutures are to be placed. Hemostasis can be maintained by light cautery. Prior to passing the sutures, we typically make a partial thickness scleral flap. The role of the flap is to cover the suture and reduce the risk of erosion of the suture through the conjunctiva, which is a risk factor for late postoperative endophthalmitis. Scleral flaps are not needed if the suture knot is rotated and buried in the sclera. In fact, rotation of the knot intraocularly has been demonstrated to be superior to covering the knot with a sclera flap in preventing suture erosions.[28] It is our intention to rotate and bury the suture knots in these cases, but it can be difficult to rotate 9-0 prolene or 8-0 gortex knots. Thus, we may typically prepare a scleral flap in case the knot cannot be buried. The sleral flaps can be hinged at the limbus or posteriorly. Posteriorly hinged flaps provide the best visualization of the flap bed, however. Additional viscoelastic is placed between the iris and anterior capsule to maximize space for passing the needle. One needle of the double-armed suture is passed through the main incision, between the iris and anterior capsule, then through the sclera 1.0 mm posterior to the limbus and out through the flap bed.[29] While the needle is in the scleral wall, the needle track can be slightly enlarged by scoring the sclera at the needle exit site with a pointed 15° blade. This procedure increases the likelihood that the suture knot will rotate through the sclera later in the case. The second needle is passed in a similar fashion at least 1 mm away from the first. Care must be taken to avoid tangling the suture ends. The needles are removed and the suture tension adjusted to achieve desired centration. Alternatively, an ab externo suturing technique can be used to secure the modified CTR.[30] If iris hooks have been used to stabilize the capsule, they can be removed once the sutures are passed. The suture is then temporarily secured with a slipknot. An IOL of choice is then inserted into the capsular bag and viscoelastic removed from the capsular bag and anterior chamber. If automated irrigation and aspiration are used, lowered bottle height, aspiration, and vacuum setting can help prevent reintroduction of vitreous into the anterior chamber. With the anterior chamber inflated with balanced salt solution and a normal intraocular pressure established, the centration of the capsule is re-evaluated and the suture tension adjusted to achieve the desired result. The suture is then secured, trimmed, and rotated to bury the knot. The scleral flap is then repositioned and the conjunctiva redraped to the limbus and secured. While no sutures are typically required to close the scleral flap directly, it can be sutured with a 10-0 nylon or fine absorbable suture if desired. Figure 73.10, *A* and *B* demonstrates the preoperative appearance of a patient with marked subluxation of a lens and the immediate postoperative appearance of the secured MCTR. Typically, miotics are used in these patients to constrict the pupil in order to ensure no vitreous is within the anterior chamber. It is essential that the wound be watertight to prevent anterior

migration of vitreous seen with anterior chamber collapse. If necessary, the wound should be stabilized with interrupted 10-0 nylon sutures.

Several alternative sutures are available for securing IOLs and capsular tension rings. A thorough discussion of these options is beyond the scope of this chapter. We have used 10-0 prolene and 8-0 gortex suture in addition to the 9-0 prolene. Although the 10-0 prolene is easier to work with than 9-0 prolene, in our experience it is prone to breakage a year or more after surgery.[31] Gortex suture appears to be robust and the material is easier to tie than prolene. However, Gortex suture is only available on thick tapered needles, which can be difficult to pass through the sclera. It is less likely to erode overlying conjunctiva or sclera when it is not buried, however, and is a good alternative to 9-0 prolene.

The safety and efficacy of modified CTRs have been demonstrated by several authors. Moreno-Montanes et al published a series of seven eyes with subluxated lenses from Marfan's syndrome, trauma, megalocornea and unknown etiology that received a modified CTR at the time of cataract surgery.[31] The primary complication was posterior capsule opacification in five eyes. YAG capsulotomy can be performed normally on these eyes as long as the patient is at least 2 months post-op. All eyes maintained excellent IOL centration at 1 year. Similarly, Cionni et al described 90 eyes with congenital loss of zonular support resulting from Weill–Marchesani syndrome, Marfan's syndrome and idiopathic ectopia lentis that received a modified CTR at the time of cataract surgery.[32] The authors demonstrated marked increase in lens stabilization and centration. Postoperative complications were uncommon and included increased intraocular pressure (2%), persistent iritis (3%), broken fixation suture (10%), retinal detachment (1%), and posterior capsule opacification (20%).

TYPE III INSTABILITY

Patients with type III zonular loss have little or no zonular support and require multiple suture fixation points to stabilize the lens. The absence of any significant support makes manipulation of the lens difficult without the lens migrating posteriorly. Often these eyes are best approached with the help of a retina specialist to perform a lensectomy and vitrectomy. An IOL can then be sutured to the iris or sclera. Not infrequently, patients with apparent type II instability can progress to type III pathology intraoperatively. Thus, in questionable cases of type II instability, it may be worth having a retina specialist on call if possible. Invariably, however, surgeons working on this patient population will encounter cases in which the lens wants to drop posteriorly. In these situations, a couple of options are available. First, posterior-assisted levitation of the lens can be attempted with a second instrument or viscoelastic introduced through a pars plana sclerotomy. Posterior-assisted levitation was first described by Kelman[33] as a procedure to stabilize a sinking nucleus. Others have used the technique to stabilize fragments or IOLs.[34–37] The goal of this procedure is to reposition and stabilize the lens into the anterior chamber or at the iris plane, where it can be removed with phacoemulsification or with the vitrector. Frequently, the end result of cataract removal in patients with type III instability is complete loss of the capsule. However, occasionally, a capsule can be maintained.

In eyes with minimal zonular support and an intact capsule, capsular fixation can be managed using a modified CTR as described for type II instability. However, an MCTR with two suture loops opposing each other is used (Fig. 73.2*D*). An IOL can then be inserted into the capsular bag. In eyes with no capsule, the IOL must be sutured to the iris or sclera or an anterior chamber lens used.

The decision of whether to fix the IOL to the iris or sclera or use an anterior chamber lens is made based on several factors. Surgeon preference, patient age, and other ocular pathology are the most important determinants. Anterior chamber lens design has dramatically improved since its initial development and several publications document their safety.[38–40] However, concerns regarding angle trauma, peripheral anterior synechia formation, pigment dispersion, secondary glaucoma, and cornea endothelial trauma still exist.[41–43] Thus, these lenses are probably best utilized in patients with a normal iris anatomy, angle function, and corneal endothelium. We also refrain from using these lenses in young patients with a long expected lifespan. The decision to use iris or scleral fixation is also controversial. Potential risks of iris fixation include chronic inflammation, pigment dispersion, and iris atrophy[44,45] and the use of scleral sutures can result in suture erosion and endophthalmitis.[46,47] Again, patient age is an important factor. Elderly patients with a limited expected lifespan are good candidates for either procedure. Younger more active patients will likely benefit from the more stable fixation of scleral sutures. Obviously, a normal or nearly normal iris is required for iris fixation. Below we describe both suture fixation techniques.

There are several methods and numerous variations for scleral fixation of an IOL through a small incision. In this chapter, we discuss the general principles and demonstrate our preferred approach. Alternative approaches are described in an excellent review by Por and Lavin.[48] We prefer fixation of scleral sutured IOLs in the ciliary sulcus and typically use an ab interno approach as previously described for scleral fixation of the modified CTR. One important difference, however, is that foldable IOLs that fit through small incisions do not have suture eyelets. Thus, the haptics must be snared or secured with the suture. Two general approaches can be used to secure the haptics. The first option is to tie one end of a single-armed suture to each haptic.[48–50] Each needle is then passed through the corneal incision, behind the iris to exit the sclera approximately 1.0 mm posterior to the limbus at the desired points of fixation. The IOL is inserted and gentle tension applied to center the IOL. A second bite is taken adjacent to the initial needle exit site and the needle removed. The suture is then tied to itself. An alternative option is to use a double-armed suture and lasso the haptic[51] (Fig. 73.11). Both needles of each suture are then passed as described for the MCTR to exit the sclera adjacent to each other and the suture ends tied to each other (Fig. 73.12). With both of these techniques, the suture will not rotate and thus a scleral flap is recommended to prevent late postoperative erosion of the knot. Preparation of the incision site and selection of the suture material is the same as described for suturing of CTRs above. Reforming the anterior chamber and reforming the globe prior to securing the IOL sutures will minimize the risk of overtightening the sutures and inducing corneal astigmatism.

IOL selection for scleral fixation is important. Choosing an IOL with a large optic will minimize the risk of edge glare with mild decentration. Additionally, three-piece IOLs with polymethylmethacrylate (PMMA) haptics are preferred since the inherent rigidity of the haptics help stabilize the IOL. Our preference is the Alcon MA50BM lens (Alcon Labs Inc, Fort Worth, TX) with a 6.5 mm optic and PMMA haptics. Several lenses are specifically designed for suturing to the sclera and possess suture eyelets on their haptics; however, these lenses are rigid and require enlargement of the wound to accommodate the diameter of the optic. The lenses can

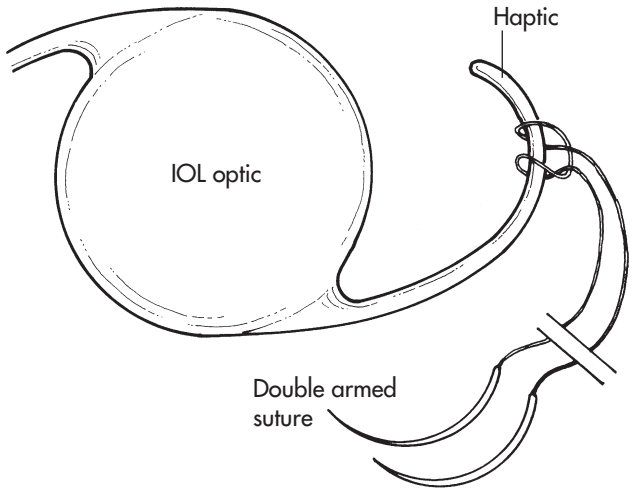

Figure 73.11. One method of securing the haptic of a standard posterior chamber intraocular lens for scleral fixation with a double-armed suture is a girth hitch.

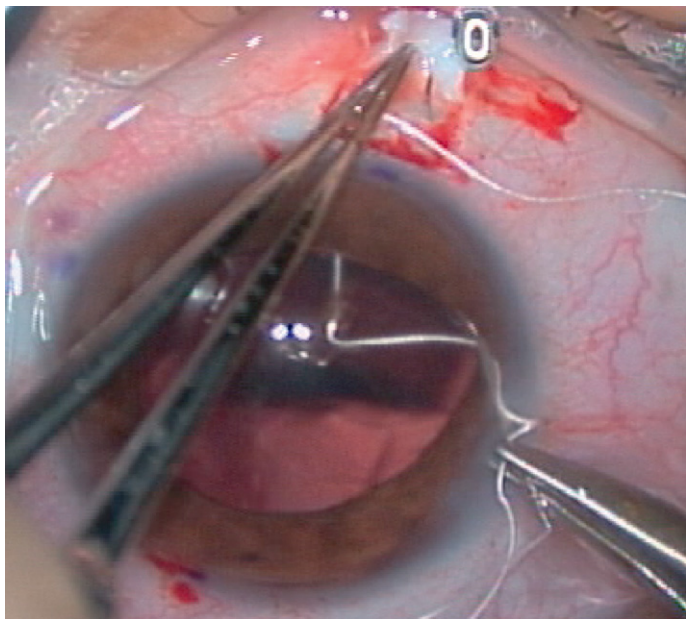

Figure 73.12. Scleral fixation of a standard PCIOL involves suturing the haptic to the sclera. In this patient one needle of a double-armed 8-0 Gortex needle has been passed. Here the pass of second needle can be seen through the main incision, behind the iris and out the sclera 1.0 mm posterior to the limbus in a previously created scleral flap. Once both needles are passed, the needles are removed and the suture secured. The sclera and conjunctiva are then closed with a suture of choice.

be secured by either suturing one end of a single-armed suture to the eyelet or passing one end of a double-armed suture through each eyelet. The advantage of the latter procedure is that the suture knot can be rotated. When passing the double-armed suture through the suture eyelet, care must be taken to ensure that the sutures are passed in similar directions through both eyelets to avoid torquing and tilting of the lens.[52] The IOL is inserted, the incision is sutured closed and the sutures secured as described above.

Iris fixation of IOLs can be achieved with iris claw lenses or suturing of standard foldable IOLs. Currently, the only iris claw lens

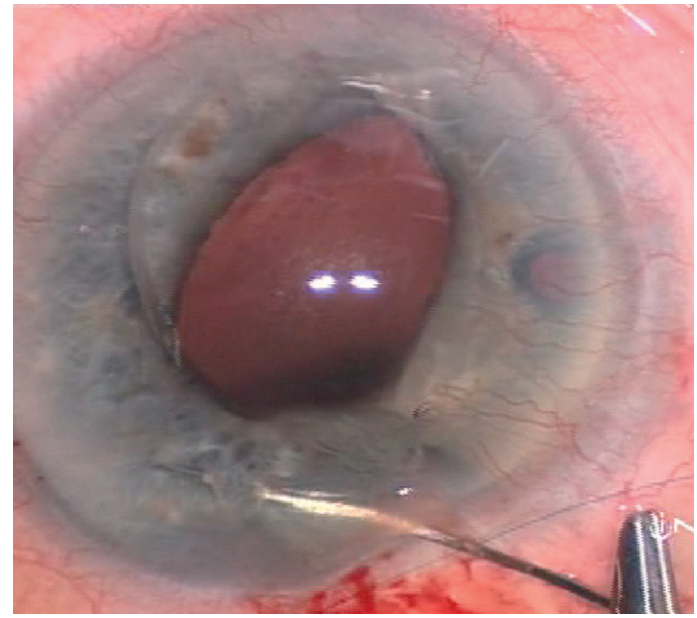

Figure 73.13. Iris fixation of a standard three piece foldable PCIOL is achieved by placing the lens in the eye with the haptics posterior to the iris and the optic captured anterior to the iris. The intraoperative photograph demonstrates passage of a CIF 4 needle on a 10-0 prolene suture through the main incision, through the iris, around the haptic and back through the iris. The needle is then passed out the cornea near the limbus. The needles are removed and the suture ends are retrieved through the main incision and secured using a Siepser knot.

available is the Verisyse (AMO, Santa Ana, CA). It has successfully been used as an alternative to sutured IOLs in eyes without capsular support and can be fixated to the anterior or posterior aspect of the iris.[53] Cost and the lack of a foldable version of this lens in the USA have limited its use for nonrefractive applications. However, further investigation of this approach is warranted.

Most iris fixated lenses are sutured. Again, several variants have been described. Our preferred approach is based on the method first described by McCannel.[54] In this procedure a standard foldable three piece IOL with PMMA haptics is introduced into the anterior chamber with the haptics behind the iris and the optic captured by the pupil anterior to the iris. Miotics are often required to achieve the capture. Folding the IOL transverse to the axis of the haptics will facilitate introduction of the haptics behind the pupil. If properly positioned, the location of the haptics will be apparent as they tent up the iris. A single-armed 10-0 prolene suture on a CIF-4 needle can then be passed through the main incision, through the iris adjacent to the haptic approximately one-third the distance from the iris insertion to the pupil margin (Fig. 73.13). The needle is then passed around the haptic, back through the iris out the cornea near the limbus on the opposite side. Often slight elevation of the optic with a second instrument is useful to stabilize the IOL and visualize the position of the haptic under the iris while passing the suture. Once the suture is passed, the needle can be removed and the suture ends retrieved through the main incision with a forceps or hooked instrument. The suture can then be tied intraocularly using a Siepser slip knot.[55] The second haptic is secured in a similar fashion and temporarily secured. The IOL is then positioned into the posterior chamber and the pupil further constricted with

miotics. Once the chamber is formed and the desired lens position obtained, the sutures can be permanently secured and trimmed. Viscoelastic is removed from the anterior chamber and the wound sutured if necessary.

CONCLUSIONS

Zonular instability greatly increases the difficulty of cataract removal and risk for postoperative IOL decentration. Technological advances such as capsular tension rings, IOL designs, and modern phacoemulsification systems have greatly improved the ophthalmologist's ability to manage these difficult patients. Detailed preoperative evaluation and staging of these eyes aids the surgeon to more accurately predict intraoperative findings and prepare for the surgery. Unfortunately, cataract surgery in patients with zonular loss remains unpredictable and the surgeon must try to prepare for all circumstances.

74 Iris biopsies and iridocyclectomy

Samir G. Farah

Iris masses can be benign or malignant. They can be primary or metastatic from extraocular neoplasms. Malignant melanoma is the most feared and most frequent primary malignancy in the anterior segment. Compared to ciliary body melanomas, iris melanomas tend to be smaller and visible, thus they are detected earlier. In contrast, ciliary body melanomas are considered more aggressive. Hidden behind the iris, ciliary body melanomas are usually detected after they have become relatively large.

In this chapter we review the current diagnostic trends of iris masses with emphasis on the different techniques of iris mass sampling and the new introduction of anterior segment optical coherence tomography (OCT) that have increased the diagnostic yield, and improved the management planning, and follow-up of anterior segment tumors. The iridocyclectomy procedure is also discussed.

IN THE CLINIC[1–8]

The diagnosis of anterior segment tumors is mostly done in the clinic. The clinical approach involves a complete ophthalmic examination, with past medical history, best corrected visual acuity, tonometry, slit-lamp biomicroscopy, gonioscopy, ophthalmoscopy with scleral depression, and transillumination of the tumor and the sclera. High-resolution photographs of the tumor should be taken to document its visible characteristics and for later comparison. Additional examinations may include water-bath ultrasonography, high-resolution ultrasound biomicroscopy (UBM), OCT, and fine-needle aspiration biopsy (FNAB). Computerized tomography and magnetic resonance imaging are done in special cases.

Usually the past medical history and the ophthalmic examination provide enough information to determine the diagnosis. A history of non-ocular cancers must be investigated: primary tumor organ location, type, treatment, and history of metastasis (Table 74.1). A past ocular history of ocular trauma, surgery, and inflammation is important.

Slit-lamp biomicroscopy and gonioscopy are essential. Inspection of the conjunctiva, the anterior chamber angle, and the iris are performed. After pupillary dilation, an examination of the ciliary body and lens is completed. Direct, indirect, and contact lens ophthalmoscopy help determine the posterior extension of an anterior segment tumor. When a suspected lesion is found, its morphology (plateau, dome, mushroom), surface (smooth, rough), color, size and width, anatomic location (e.g. iris, ciliary body), quadrant or clock hours affected, antero-posterior location (pupillary margin, mid-iris, or iris root) as well as involvement of surrounding structures (episcleral sentinel vessels, invasion of the angle, or iris root) are described. Secondary uveitis, sector cataracts, dislocated lens, scleral invasion, and posterior extension to the choroids are also noted.

Transillumination of the globe should be performed for tumors affecting the ciliary body and anterior choroid. Slit-lamp and gonioscopic photography can be extremely useful for documenting the tumor's clinical characteristics, allowing for accurate determinations of subsequent changes.

DIFFERENTIAL DIAGNOSIS OF IRIS TUMORS

The differential diagnosis of iris tumors is broad (Table 74.2). As a general guideline, the clinical differences between benign and malignant anterior segment lesions are as follows. Benign lesions tend to be flat or slightly elevated; they do not distort the iris stroma and they do not grow. Multiple or bilateral lesions are more commonly benign. Malignant melanomas generally present as solitary nodular lesions located in the lower half of the iris. They tend to be unilateral and they can be associated with abnormal vascularization, ectropion uvea, pupillary distortion, sector cataract, pigment dispersion, and glaucoma (Table 74.3). Pigment dispersion and tumor infiltration can be visualized on the corneal endothelium, the lens surface, the iris stroma, the trabecular meshwork, and ciliary processes. Secondary glaucoma is typically either melanomalytic (due to pigment dispersion) or due to a tumor growing within the aqueous outflow system. Malignant iris neoplasms also cause heterochromia, spontaneous hyphema, and chronic uveitis. Because the iris hides ciliary body tumors, the clinical differentiation between benign and malignant tumors is more difficult. Ciliary body tumors are more likely to be malignant if they induce a sector cataract, lenticular astigmatism, extrascleral extension, or a visual field defect. They can be darkly pigmented or amelanotic with evidence of vascularization. Documented growth and pigment dispersion are strong predictors of malignancy. These

tumors can also cause anterior displacement and/or infiltration of the iris (Fig. 74.1, *A* and *B*).

An early sign of an occult ciliary body melanoma is a sentinel vessel, which is one or more dilated episcleral blood vessels feeding the metabolically active tumor and is visible through the conjunctiva overlying it. Another early physical sign of an occult ciliary body melanoma is unexplained unilateral low intraocular pressure, as compared to the normal fellow eye. A difference of 5 mmHg or more may be the only initially detectable external sign of a tumor affecting the ciliary body.

COMPLEMENTARY DIAGNOSTIC TESTS

Although there have been recent advances in the diagnosis of iris tumors, it is still based on clinical and historical findings. The diagnosis of anterior segment tumors has been greatly enhanced by FNAB, UBM, and OCT. Clearly; these tests help the surgeon plan for appropriate treatments. The aim of these tests is to detect malignancy and tumor extent as early as possible, so that eye preserving surgical procedures may be done.

Table 74.3 Clinical characteristics differentiating between benign and malignant anterior segment tumors

Feature	Benign	Malignant
Elevation	Flat or slight elevated	Nodular
Number	One or more lesions	Solitary
Laterality	Unilateral or bilateral	Unilateral
Size	<3 mm	>3 mm
Growth	No	Yes
Prominent vascularization	No	Yes
Ectropion uveae	No	Yes
Iris infiltration	No	Yes
Pupillary distortion	No	Yes
Cataract	No	Yes
Sentinel vessels	No	Yes
Elevated IOP	No	Yes
Tumor seeding	No	Yes
Hyphema	No	Yes
Pigment dispersion	No	Yes

IOP = intraocular pressure.

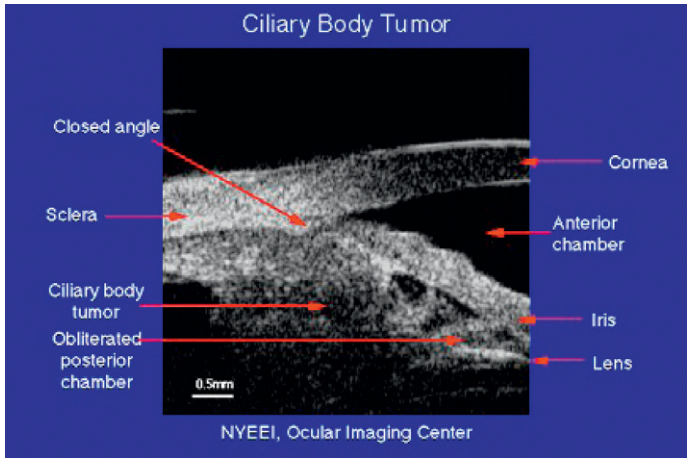
1. CYTOLOGIC CONFIRMATION: FINE-NEEDLE ASPIRATION BIOPSY (FNAB)[9–14]

The most common indications for FNAB are:

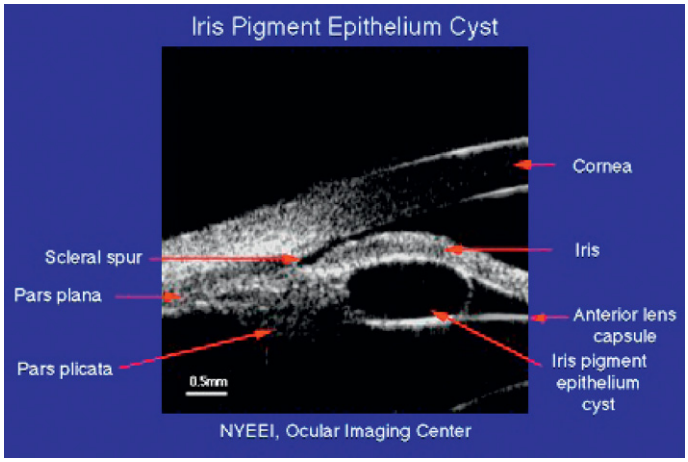
1. when noninvasive methods cannot establish the diagnosis;
2. for a presumed metastatic tumor with an undetectable primary site;
3. when the patient requests histopathology or cytology verification prior to treatment;
4. to assist in therapeutic recommendations;
5. an iris tumor in which a malignancy is suspected but cytopathologic verification is necessary before proceeding with definitive therapy of enucleation or radiotherapy;
7. an iris tumor with glaucoma, in which a surgical glaucoma procedure is contemplated after confirmation of the lack of malignancy;
8. to differentiate between primary iris tumor and secondary metastatic neoplasms to the iris thus offering guidance for therapy where primary iris tumors are managed by resection, plaque radiotherapy, or enucleation, and metastatic neoplasms are managed with systemic evaluation and treatment.[12]

Representative material can be obtained in about 88–99% of cases. FNAB 180° away from the main tumor should be done to rule out a ring melanoma.

The most commonly reported complication is intraocular hemorrhage with secondary glaucoma. No case of clinically apparent tumor proliferation or tumor seed growth in the needle tract has been noted. It seems that transcorneal sampling minimizes the risk of extraocular seeding. When FNAB is inconclusive, a surgical iridectomy may be indicated.



A



B

Figure 74.1. Ultrasound biomicroscopy (UBM) of iris masses. *A*, Ciliary body melanoma. *B*, Iris pigment epithelium cyst.

Several methods of FNAB have been described. Each technique involves proper instrumentation, planning of tumor approach, handling of harvested cells, and preparation of cytologic specimen.

Method 1: vacuum cleaner technique[14]

Patient sitting at the slit-lamp after a peribulbar block is obtained. A sterile 26- to 30-gauge needle connected to a 1 mL tuberculin syringe is introduced into the anterior chamber at a 45° to 90° angle to the lesion. The bevel is facing down and the needle opening is swept over the surface of the lesion in a 'vacuum cleaner' fashion while gentle aspiration is applied until approximately 0.5 mL of fluid is obtained. No entry into the tumor is made. The needle is withdrawn from the anterior chamber and the aspirate immediately diluted with an equal amount of 95% ethyl alcohol.

The most important limitations of this technique are an inconclusive cytopathologic diagnosis caused by inadequate sampling and risk of intraoperative bleed or laceration of the intraocular structures with the sharp needle tip.

Method 2: internal biopsy technique[9]

Instrumentation includes a 25-gauge needle attached to straight tubing, 50 cm long, attached to a 10 mL syringe. The connector tubing is essential because it prevents transmission of the movements of the surgeon's hand and syringe during aspiration to the needle tip so that the needle can remain stable within the tumor without abrupt dislodgement or shifting. The connector tubing should have proper volume (2.5–5 mL) and length (30–50 cm) thus providing adequate suction and lower resistance. The FNAB is done under the operating microscope and under local anesthesia. The entry site is temporal or nasal, approximately 90° from the meridian of the tumor. The needle, bevel side up, is passed into the tumor. The tumor aspiration point should be in a relatively avascular site and at the thickest portion. After secured entry into the tumor, a gentle back and forth sliding motion of the needle along its trajectory within the mass is performed three or four times to shave and loosen cells for aspiration. Then the full 10 mL aspiration is maintained for a few seconds with the needle in the tumor and also as the needle is withdrawn from the eye. During removal of the needle, some aqueous enters the tip and occasionally a partially or completely flat anterior chamber is found. Refilling the anterior chamber is done with balanced salt solution (BSS). The aspirated cells which are predominantly located in the needle tip are flushed into the syringe using BSS, but first air is expelled from the syringe by unscrewing the syringe from the connector tubing and slowly pushing the air completely out of the syringe and then reattaching the syringe to the connector tubing. Immediately after collection, 30 mL Shandon cytospin collection fluid is added to the BSS.

Method 3: iridectomy technique[11]

Two 0.9 mm limbal incisions are performed at distant sites to the iris tumors. A 21-gauge anterior chamber infusion cannula is inserted into the anterior chamber and intraocular pressure (IOP) elevated to 70 mmHg. A 20-gauge vitreous cutter is inserted through the second limbal incision and placed on the tumor surface in such a way that its opening is occluded by tumor tissue. With a high aspiration setting (400 mmHg) and low cutting frequency (80/min), one bite is obtained from the tumor surface. In case of hemorrhage, the infusion-controlled IOP is raised even further for a few minutes. The fluid that is contained within the cutter tube is aspirated with a 20 mL syringe.

Method 4: finger iridectomy technique (FIT)[15]

Under microscope and local anesthesia a paracentesis is created with a microvitreo-retinal (MVR) blade. Miochol is injected to constrict the pupil and then sodium hyaluronate is injected to maintain the chamber and position the iris for biopsy away from the crystalline lens. A 25-gauge vitrectomy probe is introduced and the aspiration opening rotated as to be occluded by the tumor. Aspiration/cutting is started on suction of 300 mmHg and cutting rate of 60 cuts per minute. These settings are adjusted as to maximize the efficiency of the process under direct visualization while trying to keep the cut rate as low as possible. Two to three biopsies are usually performed and each time the cutter is removed from the eye, it is placed in solution and the aspirate flushed from the effluent tube into an empty 3 mL syringe with 0.5 mL BSS. Specimens are immediately sent to the pathologist for cytological evaluation. The biopsy procedure can be repeated until the pathologist reports that the specimen is adequate for diagnosis. Then the sodium hyaluronate is irrigated out of the eye.

Intraocular biopsy by a vitreous cutter may allow the histopathologic examination of formalin-fixed paraffin-embedded tumor tissue. This increases the diagnostic accuracy of sampling. The cytospin technique is used to optimize the biopsy yield.

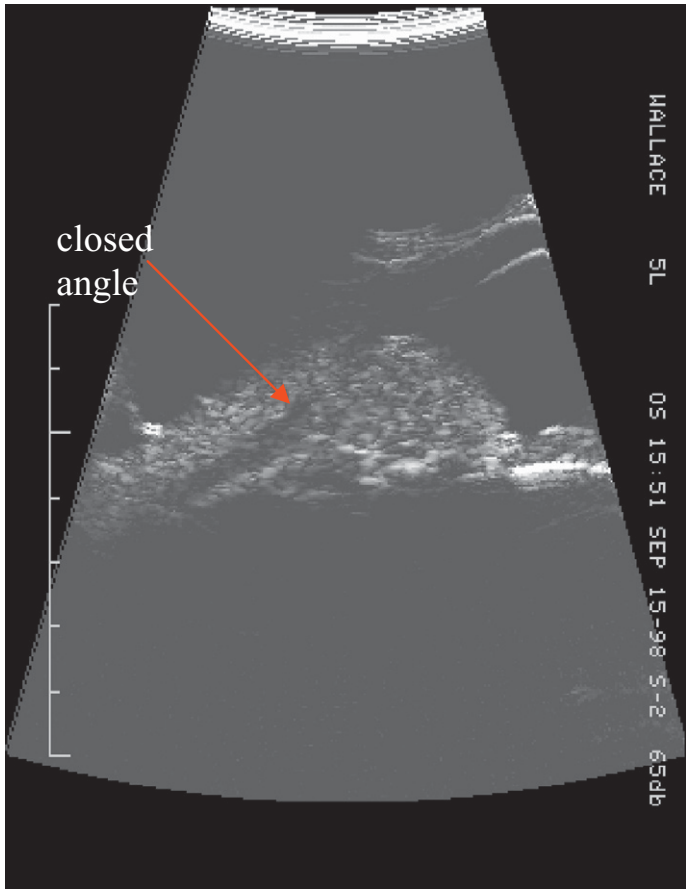


Figure 74.2. Low-frequency ultrasound with immersion technique showing iris mass with angle involvement.

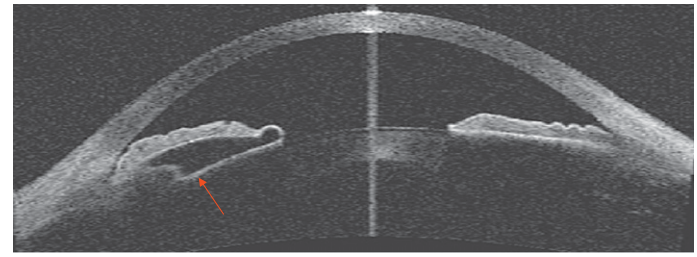

Figure 74.3. Ocular coherence tomography of iris mass. Iris cyst with narrowing of the angle.

2. VISUALIZATION PROCEDURES: ULTRASONOGRAPHY AND OPTICAL COHERENCE TOMOGRAPHY[16–19]

The diagnosis and treatment recommendations of iris and ciliary body masses are influenced by the tumor location, size, and local extension. This information is given by the ultrasound and OCT.

Ultrasound

Currently used ophthalmic ultrasounds employ 10 MHz transducers. These low-frequency transducers penetrate up to 40 mm and offer a relatively low (200–300 µm) resolution image. To optimize imaging of the anterior segment tumors, with low-frequency transducers the immersion technique is used (Fig. 74.2).

Higher frequency systems (50 MHz) offer better resolution of the anterior segment tumors. The UBM employs a 50 MHz transducer that provides high-resolution (50 µm) images up to a typical distance of 3 mm. This technique provides us with high-resolution ultrasound images of iris tumors, deep margins, and internal reflectivity (Fig. 74.1). UBM has allowed for quantitative follow-up tumor dimensions, more precise determinations of tumor borders, and a better evaluation of the involvement of the surrounding structures. UBM is an essential tool for the diagnosis, measurement, and follow-up of anterior segment tumors.

Iris melanomas (as imaged by UBM) are typically low to medium reflective and nodular arising from the iris surface or a medium to highly reflective thickening of the iris stroma. Displacement of iris surfaces results in a bowed profile, which indicates infiltration of the iris stroma. This is a common finding in that the stroma is typically involved. Tumor infiltration of the iris pigment epithelium can be seen by ultrasonography and suggests malignancy. The presence of acoustically empty (acoustic hollowing) or cystic spaces in the iris stroma has been found to be blood vessels. Small projections attached to the main tumor may be seen extending to the angle and ciliary body. Excavation of underlying uveal tissue and shadowing of subjacent soft tissues are also distinctive.

Ocular coherence tomography (OCT)

OCT is just beginning to become available for anterior segment tumors (Fig. 74.3). Light beams are directed into tissue and reflections coming from different layers are received by a detector and then processed to generate a 2 D image. It is similar to B-scan ultrasound but uses light instead of sound. It is a noncontact test with higher resolution. The light wavelength of 1310 nm allows for optimal anterior segment imaging. The axial resolution is 18 µm and the transverse resolution is 60 µm. OCT is very precise in (1) determining tumor borders, size, and location; (2) presence of satellite lesions; (3) involvement of the surrounding structures; (4) reflectivity; and (5) presence of cystic component. The absence or presence of tumor growth can be established by serial examinations.

UBM and OCT are essential in the evaluation of ciliary body abnormalities, including melanomas. They can differentiate tumors of the ciliary body from those of choroidal origin and help define the anterior border and invasion of the angle.

In conclusion, efficacy of tumor treatment, tumor infiltration, or invasion of adjacent structures, and observation for recurrence of the tumor are possible through serial UBM or OCT examinations.

3. TREATMENT[20–22]

Treatment indications for anterior segment melanomas are based on size, location, and extension of the tumor. The various methods of treatment employed follow on the type of tumor and condition of the eye. The preoperative assessment is critical for the planning of management.

The treatment options include observation, local resection, and radiation therapy (brachytherapy or proton beam irradiation). Enucleation is typically reserved for large tumors or eyes with untreatable glaucoma. As new modalities of therapy offer lower morbidity as compared to enucleation, more physicians and patients are opting for eye and vision-sparing treatments (Table 74.4).

Observation

Lesions with benign clinical characteristics present little immediate threat for ocular morbidity and can be observed for growth. Most

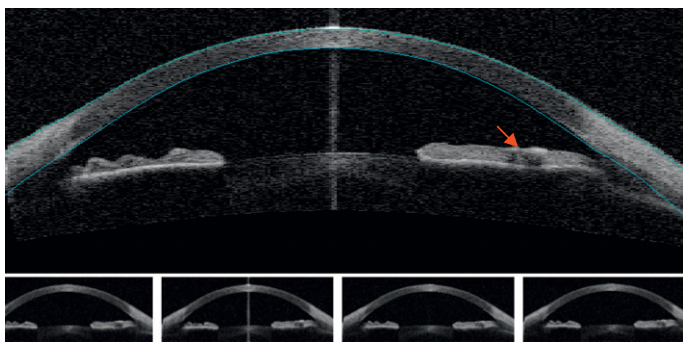
A



B

Figure 74.4. *A*, Iris melanoma confined to iris. *B*, Ocular coherence tomography precisely showing size and limits.

iris tumors and small melanocytic lesions of the ciliary body fall in this category. Lesions selected for observation must be well documented to allow objective follow-up evaluations. High-quality photographs are used to document the surface characteristics of the tumor. Tumor size, boundaries, and thickness with distance from surrounding structures should be determined by UBM or OCT (Fig. 74.4, *A* and *B*). Treatment should be considered if an anterior segment tumor demonstrates growth on serial exams or is the cause of secondary glaucoma. In case of stability of the tumor, the follow-up should be done every 6–12 months.

Local resection

The indications for excision are:

- If the lesion is impinging on the pupillary margin, interfering with vision or if impinging on the trabecular meshwork with secondary glaucoma.
- If the lesion grows rapidly.
- If the fine-needle biopsy specimen shows malignant histology.

Excision must be complete with either a sector basal iridectomy or an iridocyclectomy if the lesion affects the ciliary body.

SECTOR BASAL IRIDECTOMY[23–29]

This procedure involves removing a tumor confined to the iris with a margin of normal appearing tissue. The approach may be limbal or scleral. A scleral approach is preferred to minimize postoperative astigmatism. The incision is done 3 mm from the limbus in face of the lesion; a scleral tunnel is dissected to 1 mm in cornea. Viscoelastic is injected in the anterior chamber and the tumor resection performed by sector basal iridectomy with macroscopic free margins of 1 mm from the tumor edges.

It is important to make a large incision to allow for tumor removal without brushing the tumor cells on the adjacent tissues. At least 1–2 mm of tumor free margins and 'no touch' technique (without handling the tumor tissue directly) are planned for all surgical resections.

In case the iris mass has invaded the anterior part of the ciliary body to a minimal extent, or to avoid tractional iridodialysis in confined iris masses, a cryosurgical iridocyclectomy may be done. After a bilateral radial iridotomy around the tumor is made, the iris flap is lifted as high off the crystalline lens as possible and a cataract cryoprobe is placed on the undersurface of the iris. Following freezing for approximately 30 s, the iris is stretched to create traction on the ciliary body. The ciliary body comes forward with no sign of iridodialysis. The iris flap together with the anterior ciliary body is then excised.

The main complications of sector iridectomy are glare, hyphema, cataract, infection, and IOP fluctuations.

IRIDOCYCLECTOMY[30–43]

When the tumor is located near the iris root, ciliary body extension must be considered. Gonioscopy, transillumination, and ultrasound examination should be performed. If the ciliary body is affected, iridocyclectomy is performed (Fig. 74.5 *A* and *B*).

The indications of iridocyclectomy are (1) monocular patients, (2) elderly or chronically ill patients whose life span is presumed to be short, (3) patient refusing enucleation, (4) tumor covering less than 4 clock hours of the ciliary body.

Transscleral excision of the ciliary body is carried out after diathermy. A 90% thickness, anteriorly hinged, scleral flap is created, generally allowing 2–3 mm on each side of the tumor circumference —determined by 180° transillumination supplemented with direct tumor visualization. A triple row of penetrating diathermy is placed around the sides and posterior edges of the resection bed. The deep scleral lamella is incised down to the ciliary body and the tumor is lifted with the sclera and dissected anteriorly with a combined iridectomy. The anterior incision is made through the limbus for predominantly iris or iris–ciliary body tumors. This incision is placed anteriorly so the angle structures can be removed in en bloc resection. In cases in which there is suspicion of a possible ring mela-

Figure 74.5 *A* and *B*. Iridocyclectomy through a lamellar scleral approach.

noma, an intraoperative FNAB is performed 180° away from the mass. After the tumor is removed, if there is no vitreous loss, the incision is closed with 8-0 Vicryl sutures to the sclera and 10-0 nylon to the cornea. If vitreous loss occurred through the incision, a vitrectomy through that site is performed. In tumors that involve less than 3 clock hours of iris, the iris defect is closed with an 11-0 proline suture.

In cases with localized extrascleral extension, no scleral flap is made. The sclera and uveal tissue are incised and removed en bloc and the defect closed with a scleral graft.

The main contraindications of iridocyclectomy are: involvement of more than one third of the ciliary body or anterior chamber angle, significant extraocular extension, and contraindication for hypotensive anesthesia such as previous cerebral thrombosis or carotid artery occlusion.

The main complications observed involve vitreous and expulsive hemorrhage, retinal detachment, cataracts, residual tumor, hyphema, induced astigmatism, photophobia, phthisis, and tumor seeding being the most dreaded complications. To reduce the incidence of hemorrhage, extensive preoperative photocoagulation is applied as to encircle the tumor. Then intraoperative hypotensive anesthesia is employed.

The premanagement evaluation of ciliary body melanomas should include a thorough physical examination, with particular attention to the hepatic abdominal region and the skin and subcutaneous tissues, which are frequent sites of metastatic spread. Always obtain a chest X-ray in patients with ciliary body melanomas for the possibility of lung metastasis.

Although undetected metastatic spread at the time of diagnosis and treatment of ciliary body melanoma is a major concern in every patient, adjuvant systemic treatment currently is not advocated.

Irrespective of the treatment modality chosen, patients with ciliary body melanomas need to be followed carefully for many years. Close observation and measurement of the tumors' dimensions with any of the diagnostic tools mentioned earlier is critical. Follow-up care in treated patients includes thorough physical examinations, liver function tests, and imaging of lungs, repeated about every 6–12 months. Early detection of distant metastases may affect management and survival.

75 Iris reconstructive and restorative procedures

Andrea C. Kara-Jose, Marian S. Macsai

The inherent fragility of iris tissue and its close proximity to the corneal endothelium and anterior lens capsule create a challenge in the surgical management. The iris lies in front of the anterior lens capsule and the ciliary body, separating the anterior chamber from the posterior chamber. The iris consists of two layers: the stroma, located anteriorly and originating from the mesoderm, and the pigmented epithelium, located posteriorly and originating from the neural ectoderm. The function of the iris is dependent on both the sphincter pupillae muscle, located in the pupillary zone of the posterior stroma, and the dilator muscle, located between the stroma and the posterior layer of the pigmented epithelium. The dilator muscle extends from the iris root at the ciliary body to the sphincter pupillae muscle. The blood supply of the iris is provided by radial vessels in the stromal layer that extend from the major arterial circle of the iris in the ciliary body to form an incomplete minor arterial circle of the iris at the pupil. The endothelial cells lining the blood vessels of the iris have tight junctions that prevent passage of large molecules. These junctions, together with the tight junctions of the pigment epithelium of the ciliary body processes, create the blood–aqueous barrier. Healthy iris tissue tends to return spontaneously to its original shape when it is displaced, owing to its elastic resiliency and the action of the pupillary muscles.

IRIS DISPLACEMENT AND REPOSITION

As a result of its high mobility, the iris can be exteriorized by means of traction (with forceps) or pressure (resulting from expression or trauma). Grasping the iris with a fixation forceps produces force in two directions. One tractional force moves toward the iris root, and the other extends to the pupil margin. Awareness of the tension created toward the iris root is critical to prevent tearing of the major arterial circle of the iris and resultant bleeding. Pathologic tissue changes radically alter iris tissue mobility, resulting in inelastic, immobile tissue that may tear with traction. Excessive traction may result in an iridodialysis or significant bleeding.

An incarcerated but nonprolapsed iris should rarely be sacrificed. The most atraumatic method of repositioning an incarcerated iris is with viscoelastic material that is injected either directly through the wound or obliquely to draw the iris away from the area of incarceration. If this technique fails, a fine cyclodialysis spatula may be passed through a peripheral paracentesis to sweep the iris gently out of the wound.

Iris that is prolapsed through a wound must be evaluated thoroughly to determine if repositioning or excision is indicated (Fig. 75.1). Repositioning diseased tissue may result in intraocular inflammation and potential endophthalmitis. Exposed iris that is severely macerated or exposed for longer than 24 h should be excised and sent for culture. If a decision has been made to reposit the prolapsed iris, the tissue should be cleaned carefully with balanced salt solution soaked cellulose microsurgical sponges to remove any particulate debris and sent for culture.[1]

SYNECHIOLYSIS

Separation of posterior synechiae may be achieved with either a solid spatula (metal) or a soft spatula (viscoelastic material). A spatula utilizes blunt dissection to increase tissue tension, and applied at right angles to the adhesions. If numerous central posterior synechiae exist, a metal cannula may be placed through a peripheral iridectomy to insert viscoelastic material to protect the anterior lens capsule and lyse the synechiae with either viscodissection or blunt dissection with the cannula. A tear may occur in the lens capsule, or an unintended zonulolysis or iridodialysis may result if the adhesion is too strong. If the attachment of the synechiae is stronger than the anatomic attachment of the iris root, sharp dissection may be indicated. Iris adhesions with cortical remnants or corneal stroma frequently require excision with sharp dissection using intraocular scissors. Angulated intraocular scissors can be inserted through the peripheral iridectomy and used to cut the attachment after viscodissection is attempted. Careful dissection of the synechiae may open the ciliary sulcus, allowing for placement of a posterior chamber intraocular lens.

ENLARGEMENT OF THE PUPIL

Pupil enlargement can be performed medically or surgically. The use of mydriatics to dilate the pupil pharmacologically is useful when there are no pathologic structural changes and the tissue is

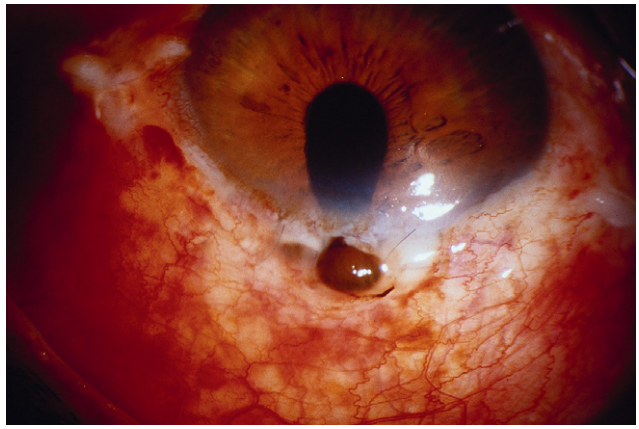

Figure 75.1. Iris prolapse through a limbal wound due to blunt trauma from a pencil in the left eye of a 9-year-old boy.

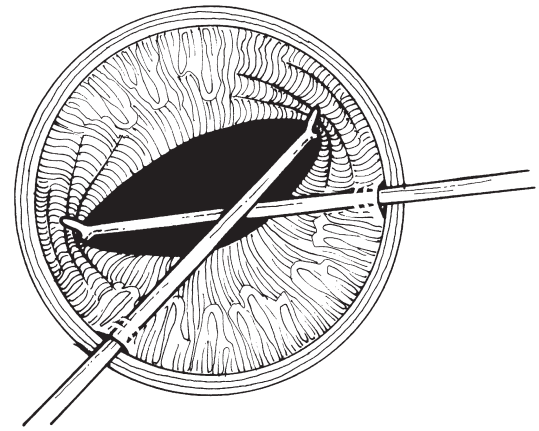

Figure 75.2. Intraoperative bimanual stretching of a pupil.

normal. If medical enlargement of the pupil is not successful, surgical enlargement of the iris may be necessary in some patients with eccentric or secluded pupils, or it may be used intraoperatively to aid in cataract extraction or vitreoretinal surgery.

ADEQUATE IRIS TISSUE

The dilation of a small pupil for cataract or vitreoretinal surgery in the presence of elastic and mobile iris tissue can be achieved with surgical methods such as pupil stretching techniques, iris hooks, or pupil expanders.

The stretching of the pupil can be performed with a push–pull technique using bimanual stretching or the Beehler pupil dilator (Moria) (Figs 75.2 and 75.3).[2,3] Both methods provide good yet temporary pupil enlargement.[4] These time-saving techniques may cause microsphincterotomies that are usually functionally insignificant.[4] Iris hooks, the Morcher polymethylmethacrylate (PMMA) pupil-dilator ring, and Graether 2000 pupil expander are other useful instruments for mechanical pupil enlargement, especially when pupil stretching is insufficient or when a more stable and larger pupil size is required (Figs 75.4–75.6).[3–5] The Morcher ring and Graether pupil expander are placed at the pupillary margin to expand and hold a formerly small pupil to around 7.5 mm during surgery.[4,6,7]

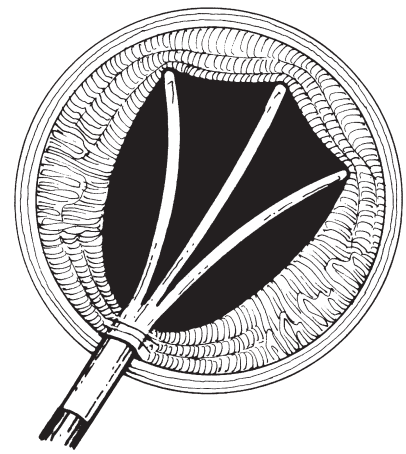

Figure 75.3. Intraoperative use of the Beehler pupil dilator.

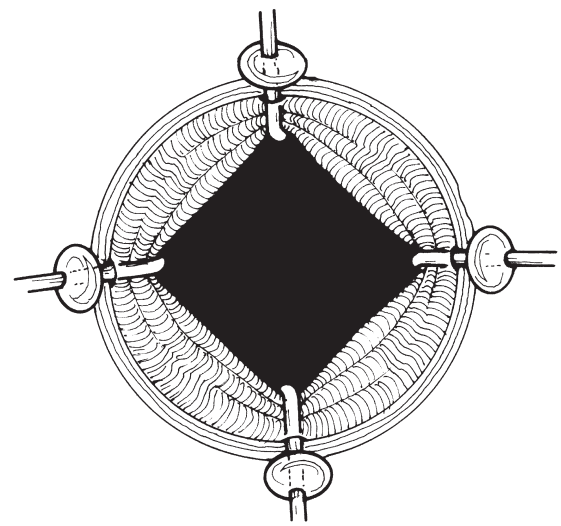

Figure 75.4. Intraoperative use of iris-retractor hooks.

INADEQUATE IRIS TISSUE

In cases of pathologic iris tissue that is inelastic and immobile, the pupil must be enlarged by surgical incision. When pathologic changes are confined to the iris sphincter, a sphincterotomy may be performed after injection of a viscoelastic into the pupillary space (viscomydriasis), which enables the insertion of angulated microscissors. It is important not to cut completely through the sphincter to the iris stroma. The sphincterotomies need not be precisely radial, but they must interrupt the continuity of the sphincter edge. After completion of the sphincterotomies, the chamber is deepened with viscoelastic, resulting in further dilation of the pupil.[8] Leaving a portion of the pupillary muscle intact preserves pupillary function while enabling mydriasis and miosis postoperatively. A larger sphincterotomy abolishes pupillary function, but this may be indicated if pathologic changes are extensive.

In some cases of extensive pathologic changes, an iridectomy may be required to center the pupil on the visual axis. A superior iridotomy is preferred as the upper eyelid position may obscure any residual abnormalities. Laser surgery with the neodymium: yttrium–aluminum–garnet (Nd:YAG) laser also may achieve adequate sphincterotomy in aphakic or pseudophakic patients (Fig. 75.7, *A* and *B*). In phakic patients, the argon laser may be used to create a sphinc-

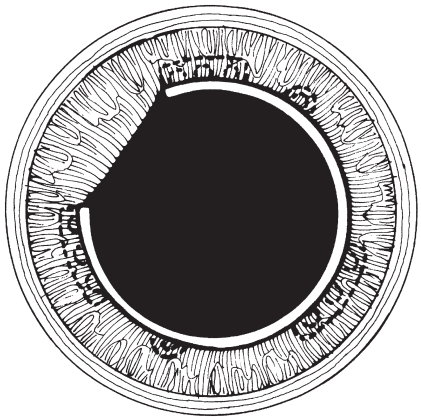

Figure 75.5. Intraoperative use of Morcher polymethylmethacrylate pupil-dilator ring.

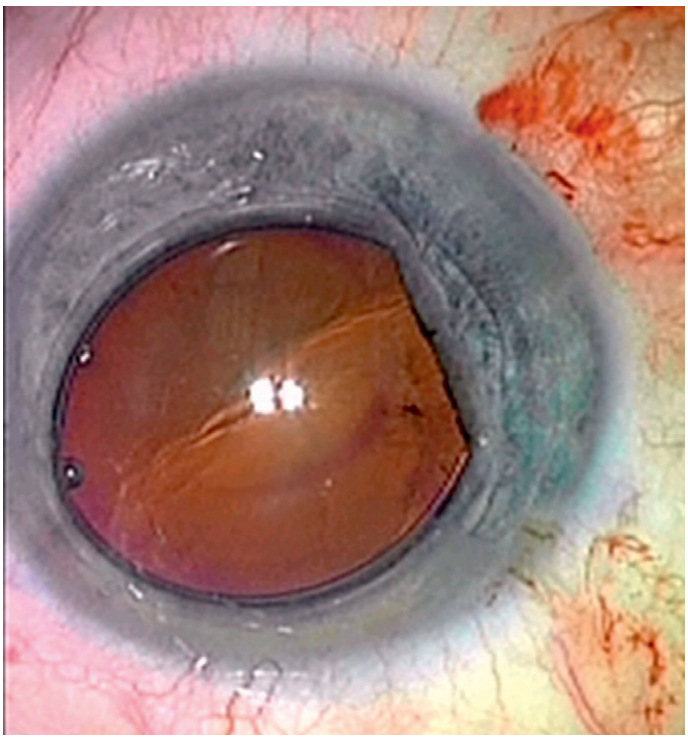

Figure 75.6. Intraoperative use of Graether 2000 pupil expander.

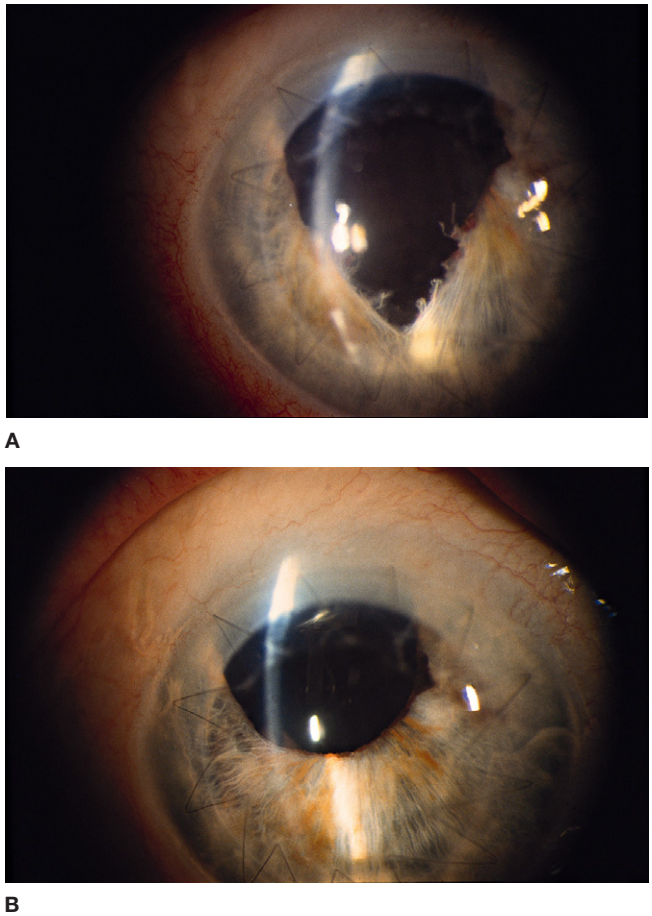
terotomy with linear photocoagulation. The argon laser decreases the risk of lens capsule rupture as compared to the Nd:YAG laser.

IRIS RECONSTRUCTION

SUTURING THE IRIS

Iris sutures are used for three basic purposes: (1) to attach iris to iris (closure of iris defects); (2) to attach iris to ciliary body (repair of iridodialysis); and (3) to attach iris to foreign material (fixation of implants). Different approaches, including transcorneal, intracameral, or transscleral methods, may be used to suture the iris. In a transcorneal or transscleral approach, the needle piercing the cornea or sclera must be very sharp and strong enough to overcome the resistance of the cornea or scleral tissue. In the transcorneal approach, multiple paracentesis incisions may simplify suture placement. Needles used for transscleral or transcorneal suturing are classified in Table 75.1.



A

B

Figure 75.7. *A*, An eccentric pupil after extracapsular cataract extraction. The eccentric placement of the pupillary margin resulted in significant visual distortion for this patient. *B*, Immediately post Nd: YAG laser sphincterotomy, the pupil is now centered more inferiorly, allowing the patient's optic axis to pass through the center of the intraocular lens.

When iris tissue is sutured with an open sky or intracameral approach, the use of a noncutting taper point microsurgery needle is recommended. Blood vessel (BV) needles have a round cross section with an atraumatic taper point, which helps to minimize trauma and tearing of the iris tissue. In iris surgery, 10-0 polypropylene (Prolene) is used when permanent or long-term support is needed as it is less prone to hydrolysis and biodegradation.

Before suture placement, sufficient space must be provided both anterior and posterior to the iris. Viscoelastic material can expand this space and protect the lens capsule and corneal endothelium at the same time. The main technical difficulty in suturing the iris involves the extreme mobility and fragility of the tissue. In a transcorneal suture, the site of needle insertion through the cornea can be defined precisely by the surgeon, as can the site of insertion of the needle into the proximal iris. Stabilizing the iris with viscoelastic or small intraocular forceps allows passage of a needle through the iris. A preplaced paracentesis tract will simplify emergence of the needle through the cornea, or a large bore needle (25-gauge) can be inserted through the intended cornea exit site and the iris suture can be placed through the hollow needle and pulled through the cornea as the needle is withdrawn.

IRIS DEFECTS REPAIR

Closure of iris defects is indicated for cosmetic reasons or to restore the normal optical axis at the eye. In addition, disruption of the iris

Table 75.1 Microsurgical needle characteristics

Model	Needle Type	Length (mm)	Curvature	Wire Diameter (mm)
CIF-4	Taper cutting point	13.34	1/4	0.20

STC-6	Spatula cutting point	16.00	Straight	0.15
PC-7	Taper cutting point	13.34	1/4	0.23
BV 100-4	Taper cutting point	5.11	3/8	0.10

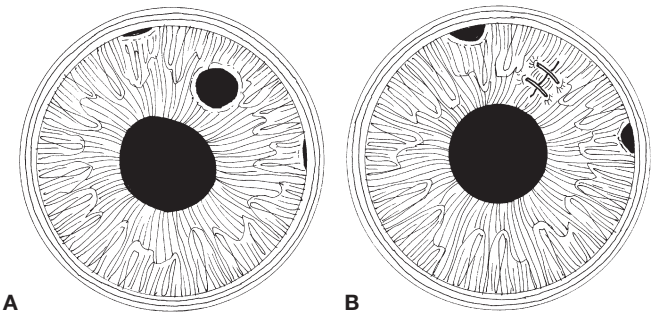

Figure 75.8. Two small limbal peripheral iridotomies are created to increase mobilization of the iris and allow closure of a stromal defect.

diaphragm may increase iris mobility and result in the formation of anterior synechiae. Restoring normal tension to the diaphragm of the iris may prevent anterior synechiae formation.

Normal iris tissue may be repaired by approximating the margins of the defect with simple interrupted sutures.[9] However, if the tissue is immobile or rigid, relaxing incisions may be required to mobilize the iris tissue.[10] These may be made at the pupil margin or in the iris stroma. Placement of peripheral iridotomies may be required to mobilize the iris tissue. The peripheral iridotomies should be placed where the imaginary transverse axis through the defect intersects with the iris root (Fig. 75.8). The edges of the stromal defect are reflected with viscoelastic. Transcorneal sutures are placed through peripheral limbal paracenteses and passed through the everted edges of the iris stromal defect to close the iris defect. Compensatory iridotomies at the iris root cause no optical disturbances when they are placed in the far periphery.

SECTOR IRIDECTOMY REPAIR

ADEQUATE IRIS TISSUE

In the presence of adequate and mobile iris tissue, several suturing techniques can be adapted to repair a sector iridectomy. Both an open-chamber and a closed-chamber approach may be successful.

Open-chamber approach

An intracameral suture can be used to repair a sector iridectomy in an open-system approach. The anterior chamber is maintained with viscoelastic and the free edges of the sector iridectomy are everted. A microneedle (BV) is introduced into the anterior chamber with a fine microneedle holder through a limbal incision and passed through both edges of the sector iridectomy. The suture is grasped, and the needle is pulled backward out of the anterior chamber through the limbal incision. The suture is tied and cut short. Excessive traction on the suture may disinsert the iris root; alternative techniques such as the Siepser knot[11]may eliminate this traction. Two or three interrupted intracameral sutures may be required for closure of the iridectomy.

Closed-chamber approach

Single-armed, peripheral approach

The repair of sector iridectomy in a closed-chamber is based on the concepts first described by McCannel.[12] The McCannel technique is a transcorneal peripheral approach that uses a longer needle such as the Ethicon CIF-4 and a single-armed suture. The surgery may be performed in a phakic or aphakic eye. In the McCannel technique, a limbal paracentesis wound facilitates transcorneal passage of the suture. However, the iris is distorted as it is pulled toward this limbal paracentesis tract when the polypropylene suture is cut. A modification of this technique, utilizing transcorneal 10-0 polypropylene suture and a paracentesis in the same meridian as the sphincter tear, is demonstrated in Figure 75.9.

An alternative iridectomy repair is the Shin modified McCannel's technique.[13] A 1.6-cm 25-gauge needle tip pierces the proximal iris wound margin from anterior to posterior and then pierces the distal wound edge from posterior to anterior and subsequently exits through the opposite limbus. A 10-0 polypropylene suture is threaded into the lumen of the 25-gauge needle until it reaches the other end. The needle is removed, leaving the suture in place.

An improvement on the McCannel technique is the Siepser slip knot.[11,14] This method is useful to tie sutures in the anterior chamber while minimizing iris distortion and is elaborated in Figure 75.10. With the development of bimanual surgical instrumentation for cataract surgery, iris surgery has become easier for the surgeon who has mastered bimanual techniques. MST technologies have developed intraocular microforceps that allow the surgeon to stabilize iris tissue for suturing, and aid in suture manipulation. When space allows, these forceps can be used for internal fixation and cutting of the suture without moving in and out of the eye several times.

INADEQUATE IRIS TISSUE

In the presence of an inadequate or insufficient iris tissue, closure of sector iridectomy can present a significant surgical challenge, as simple closure with interrupted sutures results in distortion of the pupil and may result in optical aberrations. To maintain a central pupil, relaxing incisions must be made to lengthen the iris tissue without increasing tension on the pupil. A large sector iridectomy can be converted into a peripheral iridectomy that is visually insignificant. This may be accomplished by placing numerous small

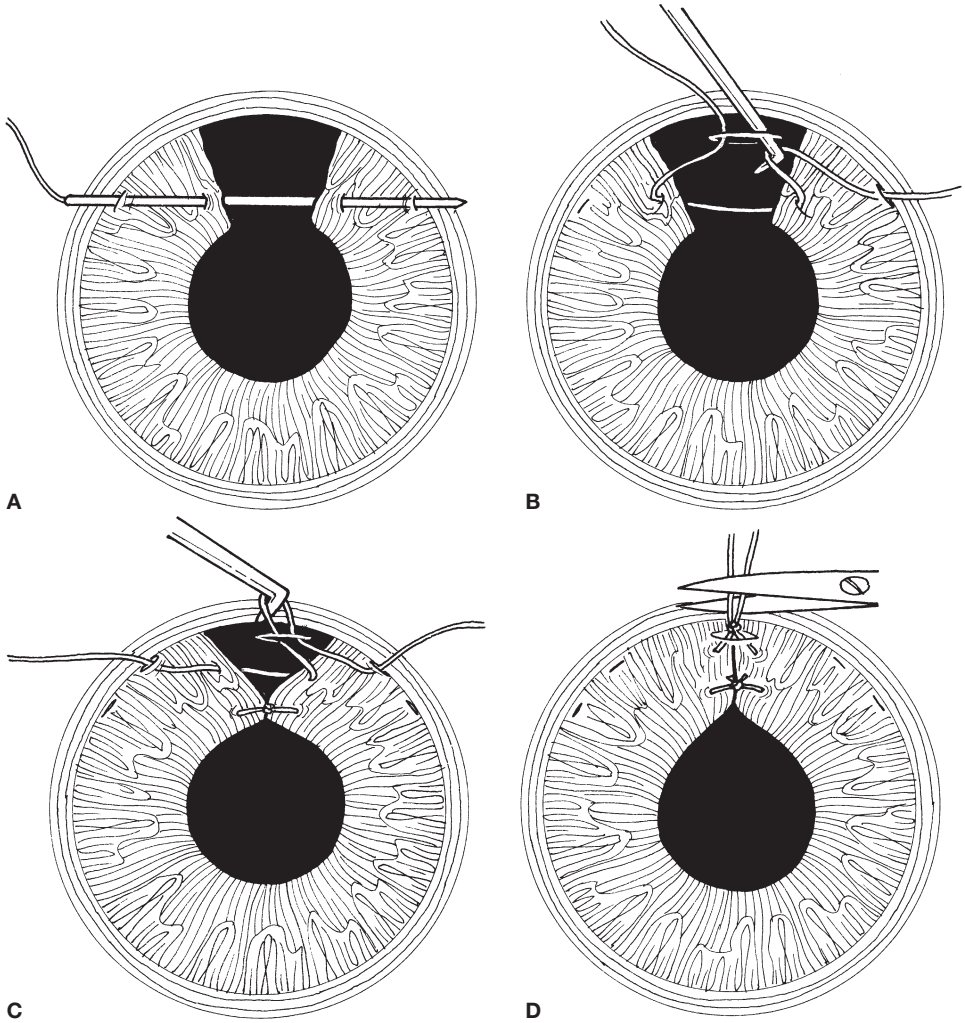

Figure 75.9. *A*, After placement of a self-sealing paracentesis in the meridian of the iris tear, viscoelastic is used to maintain the anterior chamber. The transcorneal suture is passed perpendicular to the edge of the iris laceration as the needle is passed through each edge of the iris and then is driven out through the peripheral cornea. *B*, After the needle is pulled through the cornea, a Sinskey hook is introduced through the paracentesis tract and around the suture. The hook draws the free end of the polypropylene suture back through the cornea as it exits the paracentesis tract. *C*, A second suture is passed in the same manner. The suture then is tied securely with three or four square knots. *D*, The ends are cut short by drawing the knot up to the wound. In the case of large lacerations, two or more sutures may be needed to close the laceration.

peripheral sphincterotomies at the pupillary margin and numerous microincisions along the edge of the sector iridectomy. The microincisions at the edge of the sector iridectomy are cut into the iris stroma to increase the mobility of the scarred tissue. The necessary degree of relaxation is determined by drawing the iris into the desired position using a small hook or microforceps, until the tissue may be advanced sufficiently to close the sector iridectomy with numerous interrupted sutures through the iris stroma (Fig. 75.11). If the pupil is to retain a mydriatic response postoperatively, sutures should be placed only in the stroma, not in the iris sphincter. Thus, the sector iridectomy is converted into an optically insignificant peripheral iridectomy.

In the aniridic patient or a patient who has had traumatic loss of iris tissue, iris replacements may be placed during cataract extraction.[15–21] Complete or partial replacement of the iris can be achieved with intracapsular iris segments or complete interdigitating iris replacement capsular tension rings. While readily available in the international market, these iris replacement systems remain investigational in the USA as of the publication of this chapter.

BLOWN PUPIL REPAIR

A closed-system suture technique was described by Behndig to correct postoperative atonic pupil or traumatic mydriasis using a lasso suture through three small entries, with minimal surgical trauma and induced astigmatism (Fig. 75.12).[22] The pupil suture tension can be regulated for the desired pupil size prior to tying the final knot, which will constrict the pupil.[22]

DISINSERTED IRIS REINSERTION (IRIDODIALYSIS REPAIR)

A traumatic iridodialysis should be repaired when it is large enough to cause visual aberrations, multiplopia, or glare. Once the resultant hyphema is resolved, repair of the iridodialysis should be performed before the development of significant scar tissue, which will decrease the mobility of the iris. Resuspension of the peripheral iris stroma to the sclera is the goal of these procedures.

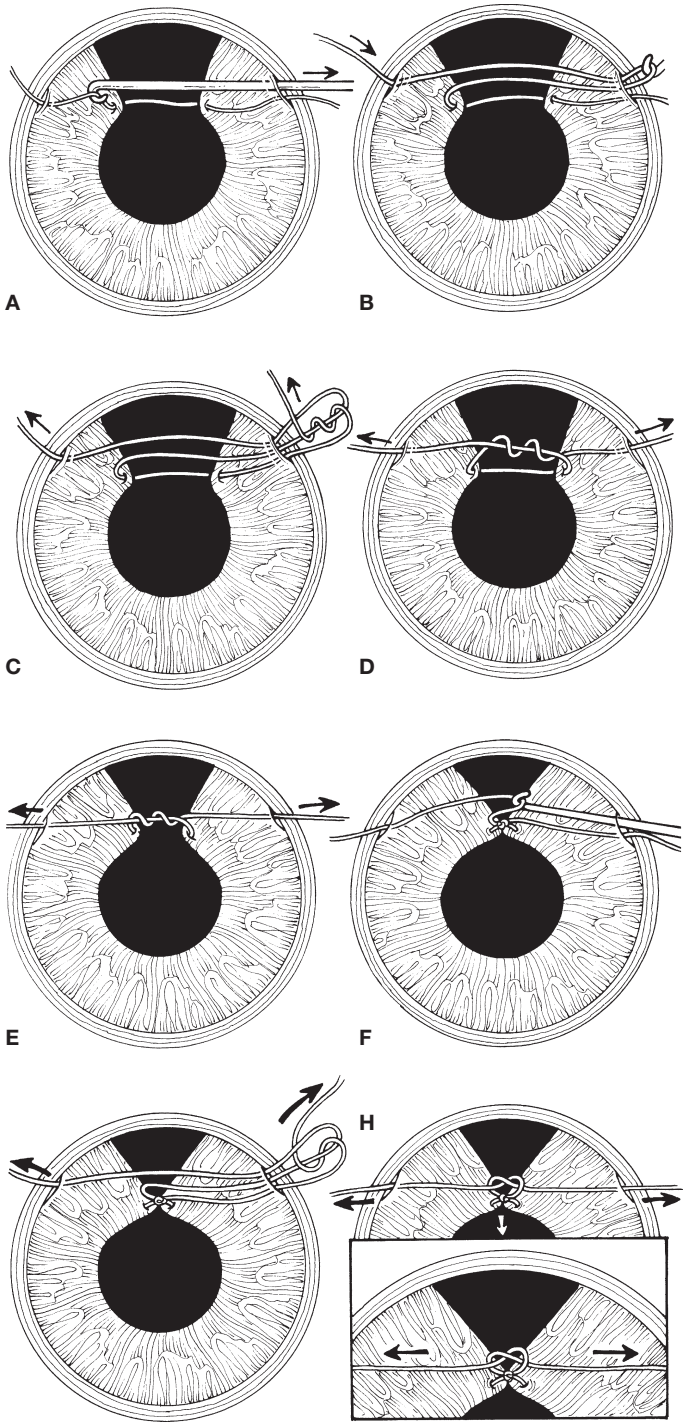

Figure 75.10. *A*, Two limbal paracenteses are created in line with the planned suture tract. The 10-0 polypropylene suture is passed through the entry paracentesis, through the opposite edge of the laceration and out through the other paracentesis. *B*, A microhook is used to manipulate the distal suture within the anterior chamber and create a large loop, which is pulled out through the entry paracentesis. *C*, The suture end is tied to the loop with a simple double-throw slip knot. *D–E*, Both suture ends are pulled outwards and the knot slips down apposing the iris defect edges. *F*, The hook is introduced and the distal suture is pulled out through the entry site. *G*, The suture end is tied to the loop with a single throw. *H–I,* The slip knot is drawn down over the first tie to lock the square knot in place.

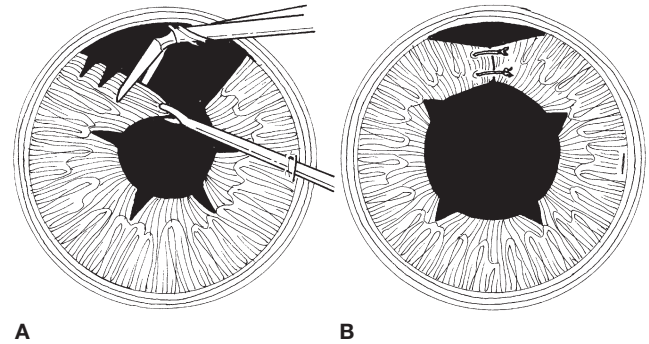

Figure 75.11. Microincisions are made at the edge of the sector iridectomy to increase mobility of the scar tissue after numerous small peripheral sphincterotomies have been performed at the pupillary margin. Mobilized tissue is closed with interrupted 10-0 polypropylene sutures. The most peripheral aspect of the sphincter iridectomy is not fully closed, thereby converting the sphincter iridectomy into an optically insignificant peripheral iridectomy.

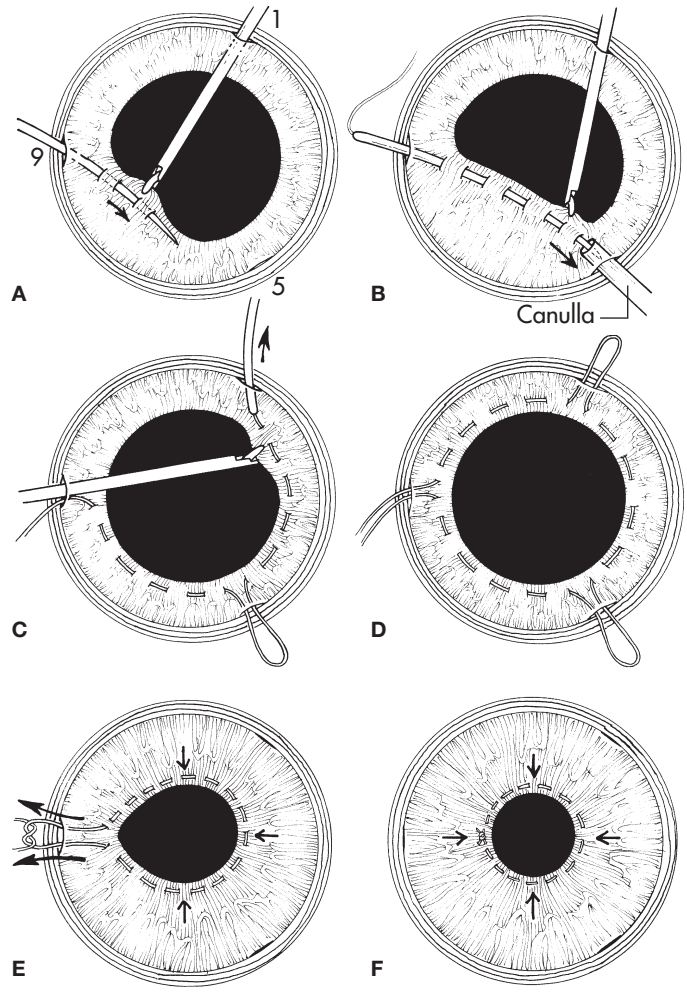

Figure 75.12. *A*, The needle with a 10-0 polypropylene suture is inserted through 9. A suture is made outside the pupil margin assisted by a forceps. *B*, This step is repeated, resulting in a continuous row of suture bites in the iris toward 5. Then with the help of a cannula, the needle is removed through 5. *C–D*, The suturing steps are repeated to place a continuous loop around the pupil margin. *E*, The suture ends are tied. *F*, The pupil size is regulated by the loop tension.

OPEN-CHAMBER APPROACH

It is easier to repair an iridodialysis with an open-system technique, but this requires a large wound (usually around 90–180°) that is associated with increased astigmatism and potential wound instability. A full-thickness scleral incision is placed in the iridodialysis quadrant. The iris edge is grasped with a forceps or iris hook, drawn to the wound edge, and then sutured to the sclera.[7]

CLOSED-CHAMBER APPROACH

Single-armed, peripheral approach

McCannel was one of the first to describe a closed-chamber technique for iridodialysis repair[12] using a 10-0 nylon suture on a curved needle, and it was further modified by the development of the 17-mm straight McCannel needle with 10-0 polypropylene.[23] A 10-0 nylon suture on a curved needle is passed through the limbus, under a small conjunctival flap in the quadrant of the iridodialysis, and then passed under the peripheral, torn iris root (Fig. 75.13, *A*) and out through the cornea. A small limbal stab incision is made beside the suture entry site and a small iris hook is used to pull the 10-0 suture out of the eye (Fig. 75.13, *B–D*). The two suture ends are tied, pulling the torn edge of the iris into the iris root cleft (Fig. 75.13, *F*). Other sutures can be placed in a similar manner to properly reposition the iris.[12]

Chang and Coll developed a variation of this technique[24] using a 30-gauge straight needle with a 10-0 polypropylene suture to enter the eye through a prefashioned grooved paralimbal scleral incision to catch the peripheral iris edge (Fig. 75.14). Alternatively, using a scleral flap, transcorneal sutures are passed through the disinserted iris peripherally, across the chamber angle to give an essentially normal anteroposterior iris position. The sutures exit below the scleral flap about 1 mm posterior to the limbus. The end of the sutures is brought through the scleral tunnel with a Sinskey hook and tied beneath the scleral flap. Numerous interrupted sutures can be used to resuspend the iris root.

Single-armed, cross-pupil approach

Nunziata reported a cross-pupil approach using a 17-mm single-armed straight needle on 10-0 polypropylene suture.[25] The needle is inserted through a limbal paracentesis 180° opposite the iridodialysis.

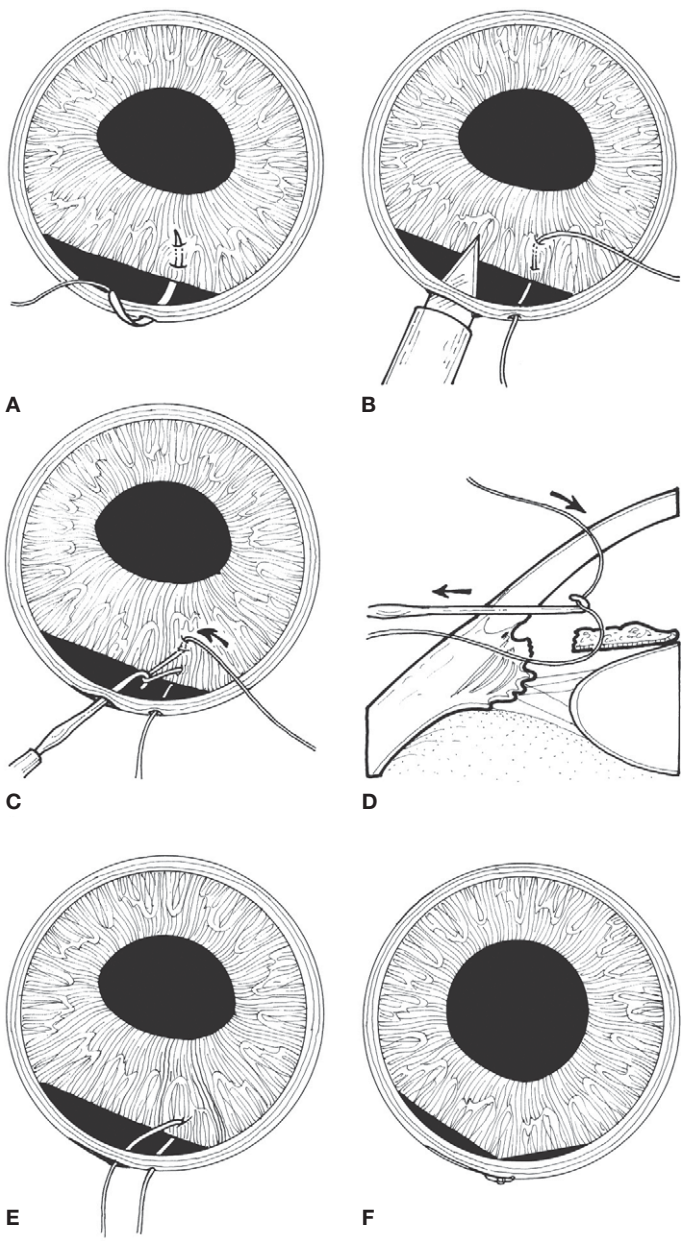

Figure 75.13. *A*, The suture is passed through the limbus, under the torn iris edge and out through the cornea. *B–D*, A limbal stab incision is made beside the entry site and an iris hook is introduced into the anterior chamber to engage the vertical suture and pull it out in a loop. *E*, The corneal suture is cut flush at its exit and its loop is drawn out in a single strand. *F*, The suture is tied pulling the torn edge of the iris into the iris root cleft.

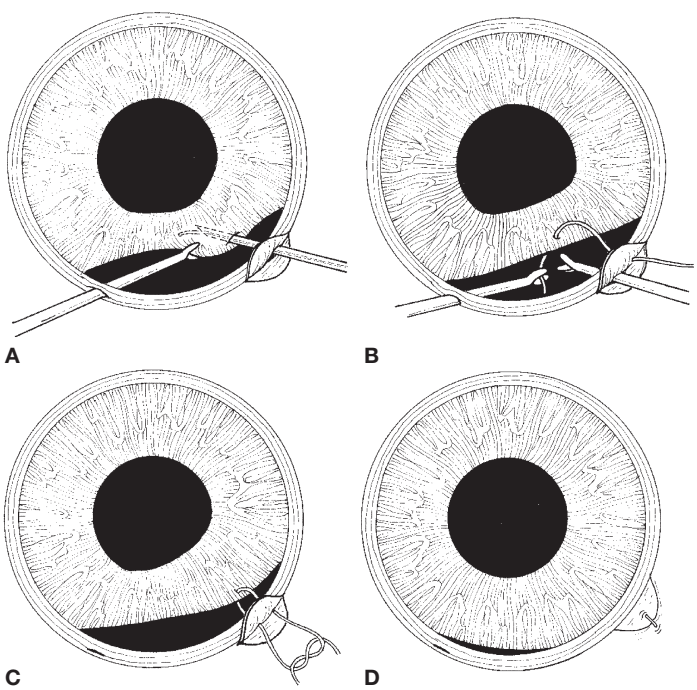

Figure 75.14. *A*, A 30-gauge needle with a 10-0 polypropylene suture enters the eye through a grooved paralimbal scleral incision and passes through the peripheral iris edge. A 25-gauge forceps, inserted through a more lateral paracentesis, unrolls the peripheral iris and assists the needle as it passes through the iris. The forceps then grasp the end of the suture as the needle is withdrawn. *B*, Another 25-gauge forceps, inserted adjacent to the initial 30-gauge entry site, removes the suture from the eye. *C*, The suture is tied. *D*, The knot is buried by closing the scleral incisions.

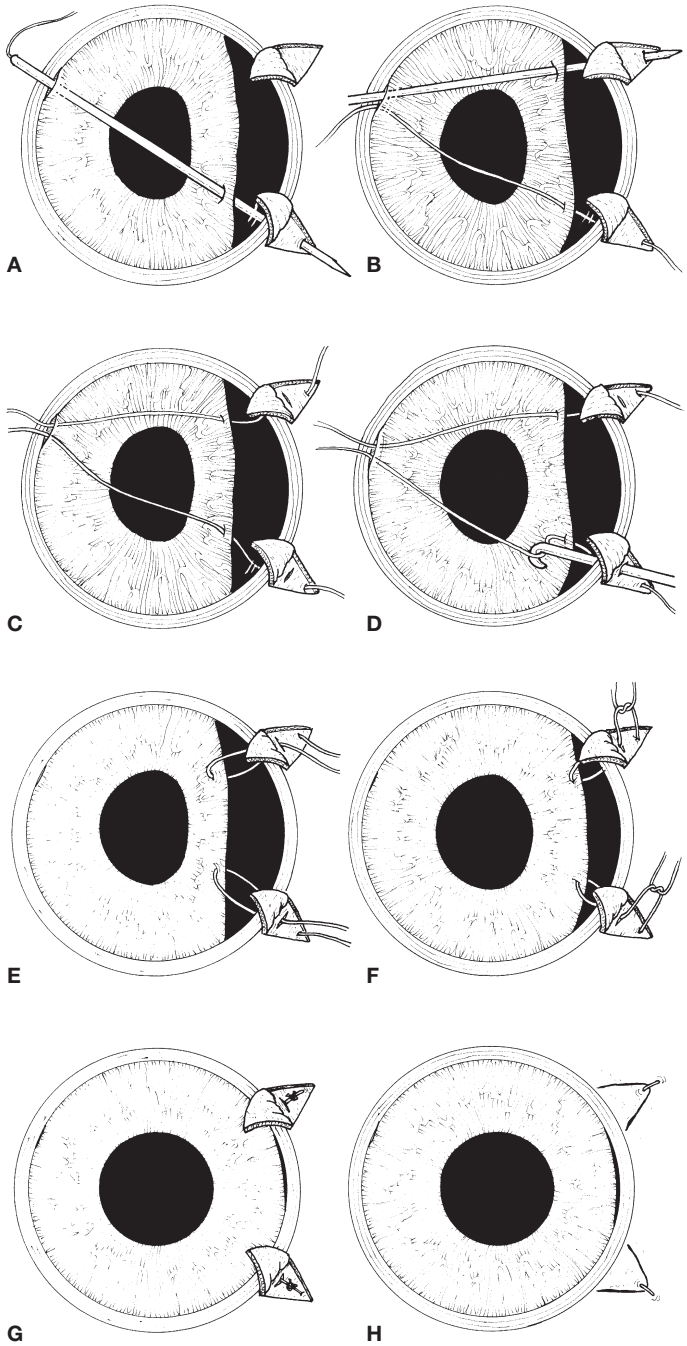

Figure 75.15. *A*, Two scleral flaps are made. A 17-mm needle passes through a limbal paracentesis, through the tear iris edge, and into the scleral bed. *B*, A second needle is introduced in a similar manner. *C*, Paracentesis are placed through the scleral bed nearby to the sutures. *D*, Iris hook is used to pull out a suture loop. *E*, The sutures are drawn out. *F–G*, The sutures are tied, bringing iridodialysis edge into the angle. *H*, The scleral flap is closed.

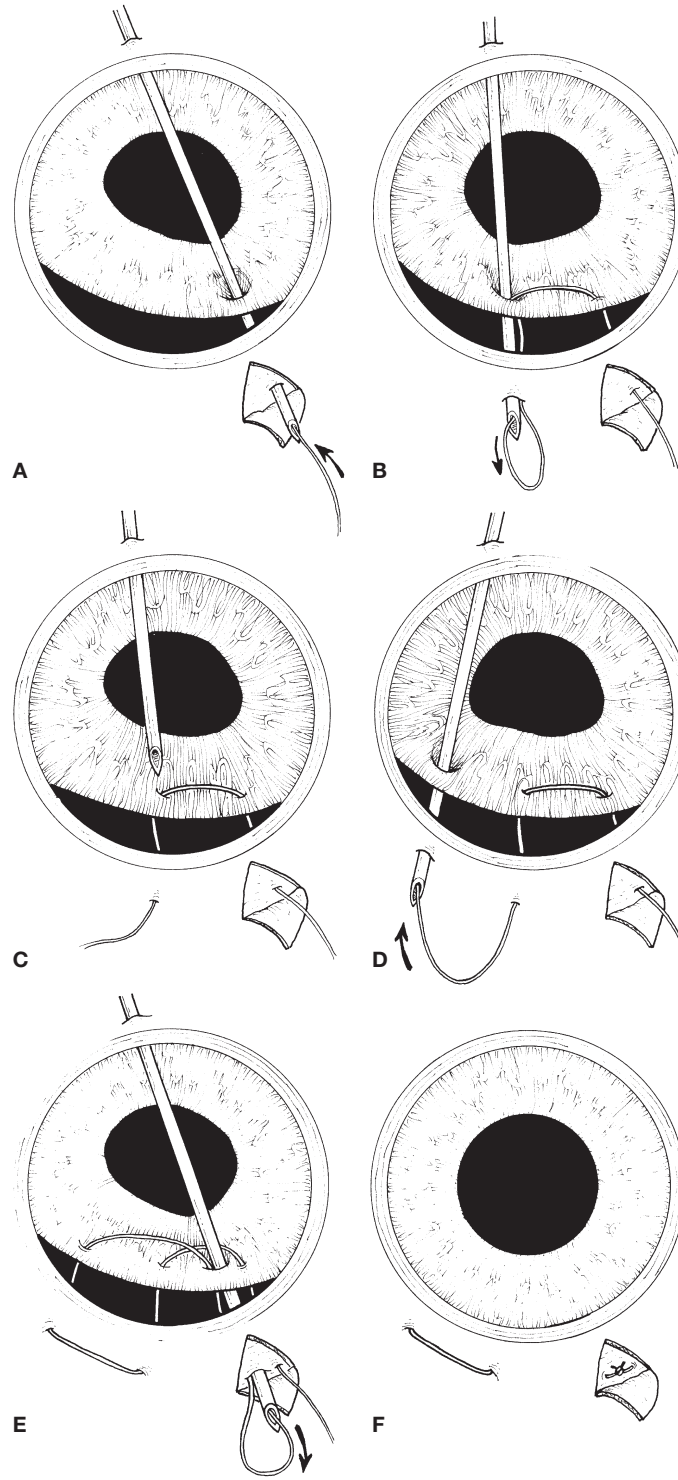

Figure 75.16. *A*, The 25-gauge needle is inserted in the anterior chamber, pierces the peripheral torn iris edge and emerges under the scleral flap. A 10-0 polypropylene suture is threaded into the needle lumen. *B*, The needle is reinserted back through the iris edge and exits 2–3 mm from the scleral flap. The suture is removed from the needle. *C*, The needle is retracted back into the anterior chamber. *D*, A third pass pierces the torn iris edge and emerges 2–3 mm from the last exit site. The suture is threaded into the needle lumen. *E*, The needle is retracted back into the anterior chamber, passed through the torn iris edge and exits under the scleral flap. *F*, The suture is removed from the lumen and tied to its other end, beneath the scleral flap.

dialysis, through the iris at the edge of the tear and out the sclera at the point of normal iris insertion under a triangular scleral flap (Fig. 75.15, *A* and *B*). A paracentesis site is made beneath the scleral flap just above the suture exit site to retrieve the other end of the suture with a microhook (Fig. 75.15, *C* and *D*). The suture is tied, repositioning the iridodialysis (Fig. 75.15, *E–G*). In a large iridodialysis, multiple fixation points are required. Another method was developed by Bardak et al as a modification of the previously mentioned technique.[26] It uses a 22-mm, plastic handled, 26-gauge hypodermic straight needle with a hole at the distal end to thread a 9-0 or 10-0 suture. Zeiter et al reported a technique in which a 3.8-cm long 25-gauge hypodermic needle is used to place a 10-0 polypropylene suture in a sewing-machine fashion (Fig. 75.16, *A–F*).[27]

Double-armed, cross-pupil approach

Wachler et al described a cross-pupil technique that uses a 10-0 polypropylene suture double-armed on 17-mm straight needles.[23] Through a limbal paracentesis placed 180° away, one needle enters the anterior chamber, passes through the peripheral dialyzed iris root, and exits through the sclera.[23] The other needle of the double-armed suture enters via the same entry site, engages the iris 1.0 to 1.5 mm adjacent to the first suture, and exits the eye in the same plane as that first suture but 1.5 to 2.0 mm laterally. The suture is tied repositioning the iris base, and the knots are rotated into the needle tract. The procedure can be repeated if necessary to adequately reposition the iris.[23]

It is important to note that nonabsorbable suture and unburied knots may erode through the conjunctiva, leading to suture-related discomfort, focal inflammation, giant papillary conjunctivitis, endophthalmitis, or inadvertent cutting of the suture by an ophthalmologist unaware of its function.[28,29] The creation of a scleral flap to cover the external portion of the sutures is imperative to prevent these problems.[29]

In conclusion, iris reconstruction and reparative procedures offer unique surgical challenges. Advances in viscoelastics, needle design and suture material have expanded our ability to face these challenges. Improved design of microsurgical instrumentation and development of artificial iris segments have vastly changed our approach to these patients. Restoration of a normal pupil, iris diaphragm, and iris root improves the visual function and cosmetic appearance of the eye. Iris defects repair can eliminate diplopia and glare, and improve the quality of vision for patients. The numerous techniques in this chapter expand the surgical armamentarium needed to successfully repair these patients and improve their visual function.

76 Conjunctival and corneal tumors

Amol D. Kulkarni, Heather A.D. Potter, Thomas J. Liesegang, and Daniel M. Albert

MICROSCOPIC FEATURES OF THE CONJUNCTIVA AND CORNEA PERTAINING TO NEOPLASIA

Stratified columnar epithelium with goblet cells covers most of the conjunctiva and transitions at the limbus, the palpebral margins, and the caruncle into stratified squamous epithelium. There is polarity or a normal sequence of maturation from the basal layers to the more superficial layers. Melanocytes are present in the basal layer of the conjunctival epithelium, and melanin granules may be transferred to adjacent basal epithelial cells.

The substantia propria is composed of fibrovascular connective tissue of varying density and thickness. It is thin in the palpebral region, creating a firm connection between the epithelium and the tarsus. In the fornices and over the globe, it is thick and loose, but at the limbus it is thin and compact as it attaches to the episclera. Fibroblasts and inflammatory cells are usually found in the conjunctival stroma. Aggregations of lymphocytes within subepithelial tissues in the fornices forming follicle-like structures, some of which contain germinal centers, are present in most 'normal' patients.

Certain regions of the conjunctiva, such as the plica semilunaris and the caruncle, have a distinct anatomy. The plica semilunaris is a structure consisting of redundant bulbar conjunctiva and is a remnant of the nictitating membrane found in some species. The caruncle is lined by a nonkeratinized stratified squamous epithelium and the underlying stroma contains structures found both in the conjunctiva and skin.

CLASSIFICATION OF CONJUNCTIVAL AND CORNEAL TUMORS

Tumors of the conjunctiva can be classified as tumors of the surface conjunctival epithelium, tumors of melanocytic origin, tumors of the adnexal structures, tumors of lymphocytic or hematopoietic origin, and tumors of soft-tissue origin (Box 76.1).[1] Tumors arise in a similar yet less frequent manner in the corneal epithelium, but tumors of the stroma or endothelium are exceedingly rare.

BENIGN LESIONS OF THE SURFACE EPITHELIUM

SQUAMOUS CELL PAPILLOMA

Squamous cell papillomas are benign tumors of the conjunctiva in which acanthotic squamous epithelium covers fibrovascular cores (Fig. 76.1). They are associated with conjunctival infection with the human papilloma virus subtypes 6, 11, 16, and 18.[2–4] In children, they are typically pedunculated, multiple, and located inferiorly in the fornix. In adults, they tend to be sessile and occur on the bulbar conjunctiva. In some cases, they have been found to grow quite large, covering the surface of the cornea and simulating a squamous cell carcinoma. Clinically, papillomas appear as pink, fleshy masses, often having an irregular, cauliflower-like surface (Fig. 76.2).

Most squamous papillomas are asymptomatic without associated conjunctivitis and can easily be observed. Large tumors may cause foreign body sensation, irritation, bleeding, or be cosmetically unacceptable. In these circumstances, the most effective treatment of papillomas is excision of the lesion without direct manipulation, with subsequent cryotherapy to the base and the resection margins. The lesions should be submitted for histopathological examination. They may recur or become multifocal after excision, and in these instances, topical interferon and mitomycin C have been employed.[5,6]

PSEUDOCARCINOMATOUS HYPERPLASIA (PSEUDOEPITHELIOMATOUS HYPERPLASIA)

The conjunctival epithelium may respond to irritation by becoming acanthotic, parakeratotic, or hyperkeratotic. Histologically, the acanthotic epithelium forms irregular nests of epithelial cells containing keratin pearls and simulating a squamous cell carcinoma. This is termed pseudocarcinomatous hyperplasia or pseudoepitheliomatous hyperplasia (PEH). The distinguishing features of PEH are that it (1) develops rapidly over weeks or months, (2) lacks nuclear

BOX 76.1 CONJUNCTIVAL AND CORNEAL TUMORS

Tumors of surface epithelium

Benign
- Squamous cell papilloma
- Leukoplakic plaques
- Pseudocarcinomatous hyperplasia
- Benign hereditary intraepithelial dyskeratosis

Intraepithelial neoplasia
- Actinic keratosis
- Conjunctival or corneal intraepithelial neoplasia (CIN)

Malignant
- Squamous cell carcinoma
- Mucoepidermoid carcinoma

Tumors of melanocytic origin

Benign
- Nevus
- Congenital epithelial melanosis
- Primary acquired melanosis

Malignant
- Melanoma

Tumors of adnexal sructures

Benign
- Oncocytoma
- Pleomorphic adenoma
- Apocrine adenoma
- Sebaceous adenoma

Malignant
- Sebaceous carcinoma

Tumors of lymphocytic or hematopoietic origin

Benign
- Reactive lymphoid hyperplasia
- Atypical lymphoid hyperplasia

Malignant
- Lymphoma
- Leukemia
- Plasmacytoma

Tumors of soft-tissue origin

Benign
- Lipoma
- Neurofibroma
- Fibrous histiocytoma
- Myxoma
- Hemangioma
- Lymphangioma

Malignant
- Fibrous histiocytoma
- Rhabdomyosarcoma
- Kaposi's sarcoma

Choristomatous tumors
- Dermoid
- Dermolipoma
- Complex choristoma

atypia, and (3) contains intraepithelial microabscesses. Because this lesion is not premalignant, simple excision is usually curative.

LEUKOPLAKIC PLAQUES

Leukoplakic lesions on the bulbar or limbal conjunctiva show epithelial thickening with hyperkeratosis. In contrast to leukoplakic plaques on other mucosal surfaces, these have little to no malignant potential and show no cytologic atypia. When associated with vitamin A deficiency, these are referred to as Bitot's spots.

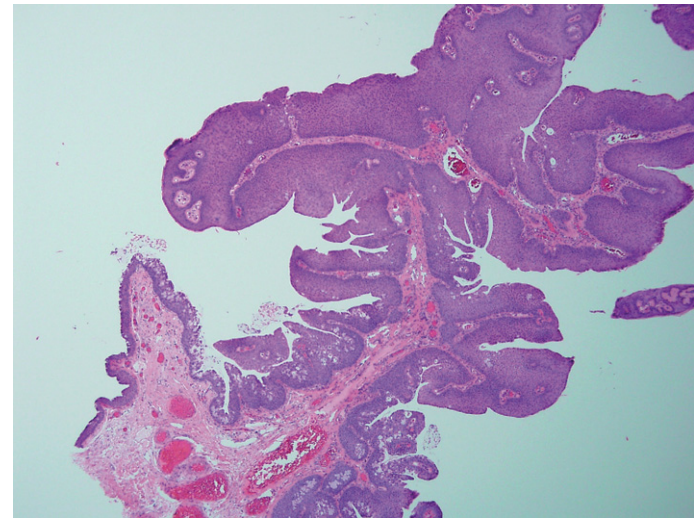

Figure 76.1. Conjunctiva papilloma with finger-like projections extending from the lesion base is seen. The surface consists of acanthotic nonkeratinized squamous epithelium lined by a core of fibrovascular tissue. The substantia propria shows a mild lymphocytic infiltration with congested vessels (Hematoxylin and eosin, ×40).

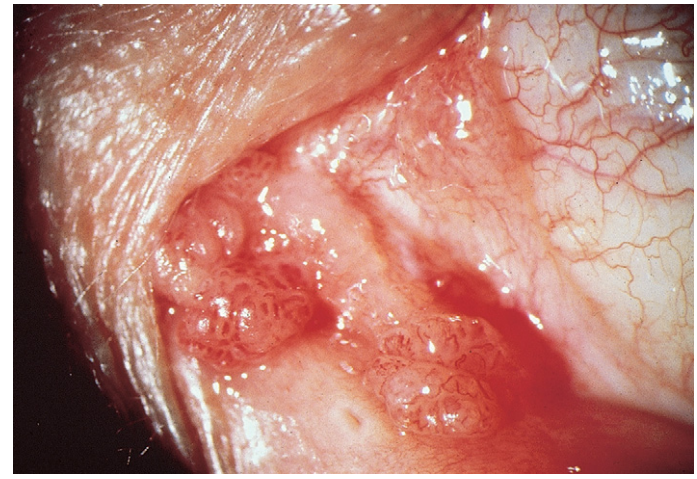

Figure 76.2. Multiple pedunculated squamous cell papillomas involving the fornix and caruncle area in a middle aged individual. When seen in young patients, they are usually of viral origin; when seen in adults, there is concern about conjunctival intraepithelial neoplasia (CIN). Treatment is with surgical excision and cryotherapy; recurrences are frequent.

BENIGN HEREDITARY INTRAEPITHELIAL DYSKERATOSIS

Benign acanthosis of the conjunctiva and oral mucous membranes, with dyskeratosis of epithelial cells, occurs in Haliwa Indians. The disorder is inherited as an autosomal dominant trait with a high degree of penetrance in descendants who lived in northeastern North Carolina. Patients develop bilateral elevated plaques on the interpalpebral areas of the limbal conjunctiva, along with dilated vessels that cause the eyes to appear red. In most cases, the lesions are asymptomatic, but extensive lesions can involve most of the bulbar conjunctiva and the cornea, resulting in corneal opacifica-

Figure 76.3. Conjunctival intraepithelial neoplasia (CIN) at the limbal area with a typical opalescent papillary appearance. Such tumors usually grow slowly, and removal is recommended at this stage to determine the histopathology.

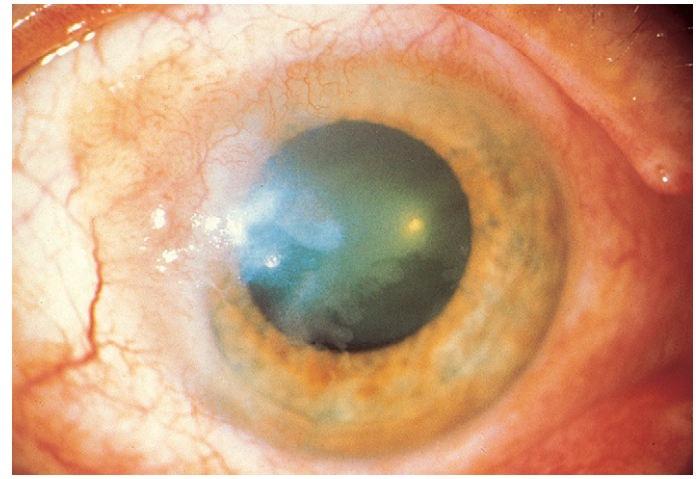

Figure 76.4. CIN involving the limbus and spreading over cornea in an elderly Caucasian male. Excision of the limbal lesion with cryotherapy is recommended. The corneal lesion can be removed with scraping since the basement membrane remains uninvolved.

tion and vascularization with marked loss of vision.[7] Plaques also develop on the oral mucosa. Complete excision is the treatment of choice, although recurrences are likely because of the inherited nature of these lesions.

INTRAEPITHELIAL NEOPLASIA OF THE SURFACE EPITHELIUM

ACTINIC KERATOSIS

Actinic keratosis, or solar keratosis, develops slowly within the interpalpebral epithelium after prolonged exposure to ultraviolet light. The epithelial change often overlies a pre-existing pinguecula or pterygium. Actinic keratosis appears as a sharply circumscribed leukoplakic plaque with atypia in the epithelium. As a result, it is considered a precancerous lesion, but its opacity and elevation distinguish it from a flatter and translucent intraepithelial neoplasia.

CONJUNCTIVAL AND CORNEAL INTRAEPITHELIAL NEOPLASIA

Conjunctival or corneal intraepithelial neoplasia (CIN) is now the preferred nomenclature generally replacing the terms dysplasia and carcinoma in situ. CIN is graded depending on the degree of cellular atypia and disorganization of epithelial cell maturation. Mild CIN consists of abnormal epithelial cells occupying a partial thickness of the epithelium. Severe CIN occurs when the atypical cells are seen in the full thickness of the epithelium. In both forms of CIN, the atypical cells are confined to the epithelium and there is a loss of polarity with suprabasalar mitoses. Also, there is minimal hyperkeratosis and parakeratosis, giving the lesion an opalescent, gelatinous surface (Figs 76.3–76.5), and an abrupt transition from normal conjunctiva corresponding to its sharply demarcated clinical appearance (Fig. 76.6).

Human papillomaviruses (HPV) 16 and 18 have been implicated in the pathogenesis of some of these lesions.[8] Human immunodeficiency virus (HIV) infection should be ruled out in persons younger than 50 years presenting with these lesions, as is the case with other severe viral dermatologic conditions.

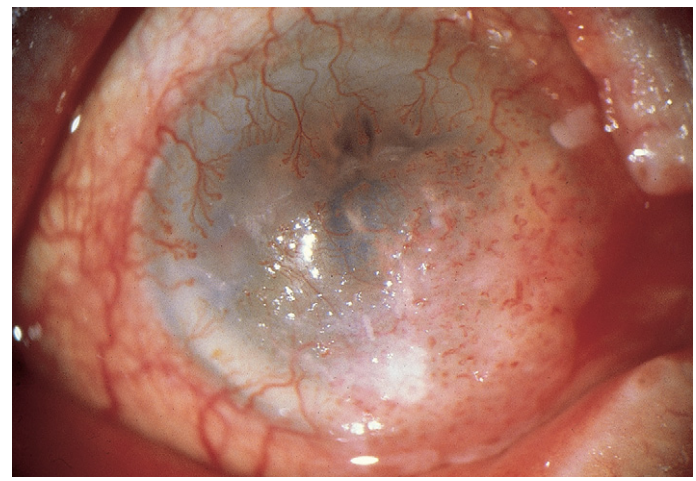

Figure 76.5. A more extensive CIN involving the limbus and central cornea. Despite its appearance, the tumor did not invade Bowman's membrane and can be removed with excision, cryotherapy to the limbal area, and superficial scraping of the cornea.

Mild and severe conjunctival intraepithelial neoplasias are precursors of squamous cell carcinoma, and excisional biopsy with careful clinical follow-up is recommended. These lesions, however, may undergo spontaneous regression.[9]

MALIGNANT TUMORS OF THE SURFACE EPITHELIUM

SQUAMOUS CELL CARCINOMA

Squamous cell carcinomas are characterized by invasion of the abnormal epithelial cells into the underlying stroma. In the USA, most squamous cell carcinomas are only superficially invasive and have a relatively benign clinical course, with intraocular and orbital invasion being uncommon.[10] Squamous cell carcinomas that arise from CIN are more likely to be poorly differentiated and display downward spread into the cornea or sclera (Figs 76.7 and 76.8).[11]

Most squamous cell carcinomas arise in the interpalpebral limbal conjunctiva and grow slowly in an elevated or papillary

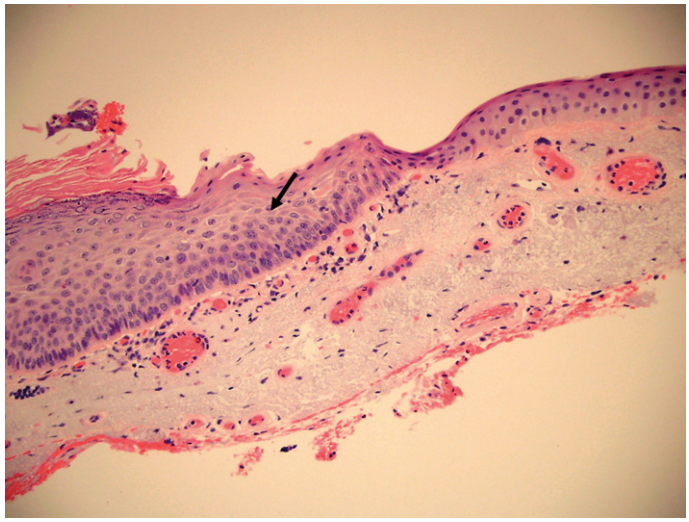

Figure 76.6. Conjunctival epithelium with normal maturation and polarity one side, and an area of abrupt change beginning in the center and extending to the other end showing epithelial thickening and nuclear atypia (arrow) is seen. This appearance is consistent with conjunctival intraepithelial neoplasia. The substantia propia also shows actinic change and mild lymphocytic infiltrate (Hematoxylin and eosin, ×200).

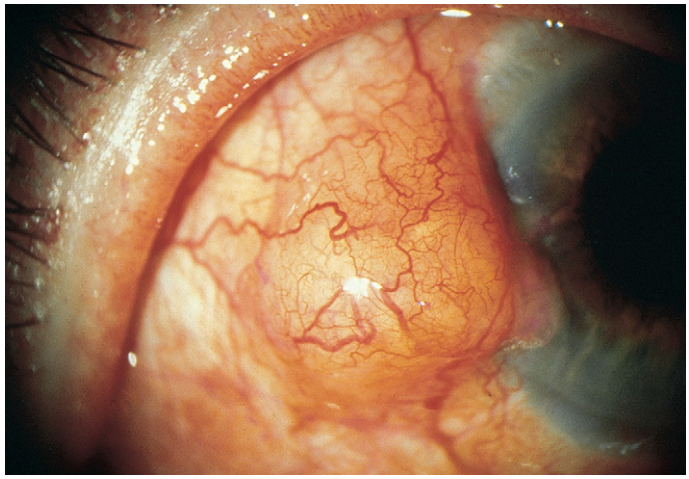

Figures 76.7. A squamous cell carcinoma adjacent to the limbus and fixed to the scleral tissue. Surgical exploration revealed scleral involvement which was resected with frozen section control until the deep and peripheral margins of the clear were free to the base and surrounding tissue.

fashion.[12] They are usually well differentiated and have a leukoplakic appearance but vary in vascularity and amount of associated inflammation.

Although these tumors are more common in the elderly, they are also seen with some frequency in young adults. As is the case with CIN, squamous cell carcinoma in a young individual should alert the physician to the possibility of HIV infection.[13,14]

Histopathologically, most are well differentiated, with exophytic growth of atypical epithelial cells. In more advanced tumors, the substantia propria is usually inflamed and contains invading masses of atypical epithelial cells that vary greatly in size, configuration, and degree of differentiation.[15,16] Squamous cell carcinoma may exhibit mucoepidermoid differentiation; mucin production may occur in only a portion of the tumor. These features may be more common in a recurrent lesion.[17] The mucoepidermoid variant of

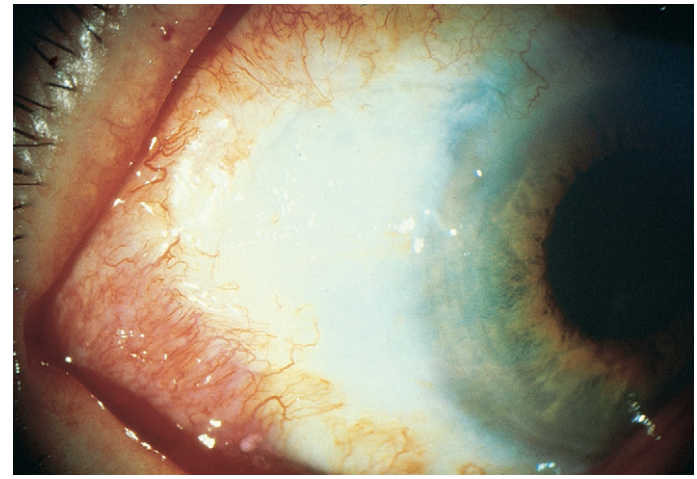

Figure 76.8. Same patient after cryotherapy was applied.

squamous cell carcinoma is more aggressive in its local behavior and may invade the eye and orbit if incompletely excised.

DIAGNOSIS OF EPITHELIAL TUMORS

Exfoliative cytology,[15,18] impression cytology,[19,20] and fine needle aspiration biopsy have been used to diagnose conjunctival epithelial neoplasia lesions. None of the aforementioned methods can help determine the depth of invasion and, hence, conjunctival biopsies are indicated when a specific tissue diagnosis is required. The biopsies may be excisional or incisional depending on the size and predicted depth of invasion. Conjunctival biopsies are discussed elsewhere in this text. Frozen sections are generally not practical for determining during surgery whether surgical margins of conjunctival and corneal epithelial tumors are clear.

MANAGEMENT TECHNIQUES FOR EPITHELIAL TUMORS

SURGICAL THERAPY

Excision of the lesion is the most accepted method of treatment for squamous neoplasia of the ocular surface. Dissection of all abnormal tissue with a wide surgical margin of 2–3 mm ensures removal of most lesions. Rose bengal staining may aid the delineation of the extent of abnormal tissue (Fig. 76.9).[21] Deep corneal invasion may require deep lamellar keratoplasty and scleroplasty (see Figs 76.5 and 76.8).[22,23] A technique analogous to Mohs' micrographic technique for cutaneous tumors has been described for corneal and conjunctival squamous lesions.[24] Extensive corneal limbal resection might necessitate limbal grafting from the opposite eye.[25,26] Excision of intraocular invasive tumors may occasionally be successful; a modified iridocyclochoroidectomy with adjunctive cryotherapy has had limited success.[22,27] Inadequate excision margins has been identified as a major risk factor for recurrence.[28] Partially excised tumors tend to recur with increased aggressiveness.[28] Excised lesions with free surgical margins have had a recurrence rate of 5%, as opposed to a 53% recurrence rate in lesions that were incompletely excised.[28] Gonioscopy is recommended to confirm that the tumor has not invaded the angle or anterior chamber. Enucleation or, more rarely, exenteration may be required in instances of intraocular or intraorbital extension.[29]

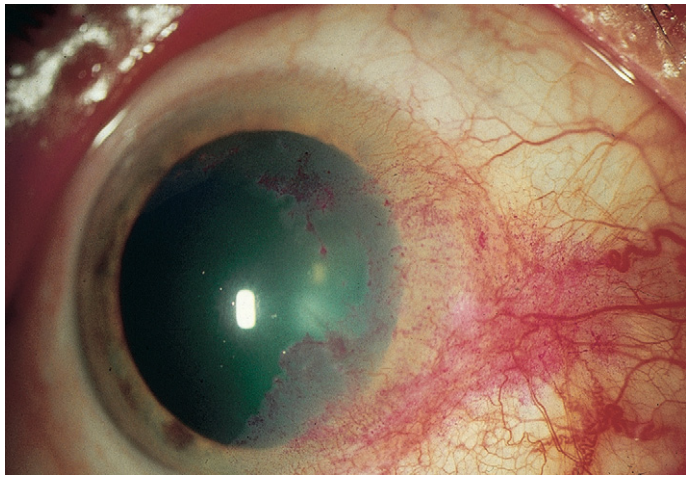

Figure 76.9. Rose bengal staining aiding determination of the extent of corneal and conjunctival involvement from a CIN. This can guide surgical therapy.

The use of a 193 nm argon–fluoride excimer laser for the removal of recurrent corneal intraepithelial neoplasia has been reported.[30] Despite its simplicity, no histologic examination can be performed as an assessment of the ablated tissue, and no evaluation of margins is possible.

RADIOTHERAPY

Generally, radiation alone is not recommended as a definitive therapy; however, it may be used for diffuse or spreading lesions, for which initial excision would be too extensive. The two most common types of radiation sources are strontium-90 and radium. Strontium 90 is a β source that delivers 100% of its dose to the most superficial layers of the tumor location.[31] A cup-shaped applicator is used to apply the therapy directly to the ocular surface. β-radiation has been used for recurrent corneal intraepithelial neoplasia.[32] γ-radiation has also been studied using radium as a source.[33] Recurrence rates range from 2 to 47%, with an average of 18%.[15] Complications include moderate to severe conjunctivitis, dry eye, cataract, telangiectasia, scarring, scleral ulceration, symblepharon, and corneal rupture.[15]

CRYOTHERAPY

Cryotherapy is effective because of its immediate thermal effect and subsequent obliteration of the microcirculation, resulting in ischemic infarction of normal and tumor tissues. Cryotherapy may also act by means of an immunologic response to liberated tumor antigens, which may play a late role in ongoing policing of residual or recurrent tumor cells at a cellular level.[15] Repeated freeze–thaw cycles are recommended to get adequate cellular destruction. Early side effects include iritis, altered intraocular pressure (high or low), thermic inflammatory edema and late corneal scarring, sector iris atrophy, ablation of the peripheral retina, ectropion, and uncommonly, corneal hemorrhage and superficial corneal vascularization.[15]

CHEMOTHERAPY AND IMMUNOTHERAPY

Topical mitomycin-C 0.02% applied four times daily for 10–22 days has been used to treat corneal intraepithelial neoplasia,[34] but only short-term follow-up has been reported. Adverse reactions included hyperemia, ocular pain, and blepharospasm; however, these symptoms disappeared quickly. Fluorouracil has also been used to treat epithelial neoplasia.[35] Other chemotherapeutic agents, including thiotepa[28] and urea,[36] have been used to treat in a limited number of patients with these lesions.

Immunotherapy with dinitrochlorobenzene requires systemic sensitization before tumor treatment by applying 2000 μg of the agent to the skin of the forearm.[37] After delayed hypersensitivity has been demonstrated, minute amounts of concentrated solution in acetone are applied to the surface of the tumor for several weeks. This form of treatment is labor intensive and requires continuous clinical monitoring and frequent application of the drug.

The recent therapeutic recommendations for squamous cell cancer include excision of the tumor and 2 mm of surrounding conjunctiva or superficial sclerotomy in adjacent areas.[38,39] A nitrous oxide cryoprobe is used to form an iceball extending 2 mm for the conjunctiva, 1 mm for the episclera tissues and limbus, and 0.5 mm for the cornea; the process is repeated twice. Recurrence rates average 12%.[15]

TUMORS OF THE MELANOCYTIC SYSTEM

Melanocytes are melanin producing cells which give rise to nevi, melanosis, and melanoma. African Americans and other heavily pigmented individuals may develop significant degrees of melanotic pigmentation of epithelial lesions (e.g. papilloma, actinic keratosis, carcinoma) that are, by definition, not of melanocytic origin. Conversely, melanocytic lesions may contain no clinically discernable pigment, or the pigmentation may be easily apparent. Melanosis oculi and nevus of Ota both involve episcleral and scleral pigmentation that can be mistaken for conjunctival pigmentation.

NEVI

Conjunctival nevi are composed of multiple nests of nevus cells and are classified based on the location of these nests. If the nests are at the junction of the epithelium and substantia propria, the nevus is termed junctional. If they are only in the substantia propria, the nevus is subepithelial. If both elements are seen, then the nevus is classified as compound. Most conjunctival nevi are compound or subepithelial. Junctional nevi are uncommon and occur primarily in young individuals.[40] The spindle-epithelioid cell, blue nevus, and cellular blue nevi are rare in the conjunctiva, but these can occur in combination with typical nevi.[41]

Nevi are almost always seen in the interpalpebral bulbar conjunctiva near the limbus.[40,42] Subepithelial and compound nevi typically elevate the conjunctival surface, and this may be attributable to the epithelial inclusion cysts commonly seen in these lesions (Figs 76.10 and 76.11). Junctional nevi, however, characteristically do not thicken the conjunctiva.[43] Over time, junctional conjunctival nevi frequently transform into compound and subepithelial nevi. The appearance of these lesions can change drastically because of an increase in the size of the nevoid nests, downward migration of these nests, and formation of epithelial inclusions. The appearance of a nevus might also change as a result of irritation. This can result in increased pigmentation, an inflammatory cell infiltrate, and increased vascularity. The same changes can be seen in malignant transformation to melanoma, so these lesions must be photographed and/or closely observed, and may require an excisional biopsy.

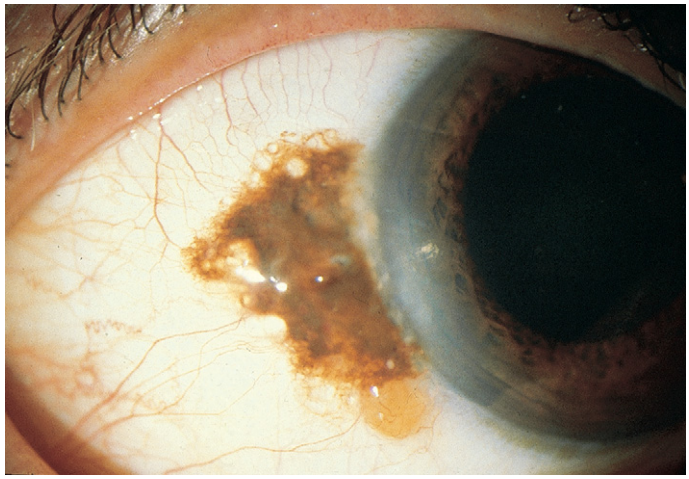

Figure 76.10. A compound conjunctival nevus in a young adult demonstrating typical pigmentary changes and cystic epithelial inclusions.

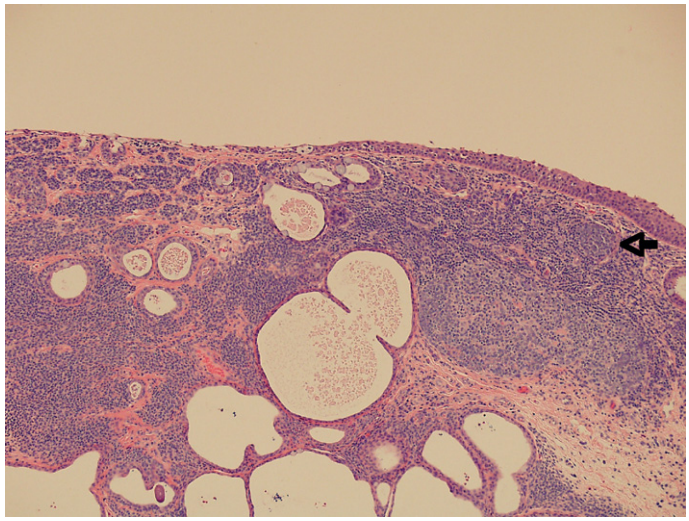

Figure 76.11. Conjunctival tissue with nests of nevus cells (arrow) in the substantia propria is seen. Some nevus cells contain pigment. The nevus cells are intermixed with cystic structures, lined by uniform epithelium including goblet cells. The substantia propria also shows scattered lymphocytic infiltrate (Hematoxylin and eosin, ×100).

Conjunctival nevi can be amelanotic and these may clinically resemble epithelial lesions or angiomas.

MELANOSIS

Melanosis is excess melanotic pigmentation and can be classified based on whether it is congenital or acquired, epithelial or subepithelial, and primary or secondary. All the congenital melanoses are primary, and they are divided into epithelial or subepithelial types. The acquired melanoses are epithelial, and they are divided into primary and secondary types (Box 76.2).

Congenital epithelial melanosis

Congenital epithelial melanosis (freckle) is a discrete stationary lesion that is present from early childhood in the basal layers of the conjunctival epithelium. The melanocytes are not atypical, and this lesion is not a precursor of melanoma.

BOX 76.2 MELANOSIS

Congenital (all are primary)
- Epithelial
- Subepithelial

Acquired (all are epithelial)
- Primary
- Secondary

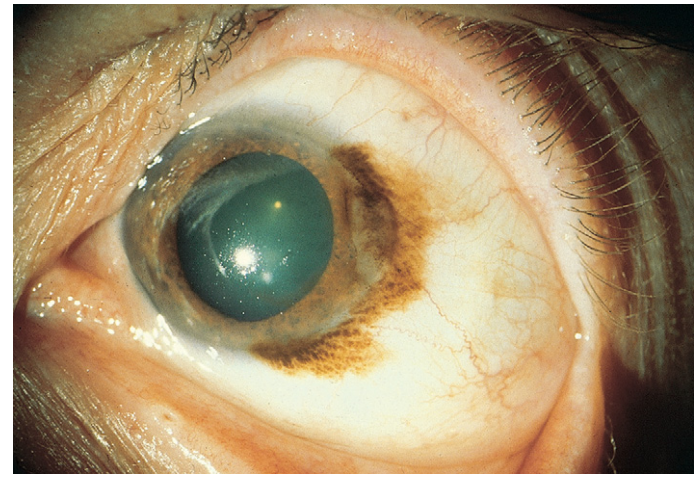

Figure 76.12. Primary acquired melanosis in a middle-aged Caucasian male. The pigmentation has increased gradually over the past 2 years. Biopsy is recommended to stage the lesion; further therapy depends on the histopathology.

Congenital subepithelial melanosis

Congenital subepithelial melanosis is actually abnormal melanocytes in the sclera and episclera deep to the substantia propria. It is seen in the conditions of melanosis oculi and nevus of Ota. They are both unilateral conditions with increased number, size, and pigmentation of melanocytes in the sclera and episclera as well as the entire uvea. The nevus of Ota additionally has increased pigmentation of the deep dermal tissues of the lids, periocular facial skin, or both. The affected tissues are a characteristic slate blue-grey, in contrast with the golden brown to brown-black of intraepithelial forms of melanosis. These conditions are occasionally associated with malignant change; most melanomas in these two conditions arise in the uveal tract or orbit, not the conjunctiva. They are more frequent in African American and Asian patients, but malignant change in these individuals is rare.

Primary acquired melanosis

Primary acquired melanosis (PAM) is a unilateral neoplastic melanocytic proliferation within the conjunctival epithelium. PAM is observed almost exclusively in Caucasian patients, especially those of European ancestry, with a prevalence of up to 36% (Fig. 76.12).[44] PAM typically begins insidiously in middle or older age as a subtle, golden brown stippling within the epithelium. It is analogous to lentigo maligna of the skin. PAM can arise in any part of the conjunctiva, although it is more common on the bulbar portion. The lesion is usually flat which helps to distinguish it from nevi. When elevated areas develop in PAM, they are often a sign of malignant melanoma. Approximately one-third of the conjunctival melanomas arise from PAM. PAM has an unpredictable course and may wax, wane, or spontaneously disappear, although its changes usually are

Figure 76.13. Primary acquired melanosis with multiple elevated nodules on the palpebral conjunctiva of the upper lid usually indicative of melanoma.

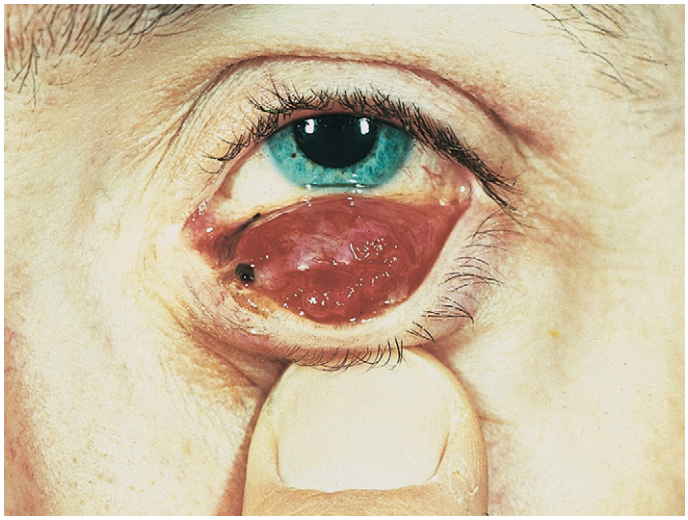

Figure 76.14. Minimally pigmented melanoma apparently arising de novo in the inferior cul de sac. Biopsy confirmed the diagnosis in this 40-year-old Caucasian. Despite exenteration, he died 16 months later with extensive metastases.

gradual. Use of the Woods lamp may indicate a larger lesion than is otherwise evident.

Histologic examination provides significant prognostic information; hence biopsy of PAM lesions is often essential for clinical management. Biopsies are classified as either PAM without atypia, which carries almost no risk of melanoma; or PAM with atypia, which carries a 50% risk of melanoma.[1,45,46] When atypical melanocytes invade the epithelium in a pagetoid fashion or replace the epithelium, the risk of melanoma is 90%; when they are confined to the basal layer of the epithelium, the risk of melanoma is 20%. Of tumors that contain epithelioid cells, 75% progress to melanoma. Lesions in which no or only minimal atypia can be detected do not progress to melanoma.[45–47] All lesions with high risk should be considered for resection, if feasible. Subtotal excision combined with cryotherapy provides effective therapy for extensive lesions that cannot be completely resected.[48]

MELANOMA

Conjunctival melanomas are rare tumors that occur predominantly in fair-skinned adults, although they have been reported in more heavily pigmented individuals. They may arise from PAM with atypia, from pre-existing nevi, or from normal conjunctiva (de novo) (Fig. 76.13). Therefore, any change in a pigmented lesion of the conjunctiva, particularly growth with increasing elevation and prominent feeder vessels, should be suspected of being a malignant melanoma (Fig. 76.14). Melanoma can be suspected clinically based on the history of the lesion and the slit-lamp biomicroscopic findings, but a histopathological examination is essential to confirm the diagnosis.

Histopathologically, conjunctival melanoma is characterized by the presence in the conjunctival stroma of atypical melanocytes exhibiting prominent nucleoli and altered nuclear : cytoplasm ratio. There may be an associated PAM lesion or nevus. Occasionally, melanoma cells are amelanotic. In these instances, certain silver stains (Fontana's and Warthin–Starry methods) may be helpful in making fine melanin granules visible by light microscopy. Also, positive immunoperoxidase staining for HMB-45, S-100 and anti-melan-A and negative staining for cytokeratin provide a reliable method for distinguishing melanocytes from epithelial cells.[49]

Conjunctival melanomas tend to be invasive, involving nerves and extending posteriorly into the orbit. The behavior of conjunctival melanomas, however, remains unpredictable in individual cases.[50] Poor prognostic factors include tumor arising from PAM, tumor thickness, involvement of the nonbulbar conjunctiva (especially invasion of the skin margin), invasion of the sclera or orbit, pagetoid spread, recurrence, and increased mitotic activity.[51–53] A better prognosis is associated with bulbar location or with an inflammatory infiltrate around the invasive tumor.

Conjunctival melanomas share with cutaneous melanomas the ability to invade lymphatics and spread initially to the regional lymph nodes, especially the preauricular and intraparotid nodes. Although lymph node involvement indicates a poor prognosis, it does not always herald widespread dissemination.

DIAGNOSTIC TECHNIQUES FOR PIGMENTED LESIONS OF THE CONJUNCTIVA

CYTOLOGY

Atypical melanocytes ascend to the surface of the conjunctival epithelium with malignant transformation; however, there are a lack of superficial melanocytes in benign nevi, primary acquired melanosis without atypia, and early primary acquired melanosis with atypia. This makes impression and exfoliative cytology less desirable as a method of diagnosing a pigmented lesion.

BIOPSY

Pigmented lesions should be documented photographically or with drawings. Significant increase in size, deepening of color, or change in appearance warrants excision. Small lesions should be removed in toto with generous margins and double freeze–thaw cryotherapy to the surgical margin. Larger lesions, such as primary acquired melanosis, require incisional biopsies taken from the thickest and most pigmented areas. A map of the biopsy sites should accompany the specimens to the laboratory. To prevent curling of the specimen,

tissue can be placed on filter paper and then immersed in fixative. A suture or dye can be used to help the pathologist orient the specimen. Many biopsy sites need no closure, but occasionally a conjunctival autograft from the opposite eye is needed. In addition to the histologic evaluation, investigational tests are being performed in some laboratories, including nucleolar organizer region evaluations and monoclonal antibody studies to HMB-45, S-100, and anti-melan-A.[49]

MANAGEMENT TECHNIQUES FOR PIGMENTED LESIONS OF THE CONJUNCTIVA

EXCISION AND CRYOTHERAPY

As stated above, a complete excision with wide margins is indicated for small suspicious pigmented lesions. Lesions of primary acquired melanosis with atypia should be completely removed if possible because of the risk of progression to melanoma. Conjunctival tissue may be fragile and should be handled carefully to provide a good diagnostic specimen and avoid dissemination of tumor cells. Although thorough microscopic excision of tumor is the preferred treatment, recurrence can still develop in up to 65% of patients with melanoma arising from PAM at 15 years follow-up.[54]

Adjunctive cryotherapy increases the success rate to 80–90% in patients with primary lesions of unifocal melanoma and is recommended at the time of the initial surgery (Figs 76.15 and 76.16). Tumor cells are more sensitive to destruction by the double freeze–thaw method of cryotherapy, with tissue temperatures between −15 and −20°C,[55] and those that are not destroyed become depigmented. Complications of cryotherapy include conjunctival symblepharon, lash loss, ptosis, pseudopterygium, corneal ulceration, iris atrophy, cataract, macular edema, anterior segment necrosis, scleral melting, and phthisis bulbi.

The value of additional removal of scleral tissue has not been determined. Peripheral corneal pigmentation can be scraped and absolute alcohol used to devitalize any remaining cells. If regional metastasis is present, regional lymph node removal along with parotidectomy should be considered if there is no sign of distal seeding; however, the prognosis in this situation remains poor. Evaluation for metastases should always be performed before undertaking these major surgical approaches.

RADIOTHERAPY AND CHEMOTHERAPY

β-radiation and radioactive plaques have been used following local excision but not in a controlled fashion. Hematoporphyrin photoradiation has been tried in only a few patients. Topical mitomycin-C has been used with limited success for treating primary acquired melanosis and melanoma. The deeper cells may remain unaffected by the drug; however, it may be useful in preventing symblepharon after extensive cryotherapy. Dacarbazine, a cytotoxic purine analog, has been used systemically to treat malignant melanoma; its effectiveness with local application is under investigation.

CARBON DIOXIDE LASER

The carbon dioxide laser has been used to destroy the conjunctival epithelium without damaging the underlying sclera. It may be useful for treating diffuse bulbar conjunctival lesions, in which the risks of treatment with cryotherapy may be excessive. It is not recommended for treating the fornices and palpebral conjunctiva or the cornea. This technique needs further evaluation before being accepted as a recommended therapy.

EXENTERATION

In patients with extensive infiltration of the conjunctiva by melanoma, there are limits to the amount of conjunctiva that can be removed.[56] An orbital exenteration may be necessary, although most patients with orbital involvement ultimately develop distant metastases.[54] The alternative is to excise all invasive nodules and treat the remaining flat areas of intraepithelial disease with cryotherapy.

OTHER PRIMARY CONJUNCTIVAL TUMORS

CARUNCLE LESIONS—ONCOCYTOMA

As mentioned earlier, the caruncle is a complex anatomic location containing elements of both the conjunctiva and skin. This com-

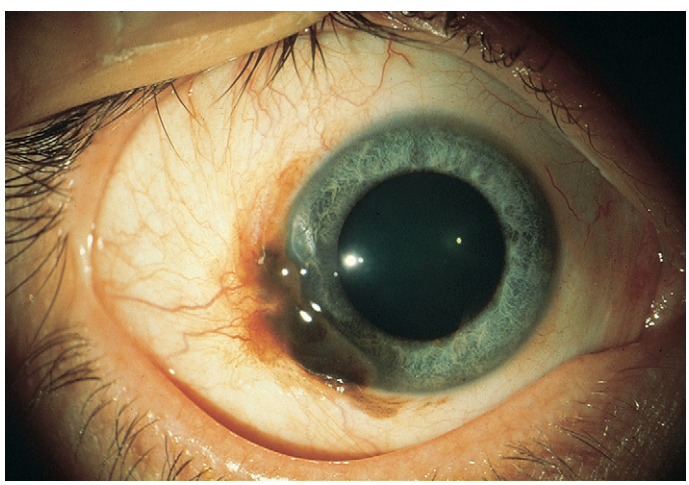

Figure 76.15. Deeply pigmented melanoma arising at the limbal area, apparently de novo, although histopathology showed elements to suggest prior nevus.

Figure 76.16. The postoperative appearance of the eye in Figure 76.15, 2 months after excision of the melanoma with a 3-mm margin and cryotherapy to the base and surrounding tissue.

plexity can result in a myriad of different lesions, the most common being papilloma, nevus, and pyogenic granuloma.[57] The caruncle also contains adnexal structures: accessory lacrimal glands, sweat glands, sebaceous glands, and hair follicles. Oncocytoma (oncocytic adenoma) is a tumor that arises from the accessory lacrimal glands.[58] Oncocytomas are usually asymptomatic, slowly enlarging, bluish cystic lesions of the caruncle in older individuals. There is a predilection for these tumors in women.[59] Observation may be the preferred approach if one is sure of the clinical diagnosis and the lesion is stable to these and many other caruncular lesions. Excision should be considered if the lesion is symptomatic or if there is a question regarding the clinical diagnosis.

SEBACEOUS GLAND TUMORS

Sebaceous carcinoma arises almost exclusively in the skin of the eyelid and is extremely rare in the skin elsewhere. In the periocular area, it most commonly arises in the Meibomian (tarsal) glands, and less commonly in the sebaceous glands of the lashes, the caruncle, or the skin of the eyebrows. Sebaceous carcinoma is usually seen in elderly patients, with a female preponderance in incidence. It may present as a firm nodule resembling a chalazion, with a diffuse, plaque-like thickening of the tarsus, or a generalized erythema of the lids, with conjunctival injection simulating a chronic blepharitis or conjunctivitis. This clinical picture is referred to as the masquerade syndrome[60] (Fig. 76.17).

Diagnosis of this tumor requires biopsy. The involved epithelium is very friable, and if the biopsy specimen is not carefully handled, the abnormal cells may be lost. It is often necessary to obtain multiple biopsy specimens from the lid margin as well as the palpebral and bulbar conjunctiva to determine the extent of intraepithelial involvement. The tissue may either be submitted fresh or in 10% neutral-buffered formalin. In either instance, prior to tissue processing, a frozen tissue section and subsequent staining with Oil Red O can be useful diagnostically.

Histopathologically, sebaceous carcinoma usually appears as finger-like projections and lobules of large, cohesive cells with foamy cytoplasm, increased nuclear to cytoplasm ratio, and prominent nucleoli. Mitoses are usually prominent. In certain lesions, central necrosis of the tumor lobules is seen; this is termed a comedo pattern. Intraepithelial spread to the conjunctiva, cornea, or skin of the eyelids may be observed in sebaceous gland carcinomas. There are two patterns of intraepithelial spread: pagetoid (so called because of analogy to Paget's disease of the breast) and carcinoma in situ-like. The neoplastic cells in pagetoid spread invade the overlying epithelium as single cells or as small nests of cells that typically do not form intercellular bridges with the surrounding normal squamous epithelial cells. The spread also can be a diffuse process, with full-thickness replacement of surface epithelium by neoplastic cells, resembling squamous cell carcinoma in situ. Many times, the intraepithelial spread will elicit a chronic inflammatory response, thus producing the clinical picture of chronic blepharitis or conjunctivitis. Rarely, there may be intraepithelial sebaceous neoplasia of the conjunctiva and cornea without an underlying invasive carcinoma.[61] The epithelium of the conjunctiva, cornea, or epidermis of the lids often displays multifocal involvement, with skip areas of unaffected epithelium. In cases that pose a diagnostic dilemma, immunohistochemical staining can be employed. Positive staining for epithelial membrane antigen (EMA) and BRST-1 in sebaceous carcinoma distinguishes this from basal cell carcinoma, and positive staining for Cam 5.2 can rule out squamous cell carcinoma.[62]

A worse prognosis is indicated if the origin of the tumor is in the upper eyelid, if the size is 10 mm or more, if the origin is from Meibomian glands, when duration of symptoms is more than 6 months, with infiltrative growth pattern, with moderate to poor sebaceous differentiation, and when invasion of lymphatic channels is present. The treatment is primarily surgical, with wide local excision of the lesion until the surgical margins are histologically clear of tumor. Adjunctive cryotherapy is effective. Because of pagetoid invasion, the Mohs' surgical technique has been less successful in the management of sebaceous carcinoma than in basal cell or squamous carcinoma.[63] Many patients with diffuse pagetoid invasion or carcinoma in situ-like changes involving the skin of the lid, the conjunctiva, and the cornea require orbital exenteration. Sebaceous carcinomas are relatively radioresistant, and radiotherapy is unlikely to control the disease.[64] Removal of involved regional lymph nodes has resulted in long-term survival of some patients.[65]

Figure 76.17. The 'masquerade syndrome' of sebaceous cell carcinoma in an elderly woman with prolonged unilateral ocular irritation and conjunctival injection.

KAPOSI'S SARCOMA

Kaposi's sarcoma of the conjunctiva was previously a rare disease, primarily occurring in older individuals with similar lesions on the skin.[66] It is now encountered almost exclusively in the palpebral or forniceal conjunctiva of younger individuals with acquired immune deficiency syndrome (AIDS).[67] It can be one of the earliest clinical manifestations of AIDS. Histopathologically, the tumor shows capillary clusters in a malignant spindle cell stroma. A characteristic finding in Kaposi's sarcoma is the presence of multiple, small, PAS-positive intracellular hyaline globules that are believed to be degenerated erythrocytes.[68] Often there is a lymphocytic infiltrate that has led to the term 'malignant granulation tissue.' The lesions are classified in AIDS patients into three types: Type I and type II tumors are patchy and flat and of less than 4 months' duration. They are different in that type II has plump endothelial cells and foci of immature spindle cells. Type III tumors are nodular and elevated with a duration of more than 4 months.

This aggressive tumor presents as a chronic reddish dermal mass in the skin or as a reddish conjunctival lesion (Fig. 76.18). Human herpes virus 8 has been detected in the vascular endothelial cells

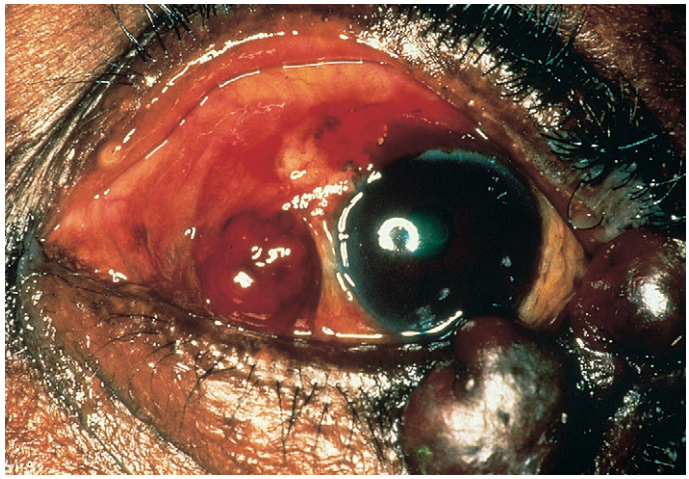

Figure 76.18. Multiple lesions of Kaposi sarcoma of the eyelid and conjunctiva in a patient with AIDS.

lining vascular spaces and perivascular spindle cells in Kaposi's sarcoma lesions.[69] In addition to its prevalence in AIDS, Kaposi's sarcoma is also associated with malignant lymphoma, leukemia, or a distant primary carcinoma.

Therapy for Kaposi's sarcoma associated with AIDS is based on cryotherapy and surgical excision.[70] An alternative therapeutic approach is radiation, as these tumors are highly responsive. Additionally, chemotherapy and immunotherapy have been described.[71–73]

VASCULAR LESIONS

The various vascular lesions that can be present on the conjunctiva include capillary hemangiomas in children, cavernous hemangiomas in young adults, and racemose hemangiomas as a part of Wyburn–Mason syndrome. Lymphangiomas that are commonly regarded as orbital lesions may have a more superficial conjunctival component.

LYMPHOID TUMORS

Lymphoma can occur as an isolated conjunctival lesion (Mucosa Associated Lymphoid Tumors—MALToma) or can be a component of systemic lymphoma. The classical clinical appearance is that of a 'salmon patch,' consisting of pink diffuse elevated forniceal mass in the substantia propria or deep to the Tenon' capsule. A biopsy is essential to make a definitive diagnosis and classify the lesion into the cell of origin. Most lesions are B cell lymphoma; however, T cell lymphoma can rarely occur. Histopathologically these lesions consist of sheets of pleomorphic and atypical lymphocytes many times displaying a nuclear cleft. A monotonous uniform lymphoid cell population is suggestive of MALToma (Fig. 76.19). Immunohistochemical staining is useful in identifying the cell type. The commonly used markers include CD20 for B cell lymphoma, CD3 for T cell lymphoma, CD10 for follicular cell lymphoma, and cyclin D1 for mantle cell lymphoma. A thorough clinical workup is essential in all patients to rule out systemic lymphoma. External beam radiation is useful for localized conjunctival involvement; however, adjuvant chemotherapy is necessary in cases of systemic lymphoma. The other treatment modalities that have been used include excisional biopsy, cryotherapy, and local interferon injections.

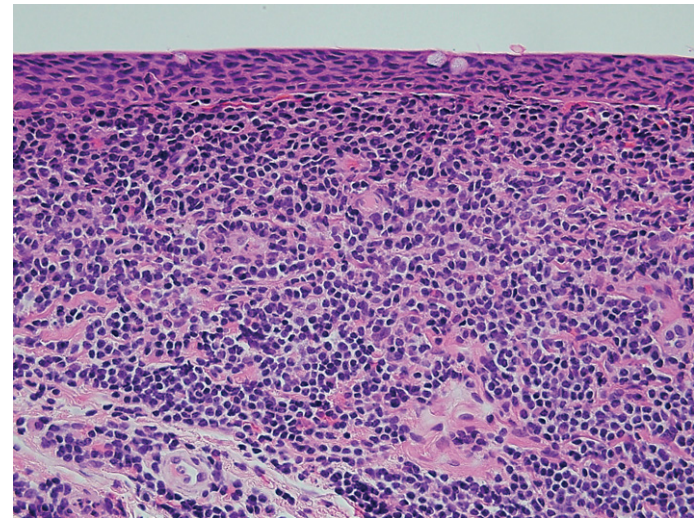

Figure 76.19. Conjunctival tissue with lymphoid infiltration in the substantia propria is seen. The infiltrate consists of monotonous uniform lymphoid cell population consistent with MALToma (Hematoxylin and eosin, ×400).

SOFT TISSUE, HEMATOPOIETIC, NEURAL AND HISTIOCYTIC TUMORS

Although most of these tumors arise in the eyelids and orbit, rarely conjunctival involvement can be seen. The various tumors include fibroma, fibrous histiocytoma, lipoma, myxoma, leukemia, neurofibroma, neurilemoma, xanthoma, juvenile xanthogranuloma, and metastatic tumors.

77 Temporary keratoprosthesis

Elmer Y. Tu, Joel Sugar

INTRODUCTION

Performing keratoplasty for a visually significant corneal opacity is usually most successful after optimizing the condition of the eye. If visualization is adequate, other medical and surgical interventions are performed prior to keratoplasty to minimize trauma to the new graft and to improve the likelihood of graft survival. In these cases, the amount of time to achieve optical clarity is usually not critical and is indeed often unpredictable, taking days to weeks in many cases. In situations where there is a more urgent need for visualization, as in the case of retinal detachment or other acute surgical disease, a number of surgical options are available. These include combining the procedure with concurrent penetrating keratoplasty, utilizing endoscopic vitrectomy, or placement of a temporary keratoprosthesis (TKP).

Combined surgery with visualization through a new graft presents many challenges.[1] The transplant tissue may not be optically clear secondary to irregular or edematous epithelium, stromal haze, and/or stromal folds. Even with epithelial debridement, the clarity of the graft at the time of the surgery is highly unpredictable. The new graft, sutured to withstand high intraocular pressures often utilized in complex retinal surgery, may present significant peripheral aberrations, restricting the field of view. Finally, extensive intraocular manipulation and irrigation may reduce the viability of the transplanted endothelium. Lamellar procedures may offer more rapid rehabilitation, but, at present, it is unclear whether they will reliably allow contemporaneous retinal surgery.[2,3] Endoscopic vitrectomy circumvents media opacities entirely, but the equipment is expensive, the surgery more technically challenging, and the therapeutic options more limited for the retina surgeon.[4]

TKPs have transformed the performance of combined corneal and retinal surgery. They can provide excellent, wide field visualization of the posterior segment, withstand elevations in intraocular pressure and extensive manipulation, as well as avoid trauma to the new corneal graft. Since their introduction, they have undergone a number of modifications to improve their ease of implantation and increase their utility in posterior segment surgery.

DESIGN

The requirements for a functional TKP are significantly different from those of a permanent keratoprosthesis. There is no need for integration or biocompatibility, but the TKP should leave the host corneal rim structurally intact to accommodate the new cornea. A TKP should allow an excellent view of not only the posterior pole, but clear peripheral retinal visualization as well. The TKP also needs to withstand manipulation and high intraocular pressures characteristic of some retinal procedures while keeping a tight seal at the prosthetic–corneal junction. Secondarily, the prosthesis should be simple and quick to apply, should not interfere with retinal instrumentation and should minimize the number of special lenses and equipment needed.

There is some variation in design of currently available TKPs, but some design elements are shared (Table 77.1). To ensure a tight seal and stability, TKPs either consist of a screw type mechanism to create areas of tight pressure apposition of the host corneal rim to the ridges of the TKP or a wide anterior flange to increase the surface area in contact with the cornea (Fig. 77.1, *A* and *B*). These allow the TKP to remain closely applied when the host cornea is deformed during scleral depression or during periods of high intraocular pressure. Current TKPs are fixed with two to six sutures facilitating rapid placement and do not require scleral fixation. The optical elements have been widened and the cylinders shortened to expand the viewable field and allow use in pseudophakia and, in some cases, phakia. Some prostheses include an integrated infusion port to allow anterior pressurization of the eye and, in selected cases, obviate the need for pars plana infusion. Finally, the curvature and index of refraction approximate those of the normal cornea to allow the use of standard vitrectomy lenses.

INSTRUMENTATION

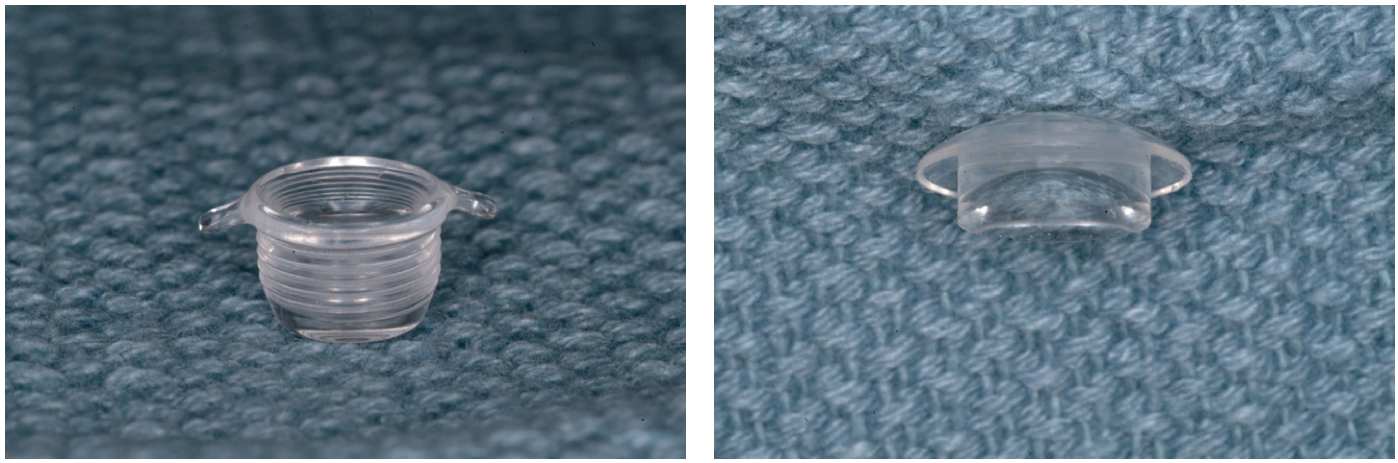
LANDERS-TYPE KERATOPROSTHESES

The introduction of the three Landers-type keratoprostheses in 1981 revolutionized the performance of combined corneal–retinal

Table 77.1 Characteristics of available temporary keratoprostheses

	Landers Type 2	Landers Wide Field	Eckardt	Aachen	Cobo
Material	PMMA	PMMA	Silicone	Silicone rubber	Quartz/stainless steel sides
Cylinder width	5.0 mm	6.2, 7.2, and 8.2 mm	7.0 and 8.0 mm	7.0 mm	6.5–8.5 mm
Cylinder length	6.2 mm	1 mm	1.6–2.8 mm	0.5 mm	5.0 mm
Refractive power	–135.6 D Air –85.4 D Aphakia		–35 D Air		Plano
Anterior curvature	7.8 mm	15.5 mm	7.8 mm	7.9 mm	Plano
Overall diameter	10 mm	14 mm	10 mm	14 mm	9.5 mm

PMMA = polymethylmethacrylate



A B

Figure 77.1. *A*, Landers type 2 temporary keratoprosthesis (TKP), note the 'screw' type scoring of the cylinder creating lines of tight apposition to the host cornea and the two struts for additional suture support. *B*, Eckardt TKP, note the wide flange and short optic to accommodate pseudophakos.

surgery.[1] All three types were re-usable and made entirely of polymethylmethacrylate, consisting of central cylinders with a 5.0-mm wide optic and a 6.2-mm cylinder. Type 1 was a simple threaded optical cylinder with a small anterior flange while type 2 (Fig. 77.1, *A*) is of similar design but with two posteriorly angled, radial struts allowing suture fixation to paracentral cornea. Type 3 was a smooth cylinder with a circular wheel-type flange, which allowed broad suture fixation. With proper fixation, the prostheses remained stable at intraocular pressures of up to 70 mmHg.[1]

A third generation wide-field design (Fig. 77.2) was introduced in 1993 with a central cylinder shortened to 1 mm with an overall diameter of 14 mm, six integrated suture holes, and is available in optical cylinder widths of 6.2, 7.2, and 8.2 mm.[5] The addition of an infusion port in 1996 added the further capability of anterior infusion with or without pars plana infusion.[6]

Operative technique

A Flieringa ring is recommended to support the peripheral corneal rim and provide counterpressure for insertion of the TKP. The ring is also helpful in supporting the vitrectomized eye, which has a tendency to collapse once the TKP is removed, especially when an air–fluid exchange has been performed. The center of the trephination is marked and a 6.0-mm corneal trephination performed. The TKP is then twisted back and forth and advanced into the eye until the anterior flange is in contact with the corneal surface. Two 6-0 silk sutures or 8-0 nylon sutures are placed over the horizontal

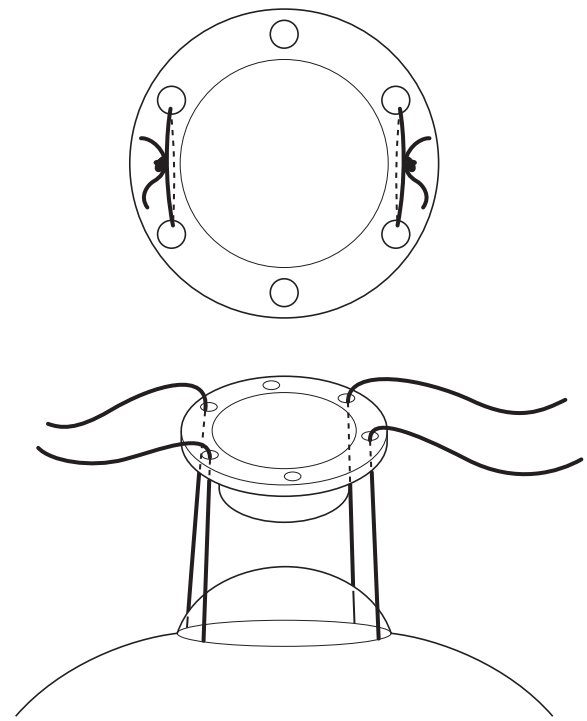


Figure 77.2. Wide field Landers with alternative method of suture fixation. Note the six holes for radial sutures can also be used as entrance and exit suture access with the suture tied over the flange.

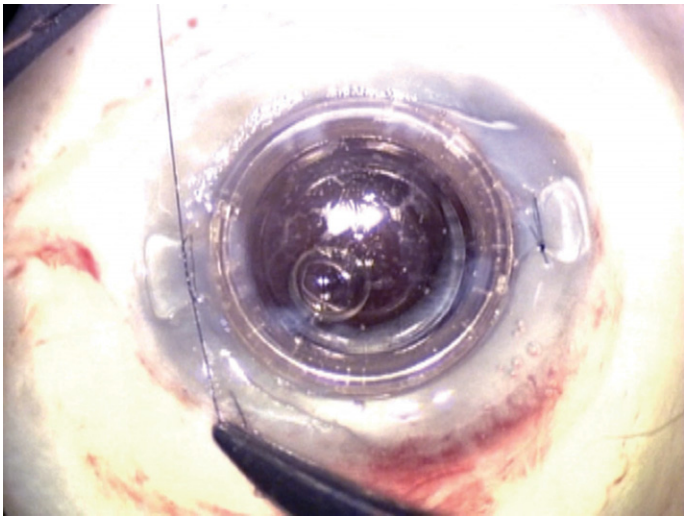

Figure 77.3. Landers type 2 TKP with sutures in place providing additional support to prevent intraoperative extrusion.

struts to secure the type 2 keratoprosthesis (Fig. 77.3). At the end of the case, the donor cornea is punched with a 6.5-mm trephine and the cornea secured with 10-0 nylon.

The Landers wide-field keratoprosthesis is also placed with a Flieringa ring, but utilizes a recipient bed 0.2 mm smaller than the optical cylinder and is secured with six interrupted 5-0 Mersilene sutures passed through the six peripheral suture holes in the anterior flange through limbal tissue.[6] The sides of the cylinder are smooth and short, making insertion less difficult. Alternatively, two 6-0 silk sutures may be passed, one from 2 to 4 o'clock and the other 8 to 10 o'clock.[7] The two ends of the suture are then passed through the corresponding suture holes loosely. The keratoprosthesis is pushed aside and the 7.0-mm trephination performed. The four suture ends are then pulled taut and tied over the anterior flange tightly, securing the TKP (Fig. 77.2). At the end of the case, the donor cornea is punched with a 7.5-mm trephine (0.3 mm larger than the optical cylinder) and secured with 10-0 nylon.

ECKARDT KERATOPROSTHESIS

The Eckardt keratoprosthesis (Fig.77. 1, *B*) was introduced in 1987 and is made entirely of silicone with a 7.0-mm wide and 2.8-mm long central cylinder.[8] An 8.0-mm diameter cylinder is also available. It has a wide silicone flange, which conforms to the anterior corneal surface, maintaining a tight seal even with deformation of the corneoscleral rim. The wide optic and short cylinder allows excellent peripheral visualization as well as compatibility with pseudophakos. Since securing sutures are placed through the silicone material there is considerable flexibility in suture placement, especially in traumatized eyes to avoid areas of unstable cornea. The TKP can be reused until repeated suture holes reduce its ability to create a watertight seal.

Operative technique

A Flieringa ring is recommended to support the corneoscleral rim since insertion requires significant support.[8] The collapse of the globe on removal of the TKP can be avoided by filling the eye with perfluoro-octane.[9] The original recommended corneal bed trephination was 6.5 mm, but a 6.7-mm trephination has been found to allow easier insertion and a continued watertight closure. One edge of the cylinder is placed against the corneal rim and the keratoprosthesis pushed down into the opening, creating a seal. If the pars plana infusion is pre-placed and open, the occlusion of the trephination should cause the pressure in the globe to rise, expanding the corneal rim opening enough to 'pop' the keratoprosthesis into position. While pressing down in the center of the Eckardt to prevent extrusion, four or six 8-0 or 9-0 nylon sutures are evenly spaced circumferentially and passed from the limbus centrifugally, continuing intrastromally and exiting at the junction between the flange and central cylinder (Fig. 77.4, *A* and *B*). If the infusion cannot be pre-placed or opened because of poor visualization, placement of the first suture and lifting, and stretching at the limbus 180° away should allow the implant to be pushed into position. Inclusion of some of the optical cylinder in the suture does not reduce the surgeon's view or stability of the TKP (Fig. 77.5). Because the opening is stretched to the size of the optical cylinder for an extended period of time, the corneal donor is later punched with a 7.25-mm trephine to fit properly and secured using 10-0 nylon. A method has been described to allow larger donor grafts by partial thickness trephination of the larger graft prior to the smaller central trephination.[10] Performing the central trephination after the destabilizing outer trephination may be made easier by pressurizing the eye (Fig. 77.4, *C*). The secondary rim is then removed with scissors after removal of TKP resulting in a larger pre-cut recipient bed.

AACHEN KERATOPROSTHESIS

The Aachen keratoprosthesis is made of soft silicone rubber with a 7.0-mm wide and 0.5-mm long central optic.[11] It is designed as a permanent keratoprosthesis, but may be used as a TKP.[12] The design features a wide anterior flange, which overrides the sclera and provides optics similar to the Eckardt and wide-field Landers keratoprostheses. The material withstands suturing well and is well-tolerated. Its short optical cylinder lends itself to use in pseudophakic and possibly phakic eyes.[12]

Operative technique

It is recommended that a pars plana infusion port be pre-placed prior to dissection. Its 7.0-mm optic is designed to fit into a 6.8-mm corneal trephination. The optical cylinder is placed and with downward pressure screwed into place. Like the Eckardt keratoprosthesis, the TKP is not self-retaining and downward pressure needs to be maintained to prevent extrusion prior to suturing. Reducing the infusion flow may aid in keeping the TKP in place during fixation. The haptic is then sutured to host sclera with 4 7-0 nylon sutures with subsequent fixation of the circumferential ring to the more peripheral sclera. A 7.0-mm donor graft is recommended.

COBO KERATOPROSTHESIS

The Cobo keratoprosthesis (Fig. 77.6) is made of quartz and constitutes an inverted, truncated cone when in proper orientation. It is 6.5 mm at its internal base, expanding to 8.5 mm at the top. It has an integrated 40-mm infusion handle for injection of fluid or air to tamponade choroidal hemorrhage (Fig. 77.7). It is meant primarily for emergency use during open-sky procedures when expulsion of intraocular contents is imminent and because of its design can quickly fit various trephination sizes without custom sizing. It may also be used to restore intraocular pressure if delay in securing the graft is anticipated. The plano curvature allows a clear view of the anterior segment while in place.

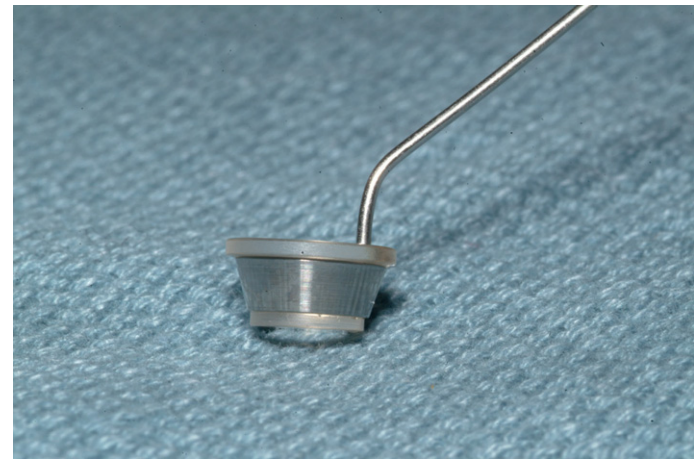

Figure 77.6. Side view of the Cobo temporary keratoprosthesis (TKP). Note the truncated cone profile allowing it to tamponade corneal openings from 6.5 to 8.0 mm.

Operative technique

In order to be effective, the Cobo keratoprosthesis should be assembled with flexible tubing and primed with balanced salt solution prior to every case and available for immediate use, especially for high-risk cases. Once the need for the keratoprosthesis is recognized, the inverted cone is placed into the wound deep enough to achieve occlusion. The instrument will fit trephinations from 6.5 to 8.0 mm obviating the need for sizing preoperatively. Once in place, an infusion of balanced salt solution or gas is started to raise the intraocular pressure and tamponade the hemorrhage. This may be held in place, or sutured with two horizontal overlay mattress sutures 90° apart. The suture can be tucked into a superficial circumferential groove at the top of the keratoprosthesis for more stability. After control of intraocular structures is achieved, the preplanned corneal donor button can then be sutured in place.

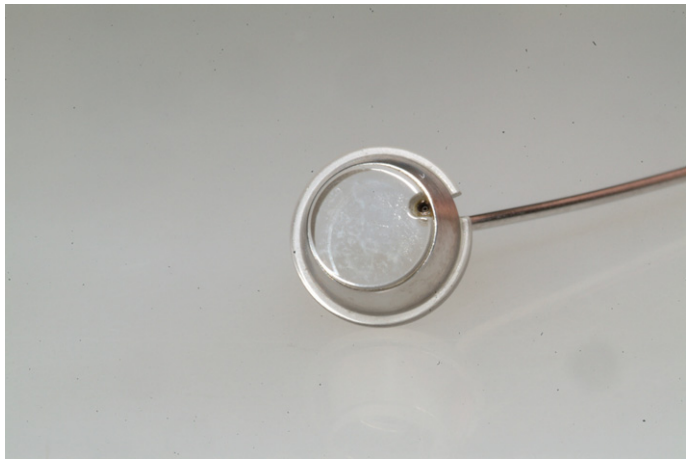

Figure 77.7. Cobo temporary keratoprosthesis (TKP), bottom view. Note opening for infusion suitable for air or fluid to raise intraocular pressure.

USES

Cases suffering from both anterior and posterior segment disease, especially of an acute nature, tend to have more severe disease and a poorer prognosis. The indications are predominantly trauma, but may also consist of nontraumatic conditions including silicone keratopathy, bullous keratopathy, blood staining, endophthalmitis, cataract and retinal surgical complications, and uveitis.[12–15] While the use is primarily to allow visualization during pars plana vitrectomy, the Eckardt keratoprosthesis has also been reported as an aid to allow small incision cataract surgery during combined penetrating keratoplasty (PKP) and cataract extraction surgery[16,17]. The Aachen keratoprosthesis has been reported to be used as a 'bridge' prosthesis, sutured in place for 8 weeks before definitive PKP.[18] We have used the Eckardt in the same manner for several days prior to eventual PKP without complication or extrusion. The Cobo keratoprosthesis is unique in that it is designed to be an emergency instrument for use during routine PKP to prevent anterior migration of intraocular contents through an open-sky approach. Because of its versatility of sizing and integrated infusion port, we have utilized it during vitrectomy cases to clear dense anterior vitreous membranes when the pars plana infusion port was not visible. Vitrectomy lenses can be utilized over the surface of the Cobo keratoprosthesis.

OUTCOMES

As stated previously, the cases requiring combined surgery involve acute 'multisystem' diseases, carry a very poor prognosis and can represent an extraordinary intervention to salvage the eye. A number of studies have examined the outcomes of combined TKP/pars plana vitrectomy. Most studies show an early postoperative increase in visual acuity in a little less than 50% of cases, but this number decreases to 16–21% on longer term follow-up.[15,19] The vast majority of cases with measurable vision cite visual acuities of count fingers or worse. Still 50–70% of patients had either improved or stable vision on last exams.[13,15] Graft survival is difficult to assess in these patients in comparison to normal grafts because of the severe co-morbidities in these patients. A very high rate of phthisis bulbi and hypotony (37–52%) is noted and is the most common cause of graft failure. Gallemore et al[10] reported that 70% of their grafts remained clear, but it should be noted that their series included a lower percentage of trauma patients and a lower preoperative retinal detachment rate, two risk factors for graft, and surgical failure. Other studies had graft clarity rates of 42% at 3 months and another of 65% at 1 year.[14,15] Silicone oil was also a significant risk for graft failure.[13] As expected, smaller grafts utilized in cases of TKP led to more irregularity, steeper corneas, and higher astigmatism postoperatively[10]. The above-described modification to allow larger grafts reduces these complications.

SUMMARY

The instrumentation is simple, and TKPs provide an excellent view of the posterior segment for pars plana vitrectomy. In these severely diseased eyes, graft clarity rates are acceptable and allow earlier surgical intervention. Despite the often poor visual and anatomic outcomes in cases necessitating combined TKP/pars plana vitrectomy, this technique allows surgical intervention in eyes otherwise destined for phthisis.

78 Permanent keratoprostheses

Kaevalin Lekhanont, Vasudha Panday, Esen Karamursel Akpek

Diseases of the cornea are a major global cause of blindness, ranking second only to cataract, with an estimated 10–15 million affected people worldwide. Corneal transplantation, whether penetrating or lamellar, has become the main visual rehabilitation surgery for such disorders. Penetrating keratoplasty is the most frequently performed and most successful solid tissue transplantation, with a success rate greater than 90% for low-risk cases, such as patients with keratoconus, traumatic corneal scars, and corneal dystrophies and degenerations.[1] However, the success rate of penetrating keratoplasty is exceedingly low for patients with ocular surface disorders such as Stevens–Johnson syndrome (SJS), ocular cicatricial pemphigoid (OCP), chemical burns, severe keratoconjunctivitis sicca, stem cell deficiencies, and severe vascularization resulting from other causes.[2] Pediatric keratoplasty is also a high-risk procedure with very limited success. In addition, there is another, larger group of patients who have repeated graft failures, for whom a subsequent graft carries a poor prognosis.[2]

Keratoprosthesis surgery, the transplantation of an artificial cornea, is a potential alternative for restoring vision in these patients with complicated corneal blindness. Some indications for keratoprostheses and limbal stem cell transplantation overlap. In these cases, one has to consider the advantages and disadvantages of both techniques. Limbal stem cell transplantation seems to be less destructive to the anterior segment, and in successful cases the patients may have a larger visual field. However, the lifelong need for systemic immunosuppression and the high risk of rejection in the short term are distinct disadvantages.

There are two types of keratoprostheses: temporary and permanent. A temporary keratoprosthesis is used to help visualize the posterior segment of patients with corneal diseases intraoperatively and is removed after surgery (see preceding chapter). A permanent keratoprosthesis is a device implanted in the eye, similar to the human donor cornea used in penetrating keratoplasty. In this chapter, the term keratoprosthesis is used to mean a permanent keratoprosthesis, unless otherwise indicated.

Keratoprostheses have been in use for more than two centuries, but substantial improvements in device designs, techniques, and clinical management have been achieved only over the past few decades, with variable, but growing, success. The history of keratoprosthesis development dates back to Guillaume Pellier de Quengsy, a French ophthalmologist who in 1789 suggested replacing an opaque cornea with a silver-rimmed glass window.[3] In 1853, Nussbaum placed a quartz crystal implant in a rabbit eye, and later performed the first such surgical procedure in a human.[4,5] Initial attempts to develop other types of keratoprostheses were continued by many pioneers over the following 50 years, but all failed.[6] In the early 20th century, interest in keratoprostheses abated with the introduction and increasing success of penetrating keratoplasty, until it became apparent that penetrating keratoplasty was not the answer for all cases. As new, inert plastic materials such as polymethylmethacrylate (PMMA) were introduced, keratoprosthesis research again drew attention, particularly in the early 1950s. Unfortunately, despite promising results in the early postoperative period, the procedures were catastrophic failures due to extrusions of the keratoprosthesis, endophthalmitis, or other adverse outcomes. In the 1990s, several new-generation keratoprostheses made of biomaterials were introduced, with the assumption that porous materials would improve biointegration by host tissue, preventing extrusion. Comparisons between the various devices and techniques can be difficult because of differences across studies in sample size, type of patients recruited, data profiles, and duration of follow-up.

Keratoprosthesis designs can be categorized into three main groups. The first type uses a transparent, rigid central optic attached to a peripheral skirt/haptic. It is usually implanted and secured to the corneal stroma, and occasionally is covered with autologous mucous membrane and/or eyelid skin. The haptic can be made of several kinds of materials that supposedly allow for biological incorporation by host tissue; these include: Dacron, Proplast, polytetrafluoroethylene (PTFE), polyurethane, other copolymers, and dental bone. The optic portion is made of medical-grade PMMA. The osteo-odontokeratoprosthesis (OOKP) is an example of this design.

The second type of keratoprosthesis consists of a flexible-plate optic with a porous peripheral skirt that supports tissue ingrowth and stability of the device. This type is designed to be implanted in an intra-stromal pocket. AlphaCor is a classic model of this version. BIOKOP II is another example.

The third type is a 'collar button' shaped device, consisting of two plates made of PMMA and joined by a central stem. This device is implanted with the plates sandwiching the corneal donor ring between them, then sutured in place in the same way as standard penetrating keratoplasty. A representative of this group is the Boston keratoprosthesis. Only the Boston and AlphaCor devices have been approved by the US Food and Drug Administration (FDA) and are available for clinical use.

BOSTON KERATOPROSTHESIS

The Boston KPro has been under development since the 1960s. The FDA approved it in 1992. Unlike most other designs, it is a nonintegrated keratoprosthesis. The Boston KPro is made entirely of medical-grade PMMA and comes in two main types. Type I, the single 'collar button' design, is the most commonly used in the USA. It consists of two plastic parts: an anterior plate, 5.0–7.0 mm in diameter, attached to a 3.35-mm diameter central stem with screw threads, and a removable back plate, 7.0–8.5 mm in diameter, with eight holes of 1.3-mm diameter (Fig. 78.1). A new threadless design has 16 holes, 1.2 mm each. The device requires donor corneal tissue to be sandwiched between the two plates, and the entire device is then sutured into the eye (Fig. 78.2). The holes in the back plate are postulated to enhance nutrition and hydration of the clamped corneal stroma adjacent to the stem and to help prevent necrosis of the surrounding tissue and extrusion of the device. The interplate distance is 0.50–0.60 mm. The titanium locking ring is a recent addition, used to secure the unit after assembly and to prevent unscrewing of the back plate in situ.[7] Type 1 Boston KPro allows a maximal 60° field of vision. This type of device is suitable for eyes with sufficient tear secretion and normal blinking.

The type II device is similar to type I, except for an additional 2-mm long anterior nub for through-the-lid implantation. The front plate is usually 6 mm in diameter and the back plate is 8.5 mm. The back plate also has eight holes of 1.5-mm diameter. Use of the Boston KPro II is reserved for extreme dry eye conditions and end-stage ocular surface diseases such as OCP and SJS, in which there is a lack of fornices to support a good tear film. The type II device allows a maximal visual field of 40°. Both types of Boston KPro have a range of dioptric powers to match the axial length of the patient's eye and are suitable for pseudophakia or aphakia.

The Boston KPro is generally considered suitable for patients with bilateral corneal blindness who have potentially usable vision but little or no chance of success with standard penetrating keratoplasty, such as patients with end-stage SJS or OCP, or after severe chemical burns or repeated graft failure with poor prognosis for further grafting. Generally, visual acuity in the affected eye should be less than 20/400 and the fellow eye should have suboptimal vision.[8] Patients must have no end-stage glaucoma or retinal detachment.

In cases of corneal blindness with clear remaining ocular media and functioning retina and optic nerve, keratoprosthesis surgery can give immediate, excellent, vision. However, the prognosis for long-term success with Boston KPro surgery varies with preoperative diagnosis and with the degree of ocular surface inflammation.[7,8] Clearly, the most favorable group for receiving the Boston KPro is patients with multiple graft failures in noninflammatory conditions such as bullous keratopathy, trauma, and other corneal dystrophies. Patients with graft failures after infectious keratitis (viral, bacterial, or fungal) are also likely to have a good prognosis. The prognosis for patients with a previous history of recurrent herpes simplex (HSV) is especially favorable, with no increased rate of melting or extrusion.[7] On the other hand, patients with an underlying autoimmune or inflammatory ocular surface disease, such as OCP and SJS, have the worst prognosis.[7,8] Patients who have sustained chemical burns have an intermediate, fair prognosis. The differences in prognosis seem to correlate with the degree and chronicity of preoperative inflammation. In patients with SJS, the smoldering inflammation around the implanted keratoprosthesis makes the tissue vulnerable to de-epithelialization and hence necrosis, melting, leakage, and secondary infection. The clinical findings that suggest a smoldering active immunologic process in these cases are consistent with the results of histopathologic studies, which show marked acute and chronic inflammatory reactions in the area of the keratoprosthesis–cornea junction and at the periphery of the originally healthy corneal graft.[9] Additionally, patients with SJS are often younger and thus a conservative approach is recommended for this group.

An ongoing multicenter Boston keratoprosthesis study[10] is gathering data on Boston KPro I implant procedures since January 2003. The preliminary results from 101 eyes (106 procedures) at 16 centers show a retention rate of 95.3%. There has recently been a report of Boston KPro surgery in carefully selected children with complex

Figure 78.3. Type I Boston keratoprosthesis in situ in a 22-month-old girl with a history of Peters anomaly, 6 months after surgery with no complications.

ocular diseases who are at high risk for graft failure, with promising results[11] (Fig. 78.3). The excellent optical properties of PMMA and the lack of induced postsurgical astigmatism may accelerate visual recovery, reducing the risk of amblyopia. The Boston KPro may thus have a future role in the management of pediatric corneal blindness. Nevertheless, one should recognize that a failure of keratoprosthesis surgery can be associated with much more serious complications than repeated graft failures.

Although uncommon in properly selected cases, necrosis of tissue around the keratoprosthesis, with subsequent melting, can lead to aqueous leakage, infection, or extrusion of the device. The continuous use of a large-diameter soft contact lens with high water content in the postoperative period has significant protective value.[12] Postoperative use of medroxyprogesterone 1% suspension is also helpful in preventing/treating melting.

Patients requiring keratoprosthesis have usually had multiple previous eye surgeries, episodes of inflammation, or autoimmune diseases such as OCP, SJS, or rheumatoid arthritis. Therefore, postkeratoprosthesis inflammation can be a significant issue in these patients. Chronic or profound postoperative inflammation can cause retro-prosthetic membrane, glaucoma, epiretinal membrane, and vitreous opacities.

Approximately 30% of eyes receiving a keratoprosthesis eventually develop retro-prosthetic membranes.[13] Postoperative uveitis, vitreous hemorrhage, multiple ocular procedures, vitrectomy, and diabetes mellitus are known risk factors. Some investigators suggest using steroid injections at the first sign of membrane formation.[6] Most retro-prosthetic membranes are amenable to Nd:YAG laser treatment, but energy higher than 2.0 mJ should be avoided because the device can crack or become pockmarked. If the membrane is thick or vascularized, it is more safely managed by surgical excision.[13] In refractory cases, repeat keratoprosthesis surgery might be preferable.

In the past, the rate of endophthalmitis following keratoprosthesis surgery was higher than for other intraocular procedures. However, bacterial endophthalmitis has now been almost eliminated by a postoperative prophylactic antibiotics regimen. It is crucial to emphasize to patients the critical role of lifelong prophylactic use of topical antibiotics. Most cases of bacterial endophthalmitis are caused by gram-positive organisms, and patients with SJS or OCP are at the highest risk.[14] The current postoperative antibiotic regimen typically includes fourth-generation fluoroquinolone and vancomycin (14 mg/mL) eye drops. To date, no vancomycin resistance has emerged.[15]

Sterile endophthalmitis, or a peculiar phenomenon of sudden reversible, massive vitritis with reduced vision, is seen in a small percentage of patients.[16] The clinical pictures of sterile and infectious endophthalmitis can be varying and perplexing, but, in general, the sterile type has a more insidious onset, with hardly any external signs of inflammation such as conjunctival injection and without ocular pain. This condition is thought to result from some sort of immune reaction.

Nevertheless, in all patients suspected of having endophthalmitis, vitreous tapping as well as intravitreal and intravenous antibiotics should be vigilantly administered. The initial intravitreal antibiotics of choice are 1.0 mg vancomycin and 0.4 mg amikacin, though these doses are tailored once the culture results become available.[15] The most common organisms are endogenous flora, including *Streptococcus* species, *Staphylococcus* species, *Propionibacterium* acnes, *Candida* species, *Cryptococcus* species, and *Moraxella* species.[13] Vitrectomy may eventually be necessary.

With the dramatic decrease in incidence of postoperative endophthalmitis, glaucoma is now the primary vision-threatening complication following Boston KPro surgery. In addition to postoperative worsening of pre-existing glaucoma, new glaucoma can develop after surgery, particularly in patients with chemical burns or autoimmune diseases. Current reports show that glaucoma is present in about two-thirds of patients receiving Boston KPro.[17] Gradual closure of the anterior chamber angle is the most likely mechanism.[6] The problem is more difficult to detect and manage in patients with Boston KPro because of the inability to measure intraocular pressure (IOP) directly. Standard tonometry can give erroneous readings, and digital palpation seems to yield the most reliable measurement. Visual fields and serial optic nerve pictures should be obtained during follow-up of these patients. Although topical and systemic glaucoma medications are usually effective, most patients will require a glaucoma tube shunt surgery or a cilioablative procedure at the same time as or soon after the KPro surgery.

Boston KPro has several advantages, including the simplicity of the surgical technique, minimal postoperative discomfort, immediate visual recovery, the ability to view the posterior pole from the first postoperative day, the short time frame to achieve maximal visual rehabilitation, and good cosmetic appearance. However, the long-term prognosis for patients with underlying inflammatory ocular surface diseases needs to be improved.

ALPHACOR KERATOPROSTHESIS

AlphaCor, originally known as the Chirila Kpro, was developed in an attempt to create an alternative to human donor cornea for high-risk cases of corneal blindness that are unlikely to be successfully treated with a donor corneal graft. In other words, the device provides another option for treatment that lies somewhere between a low-risk graft and traditional keratoprostheses such as the OOKP that is indicated for bilaterally blind patients with end-stage dry eyes.[18] The AlphaCor keratoprosthesis has recently been approved by the FDA and is now commercially available in the USA.

AlphaCor artificial cornea is a hydrophilic, soft, flexible, biocompatible one-piece device made entirely of poly (2-hydroxyethylmethacrylate) (PHEMA) (Fig. 78.4). PHEMA was selected for this

Figure 78.4. The one-piece, flexible AlphaCor device, consisting of a transparent optic and a biointegrating skirt made of PHEMA.

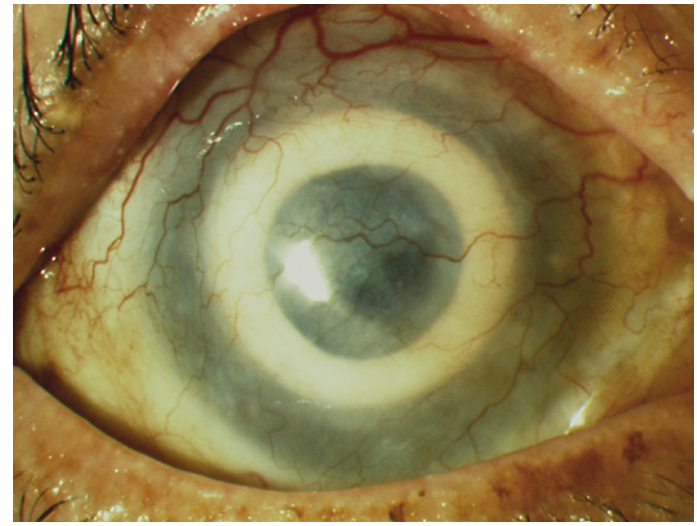

Figure 78.5. AlphaCor keratoprosthesis implantation, after stage 1. The device is covered by the conjunctival flap.

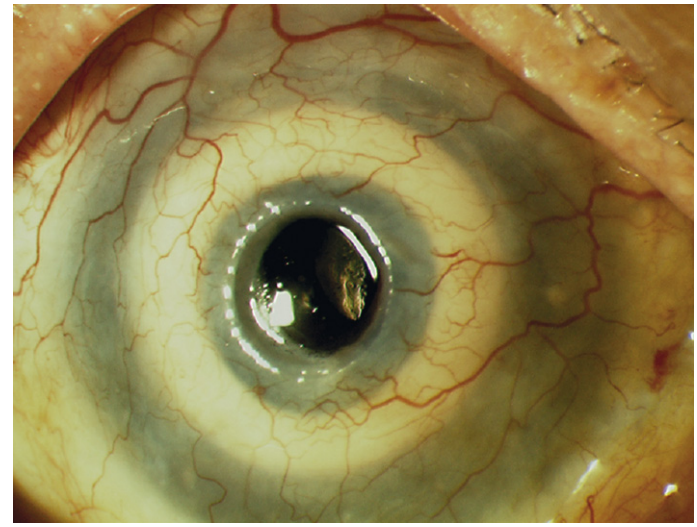

Figure 78.6. AlphaCor keratoprosthesis after stage 2 of implantation.

device because of its hydrophilic properties, flexibility, and ability to take on different physical characteristics with changes in its water content. The device consists of a central optic region surrounded by a peripheral skirt that is chemically identical except for its water content.[19] The outer skirt is macroporous, has a high water content, and promotes bio-integration via cellular ingrowth and collagen deposition.[20] The transparent optic has a relatively low water content, is microporous, and provides the refractive power and the optical clarity. These two concentric regions are joined by a zone known as the interpenetrating polymer network (IPN), a permanent junction that prevents dehiscence, leakage, or downgrowth at the interface. The AlphaCor device has a radius of 7.0 mm and a thickness of 0.5 mm. The refractive index of hydrated PHEMA gel is 1.43. There are two versions of the device designed to deliver the appropriate power in the human eye. AlphaCor-P has a lower power (approximately +42 D) for either phakic or pseudophakic eyes, and AlphaCor-A has a refractive power of about +58 D, suitable for aphakic eyes.[18]

AlphaCor is implanted in a two-stage surgical procedure.[21] Briefly, stage 1 begins with a 360° conjunctival peritomy and corneal epithelial debridement. A superior half-thickness incision extending about 180° is made at the sclera, 1–1.5 mm posterior to the limbus, and extended into the cornea at 50% depth with a lamellar dissecting blade. The dissection continues to form an intralamellar pocket about 7.5 mm in diameter. The superior flap is retracted inferiorly, allowing the posterior lamella to be visualized. A central opening is then created with a 3-mm disposable trephine in the posterior corneal lamella. The AlphaCor device is positioned within the pocket, carefully centering the optic over the posterior opening. The superior flap is replaced and sutured at the limbus with interrupted 10-0 nylon sutures. A Gunderson flap is pulled to cover the entire corneal surface (Fig. 78.5). The conjunctival flap is not always needed but is recommended with this device.[21] After 8–12 weeks, stage 2 of the procedure is performed to expose the optic by removing the conjunctiva and anterior corneal lamella, using a 3-mm disposable trephine and scissors. Topical anesthesia is usually applied (Fig. 78.6).

Multicenter clinical trials of this device have been in progress for more than 5 years, with promising outcomes.[18] The probability of AlphaCor retention at the end of 1 year is 82%, and postoperative best-corrected visual acuity ranges from light perception to 20/30. No cases of serious complications such as endophthalmitis or device-related rhegmatogenous retinal detachment have been reported. Cosmetic outcomes are acceptable. In contrast to the Boston KPro, AlphaCor does not seem to lead to glaucoma in a significant proportion of patients.

Anatomical failure is related to loss of corneal stromal tissue adjacent to the device skirt. Stromal melting is the most common complication, observed in 41.5% of cases and strongly associated with a history of ocular HSV infection.[21] A history of ocular HSV is therefore considered a contraindication for AlphaCor implantation. There is an association, although not statistically significant, between concurrent or subsequent cataract surgery in patients with an AlphaCor implant and melting-related complications.[19,22] Likewise, a possible association between a history of chemical injury and postoperative melting has been recorded.[23] It is thought that reactivation of HSV or retained lens material after cataract surgery may stimulate chronic inflammation, which can upregulate inflammatory cytokines, reduce bio-integration, and facilitate melting of corneal stroma anterior to the device.

Medroxyprogesterone is a progestational steroid with mild anti-inflammatory effects and has anticollagenase activity with less inhibition of collagen production than corticosteroids. Earlier

reports suggest a potential utility for medroxyprogesterone as eyedrops following AlphaCor implantation to prevent the onset or suppress the severity of stromal melting, particularly in high-risk cases.[24] When melting occurs, initial management is first aimed at improving the quantity and quality of the tear film with artificial tear supplements, punctal occlusion, bandage contact lens, or lateral tarsorrhaphy. In non-responsive cases, reconstructive surgery may be needed. Removal of the device and donor cornea replacement is reserved for refractory cases to maintain ocular integrity and prevent any serious complications.

Optic problems occur in about 11% of cases, and are related to surface spoliation or deposition of substances in the hydrogel, reducing its transparency.[25] Diffuse white deposition, confirmed by histological study to be calcium phosphate, is associated with prior co-administration of topical steroids and beta-blockers. A brown discoloration is associated with patient-related or environmental conditions, particularly cigarette smoking and some ophthalmic prescription medications (e.g. levobunolol). Optic complications have not been observed in PMMA devices.

Retro-prosthetic membranes occur in about 9% of patients during the first year after surgery.[26] Systemic risk factors are higher in African Americans and in patients with hypertension or diabetes. Perioperative manipulation is likely to contribute to the incidence of retro-prosthetic membranes. To minimize this complication, peri- and postoperative preventive measures such as subconjunctival steroid injections and topical steroids may be used, particularly for patients at high risk. If an early retro-prosthetic membrane forms, management by Nd:YAG laser has proved successful. However, thick and vascularized membranes are difficult to remove by laser. Recurrences are common.[17] Surgical treatments via a limbal approach, vitreoretinal techniques, or removal of the device and donor graft replacement may be required. Adjunctive heparin or recombinant tissue plasminogen activator (rTPA) may be beneficial in some cases.

In summary, despite the challenges of maintaining clarity and retention, clinical experience with AlphaCor is encouraging. The AlphaCor device should not be used in eyes with severe ocular surface disease, significant dry eye, or active/smoldering inflammation.[18,19] It is important to control IOP before surgery. Any topical therapy after implantation should be carefully considered to prevent optical spoliation. Results from longer-term studies are needed to allow comparisons between this device and the Boston KPro.

OSTEO-ODONTOKERATOPROSTHESIS (OOKP)

The OOKP was first described by Strampelli in the early 1960s[27] and was modified over the years by Falcinelli and co-workers.[28] It was originally designed to improve the biointegration of the device with host corneal tissue by encircling the optical cylinder with an autologous tissue such as tooth, bone, or cartilage. The OOKP has a reputation for the best long-term retention and low rate of infection.

The OOKP has an optical cylinder made of PMMA glued to a biological haptic made of the autologous osteodental lamina. It was the first keratoprosthesis to use biological material as a supporting carrier or haptic. The haptic is prepared from the root of a tooth with its surrounding alveolar bone, ligament, and periosteum.[28] All cases of bilateral corneal blindness resulting from severe ocular surface diseases such as severe dry eye, limbal stem cell insufficiency, or densely vascularized corneas—for which there is virtually no reasonable expectation of medium or long-term success with other well-established methods such as penetrating keratoplasty, lamellar grafts, or limbal stem cell transplantation—are good candidates for the OOKP.[6]

The surgical procedure is complex and consists of two steps separated by a period of 2–4 months; it requires cross-specialty expertise.[29,30] Step 1 includes preparation of the anterior bulbar surface and the osteodental acrylic (ODA) complex. After a 360° conjunctival peritomy, a lamellar keratectomy is performed to remove any degenerative pannus or scar tissues. The anterior bulbar surface, including the cornea and sclera up to the muscle insertions, is covered by a buccal mucosal membrane graft to create a new ocular surface. The buccal mucosa is harvested from the patient's cheek at the time of surgery and trimmed to approximately 2 mm in thickness, large enough to avoid any retraction once in place. If the mucous membrane is inadequate, the patient's lid skin, after removal of the tarsal plate, can be used in a 'transpalpebral approach.' A scleral shield is applied in some cases to avoid shrinkage of the fornices for a few weeks after step 1 surgery.

The patient's own monoradicular tooth is harvested to prepare an osteodental lamina. When the available osteodental lamina has too small a surface to fit an optical cylinder (due to dental or periodontal diseases), two teeth are extracted to prepare two laminae, which are then glued together to create a single lamina with a larger surface. Generally, the superior canine is the most suitable tooth because it has the longest and largest root with the greatest quantity of alveolar bone. For patients who have no suitable tooth for implantation, a tooth from an HLA-matched, first-degree relative can be used. The osteodental tissue is suitably shaped to a rectangular lamina, approximately 9–10 mm by 14.5–16 mm and 2.5–3.25 mm thick. The periosteum is preserved and used to circumscribe the alveolar tissue. The lamina is drilled through the dentine and alveolar bone to generate a central hole about 3.7 mm in diameter. The PMMA optic is inserted into the hole and cemented in place. The resulting ODA complex is then temporarily buried into a subcutaneous pocket, often just below the lower orbital rim of the fellow eye, and allowed to vascularize for 2–4 months.[6,30]

In step 2, the ODA complex is retrieved from the pocket, and the surrounding excess soft tissue is trimmed. The buccal mucosal graft in the eye is partially detached and reflected to expose cornea. A full-thickness, central corneal trephination is performed, followed by complete iridectomy, lens extraction (either natural lens or intraocular lens) plus posterior capsulotomy and anterior vitrectomy. The ODA complex is then implanted into the central trephination, and the borders of the lamina are sutured to the cornea and sclera. The buccal mucosa is repositioned on top of the ODA complex and secured in place, after making a hole through the mucosal graft in the region corresponding to the PMMA optic cylinder.

Topical steroids and antibiotics are given postoperatively. Topical antibiotics should be continued once daily indefinitely. Additional systemic corticosteroids are recommended to prevent excessive intraocular inflammation, and systemic anti-glaucoma medications should be given if the IOP remains elevated, as is frequently the case. A cosmetic scleral shield with a central opening for the anterior optical cylinder is usually applied 1 month after surgery, to improve cosmetic appearance and protect against dehydration.[29]

Although the OOKP technique is a complex and invasive surgical approach, it provides tight bio-integration and a better long-term retention rate with satisfactory functional visual outcome than is currently attainable with other types of keratoprosthesis.[29,30] Long-term outcomes in 181 cases of OOKP procedures showed an 85% probability of retention 18 years after surgery.[30]

The other advantages of OOKP, related mostly to its unique biological properties, include low rates of cylinder extrusion, aqueous leakage, endophthalmitis, epithelial downgrowth and retro-prosthetic membranes.[6,30]

However, some patients experience partial bone resorption of the osteodental lamina, causing decentration of the optic cylinder. The exact mechanism remains unclear, but epithelial downgrowth and localized inflammation seem to play an important role. Preservation of the alveolar-dental ligament is essential for maintaining the integrity of the device.[17] An evaluation of the status of the OOKP lamina with appropriate imaging studies is thus mandatory so that prophylactic measures can be taken to prevent subsequent complications. Glaucoma is the most vision-threatening complication in OOKP cases, occurring in 7–75% of patients, depending on the report.[29] Other limitations of OOKP are a limited visual field, the inability to measure IOP, and the extensive interventions required in the anterior segment, which can predispose to several complications. This demanding and time-consuming surgery may place a great burden on patients, family members, and surgeons alike.[29]

A tibial keratoprosthesis (TKPro) is a variant of the OOKP.[31] A cortical chip of tibial bone serves as an alternative material for a biological haptic in cases where no suitable tooth is available. The implantation procedure is the same as for a general OOKP. However, resorption of tibial bone might be faster because of the considerably higher turnover of bone than of dentine, resulting in reduced long-term stability.

SEOUL-TYPE KERATOPROSTHESIS

The Seoul-type keratoprosthesis (S-KPro) consists of three parts: a central PMMA optic 4 mm in diameter surrounded by a mushroom-shaped anterior flange, a porous polymer skirt made of polyurethane or polypropylene, and U-shaped polypropylene haptics.[32] The anterior flange is dark brown in color to mimic the iris color of Asian patients. Fibrovascular ingrowth and biointegration occur at the skirt portion. The main difference between previous keratoprostheses and the S-KPro is the manner of fixation to the eyeball. S-KPro has a double-fixed design, which includes external corneal fixation of the skirt and internal scleral fixation of the haptics. Another characteristic of the S-KPro is the polyethylene glycol-grafting polymerization of the optics to improve tear stability and reduce cell adhesion, in the expectation that this will decrease the incidence of retroprosthetic membrane after surgery.

The surgical technique is complex.[32,33] After pupil dilation, the patient's cornea is trephined halfway through, with a 6-mm diameter. A 360° intralamellar dissection is then performed with a disposable crescent blade, toward the limbus to make an intrastromal pocket 2 mm in length. After excision of the trephinated cornea, capsulorrhexis of the lens capsule is performed and a nucleus is removed. The residual cortex and part of the anterior vitreous are also removed with a vitreous cutter. A sector iridectomy is then performed. The S-KPro is placed into the eyeball and the haptics are fixed to each side of the sclera with 10-0 polypropylene suture, from the inside out (ab interno technique). The skirt is inserted into the previously prepared corneal pocket, and secured with 10-0 nylon interrupted sutures to the anterior lamellar part of the cornea. Amniotic membrane transplantation is performed to protect the surface of the S-KPro.

The preliminary results with this device suggest the important role of scleral fixation of the haptics in providing adequate stability to prevent extrusion, even in the case of in situ loosening or absence of corneal support. Anatomical success without extrusion was achieved in 6 of 7 eyes during an average follow-up of 25.6 months. Partial extrusion was found in one patient with advanced glaucoma. One patient experienced retinal detachment after exchange of S-KPro. Enterococcal endophthalmitis developed in one patient with OCP. Retro-prosthetic membrane occurred in one case and was treated with Nd:YAG laser membranotomy.[33] Inability to use an adjunct glaucoma drainage shunt is the primary drawback of the S-KPro.[33] Also, the IOP cannot be directly measured as well as with the more conventional keratoprostheses.

BIOCOLONIZABLE MICROPOROUS FLUOROCARBON HAPTIC (BIOKOP) KERATOPROSTHESIS

The BIOKOP keratoprosthesis was developed to improve the integration of the keratoprosthesis and surrounding host tissue, in accordance with the concept of biocompatibility that underlies AlphaCor. The BIOKOP has two models. BIOKOP I consists of a skirt, 9 mm in diameter, made of microporous fluorocarbon, and a PMMA optic, 4 mm in diameter and 2.67 mm long, providing a visual field of 110–130°. BIOKOP II has the same haptic design, but its 7-mm diameter soft optic is made of medical-grade polydimethylsiloxane (PDMS) coated with polyvinylpyrrolidone.[34] The surgical procedure is described by Legeais and Renard.[34] The outcomes for patients with severe ocular diseases, after 5 years of follow-up, were disappointing.[35] Nearly half of the patients had blindness caused by retinal detachment, endophthalmitis, or phthisis bulbi.

SUPRA-DESCEMETIC KERATOPROSTHESIS

A novel, nonpenetrating, lamellar supra-Descemetic synthetic cornea (sDSC) implantation has recently been developed to avoid the necessity of entering the anterior chamber, leaving the Descemet membrane and the endothelium intact. In theory, this technique minimizes the risk of complications attributed to the penetrating nature of the other keratoprostheses, such as epithelial downgrowth, endophthalmitis, and retinal detachment.[36] The pre-Descemetic implant is a one-piece device with an overall diameter of 7 mm. A central optic zone, 4.5 mm in diameter and 450 µm in thickness, is surrounded by a 100-µm thick outer flange. The flange has 24 holes, 350 µm in diameter, allowing for nutrient transfer and tissue ingrowth. To date, the procedure has been performed only in rabbit models.[37] Three different materials were tested to evaluate the biocompatibility of the device: hydrophobic PMMA, hydrophilic hydroxyethylmethacrylate-methylmethacrylate (HEMA-MMA), and hydroxyethylmethacrylate-*N*-vinylpyrrolidone (HEMA-NVP). HEMA-MMA showed the most promising results, with a clear Descemet membrane and no vascularization or scarring.[37] However, opacification of the remaining stromal tissue may compromise the potential visual benefit in the long run. Ingrowth of fibrous tissue beneath the optic can also occur, reducing visual outcome. Further studies are needed to develop this device.

TISSUE-ENGINEERED CORNEAS

Tissue engineering is a novel area of research with widespread applications. In recent years, in vitro reconstruction of skin cells and blood vessels has been accomplished.[38] Similar attempts have been made in the area of bioengineered corneal tissue, with some

degree of success.[39] To ensure the viability of tissue-engineered corneas, several requirements must first be met. First, the tissue must have the same optical clarity as the native cornea. Second, it must have enough tensile strength to withstand intraoperative manipulation and suturing. Third, the tissue must be compatible with the ocular surface into which it is being implanted. Lastly, some form of surface re-innervation is essential to maintain hydration and decrease the risk of infection.[40]

At least three of the five layers of the cornea need to be effectively engineered to create a successful corneal substitute: epithelium, stroma, and endothelium. Each component can now be regenerated successfully. Corneal epithelium can be cultured using limbal stem cells with different tissue types as a scaffold for cell growth. Human amniotic membrane and cross-linked human fibrin gel have been used to successfully grow corneal epithelial cells.[41,42] The stromal component can be reconstructed by mixing corneal keratocytes with either bovine type I collagen[38] or with human types I and III collagen.[43] Both have been shown to replicate human corneal stroma, without Descemet or Bowman membrane.[38] Human corneal endothelial cells have been regenerated on type IV collagen-coated dishes.[44]

Several research groups have attempted to bioengineer complete corneal equivalents, with all three layers cultured simultaneously. Fibrillar collagen sponge or gel was used to culture all three requisite cell types.[45] Co-cultures of epithelial/endothelial and epithelial/keratocyte pairs were also investigated. Epithelial and endothelial cells formed a monolayer on the surface of the sponge; an epithelial/endothelial co-culture displayed epithelial migration, with the cells forming three to four cell layers on the sponge surface. Keratocytes migrated and proliferated, repopulating the matrix of the sponge. This collagen sponge model demonstrated excellent transparency and could potentially be used to modulate the wound-healing response. However, extensive contraction of the matrix occurred, which could limit transparency and wound-healing abilities.

Another bioengineered corneal equivalent used bovine or human collagen thermogel as the scaffold, with human corneal epithelial cells and stromal cells.[42,46] Human fibroblasts were induced to produce collagen in sheets, which were then stacked together and seeded with epithelial cells. Endothelial cells were not initially included, but subsequent research has focused on including these cells.[47] This method was unique in its approach, but the tissue produced did not have the structural integrity to withstand implantation. However, important elements of the wound-healing response were evident.

Recently, scaffolds of type I collagen were cross-linked with a copolymer based on *N*-isopropylacrylamide, acrylic acid, and acryloxysuccinimide.[48,49] This yielded a gel with superior optical clarity and better tensile strength that could withstand manipulation and suturing. An additional important characteristic unique to this model is the ability of the host tissue to generate neural ingrowth into the gel. Implantation of this model into Yucatan pig corneas successfully demonstrated in vivo regeneration of the host corneal epithelium, stroma, and nerves at 3 weeks post-implantation. The presence of the nerves also seemed to improve epithelial growth and provide protection to the epithelium from external injury.

The main requirements for bioengineered corneas—namely optical clarity, tensile strength, and innervation—continue to be challenging. Each of the above three bioengineered corneal substitutes described above fulfills some of these requirements. As progress continues in engineering the requisite cell types, alone and in combination, viable implantable corneal constructs may well become available in the not too distant future.

79 The Boston keratoprosthesis

Stephen G. Waller, Claes H. Dohlman

As we pass the centennial of the first successful human corneal transplant, there is much to celebrate.[1] Sight has been restored to hundreds of thousands of patients worldwide. The majority are successful by any reasonable standards, and excellent vision persists for years or decades for many recipients. However, a portion of these allografts fail, often due to underlying disease, occasionally due to repeated rejection episodes. The rate of transplant performed for failed graft is increasing, being 12% in a recent large USA study.[2] Undoubtedly, there is an additional percentage of patients with high risk for failure who are never suitable candidates for this surgery. Patients with Stevens–Johnson syndrome, severe chemical burn, ocular cicatricial pemphigoid, and a history of multiple graft failures all carry a dismal rate of success with standard keratoplasty.[3–5] Fortunately, some of these patients are candidates for keratoprosthesis as a means of visual rehabilitation.

Keratoprosthesis surgery is experiencing a dramatic increase in its clinical application. While the authors believe that fewer than 15 keratoprostheses were implanted in the USA in 1992, the Boston keratoprosthesis and the implantation procedure we describe in this chapter have now been utilized in over 1000 cases (2006). We expect as many as 400 may be placed in the year 2007 alone. The Kaplan–Meier survival analysis of 173 type I keratoprosthesis patients, excluding those with end-stage autoimmune disease or severe chemical burn, showed only two (both with likely autoimmune disease) requiring surgical revision in 36 months of follow-up (Aquavella, Sippel, Dohlman, April 2006, unpublished data). About a dozen centers worldwide are seriously involved in keratoprosthesis programs, and scientific conferences and peer-reviewed publications are increasingly common. While our cases are performed in Boston, other centers are reporting considerable success with the Boston keratoprosthesis.[6,7]

The authors believe that the prognosis for keratoprosthesis has improved in recent years, and that technical and scientific advances have led to expanding indications for this procedure (Table 79.1). Since we have no experience with other keratoprosthesis devices and surgery, we will focus on the Boston keratoprosthesis exclusively in our discussion.

HISTORY

The concept of an artificial cornea for the treatment of blindness was first suggested in writing in 1789 by the noted French surgeon, Pellier de Quengsy.[8] He recommended the implantation of a glass lens held by a silver ring, and described the surgical procedure and necessary instruments. Nussbaum published the results of the implantation of a quartz crystal in human corneas in 1853.[9] The German literature includes at least four additional 19th century reports of innovative design and insertion techniques.[10–13]

With the first successful human allograft in December of 1905, attention was diverted away from keratoprosthesis development. After the initial excitement of this innovation was tempered by graft limitations and failures, Verhoeff inserted a quartz button into a human cornea, achieving brief success.[14] Filatov reported a full-thickness glass device implanted into the opacified cornea of a patient in 1935.[15] The glass was surgically covered with a double conjunctival flap, and the patient briefly recovered 1/200 ambulatory vision.

The World War II discovery that the transparent windscreen material used in aircraft canopies, polymethylmethacrylate (PMMA), was well tolerated by the eye, led to its adaptation for intraocular lens use. It also stimulated experimentation by several investigators to show that discs of this plastic could be retained in the cornea of rabbits.[16–18] Another period of human use ensued, but the severe complications encountered in the postoperative period once more slowed the rate of keratoprosthesis progress.

Among the most active work on keratoprosthesis in the past 40 years has come from Strampelli and colleagues.[19–22] His osteo-odontokeratoprosthesis technique uses osteodental lamina from a tooth as the skirt for a PMMA optical cylinder. The tooth is harvested in a first surgery from the keratoprosthesis recipient, and then the device is implanted into the cornea in a second surgery and covered by lid skin or a buccal mucosal graft. The procedure has a reputation for stability and low rate of infection.

Other investigators have replaced the autologous tooth skirt with porous plastic materials that are considered 'biocolonizable'.[23–25] Russian surgeons, using devices of different design and a PMMA

Table 79.1 Factors improving Boston keratoprosthesis outcomes

Identification of prognostic categories of patients
Design of device
Use of fresh graft tissue as carrier for keratoprosthesis
Placing posterior plate (haptic) totally behind graft
Posterior plate holes to facilitate nutrition and hydration of graft
Tissue coverage (conjunctiva, tarsorraphy, soft contact lens)
Minimize evaporative forces on surface
Glaucoma shunt implant
Aggressive steroid regimens
Prophylactic topical antibiotics for life
Nd:YAG laser membranectomy
Repair techniques
Meticulous, frequent clinical follow-up

optical core, have implanted a large number of patients, many suffering from chemical burn sequellae and its dismal prognosis.[26–27] A core-and-skirt device, utilizing a hydrogel sheet with porous edges as an artificial cornea, has also shown promise.[28] Now known as the AlphaCor keratoprosthesis, it is implanted intrastromally and covered primarily with a conjunctival flap. The center of the device is surgically exposed later. The ingenious Seoul-type keratoprosthesis has also had reported success.[29] These devices are discussed in Chapter 79.

GENERAL CONSIDERATIONS

The combined experience of surgeons pre-eminent in the development of keratoprosthesis surgery worldwide may have amounted to merely 5000 cases during the past half-century, a trivial number compared to the number of corneal blind. The published results of keratoprosthesis outcomes are often difficult to interpret, as follow-up and device survival times are sometimes not cited. Considerable literature focus on device design and materials has overshadowed attention to postoperative biological complications, particularly glaucoma, retroprosthetic membranes, tissue melting, and retinal detachment. Despite these limitations, a considerable body of knowledge in this complex field has accumulated.

In this chapter, we report our experience and outcomes after implantation of the Boston keratoprosthesis at the Cornea Service of the Massachusetts Eye and Ear Infirmary. For a number of years, we have used this medical-grade PMMA keratoprosthesis of collar-button design, the general configuration being suggested by Dorzee, Barraquer, and earlier work at our center.[30–32] The device consists of a front and back plate, joined by an optical stem, and locked in place by a titanium c-ring.[33] The optical portion is manufactured with a range of dioptric powers to fit the axial length of the patient's eye and the aphakic or pseudophakic situation.

The keratoprosthesis comes in two main designs (Fig. 79.1). The simple collar-button, or type I, is the device of choice for patients with a reasonable blink and tear production, the more common situation for our keratoprosthesis cases. It is implanted into a fresh donor corneal graft, which is then sutured into the patient's cornea

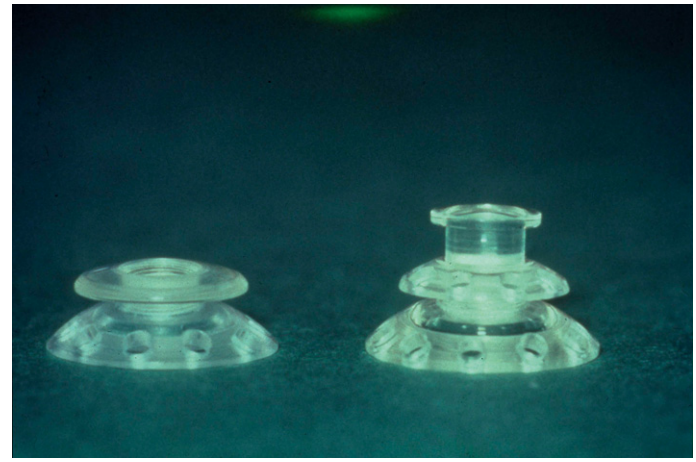

Figure 79.1. Boston keratoprosthesis, type I and type II.

Table 79.2 Keratoprosthesis design

	Type I	Type II
Front plate diameter	5.0–6.0 mm	7.0 mm
Back plate diameter	7.0–8.5 mm	8.5 mm
Stem diameter	3.35 mm	3.35 mm
Inter-plate distance	0.6 mm	0.6 mm
Hole diameter	1.3 mm	1.5 mm
Anterior–posterior length	3.7 mm	4.7 mm
Visual field	60°	40°

in the standard manner. The wide plates prevent the device from tilting off axis. The optical stem is short, giving the patient a generous visual field, and providing the surgeon a good view with the slit lamp, helpful for Nd:YAG laser membranectomy and for viewing the posterior eye structures. The design of the type I device includes a low profile, to minimize the tendency for adjacent graft dellen and to allow a soft contact lens to fit comfortably over it. Holes in the back plate permit better nutrition and hydration into the donor allograft from the aqueous side in an effort to reduce the tendency for graft necrosis and subsequent extrusion of the device.

Cases with end-stage dry eye conditions are suitable candidates for the type II Boston keratoprosthesis, designed for through-the-lid applications. Tarsorraphy is believed to reduce tissue dehydration and melting in these cases and the type II device has a 2 mm long anterior nub to penetrate the skin or pass between the lids. It is otherwise similar to the type I device (Table 79.2). The keratoprosthesis can be purchased from The Massachusetts Eye and Ear Infirmary, Boston, Massachusetts.

PREOPERATIVE ASSESSMENT

Bilateral corneal blindness with light perception or hand motion vision can be an indication for keratoprosthesis surgery. If one eye has relatively good vision, the keratoprosthesis approach is less often indicated. Severe retinal or optic nerve damage, including end-stage glaucoma, or dense amblyopia are contra-indications for the procedure. Assessment of the posterior segment often will require B-scan ultrasound in these cases, and the final decision for

or against surgery can be a difficult one. Neither visual evoked response nor electroretinography testing has been particularly helpful in our experience. Monocular status, young age, or poor general health must also be considered. In patients with no other hope of recovery from bilateral corneal blindness, keratoprosthesis may be the best option.

Our experience has shown that the underlying disease process can often be the key issue in providing guidance to both surgeon and patient.[34] The etiologies with markedly worst prognosis are Stevens–Johnson syndrome and ocular cicatricial pemphigoid. The former are often young and have ongoing ocular inflammation that increases their risk of postoperative complications. Their desperate need is often exceeded by the requirement to be free of sight-threatening complications for many years. Ocular cicatricial pemphigoid patients, on the other hand, are usually older, and eventual keratoprosthesis failure might be less tragic than in a younger patient.[35] Both groups are prone to postoperative skin retraction, with tissue melting and device extrusion, and to blinding glaucoma. Close, long-term follow-up is mandatory if the patient is to have any hope of prolonged vision.

In our hands, chemical burn patients have an intermediate prognosis for success with the Boston keratoprosthesis.[34] Inflammation can eventually subside, and glaucoma is the most important long-term complication.[36] We often recommend a simultaneous glaucoma shunt procedure before or after the keratoprosthesis surgery. These patients have a tendency for retinal detachment, presumably from the chemical damage. Again, frequent and careful clinical follow-up is critical to success.

Patients with repeated graft failure, non-inflammatory edema, and trauma, tend to fare best by a wide margin.[37] Patients with the etiology of corneal infection, including those with herpetic etiology, fall within this group, with only a slightly increased risk of long-term keratoprosthesis failure. This group of patients has the least likelihood of unmanageable glaucoma, postoperative uveitis, or tendency to tissue necrosis and keratoprosthesis extrusion. Blink mechanism and tear production are often normal. Good vision is often restored rapidly with keratoprosthesis, more rapidly than with a successful re-graft.

SURGICAL TECHNIQUE—TYPE I DEVICE

Efforts in recent years to simplify the procedure of Boston keratoprosthesis implantation have led to improvements in technique.[37] The present one-step surgical procedure does not require autologous tissue from other body sites (e.g. teeth, fascia lata). We prefer general anesthesia when safe, as the keratoprosthesis surgery usually takes longer than a standard keratoplasty. We recommend an intravenous antibiotic (cefazolin 1.0 g if no allergy or other contraindication) dose be given at the beginning of surgery. The list of preoperative materials is shown in Table 79.3.

The fresh donor cornea is brought to a side table and the central 8.5 mm is excised with a trephine. The patient's own cornea can be used in situations where the cost of donor corneas is prohibitive. Using a 3.0-mm punch (Acu-Punch, Acuderm Inc., Ft Lauderdale, FL), a central hole is made in the donor material. It is important that the opening be centered well and not be eccentric. The front plate is placed with its anterior surface down and the stem up on an adhesive tape (included in the set), and viscoelastic is applied to the screw threads of the stem. The graft is gently pushed over the stem until its front surface is fully up against the anterior plate. The posterior haptic plate is screwed into place and locked with the titanium snap ring (see Fig. 79.2). The graft–prosthesis combination is placed back into the storage solution while attention is turned to the patient.

On those occasions when a glaucoma shunt is indicated, insertion of the tube into the anterior chamber should occur before the cornea is trephined. Using a trephine with a 0.5 mm smaller diameter (usually 8 mm) than the prepared graft, the patient's cornea is cut

Table 79.3 Materials to prepare before surgery

Boston keratoprosthesis type I or II, with suitable dioptric power (Massachusetts Eye and Ear Infirmary, Boston). Package includes adhesive patch and spanner wrench to facilitate keratoprosthesis assembly (JG Machine, Woburn, MA)
Donor cornea (patient's own cornea can be used if necessary)
Troutman punch device (Pilling Weck Surgical, Ft. Washington, PA)
Trephine blades, 8.0 and 8.5 mm (Storz # E3095)
Skin punch, 3.0 mm (Acuderm, Ft. Lauderdale, FL)
Hessberg–Barron vacuum trephine (Barron Precision, Grand Blanc, MI)
Universal trephine handle
Standard keratoplasty instrument set
Irrigation/aspiration unit, vitrectomy unit, and light pipe
Fine bipolar cautery
Plano soft contact lens (Kontur Lens, Richmond, CA). We recommend 16.0 mm diameter and 9.8 mm base curve.
Video recording capability (optional but useful)
If needed, glaucoma valve shunt and Tutoplast (Ahmed S-2, New World Medical, Rancho Cucamonga, CA)

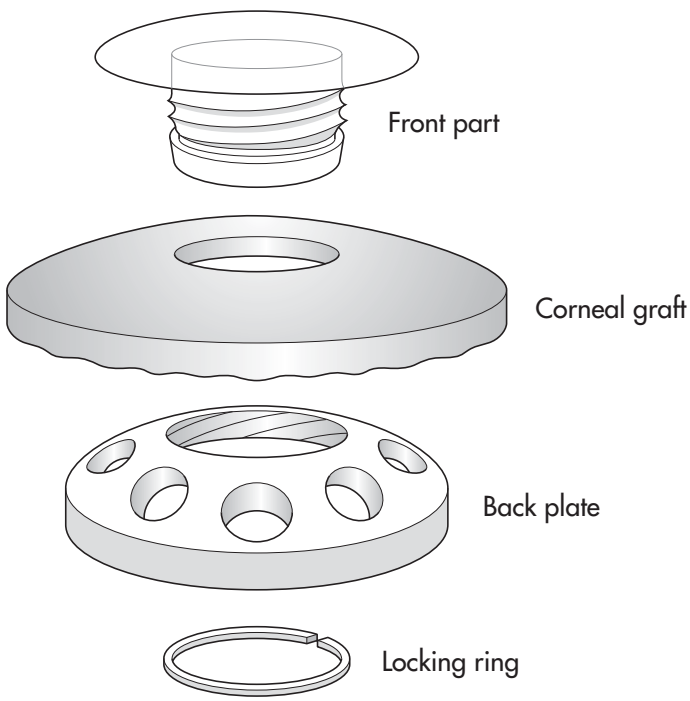

Figure 79.2. Principle of assembly of a type I device.

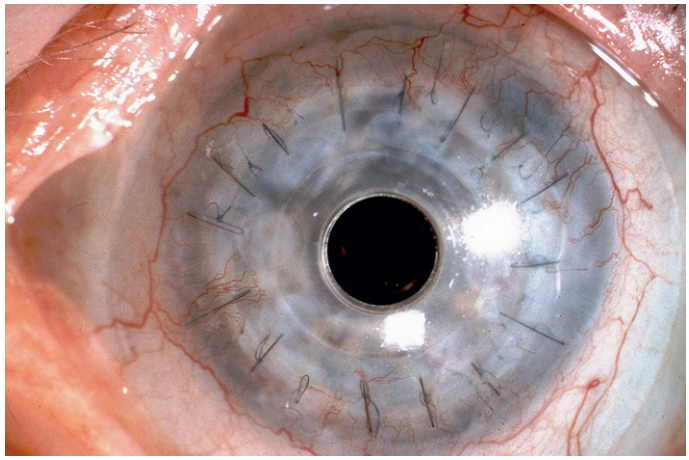

Figure 79.3. Postoperative example of a type I device in place.

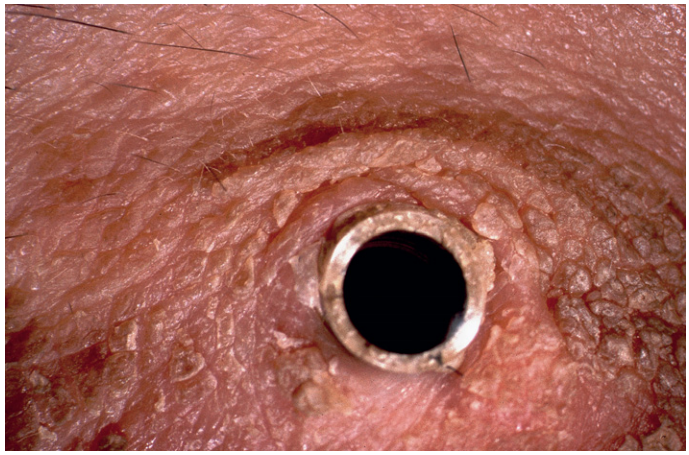

Figure 79.4. Postoperative example of a type II device in place.

to partial depth. Bleeding vessels are cauterized and the trephination is completed. One or two iridotomies are made and the native lens is excised by extracapsular technique. If the patient is pseudophakic, the intraocular lens should remain in place and a device with corresponding optical power can be chosen. If vitreous is evident, a deep core vitrectomy is necessary and all efforts should be made to prevent any bleeding into the posterior chamber.

The graft–prosthesis unit is now placed into the trephined opening in the cornea, and sutured in place with 12 9-0 nylon sutures. The knots are buried. A bandage contact lens is applied and antibiotic drops are administered to complete the surgery (Fig. 79.3). If a bandage contact lens is not available, we recommend performing a total conjunctival flap with central opening. This is easiest done prior to the trephination. In more extreme cases of exposure, partial lateral and medial permanent tarsorraphies may be required, allowing only the plastic optic to be exposed.

SURGICAL TECHNIQUE—TYPE II DEVICE (Fig. 79.4)

The surgical principles for the type II device are similar to those described for type I, although the surgery is more complicated and time-consuming. A glaucoma shunt is often necessary in these cases.[36] The fornices must be cleaved to allow for implantation of the graft–prosthesis combination. The keratoprosthesis is placed so that the optical nub protrudes through the closed lids, as originally described by Cardona and DeVoe.[38] An alternative technique is to perform a tight permanent tarsorraphy on both sides of the protruding optic nub.

OUTCOMES

Meticulous and frequent clinical follow-up are key to successful, long-term keratoprosthesis survival. In most cases, the severe complications are seen within the first postoperative year. However, the risk of potential complications continues for the life of the keratoprosthesis, and close monitoring with early diagnosis offers the best chance of successful treatment. We see postoperative cases that are doing well at 1 day, 1 week, 3 weeks, and then monthly intervals after surgery. The anterior surface of the type II device can be cleaned as necessary with baby shampoo and a cellulose sponge during examinations.

Sharing the postoperative responsibility with a glaucoma colleague is wise. With the drastic reduction in endophthalmitis,[39] glaucoma is probably the most serious complication of keratoprosthesis surgery. Its pathogenesis is multifactorial, but gradual closure of the anterior chamber angle is the most likely cause of marked aggravation of intraocular pressure. Tonometers are not useful in this clinical situation, so glaucoma evaluation should include finger palpation of the globe for intraocular pressure assessment, as well as visual field examination and visualization of the optic nerve head. Topical glaucoma medications have some effect in type I keratoprosthesis patients, although their effect seems somewhat diminished compared to more routine glaucoma eyes. Oral carbonic anhydrase inhibitors, as expected, have the usual effect, and are the only choice in the type II case. They should be used with great caution in patients with Stevens–Johnson syndrome and avoided in patients with sulfa allergy. Ahmed valve placement at the time of keratoprosthesis surgery has been a significant advance in the treatment of this condition.

We use postoperative prophylactic antibiotics indefinitely. An oral antibiotic, such as cephalexin 500 mg twice or three times daily is used for 10 days following surgery. A topical fourth-generation fluoroquinolone is used initially four times daily, then tapered to once per day (twice daily for type II keratoprosthesis patients). In autoimmune cases (Stevens–Johnson syndrome, ocular cicatricial pemphigoid, etc.), we also recommend vancomycin 14 mg/mL with benzalkonium preservative once daily, and our patients use both topical medications as long as the keratoprosthesis is in place. In cases of recurrent herpes simplex, a systemic antiviral (acyclovir 400 mg twice daily) is recommended on a permanent basis. The rare endophthalmitis is usually from gram-positive organisms in our experience, and vision can be lost in hours. Should endophthalmitis occur, immediate 'tap and inject' are crucial. An aqueous tap via the limbus for smear and culture and an injection of 1.0 mg vancomycin, 0.4 mg amikacin, and 0.4 mg dexamethasone are performed. The patient should be hospitalized for topical and intravenous antibiotics, and a vitrectomy performed later as necessary. We have not had any postoperative endophthalmitis cases since the institution of this prophylactic antibiotic regimen.[40,41] Patients with autoimmune disease or severe chemical burns may require a more aggressive antibiotic regimen than in the majority, non-autoimmune, cases. It is particularly important to impress upon the patient that compliance for life is mandatory.

Both devices, particularly the type II, are susceptible to adjacent tissue necrosis, and close observation for this complication is indicated. Necrosis with the type I device is now very rare. However,

early evidence of a surface melt near the edge of the type I anterior plate, that threatens to become a substantial gap between the stem and adjacent tissue, should be treated aggressively. Total replacement with a fresh graft–prosthesis combination is recommended.

In the type II keratoprosthesis, the adjacent skin can retract away from the nub due to evaporative damage to the skin edge. Topical methylprogesterone 1% suspension twice daily reduces necrosis around the incision, presumably due to suppression of collagenase synthesis.[42] Topical tetracycline 1% suspension, a direct collagenase inhibitor, has been less helpful in our hands. Skin revision is advisable when the skin retracts to the edge of the front plate. A horizontal lid skin incision with undermining and freshening of the edges, followed by 6-0 nylon suture looped around the nub, will usually restore the interface integrity.[37] If a frank leak and hypotony occurs with either type of keratoprosthesis, the entire keratoprosthesis–graft system should be replaced.

Addition of a continuous-wear bandage plano soft contact lens after type I keratoprosthesis surgery has created a remarkable improvement in the stability of the postoperative course.[43] Before its use, evaporation and irregular drying of the corneal graft tissue around the device led to dellen formation, epithelial defects, and stromal thinning. The lens seems to diffuse evaporative forces and allow better hydration of the eye surface. Inadvertent lens loss and replacement can increase the cost of care.

After type I surgery, a postoperative topical corticosteroid is tapered from four applications per day to a lower dose during the first postoperative months, depending on clinical circumstances. The type II patients may require occasional sub-Tenon triamcinolone injections during the first postoperative months to reduce the prolonged intraocular inflammation common in these patients. Injection of 40 mg triamcinolone a few days after surgery, then every 2–3 weeks for several more months, will often keep exuberant, self-destructive inflammation at bay.

We have seen sudden, massive vitritis in a few patients with reduction of vision to hand motion. There is no accompanying pain, tenderness, or redness, but the vitritis otherwise appears as an infectious endophthalmitis, and should be so treated. Within a few weeks or months, the vitreous clears and vision returns to baseline, leading to our opinion that this is an immune event.[44]

Another immune event is the formation of a retroprosthetic membrane after prolonged, severe inflammation in autoimmune eyes. Vision is dramatically worsened, and triamcinolone injections are indicated at the first sign of membrane formation. Once formed, the Nd:YAG laser should be used to open the membrane before it becomes too thick or vascularized.[45] Laser pulses with energy above 3.0 mJ can crack or mark the optical portion of the device. If the laser cannot cut the membrane, a closed vitrectomy and membranectomy under high infusion pressure are necessary to restore vision.[46]

Retinal detachment is not common following keratoprosthesis placement, but it does occur. It can be rhegmatogenous or tractional in nature, and prognosis is ominous. Diagnosis is by direct visualization or B-scan ultrasonography. Multiport vitrectomy should be performed and long-acting tamponade used.[46]

In conclusion, keratoprosthesis offers a visual rehabilitative option to patients whose prognosis for standard keratoplasty is poor. The outcome of the type I device compares favorably with keratoplasty for multiple graft failures in nonimmune disease.[47] It is perfectly reasonable for any ophthalmologist with experience in corneal surgery to perform this type of operation. It should be re-emphasized, however, that keratoprosthesis in the autoimmune diseases fares much worse and we recommend that these cases be referred to surgeons with considerable experience.

Several clinical groups around the world have contributed substantially to progress on preventing and treating the complications of keratoprosthesis implantation during the last few decades. The rapid rehabilitation and improving long-term outcomes of keratoprosthesis will undoubtedly increase the use of this device in the worldwide ophthalmic community.

80 Classification and terminology of refractive surgery

George O. Waring

Most specialized fields develop their own technical terminology and jargon. Refractive surgery is no exception. The penchant for professional shorthand has produced jargon such as 'keratorefractive' surgery, a Greek–Latin hybrid that flows easily from the tongue and pen of those enamored by neologisms. Some surgeons have become 'keratomists,' and their patients are 'keratotomized.' Words have been invented, such as 'lenticle,' instead of the correct term, 'lenticule'—the piece of tissue or synthetic material used to change corneal shape. Commercial trademarked terms have appeared. Eponyms abound. Common use of some colloquial terms has fixed them in our vocabulary. For example, some say 'myopic LASIK' (is the LASIK myopic?), instead of the more precise designation: LASIK for myopia. Thus far we have been spared 'myopic intracorneal rings'.

To clarify the language we use in this rapidly changing area of ophthalmology, I propose a classification of refractive surgery, which I hope is broad enough to include all procedures that have a major refractive component, systematic enough to organize our present knowledge, clear enough to distinguish techniques in current use from those of historical interest, flexible enough to accommodate new developments, and precise enough to decrease the proliferation of jingly keratospeak.

REFRACTIVE SURGERY

Refractive surgery is any operation intended to alter the refractive state of the eye.[1] Thus, laser in situ keratomileusis (LASIK), cataract extraction with implantation of an intraocular lens (IOL), and Descemet's stripping endothelial keratoplasty (DSEK) are all forms of refractive surgery. Refractive corneal surgery refers to corneal operations that are intended to alter the refractive state of the eye. This type of surgery is popularly referred to as both *refractive keratoplasty*, an appropriate term because keratoplasty means 'molding the cornea', and keratorefractive surgery.

All IOL implantations—both aphakic and phakic—qualify as refractive surgery; indeed, the phrase 'refractive cataract surgery' has become popular as more meticulous attempts to correct the total refractive state of the eye at the time of cataract surgery have evolved: correcting the spherical error with an IOL, correcting the astigmatism with transverse keratotomy (either in the cornea or as part of the limbal incision) or with a cylindrical IOL, and correcting presbyopia with a multifocal or accommodating IOL.

CLASSIFICATION OF REFRACTIVE SURGERY

The classification I propose (Table 80.1) is based on surgical technique. It describes basic techniques that can be applied to many refractive errors, such a keratomileusis for both myopia and hyperopia. It accommodates new techniques that are modifications of previously used ones, such as LASIK as a modification of keratomileusis. It requires only one description of a technical procedure that is used in different refractive operations, such as the use of a microkeratome in keratomileusis.[2]

The classification specifies first three broad categories of refractive surgery: refractive keratoplasty, IOLs, and scleral surgery. The classification then specifies basic surgical techniques such as keratomileusis and refractive keratotomy, presenting variation in each technique. The classification also divides all techniques into two basic groups: those in active use in 2007 and those used less frequently or of historical interest only.

LAMELLAR REFRACTIVE KERATOPLASTY

Lamellar refractive keratoplasty involves altering the central curvature of the cornea to change its refractive power. Changing the refractive index with a corneal inlay or the optics with a small aperture inlay is refractive corneal surgery as well. There are three basic lamellar refractive keratoplasty techniques:

1. *Keratomileusis* ('to curve the cornea') is the creation of an anterior disc or flap of corneal tissue. The stromal surface of the bed (or, in the past, the disc) is then reshaped to effect a refractive change by changing the radius of curvature of the cornea most commonly with an excimer laser. The disc or flap is then replaced and allowed to adhere on the cornea.
2. *Intracorneal inlay or lens* ('keratophakia, lens in the cornea'). Placing an intracorneal lens in the power beneath the lamellar flap changes the anterior curvature of the cornea. Placing a

Category of Surgery	Basic Surgical Technique	SPECIFIC SURGICAL TECHNIQUES Variation of Surgical Techniques or Material	Techniques in Active Use in 2007	Techniques Used Less Frequently or Abandoned
I. Refractive keratoplasty				
A. Lamellar				
	1. Keratomileusis (KM): Cutting planoanterior Corneal flap	a. Anterior corneal layer	i. Hinged flap	ii. Complete disc
		b. Methods of cutting flap or disc	i. Mechanical microkeratome	
			a) Automated advance	b) Manual advance
			a) Mechanical or manual advance	
			c) Oscillating blade	d) Rotating blade
			ii. Femtosecond laser (raster or circular beam path)	iii. Water jet
				iv. YAG laser
		c. Attachment of flap or disc	i. No sutures: tissue adhesion and endothelial pump	ii. Sutures
		d. Source of tissue for flap, disc	i. Patient (autoplastic)	ii. Donor (homoplastic or allograft
				a) Lenticule placed on patient corneal surface
				i. Epikeratoplasty with refractive power (H,A)
				ii. Plano lamellar onlay (KC)
				b) Donor—lenticule under disc or flap (homoplastic)
				i. Keratophakia—donor disc with power (H,A)

				i. Additive keratoplasty for keratoconus—plano donor disc (KC)
		e. Location and method of refractive cut	i. Stromal bed—excimer laser, 193 nm (laser in situ keratomileusis-LASIK) (M,H,A,P)	iii. Stromal bed—microkeratome —
				a) Automated lamellar keratoplasty (ALK) (excise plano disc) (M)
				b) Keratokyphosis (refractive mold in microkeratome) (M,H)
				ii. Stromal side of disc
				a) Cryolathe (M,H)
				b) Non-freeze (microkeratome cut made on suction mold)
				c) Excimer laser
			a) Beam delivery method	
			i) Flying or scanning spot—random pattern	
			ii) Translating slit	
			b) Spherical ablation pattern	
				iii) Single-zone diameter
				i) Multiple-zone diameter (e.g. optical + transition)
				ii) Blended ablation zones
			c) Cylindrical ablation pattern	
			i) Flatten steep meridian	
			ii) Steepen flat meridian	
			d) Timing of treatments	
			i) Single treatment	
			ii) Multiple sequential treatments (enhancements, retreatments)	
			iii) Treatment after IOL implantation (bioptics)	

Refractive error treated: M, myopia; H, hyperopia; A, astigmatism; P, presbyopia; KC, keratoconus (all grades)

		c. Posterior chamber open loop or plate	
		i) Lens capsule support	
			a) Within capsular bag
			b) Ciliary sulcus
		ii) No capsule support	
			a) Iris sutured
			b) Trans-scleral
III. Scleral surgery			
	A. Posterior scleral support (M)		
			1. Strips of sclera, fascia lata, synthetics
	B. Equatorial implants (M)		
			1. Plaques of sclera, subtenons, in four oblique quadrants
	C. Anterior radial sclerotomy (P)		
			1. Radial incisions with or without separators
			2. Laser radial sclerectomy (nm)
	D. Anterior scleral expansion bands (P)		
			1. Synthetic inlays in lamellar tunnel

Refractive error treated: M, myopia; H, hyperopia; A, astigmatism; P, presbyopia; KC, keratoconus (all grades)

small aperture inlay beneath the corneal flap increases the depth of field for presbyopia correction. Placing a ring segment paracentrally in a tunnel flattens the central cornea to treat myopia.

3. *Lamellar keratoplasty* is a form of corneal transplantation in which donor lamellar tissue (without induced changes in corneal power) replaces diseased anterior corneal tissue to preserve more normal corneal endothelium or to replace diseased posterior corneal tissue when the anterior cornea is not diseased. An onlay plano donor may be placed to flatten the cornea and help treat keratoconus (epikeratoplasty).

KERATOTOMY

Keratotomy ('*cutting the cornea*') involves making a partial-thickness incision into the cornea to change its radius of curvature and refractive power. The term 'refractive keratotomy' designates all such incisions. A description of the pattern of the incisions usually modifies the term,[6] such as radial for myopia or transverse across the steep corneal meridian (arc-T) for astigmatism. Radial keratotomy for myopia is not in current clinical use; however, transverse keratotomy for astigmatism is used—in three basic arcuate patterns: (1) arcuate keratotomy in the cornea or in a penetrating keratoplasty wound, (2) 'limbal relaxing incision' approximately 1 mm inside the limbus, and (3) as part of an IOL implant procedure. The transverse incision is placed perpendicular to the steep meridian (the plus refractive cylinder) for the purpose of flattening that meridian and reducing astigmatism—although it can certainly induce astigmatism as well.

KERATECTOMY

Keratectomy ('*excision of a piece of cornea*') is used to change the refraction of a cornea. There are three basic types of keratectomy: (1) keratectomy with an excimer laser, (2) wedge-shaped keratectomy (wedge resection) to decrease astigmatism after penetrating keratoplasty[9] or cataract surgery, and (3) a lamellar crescentic keratectomy for Terrien's marginal degeneration or pellucid degeneration.[10] Revising and resuturing a slipped or separated corneal or limbal wound acts like a keratectomy because it steepens the cornea in the meridian of surgery.[11,12]

LASER REFRACTIVE CORNEAL SURGERY

Because the field of laser refractive corneal surgery[13] is expanding rapidly, I present here more detail concerning the classification and terminology used in laser corneal surgery (Fig. 80.1).

Fundamental to all designations is the fact that the pulsed excimer (193 mm) laser light removes tissue from the cornea. The mechanism on the tissues is a photochemical one: the laser photons

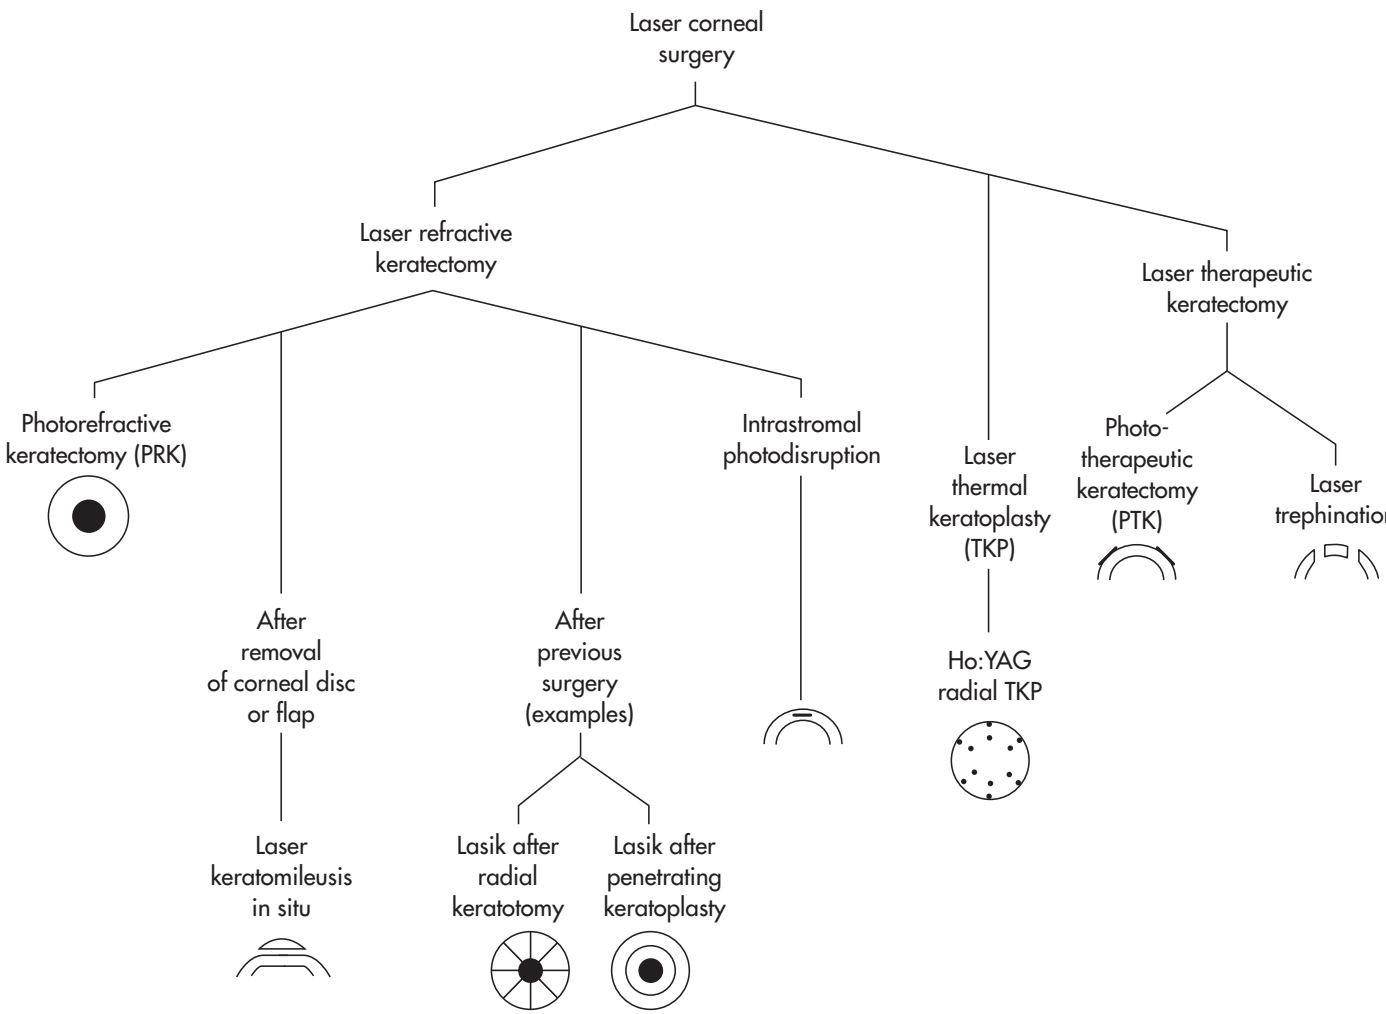

Figure 80.1. Classification and preferred terminology for laser corneal surgery. (Modified from Waring GO. Refract Corneal Surg 1990; 6: 318.)

breaking molecular bonds, with fragments flying from the surface at supersonic speeds. This process has been designated *photoablative decomposition*—photoablation for short. This process contrasts with the more familiar photocoagulation of an argon laser and photodisruption of an Nd:YAG laser emitting at 1064 nm.

The use of other types of lasers in corneal surgery complicates the terminology. For example, femtosecond laser (1053 nm) produces photodisruption by shock waves, not photoablation. So, intrastromal surgery performed with this type of laser is called intrastromal photodisruption, not intrastromal ablation.

The generic term 'laser corneal surgery' can easily be modified to the terms 'laser refractive corneal surgery' or 'laser therapeutic corneal surgery', to designate the two major categories. Because lasers remove tissue, the term 'keratectomy' is used in the proposed terminology.

There are three types of laser refractive surgery keratectomy: (1) removal of a graded amount of tissue from the anterior central cornea, (2) removal of a graded amount of stroma after a microkeratome flap resection (laser keratomileusis), and (3) intrastromal photodisruption 0 used today to create cuts in the cornea.

The term 'photorefractive keratectomy' has come to mean the central removal of a specific profile of Bowman's layer and anterior stroma to change the anterior curvature of the cornea. This is a good example of how the usage of language determines its meaning because, strictly speaking, the term 'photorefractive keratectomy' refers to all types of excimer laser refractive corneal surgery. Nevertheless, photorefractive keratectomy, in both its original and its present meanings, designates the refractive reshaping of the anterior corneal surface after removal of the epithelium. In this sense, it is a type of anterior surface ablation. Two other types of surface ablation involve specific techniques of removal and then replacement of the epithelium: laser epithelial keratomileusis (LASEK) folds back a corneal flap that is loosened with alcohol and replaces it after the excimer laser ablation and epiLASIK aims to create an epithelial flap with a microkeratome, using a dull blade to separate the epithelium from the underlying tissue with subsequent replacement of that epithelial flap.

Removing stromal tissue without disrupting the surface of the cornea requires a nonultraviolet laser that is not absorbed by the cornea but that can focus energy within the stroma, such as an Nd:YLF laser. This creates an intrastromal cavity by photodisruption, but this technique is not used clinically.

Another surgical use of the laser is to refine the result of a previous refractive surgical procedure, such as LASIK after radial keratotomy.

Laser therapeutic keratectomy comes in two varieties. The first involves the removal of a superficial corneal opacity or irregularity. Some have termed this 'superficial keratectomy', which is accurate but inadequate because the term also includes photorefractive keratectomy, which is a type of superficial keratectomy. Again, usage dictates meaning, and the term 'phototherapeutic keratectomy' generally means the removal of anterior diseased layers of the cornea—presently with an excimer laser.

There is a second type of laser therapeutic keratectomy, laser trephination: using a femtosecond laser to make circular or other shaped incisions for penetrating or lamellar keratoplasty.

During cataract surgery

The implantation of IOLs at the time of cataract extraction is standard practice for correcting the aphakic hypermetropia that would result from leaving the eye without its crystalline lens. Lens styles and implementation techniques continue to evolve and improve, with most lenses now being placed within the lens capsule (capsular bag), the anterior portion of which has been removed with a continuous circular capsulorrhexis. These lenses correct the spherical refractive error, based on preoperative IOL power calculations. Lenses with a cylindrical correction must be aligned with the known astigmatic axis of the cornea, and lenses with multifocal or accommodative capability can be used in selected patients to obviate the need for near spectacle correction that would otherwise be needed because of the absence of accommodation.

Refractive lens exchange

Patients who are ametropic and presbyopic after approximately the age of 45 years, and who wish both refractive disorders to be treated, may elect to have their clear crystalline lens removed and replaced by a multifocal or accommodating IOL—the technique known as refractive lens exchange. As of 2007, this is an appropriate option because there is no generally accepted excimer laser pattern that can create a multifocal cornea for presbyopia—and certainly not an accommodating cornea!

Phakic intraocular lenses

Phakic IOLs are implanted in an eye with retention of the normal crystalline lens (therefore remaining phakic). There are three major indications for this type of lens: (1) high myopia and high hyperopia outside the range reasonably treatable with an excimer laser, (2) corneas that are thin or somewhat irregular (e.g. keratoconus suspects) but that allow good spectacle-corrected visual acuity, and (3) patient preference.

PENETRATING KERATOPLASTY

The major reason for performing a penetrating keratoplasty is to replace the central portion of a scarred or distorted cornea by clear regular donor tissue. Between 1940 and 1980, the major clinical challenge was to maintain a clear graft. However, now that grafts remain clear in approximately 85% of cases,[14,15] control of the refractive effect of the donor has become increasingly important, especially when an IOL is used, as in a combined penetrating keratoplasty, cataract extraction, and IOL implantation (triple procedure). The surgeon not only must control factors that affect the spherical power of the graft (such as wound configuration, suture pattern, and donor size) but also must select an IOL power that approximately matches the final refractive power of the graft and the axial length of the globe.[16]

Control of astigmatism during and after penetrating keratoplasty is an important refractive component. Creating a uniform wound configuration by using a mechanical or femtosecond laser trephine and ensuring regular suture placement and tension will help diminish astigmatism. Adjustment of sutures after surgery can do the same, either by selective removal of interrupted sutures in the steep semimeridian or by adjustment of the tension on a running suture to distribute it more evenly and create a more spherical cornea.[9,17,18]

LAMELLAR KERATOPLASTY

Although lamellar keratoplasty using manual dissection techniques was used with varying frequency in the past, it was abandoned in most cases in the 1980s and 1990s because the quality of vision was not as good as that achieved with contemporary penetrating

keratoplasty. However, two new techniques of lamellar keratoplasty are being used with increasing frequency, and increasingly improved refractive outcomes.

The first is deep lamellar keratoplasty, using either a microkeratome or an air dissection technique that allows removal of almost all of the corneal stroma down to Descemet's membrane, leaving a minimal interface between the lamellar donors with less disruption of the quality of vision after surgery. This technique is indicated when the corneal endothelium is healthy, but the stroma is not, as in keratoconus, stromal corneal dystrophies, and anterior stromal scarring.

The second technique is endothelium keratoplasty, in which the diseased endothelium and Descemet's membrane are removed, retaining the more healthy anterior corneal layers, as in Fuchs' endothelial dystrophy. The variants of this technique include a deep lamellar resection in which some of the posterior cornea is also removed and the Descemet's stripping technique in which only Descemet's membrane and the endothelium are removed. The donor cornea is folded and inserted through a limbal incision. From the refractive point of view, this technique has great promise, since it preserves the basic anterior corneal curvature and general preoperative refractive state of the eye.

THERMAL KERATOPLASTY

Techniques of thermal keratoplasty are over 100 years old. A large variety of techniques have been abandoned, including the use of a temperature-controlled flap probe to flatten the cornea and keratoconus, using a hot tip probe penetrating deeply into the stroma and shrinking the collagen paracentrally to steepen the center and treat hyperopia, holmium:YAG laser thermal keratoplasty to create focal spots of intrastromal thermal coagulation paracentrally to steepen the central cornea, and others.

Currently, the only technique of thermal keratoplasty in clinical use is radio-frequency current (350 kHz), known as conductive keratoplasty (CK), with applications of approximately eight burns around a 7 mm- and/or an 8 mm-diameter circle, which shrink the stroma, steepening the central cornea and rendering the eye more myopic. Currently, the technique is used primarily to treat emmetropic presbyopes by creating monovision for near vision in one eye.

SYNTHETIC PROCEDURE VERSUS TISSUE ALTERATION

Another way to classify techniques of refractive surgery is to distinguish two broad categories: synthetic materials such as intracorneal ring segments and IOLs, as opposed to techniques that alter tissue by cutting or removal, such as refractive keratotomy and keratomileusis. The major distinction between the two is that surgery that uses synthetic materials is reversible, that is the material can be removed and the eye returns to its preoperative condition in most cases. This has a great appeal to patients. Both types of procedures are adjustable: synthetic procedures are replaceable, and tissue alteration procedures are modifiable with repeated (enhancement) surgery.

Of course, combinations of synthetic and tissue-altering techniques can be used, most commonly with the implantation of an IOL followed by a LASIK or PRK to adjust the refractive result, a technique known as bioptics (one optic in the eye and the second optical change in the cornea).

One can conceive of future procedures that might also combine these two elements. An example is laser-adjustable synthetic epikeratoplasty (LASE), in which the corneal epithelium is removed and an onlay of synthetic material with a specific refractive correction is bonded to Bowman's layer and allowed to re-epithelialize. If the refractive outcome is inaccurate, the epithelium can be removed and an excimer laser photorefractive keratectomy performed on the acellular synthetic material without concern for wound healing, allowing the epithelium to resurface the synthetic lenticule. If the procedure is ineffective or complicated, the synthetic lenticule can be removed, allowing the cornea to re-epithelialize and return to its original condition.

OTHER CLASSIFICATION SYSTEMS

There are other approaches to the classification of refractive corneal surgery. One is to use the ametropia being treated[22]—myopia, hyperopia, aphakia, or astigmatism—as the basis, but this requires repeated description of similar surgical techniques for each refractive error, such as keratomileusis for myopia and for hyperopia. A more abstract classification is based on the type of alteration of the cornea: resection of tissue (e.g. keratomileusis and wedge resection), relaxation of the tissue (e.g. transverse keratotomy and suture removal), addition of material (e.g. corneal inlay and epikeratoplasty), substitution of tissue (e.g. penetrating keratoplasty), retraction of tissue (e.g. thermal keratoplasty), and compression of tissue (e.g. tight sutures and epikeratoplasty for keratoconus). One may also classify refractive corneal surgery in bioengineering terms: changes in corneal volume, thickness, surface area,[23] and, in the future, even stress–strain forces. Meanwhile, a classification based on surgical technique (see Table 80.1) will enhance communication and understanding among those interested in refractive surgery.

81 Principles of biomechanics in refractive surgery

William J. Dupps, Jr.

Few biological systems are as functionally sensitive to changes in tissue geometry as the eye. Even with elegant ocular registration, high-speed tracking systems, and the submicron surgical precision afforded by the excimer laser, discrepancies between intended and realized optical outcomes in photoablative refractive surgery still occur and are often visually significant. Accordingly, corneal refractive surgery is evolving into a field whose precision is limited primarily by the innate biological and biophysical responses of the patient. This chapter surveys corneal biomechanical behavior and highlights its increasingly important role in improving the safety and predictability of refractive surgery.

THE GEOMETRIC–EMPIRICAL MODEL OF PHOTOABLATIVE KERATOREFRACTIVE SURGERY

The ablation algorithm is the fulcrum of surgical control in photoablative refractive surgery. As such, it can be modified, either at the proprietary level or with surgeon-adjustable spherical offsets, in an attempt to reduce unexpected visual outcomes through the process summarized in Figure 81.1. This process begins with the surgical candidate's preoperative measurements. While our conceptualization of the patient is based on an extensive history and physical examination, the surgical recipe is ultimately determined from a reduced data set based largely, if not solely, upon the phoropter refraction (in conventional laser vision correction), the wavefront aberration map (in custom or wavefront-guided procedures), or the corneal topography map (in topography-guided ablation).

From any of these numerical representations of the patient, a treatment algorithm is derived (depicted as a 'black box' in Fig. 81.1) that is optimized for producing the desired corneal power change in a typical patient. Although the details of platform-specific ablation algorithms are protected for proprietary reasons, all ablation routines appeal at some level to the shape-subtraction[1] model of refractive keratectomy that was specified in geometric terms by Munnerlyn et al in 1988.[2] In the familiar reduced form of the model for myopia, t_o represents the central stromal ablation depth in microns, S the diameter of the ablation in millimeters, and D the dioptric correction attempted. According to this model, photoablative subtraction of the specified thickness profile from the corneal surface should produce the intended refractive shift.

In practice, however, early investigators noted systematic discrepancies between intended and measured outcomes that prompted empirical modifications of the algorithm. What are some sources of this predictive error? In every step of the surgical process depicted in Figure 81.1, a certain degree of imprecision exists, even if clinically insignificant when considered alone. But these small uncertainties propagate through the surgical process and manifest as outcome variability that is no less than the sum of the errors from every stage of the process. For example, imprecision or inaccuracy in the refraction used to generate the ablation algorithm preoperatively and to assess its effectiveness postoperatively contribute error that limits the precision of the next surgical plan. Objective assessments of refractive status such as wavefront aberrometry afford certain advantages over subjective refraction[3] but errors in reproducibility, although low in many cases,[4] are still nonzero. Furthermore, the laser–tissue interaction itself is complex, and ablative efficiency is affected by corneal hydration, ambient humidity, ablation plume interference, laser beam incidence angle, laser energy nonuniformities, and multiple surgical variables that exert their influence through similar mechanisms. For treatments that are neither wavefront-guided nor aspheric (where the latter have been called 'Wavefront-Optimized®' on the Allegretto Wave platform), the ablation pattern incorporates simplifying assumptions such as paraxial optics and spherical corneal surfaces that contribute additional error at the intraoperative stage.[5]

While imprecision due to measurement error, algorithm simplifications, and laser-tissue interaction nonidealities is important to address, the individual patient's response to surgery is the most important and most challenging source of outcome variability in refractive surgery. The shape-subtraction paradigm of refractive keratectomy assumes that the cornea is biologically and biomechanically inert.[6] Our experience with incisional refractive surgeries such as radial keratotomy has taught us that the cornea is anything but mechanically inert. Biomechanics figure prominently in any surgery in which corneal tissue is removed or incised, including routine LASIK, and the effect is more profound when we operate on corneas altered by previous refractive surgery or penetrating

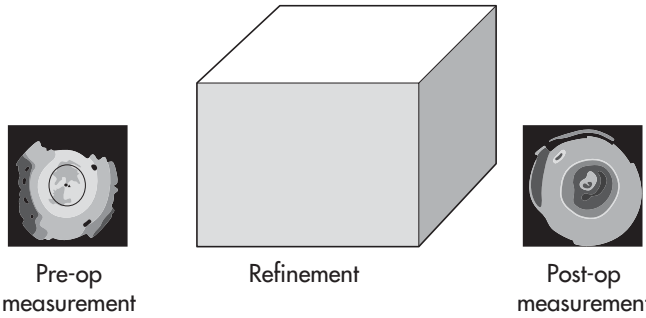

Figure 81.1. Surgical outcomes are leveraged through the ablation algorithm. Algorithms are specific to each laser vision correction platform and generally provide for surgeon-specific spherical modifications based on personal nomograms. Preoperative measurements are used to generate the ablation recipe, surgery is performed, and then postoperative measurements are obtained. Results may be compared to attempted corrections to evaluate the performance of the algorithm and nomogram and to make modifications. The refractive effects of the biomechanical and wound healing responses are not accounted for explicitly in laser algorithms, although empirical adjustments have been partially successful in reducing the systematic error associated with these effects. Further refinement and improved predictability in individual patients will depend on novel preoperative measurements capable of better-predicting patient-specific biophysical and biological responses.

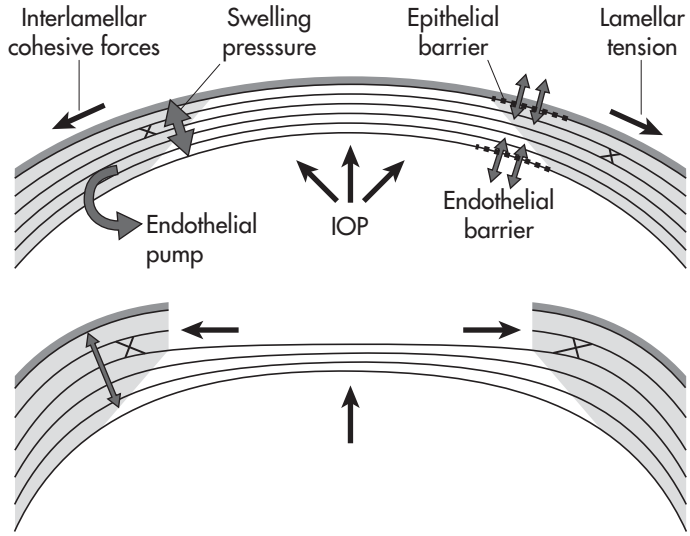

Figure 81.2. Biomechanical forces in the cornea and a model of biomechanical central flattening associated with disruption of central lamellar segments. A reduction in lamellar tension in the peripheral stroma reduces resistance to swelling, and an acute expansion of peripheral stromal volume results.[10] Interlamellar cohesive forces[11] and collagen interweaving,[12] indicated by grey shading, are greater in the anterior and peripheral stroma and provide a means of transmitting centripetal forces to underlying lamellae. Because the central portions of these lamellae constitute the residual stromal bed (RSB), flattening of the optical surface occurs, resulting in hyperopic shift. The degree of flattening is associated with the amount of peripheral thickening.[10] This phenomenon is exemplified clinically by PTK-induced hyperopic shift but is important in any central keratectomy, including PRK and LASIK. Offsetting elastic weakening and steepening of the RSB may occur,[13] and the threshold for inducing irreversible (plastic) or progressive (viscoelastic) steepening (or ectasia) is a matter of ongoing clinical concern.

keratoplasty. And while the iterative loop in Figure 81.1 is valuable for retrospective adjustment of systematic errors in large patient series, it is of little value in preventing the idiosyncratic or random errors attributable to biological and biomechanical variation, particularly if we have not identified critical preoperative predictors of response or have no capabilities to measure them.

The corneal biomechanical response manifests clinically as (1) intraoperative corneal shape changes affecting the immediate postoperative refractive state; (2) ongoing postoperative shape changes that contribute to refractive regression, irregular astigmatism, and ectasia; and (3) an increased propensity toward shape change when challenged by altered hydration, hypoxia, or subsequent surgery. The importance of these biomechanical responses is greater than ever in an era of wavefront-guided treatments for correction of higher-order optical aberrations.[7–9] Continued empirical refinement and major advances in laser delivery platforms[3] have markedly improved the predictability of outcomes, and most often the remaining imprecision leads to minor refractive errors that fall within a well-tolerated range. In some cases though, a predisposition to mechanical instability or abnormal healing can lead to gross over- or undercorrection or sight-threatening complications such as keratectasia.

STRUCTURAL FOUNDATIONS OF THE BIOMECHANICAL RESPONSE

The cornea is a complex biomechanical composite whose behavior depends on its structural subcomponents and their organizational motifs (Fig. 81.2). Bowman's layer and the stroma are the only collagenous layers of the cornea and thus provide the majority of the cornea's tensile strength. The epithelium is attributed a minimal role in this tensile strength, and its removal causes little or no change in the anterior corneal curvature.[14] The extensibility and low stiffness of Descemet's membrane ensure its laxity over a broad range of intraocular pressures (IOPs)[15] and may serve as a high-compliance buffer to protect the endothelium from the effects of high stromal stresses. The role of Bowman's layer, an 8–12 μm-thick acellular condensation of stroma with more randomly oriented collagen fibrils,[16] has been a subject of controversy.[17,18] Although some have proposed a structural role distinct from that of the stroma, extensiometry studies in normal corneas suggest that removal of Bowman's layer does not measurably alter the bulk mechanical properties of the cornea.[18] The biomechanical importance of Bowman's layer in abnormally thin or ectatic corneas is suggested by the fragmentation of Bowman's layer observed during histological examination of keratoconic tissue.

The mechanical response of the cornea to injury is dominated by the stroma. On a weight basis, the stroma is approximately 78% water, 15% collagen, and 7% noncollagenous proteins, proteoglycans, and salts.[19] A total of 300–500 lamellae run from limbus to limbus and are stacked with angular offsets; this orientation becomes increasingly random in the anterior stroma where significantly more oblique branching and interweaving are noted.[16] Interlamellar branching is also more extensive in the corneal periphery than in its center (Fig. 81.2).[20,21] Interweaving of collagen bundles between neighboring lamellae provides an important structural mechanism for shear (sliding) resistance[22] and sharing of tensile loads between lamellae.[6,10] In addition, X-ray diffraction studies provide evidence of a predominantly circumferential fibril orientation in the corneal periphery[23] that may favor conservation of limbal circumferential dimensions even in ectatic disease.[24] Proteoglycans play a critical

role in collagen fibril assembly and spacing,[25] and their mechanical importance may be greater than currently recognized.

CORNEAL MATERIAL PROPERTIES

The mechanical properties of the cornea and its constituent materials link the cornea's morphology to its mechanical behavior under the stresses of surgery or disease. In the terminology of material science, the cornea is a complex anisotropic composite with nonlinear elastic and viscoelastic properties. It is a *composite* because its properties are determined by the interaction of disparate materials like collagen and a polyanionic ground substance and *anisotropic* because its properties are not directionally uniform. The cornea is also highly heterogeneous in the central to peripheral, anterior to posterior, and rotational dimensions. A generalized solution of the three-dimensional equations describing such a complex system is untenable, and reduction of the problem to the linear, isotropic case is used to arrive at the more familiar definitions of Young's modulus and other properties described below.

Friedenwald defined the *ocular rigidity coefficient* and performed some of the earliest characterizations of ocular biomechanical properties.[26] A pressure–volume curve is recorded during a volumetric distention experiment and provides a measure of whole-globe stiffness. This relationship is characterized by the slope of the pressure–volume curve (mmHg/μL). It is nonlinearly dependent on IOP and has been shown to increase with age.[27] Its utility in refractive surgery remains to be demonstrated and may be limited to the extent that corneal contributions to rigidity are inseparable from scleral and uveal components.

The *elastic (or Young's) modulus* may be one of the most critical material properties in understanding the corneal response to refractive surgery[13] and provides an indicator of stiffness. An *elastic* material regains its original geometry when an imposed stress is removed and does so in a reversible manner along the same stress–strain pathway. The elastic modulus is traditionally measured in excised tissue with an extensiometer that measures force generation during steady axial elongations of the sample. The slope of *stress* (force per unit area, N/m^2) over *strain* (a dimensionless quantity defined by the current length divided by the starting length) is calculated for a representative portion of the curve. A high modulus indicates a stiff or low-compliance material. While most biological soft tissues approximate linear elastic behavior when a small range of stresses is considered, their overall elastic behavior is highly *nonlinear*. A linear approximation can be obtained from the instantaneous slope of the stress–strain curve (*tangent modulus*) or as a chord between two points on the curve (*secant modulus*).[28]

In Figure 81.3, *A*, an example of nonlinear elastic behavior in a donor cornea specimen is presented. Nonlinearity arises from an initially slow uptake of load as the collagen takes up slack, followed by stiffening as maximal fibril recruitment is approached. *Plastic* responses such as *yield* and *failure* occur when a permanent strain is incurred and the material does not recover its original configuration upon unloading.

The range of reported values for the elastic modulus of the human cornea spans orders of magnitude.[29] Although some biological variability is expected, this variability also reflects the challenges of obtaining representative data with a range of tissue hydrations, loading conditions, and experimental techniques in ex vivo tissue. It should also be clear from the above discussion that a nonlinear function does not allow definition of a single modulus value but, instead, requires its definition as a function of load or as a mean value over a specified loading interval. Membrane inflation experiments in normohydrated donor globes provide a more physiological alternative to extensiometry[30] but do not abrogate the ultimate need for in vivo measurement techniques.

Poisson's ratio is a conversion for relating strain in one direction to secondary strain in the transverse direction. A stromal lamella under tensile stress will thin or narrow to some degree in its other dimensions. An out-of-plane/in-plane strain ratio of 0.49 is typically assumed because it approximates the cornea's fluid-filled, near-incompressible status. In reality, Poisson's ratio is a true physical property of the tissue and not a constant; as such, its role as a variable in elastic, plastic, and viscoelastic thinning of the residual stromal bed (RSB) after LASIK could be important.

Viscoelastic properties arise from the time-dependent nature of biomechanical responses and are a feature of all biological soft tissues. These properties are represented by the phenomena of *hysteresis*, *stress relaxation*, and *creep*. As opposed to the symmetric loading and unloading behavior of purely elastic materials, viscoelastic materials return to their pre-stress configuration via different stress–strain pathways that depend on loading rates. This discordance between loading and unloading behavior can be partially characterized by *hysteresis*. Viscoelastic *creep* is a time-dependent elongation that occurs under a sustained stress (such as IOP) and may be an important contributor to the mechanics of ectasia.[31] Finally, Figure 81.3, *B* illustrates a viscoelastic *stress relaxation* experiment in which strain is increased then held constant while a slow time-dependent relaxation of the load is observed.

Shear strength describes stromal resistance to sublayer sliding. The shear resistance provided by collagen interweaving and other matrix forces may be related to metrics such as the interlamellar cohesive strength.[11,21] Corneal shear strength is low relative to its tensile strength[32] but provides a mechanism for load transfer between lamellae that may contribute to hyperopic shift after photoablation according to the model presented in Figure 81.2 and discussed below.[10] Abnormalities of bending strength and lamellar sliding also have potential relevance in the pathogenesis of ectasia.[24,33,34]

COMPUTATIONAL MODELING IN REFRACTIVE SURGERY

The ultimate goal of any corneal modeling effort in this setting is development of an accurate simulation vehicle for optimizing the accuracy and safety of refractive surgery procedures. Models of corneal refractive surgery range from conceptual models to complex computational simulations that integrate structural, biomechanical, and optical representations of the corneal response. Complex structures like the cornea can be divided into a mesh of representative geometries ('finite elements') with their own material properties; the physical solutions during a surgical or disease simulation can then be obtained iteratively from element to element until the solution for the entire structure is obtained. Geometric data sets can be used as a scaffold for superimposing substructural features. The predictive value of any model depends on valid input, and recent progress in anterior segment imaging has improved our ability to accurately measure corneal geometry.

Finite element analysis has been used in attempts to simulate surgical results in radial keratotomy,[35–38] astigmatic keratotomy,[39–41] phototherapeutic keratectomy,[42,43] PRK,[44,45] and LASIK.[45–47] Even with the most elegant models, however, assignment of appropriate material properties is a great challenge and has a profound impact

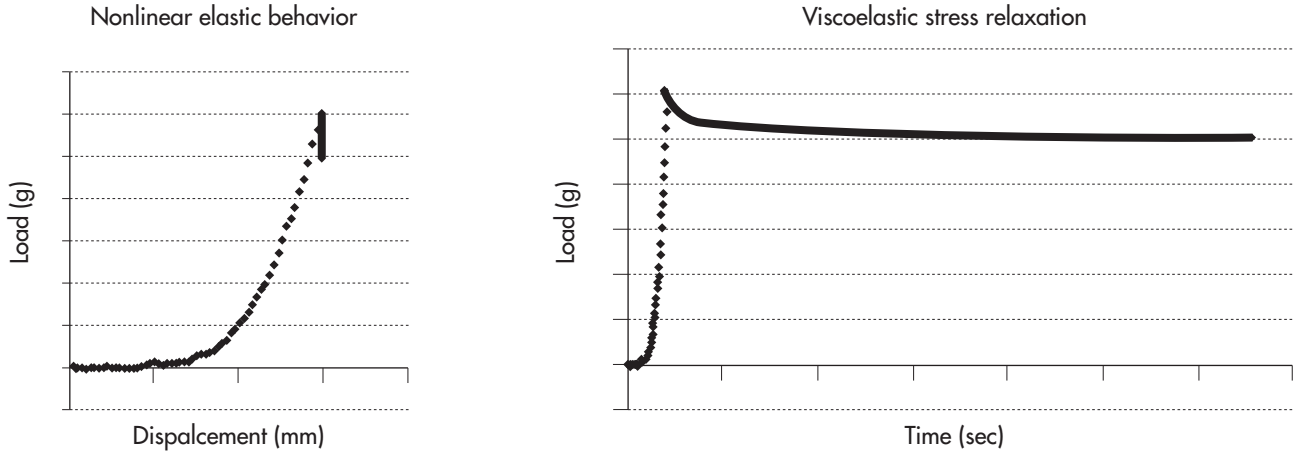

Figure 81.3. Experiments illustrating elastic (*A*) and viscoelastic (*B*) behavior in a 7-mm, full-thickness horizontal corneal strip from a 63-year-old donor. *A*, Progressive stretching of the sample and measurement of the induced load allow calculation of the elastic modulus from the slope of the stress–strain relationship. The relationship is nonlinear. *B*, A second experiment in which a constant displacement is imposed in the same sample demonstrates time-dependent stress relaxation, a viscoelastic property of biological soft tissues.

on the accuracy of surgical simulation and optimization. For example, if heterogeneity of the elastic modulus and the stromal swelling pressure are neglected, then an elastic thin-shell model of the cornea fails to predict hyperopic shift in PTK as discussed below.[42] Models that incorporate these properties and their heterogeneous distribution[37,43] are better capable of representing clinical results but are still exquisitely sensitive to errors in specified material properties, particularly the elastic modulus.[13,31] To the extent that material property values from ex vivo experiments reflect in vivo properties of the typical surgical candidate, models based on such measurements have the potential to reduce systematic error at the populational level. The utility of computational simulations will be further increased when clinical techniques for measuring key properties in individual patients are refined and then integrated into the modeling process.

CLINICAL MEASUREMENT OF CORNEAL BIOMECHANICAL PROPERTIES

Traditional extensiometry, despite its limitations, has revealed deficits in elastic tensile strength in keratoconus[48] and suggests a diagnostic role for elastic modulus determination in the clinical setting. The obvious lack of suitability for in vivo testing, however, has led to accelerated efforts to develop nondestructive, noninvasive tools for clinical biomechanical property measurement.

Ultrasonic shear wave propagation velocity has been investigated as a method for measuring the elastic modulus without need for tissue destruction.[49,50] Recent experiments with a prototype handheld device (Sonic Eye, PriaVision, Inc., Menlo Park, CA) have demonstrated the ability to measure directional and regional stiffness differences in porcine[50] and human donor globes,[51] corneal stiffness changes with keratotomy, and marked increases in stiffness with stromal collagen crosslinking, which also produce artifactual increases in applanation pressures.[50] Young's modulus is related to the product of corneal density and the square of the wave velocity measured between the two transducer tips, which are positioned along the anterior corneal arc. Stiffness is measured *in the plane of the lamellae*, similar to traditional extensiometry, and thus may be more comparable to published elastic modulus values than properties elicited from out-of-plane perturbations. Signal attenuation in the presence of the precorneal tear film is the primary challenge to clinical implementation, and developmental efforts are ongoing.

The commercially available Ocular Response Analyzer (ORA, Reichert, Inc., Depew, NY) utilizes a high-speed air-puff to quantify the dynamics of corneal deformation and recovery as an indicator of corneal hysteresis (CH).[52] Figure 81.4 illustrates a typical response waveform. In- and outgoing applanation events are indicated by the two peak intensities of reflected infrared light (in red), and the air pressures (in green) intersecting these two applanation events are recorded as P_1 (ingoing) and P_2 (outgoing). Corneal hysteresis is simply the difference between the in- and outgoing applanation pressures ($P_1 - P_2$), where a higher CH indicates a greater capacity for absorption of kinetic energy (a *viscoelastic* property). Eyes with more viscoelastic 'momentum' produce a higher CH due in part to a delay in deformation (and therefore applanation) relative to the onset and decay of the pressure stimulus. As illustrated in Figure 81.4, this viscous delay shifts the applanation peaks to the right, resulting in a rise in P_1, a decrease in P_2, and an increased CH. The corneal resistance factor (CRF) is derived from the same dual-applanation signal and is proposed to be a measure of the *elastic* resistance of the cornea. The formula for the CRF is similar to CH but incorporates an empirical adjustment (k_{CRF}) to P_2 ($CRF = P_1 - k_{CRF}P_2$) designed to reflect a greater dependence on central corneal thickness (CCT) and IOP. The ORA also reports two IOP values: the Goldmann-correlated IOP (IOP_G) derived from the mean of P_1 and P_2 and the cornea-compensated IOP (IOP_{CC}). The IOP_{CC} was designed to be less sensitive to corneal properties than traditional applanation tonometry and was calibrated empirically to be relatively unaffected by LASIK.

The ORA is being investigated in glaucoma, keratoconus, and refractive surgery patients. Both CH and CRF are lower after LASIK[52,53] and in eyes affected by keratoconus.[52] Lower CH has also been associated with a higher risk of visual field progression in a cross-sectional study of glaucoma patients.[54] The role of these measurements in screening refractive surgery candidates for ectasia risk or evaluating the risk of optic neuropathy in glaucoma suspects is an important area of investigation, and the ORA clearly provides novel information about biomechanical risk for which CCT is an incomplete proxy. Both CH and CRF measure the *bending resistance* to a high-speed insult without regional or directional discrimina-

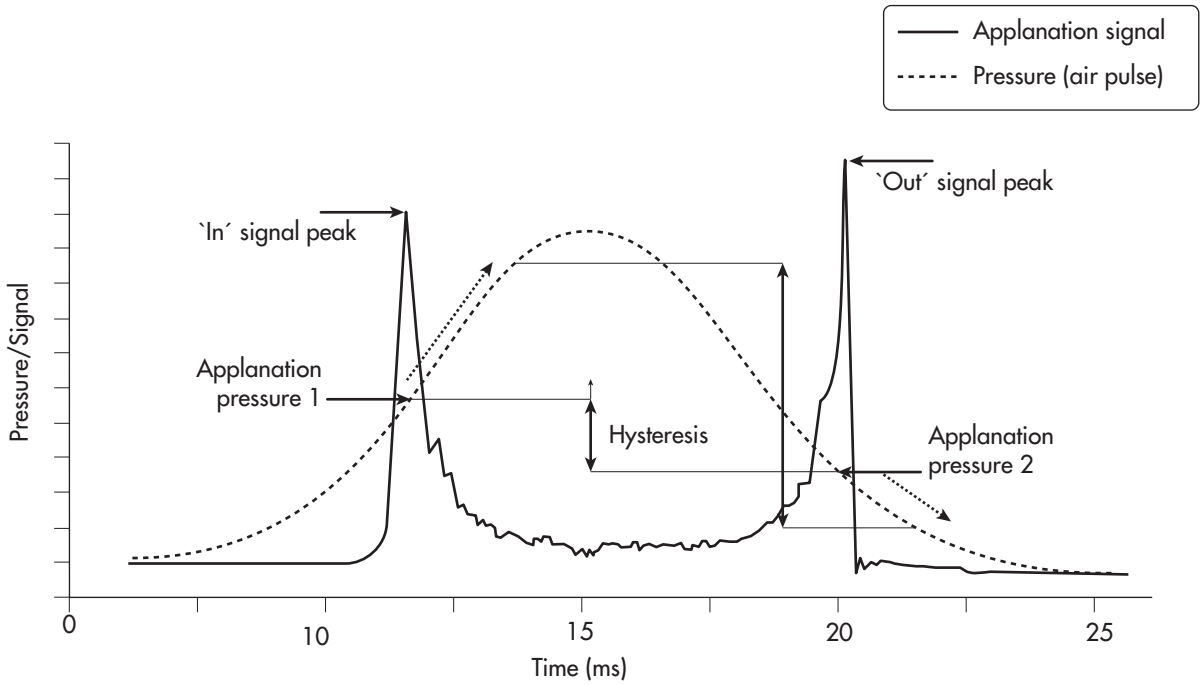

Figure 81.4. A typical response waveform for the Reichert Ocular Response Analyzer. In- and outgoing applanation events are indicated by the two peak intensities of reflected infrared light (in red). The air pressures (in green) intersecting these two applanation events are recorded as P_1 and P_2. Corneal hysteresis (CH) is the difference between the in- and outgoing applanation pressures ($P_1 - P_2$). A higher CH indicates a greater viscoelastic capacity for absorption and thus damping of kinetic energy. Eyes with more viscoelastic damping capacity result in greater dissipation of perturbation energy and thus a delay in applanation relative to air pressure. This viscous delay shifts the applanation peaks to the right, resulting in a higher P_1, a lower P_2, and an increase in CH. (Figure adapted from Luce[52] and modified.)

tion, and the values are not directly comparable to measurements of the corneal elastic modulus by techniques described above. The morphology of the infrared signal contains additional information that is not represented by CH or CRF, and further analysis of these signal features is underway.

Other emerging techniques include measurements of bending resistance to stepwise indentations during Placido-ring topographic imaging,[55] interferometric determinations of apical displacement during IOP changes,[56] and two- and three-dimensional corneal optical coherence elastography.[57] Because different combinations of perturbations and imaging modalities interrogate entirely different aspects of the ocular biomechanical state, investigators will need to determine which measures are best suited for answering a particular clinical question.

THE BIOMECHANICAL RESPONSE TO KERATECTOMY

Several forces contribute to the preoperative steady state and undergo complex disruptions during corneal refractive surgery (Fig. 81.2). The hydrophilia of stromal glycosaminoglycans contributes to a negative intrastromal fluid pressure under which the entire stroma is heavily compressed.[58] The IOP manifests both as a centripetal force and as a lamellar tension[19] to counteract this stromal swelling pressure, which is also balanced by tear film evaporation, the epithelial and endothelial barriers, and active endothelial transport.[59] Cohesive forces between lamellae provide further resistance to expansion of the interfibrillary space during swelling, and their greater relative strength in the peripheral and superior cornea may have implications for the inferocentral predilection of keratoconus[11] and in induced astigmatism after ablation and flap creation.

During LASIK, PRK, or any other procedure involving central ablation, an immediate circumferential severing of corneal lamellae is produced. In simple elastic shell models, this results in a forward herniation that, if considered alone, would result in corneal steepening.[42] However, central ablation also relaxes lamellar tension in residual peripheral lamellar segments, which decreases local resistance to swelling and results in peripheral stromal thickening.[10] Expansion of the peripheral stroma's dimensions and any limbal displacement owing to lamellar disruption may generate centripetal stress in underlying lamellae through the dense interlamellar connections at the margin of the ablation zone. Because the central portions of these lamellae comprise the new anterior surface, there is resulting central flattening (Fig. 81.2). This flattening response appears to dominate any central steepening tendency when ablation is limited to the anterior stroma, but progressively deeper insults result in a net shift toward corneal steepening[14,60] and can ultimately result in ectasia. The elastic modulus of the residual stroma bed and the shear (sliding) resistance in the bordering peripheral stroma may influence the rate of ablation-dependent flattening and the depth at which flattening effects lose ground to pre-ectatic elastic steepening.

This model provides a rationale for hyperopic shifts that occur even before the onset of epithelial healing and in the absence of a concave ablation profile. This response is most clearly demonstrated by unintended hyperopic shift during PTK, in which an ablation depth-dependent flattening can be observed in donor and clinical studies despite attempts at a uniform (and thus plano) ablation profile.[10,61] In a multivariate paired-control donor analysis of PTK-

induced hyperopia, biomechanical peripheral thickening was more strongly associated with the degree of flattening than the measured ablation pattern itself.[10] While the relative influence of ablation profile is presumably greater in ametropic treatments than in PTK, this analysis demonstrated in a controlled fashion that changes in central curvature are not solely a product of ablative shape subtraction.

In clinical practice, an intrinsic flattening response augments the effects of a myopic procedure and impedes efforts to correct hyperopia. This is supported by the fact that large overcorrections must be attempted to effectively treat high levels of primary hyperopia.[62] If an identical algorithm is used to treat secondary hyperopia of the same magnitude (i.e. after previous myopic LASIK), significant overcorrection results. This difference in effectiveness can be attributed to fundamental differences between the biomechanical status of a virgin cornea and that of a surgically altered cornea that has adapted to an entirely different load-bearing milieu. Larger treatment zones may reduce the tendency toward biomechanical central flattening[63] by distancing the central cornea from the effects of peripheral stromal poroelastic forces.

A COMPARISON OF SURFACE ABLATION AND LASIK

During any procedure involving central ablation, an immediate circumferential severing of corneal lamellae occurs and triggers the cascade of biophysical changes presented in the previous section. LASIK clearly represents a more complex biomechanical insult than surface ablation (PRK, LASEK, or epi-LASIK), and its effects are additive to those described above. First, the total depth of the lamellar disruption is greater for a given refractive correction and will alter the balance between hyperopic effects and steepening effects from weakening of the corneal cap. Depth-dependent differences in corneal properties will affect this balance and likely vary from eye to eye and patient to patient.[64] Creation of the LASIK flap even without subsequent photoablation induces hyperopia, astigmatism, and higher-order aberrations that depend on hinge position and microkeratome type.[65,66] The meniscus-shaped flap produced by some mechanical microkeratomes interrupts more lamellae in the mid-peripheral bed than in its center, possibly potentiating the biomechanical response[67] and confounding nomogram adjustments based on central flap thickness estimates. The optical effects of flap creation may not be limited only to changes in the residual stromal surface but may also extend to shape changes *within the flap* related to the circumferential keratotomy of flap creation.[64]

To account for the separate effects of flap creation and photoablation, some have investigated a staged procedure incorporating a remeasurement delay after flap creation.[68,69] This approach is more strongly advocated for correction of ametropia and astigmatism after penetrating keratoplasty, where the biomechanical and wound healing responses to flap creation are far less predictable.[70,71] Sub-Bowman's keratomileusis (SBK) involves creation of a stromal-epithelial flap 90 μm in depth or thinner, often facilitated with a femtosecond laser, and could provide modest advantages over traditional LASIK by reducing variability associated with the depth-dependent biomechanical response. Femtosecond lasers may also allow more precise specification of flap morphology, thus reducing the astigmatic effects of flap creation and improving nomogram quality by reducing variability between patients. But even absolutely repeatable flap geometry cannot eliminate the differences in residual stromal and flap responses due solely to the specific biomechanical makeup of the patient's cornea. Biomechanically 'neutral' flap patterns could be explored to minimize unintended refractive effects that affect the aggregate of patients, but predictors of individual responses will be necessary to prevent undesired outcomes in patients not represented by the mean.

By circumventing the immediate and long-term biomechanical effects of flap creation on the cornea, surface ablation significantly reduces the number of variables and range of effects that can adversely affect the optical predictability of laser vision correction. But many of these advantages are offset by the greater impact of wound healing on the predictability of surface ablation procedures,[64] which is a subject beyond the scope of this chapter.

ECTASIA

Debate continues about whether postrefractive surgery ectasia is an iatrogenic condition or a subclinical keratoconus that manifests after laser vision correction. Clinical risk factors for post-LASIK ectasia include high myopia, forme fruste keratoconus, and low RSB thickness.[72] While a lower limit of 250–300 μm has been recommended for the RSB thickness,[73] its actual value cannot be wholly determined preoperatively because it is affected by microkeratome predictability and a stromal ablation rate that varies with hydration and from patient to patient. Most importantly, even the most accurate estimates of RSB thickness will not fully account for elastic and viscoelastic risk factors, just as presence of a presumably normal CCT does not rule out keratoconus.[74] Because focal weaknesses produce marked increases in local stress, spatial inhomogeneities in material strength may be more important than bulk properties in some cases. Conversely, evenly distributed material strength may allow for long-term stability of some corneas with an RSB thickness less than 250 μm.[75]

Previous sections have commented on possible biomechanical abnormalities in keratoconus and post-LASIK ectasia. Elastic steepening with progressive central thinning is inversely related to the elastic modulus of the residual central corneal bed.[13] However, an elastic forward protuberance of the cornea must be distinguished from ectasia. Although the former can be a precursor of ectasia,[13] ectasia requires a progressive deformation, by definition, and is therefore a viscoelastic phenomenon.[31] Furthermore, immediate postoperative increases in central posterior corneal elevation often noted on scanning slit topography do not necessarily represent a pre-ectatic anterior vaulting. Instead, posterior corneal steepening may reflect a relative *posterior* movement of the peripheral stroma in response to the differential swelling described previously.[10,76] Artifactual posterior steepening can also result from minification of the central posterior radius of curvature after myopic photokeratectomy.[77] LASIK may introduce a greater risk of viscoelastic failure than surface ablation procedures because of deeper forays into the posterior stroma. Lower keratocyte density, less collagen interweaving, and more hydrophilic proteoglycans may all contribute to a region more prone to viscoelastic failure and abnormal repair. Intrastromal ring segments and ultraviolet light/riboflavin-mediated collagen crosslinking are two biomechanical approaches under investigation for modifying structural stability in affected patients.

IOP MEASUREMENT AFTER REFRACTIVE SURGERY

Friedenwald acknowledged the importance of corneal resistance in applanation tonometry in 1937.[26] Many studies have demonstrated a decrease in applanation pressures after myopic PRK and LASIK

that was initially attributed to decreases in CCT.[61] Other studies demonstrating decreases in central applanation pressures after hyperopic LASIK—without a decrease in CCT[78]—suggest that a decrease in corneal resistance to applanation does occur and can affect IOP measurement independently of the CCT. A sensitivity analysis of the various factors influencing applanation pressure suggests that the elastic modulus may be considerably more influential than corneal thickness or curvature.[79] Using pneumotonometry to compare responses between PRK and LASIK over 36 months, LASIK exhibited a greater long-term drop in apparent IOP than PRK in two populations with carefully matched refractive corrections, providing support to the possibility of procedure-specific reduction in corneal resistance.[80] This issue and the important role of CCT in risk of progression from ocular hypertension to glaucoma[80] have spawned efforts to distinguish corneal biomechanical properties from true IOP using devices such as the Ocular Response Analyzer[33] and the Dynamic Contour Tonometer (DCT).[68,81] The DCT provides a measure of IOP without applanation of the cornea, thus reducing the influence of corneal properties and corneal thickness on the measurement.

BIOMECHANICS AND WOUND HEALING

The cornea undergoes significant biomechanical alterations during and after refractive surgery. Wound healing is also a major factor in refractive overcorrection, undercorrection, regression, and induction of irregular astigmatism.[82] Wound healing plays a key role in ongoing maintenance and modification of the biomechanical steady state, and investigation at the interface of these fields promises to bring new insights to the field of refractive surgery. For example, a histopathological study in LASIK flaps of organ donors found a relationship between wound maturity and resistance to flap distraction (lifting) forces.[83] Flap cohesive strength was maximal at the flap margins, was associated with hypercellular fibrotic scars, and increased as a function of postoperative time. Flap-edge cohesion was only 28% that of normal specimens, however, and was adversely affected by the presence of epithelial ingrowth. The central interface was characterized by primitive scar and presented far less cohesive strength. The contribution of flap cohesion to the overall biomechanical stability of the cornea is not known but it may be a factor in late flap dislocation and ectasia.

Given that one evolutionary goal of healing is restoration of mechanical integrity,[71] mechanisms must exist by which keratocytes or their derivatives 'sense' local changes in stress or strain and then respond with an appropriate (or inappropriate) series of actions for remodeling such areas to decrease the mechanical stimulus. The matrix-deforming interactions of corneal fibroblasts and collagen gels have been characterized in culture under direct visualization.[72] As our understanding of these processes improves, so will our ability to offer rational interventions for improving the predictability of refractive surgery and minimizing its complications.

ACKNOWLEDGMENTS

This work was supported in part by U.S. Public Health Service grants NIH 8K12 RR023264 (National Center for Research Resources, Multidisciplinary Clinical Research Career Development Programs Grant), 1KL2RR024990, and 1L30 EY017803-01, and by a Research to Prevent Blindness Challenge Grant to the Department of Ophthalmology, Cleveland Clinic Lerner College of Medicine of Case Western Reserve University. The author is a recipient of a Research to Prevent Blindness Career Development Grant. The author thanks Cynthia Roberts, PhD, mentor and colleague, and Todd Doehring, PhD, for his contributions to Figure 81.3.

82 Preoperative evaluation of the refractive surgical patient

Marjan Farid, Roger F. Steinert

INTRODUCTION

A thorough preoperative assessment of a refractive surgery patient and education of the patient based on the result of the evaluation are of paramount importance for achieving successful postoperative outcomes. Determining whether the patient is a good candidate for surgery is the primary question during the evaluation. The preoperative assessments of patients undergoing refractive surgery consist of four elements: (1) a complete medical and ocular history, (2) a comprehensive examination of the entire visual system, (3) ancillary testing of the refractive status and anatomy of the optical system, and (4) information transfer from the patient to the surgeon about the patient's visual needs and expectations and information transfer from the surgeon and staff to the patient about the goals, risks, and outcomes of the treatment options. These key steps drive both technical refractive success and patient satisfaction.

COMPREHENSIVE HISTORY

PAST MEDICAL HISTORY

Medical and surgical history as well as current and prior medications should be well documented during the preoperative assessment. Connective tissue diseases such as systemic lupus erythematosis, rheumatoid arthritis, and polyarteritis nodosa may affect corneal wound healing after surgery. Postoperative corneal melting and perforation have been reported in patients with active or uncontrolled connective tissue diseases.

Patients with diabetes should be considered with caution, as they may also have problems with corneal epithelial healing, with persistent epithelial defects that could take several months to resolve. The judicious use of preoperative and intraoperative artificial tears helps minimize corneal toxicity and decrease the incidence of erosions. Besides the increased risk of retinal disease, uncontrolled diabetes mellitus is notorious for altering the lenticular hydration status with fluctuations in refraction. Multiple refractions may be needed to ensure stability of the refractive error to be corrected prior to surgery. Patients with diabetes also tend to have a hastened progression of cataract formation. This may influence decisions about the type of refractive surgery (e.g. lens extraction and intraocular lens (IOL) implant vs laser in situ keratomileusis (LASIK).

Several medications can also potentially result in poor corneal healing including isoretinoin (Accutane, Hoffman-La Roche, Inc, Nutley, NJ), amiodarone (Cordarone, Wyeth, Collegeville, PA), and sumatriptan (Imitrex, GlaxoSmithKline, Research Triangle Park, NC). Furthermore, medications that worsen dry eye symptoms, including anticholinergics, hormone replacement therapy, and antihistamines, will affect overall corneal epithelial regeneration and healing. Corticosteroids hasten the progression of cataracts. Use of systemic corticosteroids or chemotherapeutic agents will also increase risk of infection and affect healing by affecting immune status, as will HIV and some malignancies.

Unstable refraction and altered corneal hydration states may also be seen in pregnancy and breastfeeding. It is generally recommended to wait at least 3 months after delivery and until breastfeeding has been stopped before considering refractive surgery. Caution should be taken in patients with cardiac pacemakers or defibrillators, as the effects of excimer laser and femtosecond laser electromagnetic emissions are unknown.

OCULAR HISTORY

The pertinent ocular history includes history of dry eye symptoms, blepharitis, recurrent erosions, cataract surgery, glaucoma, and retinal disease or retinal lasers/surgery. A list of ocular medications may clue the physician to current ocular problems. Caution should be taken in patients with a prior history of herpes simplex keratitis. In such patients, prophylactic systemic antivirals for several months before and after surgery are warranted. Precautions and risk awareness need be addressed in patients with glaucoma, as intraocular pressures will be elevated for a brief period of time during the creation of the flap in LASIK and applanation pressure measurements will be artifactually lower postoperatively. A history of retinal surgery or laser treatment for diabetic macular edema or proliferative disease is a relative contraindication to refractive surgery as the visual potential in those patients tends to be suboptimal.

In cases of high amblyopia in the fellow eye, patients should be discouraged from refractive surgery as they should be wearing polycarbonate glasses for protection of their one good eye.

Verification of refractive stability is very important. If the glasses or contact lens prescription has been changing significantly over the past few years (usually defined as greater than 0.5 D in sphere or cylinder), then the patient may not yet be a good candidate for refractive surgery. A history of contact lens wear needs to be obtained. This includes type of contact lens (soft vs. rigid), wearing schedule, length of use, and age of current lenses. The use of contact lenses should be discontinued several weeks prior to refractive surgery. Corneal warpage, or change in the shape of the cornea, can occur with long-term use of contact lenses. As rigid contact lenses have a greater influence on corneal shape, most refractive surgeons recommend that patients discontinue use at least 3 weeks prior to surgery. Soft contact lenses should be discontinued for at least 1–2 weeks prior. Repeat refractions and corneal topography measurements every few weeks may need to be obtained in patients with unstable corneas until stability has been established.

COMPREHENSIVE EXAMINATION

A comprehensive ophthalmic examination starts with measurements of uncorrected visual acuity at distance and near. The power of the current glasses should also be noted and visual acuity with current prescription also obtained. At this point, a manifest refraction should be done with defogging to minimize overminusing the patient. This best-corrected visual acuity should be documented. After dilation, a cycloplegic refraction is performed. If there is a significant (>0.75 D) discrepancy between the cycloplegic and manifest refractions, the patient should be brought back for a repeat manifest refraction. An overminused manifest refraction in the myope or latent hyperopia in the hyperope is usually the culprit.

A pupillary examination should be done prior to dilation. The pupillary examination should show appropriate reaction to light and no pathologic anisocoria or relative afferent pupillary defect before proceeding with refractive surgery. Furthermore, a measurement of the pupil size under mesopic conditions needs to be performed to determine the treatment zone for the laser if conventional treatment is being performed. This can be done with the patient fixating at distance in dim illumination (closely reflecting light during nighttime activities) while using a near card with pupil sizes, or, preferably, with a light amplification or infrared pupillometer. In conventional, nonwavefront-guided ablations, the effect of spherical aberration can be reduced when the optical zone is larger than the mesopic pupil size. Pupil size alone, however, does not seem to be an accurate predictor for who will experience postoperative halos and glare.

Ocular motility and presence of any tropias or phorias should also be evaluated at this time. Altering best-corrected visual acuity may cause phorias to become tropias. Patients need to be made aware of this risk and appropriate preoperative orthoptic evaluation done. Confrontation visual fields and general orbital anatomy assessments should also be done on all patients. High brows with deeply set globes or narrow palpebral fissures will present a difficulty in flap creation with the microkeratome, prompting the use of a femtosecond laser to create the flap or a shift to surface ablation instead of LASIK. Placing of the suction ring for the femtosecond laser can also be challenging in patients with extremely narrow palpebral fissures.

A complete slit-lamp examination starting with an external examination to a full dilated fundus examination should be performed routinely as part of the initial preoperative assessment. External disease such as blepharitis or ocular rosacea should be noted and treated prior to embarking on any type of ocular surgery. Particular attention should be given to the corneal surface to assess for aqueous tear deficiency, including a diminished tear meniscus, short tear film breakup time, and presence of punctate staining of the corneal or conjunctival surface. Refractive surgery will tend to worsen dry eye issues, especially during the first few postoperative months. Patients should be made aware of this risk and optimized with judicious use of artificial tears preoperatively and possible placement of punctal plugs before or during surgery. Careful examination of the cornea should be done to rule out any undiagnosed corneal dystrophy. Endothelial dysfunctions such as Fuchs' dystrophy and corneal thickening or frank edema are contraindications for refractive surgery. Basement membrane dystrophies can increase the risk of flap complications, and, in that situation, surface ablation treatment (e.g. photorefractive keratectomy (PRK)) would be preferable to LASIK, as PRK may be therapeutic. Signs of corneal ectasia such as keratoconus or pellucid marginal degeneration are absolute contraindications to refractive surgery, as postoperative corneal instability and ongoing ectasia are likely in these patients.

The dilated examination should note the presence of cataract or any lenticular changes that may alter the decision to do corneal laser treatment. Even visually insignificant changes in the lens, especially in patients over the age of 50 years, should prompt discussion with the patient of the future need for cataract surgery and the alternatives of postponing refractive correction until the time of cataract/IOL surgery or undergoing refractive lens exchange in lieu of corneal laser ablation. If the patient chooses to proceed with corneal laser treatment, the preoperative refractions and keratometry measurements as well as amount of laser ablation performed should be given to the patient to aid the future cataract surgeon in the IOL calculations. Shallow anterior chambers should be noted as it is a contraindication for certain phakic IOLs. An anterior-segment optical coherent tomography (OCT) scan (Visante OCT, Carl Zeiss Meditec, Dublin, CA) can be helpful in making this assessment. Finally, the fundus examination should rule out macular or optic nerve pathology that may affect best-corrected visual acuity. Histories of laser treatment for diabetic retinal disease or macular degeneration are contraindications for refractive surgery. Optic nerve disease, such as advanced glaucoma or optic nerve pallor, is also a general contraindication for refractive surgery. Lastly, patients with high myopia or history of retinal tears/detachments should be advised that laser vision correction will not lower their risk of further retinal disease. Strict retinal monitoring and retinal detachment precautions would still need to be observed.

Intraocular pressure measurements should be done on all patients after corneal topography and refraction. There are multiple risks in refractive surgery for patients with glaucoma. Flap creation, whether it is done with a microkeratome or the femtosecond laser, will significantly elevate the intraocular pressure for a short period of time intraoperatively and may snuff out the nerve in advanced glaucoma. Furthermore, patients need to be on corticosteroids, often for several months after surgery and will risk having steroid response

elevations in their pressures. Lastly, the thinning of the cornea after refractive surgery will affect accurate IOP measurements in the future.

ANCILLARY TESTING

There are several additional tests including corneal topography, pachymetry, and wavefront analysis that need to be obtained during the preoperative assessment, which will guide treatment options. Corneal topography is obtained to determine the overall shape of the cornea and to detect any irregular astigmatism that may indicate subclinical corneal ectasia. Computerized videokeratography has largely taken the place of manual keratometry for determining corneal curvature in the setting of keratorefractive surgery preoperative assessment. Placido disk, scanning slit beam, rotating Scheimpflug photography, and high-frequency ultrasound systems are some of the different techniques employed to gather data on corneal shape. By imaging the cornea, these systems of topography provide color maps that represent the overall curvature and power of the cornea. When using a microkeratome for creating the LASIK flap, flat corneas (<40 D) may be at increased risk for small flaps or free caps whereas steep corneas (>48 D) increase the risk of buttonhole flaps. With the advent of the femtosecond laser for flap formation, this problem has mostly been nullified. Spherical corneal shape or regular astigmatism indicates a generally healthy cornea for keratorefractive surgery, whereas a significant finding of irregular astigmatism may indicate keratoconus, pellucid marginal degeneration, or corneal warpage from contact lens wear. If contact lens-induced warpage is suspected, serial topography and refraction measurements should be obtained to ensure that the cornea has returned to a stable shape and refraction prior to keratorefractive surgery. Preoperative topographic analysis can also disclose any disparity between the refractive astigmatism and the corneal cylinder, possibly accounted for by lenticular astigmatism, significant posterior corneal curvature, or inaccurate refraction. In the case of lenticular astigmatism, because the refractive astigmatism is treated with the laser, the patient needs to be aware that there may be a return of astigmatism in the future following cataract surgery. After surgery, the preoperative topographic analysis provides the baseline against which postoperative results are measured.

In evaluating patient risk factors for postoperative ectasia, certain clinical signs should raise suspicion and videokeratography plays an important role in confirming the diagnosis. A group of refractive surgeons identified possible risk factors for the development of ectasia after refractive surgery.[1] In addition to the typical clinical signs of keratoconus, high myopia, thin corneas, a low calculated residual stromal bed thickness, and asymmetrical corneal steepening on topography raise suspicion for risk of ectasia. There is no single distinguishing feature or clinical test that can definitively predict which normal-appearing corneas will develop ectasia after LASIK. The report concluded that videokeratography should be performed on all patients preoperatively and that any asymmetric inferior corneal steepening or asymmetric bowtie patterns with skewed steep axes, which are suggestive of forme fruste keratoconus, are unsuitable for LASIK. Similarly, 'crab-claw' patterns with central flattening are high risk for pellucid marginal degeneration and should be avoided for LASIK. In the case of irregular inferior steepening on topography, most physicians will use adjunctive pachymetry measurements showing inferior or inferocentral corneal thinning correlating with the topography before making a final diagnosis of subclinical ectasia. The decision to perform LASIK should be based on multiple factors and not necessarily rely on topography alone. Some of these cases of apparent subclinical keratoconus may be artifacts of the topography system. In Placido image systems, deviations of the corneal apex from the visual axis are generally depicted as patterns resembling keratoconus. Patients who do not fixate precisely may also give this type of pattern. Finally, development of ectasia can occur even in the absence of any risk factors, suggesting that in some cases ectasia may not necessarily mean that LASIK was the causative factor.

BOX 82.1 RISK FACTORS FOR POSTOPERATIVE ECTASIA*

1. Keratoconus
2. Subtle signs of keratoconus on keratometry (non-superimposed mires, irregular mires)
3. High myopia
4. Thin corneas
5. Low calculated residual bed thickness
6. Abnormal video keratography such as:
   a. asymmetric inferior corneal steepening
   b. asymmetric bowtie patterns with skewed steep axes
   c. 'crab claw' patterns with central flattening
   d. interior corneal thinning

*Source: Binder PS, Lindstrom RL, Stulting RD, et al. Keratoconus and corneal ectasia after LASIK. J Cataract Refract Surg 2005; 31(11): 2035–2038.

There are a paucity of data in regard to surface ablation and ectasia. It is not yet known whether risk factors for postoperative ectasia after LASIK also predict ectasia after surface ablation.

To determine adequate corneal thickness prior to surgery, corneal pachymetry measurement is performed. Corneal pachymetry can help diagnose subclinical keratoconus when measurements are unusually thin (especially in the inferocentral area) or pending endothelial decompensation when readings are unusually thick. In both of these situations, keratorefractive surgery would be contraindicated. In the case of a Fuchs' suspicion, specular microscopy may be a helpful adjunct. Besides ultrasound pachymetry, pachymetry maps are now available on several topography systems such as anterior-segment OCT and are helpful in localizing areas of thinning at various locations.

Calculation of residual stromal bed thickness is vitally important for optimizing results and lowering the risk of postoperative ectasia. The strength and integrity of the postoperative cornea depend on the amount of residual stromal bed thickness. The residual stromal bed thickness is calculated by subtracting the flap thickness and the amount of laser ablation depth from the preoperative central pachymetry measurement. There are no conclusive data on exactly how much residual stromal bed thickness will cause instability and ectasia. Many surgeons currently utilize a guideline of a minimum of 250 µm and some surgeons add a further limit of 50% of the preoperative corneal thickness, whichever is greater. A specific minimum acceptable preoperative pachymetry limit is not yet established, but some surgeons view any cornea thinner

than 470–480 μm as a contraindication to LASIK, even with entirely normal-appearing topography.

The actual flap thickness obtained with the microkeratome is variable. Intraoperative pachymetry to determine flap thickness should be considered if there is a risk of inadequate residual stromal bed thickness. If the calculated residual stromal bed would measure below the acceptable minimum, then the flap should be replaced and a surface ablation such as PRK should be considered as a later procedure after the flap has healed.

A wavefront optical analysis has become commonplace in preoperative assessments for keratorefractive surgery. A detailed evaluation of higher-order aberrations of the visual system is obtained. This information can then be directly fed into the excimer laser computer, which then performs a wavefront-guided or 'custom' ablation. This system therefore not only treats lower-order aberrations (myopia, hyperopia, and regular astigmatism) but also addresses the higher-order aberrations such as spherical aberration and coma that may cause significant visual disturbances despite good high-contrast visual acuity. The wavefront analysis has the potential for being particularly valuable in retreatments and in the evaluation of persistent postoperative visual disturbances. Although the treatment is based on the wavefront analysis, the surgeon should carefully compare the data to the manifest refraction to prevent input errors.

PATIENT EXPECTATIONS

An understanding of the patient's expectations and motives for desiring refractive surgery is the most important part of the preoperative assessment. The refractive and emotional goals of the patient should be discussed. Individuals who have unrealistic expectations such as a guarantee of 20/20 vision and 'perfect' results or believe that refractive surgery will 'change their lives' should be discouraged from having refractive surgery. Candidates should be motivated by a desire to reduce their dependence on glasses or contact lenses. The occupational and recreational activities of the patient should also be discussed. The refractive goals of the patient may vary based on their social and occupational needs. Furthermore, the physician will need to know if the patient's activities place him or her at a higher risk for ocular trauma. In the case of a wrestler or basketball player, for example, the physician may opt to perform a surface ablation where a risk of flap trauma would not be an issue.

A discussion of the patient's age and the issue of presbyopia should be done at this time. Patients need to understand that after the age of 40 years, accommodation for near work will become compromised. Myopic patients, who could read well by simply taking off their glasses, need to understand that once they are corrected to emmetropia, they will not be able to read without glasses. A discussion regarding monovision should take place with these patients. In monovision, the dominant eye is usually treated for distance, and the nondominant eye is left slightly myopic for near vision. The degree of monovision for the near-corrected eye is determined based on patient's desires and amount of anisometropia tolerated. The side effects of monovision including loss of depth perception and anisometropia should be discussed with the patient. Before committing to monovision, a trial frame simulation and, in many cases, a contact lens trial can be given to determine if the patient will be happy with the refractive goal.

PATIENT EDUCATION AND INFORMED CONSENT

The final element in the preoperative evaluation, therefore, is the determination that refractive surgery in general and one or more specific procedures in particular are appropriate for the individual patient. For the physician, this assessment is a combination of an analysis of the objective outcome data and of the patient's understanding of the procedure and expectations. For the patient, a fully informed decision requires the transfer of large amounts of information about refractive errors, the treatment method, the risks and benefits of the proposed treatment, and the alternatives. A discussion of the expected uncorrected visual acuity, possible need for reading glasses after surgery, the chance of needing an enhancement, and whether or not maximal surgery is being performed initially needs to take place. Common side effects including halos/glare, an overall change in quality of vision, and worsening dry eye symptoms need to be addressed. Furthermore, the patient also needs to be aware of the risks of severe complications, including loss of best corrected visual acuity and severe visual loss, as well as flap complications and the possible need for revision due to displacement, striae, or epithelial ingrowth. The alternatives to refractive surgery including glasses or contact lenses should be offered.

The informed consent should be read and reviewed by the patient prior to surgery and before dilation or sedation. Patient education and informed consent is a complex process that is never perfect. Aids to effective communication of technical material include brochures, booklets, videotapes, and the consent form itself. These do not replace, but only supplement, a personal discussion with a professional and the opportunity for the patient to ask questions.

83 Interpreting corneal topography, tomography, and wavefront analysis

Carole A. Cooke, Charles N. J. McGhee

As a result of the emergence, development, and refinement of excimer lasers over the last quarter century as well as the exponential public interest in the permanent surgical correction of refractive errors, refractive photoablative surgery is now widely accepted by ophthalmologists and the general public. Driven by the increased interest in refractive surgery and key technical developments such as the personal computer and video frame grabbers, there also have been dramatic developments in videokeratoscopy and corneal analysis in the same time period. In the era of photorefractive keratectomy (PRK), laser in situ keratomileusis (LASIK), incisional refractive surgery, and clear lens extraction, a thorough understanding of corneal topography, tomography, and wavefront analysis is essential for any ophthalmologist who performs corneal or cataract and refractive surgery or who manages patients who have previously had refractive procedures.

In the refractive surgery setting, corneal topography, tomography, and wavefront analysis are utilized in three main areas: (1) accurate assessment preoperatively, (2) determining and monitoring change after surgery, and (3) planning enhancement procedures. These issues, although inter-related, will be discussed separately in this chapter.

ASSESSING THE REFRACTIVE SURGERY PATIENT PREOPERATIVELY

Before refractive surgery it is imperative that patients are carefully screened for potential corneal abnormalities. The surgeon should always personally examine the topography/tomography map for each case preoperatively.[1] In order to become competent in detecting the abnormal, a thorough knowledge of topography of the normal cornea is obviously vital.

THE NORMAL CORNEA—TOPOGRAPHY AND TOMOGRAPHY

Placido-based corneal topography is discussed in greater detail in Chapter 9 by Klyce and Oshika, and the essentials of corneal tomography are covered in Chapter 10 by Wheeldon and McGhee; therefore, only a concise review of the relevant interpretation of these investigations with respect to refractive surgery will be provided in this chapter.

The normal cornea is a prolate shape that flattens peripherally, especially in the nasal region.[1] Although the exact topographic features of each cornea are unique,[2] generally the central cornea has an average radius of curvature of 7.8 mm, which equates to an average central power of 43.5 D.[3] However, the range of power found in the normal human cornea is 39.0–48.0 D, and a very small percentage of emmetropic patients with normal corneas can have a central power as high as 50.0 D or more.[4] Interestingly an individual's corneas are often nonsuperimposable mirror images of each other, i.e. they exhibit enantiomorphism[2] (Fig. 83.1), and knowledge of this concept is useful in that comparison of corneal topography with the contralateral eye may help in deciding whether a cornea is 'normal' or not.

Bogan and coworkers[5] initially described a now widely recognized classification of computerized corneal topography illustrating the variation in a normal population. They described five subgroups based on patterns seen on color-coded topographic maps: round, oval, symmetric bow tie, asymmetric bow tie, and irregular. Some workers include oval with round in a combined category because neither is associated with significant corneal astigmatism. Analysis of corneal topographic maps with too sensitive a scale, i.e. small dioptric steps, can be confusing by highlighting minor features that are not clinically relevant.[1] Smolek and coworkers, building on their earlier work, have proposed a Universal Standard Scale (USS) based on both scientific principles and clinical usefulness where the contour interval is set to 1.5 D.[6] Most corneas are toroidal aspheres and, as the prevalence of astigmatism increases with increasing ametropia,[7] it is unsurprising that the most common patterns identified are symmetric and asymmetric bow ties.[5] Whilst placido-based corneal topography will only measure corneal surface aberrations, wavefront analysis includes aberrations from the eye as a whole.

The Orbscan (Orbtek, Inc.) is discussed fully in Chapter 10. Currently, Orbscan is perhaps the most widely used topography instrument for corneal surgeons;[8] therefore, normal values have been included in this chapter. Curvature maps are comparable to other instruments, but anterior and posterior elevation maps can also be created using a best-fit sphere to the surface measured. This allows

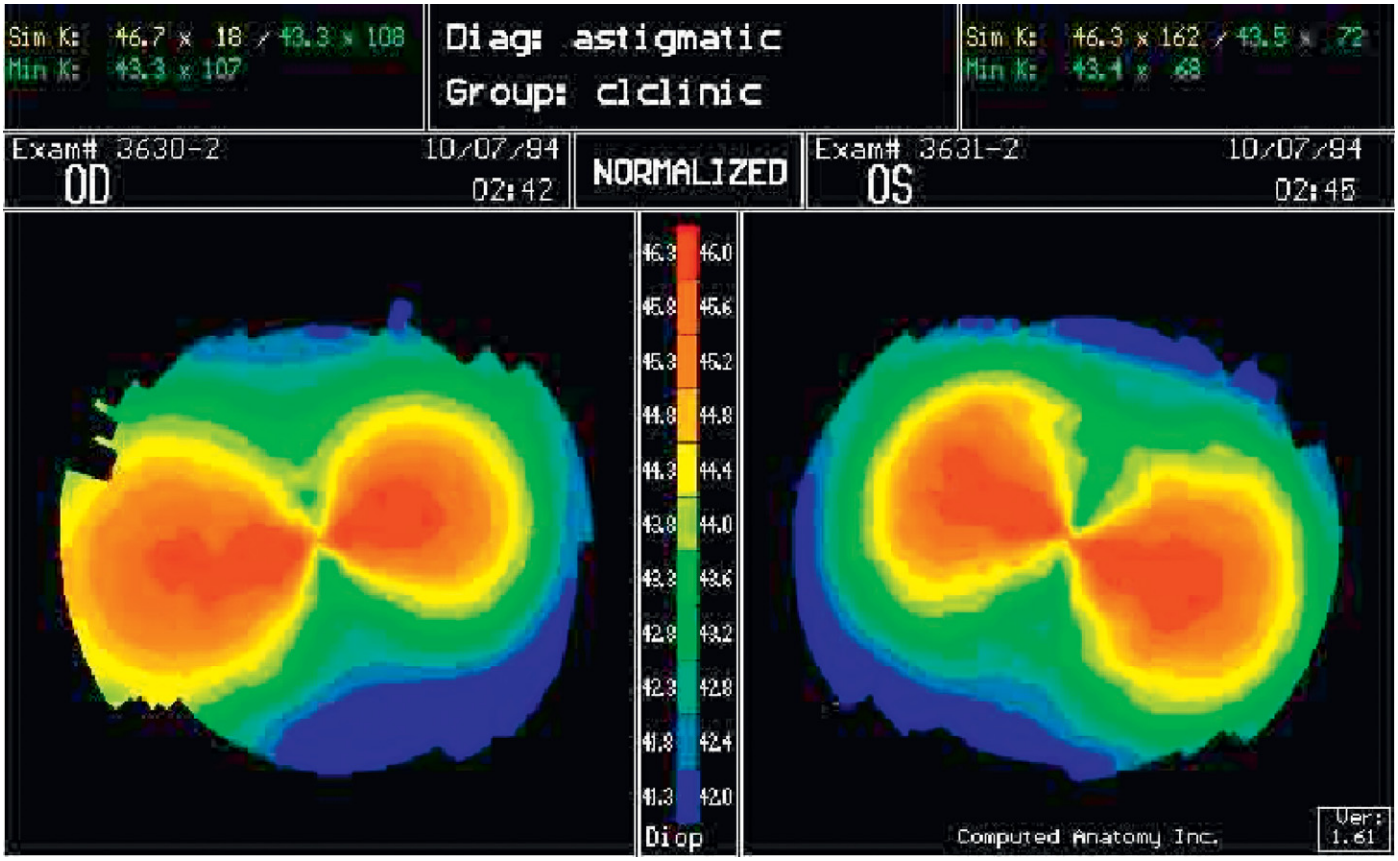

Figure 83.1. Axial power map of enantiomorphism—an individual's corneas are often non-superimposable mirror images of each other.

microdeviations in the surface shape to be noted.[8] The normal anterior elevation value is taken to be less than 16.5 μm,[9] whereas the normal maximum value of the posterior elevation map is generally less than 40 μm.[8,9] When compared to ultrasound pachymetry, the Orbscan overestimates corneal thickness in normal corneas but underestimates post-LASIK pachymetry.[8]

THE NORMAL CORNEA—WAVEFRONT ANALYSIS

Topography measures corneal power in diopters or millimeters of radius of curvature, whereas wavefront aberration describes departure from perfection in the total optical system. In the human eye, once the sphere and cylinder are corrected for, any residual deviations are termed higher-order aberrations.[10] Wavefront analysis is a measuring system that accounts for all these elements of the optical system,[11] and wavefront-guided laser treatment can theoretically correct higher-order aberrations.[10] Before the application of wavefront analysis, only corrections of the spherical and cylindrical errors were widely considered in refractive surgery. However, wavefront systems can describe refractive error to within 0.05 μm—theoretically up to 50 times more accurate than standard topography-based systems. In addition, various errors previously described under the umbrella term 'irregular astigmatism' can now be further defined with wavefront as other higher-order aberrations.[11] In order to understand the concept of wavefront analysis, a few relevant terms and concepts will first be explained.

Point spread function

The point spread function (PSF) is a measure of what subjects would observe if they looked at a distant point of light like a star. The emmetropic image would be a circle of finite size instead of a point, due to diffraction at the pupillary margin; however, other aberrations in the eye can further alter the PSF (Fig. 83.2).[11]

Wavefront aberrometers

Wavefront sensors are technically aberrometers. They measure light wave distortion as it travels through the eye's optical system. They do not measure diffraction or chromatic aberrations.[12] If an optical system has aberrations, reflected or refracted rays do not converge to one image point. The wavefront aberration is the optical path situated between the true wavefront and the ideal reference wavefront measured in the exit pupil as a function of position within the pupil (Fig. 83.3).[13] Pupil size during the examination is important and should be documented, because as the pupil size increases, so do higher-order aberrations.[12] It is always important to recall that factors such as the condition of the tear film, head tilt, or ability to fixate can all influence corneal topography or wavefront sensing.[14] Various wavefront sensing devices based on different principles of wavefront analysis are available commercially.[12]

These include

1. *Shack–Hartmann aberrometry*: Shack–Hartmann devices evaluate the light bounced back from the eye (outgoing reflection). Numerous lenses (lenslets) focus the reflected wavefront.[12] If there are no optical aberrations in the system, a uniform pattern

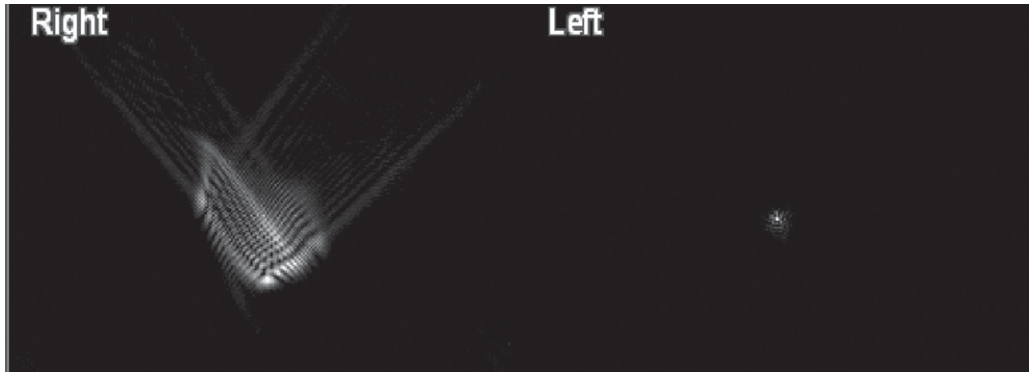

Figure 83.2. Point spread function images from the Nidek OPD-Scan. The left eye sees the image as a circle of finite size instead of a point. Significant aberrations in the right eye significantly alter the PSF.

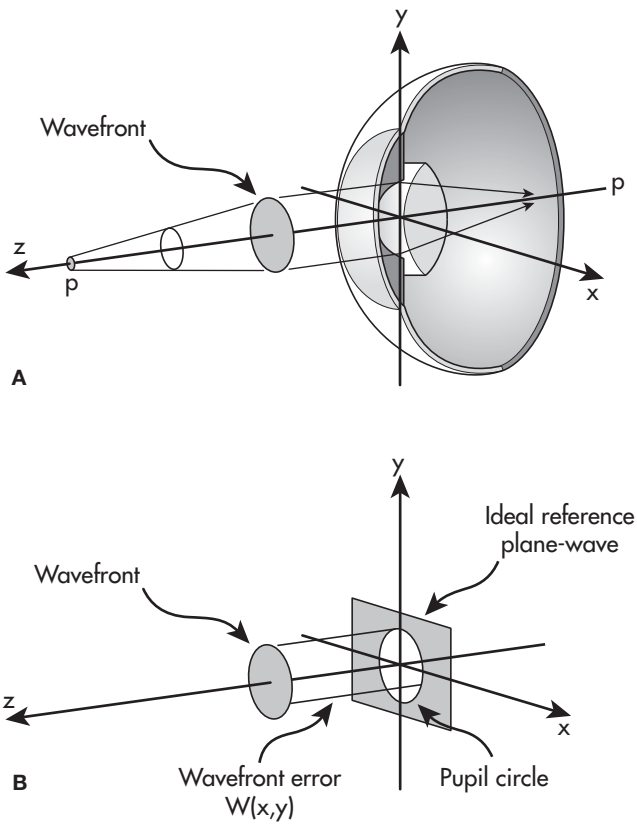

Figure 83.3. Wavefront diagram. The wavefront aberration is the optical path situated between the true wavefront and the ideal reference wavefront measured in the exit pupil as a function of position within the pupil. (Diagram redrawn and reproduced courtesy of Nisha Sachdev, MD, PhD.)

of perfectly spaced dots will be seen. In eyes with significant aberrations, the image will be distorted. Examples of devices using this principle include the LADARWave (Alcon Surgical, Fort Worth, TX)[12] and the Zywave Aberrometer/Wavefront Analyser (Technolas GmbH of Munich, Germany) in the Bausch & Lomb Orbscan combined aberrometry/topography device (B&L Surgical, Claremont, CA).[11] Other devices include the WASCA (Meditech, Jena, Germany) and WaveScan (VISX, Santa Clara, CA).[12]

2. *Tscherning and ray tracing aberrometry*: The retinal image formed is imaged (retinal imaging aberrometry) and then evaluated by charge-couple device sensors that determine the deviation of the spots from the ideal.[12] Examples of devices using this technology include the WaveLight (WaveLight Technologies, Erlangen, Germany) and the Schwind aberrometers (Schwind, Kleinosterm, Germany).[12]
3. *Slit skiascopy*: This is double-pass aberrometry and is available as the Nidek OPD-Scan (ARK 10000 Optical Path Differences Scanning System, Gamagori, Japan). An infrared slit beam scans the retina, and the reflected light is measured to create a wavefront pattern.[12] The OPD-Scan can also measure corneal topography, autorefraction, and keratometry.[15] It has been found to be useful in detecting differences in ocular aberrations between normal, keratoconic, and postkeratoplasty eyes. Root-mean-square (RMS) values are generally higher in the latter two groups; therefore, this technique is reported to have uses beyond refractive surgery.[15]

Wavefront analysis and polynomials

There are several methods used to mathematically describe wavefront data. A set of measured wavefront slopes over the complete pupil are given, and reconstruction algorithms fit the data to a set of polynomials with a least-square technique. Usually these are Zernike or Taylor polynomials, which reduce the absolute error between the slopes measured and the reconstructed wavefront.[14] Zernike polynomials are now the most widely understood mathematical functions used to describe wavefront analysis, and the aberrations are classified in a pyramid of increasing complexity (Fig. 83.4). Each polynomial represents a specific element of distortion of the wavefront. Zero order refers to the *piston* of the lens system (the mean of the *wavefront* profile across the pupil of an optical system that has no effect on image quality),[13] first-order aberrations are *tilt* or *tip*, and second order aberrations are simply *defocus* (sphere and cylinder). Third order aberrations are *coma* and *trefoil*, whilst *spherical aberration* is a fourth-order aberration.[11] Once defocus errors are corrected for, spherical aberration is probably the most important of the higher-order aberrations.[10] One can continue classifying further orders of increasingly less significant higher-order aberrations, but clinically more than 99% of wavefront error is contained in the first four orders of a Zernike expansion.

In one study of wavefront aberration of 108 healthy eyes from a young university student population (measured with a 5 mm pupil), of the total aberrations second order accounted for 90.8%, third order 6.4%, fourth order 2.6%, and fifth order merely 0.2% (Fig. 83.5).[16] Higher-order aberrations will also increase with pupil size, and Zernike coefficients are only relevant for the specific pupil

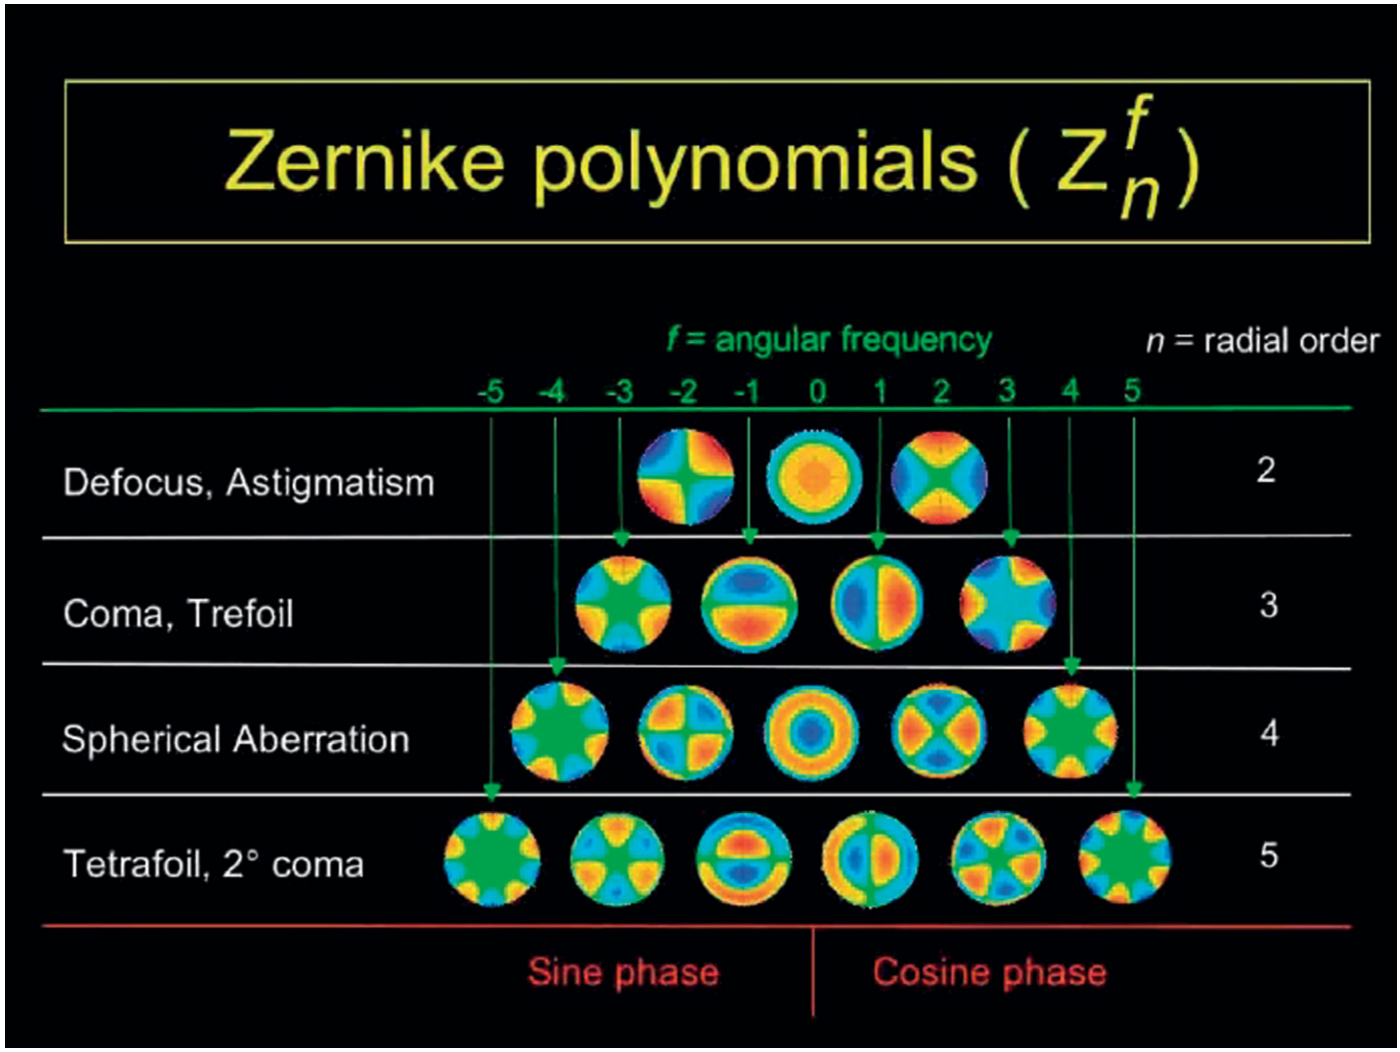

Figure 83.4. Zernike polynomials pyramid, second to fifth orders. (Diagram redrawn and reproduced with courtesy of Nisha Sachdev, MD, PhD.)

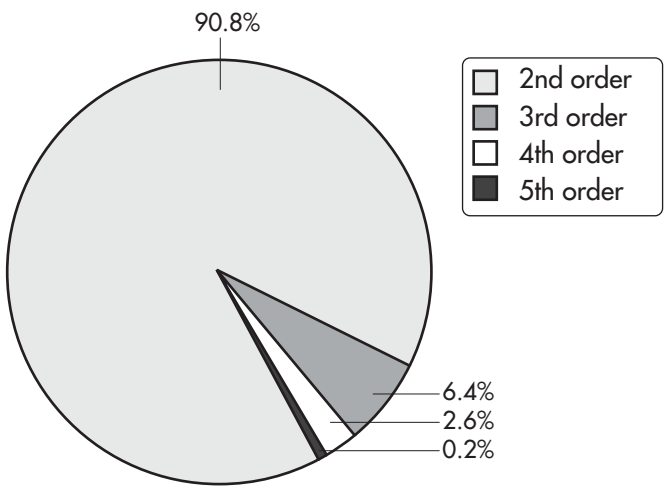

Figure 83.5. Impact of each Zernike polynomial order on the total RMS value for a 5-mm pupil. (Data taken from Castejon-Mochon JF, Lopez-Gil N, Benito A, Artal P. Ocular wave-front aberration statistics in a normal young population. Vision Res 2002; 42(13): 1611–1617.)

diameter at which they were measured (Fig. 83.4). As we move down the Zernike polynomial pyramid, the wavefront maps get increasingly complicated,[13] and wavefront error concentrated near the center of the pyramid adversely affects visual acuity more than modes near the edge of the pyramid.[17]

As Zernike polynomials use only a limited number of Hartmann–Shack lenslets to generate the wavefront, they therefore cannot represent all known aberrations particularly in significantly aberrated eyes.[18] Fourier mathematical analysis of corneal topography power data has been reported to be a powerful method of extracting clinically meaningful descriptors.[19] Indeed, in wavefront analysis, Fourier algorithms use approximately 240 Hartmann–Shack spots (for a 7-mm pupil) and therefore more data are available to create the wavefront.[18] Theoretically, the Fourier approach can therefore fit corneal and wavefront error surfaces in eyes with greater aberrations.[20]

Root-mean-square error

The RMS error is the spot-size error of the overall wavefront error and is a term that describes the error magnitude without describing its nature or where the main components are. It is calculated by taking all the errors above and below the reference plane and squar-

ing them. The mean value is then taken to be the RMS error. Its value indicates the quality of the retinal image. HOMS represents the higher-order aberrations RMS error.[11] In Castejon–Mochon's university student study population cited above, the 5-mm pupil total RMS mean value was 1.49 μm.[16]

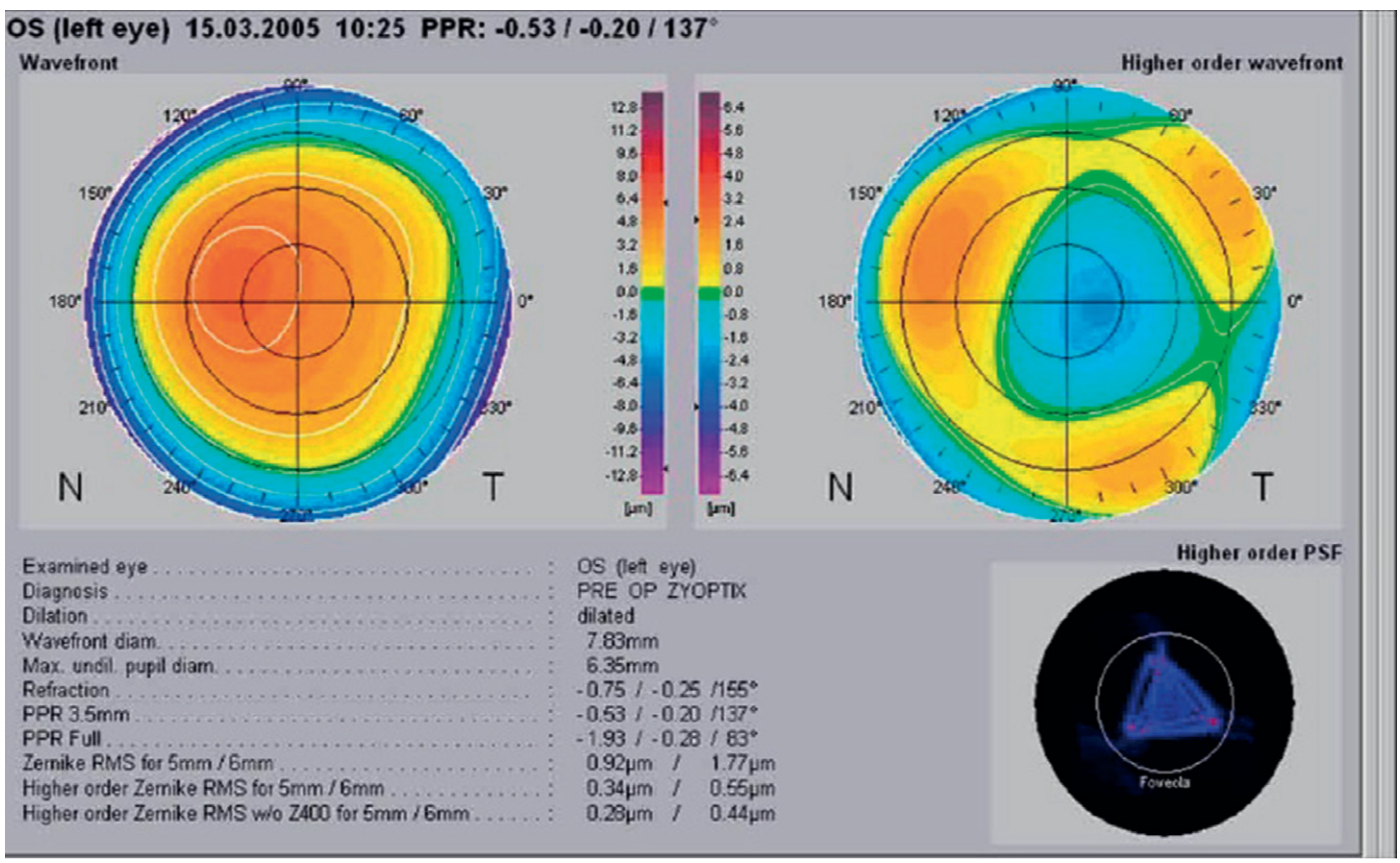
To deliver wavefront-guided treatment, a small scanning spot laser, with a fast, accurate eye tracker, is required.[12] A 1-mm beam has been found to be small enough to correct up to the fifth-order higher aberrations, although some lasers use a 0.50-mm laser spot.[21] Eye-tracking systems can follow and compensate for small eye movements, but all procedures require patient cooperation. Error may also arise due to inaccurate calibration between the video camera and the scanning mirrors. Verification of machine calibration should be performed before each customized treatment.[14]

TOPOGRAPHY AND WAVEFRONT ANALYSIS—THE ABNORMAL CORNEA

Computerized videokeratography (CVK) is an invaluable tool when screening potential candidates for refractive surgery. As already discussed, there is wide variation in corneal power and shape across the normal population. It is important to exclude changes due to artefact from factors such as poor tear film or poor alignment before diagnosing an abnormality. Analysis may need to be repeated and the videokeratoscopic ring visualized before making a final decision. Particularly for LASIK ablations, good preoperative screening with topography to exclude ectatic corneal degenerations is imperative to avoid disastrous consequences.[1] Contemporary devices, such as the Nidek OPD-Scan, may now include both wavefront and topographic analyses that can produce useful data even on highly distorted corneas, e.g. following penetrating keratoplasty (Fig. 83.7).

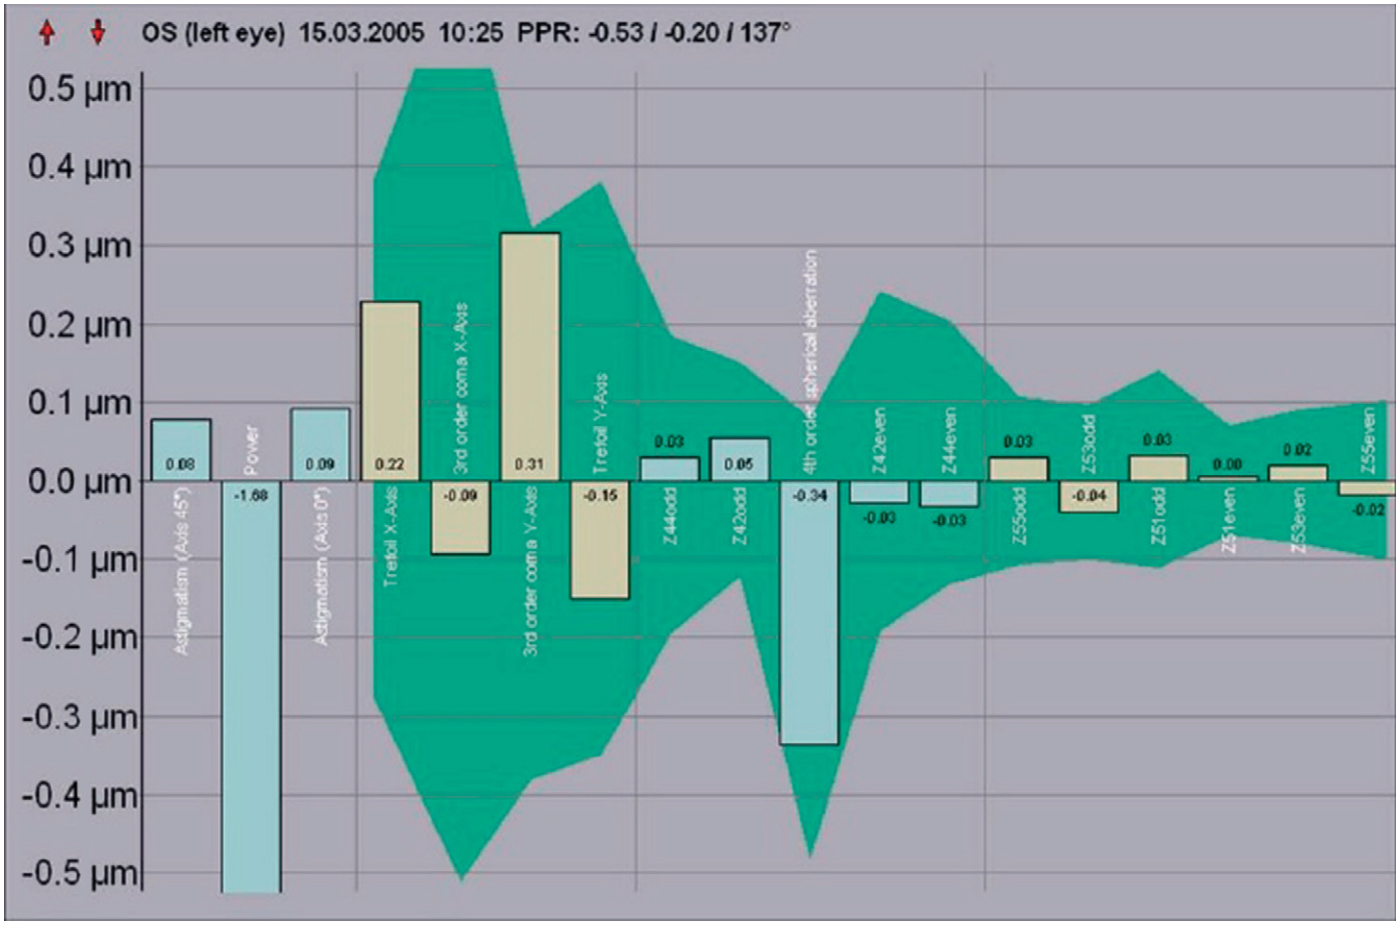
Undiagnosed keratoconus

The presence of visual symptoms or clinical signs can vary widely in this condition. The prevalence of clinically significant keratoconus is 0.03–0.05% but, in fact, may be as high as 6–12% in patients requesting refractive surgery.[7] This higher prevalence is probably due to the fact that keratoconic patients self select toward seeking a refractive procedure due to increasing blur. Highly sensitive detection programs for screening and diagnosis of subclinical and



A

Figure 83.6. Zywave aberrometer/wavefront analyzer (Bausch & Lomb) of a healthy eye with a modest refractive error (–0.75 D/–0.25 D × 155°) and modest wavefront aberration. Image A demonstrates the whole wavefront on the upper left and the higher-order wavefront on the right as color-coded maps. The statistics below the maps highlight a total Zernike RMS of 0.92 μm and HOA RMS of 0.34 μm (both for a 5.0-mm pupil) and a higher-order PSF image.



B

Figure 83.6. continued *B*, Image B provides a graphic breakdown of the contribution of the individual Zernike polynomials.

clinical keratoconus have proven valuable. Subclinical topographic changes have been identified by Maguire and Bourne[22] and Rabinowitz and McDonnell,[23] who found central corneal power, difference in central corneal power between fellow eyes, and steepening of the inferior cornea compared with the superior cornea to be significantly different in patients with keratoconus compared with control patients. Maeda et al developed an automated system using computer-assisted videokeratoscopy to differentiate keratoconus patterns from other conditions including the Keratoconus Predictability Index (KPI) and the Keratoconus Index (KCI).[24] These and other such guidelines are now incorporated into software programs on corneal topographers to help surgeons assess the risk of forme fruste keratoconus in suspicious cases. Further details regarding interpretation of placido-based corneal topography can be found in Chapter 9.

Pellucid marginal degeneration

This condition is probably part of the spectrum of keratoconus, but some authors believe that it has a distinct topographic appearance: characterized by against-the-rule astigmatism and arcuate claw-shaped inferior corneal steepening. Some of the software programs that screen for keratoconus will not detect changes associated with pellucid marginal degeneration. The surgeon must be alert to this fact as these eyes are potentially at high risk of ectasia if LASIK is performed.[1]

Displaced apex syndrome

A subgroup of corneas may demonstrate *displaced apex syndrome* with the zone of greatest corneal power displaced inferiorly with an elevated inferior–superior cornea value, but no clinical signs of keratoconus and a history of stable refraction for a number of years. Wide-field slit-scanning pachymetry (see Chapter 10) may be useful in discriminating between the topographic variant of displaced apex and early keratoconus. Two studies have demonstrated that PRK or PARK in eyes with nonkeratoconus, atypical inferior steepening is associated with outcomes that are not statistically different from those with similar refractive errors and 'normal' topography.[25,26] However, LASIK is perhaps best avoided in these patients.

Contact lens-related corneal warpage

This condition has been defined as contact lens-induced change in corneal topography not associated with corneal edema. Warpage is most commonly linked with rigid polymethylmethacrylate lenses, is less common with rigid gas-permeable lenses, and infrequent in soft contact lens wearers.[27] Initial topography demonstrates flattening of the corneal contour underlying the resting position of the decentered contact lens. Superior-riding lenses cause topographic changes similar to keratoconus.[27] Topographic screening to establish stable topography before refractive procedures is mandatory. There is no gold standard for the period of discontinuation of contact lens wear required before surgery. Many surgeons stop all contact lens wear

Figure 83.7. Nidek OPD-Scan (ARK 10000 Optical Path Differences Scanning System, Gamagori, Japan) of a cornea postpenetrating keratoplasty. Clockwise from top left, an axial topographic power map highlights significant oblique astigmatism (–7.05 D @ 139°), the Zernike OPD bar chart records a highly aberrated wavefront with a total RMS of 3.046, the classifier statistics include, amongst others, SimK, potential visual acuity, surface regularity index, and surface asymmetry index, and the final classifier graph (erroneously in this case) classifies this corneal topography with a 99.0% association with pellucid marginal degeneration.

for 2 weeks prior to surgery, but for RGP wearers some experts suggest 1 week of discontinued lens wear for every year of use. Tsai et al studied 55 eyes of rigid gas-permeable contact lens wearers seeking refractive surgery and reported that 43.6% of these eyes took longer than 3 weeks of discontinued contact lens wear to reach topographic stability. The main factor that correlated with the time to refractive stability after discontinuation was the total length of time of contact lens use. As a result, they suggest that RGP wearers should be advised to cease lens use for 6 weeks before assessment and specifically advised that multiple visits may be required before stability is evident.[28]

The physiologically thin cornea

Orbscan and Oculus Pentacam topographic maps include wide-field pachymetry, and thus abnormal corneal thickness can be readily identified. For particular patients, the degree of laser ablation necessary to treat the refractive error must be considered in the context of their residual corneal thickness. Candidates with particularly thin corneas should be excluded from LASIK treatment if the residual bed thickness is too low to avoid the risk of post-LASIK ectasia. As previously noted, it should be remembered that the Orbscan overestimates corneal thickness in normal corneas.[8]

DETERMINING AND MONITORING TOPOGRAPHIC AND WAVEFRONT CHANGES POSTOPERATIVELY

Topographical analysis of eyes following refractive surgery is necessary in many situations. Firstly, it can be difficult to determine the exact cause of patient dissatisfaction after photoablative laser surgery particularly when the patient has good unaided Snellen vision.[29] Topography and wavefront analysis can be invaluable tools in these patients to gain important information such as ablation centration. Secondly, it is useful to monitor patient progress, and in particular the posterior elevation map may show subtle signs of post-LASIK ectasia in cases of unexpected regression. Finally, it is paramount that surgeons continue to monitor and improve the quality of their practice, and topography is vital when auditing results or conducting research. High-quality, reproducible topographic images should be obtainable from all eyes no later than 1 month after PRK or LASIK.

Ablation pattern classification

Corneal topography in early PRK studies established that ablation zone patterns were variable and may change for up to 1 year postoperatively.[30] Numerous topographic patterns after PRK have been described and two large series highlight most of these.[31,32] Lin[31] classified 502 consecutive eyes 1 month after PRK into one of four ablation zone patterns: uniform, 44%; keyhole, 12%; semicircular, 18%; and central island, 26%. The central island group constituted most eyes that lost lines of best-corrected spectacle visual acuity (BSCVA), although, with gradual resolution, only 2% demonstrated central islands 12 months postoperatively. Hersh and Schwartz-Goldstein,[32] reporting data on 181 eyes, described seven topography patterns: homogenous, 58.6%; keyhole or semicircular, 2.8%; toric with axis, 17.7%; toric against axis, 2.8%; irregularly irregular, 13.8%; and 4.4% showed focal topographic variants. In this study, using a Summit excimer laser (Summit Technologies, Watertown, MA), no central islands were identified. At 1 year, a significant improvement in topographic appearance was noted, with 54.3% demonstrating an evolution to a topographically better group, 17.4% remaining in an equivalent category, and 28.2% changing to a poorer category.[32]

Hersh[33] suggested a standardized eight-category classification of ablation zone topography after photoablative surgery. This system is based on the use of subtraction maps and creates the following categories: homogeneous, toric with axis, toric against axis, semicircular, keyhole, central island, irregularly irregular, and focal topographic variant.[33] Clinically important topographic changes after LASIK or PRK include irregular astigmatism, smaller than predicted optical zones, decentration, and of course central islands or peninsulas.[29]

Steep central islands

A steep central island is an area of steepening in the central cornea that leads to multifocality. It can occur after both PRK and LASIK.[34] There are several definitions of a central island, including central area of as little as 1 D increased power and 1 mm diameter relative to the surrounding ablation zone.[33] A 'steep central island' may be better defined as a well-circumscribed, usually central, circular, or oval area of relatively greater corneal topographic power (>3 D) within the region of reduced corneal topographic power created by excimer laser PRK or PARK (Fig. 83.8).[35,36] A central island in effect is an area of insufficient tissue removal by the excimer laser[37] and may contribute significantly to delayed visual rehabilitation and visual symptoms such as monocular diplopia and decreased best-corrected visual acuity.[31]

Central steep islands were relatively common and previously reported mainly after surgery with broad-beam lasers; however, they are rarely encountered with modern algorithms and flying-spot and scanning-slit laser treatments.[38] Theories regarding the origin of central islands are varied, including localized 'cold spots'[36] or differences in laser beam profile and diameter, laser energy absorption by the rising plume of photoablative products, regional differences in hydration of the cornea during photoablation,[39] and an increased stimulus to epithelial healing/hypertrophy (in PRK) over the central, more deeply ablated treatment zone. However, central islands have been demonstrated before re-epithelialization, suggesting a stromal rather than epithelial origin.[40]

Most transient central islands after LASIK are as a result of flap or bed hydration or stromal swelling.[37] Transient early postoperative visual problems induced by central topographic islands were problematic, with up to 32% of eyes with central islands losing two lines of BSCVA at 2 months after PRK compared with 8.7% loss of two lines in eyes not demonstrating islands at the same time point.[35] Although the natural history of such islands is typically that of spontaneous resolution, usually within 6 months,[31,35] accompanied by recovery of lost lines of BSCVA, modifications that have largely eliminated islands have been incorporated to excimer laser treatment algorithms to reduce their occurrence and speed visual rehabilitation. However, following LASIK, if a central island has not improved over the first 4 months and the patient is symptomatic, then customized laser treatment may be necessary.[29] As most steep central islands are not symmetrical, Hafezi et al proposed that customized ablation algorithms are necessary.[34]

Post-LASIK ectasia

LASIK reduces the cornea's tensile strength.[41] Post-LASIK ectasia is characterized by increasing corneal protrusion or steepening, often inferiorly. The incidence of corneal ectasia after LASIK has been reported to range from 0.04 to 0.6%. It is particularly a risk in eyes that have had higher corrections and have a thin residual bed (typically less than 250 μm).[41] It will usually become manifest within a year of LASIK surgery but can present much later (Fig. 83.9). To minimize the risk of post-LASIK ectasia, careful preoperative topographic analysis should be performed and LASIK avoided in those with asymmetric, inferior steepening that may signify conditions such as forme fruste keratoconus.[41] In addition, surgeons should beware of the patient with an unstable refraction preoperatively and central pachymetry of less than 490 μm. Intraoperative pachymetry of the residual bed is useful should an enhancement be required at a later stage.

Centration issues

Decentration of ablation zone occurs when the centre of the ablation zone does not correspond to the intended optical center, e.g. center of the virtual pupil.[42] This was particularly problematic with early excimer laser systems using small ablation zones and noncoaxial microscopes. The commonest cause of decentration is believed to be due to poor patient fixation and the latter can particularly be a problem during LASIK surgery, as it is difficult for the patient to

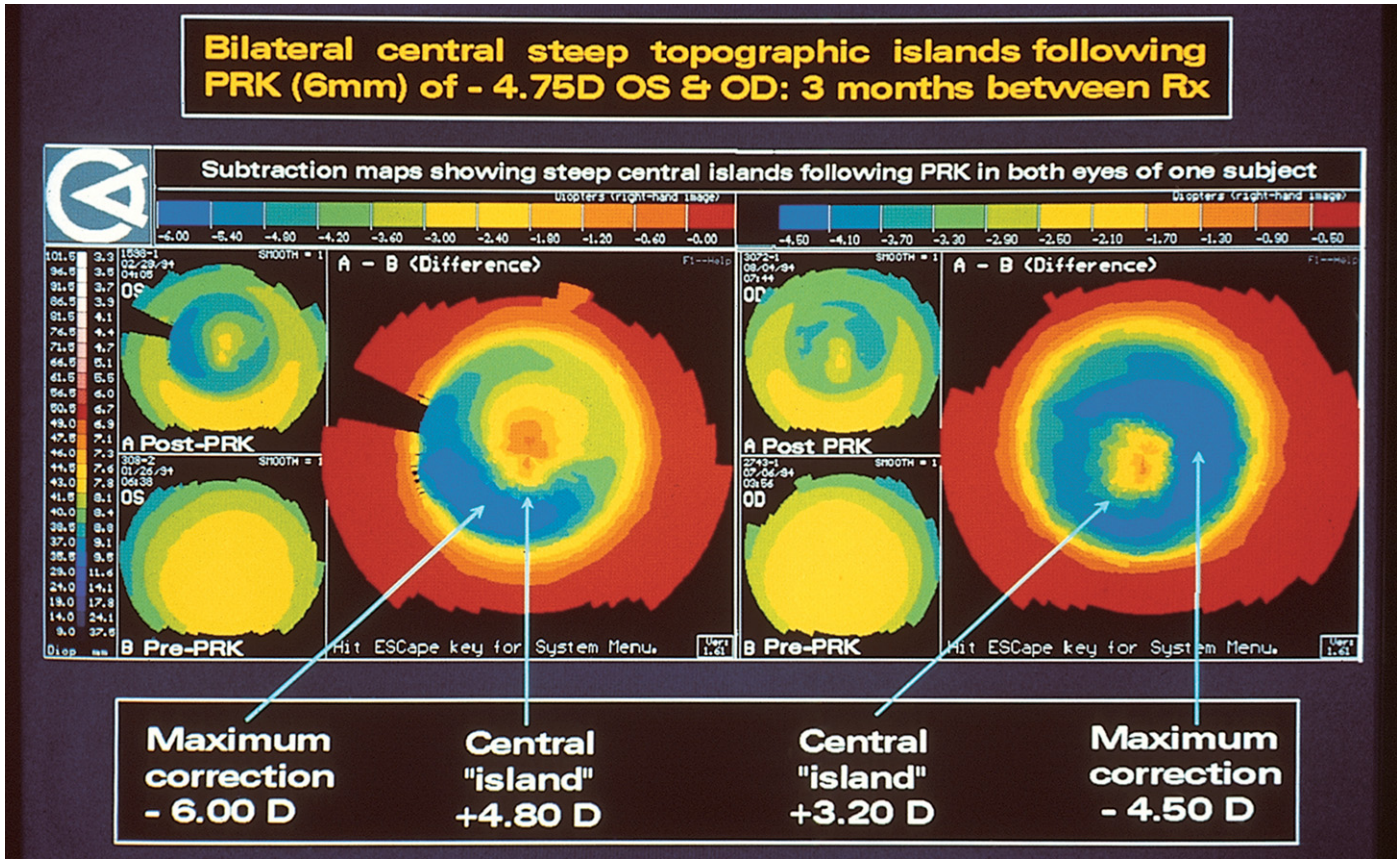


Figure 83.8. Preoperative, postoperative, and differential power maps for bilateral (–4.75 D OS and OD) PRK using a 6.0 mm treatment zone in the same patient (treatments 3 months apart). The subtraction maps clearly show steep central corneal islands, with greater than 3 D central power. Difference scales using 0.6 D increments OS and 0.4 D increments OD.

see the fixation beam once the flap has been elevated.[37] A positive angle kappa can also cause difficulties.

Centration is especially important in hyperopic eyes, and excellent centration is possible even in eyes with positive angle kappa when the ablation is centered over the coaxially sighted corneal light reflex.[43] Most surgeons recommend that pharmacological pupil dilatation should be avoided on the day of surgery to aid in centration,[37] but occasionally an excimer laser device such as LADARVision system (Alcon Laboratories) requires pupil dilation preoperatively.

Decentration causes multifocality of the optical zone[42] and a decentration of more than 1 mm may be associated with troublesome night-time symptoms of glare and haloes in younger patients with large pupils, particularly if true optical zones (as opposed to diameter of ablation including blends) of 5-mm diameter or less have been used. In a study of 38 eyes treated with a 5-mm ablation zone, multivariate analysis demonstrated that ablation zone decentrations of less than 0.89 mm from the pupil center were not associated with untoward visual symptoms.[44] Nonetheless, greater decentrations can be associated with persistent glare, halo, and induced astigmatism of up to 6.4 D.[45] Accurate centration of the ablation is particularly important when treating astigmatism with an elliptical ablation zone, or in the correction of hypermetropia with small optical zones (Fig. 83.10).

Eye-tracking systems in the current generation excimer laser systems have reduced decentration problems significantly.[42] In a cohort of patients who had PRK with a small beam tracking excimer laser by Coorpender et al, the mean decentration in 49 eyes was 0.42 mm and only 6% of corneas had a decentration of more than 1 mm.[46] Management options for decentered ablations after LASIK include topographically supported customized ablation (TOSCA). This has been reported to allow correction of the eccentric ablation and reduction in higher-order aberrations, without causing overcorrection. This may be a useful technique for patients with decentrations and a very high amount of higher-order aberrations, as wavefront aberrometers may not have the ability to measure the latter.[42] Failure to document the difference between true decentration and differential regression (healing) of the ablation zone can be difficult, and therefore early rather than late topographical analysis is advisable.

Regression and healing

Regression is the gradual loss of initial refractive correction. It occurs much more frequently after PRK than after LASIK. This may be because with larger epithelial defects there is a greater stimulus for epithelial regeneration and stromal cellular change.[47] Corneal topography is vital in documenting the postoperative course of refractive surgery. Despite limited opportunity for intervention in the healing process, early topography is important if the practitioner is to avoid such common pitfalls as asymmetric healing being mistaken for decentration[29] or preferential healing of a cylindrical correction being presumed to be a primary undertreatment. Such topographic information is vital in the planning of excimer laser retreatment (Fig. 83.11).

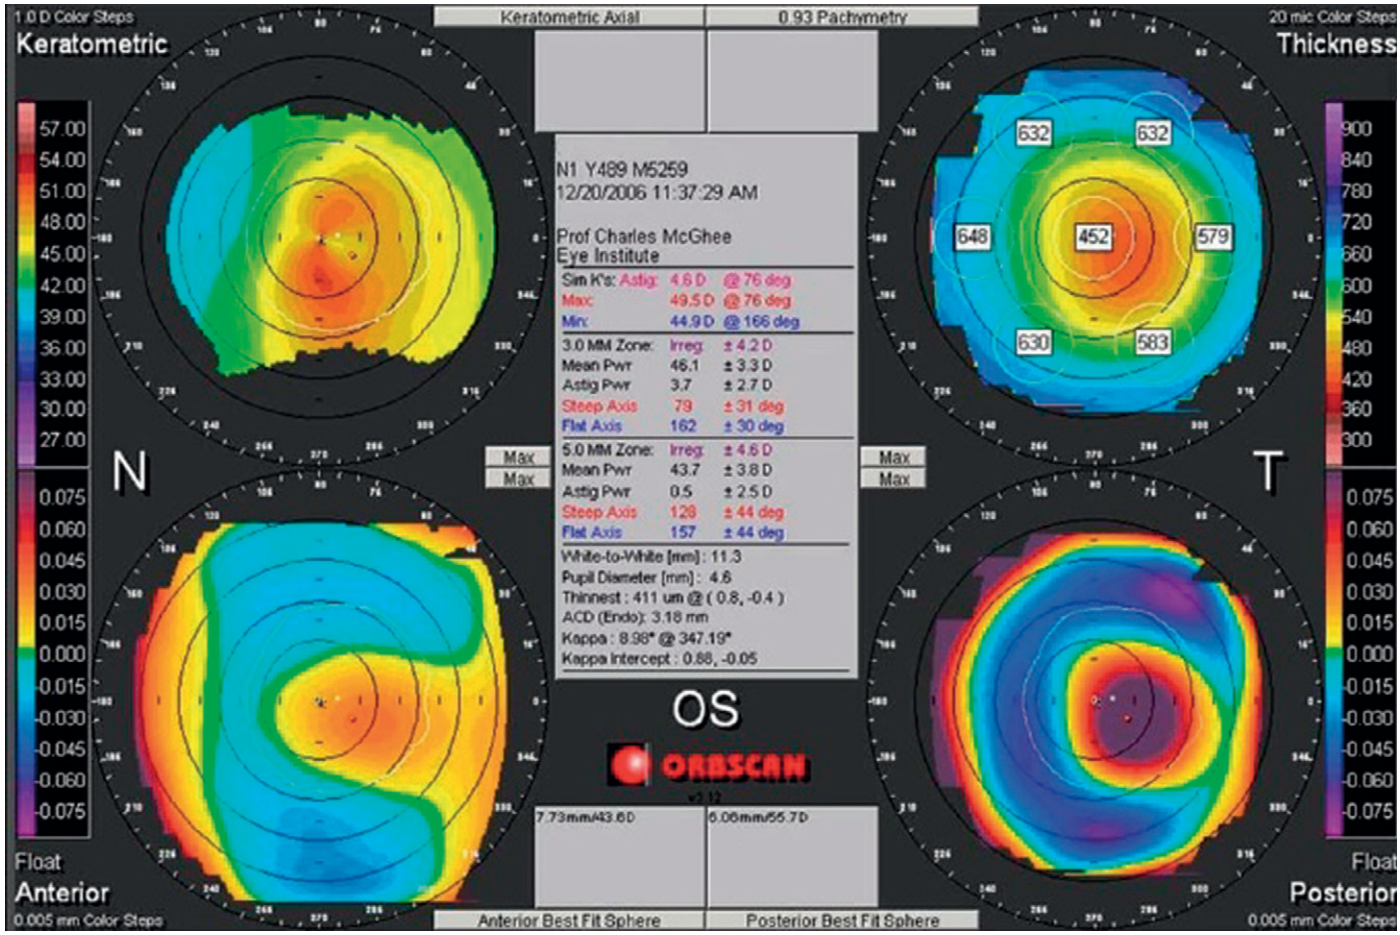

Figure 83.9. Orbscan II quad map showing keratectasia 3 years after a myopic correction of approximately –3.00 D. Clockwise from top left: the keratometric map highlights a very steep bowtie/central cone appearance with SimK values of 49.5 and 44.9 D @ 166°, the thickness map shows central corneal thinning with the thinnest measurement of 411 μm slightly inferotemporal to center, the posterior elevation map reveals confirmatory paracentral forward vaulting of more than 75 μm, and the anterior float map exhibits a paracentral elevation of approximately 40 μm (both posterior and anterior elevation maps are relative to best-fit spheres).

Epithelial ingrowth after LASIK can also cause pseudodecentration, because the epithelium elevates the flap peripherally and appears to decenter the ablation zone. Removal of this epithelial tissue after lifting the flap should correct this problem, although epithelial ingrowth is difficult to fully eradicate.[29] More recently, anterior segment OCT has been used to measure the thickness of the corneal layers and therefore may help determine in an individual patient whether regression is due to epithelial hyperplasia or stromal healing. This knowledge is important as the former may resolve very slowly and change the refraction, so any enhancement procedure should be delayed.[47]

Wavefront-specific changes

LASIK and PRK introduce higher-order aberrations whilst treating lower-order errors.[12] Indeed, some higher-order aberrations in myopes may increase after wavefront-guided LASIK. There is simultaneous induction and reduction of these aberrations contributing to the overall change.[48] Flattening the cornea by myopic laser treatment reduces its natural prolate shape and hence increases spherical aberration.[11] A strong correlation has been reported between post-LASIK patients' visual symptoms and higher-order aberrations analyzed at scotopic pupil size with the LADARWave wavefront device.[49]

PLANNING ENHANCEMENT PROCEDURES

Most topography devices can create pre/postoperative differential or subtraction maps, which show the changing effect of the initial laser treatment.[50] It must be remembered, however, that when analyzing a subtraction map, there may actually be a slight over- or underestimate of the refractive change compared to subjective refraction. Therefore, although the topographic map may be considered as a template for retreatment planning, it must be guided and modified by the manifest refractive error. It is imperative that stability is reached before retreatment is considered and generally this is achieved at 3 months, or later, following laser ablation.[50] Topography maps should be analyzed carefully for signs of post-LASIK ectasia where retreatment is obviously contraindicated and the Orbscan posterior elevation map is useful in this situation.[50]

Residual stromal bed measurement

Due to the risk of post-LASIK ectasia, knowledge of the residual stromal bed thickness is crucial before enhancement is to be considered. The standard of 250 μm as the residual stromal bed after LASIK has been rather arbitrarily adopted. Significant variability in predicted flap thickness and actual thickness exists when flaps are

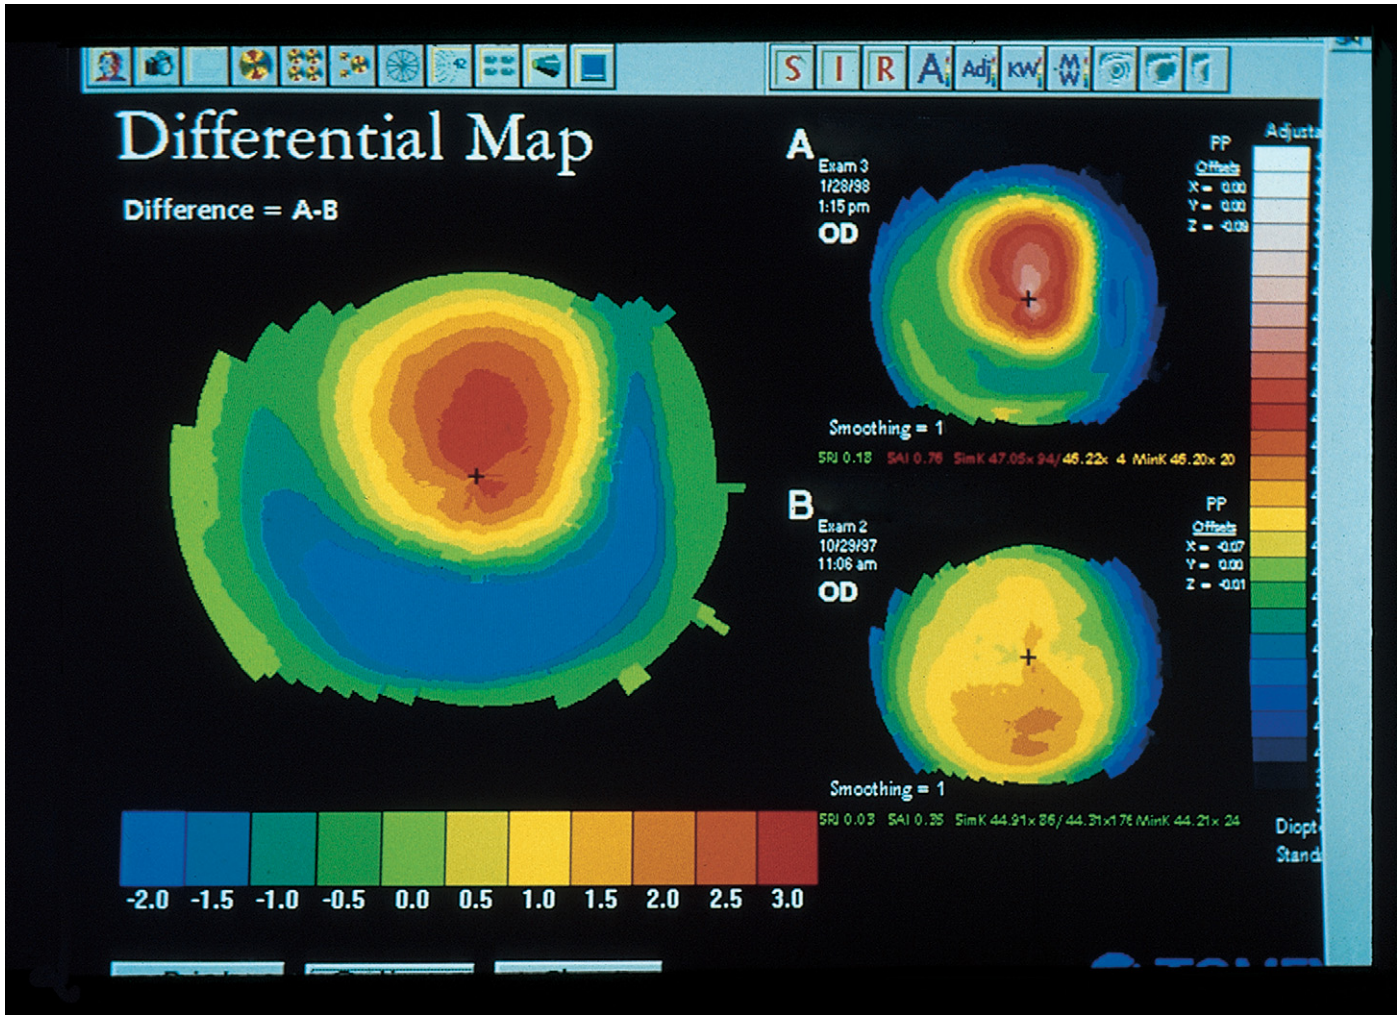

Figure 83.10. Not to be confused with a central topographic island, this difference map shows a slightly superiorly decentred hypermetropic treatment zone with an area of increased power located superior to the corneal vertex, circumscribed by an annulus of decreased corneal power (difference map power scale –2.00 to 3.00 in 0.5 D steps).

created with a microkeratome. If intraoperative pachymetry has been performed at the initial LASIK treatment then this can be accurately calculated. Other options include in vivo confocal microscopy, which can determine the actual residual stromal bed thickness before considering enhancement.[41] Anterior-segment OCT can be used to measure the flap and stromal bed thickness but has been found to be of use only within the first few weeks of surgery. Beyond this, the interface is more difficult to accurately detect due to healing. This noncontact technique has the advantage over intraoperative ultrasound pachymetry in that the latter requires direct contact with the corneal stroma, which theoretically may increase the risk of keratitis and may affect the ablation profile due to irregular corneal hydration.[51] Interestingly, OCT has been reported to successfully detect the interface from previous LASIK treatment in donor corneas up to 15 months postmortem.[52]

Irregular astigmatism

In addition to the retreatment of simple undercorrection or regression in cases of well-centered, regular ablations, the refractive surgeon frequently encounters cases of irregular astigmatism. Ablation-related problems that lead to irregular corneas include small or decentered optical zones and irregular ablations.[53] Irregular astigmatism is associated with higher-order aberrations such as coma, trefoil, and secondary astigmatism, which can all be detected with wavefront analysis.[54] With wavefront-guided surgery, in theory the final anterior corneal surface can be remodeled to compensate for internal aberrations to make the sum of all aberrations equal to zero. However, in practice this is hindered by various factors including limited ablation precision, flap induced new aberrations, and changes in aberrations with age.[53] When dealing with irregular astigmatism, anterior corneal aberrations predominate; therefore, some surgeons argue that treatment should be directed at correcting the abnormal corneal contour, rather than considering aberrations that come from intraocular structures. Topography-guided treatment uses only corneal front surface data, and internal structures of the eye are not considered. It is therefore useful when treating irregular astigmatism, as, in theory, it is possible to re-create the normal aspheric corneal shape. Media opacities do not pose a problem as surface reflections are the only necessary consideration and very irregular corneas can be measured, which may be beyond the capability of wavefront systems.[53]

OTHER CONSIDERATIONS

Overnight orthokeratology has undergone a resurgence in interest in the last few years. This term refers to the overnight wear of

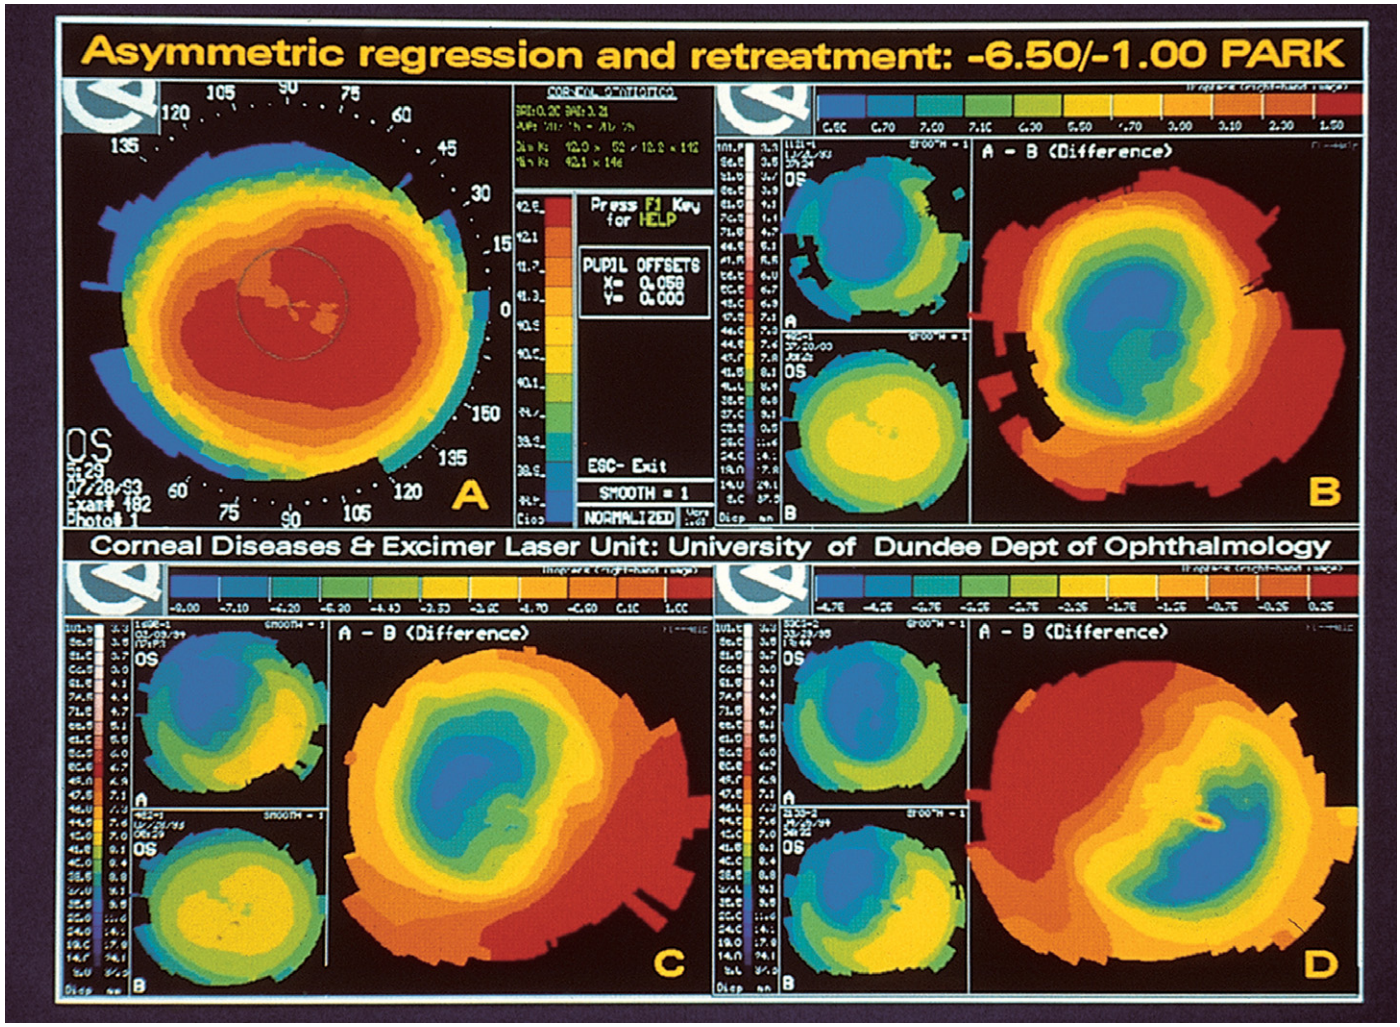

Figure 83.11. Preferential healing and myopic regression of a –6.50/–1.00 D PARK ablation can lead to a CVK map appearance suggestive of ablation zone decentration. *A*, The preoperative power map shows an aspheric cornea (normalized scale in 0.4 D steps). *B*, The difference map, comparing preoperative and 1-month postoperative data, shows a reasonably well-centered, vertically oval ablation (difference scale in 0.8 D steps). *C*, The difference map comparing preoperative and 7 months postoperative data reveals what could be mistaken for a simple superonasal decentration; however, comparison of the two difference maps reveals that the change in ablation zone appearance is due to asymmetric healing—as indicated by increasing power in the inferotemporal quadrant of the ablation site (difference scale 0.8 D increments). *D*, Following retreatment, pre-retreatment subtracted from post-retreatment provides a difference map showing that focal retreatment can be successfully guided by the difference map and manifest refraction to correct the area of asymmetric healing identified in *C* (difference scale using 0.5 D steps).

specially designed rigid gas-permeable contact lenses, which flatten the anterior corneal curvature and subsequently the subject experiences improved unaided vision the following day after lens removal. Corneal topography in these patients is similar to that after LASIK surgery in that there is central flattening and a steeper ring in the mid-periphery.[55] The changes are temporary, but it is a procedure that is considered a useful alternative to corneal surgery in certain situations. These include patients who are too young for LASIK and residual myopia after LASIK unsuitable for an enhancement procedure.[55]

CONCLUSIONS

In summary, our knowledge of the pre- and postoperative assessment of the surgical correction of refractive errors has advanced rapidly in part because of the significant improvements in corneal topography and tomography systems. With the development of real-time eye tracking, flying-spot laser beams, and wavefront analysis it is theoretically possible to custom ablate corneas with asymmetric or irregular topographies. In such cases, the ability of the corneal or cataract and refractive surgeon to fully understand the full potential of corneal topography/tomography and wavefront assessment takes on even greater importance. Indeed, as the relationship between corneal topography and visual performance is further elucidated, the central question may finally be answerable, what shape should the cornea be?

84 Lessons from radial keratotomy

Mitul R. Vakharia

Radial keratotomy (RK) was the primary refractive surgery in the USA in the 1980s and into the 1990s, with several hundred thousand being performed.[1] With the advent of excimer laser refractive surgery and the long-term complications of RK identified in the mid-1990s, RK has become an 'RKhaic' corneal refractive surgery,[2] alongside keratomileusis,[3] automated lamellar keratoplasty,[4] epikeratophakia,[5] laser thermal keratoplasty,[6] and hexagonal keratotomy[7] (Fig. 84.1, *A–E*). Nevertheless, as the prototype of modern refractive surgery and the forerunner of incisional corneal surgery, there are many lessons to be learned from RK for today's corneal surgeon.

HISTORY OF INCISIONAL KERATOTOMY

The surgical correction of astigmatism was first proposed in 1869 by Dutch ophthalmologist Herman Snellen, who suggested that incisions within the steep corneal meridian might affect astigmatic magnitude.[8] In 1885, Norwegian ophthalmologist Hjalmar Schiotz confirmed Snellen's hypothesis by reporting significant corneal flattening with the placement of a corneal incision tangential to the steep meridian after cataract surgery.[9] American ophthalmologist William Bates in 1894 observed that, in patients with corneal scars, there was flattening of the corneal surface along the meridian of tangential scars.[10]

The scientific groundwork for modern incisional keratotomy was laid in 1898 by Dutch ophthalmologist Jan Lans, who conducted extensive studies in rabbits and demonstrated that anterior tangential corneal incisions resulted in corneal flattening in the meridian of the incisions.[11] Lans further demonstrated that deeper and longer incisions were associated with greater flattening, and there was associated steepening in the meridian 90° away from the tangential incision.

The work of these early ophthalmic pioneers was largely ignored until the late 1930s, when Japanese ophthalmologist Tsutomu Sato noted that patients with keratoconus who experienced breaks in Descemet's membrane developed significant corneal flattening and reduction of myopia.[12] Not yet recognizing the role of the corneal endothelium, Sato reported surgical corneal flattening by posterior radial incisions of the corneal endothelial surface, later combined with anterior radial incisions for an enhanced effect.[13] Unfortunately, long-term follow-up of this procedure demonstrated bullous keratopathy in up to 70% of patients.[14,15]

In the 1970s, Russian ophthalmologists Beliaev, Ilyina, Durnev, Fyodorov, and Yenaliev modified and perfected modern techniques of anterior corneal RK.[16–20] Their work defined a central clear optical zone and surgical variations that could titrate the effect of the procedure. Beginning in 1978, Bores et al performed the first RK procedures in the USA and published their optimistic results.[21]

PROSPECTIVE EVALUATION OF RADIAL KERATOTOMY STUDY

The National Eye Institute funded the Prospective Evaluation of Radial Keratotomy (PERK) study in 1980 to evaluate the safety and efficacy of a standardized surgical technique for RK and measure its predictability and stability.[22] The Vision Program Ad Hoc Committee and the National Advisory Eye Council approved funding of the PERK study on human subjects despite the lack of previous vigorous animal testing, as RK was already being performed on humans and they wanted to evaluate its safety and efficacy before it gained widespread application.[2]

The PERK data were collected from 12 investigative ophthalmic surgeons at nine clinical research centers, on 793 eyes of 435 patients with 2–8 D of myopia and 1.5 D or less of astigmatism. These patients were treated with eight RK incisions extending from a central clear optical zone to the limbus. The radial incisions were directed centrifugally, which is known as the American method of incision, starting at the central clear optical zone and extending toward the limbus. These were in contrast to centripetal incisions, known as the Russian method of incision, which showed more efficacy due to deeper incisions but were deemed less safe due to the potential for overshoot into the central clear optical zone. The differences in depth were due to differences in force vectors, as illustrated in Figure 84.2, *A* and *B*.

The incisions were made with a guarded diamond blade, with two footplates to stabilize the incision, and a 45° cutting angle. The footplates were set at a depth equal to 100% of the thinnest paracentral corneal thickness by ultrasound pachymetry. Preoperatively

B

Figure 84.2. Different vector forces generated by the two incision methods result in significant differences in incision depth. *A*, In a centripetal (uphill) incision, the vertical knife edge performs the incision with a force vector relatively parallel to the corneal tissue, enabling a uniformly deep incision. *B*, In a centrifugal (downhill) incision, the angled knife edge performs the incision at an oblique angle relative to the tissue plane, displacing the blade tip upward, resulting in more variable incision depth.

designated central clear optical zones measured 3.0, 3.5, or 4.0 mm in diameter, corresponding to subjects classified as having high, middle, or low myopia levels, respectively.

The PERK research teams achieved an 88% patient follow-up rate 10 years after surgery, and these data were published in 1994.[23] Ten-year follow-up data demonstrated an uncorrected visual acuity of 20/20 or better in 53% of eyes and 20/40 or better in 85% of eyes. Among a subgroup of 310 patients at 10-year follow-up who had bilateral RK, 70% reported not wearing spectacles or contact lenses for distance vision. These data for efficacy were encouraging, although not on par with modern refractive surgery outcomes.

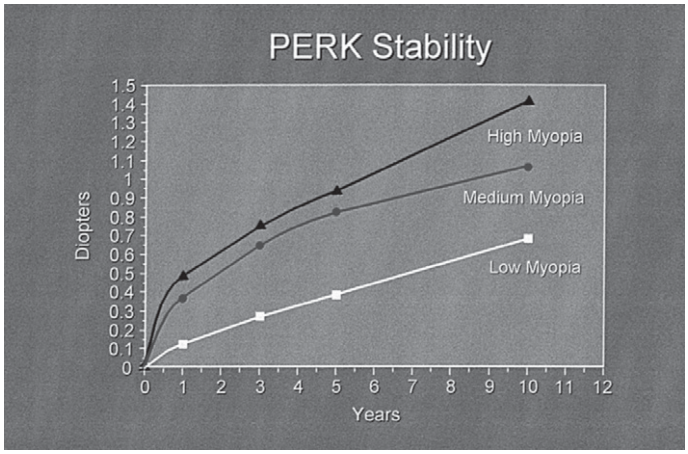

Figure 84.3. For all three groups of eyes in the PERK study based on preoperative myopia, the average spherical equivalent cycloplegic refraction showed a progressive hyperopic shift over time. Even at 10 years after surgery there was no trend toward stabilization of refractive error.

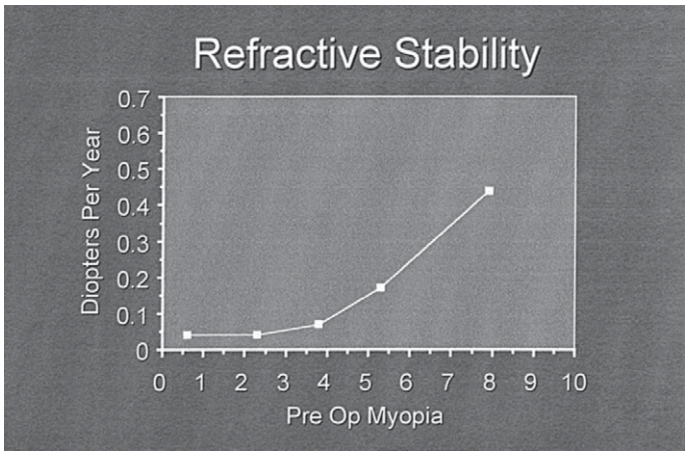

Figure 84.4. One- to three-year follow-up data from another study[25] showed the rate of progressive hyperopic shift after RK was greater for higher amounts of preoperative myopia.

However, the data for predictability and stability were not encouraging and ultimately led to the disuse of the procedure. Four-year follow-up data for refractive outcome following surgery showed a 90% prediction interval that was 4.42 D wide, indicating a lack of predictability.[24] Ten-year follow-up data showed a significant progressive hyperopic shift, with an average change of +0.21 D per year from 6 months to 2 years after surgery and an average change of +0.06 D per year from 2 to 10 years after surgery. A consistent rate of hyperopic shift 10 years after surgery was particularly worrisome as it showed no sign of stabilization, and another study showed the rate was higher for higher amounts of preoperative myopia (Figs 84.3 and 84.4).[23,25]

Additionally, an analysis of a subset of patients 11 years after surgery showed persistent diurnal fluctuation in refraction, with a mean change in spherical equivalent of 0.31 ± 0.58 D of increased myopia from morning to evening, with 13% of patients experiencing a decrease in uncorrected visual acuity of two to seven Snellen lines over the course of the day.[26] Ten-year follow-up data showed a loss of best spectacle-corrected visual acuity of two or more Snellen lines in 3% of patients, an unacceptable safety profile by today's standards.[23] Furthermore, 6-year follow-up data of the PERK

study showed that only 60% of patients were 'highly satisfied' with the results of surgery, and this correlated with having a visual acuity of 20/20 or better in at least one eye.[27] These data showed that a 20/20 outcome should be the goal of refractive surgery, and RK could not consistently provide such results.

SURGICAL PROTOCOL FOR RADIAL KERATOTOMY

What follows is a general surgical protocol for the safe and effective delivery of RK. This section is partly for historical interest and partly for surgeons who may still be performing RK in parts of the world where excimer lasers are prohibitively expensive. This section also contains details that would be of interest to any surgeon performing any form of incisional corneal surgery.

The screening preoperative assessment for RK includes a stable cycloplegic refraction and a series of measurements of paracentral corneal pachymetry. This is done with an ultrasound pachymeter at eight points circumferentially, 1.5 mm from the optical center, which is identified by the patient focusing on a point light source. The thinnest paracentral pachymetry is used to determine the depth setting of the guarded diamond blade, which is set at 100% of this value. This allows the deepest possible incisions for greatest efficacy, while minimizing the risk of perforation.

The advent of computerized corneal topography has allowed the identification of subclinical keratoconus in the preoperative screening examination, which is a contraindication to RK. Corneal topography also determines the precise axis and amount of astigmatism, which was concurrently treated with later incisional nomograms. Corneal topography is also essential in the identification of postoperative-induced irregular astigmatism and surgical planning for incisional enhancement procedures, which later became more conventional.

Routine preoperative topical medications include 1% pilocarpine to constrict the pupil, as this gives the surgeon a better estimation of the visual axis around which to center the treatment. Topical anesthetic is also given, with a potential regimen being two drops of 0.5% tetracaine given 5 min apart, followed by two drops of 4% lidocaine given 5 min apart. Although there is no convincing clinical evidence that prophylactic topical antibiotics decrease the incidence of bacterial keratitis, a broad-spectrum topical antibiotic is used due to its low cost and ease of administration. A sedative such as 10 mg of oral diazepam could also be given 20 min before the procedure as an anxiolytic and an eyelid muscle relaxant.

The patient is positioned on the operating table with the nonsurgical eye patched to facilitate fixation on the operating microscope light. A folded towel may be placed beneath the patient's shoulders to help maintain the chin-up position and provide improved exposure during placement of the superior incisions. The surgical eye is prepared with periocular povidone-iodine (Betadine) solution and an eye drape over the patient's face after excess Betadine has been dried with sterile 4 × 4 gauze. The patient is then instructed to blink frequently to prevent epithelial desiccation, which may lead to excessive friction during incision. The surgeon then instills an additional drop of anesthetic into the fornix before placing the eyelid speculum.

To determine the visual axis, the PERK study group recommended the patient fixate on the microscope light while the surgeon looks through one eyepiece and marks the epithelial surface at the light reflex, at the opposite lower border. For example, if the surgeon views through the right eyepiece, then the mark is placed on the left lower border of the light reflex. The cornea must be well centered within the operative field to avoid parallax-associated decentration. Alternatively, the center of the pupil can be marked to estimate the visual axis.

Marking is done by placing a drop of fluid to enhance the corneal light reflex, gently indenting the epithelium with a Sinskey hook and then using a spear sponge to make the indentation more apparent. A central clear optical zone marker of predetermined diameter is centered over this indentation by aligning the cross-hairs with the indentation. The surgeon may apply a quarter-revolution turn to the central clear optical zone marker to enhance the marking and again gently dry with a spear sponge. A radial marker is then centered with respect to the central clear optical zone mark, and moderate pressure is applied on the epithelium for several seconds.

The paracentral corneal thickness at the thinnest paracentral site (determined at the screening examination) is confirmed with ultrasound pachymetry. The diamond blade is then set to 100% of this depth, which can be confirmed using a calibrating microscope. The surgeon then incises the thinnest quadrant first and the thickest quadrant last. This incision sequence can reduce microperforation because the cornea slightly thins further throughout the procedure due to desiccation.

RADIAL KERATOTOMY TECHNIQUE

As alluded to earlier, the Russian-method (uphill) centripetally directed incisions provide consistently deeper incisions than the American-method (downhill) centrifugal incisions that were used in the surgical protocol of the PERK study (Fig. 84.2).[22] These deeper incisions were found to be more effective in reducing myopia but were less safe due to the potential for overshoot into the central clear optical zone.

An incisional technique, which combined the safety of the centrifugal method with the efficacy of the centripetal method, became a popular RK procedure, known as the *combined technique*.[28] The incision is begun at the central clear optical zone, extends out toward the limbus, and then reverses direction back toward the central clear optical zone without invading that zone (Fig. 84.5, *A–C*). In a study conducted on human cadaveric eyes, eight incision RK with a 3-mm central clear optical zone was performed comparing the three incision methods, and the combined technique achieved more corneal flattening (9.3 ± 1.7 D) than the centrifugal (4.2 ± 1.5 D) or the centripetal method (7.7 ± 2.8 D).[28]

The surgeon incises along the radial marks entering at the central clear optical zone margin, with sufficient pressure to indent the cornea slightly. After a 2 s pause, gentle pressure is applied toward the central clear optical zone, undermining it (Fig. 84.5, *A*). The centrifugal (downhill) radial incision then is initiated while the diamond blade is reoriented perpendicular to the tissue plane with slight indentation pressure, extending to 1 mm from the limbus. Without removing the diamond blade from the incision groove, the surgeon reverses the incision direction returning back to the central clear optical zone margin (Fig. 84.5, *B*), with slightly less indentation pressure during this uphill pass. The diamond blade should then be removed from the incision groove without any pressure being exerted against the central clear optical zone, resulting in a deep, effective, and safe incision (Fig. 84.5, *C*). Postoperatively, a topical NSAID is used immediately for analgesia along with a broad-spectrum antibiotic, and the antibiotic with or without the NSAID is continued four times daily for 5 days.

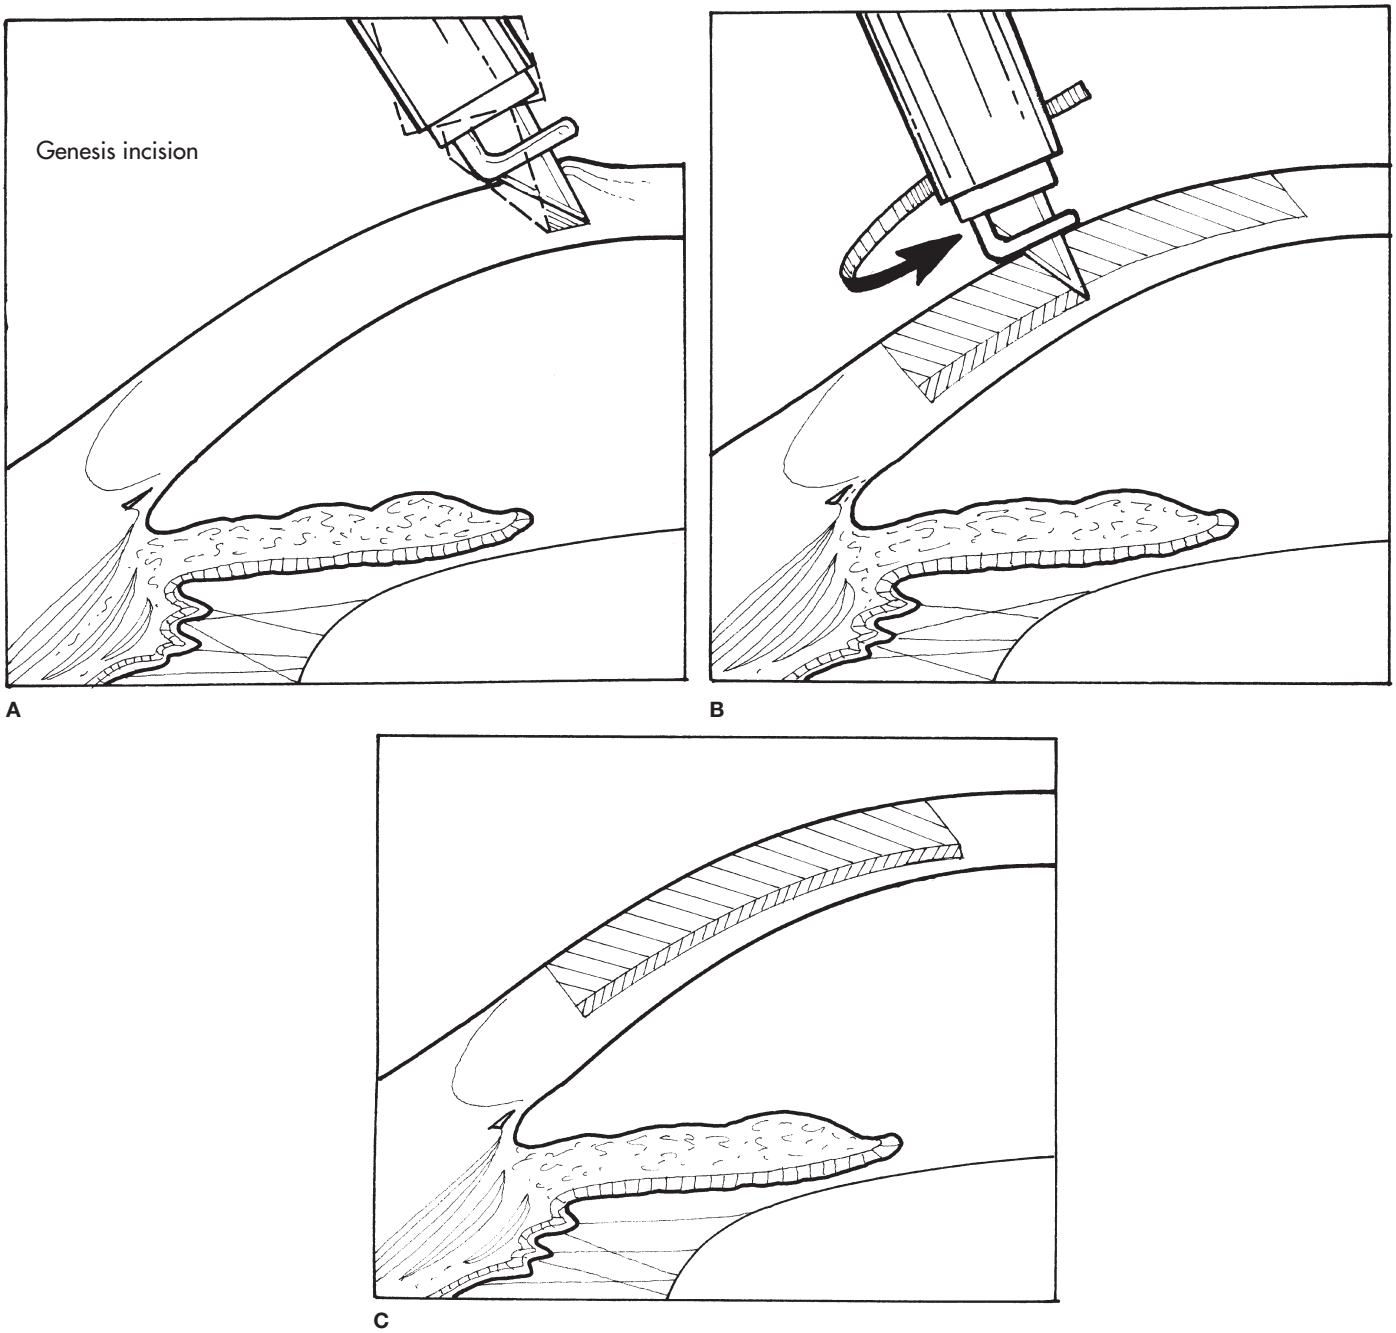

Figure 84.5. *A*, Initial corneal entry is with the diamond blade tip at a slightly oblique angle. After a 2 s pause, the optical zone margin is slightly undermined before perpendicularly orienting the diamond blade to perform the centrifugal (downhill) incision. *B*, The completed centrifugal incision is followed by a reversal in incision direction without removing the diamond blade. This centripetal (uphill) incision is deeper and guided within the initial incision. *C*, The completed *combined technique* incision has the advantages of each incision method, resulting in a uniformly deep and safe incision, with slight undermining of the optical zone margin for maximal efficacy.

The ideal RK incision should terminate 1 mm from the limbus to prevent neovascularization. The incision should remain at least 80% of corneal stromal depth throughout its length. At its central extent, the incision should undermine slightly at the margin of the central clear optical zone (Fig. 84.5, *A*), which enhances its efficacy.

The guarded diamond blade used in *combined technique* RK has a 45°-angled edge (the 'front' surface), which is the centrifugal cutting component in the combined technique, and is sharpened along its entire length. The vertical edge (the 'back' surface) has a cutting edge for only 250 µm from the blade tip (Fig. 84.6). The blunt upper part of the blade's vertical edge prevents unwanted invasion of the central clear optical zone margin during the final centripetal return in the combined technique.

Thinner diamond blades, although more susceptible to damage, were found to offer less resistance during incision, thereby providing a more consistent depth of incision. The 45° cutting angle of the diamond blade was also determined after experience with more acute angles, which meandered due to insufficient resistance, and broader angles, which offered too much resistance on initial insertion. The two footplates of the guarded diamond blade allow for precision of incision depth as well as forgiveness of nonperpendicular pressure by the surgeon, as shown in Figures 84.7, *A* and *B*

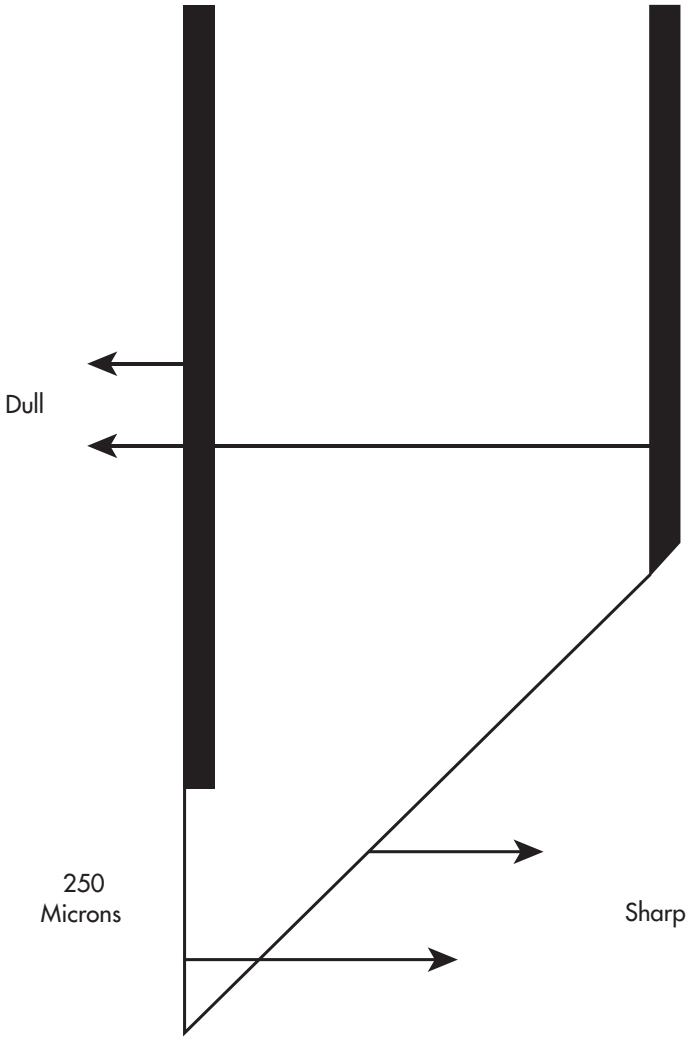

Figure 84.6. The diamond blade design for the *combined technique* incision has a 45°-angled edge, which is sharpened along its entire length, and a vertical edge, which is sharpened only 250 μm from the blade tip. The sharp part of the vertical edge provides additional depth of incision during the reverse centripetal pass, while the dull part of the vertical edge allows the blade to remain guided within the initial incision during this reverse pass.

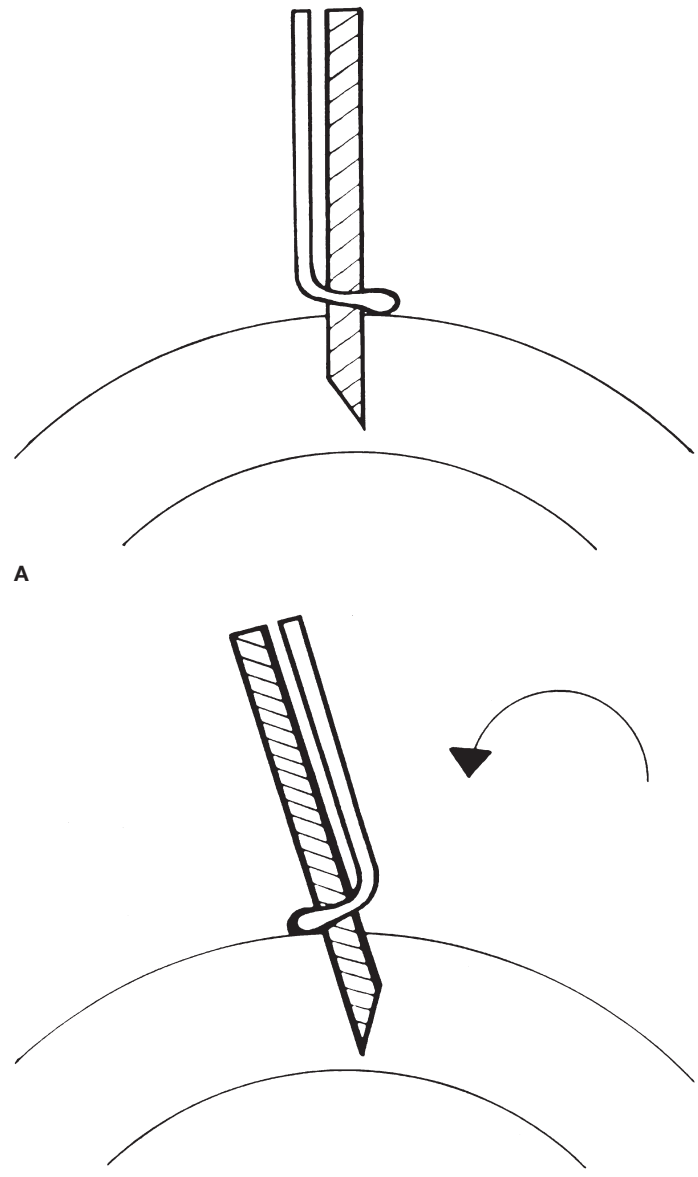

Figure 84.7. *A*, The footplates allow the guarded diamond blade to achieve a consistent depth of incision regardless of indentation pressure. *B*, The depth of incision remains consistent even when asymmetric pressure by the surgeon rocks the blade toward the vertical edge as shown. When the blade is rocked toward the angled edge, the blade tip can be displaced upward, resulting in some variability of incision depth.

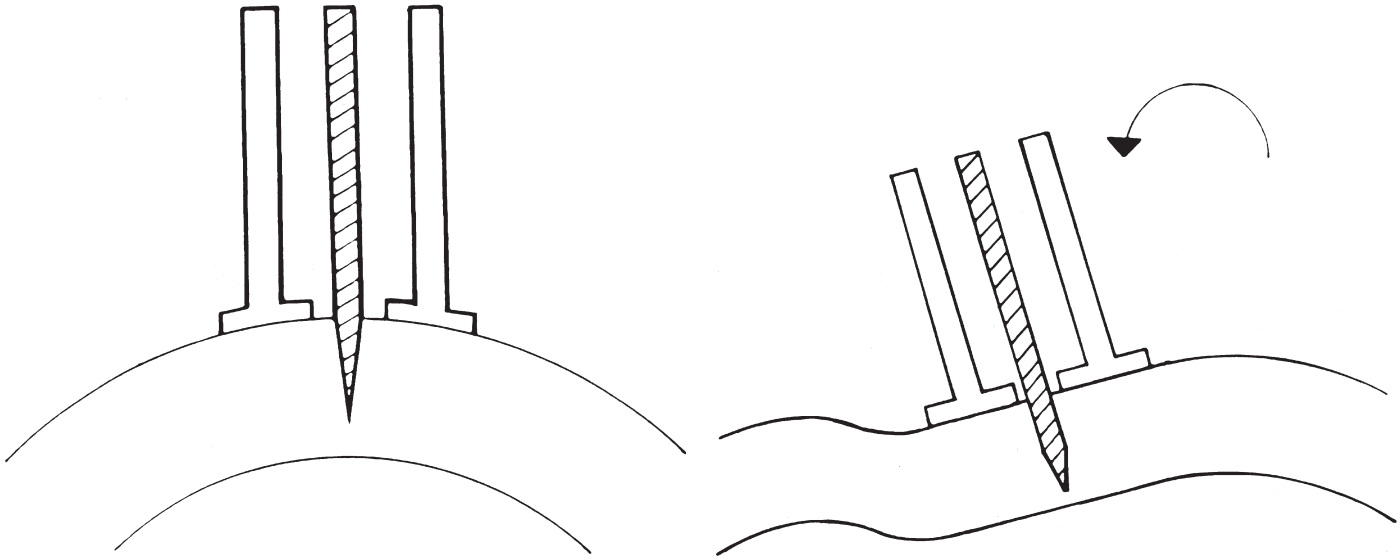
and 84.8, *A* and *B*. The spacing between footplates was found to affect incision depth by allowing more or less bowing of the cornea between the footplates and contact with the diamond blade, and this spacing was also made uniform.

Numerous incisional nomograms were developed by experienced RK surgeons, attempting to offer greater predictability of results and guiding the titration of enhancement procedures. Nomograms were also developed for the incisional treatment of astigmatism. Later nomograms took patient age into account, as it became apparent that age accounted for almost 1 D of greater refractive effect per decade of subject age.[29] Surgeons generally would aim for 0.50–1 D of residual myopia to allow for hyperopic shift, adjustment for presbyopia, and possible enhancement procedures, as there was no effective surgical treatment at the time for hyperopia from overcorrection.

Nomograms would vary the incisional factors that cause central corneal flattening, which include (1) the number of incisions, (2) the depth of the incisions, and (3) the length of incisions either centrally or peripherally. Regarding the number of incisions, it was found that approximately 90% of the effect of a 16-incision RK was present after the first eight incisions, and 70% occurred after the first four.[30] This 'law of diminishing returns' led to the development of nomograms using eight incisions or less. The depth of incisions is affected by incision technique as discussed earlier, and at least 80% corneal stromal depth is required for efficacy.[30] Shallow incisions were a common cause of undercorrection. With regard to incision length, the original Russian technique of peripheral extension to the limbus was found to have little refractive effect and carry a risk of neovascularization and increased pain.[30–32] Central incision length, namely the size of the clear central optical zone, was found to be the primary parameter in all RK nomograms, with smaller optical zones leading to more



A B

Figure 84.8. *A*, The broad area of contact between the footplates and the epithelium provides a consistent incision depth. *B*, This broad footplate base allows the depth of incision to remain consistent despite lateral asymmetric pressure by the surgeon as shown.

corneal flattening. However, attempts to correct greater degrees of myopia with smaller optical zones led to complications including disabling glare, irregular astigmatism, and loss of best-corrected visual acuity.[33] Ultimately it was thought that 6 D or less of myopia could be treated safely, with a central clear optical zone no smaller than 3 mm.[1,33,34]

COMPLICATIONS

Many of the long-term complications of RK were discovered by follow-up of the PERK study patients as discussed earlier, namely poor predictability, progressive hyperopic shift, diurnal fluctuation, and loss of best-corrected visual acuity. There were also intraoperative complications such as self-sealing microperforation in 4–10% of patients and frank perforation, which required nylon suture closure in 0.2% of patients in later studies.[32,35] Other long-term complications, which would be unacceptable by today's standards, include relatively high rates of irregular astigmatism, significant glare, loss of contrast sensitivity, neovascularization, epithelial inclusion cysts, subepithelial fibrosis, endothelial cell loss, bacterial keratitis, and even endophthalmitis.[32,36–39] Traumatic globe rupture along RK incisions have been reported as late as 18 years after surgery,[40] as the force required to rupture a porcine model globe after standard RK is only around a third of the force required to rupture an unoperated eye.[41] Case reports of RK incision dehiscence during phacoemulsification surgery suggest that a scleral tunnel incision can minimize corneal manipulation and reduce this complication.[42]

LASIK FOLLOWING RADIAL KERATOTOMY

The advent of excimer laser refractive surgery has not only supplanted RK as the primary refractive procedure but also provided a modality to treat the significant number of under- and overcorrected RK patients. PRK after RK showed a high risk of postoperative haze,[43] but LASIK after RK has consistently shown a reduction in refractive error with relatively few complications, as presented in a recent review of multiple studies.[44] The largest of these studies, of 80 and 69 eyes, showed similar results with preoperative mean spherical equivalent of $+2.36 \pm 1.17$ and $+3.40 \pm 1.60$ D, and postoperative mean spherical equivalent of $+0.62 \pm 0.61$ and -0.32 ± 1.2 D, respectively.[45,46]

The most common complication in both of these studies was a 5–6% rate of epithelial ingrowth, sometimes accompanied by loss of best-corrected visual acuity. Patients having LASIK after RK should, therefore, be monitored closely for any signs of epithelial ingrowth and treated with an early flap lift and scraping with any signs of progression. There was also a 12% rate of RK incision opening within the LASIK flap in one of these studies, but careful flap repositioning after ablation followed by 1 day of bandage contact lens wear resulted in no loss of best-corrected visual acuity in any of these patients.[46] A recent study of 11 RK eyes using the femtosecond laser for LASIK flap creation showed a 100% rate of RK incision opening within the LASIK flap due to disruption by the microcavitation bubbles and the greater resistance required to lift a femtosecond laser flap.[47] This study also showed an 18% rate of loss of best-corrected visual acuity, higher than in studies using a microkeratome, likely due to greater postoperative inflammation from femtosecond laser treatment.

LEGACY OF RADIAL KERATOTOMY

As a recent survey of refractive surgery in the USA shows RK to be nearly extinct less than 25 years after the PERK study began,[48] it is easy to become cynical about new procedures that are introduced today with equal enthusiasm. However, the important lessons learned from RK continue to have significance in modern refractive surgery. Radial keratotomy introduced the concept of an optical zone and provided our first understanding of the critical relationship between the optical zone and the pupil size with regard to symptoms of glare and contrast sensitivity.[36] The intricacies of the guarded diamond blade, which was refined for RK, are very relevant to modern incisional corneal surgery, and the corneal tissue response to astigmatic keratotomy, limbal relaxing incisions, and even clear

corneal cataract incision architecture are based on the knowledge gained from the various studies of RK.

But perhaps the lasting legacy of RK is the field of refractive surgery, which began its emergence with RK in the early 1980s. The idea that a patient's refractive error could be corrected surgically to reduce dependence on spectacles and contact lenses has created a demand that we still strive to meet today with new investigations and new procedures. Radial keratotomy introduced our approach to a patient presenting for elective refractive surgery, which today is among the most common ophthalmic surgeries performed in the USA.[49] As a recent European study of RK for the treatment of early keratoconus indicates,[50] perhaps the concepts and techniques of RK will be revisited in the future.

85 Astigmatic keratotomy and peripheral corneal relaxing incisions

David R. Hardten, Daniel H. Chang

INTRODUCTION

Correcting astigmatic refractive errors utilizing incisional techniques was among the first refractive corneal procedures performed. Astigmatism in the naturally occurring state is common, and up to 95% of eyes have some clinically detectable astigmatism, with up to 75% of the general population having clinically significant astigmatism.[1,2] This chapter provides an overview of astigmatic keratotomy and peripheral corneal relaxing incisions for the correction of astigmatism.

HISTORY

It appears that astigmatic keratotomy may have been the first corneal refractive surgical procedure performed by ophthalmologists. In 1885, Schiötz,[3] a Norwegian ophthalmologist, reported the case history of a patient who developed 19.50 D of astigmatism after cataract surgery. Four months postoperatively, he used a von Graefe knife to make a 3.5-mm penetrating incision at the limbus in the steep meridian, which reduced the astigmatism to 7.00 D. Lucciola of Terrin, Italy, was the first surgeon to report using nonperforating corneal incisions to correct astigmatism.[4] In 1894, Bates,[5] of New York City, described six patients who developed flattening of the cornea in the meridian that intersected a surgical or traumatic scar. He postulated that incisions of the cornea, made at right angles to the steeper meridian, might be used to correct astigmatism.

A Dutch ophthalmologist, Lans,[6] performed one of the first systematic studies of refractive surgery while at the University of Leiden in 1896. His doctoral thesis titled 'Experimental Studies of the Treatment of Astigmatism with Non-perforating Corneal Incisions' described carefully planned experimentation in rabbits to evaluate patterns of keratotomy, keratectomy, and thermokeratoplasty. These studies also defined some basic principles of astigmatic keratotomy. Lans showed that flattening in the meridian perpendicular to a transverse incision was associated with steepening in the opposite meridian and that deeper and longer incisions had a greater effect.

Even though radial keratotomy is rarely used today, its history is intertwined with that of astigmatic keratotomy. In 1939, Sato et al[7–13] of Tokyo observed that spontaneous breaks in Descemet's membrane in patients with keratoconus could flatten the cornea and reduce their myopia. Sato discussed the concept of coupling, in which transverse incisions might be expected to flatten the steep meridian while simultaneously steepening the flatter meridian.

In the early 1970s, Fyodorov and associates[14–16] varied Sato's technique and introduced the concept of radial incisions performed only in the anterior peripheral cornea and sclera. These investigators varied the diameter of the central clear zone according to the degree of correction desired. Fyodorov and Durnev[17] also devised a multifactorial formula using patient and surgical variables in an attempt to improve predictability of the procedure. Fyodorov and Durnev[18] discussed using several nonperforating anterior keratotomy patterns to correct myopic astigmatism.

The first RK procedure in the USA was performed by Bores and coworkers in 1978.[19] Subsequently, there has been substantial laboratory and clinical research, including technological advances in ultrasonic pachymeters and diamond micrometer knives that have made incisional procedures more predictable. In 1980, the National Eye Institute funded the Prospective Evaluation of Radial Keratotomy (PERK), which helped to define the safety and efficacy of RK.[20] Predictability, refractive instability, and visual quality are limitations of these procedures.[21–24] These problems, which could not be overcome by improved techniques and refined nomograms—as well as advances in the excimer laser—led to the rapid increase in excimer-based techniques with the concurrent decrease of incision-based techniques for the primary correction of refractive error in the mid- and late 1990s.[25] Nevertheless, the adjunctive use of incisional techniques such as astigmatic keratotomy and peripheral corneal relaxing incisions concurrently with other surgical procedures remains an excellent modality for the correction of astigmatism.

PRINCIPLES OF INCISIONAL KERATOTOMY

The cadaver eye model has played a major role in predicting qualitative and quantitative results achieved with incisional refractive surgery.[26–32] Corneal incisions increase the radius of curvature in a direction perpendicular to the incision, as if tissue were being added.

Arcuate or transverse incisions therefore flatten the cornea in the meridian perpendicular to their location (with compensatory steepening of the orthogonal meridian).

ASTIGMATIC KERATOTOMY

Several basic incisional patterns have been investigated, including nonperforating, straight transverse, and arcuate keratotomy incisions, for the reduction of astigmatism (Figs 85.1–85.3). The following principles of astigmatic keratotomy[33] apply to all types of astigmatism:

1. Astigmatic keratotomy incisions are placed in the steep corneal meridian. This is the meridian that is parallel to the plus-cylinder refraction axis and has the greatest power on central keratometry (Fig. 85.4).
2. Coupling refers to the ratio of corneal flattening along the incised meridian relative to the steepening along the unincised orthogonal meridian 90° away. Most arcuate incisions near the limbus are considered to have a coupling ratio of 1, and there is no change in the spherical equivalent. The exact coupling ratio depends on the length, location, and depth of the incision. Relatively short transverse incisions measuring 1–1.5 mm or arcuate incisions approximating 20° tend to flatten the incised meridian more than they steepen the unincised meridian 90° away, thereby creating a hyperopic shift in the spherical equivalent (coupling ratio >1). Transverse incisions measuring 2–5 mm in length or arcuate incisions of 30–90° create a coupling ratio that approximates 1. Longer transverse incisions measuring 5–6 mm or arcuate incisions of 90–120° tend to induce more steepening in the orthogonal meridian than flattening in the incised meridian, thereby creating a myopic shift in the spherical equivalent (coupling ratio <1).
3. The astigmatic change per unit length of arcuate keratotomy incision varies inversely with the optical zone size. Therefore, transverse incisions at a 5 mm optical zone produce greater astigmatic correction than incisions placed near the limbus (limbal relaxing incisions). However, since the amount of

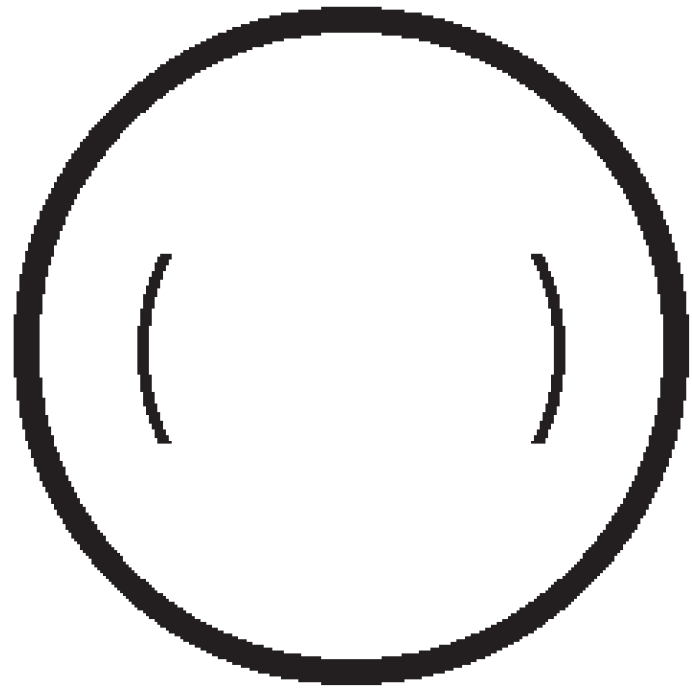

Figure 85.2. Arcuate incisions follow the same curvature as the limbus. These are most commonly used as they induce the least amount of irregular astigmatism compared to the other patterns. (Courtesy of VISX, Santa Clara, CA.)

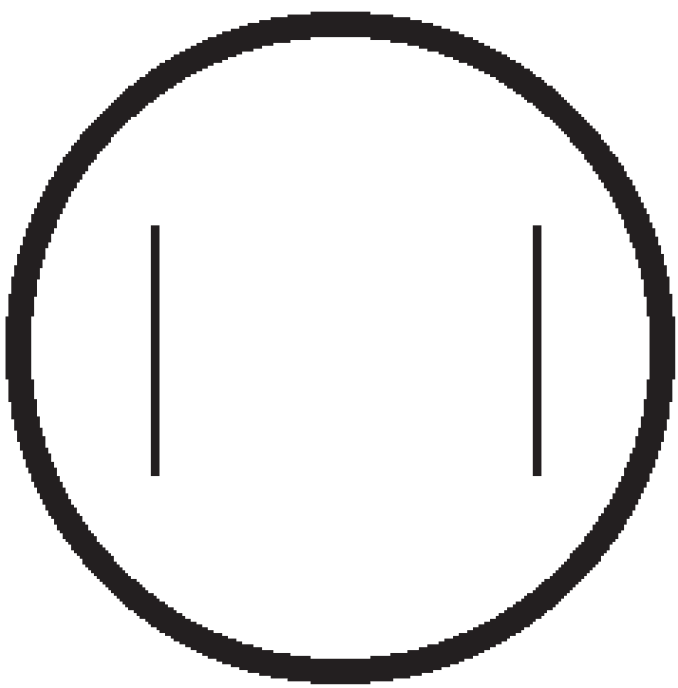

Figure 85.1. Multiple patterns of incisions can be used to reduce astigmatism. A transverse incision is a straight incision that is perpendicular to a radial incision. If these incisions are made very long, significant irregular astigmatism can occur, so are not used for significant degrees of astigmatism. (Courtesy of Meditec, Jena, Germany.)

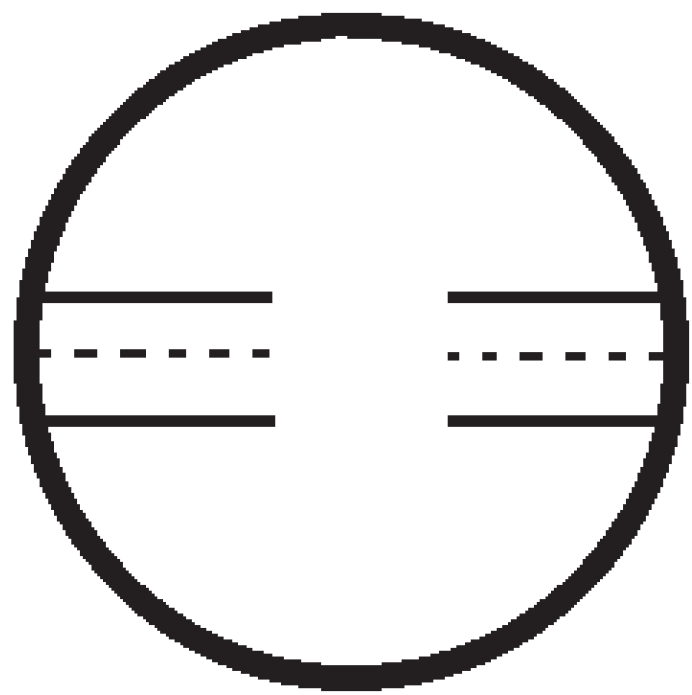

Figure 85.3. Semiradial incisions are parallel to a radial incision, yet set apart from the radial incision. In this figure, the dashed lines represent radial incisions and the solid lines, semiradial incisions. These incisions are not commonly used, as they also lead to greater irregular astigmatism than arcuate incisions. (Courtesy of VISX, Santa Clara, CA.)

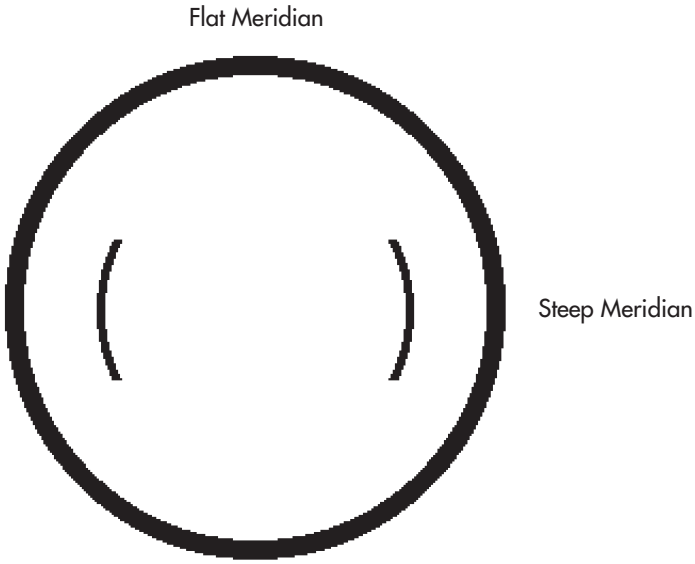

Figure 85.4. To reduce astigmatism, incisions are placed in the meridian that has the steepest corneal curvature, thus creating a more spherical cornea. (Courtesy of Alcon, Fort Worth, TX.)

induced irregular astigmatism and glare also varies inversely with the optical zone size, incisions at an optical zone less than 7 mm are rarely used.

4. Most of the effect of arcuate incisions is achieved with the first symmetric pair of keratotomy incisions; this accounts for about two-thirds of the effect. Placement of an additional pair of incisions will increase efficacy 25–33%, but this is now rarely used because of an increase in irregular astigmatism.
5. Transverse or arcuate incisions should not cross radial or semiradial incisions. Previous clinical studies have shown that when two incisions intersect, the point of intersection undergoes poor wound healing, which often leads to epithelial inclusion cysts, exaggerated scar formation,[34,35] and early and late wound dehiscence.

RADIAL KERATOTOMY (See Chapter 84 also)

Although no longer routinely performed in the USA,[36] basic principles are described for conceptual purposes of understanding corneal biomechanical properties. There are four surgical variables that can be adjusted to achieve the desired result.[37–41]

1. A smaller-diameter central clear zone has a greater net effect such that RK incisions with an optical zone of 6 mm or greater have virtually no effect on the refractive error.[42]
2. The degree of central corneal flattening varies directly (but nonlinearly) with the number of incisions. Four radial incisions achieve greater than 70% of the effect of eight incisions.
3. The degree of central corneal flattening varies with the depth of the incisions such that a double-pass technique offers a deeper incision centrally with less risk of inadvertently entering the clear optical zone.[43–45]
4. Incisions do not need to be carried to the limbus to achieve a near-maximal effect.[42,46]

The degree of correction and the patient's age affect the outcome of incisional keratotomy.[39–41,47] Patients older than 30 years have an increased effect of 1.5–2% per year over the age of 30 years, and patients younger than 30 years have a lesser effect of 1.5–2% per year under the age of 30 years. Other variables that affect the outcome and are hard to predict or control include corneal curvature, preoperative intraocular pressure, gender, corneal thickness, corneal diameter, axial length of the globe, and ocular rigidity. Most studies show that male patients, high intraocular pressure, larger corneal diameter, a thicker cornea, a flatter cornea, and a higher ocular rigidity tend to result in a greater effect.

PATIENT SELECTION

Because of its inherent unpredictability, instability, and poor visual quality, radial keratotomy has largely been abandoned for more modern techniques.[36,48] Astigmatic keratotomy is less commonly performed as a primary procedure for the correction of refractive error but remains a useful adjunct at the time of cataract surgery.[49–51]

Astigmatism greater than 0.5 D is seen in 44% of the population; 8% of the total population has astigmatism of 1.5 D or greater.[1] Generally, about 10% of the population can be expected to have astigmatism greater than 1 D. At this level, the quality of uncorrected visual acuity might be considered unsatisfactory. An astigmatic refractive error in the range of 1–2 D might be expected to reduce uncorrected visual acuity to the 20/30 to 20/50 range, and 2–3 D likely reduces uncorrected visual acuity to the 20/70 to 20/100 range.[52]

Visually significant astigmatism is also quite common after surgery. After extracapsular cataract extraction, astigmatism greater than 1 D is extremely common,[53] with astigmatism greater than 3 D being present in as many as 20% of cases. High astigmatism after penetrating keratoplasty is even more common, with astigmatism being greater than 1 D the norm.[54] Troutman and Swinger[55] estimated that nearly 10% of all penetrating keratoplasties are complicated by high postoperative astigmatism. The use of intraincisional relaxing incisions to correct this common postoperative problem is less predictable than correction of naturally occurring astigmatism.[55–61]

Patients considering astigmatic keratotomy and peripheral corneal relaxing incisions should have stable refractions for best results. Corneal topography can help ascertain which patients might be poor surgical candidates because of preclinical keratoconus, irregular astigmatism, or some other corneal abnormality. Topography maps are helpful in preoperative assessment, surgical planning, and postoperative monitoring of patients undergoing incisional keratotomy.

Nomograms for astigmatic keratotomy are based on averages for large numbers of procedures, so the outcome of surgery cannot be predicted for an individual eye. Additional refractive keratotomy or excimer laser vision correction may be needed to achieve the desired result, and spectacles or contact lenses may still be required for best visual acuity, even after surgery.

TECHNIQUE

Manifest refraction is performed preoperatively. In most cases, the keratometric, topographic, and refractive cylinder power and axis will be compatible. In cases of significant disparity, remeasurement is warranted; but lenticular or posterior corneal astigmatism may account for a difference in refractive and anterior corneal cylinder. Primary astigmatic keratotomy for naturally occurring astigmatism is based on the refractive cylinder and axis. At the time of cataract surgery and for postkeratoplasty astigmatism, keratometric values

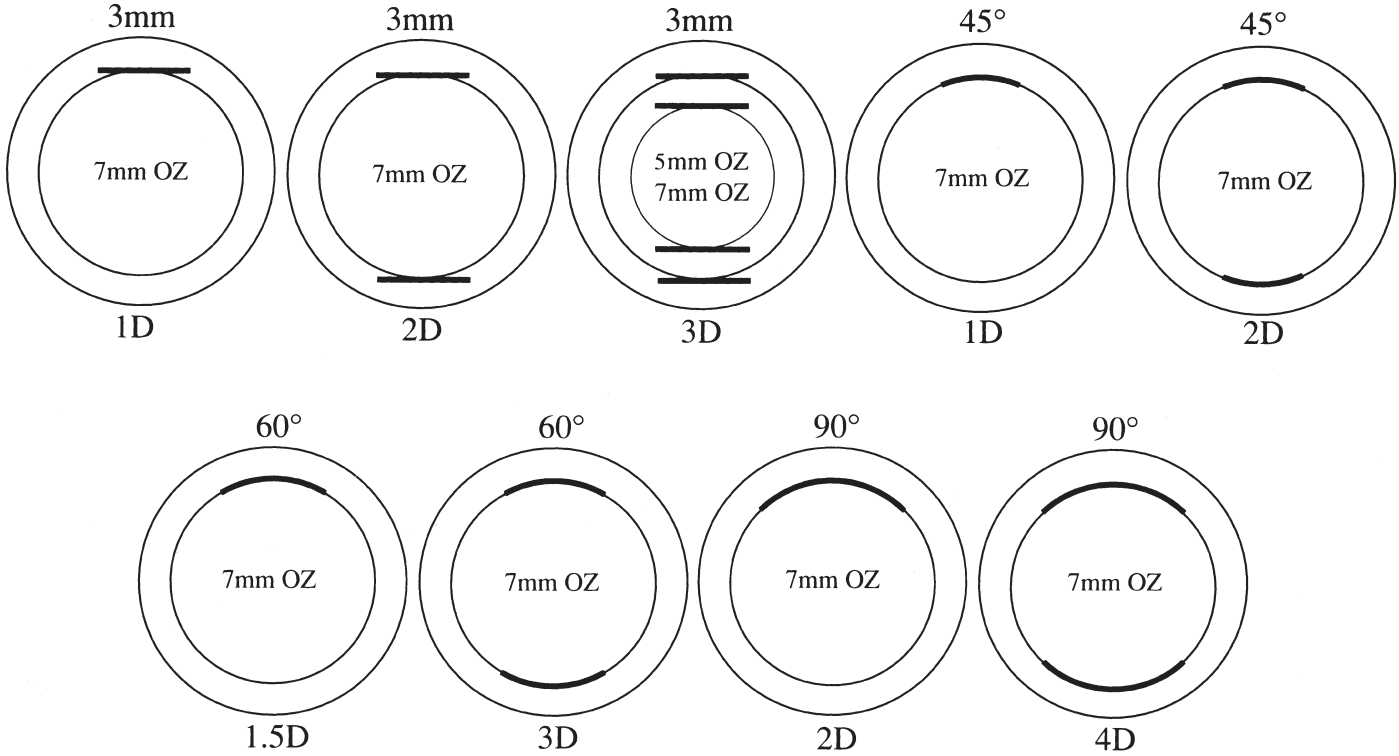

Figure 85.5. Lindstrom nomogram for astigmatic keratotomy. (Courtesy of Aesculap-Meditec, Jena, Germany.)

and topographic maps are generally used in conjunction with the refractive cylinder and axis.

Arcuate keratotomies are placed coincident with an optical zone, typically 7 mm or larger. Transverse incisions are easier to make, yet may induce more irregular astigmatism than arcuate keratotomies. Incisions placed closer to the center of the visual axis induce more glare secondary to irregular astigmatism and carry a greater risk of inadvertently violating the visual axis. Arcuate keratotomy corrections are shown in Figure 85.5 and Table 85.1.

When using these nomograms, it is assumed that the transverse incisions flatten the steeper meridian the same amount as they steepen the flatter meridian (a coupling ratio of 1); so the net effect is no change in the spherical equivalent. This applies to paired arcuate incisions between 30° and 90°, similar to 3 mm-long paired transverse incisions. Arcuate incisions less than 20° have a coupling ratio greater than 1, and arcuate incisions greater than 100° have a coupling ratio less than 1. Arcuate incisions greater than 90° are not recommended because the coupling ratio diverges from 1, and late wound dehiscence is more common. In general, limiting the initial procedure to arcs of less than 60° is preferred.

Younger patients tend to achieve a lesser effect than older patients, therefore the nomogram is adjusted according to the patient's age. The expected result should be decreased by 2% per year for patients younger than the age of 30 years and increased by 2% per year for patients older than the age of 30 years.

Equipment needed includes an operating microscope, arcuate keratotomy markers, a diamond knife, and an ultrasonic pachymeter. The patient is centered under the operating microscope, and the eye is positioned perpendicular to the microscope. The eye is anesthetized with 0.5% proparacaine. The patient fixates on the operating microscope light, which is turned to a low level, or a red fixation light mounted on the microscope. The optical zone is then marked with an appropriate optical zone marker, depending on the amount of astigmatism to be corrected. Special arcuate keratotomy markers are available that imprint both the desired optical zone and a graduated scale (Figs 85.6 and 85.7). The marker blades can be coated with ink for better visualization.

The steeper meridian is marked with a skin-marking pen using preoperative landmarks and an axis marker. Use of photokeratoscopic guidance from a corneal topographer can be beneficial in identifying the axis of astigmatism. By superimposing a printout of the eye image over a printout of the computed axial map, surgical planning and location of incisions can be diagramed. Intraoperatively, correlation of iris landmarks from the eye image printout to the actual eye can be used to help determine the proper rotational alignment independent of cyclorotation.

The corneal thickness coincident with the intended optical zone in the steepest meridian is measured on both sides of the cornea intraoperatively with ultrasonic pachymetry. A diamond knife blade is set at 50 μm deeper than the thinnest paracentral pachymetry measurement or at 100% of the thinnest pachymetry reading at the desired optical zone. For 9 or 10 mm optical zone incisions, many surgeons set the blade at a fixed 600 μm setting.

The patient is asked to fixate on the operating microscope light or the fixation light. The knife is placed into the cornea and allowed to seat for a second. This is followed by a slow, steady guidance of the knife through the incisions (Fig. 85.8). A front-cutting knife allows the surgeon good visibility while pushing through the length of the keratotomy incision, thus improving accuracy. A square blade may provide better tracking. When combining the surgery with cataract surgery, performing the astigmatism incisions first allows for a firmer globe that facilitates the placement of the astigmatic incisions.

The patient is generally seen 1 day and 1 month postoperatively. Topical antibiotics are continued until the corneal epithelium is

Table 85.1 ARC–T 8–9 mm nomogram

How to use this nomogram

- Identify the patient's age and the diopters of refractive cylinder that you wish to correct.
- Find the patient's age in the first column on the left.
- Move to right until you reach the surgery results closest to the refractive cylinder of the patient. In order to avoid overcorrection, typically you would select a surgical goal somewhat less than the actual refractive cylinder. The column heading then tells you which surgery is typical to achieve closest to this result.

Example

- A 45-year-old patient with a refractive cylinder of 2.25.
- Moving to the right on the Age 45 line, you see that 2.25 falls between 1.95 and 2.60. Looking at the column headings, you see that a Paired 60° ARC-T will correct 1.95 D of cylinder. A Paired 90° ARC-T will correct 2.60 D of cylinder.
- In this case you would typically perform a Paired 60° ARC-T procedure.
- Expected surgical results were calculated using Lindstrom's formula:

$\Delta D = [100 + (\text{Age} - 30) \times 2] \times [\Delta D \text{ at age } 30] \times 0.01$

Find patient age, then move right to find result closest to refractive cylinder without going over.

re-epithelialized. The 1-month result correlates well statistically with the 1-year result, but additional astigmatic enhancement should not be considered until the refraction and keratometry measurements are stable.

INCISIONS WITH CONCURRENT CATARACT SURGERY

The principles of astigmatic keratotomy and peripheral corneal relaxing incisions can be a useful adjunct in refining refractive outcomes at the time of small-incision cataract surgery.[49–51] The cataract wound itself is an incision that can alter the astigmatism of the eye. Variation of the incision parameters such as length, width, and location can be useful but requires rotation around the operating table and adjustments of the hand position and technique. Additionally, with increasing awareness of wound placement and construction for the prevention of bacterial endophthalmitis after cataract surgery,[62] altering wound anatomy for astigmatism control may compromise the self-sealing quality of the incision. Some authors have suggested the creation of an opposite clear corneal incision during cataract surgery to augment the astigmatic effect of the cataract wound.[63] While this approach may be advantageous without requiring the acquisition of additional skills or equipment, creation of a second full-thickness incision may increase the risk of postoperative infectious complications.[64]

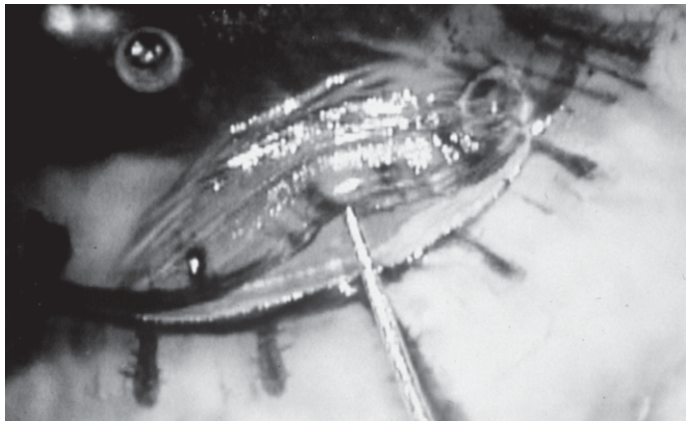

Figure 85.6. An arcuate keratotomy marker can be used to mark the orientation and length of incisions. The marker is aligned in the proper orientation of the steep axis of astigmatism, and the incision then is created along the line of the marker. (Courtesy of Bausch & Lomb, Rochester, NY.)

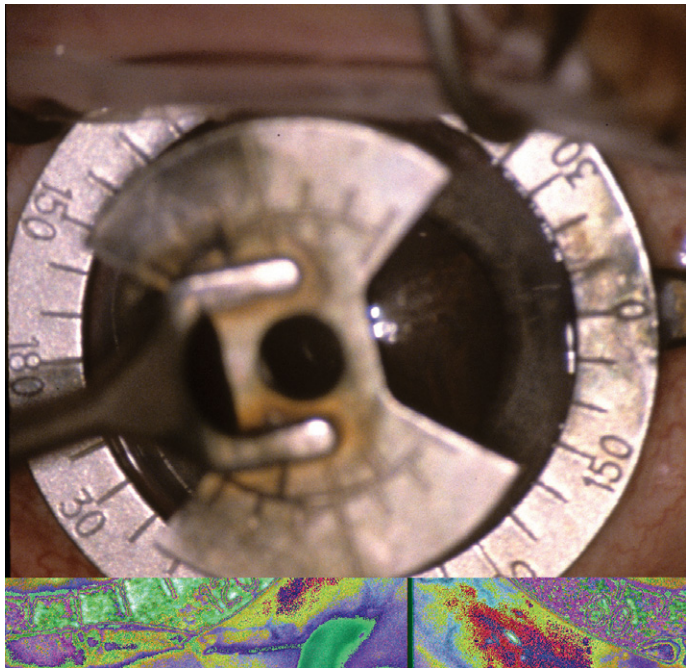

Figure 85.7. Using an AK marker to make an imprint with or without ink on the cornea can be helpful in aligning the AK incisions on the correct axis. Marks on the conjunctiva can be used to align the reticule to the proper orientation. A marker that marks at a 9-mm optical zone can be used, although using a 7-mm marker and following the outer tips of the marks also allow an incision at the 9-mm optical zone. A reticule is used to align with marks at the 3 and 9 o'clock positions to verify the axis of the incision. (Courtesy of Nidek, Fremont, CA.)

Since most surgeons prefer a single approach to the majority of their cases,[48] the use of peripheral corneal relaxing incisions in conjunction with a small-incision cataract wound surgery is an effective method of astigmatism control.[51] Although most surgeons prefer a clear corneal temporal wound, peripheral corneal relaxing incisions can be used with any wound, provided that the surgeons accounts for the astigmatic effect of the wound. The peripheral corneal relaxing incisions can be placed before or after the cataract surgeon, although large incisions at the phaco wound may case excess gaping and fluid egress.

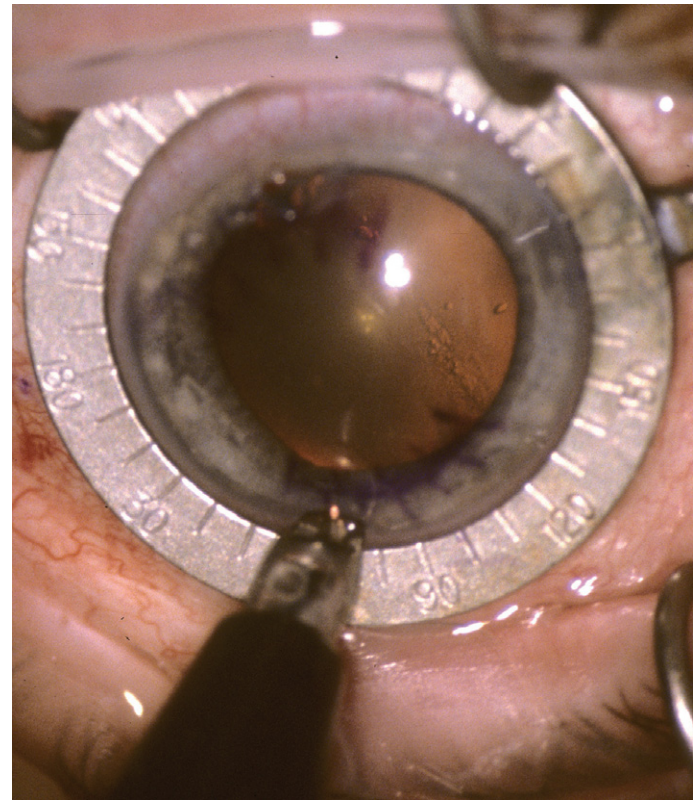

Figure 85.8. A slow, steady movement of the knife in the tissue is used to follow the marks for the incision. A reticule is used to align with marks at the 3 and 9 o'clock positions to verify the axis of the incision. (Courtesy of Nidek, Fremont, CA.)

INCISIONS FOR POSTKERATOPLASTY ASTIGMATISM

High corneal astigmatism is a common complication after penetrating keratoplasty. While there are now many modalities for reducing postkeratoplasty refractive error, incisional techniques such as relaxing incisions, compression sutures, and wedge resections remain useful in the correction of large degrees of astigmatism.[65]

In eye-bank eyes, a marked disparity in the magnitude of change after symmetric 60–90° incisions indicated a narrow surgical 'safe' zone. Clinically, marked under- and overcorrections have been achieved in postkeratoplasty astigmatism with the use of relaxing incisions, making the determination of a suitable endpoint somewhat difficult.

The operative procedure involves careful dissection of the graft–host interface in a graded fashion. A gradual and careful deepening of the incision in the graft–host interface with use of a metal knife appears to be more controlled than with use of a diamond knife. In some cases, blunt dissection with the noncutting edge of the knife may actually be helpful. The use of a surgical keratometer is helpful for assessing the endpoint. Alternatively, the patient's keratometric values can be obtained intermittently with use of a conventional keratometer until the desired endpoint is obtained. The preferred endpoint is a spherical cornea or slight (up to 33%) overcorrection in most cases. Longer incisions, however, tend to progressively gape as they heal; and in 75–90° incisions, it may be desirable to leave a small amount of undercorrection. An appro-

priate incision length should never exceed 90° of the circumference of the graft.

A major disadvantage of incisions in the graft–host interface is the possibility of wound dehiscence. To avoid this complication, incisions can be placed in the donor graft. Standard 600 µm deep paired 60° incisions placed 6 mm apart resulted in a decrease of postkeratoplasty astigmatism from 10.99 to 3.33 D.[66] Interestingly, the amount of astigmatic correction was linearly proportional to the amount of preoperative corneal astigmatism, suggesting that nomograms for correcting naturally occurring astigmatism may not apply to postkeratoplasty corneas.

COMPRESSION SUTURES

The addition of compression sutures to either relaxing incisions or arcuate keratotomy incisions can markedly increase the net effect of astigmatic correction. Compression sutures can be placed on each side of the graft–host interface 90° away from the astigmatic incisions. Suture depth should be about 75%. The sutures are tied with a slipknot and adjusted under keratometric or intraoperative computerized topographic control until the eye is spherical or an overcorrection of 33% is achieved. The knots are cut short and then buried. The use of 11–0 polyester suture can be advantageous over 10–0 nylon because, if perfect surgical correction of astigmatism is achieved, it may be desirable to leave the sutures in place for extended periods of time. Nylon will hydrolyze in 2–5 years, whereas polyester suture will last longer than 7–10 years. Compression of the corneal tissue with conductive keratoplasty in the meridian opposite of the relaxing incisions can also be considered.

WEDGE RESECTION

The wedge resection technique is reserved for correction of large degrees of postkeratoplasty astigmatism. In general, resection of 0.1 mm of tissue results in about 2 D of astigmatic correction. This operation is reserved for patients with greater than 10 D of astigmatism; it is capable of correcting up to 20 D of astigmatism. Wedge resection, however, requires prolonged postoperative rehabilitation because of the placement of multiple sutures, which induce a significant amount of irregular astigmatism. Nevertheless, the alternative to wedge resection is repeating penetrating keratoplasty. Therefore, an attempt at wedge resection may be preferable to immediate repeat keratoplasty.

The overall effect of wedge resection is to steepen the flatter meridian about twice as much as it flattens the steeper meridian. The net effect is an increase in myopia or a decrease in hyperopia. For example, if the preoperative refraction was $-6.00 + 12.00 \times 90°$ and keratometry was $40.00/52.00 \times 90°$, a perfect result should give postoperative keratometry measuring 48.00/48.00 with a refraction of –2 D. This would result in a 2 D myopic shift.

COMPLICATIONS

OPERATIVE COMPLICATIONS

Corneal perforations may be identified as a microperforation (in which a loss of one or two drops of aqueous humor) or as a macroperforation (in which there is shallowing of the anterior chamber). Macroperforation usually requires termination of the procedure and possible closure of the perforation with suture. The PERK study reported a 2.3% microperforation rate, with no cases requiring suturing or termination of the surgery.[67] Most microperforations occur in the inferior and temporal cornea, where the cornea is relatively thinner, although they may appear in any location.[68–70] Macroperforations occur with a frequency of 0–0.45%[70–73] and can result in scar formation at the level of Descemet's membrane, damage to the corneal endothelium, iridocorneal adhesions, and laceration of the anterior lens capsule.[74]

POSTOPERATIVE COMPLICATIONS

Complications such as epithelial iron lines,[75] anterior corneal epithelial basement membrane changes,[76] epithelial inclusion cysts,[24,77] and epithelial ingrowth[78]—as seen after RK—are occasionally noted after astigmatic keratotomy and peripheral corneal relaxing incisions. Incisions that cross the limbus may cause bleeding into the wound, stimulating a vascularized limbal scar, and enhancing growth of neovascular vessels into the wound.[79] Intersecting incisions produce severe wound gape and significant degrees of scarring.[34,80] Intersecting radial and transverse incisions creates a wound gape at the area of intersection that fills with stromal scarring and is frequently accompanied by extensive subepithelial opacification spreading out from the wound (Fig. 85.9).[81] Such scars induce irregular astigmatism but also substantially increase light scattering and glare.

Bacterial or fungal keratitis, with the infiltrates contiguous to the keratotomy scars, can occur in the immediate postoperative period or can be delayed several years after incisional keratotomy.[71,82–86] The persistent epithelial plug in the keratotomy wound is implicated in delayed bacterial and fungal keratitis.[87] Bacterial endophthalmitis may occur due to corneal perforation and introduction of microorganisms into the eye, either during or shortly after the surgical procedure.[88–91]

Any corneal incision results in a scar that does not have the same tensile strength as the original cornea. This is true not only after incisional keratotomy but also after corneal transplantation or acci-

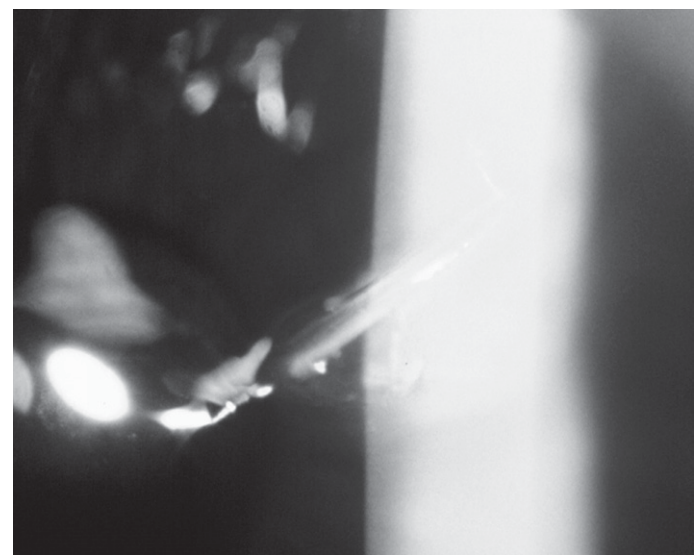

Figure 85.9. Crossing radial or astigmatic incisions can cause areas of poor wound healing with ectasia of the tissue or scar formation and epithelial inclusion cyst formation. (Courtesy of WaveLight, Erlangen, Germany.)

dental trauma.[92] There are several reports of traumatic rupture of keratotomy scars after blunt trauma.[93–95]

Blepharoptosis is a reported complication of incisional keratotomy.[96,97] Because retrobulbar injections and superior rectus bridle sutures were not used in the cases reported, the most likely cause of blepharoptosis was damage to the levator aponeurosis by the eyelid speculum. It has been suggested that a gentle wire speculum might be less likely to induce ptosis than a solid, rigid eyelid speculum.[97]

REFRACTIVE COMPLICATIONS

The most frequently reported complication of astigmatic keratotomy and peripheral corneal relaxing incisions is an inaccurate outcome—overcorrection, undercorrection, and induction of irregular astigmatism. Diurnal fluctuation of vision and progressive shifts in refraction, as seen with RK, are rare.[98–100]

Refractive over- and undercorrection after incisional keratotomy can be managed by spectacles or contact lenses. Contact lenses are advantageous if anisometropia is present, but contact lens fitting after incisional keratotomy has its own unique problems. Neovascularization of perilimbal incisional scars has limited the fitting of patients with soft contact lenses.[101,102]

For the surgical management of overcorrections after astigmatic keratotomy, one can reopen previously placed keratotomy incisions and then close with interrupted sutures instead of placing additional astigmatic incisions.[103] Suture pattern can be varied based on the number and location of incisions.[104,105] Previously placed incisions can be bluntly opened with a Sinskey hook and then copiously irrigated with balanced salt solution to the depth of the incision. The incisions can then be closed with two or three 10–0 nylon or 11–0 polyester sutures. Intraoperative control of suture tension with a surgical keratometer or intraoperative computerized topography and the use of slipknots are helpful. The sutures are used to obtain a spherical result or a slight overcorrection of up to one-half of the preoperative cylinder in the appropriate direction. The overcorrection is important because much of the effect will decay with time.[106] Selective suture removal can begin 8 weeks after suture placement as needed.

Although potentially beneficial in the short term, suture techniques can be meticulous, challenging, and yield unpredictable refractive results. With the advent of the excimer laser, PRK[107] and LASIK[108–110] have been used to correct induced refractive errors after incisional keratotomy. Although early studies of PRK after RK without the use of mitomycin C resulted in significant anterior stromal scarring and haze, the addition of mitomycin C has reduced this unwanted complication.[111] Wavefront-guided technologies offer exciting new possibilities for treating postoperative refractive complications after incisional keratotomy with both LASIK and PRK.

CONCLUSION

Although once a mainstay of refractive surgery, incisional keratotomy is now reserved for specific applications where safety and efficacy are still comparable to modern techniques. Although technologic advances have introduced newer methods for correcting refractive error, it appears that modern incisional surgery will continue to have a role in the future of refractive surgery as a reliable method of correcting low degrees of astigmatism, particularly at the time of small incision cataract surgery. Therefore, a thorough understanding of the corneal biomechanical response to incisional keratotomy will continue to be important to corneal and refractive surgeons.

86 Conductive keratoplasty

Richard L. Lindstrom, H.L. Rick Milne, Michael Gordon

INTRODUCTION

Conductive keratoplasty (CK) is a laserless, nonablative, radiofrequency-based collagen shrinking treatment that has been shown to change corneal curvature effectively and safely in numerous clinical trials. Conductive keratoplasty was first used to treat spherical hyperopia,[1–4] and was approved by the USA Food and Drug Administration (FDA) for the treatment range of +0.75 to +3.25 D in patients aged 45 years or older in April 2002. Clinical experience with this refractive group revealed that patients frequently gained near vision without losing as much distance vision as could be expected. This observation led to the exploration of a new CK application—the treatment of presbyopes in the nondominant eye to improve near visual acuity without marked loss of binocular distance vision.

In March 2004, CK was approved by the FDA for treating symptoms of presbyopia in emmetropes or mild hyperopes (+1.00 to +2.25 D), 40 years of age or older, through induction of 1.00–2.00 D of myopia in the nondominant eye. Other potential uses of the CK technique under investigation include treatment of over- or undercorrections following LASIK or other excimer laser procedures, enhancing outcomes of cataract surgery, and treating astigmatism.[5–9] This chapter will explain the mechanism of action of CK, how to perform the procedure, and its application for treating hyperopia, presbyopia, and other conditions.

HISTORY OF CORNEAL STEEPENING PROCEDURES

While hyperopia and presbyopia share little but the inability of patients to see well at near, both conditions have been treated through corneal steepening procedures. Early attempts to steepen parts of the cornea involved direct, local application of heat, which became known as thermokeratoplasty. In the late 19th century, Dutch ophthalmologist L. J. Lans induced collagen shrinkage with resultant corneal curvature changes by heating rabbit corneas.[10] Since then, various attempts have been made to shrink corneal collagen in humans. The Russian surgeon, Svyatoslav Fyodorov, was the first to use thermokeratoplasty to change corneal refraction in 1981. Using a probe tip heated to 600°C, he and other investigators applied controlled thermal burns to a reported depth of 95% to treat spherical hyperopia and hyperopic astigmatism.[11–13] Although high hyperopic corrections were achieved, later studies showed lack of predictability and marked regression.[14–16]

Also in the early 1980s, Rowsey and Doss developed the Los Alamos thermokeratoplasty probe.[17] This instrument heated stromal collagen by means of radiofrequency waves instead of by direct thermal conduction from a heated instrument.

However, the topographical effect with this probe was short lived, and testing was terminated.

Subsequently, several types of lasers were used in attempts to change corneal curvature with varying results. Of these, the only commercially successful system for steepening the central cornea to treat hyperopia was the noncontact method of holmium:YAG laser treatment by Sunrise Technologies of Fremont, California. This system came to be known as laser thermal keratoplasty (LTK). Early histology studies in animal eyes showed a cone-shaped zone of collagen shrinkage in the stroma after LTK treatment.[18] A later histology study in rabbit and human corneas showed a broad spectrum of histological changes in the epithelium and stroma, and a brisk wound healing response.[19] Among the questions that remained after study completion was the extent of postoperative regression induced by new collagen formation during stromal wound healing following LTK.

For treatment of hyperopia, LTK was applied to the surface of the cornea in one or two rings (at the 6- and 7-mm optical zones) of eight focal spots in each ring, while the patients sat with their chin in chin rests. A foot switch activated the simultaneous release (to all spots at once) of Ho:YAG infrared laser energy. Clinical studies with 2-year follow-up of LTK treatment of hyperopes were published.[20–22] The FDA approved the Hyperion LTK device in June 2000 for treatment of patients 40 years of age or older with a stable refraction of +0.75 to +2.50 D and less than 0.75 D of astigmatism. Approval was based on results from a study cohort of 612 eyes, with 80% available for analysis at 12 months and only 12% at 24 months postoperatively.[23] Longer-term data of Sunrise LTK showed disappointing efficacy,

predictability, and stability, and the device is no longer manufactured by Sunrise Technologies.

In the 1990s, Antonio Mendez, MD, studied radiofrequency as an alternative to procedures that applied heat directly to the corneal surface.[24] His success in denaturing collagen and steepening of the cornea led to the development of the Conductive Keratoplasty® procedure (CK), performed with the ViewPoint CK System (Refractec Inc., Irvine, CA). Conductive keratoplasty was approved by the FDA in April 2002 for the treatment of mild to moderate (0.75–3.00 D) previously untreated, spherical hyperopia in persons aged 40 years or older. This was followed by the approval in March 2004 of CK to reduce the symptoms of presbyopia in presbyopic hyperopes (+1.00 to +2.25 D) or emmetropes through induction of a mild myopia in the nondominant eye. Other potential uses of the CK technique under investigation include treatment of over- or undercorrections following LASIK or other excimer laser procedures, enhancing outcomes of cataract surgery and treating astigmatism.

THE PRESBYOPIC CONDITION AND TREATMENT OPTIONS

PRESBYOPIA PREVALENCE

Although CK was shown to be an excellent treatment for hyperopia, its most popular use is in the treatment of presbyopia. This is due to the large and growing number of presbyopes worldwide and their desire for improved functional near vision without spectacles. Eighty-six million Americans (baby-boomer generation) and 73 million Eastern and Western Europeans are currently 41–59 years old and are or will soon become presbyopic. Although the myope may have delayed onset of presbyopia, the condition spares no one as it is universal and correlated with aging. Beginning with the age of 40 years, the nearest point that can be focused recedes gradually, leading eventually to the need for spectacles for near tasks, such as reading, and perhaps even for focus at an intermediate distance.

Studies indicate that many presbyopes, especially emmetropic presbyopes who did not need an optical correction in their younger years, dislike wearing spectacles to perform common, everyday tasks and are interested in a treatment that can extend the period of spectacle-free near vision. However, unlike young myopes seeking refractive correction, patients seeking surgical correction for presbyopia are greatly concerned about procedure safety and are decidedly more averse to risk. Many presbyopes would rather stay with their spectacles than undergo a procedure they perceive as risky. In addition, many older patients have subclinical dry eye that can become problematic following LASIK. Thus, the CK procedure, which does not require the creation of a flap or ablation with a laser can be especially appealing to the older presbyopic patient. Furthermore, the safety of CK has been demonstrated in clinical trials and in the vast majority of patients treated by numerous surgeons after the trials. Other available procedures for improving near vision in presbyopes, on the other hand, such as monovision LASIK or PRK, are associated with compromised stereopsis for central vision, small reductions in binocular acuity, and reduced contrast sensitivity.[25]

TREATMENT OPTIONS FOR PRESBYOPIA

Treatments for presbyopia can be grouped into those for phakic eyes and those for aphakic eyes. Dan Durrie, MD, has developed a model grouping presbyopic patients into stages and his recommended treatment is that those who are risk averse, have good distance vision, less than 1+ to 2+ nuclear sclerosis, and need only spectacles for near are treated with NearVision CK, while those with 1+ to 2+ lens changes or a family history of lens changes are treated with cataract surgery and intraocular lens (IOL) implantation (D. Durrie, personal communication). In this way, the aging patients receive a continuum of care from their ophthalmologists.

For phakic presbyopes, excimer laser procedures, including monovision PRK and monovision LASIK, have been successfully applied, with patients showing a fairly high degree of satisfaction regarding visual outcome and postoperative function.[26–32] However, compromises in binocular vision; reduced contrast sensitivity, especially at higher spatial frequencies; and reduced stereoacuity are sequelae of these procedures, and careful patient education and selection are essential for postoperative patient satisfaction. In addition, LASIK surgery itself is associated with certain safety issues, such as the risks of flap creation and management, severing of corneal nerves that causes dry eye, healing problems, and possibility of diffuse lamellar keratitis.[33–36] As mentioned above, safety issues are a major concern with older patients and can be the deciding factor in a patient's decision to undergo a procedure.

THE CK SYSTEM

The CK procedure is performed with the ViewPoint® CK System (Fig. 86.1, *A* and *B*) and is based on the delivery of radiofrequency energy through a fine tip (Keratoplast® tip) inserted into the peripheral corneal stroma. Energy delivery at the treatment spots causes collagen in the area surrounding the tip to shrink and form a uniformly cylindrical thermal lesion in the stroma. A full circle of CK spots, applied to the peripheral cornea, produces a 'cinching' effect that increases the curvature of the central cornea. The peripheral cornea flattens and the central cornea steepens. This produces a myopic shift (Figs. 86.2 and 86.3). Figure 86.4 shows a Pentacam image of the optical changes in the cornea and in the entire optical system of the eye following NearVision CK. This analysis may explain why CK improves patients' near vision without the patients losing functional distance vision.

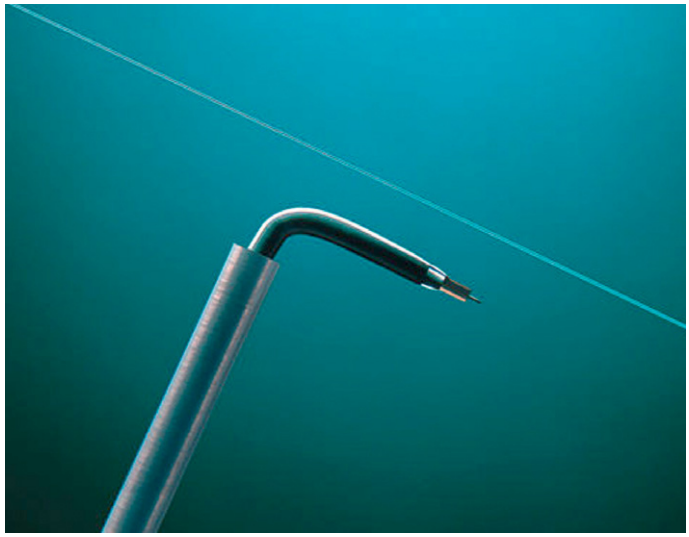
The Keratoplast tip only delivers radiofrequency energy and acts as a heat sink, rather than as a heat source. The increase in tissue temperature progresses from bottom (deep in the stroma) to top (corneal surface), and corneal tissue is exposed to the same temperature at the bottom of the probe as at the top of the probe. This is in contrast to treatment with the Sunrise LTK system, which had a significant axial gradient and produced the highest temperatures at the corneal surface because of the high absorption of light energy in water. The Ho:YAG beam is attenuated as it passes through the cornea so that the heat energy diffuses radially and axially into the tissue. The result is a cone-shaped collagen shrinkage zone,[37] with corneal denaturation decreasing from top to bottom. The footprint after CK treatment is cylindrical and extends deep into the stroma to approximately 80% depth (Fig. 86.5). This is in contrast to the conical stromal footprint that was reported with the LTK technique.[18]

PERFORMING THE CK PROCEDURE FOR THE TREATMENT OF PRESBYOPIA

PATIENT SELECTION

For the improvement of near vision in presbyopic emmetropes and hyperopes with the CK procedure, the goal is to overcorrect the

A



B

Figure 86.1. *A*, ViewPoint® CK system. The ViewPoint CK system from Refractec, Inc. consists of a portable console, a corneal marker, choice of lid specula, a handpiece that holds the Keratoplast® tip, and a foot pedal. An insulated stop at the base of the probe controls the depth of penetration of the Keratoplast tip. Energy is delivered into the cornea by activation of the foot pedal, *B,* The Keratoplast tip (shown next to a 7–0 suture). The tip is 450 μm long and 90 μm wide and is used to deliver radiofrequency energy into the corneal stroma at selected treatment points. A cuff on the probe assures correct depth of penetration.

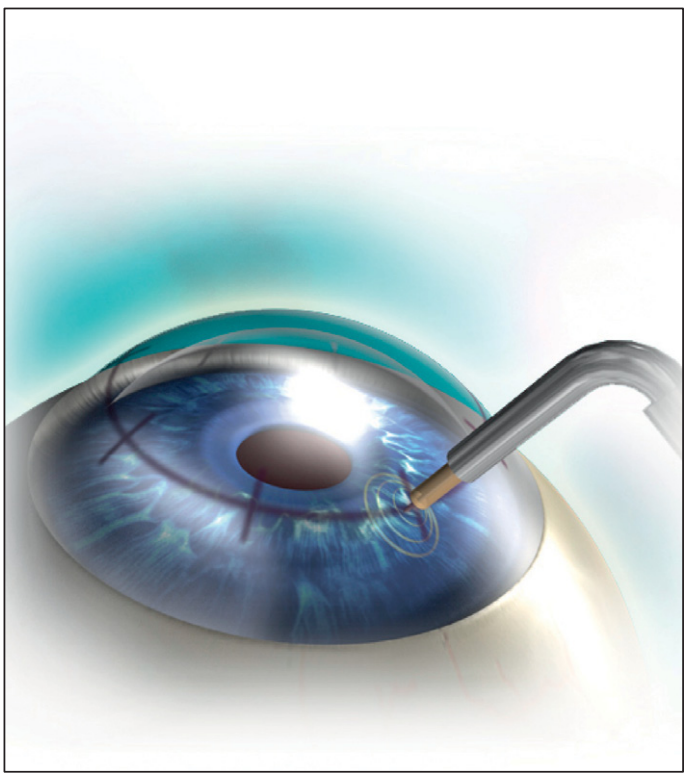


Figure 86.2. Application of treatment spot in the peripheral cornea.

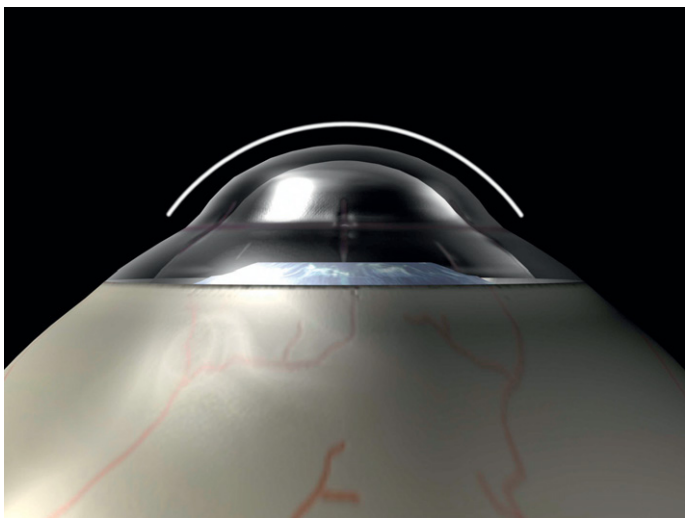

Figure 86.3. After a full circle of treatment, the peripheral cornea flattens and the central cornea steepens.

nondominant eye by inducing slight to moderate myopia, −1.0 to −2.0 D, for near vision tasks. Patients should be carefully selected for the CK treatment for presbyopia. Emmetropic and low hyperopic (+1.00 to +2.25 D) patients are the best candidates. Suitable patients should be 40 years of age or older, should have visual acuity correctable to at least 20/40 in both eyes, and should have corneal pachymetry readings of 560 μm or more at the 6-mm optical zone. Contact lens wearers should have a stable refraction. Hard lens wearers should discontinue lens use 3 weeks and soft contact lens wearers 2 weeks before the procedure. Preoperative testing includes slit-lamp examination, keratometry, pachymetry, corneal topography, eye dominance determination, near and distance vision assessment, and monovision tolerance assessment. Performing topographic corneal analysis and Orbscan anterior and posterior elevation determination will reveal eyes that should not undergo CK treatment. These include corneas with keratoconus, pellucid marginal degeneration, and those with a decentered apex or peripheral, asymmetric, or nonorthogonal astigmatism that are potential sources of induced cylinder. Eyes with significant dryness, tear-function compromise, high target anisometropia, or strong ocular dominance should also be avoided.

Setting realistic patient expectations is highly important as part of the patient selection process. Patients must understand that vision for 'daily life' is the goal of the NearVision CK procedure

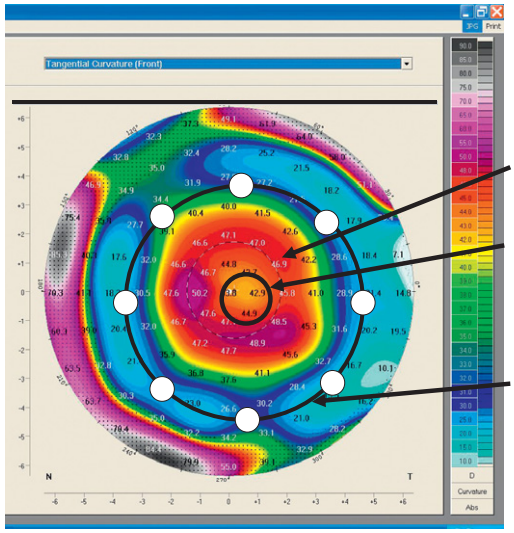

Figure 86.4. The anterior topographic surface map of a cornea treated with one ring of eight CK treatment spots applied at the 7-mm optical zone. The map shows a change to a more prolate shape, an increase of central corneal power, and slightly less increase in power in the exact central 1 mm. A modified multifocal prolate surface is created. A flattened area can be seen at the application spots (in white). The flattening increases and extends farther peripherally than it does centrally. Closer to the center of the cornea, the paracentral zone steepens, exaggerating the prolate shape of the cornea in the 3.0–4.5-mm optical zone. However, the flatter area in the central cornea is preserved. (Courtesy of Jack Holladay, MD, MSEE.)

and that, after the procedure, they will most likely need reading glasses for prolonged detailed work. The surgeon must inquire about the patient's occupation and hobbies and the possible need for the patient to wear spectacles for these activities after the surgery. If the patient finds any spectacle use unacceptable, it is best not to proceed with the surgery, for an unhappy patient will be the likely result. Because the CK procedure targets only one eye for near vision, it may not be suitable for patients who operate potentially dangerous machinery, drive frequently at night (may require a spectacle overcorrection), or engage in visually demanding work at close distances. Patients must also be aware of the naturally progressive nature of hyperopia and presbyopia and that this progression may diminish the surgical effect with time and increase their need for reading glasses. In most cases, they will retain some of the visual benefit they gained from the NearVision CK procedure even as their presbyopia advances.

PERFORMING THE CK PROCEDURE

Following screening and a discussion of expectations, the surgeon can develop a treatment plan for each patient that considers patient age, accommodative amplitude, occupation, and hobbies. For the improvement of near vision in presbyopic emmetropes and low hyperopes, the goal is to overcorrect the nondominant eye by inducing slight to moderate myopia, −1.0 to −2.0 D (myopic endpoint) through the application of 8–24 CK treatment spots. Most well-selected patients treated for presbyopia will initially need only 8–16 spots in one eye.

The CK procedure is performed with topical anesthesia. The patient lies under a 6.5× magnification microscope with his or her head aligned so that the cornea is centered in the field. The iris is parallel to floor, and the fixation light is equally spaced between

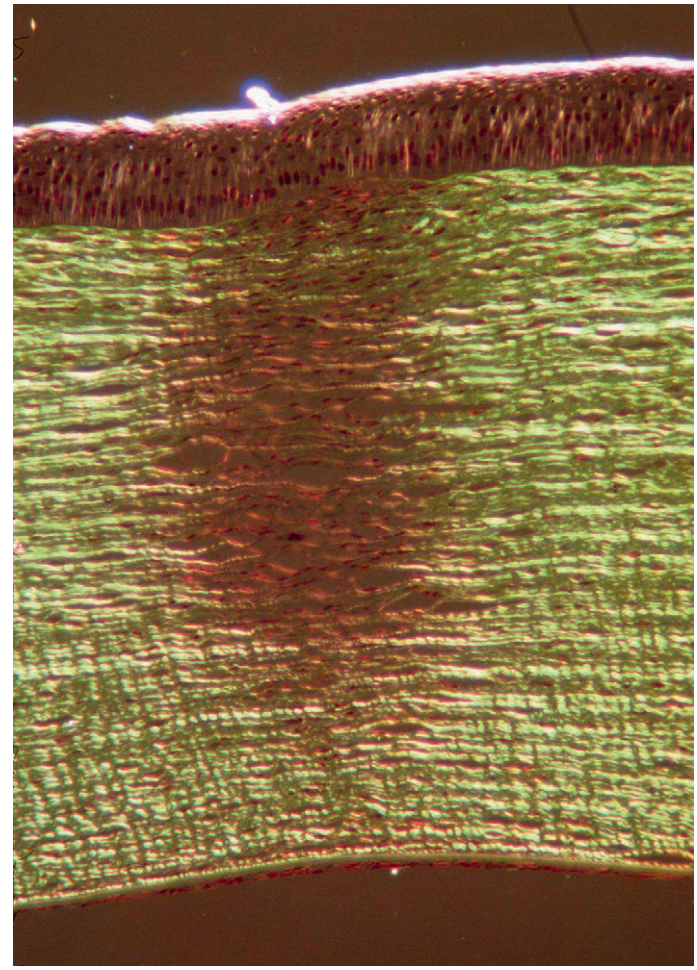

Figure 86.5. CK footprint. A polarized light micrograph of a histological section from a pig cornea, 7 days after CK treatment. The footprint (dark region) is cylindrical and approximately 80% of corneal depth. Deep treatment penetration contributes to permanence of effect.

oculars in the patient's view. A lid speculum is placed in the eye to obtain maximal exposure and provide the electrical return path. While the patient fixates on the microscope's light, the surgeon gently makes an indentation mark in the center with a Sinskey hook over the center of the entrance pupil. Precise centration, using the pupillary center, and not the corneal light reflex or the line of sight, as the centration reference is highly important in avoiding surgically induced astigmatism. After drying the cul-de-sac, the cornea is then marked with a gentian-violet-dampened CK marker, aligning the marker cross-hairs with the Sinskey mark and the 6- and 12-o'clock points on the cornea (Fig. 86.6). The motion for marking is straight down with the marker onto the corneal surface; hold and then straight up.

After proper marking, the Keratoplast tip is inserted into the stroma at the marked spots in a ring pattern around the peripheral cornea according to the supplied nomogram. Figure 86.7 shows the conventional CK nomogram for the treatment of presbyopia and the sequence of spot application. The number (8–24) and location (6-, 7-, or 8-mm optical zone or a combination) of spots determines the amount of refractive change, with an increasing number of spots and rings used for higher amounts of correction. Each radiofrequency treatment spot should be symmetrically placed to avoid surgically induced astigmatism. Tip alignment should follow three-

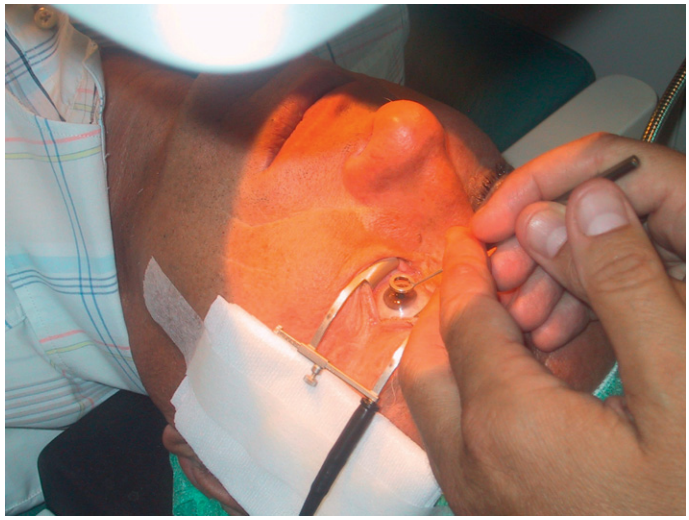

Figure 86.6. Marking a patient's eye with a corneal marker before CK.

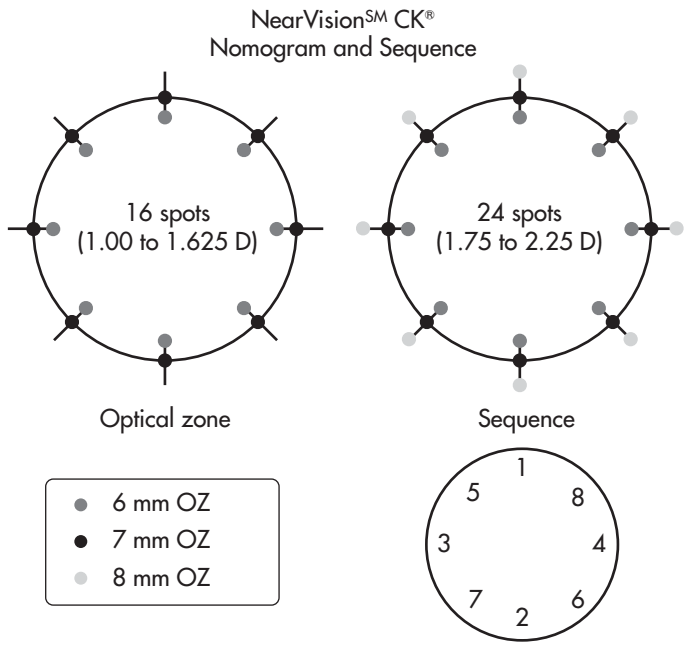

Figure 86.7. Conventional CK nomogram for the treatment of presbyopia. Sixteen spots are applied at the 6 and 7-mm optical zones (OZ) for correction of 1.00–1.625 D of correction and 24 spots are applied at the 6-, 7-, and 8-mm optical zones for 1.75–2.25 D.

dimensional principles (alignment of *x*-, *y*-, and *z*-axis). Alignment in the *x*- and *y*-axis is controlled by hitting the target mark, while alignment of the *z*-axis is controlled by the angle of approach. If the treatment takes place with an incorrectly aligned tip, the treatment effect will be less predictable. In a primary CK treatment, any induced astigmatism can be observed intraoperatively through an operating microscope that incorporates a ring light attachment.

Radiofrequency energy is applied to each treatment spot by depressing the foot pedal. A tone sounds as the energy is applied. The default setting for treatment is 350 kHz, 60% power (0.6 W) for 0.6 s. At each treatment spot, the tip is kept in place until the preprogrammed treatment time has been completed (the tone stops). The procedure is repeated until the full series of spots has been made, according to the treatment plan. After each treatment spot, the tip is cleaned with a fiber-free sponge to remove any tissue debris. Following a full circle of treatment spots, the peripheral cornea flattens and the central cornea steepens. Postoperative care includes instillation of a topical antibiotic solution, a topical nonsteroidal anti-inflammatory agent, and artificial tears, as needed.

The conventional CK nomogram was used in the trial for FDA approval of CK for the treatment of presbyopia. Following approval and wider use of the conventional CK technique and nomogram, it became apparent that refractive results varied among surgeons; some surgeons had on-target results while others had undercorrections at a greater than desired frequency. Rick Milne, MD, was the first to observe that a varied degree of corneal compression during treatment spot application accounted for the variability of surgeons' results, while poor alignment of the Keratoplast tip in the placement of an individual treatment spot and the asymmetrical placement of spots in the ring were responsible for any induced astigmatism (Milne HL, LightTouch technique for CK. Presented at ASCRS, Washington, DC, April 2005). In the conventional CK treatment, the cornea is compressed (creating a 5–7-mm dimple on the cornea) with the Keratoplast tip from the time the tip is inserted into the cornea to the time of radiofrequency energy is delivered. However, it appears that greater pressure or compression of the cornea decreases the amount of refractive change obtained with CK treatment.

In contrast to the 5–7-mm dimple created on the corneal epithelium by compressing the cornea with the Keratoplast tip in the conventional NearVision CK technique, the cornea is only minimally depressed with the tip to create a 2-mm dimple in the NearVision CK with LightTouch technique (Fig. 86.8). The desired pattern is to penetrate the cornea with the tip, hesitate about 2 s, apply energy by depressing the foot pedal, hesitate, and remove the tip. Compared with the conventional CK technique, the LightTouch technique has produced a more robust effect, more predictable results, and less or no induction of cylinder. Because of the more robust effect, fewer spots can be applied for a given refractive change, and treatment is applied to fewer optical zones.

The LightTouch nomogram shown in Figure 86.9 and Table 86.1 was developed by Rick Milne, MD, using his own technique. As seen in the table, the myopic shift is greater with LightTouch. Individual surgeon's results may vary, and it is strongly recommended that the physicians develop their own CK nomogram based on personal practice results. At this time, results after NearVision CK with LightTouch appear to be stable at 6 months, but stability in a large population of patients is yet to be determined.

PRESBYOPIA CLINICAL RESULTS WITH CONVENTIONAL NOMOGRAM

A multicenter, FDA-approval study was conducted to determine the safety and efficacy of CK for the treatment of presbyopic symptoms in emmetropic and mildly hyperopic eyes. Eligible patients were treated to correct up to 2.0 D of presbyopia. To be eligible for the study, patients had to have a preoperative spherical equivalent (SE) of plano (considered as +0.5 to –0.5 D) to +2.0 D and less than or equal to 0.75 D of refractive astigmatism, as determined by cycloplegic refraction. Screening for eligibility included a history of monovision contact lens wear or success with a contact lens trial of monovision, and preoperative assessment with the 'Loose Lens' test. In this test, handheld lenses of three dioptric powers were used: (1) a +0.75 D lens for one ring of CK treatment at 7 mm, (2) a +1.25 D lens for two rings of treatment, one each at 7 and 8 mm,

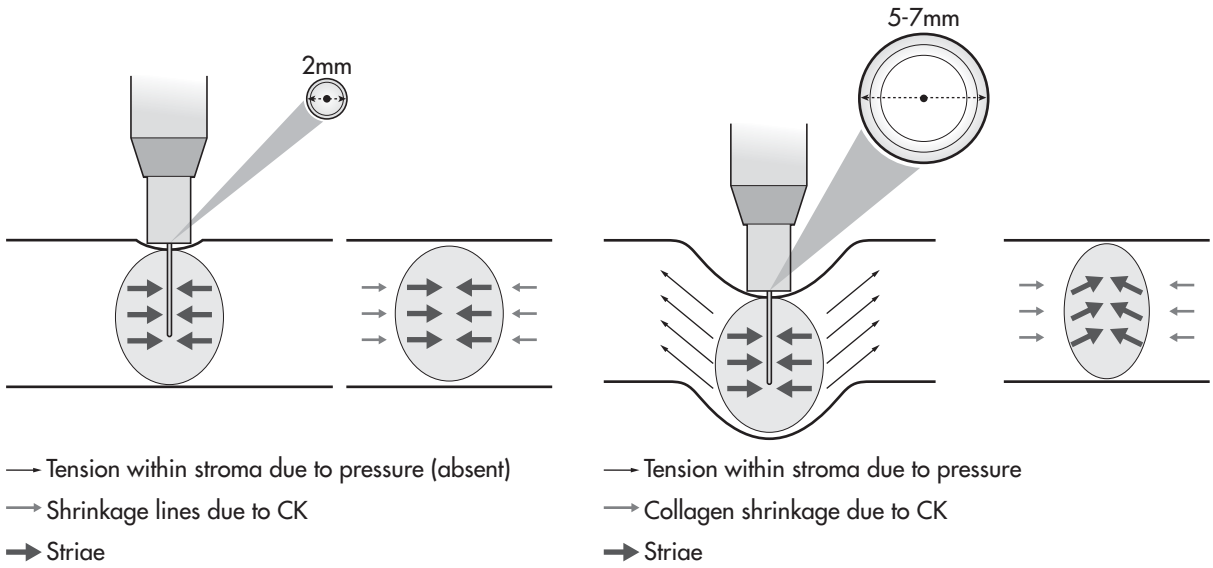

Figure 86.8. Illustration of theory behind conventional and LightTouch CK treatment. In conventional CK (left), the cornea is indented with the tip to make a 5–7-mm diameter indentation on the corneal surface. With the LightTouch technique (right), a dimple of only 2.0 mm is created. This does not create tension within the stroma and consequently the effect is greater.

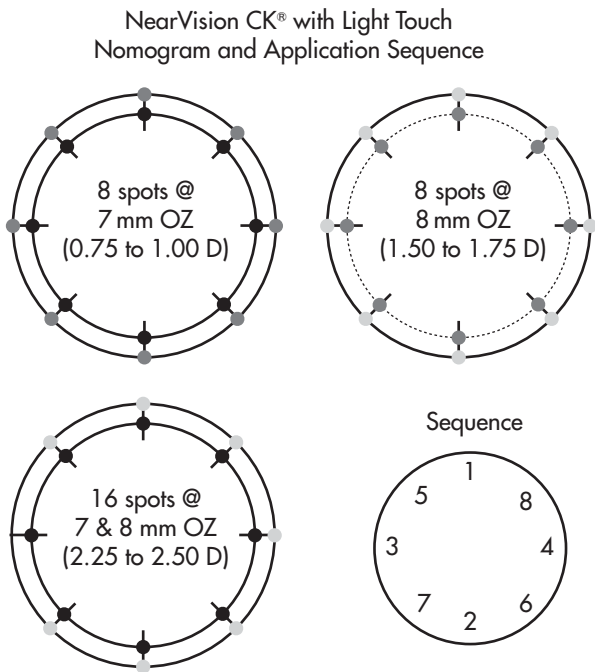

Figure 86.9. NearVision CK with LightTouch: nomogram and application sequence.

Table 86.1 NearVision CK with LightTouch: Milne Nomogram

Spot Pattern (Number of Spots and Optical Zone)	Effect with Conventional CK Nomogram	Effect with Milne's CK with LightTouch Nomogram (D)[a]
8 spots @ 8 mm	—	1.50–1.75
8 spots @ 7 mm	0.75 D	0.75–1.00
16 spots @ 7 and 8 mm	—	2.25–2.50

[a] Individual surgeons' results may differ; personal nomograms must be developed.

and (3) a +1.75 D lens for three rings of CK treatment, one each at 6, 7, and 8 mm. The 'Loose Lens' test can assess near and distance visual acuity, monovision tolerance, clarify patients' expectations, and help to determine the final surgical plan.

The target refraction was up to −2.0 D (myopic endpoint) in the nondominant eye. Emmetropic patients were treated unilaterally in the nondominant eye with an intended correction of up to 2.0 D (target of −1.0 to −2.25 D) to attain near vision in that eye. Hyperopic patients were treated bilaterally: the nondominant eye was treated up to 3.0 D (target of −1.0 to −2.0 D) to provide near vision, and the dominant eye was treated with a correction of up to 2.0 D (target of plano) to improve distance vision.

A total of 188 eyes (150 patients) at five centers in the USA who met eligibility requirements were enrolled consecutively into the study and signed informed consent forms. Of these, 150 eyes were emmetropic or hyperopic presbyopes and were treated to improve near vision. The patients' mean age was 53 ± 4.7 years, and the intended refraction was 2.03 ± 0.625. None of the eyes was retreated.

At 12 months postop, 89% of the eyes treated for near with the full correction (1.00–2.25 D) had binocular uncorrected near visual acuity (UCVA-Near) of J3 or better (newspaper-size print) (Fig. 86.10). This was a marked improvement from preoperative vision. A total of 97% had UCVA-Distance of 20/20 or better and 100% had 20/40 or better. For binocular combined UCVA-Distance and -Near, only 15% of eyes had 20/32 or better distance together with J3 or better near preoperatively. At 12 months, however, 77% had 20/25 or better distance together with J2 or better near, 89% had 20/32 or better distance together with J3 or better near, and 89% had 20/40 or better distance together with J3 or better near (Fig. 86.11). Figure 86.12 shows the percentages with the combination of 20/20 UCVA-Distance and J1, J2, and J3 UCVA-Near at 1 year. According to the patient questionnaire, 86% of eyes treated for near could read newspaper print and also had good distance

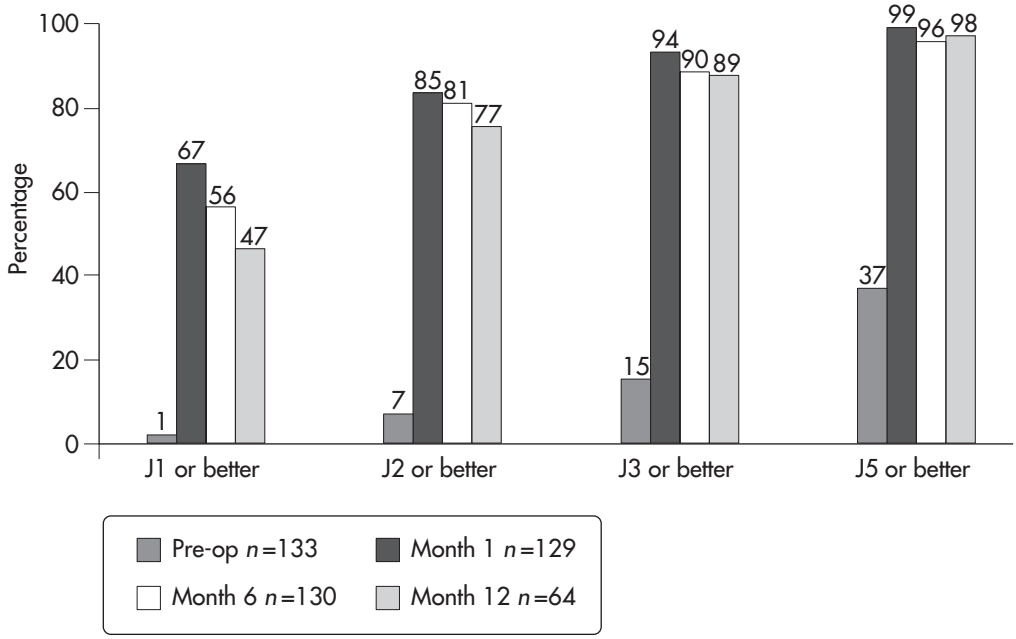

Figure 86.10. Binocular UCVA-Near 1 year after CK presbyopia treatment. Marked improvement from preoperative vision is apparent.

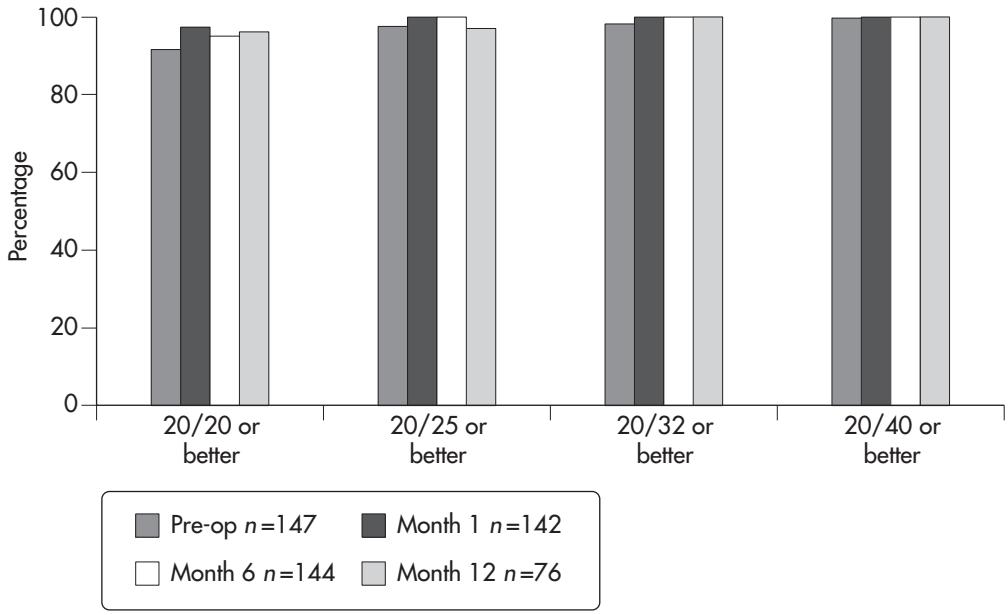

Figure 86.11. Binocular combined UCVA-Distance and Near 1 year after CK presbyopia treatment maintenance of binocular vision can be seen.

vision, as indicated by the 100% who could see a street sign (Fig. 86.13).

Safety at 12 months was exceptional. A transient loss of more than two lines of BCVA-Distance was seen in two eyes at 1 month, but this resolved in both eyes by 3 months. No eye had BCVA-Distance worse than 20/40, had an increase of >2.00 D cylinder, or had BCVA-Distance of 20/20 or better preop that became 20/25 or worse postop (Table 86.2). Mesopic contrast sensitivity with and without glare was unchanged from preop through month 12. No device-related serious adverse events occurred. Extreme/marked/moderate improvement in quality of vision was noted by 89–95% of the patients over the course of the study. A range of 79–86% reported being satisfied or very satisfied with the results. Patient satisfaction with the procedure is similar to that with monovision LASIK. Quality of depth perception was rated excellent, very good, or good in 91–93% over the study course.

CONDUCTIVE KERATOPLASTY FOLLOWING LASIK AND OTHER EXCIMER LASER PROCEDURES

Patients previously treated with LASIK who are now presbyopic can be treated safely with CK to achieve functional near vision. With CK there is no need to lift or recut the flap. Treatment involves inducing a mild myopia (refraction of −1.0 to −2.0 D) in the non-dominant eye, as described above for eyes without previous refractive surgery.

A prospective, multicenter clinical trial of CK is being conducted to evaluate the ViewPoint CK system for performing CK in emmetropic presbyopes who have previously had LASIK or PRK (Data on file, Refractec Inc.). A total of 55 patients (55 eyes) with a mean pre-LASIK MRSE of −3.33 D, a mean age of 53 years, mean pre-CK MRSE of +0.50 D, and less than 0.75 D of cylinder have undergone

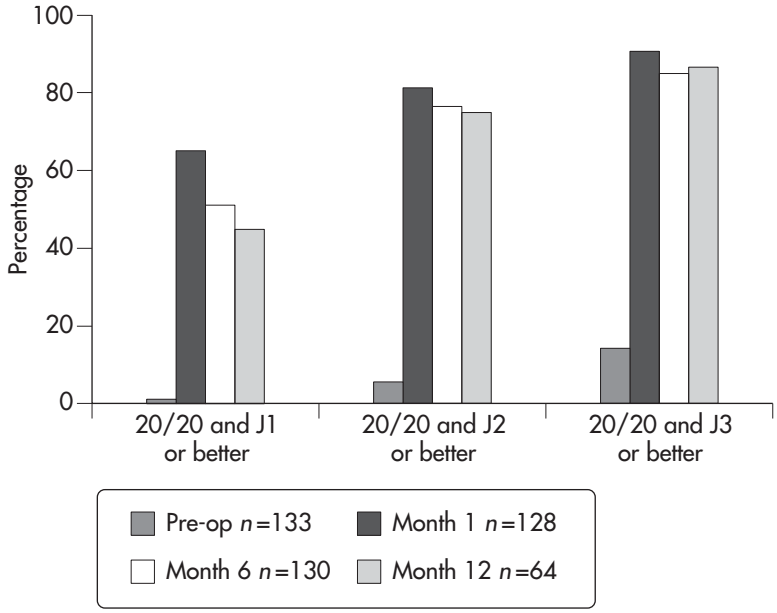

Figure 86.12. Binocular combined UCVA 20/20 Distance and J1, J2, or J3 UCVA-Near 1 year after CK.

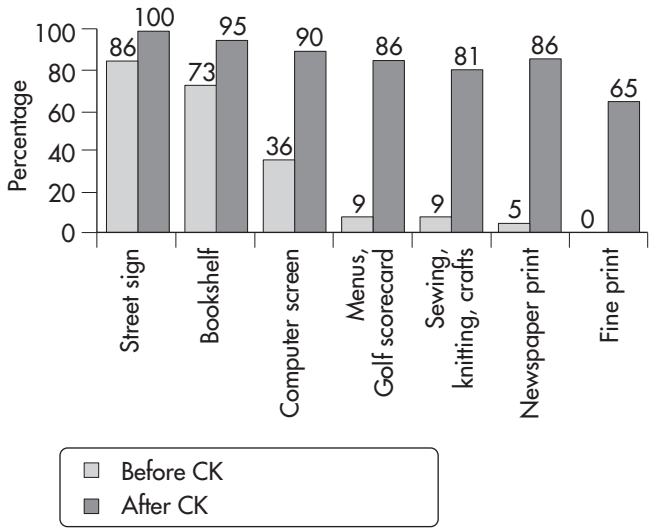

Figure 86.13. Patient subjective responses to the question: What can you see without glasses?

the procedure. All patients had residual central pachymetry greater than 400 μm and peripheral pachymetry greater than 560 μm before undergoing CK. All patients received a very conservative CK treatment in their nondominant eyes: eight CK spots at the 8.0 mm optical zone for a 1.25 D addition.

At 1 month postoperatively, the mean postoperative effect was 1.39 ± 0.394 D. Near UCVA and refractive accuracy results at 1 month are shown in Table 86.3. All results surpassed the FDA-desired target values. At 1 month, 94% of patients had J2 or better binocular near UCVA, and 98% had J3 or better. Furthermore, patients' subjective responses demonstrated very little loss of distance vision: pre-CK 98% were able to see a street sign without spectacles, while after CK the percentage was 94%. Near vision without spectacles improved markedly: 24% could see newspaper pre-CK, while after CK the percentage increased to 88%. Fine print could be read by 8% pre-CK and 76% after CK.

Safety results were similarly excellent. No eyes lost more than two lines of BCVA-Distance, and 88% showed no change from preop in induced cylinder. Of the 12% (six eyes) with induced cylinder, all had J1 or J1+ near acuity. There were no adverse events or complication with the corneal flap that had been created during the previous LASIK procedure. At 1 month, 43/50 (86%) of patients were satisfied or very satisfied with their CK procedure.

While the number of patients who have reached a 1-month postoperative follow-up in this study is small, outcomes have been very good. However, evaluation of the safety and effectiveness of treating post-excimer laser patients with CK is still ongoing in the above-described FDA-approval study. It is important to note that a greater refractive effect from CK treatment has been observed in post-excimer laser eyes compared with eyes that have not undergone excimer laser surgery, and the nomogram must be adjusted in view of this. All use of CK following previous excimer laser treatment is empirical and off-label at this time. It is best to treat these patients very conservatively, informing them that they may need additional treatments later if they are over- or undercorrected.

CONCLUSION

The large number of persons born in the USA during the 'baby-boom' following World War II are now at least 42 years of age and have undergone or will soon undergo the decrease in accommodative ability characteristic of older individuals. Many who were effectively emmetropic in their youth are now distressed by the need for near-vision spectacles, but they would not consider a surgical procedure that would free them from spectacles if they perceive the procedure as risky. CK appears to have the ideal characteristics for these presbyopic persons.

Conductive keratoplasty has a remarkable record of safety. Studies have shown a low rate of postoperative loss of best-corrected distance vision, no loss of high-frequency contrast sensitivity, and the maintenance of stereopsis. In fact, CK treatment has improved near visual acuity without an accompanying loss of binocular intermediate or binocular distance vision. Safety findings with CK stand in contrast to findings seen after monovision LASIK procedures. Furthermore, the CK procedure is not susceptible to surgical flap complications or postoperative dry eye seen after excimer laser procedures.

Table 86.2 Incidence of safety variables following CK presbyopia treatment (FDA study)

	Month 1 ($n = 90$) (%)	Month 6 ($n = 93$) (%)	Month 12 ($n = 63$) (%)
Loss of >2 lines BCVA-Distance	2	0	0
BCVA-Distance worse than 20/40	0	0	0
Increase >2.00 D cylinder	0	0	0
Patients preop ≤20/20 who had ≥20/25 postop	0	0	0
BCVA-Near worse than J3	0	0	0

Table 86.3 One-month results of CK used to treat presbyopic patients who have had previous excimer laser surgery for myopia ($n = 50$)

	% of Patients	FDA Target (%)
UCVA < J1	90	—
UCVA < J2	94	—
UCVA < J3	98	75
+0.50 D within target	74	50
+1.00 D within target	96	75

UCVA, uncorrected visual acuity.

The LightTouch technique proved effective in addressing some of the concerns associated with the conventional CK treatment of presbyopia, namely the variability of results among different surgeons and the occurrence of undercorrections. This modification of the conventional CK nomogram is pending FDA approval, but off-label use by a number of surgeons has demonstrated the same efficacy with even greater safety. Compared with conventional CK, LightTouch appears to produce a greater clinical effect with fewer treatment spots applied at a larger optical zone. Fewer treatment spots make the CK treatment more comfortable for the patient and allow a faster visual recovery. The refractive effect is more predictable, and less cylinder is induced, possibly because treatment spots are applied more uniformly and at a larger optical zone. Long-term stability is to be determined. Results differ slightly for different surgeons, and surgeons need to develop a personal nomogram.

Treatment of over- or undercorrections following LASIK or other excimer laser procedures, treatment of presbyopes who previously had LASIK, and enhancing outcomes of cataract surgery are other potential off-label applications for CK. Procedures that can correct or refine such conditions appeal to surgeons and patients alike, as they can improve vision without involving a laser procedure. The number of patients who had LASIK in their youth and are now presbyopic is large and growing. These patients, accustomed to good spectacle-free vision, are now dissatisfied with reading spectacles and are seeking other solutions. Also growing in numbers are the pseudophakes who are increasingly well read and informed about vision-enhancing procedures and also desire improved functional near vision without spectacles.

Because of its unique safety and efficacy, the CK procedure is likely to grow in popularity among surgeons and patients who do not yet have a cataract. The downsides of monovision LASIK are not likely to change, and presbyopic LASIK will not be a viable option for at least 5 years. If the CK correction regresses, an enhancement can be performed. When the patient develops a cataract, the surgeon can perform cataract extraction with implantation of one of the new-technology IOLs. If the IOL does not provide the required near vision, the surgeon can then perform CK to increase near vision. Thus CK can be a patient's entry point for a lifetime of functional near vision without spectacles.

87 The intrastromal corneal ring

Steven M. Verity, David J. Schanzlin

The alteration of the corneal stroma as a means of producing a change in the refractive status of the eye has been studied for more than half of a century. These techniques were characterized by stromal inclusions of plastic lenses and alloplastic lenticules.[1–6] A greater understanding of refractive change associated with corneal stromal addition and subtraction can be directly attributed to the work of Barraquer[7] and his law of thicknesses as applied to the cryolathe techniques. The problems of lack of tissue biocompatibility, extrusion of implants, poor predictability, and other wound healing-related issues prevented the advancement of these keratorefractive techniques. In April 1999, the USA Food and Drug Administration (FDA) granted approval of Intacs intrastromal corneal ring segments (Addition Technology, Des Plaines, IL) for the correction of low spherical myopia.

BACKGROUND

The idea of a ring-shaped device placed within the corneal stroma was initially conceived by Reynolds.[8] The device was initially developed as a 360° open-ended plastic ring manufactured from optically transparent polymethylmethacrylate. In the original conception of the device, the plastic ring had an adjustable diameter so that expansion or constriction of the ring could be titrated to correct myopic or hyperopic refractive errors, respectively.[9] The problems with this model included poor predictability and difficulty in adjustability of the keratorefractive effect. Further studies with fixed-diameter intrastromal rings placed within cadaver eyes demonstrated that a significant flattening of the corneal curvature could be achieved with the degree of flattening directly related to ring thickness. Further studies and refinement of the device allowed further characterization of the means by which the desired keratorefractive effect is achieved.[10] A nearly linear relationship between corneal flattening and ring thickness has been predicted by finite element modeling and confirmed by cadaver eye testing.[11]

Initial feasibility studies were performed in 1991 with a 0.30 mm-thick intracorneal ring in a series of patients with one nonfunctional eye. These studies, performed both in Brazil and in the USA, demonstrated that the intracorneal ring was safely tolerated within the corneal stroma, with no evidence of migration or extrusion of the device.[12,13] The study further demonstrated that elective removal of the device, after successfully tolerating its presence for over 1 year, could be safely performed with a return to baseline corneal curvatures.[14] The first sighted eye trials were initiated in Brazil in 1991 and in the USA in 1993 with five ring thicknesses, ranging from 0.25 to 0.45 mm in 0.05 mm increments. Results from these trials further demonstrated biocompatibility of the device within the corneal stroma and demonstrated that a stable myopic correction could be achieved.

Concerns regarding wound healing at the incision site prompted alterations in the design of the device. A segment design (intrastromal corneal ring segments [ICRS]) minimized the incision healing problems and greatly simplified the surgical technique because a continuous stromal channel was no longer required (Fig. 87.1).

There are several aspects of the ICRS procedure that make it unique compared to other keratorefractive techniques. Reduction of myopia occurs with the placement of the device within the midperipheral cornea. The attendant corneal flattening occurs without the removal of any tissue. The degree of myopic correction is titrated by the thickness of the implanted segments.

An additional benefit of this approach is the potential for exchange of the device, allowing adjustability of the achieved correction depending on the visual needs of the patient. This feature also allows potential reversibility of the refractive effect, as has been shown in the early clinical trials. Patients who have had the rings removed have returned to their baseline status, as determined by both refractive and topographic criteria, within 3 months after segment removal.[14]

The Intacs procedure does not involve any surgical incursion of the central cornea. Another unique feature of this procedure is the maintenance of a normal physiologic prolate corneal profile with concomitant reduction of the central corneal curvature. It is believed that maintenance of the physiologic corneal asphericity may reduce the incidence of postoperative contrast sensitivity reduction or spherical aberration errors and may be associated with better optical performance of the treated cornea.[15,16]

The surgical procedure is typically performed using topical anesthesia and is performed with the aid of a set of proprietary instruments (Addition Technology, Des Plaines, IL) designed to accomplish

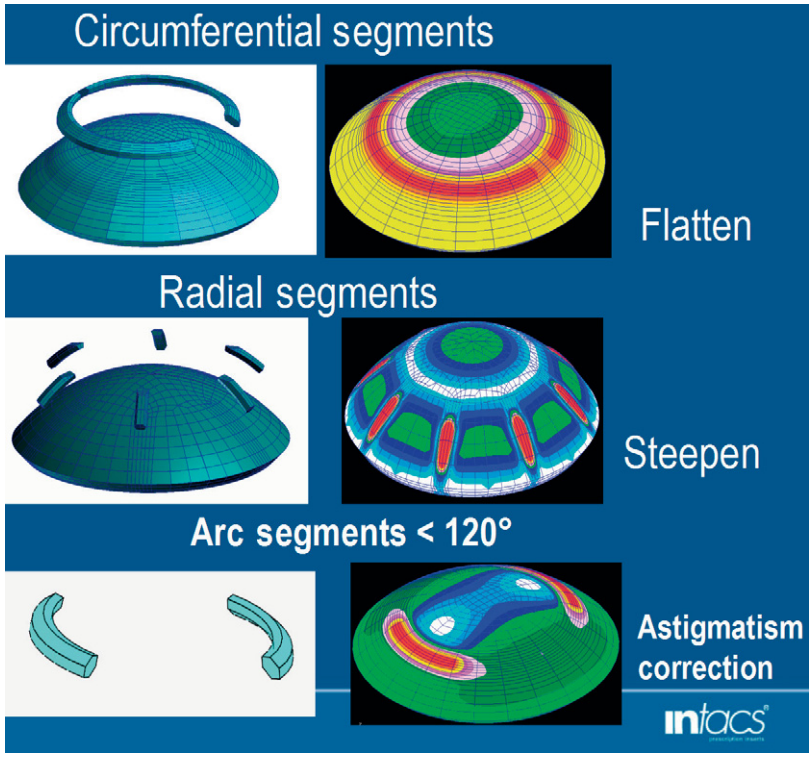

Figure 87.1. Intrastromal ring designs developed to produce various desired corneal-shape changes and refractive effects. The segment design is composed of two 150° arcuate elements. (Courtesy of Addition Technology, Inc.)

placement of the device at a stromal depth of two-thirds of the peripheral corneal thickness. The corneal center is identified and marked. An incision and placement marker is applanated on the corneal surface using the geometric center of the cornea as a landmark. A 1.2-mm radial incision is then made at the 12-o'clock position to a depth of 68% of the measured peripheral corneal thickness. A vacuum centering guide is then applied to the ocular surface and suction fixation is initiated. Blunt stromal dissection of a lamellar tunnel is performed in a clockwise and counterclockwise fashion in the paracentral cornea using stromal dissectors. The Intacs segments are then carefully threaded into the intrastromal channel and positioned so that no part of the device is situated directly beneath the incision site (Fig. 87.2). The incision is typically closed with one to two interrupted sutures to approximate the corneal wound edges. Topical antibiotics and steroids are applied for approximately 1 week.

CLINICAL TRIALS WITH INTACS

On May 3 1995, the USA phase II clinical trial of the Intacs product was initiated. A total of six investigational sites were scheduled to implant a total of 150 sighted eye patients requiring myopic correction between −1.00 and −6.00 D. Segment thicknesses to be implanted ranged from 0.25 to 0.45 mm in 0.05 mm increments for a total of five patients per thickness per site. All patients had a preoperative best spectacle-corrected visual acuity of 20/20 or better. To evaluate the safety and efficacy of the procedure, follow-up data collection included uncorrected and best spectacle-corrected visual acuity (BSCVA), cycloplegic and manifest refraction, corneal topography, keratometry, and slit-lamp biomicroscopy. A preliminary analysis was performed on available data for patients who completed 3 months of postoperative follow-up.[17] Of 99 patients, 95 (96%) had an uncorrected visual acuity of 20/40 or better. More than half of the study patients (53 of 99, 54%) saw 20/20 or better without correction. The predictability of correction appeared good, with 77% of patients within 1 D of their intended correction. At the 3-month time gate, 99% of patients were within two lines of their preoperative best spectacle-corrected visual acuity.[17] These data also revealed a slightly higher standard deviation of refractive outcomes with thicker devices, as observed in higher myopic corrections attempted with other keratorefractive procedures. Accordingly, the lower ring sizes (0.25, 0.30, and 0.35 mm) were selected for further evaluation in phase III clinical trials.

The phase III trials began in December 1996 with enrollment of 361 patients at 10 investigational sites. Enrollment criteria were restricted to patients with myopic refractive errors ranging from −1.00 to −3.50 D with less than 1.00 D of refractive astigmatism.

A 2-year follow-up analysis of 449 eyes of both phase II and phase III trial cohorts evaluating only the 0.25, 0.30, and 0.35 mm segments demonstrated that 97% of eyes achieved an UCVA 20/40 or better and 76% was 20/20 or better.[18] This did not differ significantly from the 3-month postoperative data in which 97% of eyes were 20/40 or better and 71% of eyes were 20/20 or better. Fifty-five per cent of eyes saw 20/15 or better uncorrected acuity at 2 years. Predictability of correction appeared good as 93% of eyes were within ±1.00 D of predicted correction and 73% were within ±0.50 D of attempted correction. Two eyes (1%) experienced greater than two line reduction of BSCVA; however, both eyes maintained a BSCVA of 20/20 or better. Intraoperative complications included posterior corneal perforation (one eye) and anterior corneal perforation (three eyes). Segments were not placed in five eyes due to intraoperative adverse events. All patients maintained their preoperative levels of BSCVA. Postoperative adverse events included one case of infectious keratitis and one case of shallow segment placement. These eyes were treated appropriately and a BSCVA of 20/20 was maintained. Intacs segments were removed in 37 (8%) eyes due to dissatisfaction with visual outcome, bothersome visual symptoms, or healing-related issues. Among patients who underwent elective removal due to dissatisfaction, 97% returned to within ±1.0 D of their baseline refractive error within 3 months.

POSTOPERATIVE OBSERVATIONS AND SIDE EFFECTS

Essentially all patients develop a mild stromal haze in the area of the tunnel dissection as a result of separation of the stromal fibers. This haze is generally mild in degree and visually insignificant and resolves over time. Another slit-lamp finding characteristic of the Intacs procedure is the development of small deposits within the intrastromal channel and product-positioning holes. These deposits, usually noted by the third postoperative month, are noninflammatory and are clinically insignificant. They are believed to consist of collagen and wound-healing proteoglycans.[19] Similar lamellar deposits have been reported in association with other intrastromal refractive procedures.[20–23] Deposits were seen in 68% of patients at 1 year in the phase III clinical trial.

Other clinical observations associated with the intrastromal ring procedure include corneal iron lines[24] and a temporary reduction of central corneal sensation. All of the clinical trial adverse events associated with the Intacs procedures were easily managed with or without removal of the device.

Visual side effects were noted in the phase II and phase III clinical trial patients.[18] These included difficulties with night vision (5.1%), blurred vision (2.9%), glare (1.3%), and halos (1.3%). Patients with a preoperative mesopic pupil size of 7.0 mm or greater were more likely to develop postoperative visual side effects. Patients in the earlier phases of the clinical trials were more likely to request removal of the implant due to dissatisfaction. This was due to a learning curve as to refractive outcome with the initial nomogram (a large incidence of thicker devices removed because of undercorrection in the phase II studies prompted revision of the nomogram) and inclusion of patients with large mesopic pupil sizes.

A separate analysis of the refractive effect after removal of the Intacs inserts was performed.[25] A total of 46 eyes underwent removal of the Intacs inserts after being followed in the FDA clinical trials. The primary reasons for removal were visual side effect (51%) and unresolved refractive error (48%). Removal procedures were performed with topical anesthesia and were generally brief procedures. These procedures were successful in all cases, and there were no operative or postoperative complications or sequelae. At 3 months post removal, 73% of eyes returned to within ±0.50 D and 97% were within ±1.0 D of their baseline spherical equivalent manifest refraction. Additionally, all eyes were within ±1.0 D of their original manifest refractive astigmatism. All eyes achieved a BSCVA of 20/20 or better. There were no significant safety issues as a result of Intacs removal. This study demonstrated that the refractive effects of Intacs are rapidly and completely reversed upon removal.

A smaller number of patients have undergone exchange procedures for either under- or overcorrection. These procedures, performed with topical anesthesia, consisted of dissection to the previous lamellar channel, retrieval and removal of the ring by securing its positioning hole, and, finally, replacement with a thicker or thinner device.

THERAPEUTIC INDICATIONS

KERATOCONUS

Probably the most exciting development in Intacs technology is the application of the device for treatment in therapeutic indications. Shortly after FDA approval of Intacs in the USA the first reports of applying this technology for the treatment of keratoconus became available.[26,27] The ring segments were placed in a horizontal configuration through a single temporal incision. The goal of reducing irregular astigmatism was sought by placing a thicker segment inferiorly to elevate the cone along with a thinner segment superiorly to flatten the keratoconic cornea. These procedures resulted in a significant reduction in astigmatism and an improvement in topographic regularity (Fig. 87.3). In this initial series of 10 patients, uncorrected visual acuities improved from a mean of 20/200 to 20/50 at 12 months.[27] One patient underwent removal of the device due to superficial placement but returned to preimplant status by 1 month after removal.

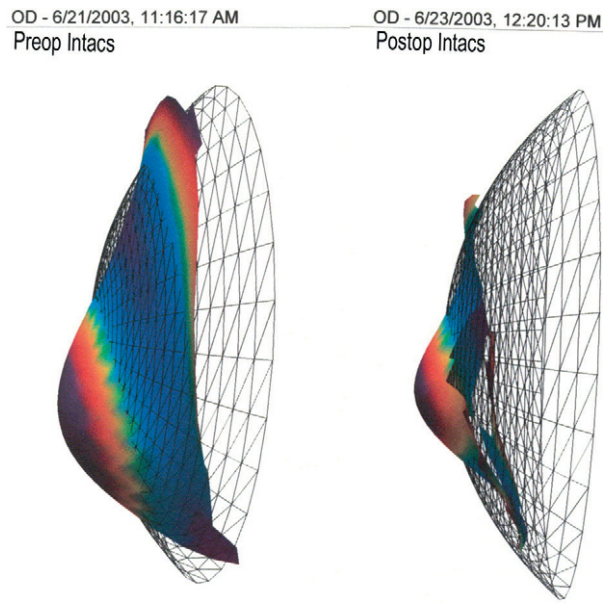

Figure 87.3. Topographic contour representation demonstrating the effects of Intacs placement in a keratoconic cornea. (Courtesy of Addition Technology, Inc.)

Siganos et al reported a prospective nonrandomized trial of 33 eyes of keratoconus patients with clear central corneas that were contact lens intolerant.[28] Segments of similar thickness (0.45 mm) were inserted based on the topographic image in an attempt to maximize corneal flattening. After an average follow-up of 11.3 months (range, 1–24 months), there was a mean improvement in UCVA of 2.5 lines (range, loss of 1 line to gain of 10 lines). Similarly, a mean improvement in BCVA of 1.7 lines (range, loss of two lines to gain of six lines) was noted. In two eyes, Intacs segments were removed due to superficial placement and patient dissatisfaction, respectively. The authors noted that the Intacs procedures had less effect in more advanced keratoconus while more encouraging results were observed in early stages of the disease. Stability of refractive effect was noted to occur after the first 9 months.

Alio et al reported reversibility data among five eyes of four patients who underwent Intacs placement in centrally clear keratoconic corneas.[29] Segments were removed between 3 and 6 months after implantation due to migration or extrusion. The authors noted that the patients' refractive and topographic statuses were returned to near baseline levels by 3 months after segment removal. Interestingly, a subset of two patients underwent reimplantation of Intacs segments at a deeper level and achieved a marked improvement in UCVA and refraction.

Colin reported the results of the first large-scale prospective clinical trial of Intacs for keratoconus among multiple sites and surgeons.[30] A total of 59 eyes were enrolled in this study. Six-month data were available for 34 eyes. Sixty-two per cent of eyes experienced a gain of two to eight lines of BCVA while 32% had no change in BCVA. Thirty-two per cent of these eyes achieved 20/50 or better UCVA, while only 4% of the patients saw this level preoperatively. While no complications were noted among eyes successfully implanted with the device, seven eyes (12%) underwent explantation of the inserts due to dissatisfaction with visual symptoms.

A number of methods to implant Intacs segments have been devised. These include inserting segments vertically through a superior incision, horizontally via a temporal incision, incision location in the steep refractive meridian, similar or dissimilar segment sizes (typically 0.25 mm ring superior and 0.45 mm ring inferior), and single or paired segment placement. Because all of these methods can result in some level of efficacy it is clear that we do not fully understand the mechanism of correction in corneal ectasia.

Alio et al reported the results of 26 eyes with keratoconus who underwent implantation of single or paired Intacs segments based on the preoperative corneal topographic appearance.[31] The devices were placed horizontally with a temporal incision. With 1 year of follow-up, both groups experienced significant improvements in both UCVA and BCVA. The mean UCVA improved from 20/100 to 20/50 in single-segment eyes and from 20/400 to 20/63 in paired-segment eyes. The level of BCVA improved in both groups from a mean of 20/50 to 20/32, postoperatively. Four eyes underwent removal of the inferior segment due to partial extrusion of the device.

Several insights as to why some keratoconus eyes respond well to Intacs while others do not were offered in a subsequent study.[32] A retrospective analysis separating good and poor responders was reported in this study. A much better response was observed among patients with low spherical equivalent refractive errors and average *K*-readings of less than 53 D. Poor responders had greater spherical equivalent refractive errors and mean *K*-readings of greater than 55 D. The authors explain that the Intacs' ability to flatten the corneal curvature is limited by the degree of the keratoconic protrusion, and this factor may be valuable in predicting patient response.

Pokroy and Levinger reported a subset of patients who underwent a secondary adjustment procedure consisting of removal, exchange, or realignment of an Intacs segment.[33] Of a series of 58 eyes, 7 eyes had additional intervention. In five of those eyes a 0.45 mm superior segment was removed, thus leaving the patient with a single 0.45 mm segment inferiorly. Only two of the eyes experienced no improvement after the secondary procedure while an average gain of almost four lines UCVA was achieved among the remainder. These data demonstrate the adjustability of effect of the Intacs insert in the keratoconus patient, a feature shared in the myopia application.

Long-term follow-up of Intacs for keratoconus has revealed stability of refraction, BCVA, and topographic parameters.[34] However, a statistically significant increase in mean *K*-value of 1.67 D over a 36-month follow-up period was noted in one group of patients.

Complications associated with intrastromal ring implantation for keratoconus has included migration of ring segments, thinning of the cornea over superficially placed segments, extrusion of segment implants, and infectious keratitis in the early and late periods after segment implantation.[35,36] Contact lens wear has been identified as a possible risk factor for infectious keratitis after intracorneal rings for keratoconus, although it is not possible to state that the placement of rings places a contact lens wearer at a higher risk of infection.

PELLUCID MARGINAL DEGENERATION

Pellucid marginal degeneration (PMD), like keratoconus, is a progressive, noninflammatory corneal ectatic disorder. In PMD the area of thinning is typically located in the inferior cornea. A characteristic crab claw appearance is noted on topography maps and is associated with against-the-rule astigmatism.

In the first case report of Intacs for the correction of PMD, the devices were implanted with a temporal incision, as in previous keratoconus applications.[37] While the patient's uncorrected visual acuity did not improve after the procedure, a hybrid contact lens (Softperm, CibaVision) allowed a corrected acuity of 20/25.

Mularoni et al reported a series of eight patients with contact lens-intolerant PMD who underwent Intacs implantation using a temporal incision and dissimilar segment sizes.[38] The patients were followed from 12 to 42 months. All patients experienced an improvement in UCVA, and six eyes (75%) had a BCVA of 20/25 or better. The mean UCVA improved from 20/325 (range, 20/1000 to 20/200) to 20/63 (range, 20/200 to 20/32) while the mean BCVA improved from 20/45 (range, 20/63 to 20/25) to 20/25 (range, 20/32 to 20/20). Refractive stability was noted to occur by 3 months postoperative. Similar results treating PMD with the Ferrara intrastromal corneal ring have been reported.[39]

INTACS AFTER LASER-ASSISTED IN SITU KERATOMILEUSIS

Intacs have been used after LASIK in a number of different circumstances. The concept of applying Intacs to correct residual myopia after maximal LASIK surgery is credited to Michiel Kritzinger, MD. In an initial series of patients, he noted an improved uncorrected visual acuity and a more prolate topographic profile after Intacs implantation.

Fleming and Lovisolo published a case report of Intacs for the treatment of myopic regression after LASIK for high myopia.[40] Ten months after LASIK the patient had a residual refractive error of −3.37 D (spherical equivalent) and underwent implantation of a 0.40 mm Intacs ring. Four months after this procedure the patient saw 20/20 without correction.

Several subsequent reports have confirmed the efficacy of Intacs for targeting residual refractive error after LASIK or photorefractive keratectomy (PRK).[41,42] Guell et al reported a series of 13 patients who underwent Intacs after LASIK for residual myopia (seven eyes), secondary ectasia (three eyes), and decentered ablations (three eyes).[41] The authors applied the standard myopia nomogram and inserted the segments in the standard fashion through a 12 o'clock incision site. Secondary procedures were performed 14 months to 6 years after the LASIK procedure. All eyes experienced an improvement in UCVA with no loss of BSCVA. Eyes with larger degrees of residual refractive error tended to remain slightly undercorrected after Intacs implantation. The authors noted that Intacs can significantly enlarge the effective optical zone of treatment and can help to correct moderately decentered ablations. One segment required explantation 7 months after surgery due to corneal thinning over a superficially placed segment.

Regression of refractive effect associated with the development of astigmatism in the postoperative LASIK patient generally suggests iatrogenic ectasia. Topography reveals a steep central or paracentral cornea, and elevation topography is associated with an elevated posterior float pattern. Symptoms may be correlated with a loss of best-corrected visual acuity.[43]

Several reports have demonstrated the efficacy of Intacs for the treatment of iatrogenic keratectasia after LASIK.[44–46] Siganos et al reported the results of Intacs implantation in three eyes of two patients.[44] Both patients had undergone LASIK a year earlier for high myopia. The Intacs were inserted using standard techniques for myopia and the standard nomogram for ring size selection. All eyes had an improvement in UCVA ranging from 20/20 to 20/25 at 9 months after the secondary procedure.

Lovisolo and Fleming applied the keratoconus surgical approach to iatrogenic ectasia cases in four patients.[45] A temporal incision was used to place dissimilar segment sizes in a horizontal configuration with a thicker segment in the inferior channel and thinner segment in the superior channel. All eyes experienced an improvement in UCVA and BSCVA, obviating the need for rigid gas-permeable contact lens correction or penetrating keratoplasty.

Longer-term follow-up data have shown stability of improvement in the refractive outcome of Intacs in the post-LASIK patient. Kymionis et al reported a series of 10 eyes of 7 patients with an average follow-up of 1 year after Intacs for iatrogenic ectasia after LASIK for high myopia.[47] In all cases, the initial refractive procedure was performed at least 1 year before secondary intervention. At the latest follow-up, the UCVA improved from 100% of patients 20/100 or worse to 90% 20/40 or better. All eyes maintained or improved BSCVA by one to two lines and had an improvement in topographic regularity. The authors noted that most eyes of this series experienced a return of BSCVA to their pre-LASIK level.

Pokroy et al reported a series of five eyes of five patients in which the single inferior segment approach to Intacs implantation was employed.[48] An average improvement of four lines of UCVA was noted after surgery; however, one eye experienced no improvement in acuity. More importantly, regularization of the corneal surface as measured by the mean inferior–superior topographic asymmetry improved from 7.88 ± 4.59 to 2.46 ± 2.77 D. This improvement in topographic regularity was associated with an improvement in BSCVA in all eyes.

The techniques of therapeutic indications for Intacs surgery continues to evolve. The ability to use the femtosecond laser for channel creation has allowed for faster surgical procedures, and the ability to customize the channel configuration by software control of the laser. A narrower channel appears to yield a more profound refractive effect and may help to prevent segment migration in the softer tissue of the ectatic cornea. A limitation of laser-created channels at this time is a restricted depth of 400 µm in the stroma.

Given the vast improvements in excimer laser technology including wavefront-guided customized corrections, initial enthusiasm for Intacs to correct low myopia has understandably waned. Nevertheless, the therapeutic indications for Intacs have brought about a resurgence of interest in this technology, and the FDA approved the use of Intacs for keratoconus in July 2004. The ability to defer or potentially obviate the need for penetrating keratoplasty for a patient with keratoconus or iatrogenic ectasia makes this surgical option a valuable resource in our therapeutic armamentarium.

88 Myopia, hyperopia, and astigmatism

Daniel G. Dawson, Fabrice Manns, Yunhee Lee

INTRODUCTION

In humans, the anterior corneal surface provides on average 72% of the eye's total refractive power (43 D of a possible 60 D). Thus, alteration of the anterior corneal curvature represents a good, efficient way to correct refractive errors. The excimer laser can be used to reshape the corneal surface by removing anterior corneal stroma in a microscopically precise process known as ablative photodecomposition. This results in nonthermal, photochemical interactions that break covalent molecular bonds of corneal tissue. Excimer laser-based keratorefractive surgery is a very accurate, precise, and safe means of permanently changing the refractive curvature of the human cornea. It has become the most commonly performed refractive corneal surgery over the last decade, particularly after it was approved by the USA Food and Drug Administration (FDA) in 1995.[1]

HISTORY OF EXCIMER LASERS

In the mid-1970s, researchers first discovered that rare gas and halogen lasers (e.g. argon fluoride (ArF), xenon chloride, and krypton bromide) could be electrically stimulated to form unstable dimers. The photons of energy released from this unstable or excited dimer could then be focused with sophisticated lenses and mirrors to create an ultraviolet (UV) laser beam with considerable energy.[2] The *ex*cited d*imer* (shortened to excimer) laser beam could be shaped to form different treatment profiles or patterns. Trokel and associates showed that the ArF excimer laser could precisely photoablate enucleated bovine cornea by cleaving chemical bonds with no evidence of thermal damage to adjacent tissue.[3] This ability to impart very high energy to corneal stroma without significant thermal effects makes this laser unique among all other ophthalmic lasers. Serdarevic and associates showed that the ArF excimer laser could photoablate a wide area of the optically used portion of the cornea to recontour the cornea and maintain corneal transparency long term.[4] This pioneering work prompted multiple investigations to better understand the use of excimer lasers in keratorefractive surgery. Seiler and Wollensak first used this technology to perform astigmatic keratotomy in 1985 and, subsequently, to perform phototherapeutic keratectomy (PTK) in 1986.[5,6] In late 1986, Marshall and associates used the ArF excimer laser to recontour the anterior corneal surface for myopia in a technique known as photorefractive keratectomy (PRK).[7] Then in 1990, Pallikaris and associates described a technique to recontour the corneal stroma beneath the surface by cutting a lamellar corneal stromal flap first and then photoablating the anterior surface of the residual stromal bed. This became known as laser-assisted in situ keratomileusis (LASIK).[8]

The ArF excimer laser utilizes a 193 nm UV wavelength that produces greater energy, approximately 6.4 eV per laser pulse, than the required 3.5 eV of energy needed to break covalent carbon–carbon bonds. This 193 nm wavelength has been shown to be safe, as it is not mutagenic or cataract forming and creates minimal thermal effects (0–9°C increase in temperature).[9–11] Endothelial toxicity from the ArF excimer laser radiation is also negligible since absorption of radiation occurs within 1 μm of the ablated tissue.[12]

The excimer lasers have evolved, and the effectiveness of laser keratorefractive surgery has markedly improved since 1987. At that time, only two excimer laser systems from two manufacturers, Summit and VISX, were available for FDA studies. Most of the excimer laser systems introduced in the market between 1988 and 1995 consisted of broad-beam lasers with no eye-tracking ability. Broad-beam lasers were the first-generation systems that had large spot diameters (5.0–7.5 mm) and relied on expanding apertures. They were advantageous in that they were fast and effective, but they had the disadvantages of irregular beam profiles or poor homogeneity that would sometimes create rough and irregular surfaces, and they were limited in their inability to create complex ablations profiles without masking devices.

Between 1995 and 1999, small scanning spot excimer lasers with eye-tracking capabilities were introduced. Scanning-beam lasers with fixed or variable size, small-diameter slit beams (0.5–2.0 mm) represented second- and third-generation excimer laser systems. These included flying spot, scanning slit, and variable spot scanning laser systems. All of these systems were an improvement over broad-beam systems, as the laser beam profiles were more Gaussian (more energy centrally than over the edges), produced smoother ablations, and could treat more complex ablation profiles. They had

the disadvantages of longer treatment times since smaller spot sizes require more pulses and of needing sophisticated video or laser radar eye-tracking systems since any misalignment of small-diameter pulses could result in significant alteration from the intended ablation profile.

From 1999 to 2003, newer systems added many upgrades and improvements to make them faster, more reliable, and more precise. They also allowed expandable optical zones and better algorithms for recontouring the cornea and had better tracking systems and faster treatment times. With this level of precision and versatility, these fourth-generation excimer laser systems had become sophisticated enough to support customized or wavefront-guided ablations.

With the advent of wavefront sensors and FDA approval of the first wavefront-guided customized excimer laser platform in October 2002, attention had now focused more on measuring and correcting optical aberrations beyond sphere and cylinder. The ultimate goal has been to achieve an aberration-free correction that is only limited by the resolution of the human retina, which is perhaps around 20/8 vision.

CONVENTIONAL ABLATION PROFILES

The focus of this chapter will be 'conventional' laser-refractive treatments. The conventional ablation profile is mainly used for the correction of spherocylindrical refractive errors: myopia, hyperopia, and astigmatism. Primary input comes from subjective refractive data as measured by manifest and cycloplegic refractions. Laser ablative correction of spherocylindrical refractive errors can be performed as a surface ablation, as in PRK; laser-assisted subepithelial keratomileusis (LASEK); and epi-LASIK or beneath a flap, as in LASIK. Conventional treatments or ablative profiles have evolved considerably over the past two decades to address many of the causes of visual disturbances or complaints, but they do not address or treat higher-order aberrations. These are optical imperfections beyond spherocylindrical refractive errors that might optically limit a patient's quality of vision. This is the realm of wavefront-guided customized laser ablation profiles, which will be discussed in later chapters.

PRINCIPLES OF MYOPIC ABLATIONS

The correction of pure, spherical myopia with the laser requires the removal of a convex lenticule of tissue, where more tissue is removed centrally than peripherally. This was mathematically described by Munnerlyn and associates who took the principles used for creating contact lenses to develop an algorithm to calculate the ablation depths and profiles for both myopic and hyperopic corrections. They developed formulas to guide tissue removal at each point on the corneal surface to change the refractive power of the cornea. The ablation depth proved to be a function of the desired magnitude of refractive power change and the diameter of the ablation.[13]

Munnerlyn equations for myopic corrections

The principle of myopic correction using the excimer laser is based on a graded removal of tissue to decrease the corneal anterior curvature, analogous to the removal of a biologic contact lens from the central corneal surface. In deriving their ablation profile formulas, Munnerlyn[13] assumed the initial and final corneal surfaces to be spherical and the optical power (D) of the excised tissue lenticule to correspond to the intended change in refraction:

$$D = (n-1)\cdot\left(\frac{1}{R_0} - \frac{1}{R_1}\right)$$

where D = change in refractive power of the cornea

n = 1.377 is the index of refraction of the cornea

R_0 = the initial anterior radius of curvature of the cornea

R_1 = the final anterior radius of curvature of the cornea.

Calculation of the ablation profile for the correction of spherical myopia (M) can be performed according to the formula:

$$t(y) = \sqrt{R_0^2 - \left(\frac{S}{2}\right)^2} - \sqrt{R_1^2 - \left(\frac{S}{2}\right)^2} + \sqrt{R_1^2 - y^2} - \sqrt{R_0^2 - y^2}$$

where $t(y)$ = the depth of tissue removal at a distance y from the optical center

y = the distance radially from the optical center

S = the diameter of the treatment zone or the tissue lenticule to be removed

R_0 = the initial anterior radius of curvature of the cornea

R_1 = the final anterior radius of curvature of the cornea.

In myopic corrections, the maximal depth of ablation occurs at the center of the treatment zone ($y = 0$) (Fig. 88.1). By using binomial expansion, this can be approximated from the above equations to the form:

$$\text{maximum ablation depth } (\mu\text{m}) = \text{ablation diameter}^2\ (\text{mm}^2) \times \text{diopters of correction (D)}/3$$

Thus, the maximum ablation depth increases linearly for an increase in diopteric power, but increases at a square exponential rate for the treatment diameter of the optical zone. For an ablation zone of 6.0 mm, a conventional myopic correction would be expected to remove approximately 12 µm/D of correction (Fig. 88.2).

A theoretical approximation of the volume of tissue removed for conventional spherical myopic and hyperopic treatments has also been derived by Gatinel and associates[14] resulting in the formula:

$$\text{volume of ablation } (\text{mm}^3) = (\text{diameter of treatment zone } [\text{mm}]/9)^4 \times \text{diopters of correction (D)}$$

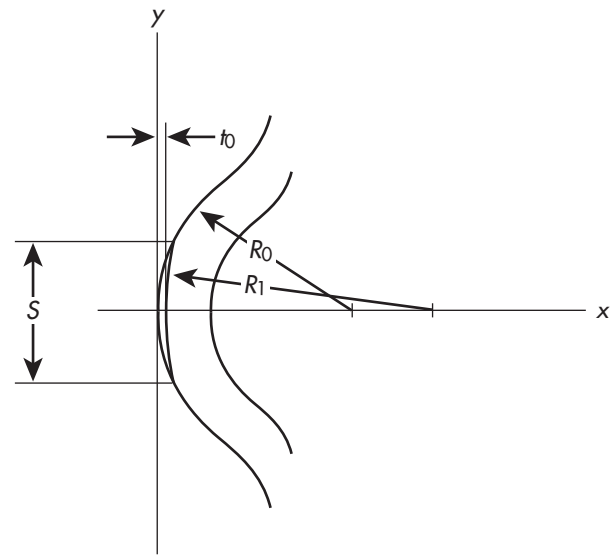

Figure 88.1. Munnerlyn myopic ablation.

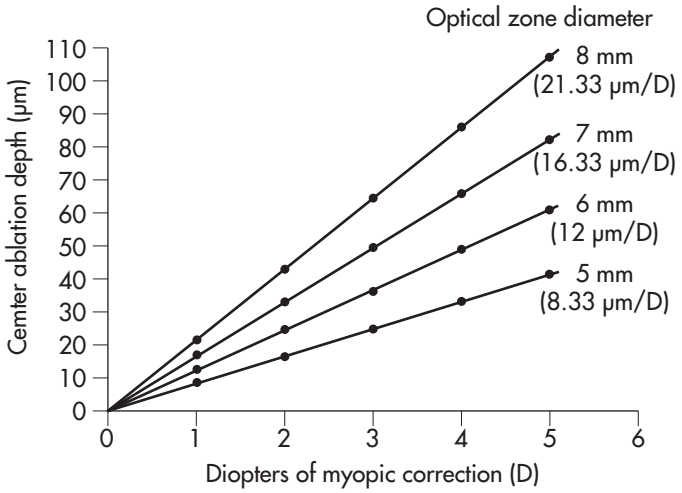

Figure 88.2. Diopters of myopic correction.

Thus, the volume of photoablated tissue also increases linearly for an increase in dioptric power, but by the fourth power for the treatment diameter of the optical zone. Overall, these theoretical, mathematical analyses show that the depth and volume of tissue removal for conventional treatments are mostly dependent on the diameter of the optical zone treatment.

Use of the excimer laser to correct myopia

With the earliest broad-beam excimer lasers, myopic corrections were accomplished with an iris diaphragm that would gradually open as the laser fired a series of pulses. The center of the cornea would receive more laser energy than the periphery and would experience greater tissue removal (Fig. 88.3, *A*). The scanning slit excimer lasers that followed would typically scan the slit across the cornea while increasing a diaphragm aperture to control the amount of laser energy applied centrally. With the subsequent scanning spot lasers, more spots could be applied centrally than peripherally to accomplish the corneal resculpting without the need of an expanding aperture (Fig. 88.3, *B*).

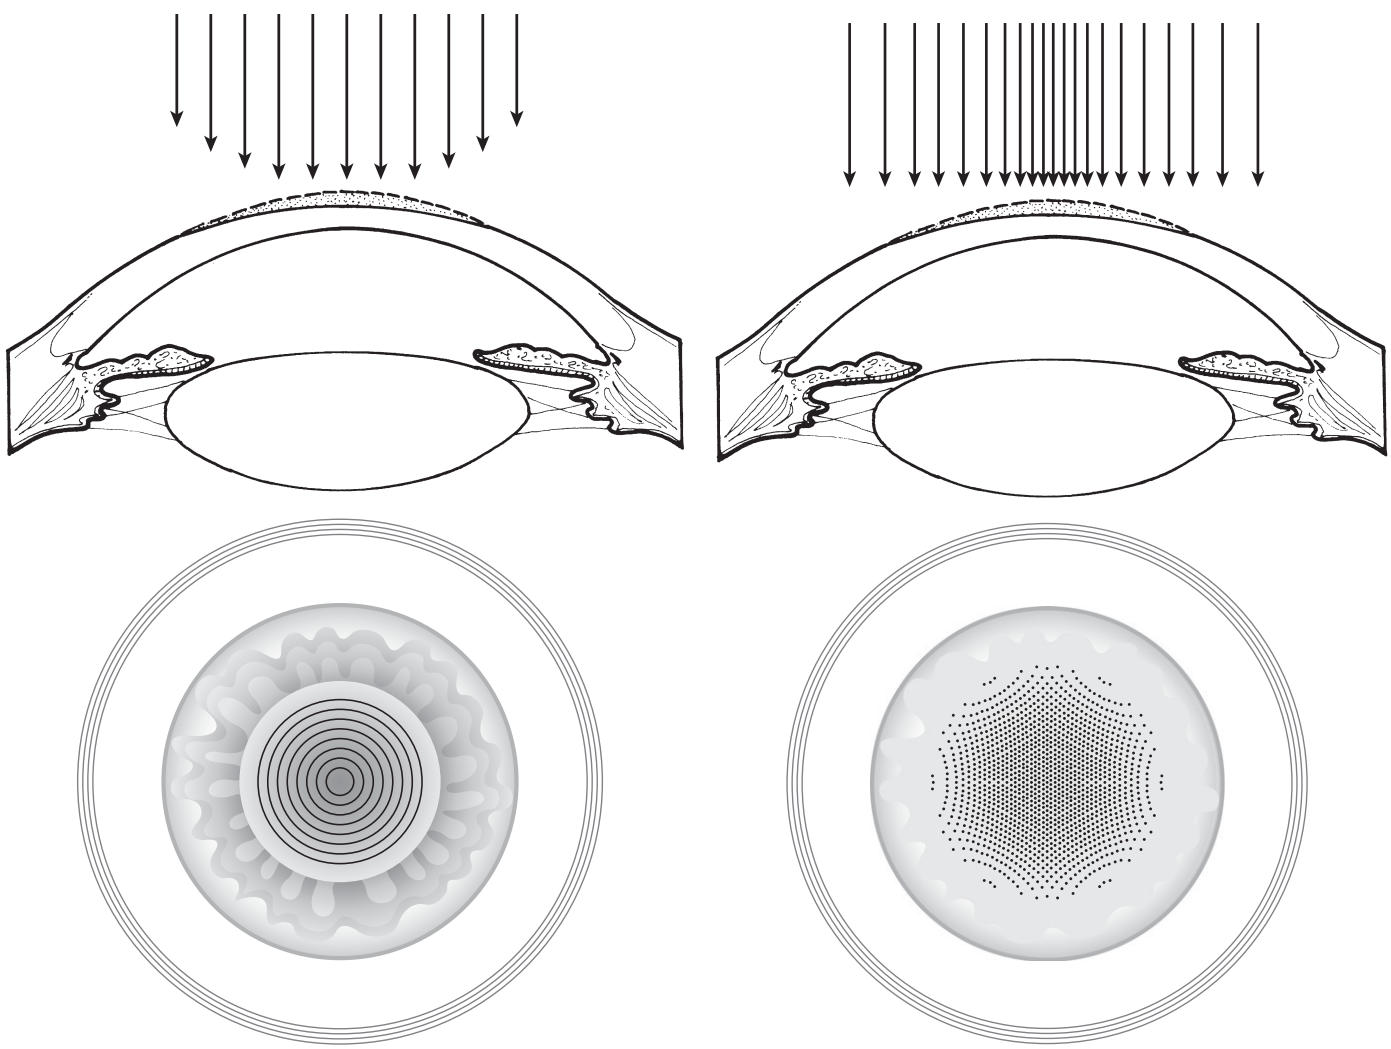

Figure 88.3. *A*, Myopic ablation broad beam. *B*, Myopic ablation scan spot.

These conventional myopic ablation profiles were effective, but were found to occasionally result in loss of visual performance (e.g. reduced mesopic or scotopic contrast sensitivity, increased glare and halos, and increased starbursts). The first myopic ablations were done at smaller diameters (4 and 5 mm in diameter) to minimize ablation depth because of concerns that deeper ablations might stimulate a greater wound healing response and scarring of the cornea. The smaller ablation zone diameters for myopic corrections actually resulted in greater regression and in greater complaints of halos and glare, presumably from the edge effect of the ablation zone with a larger pupil. To optimize visual outcomes and minimize tissue ablation depths, typical optical zone diameters are currently around 6.5 mm.

In addition, the assumptions used to derive the myopic ablation profiles had some shortcomings since the human cornea is not spherical, and this was also felt to contribute to the poor visual performance of some patients. The normal corneal contour is steeper, or has a smaller radius of curvature centrally, and is flatter with a larger radius of curvature towards the periphery. This type of contour is described as being prolate (Fig. 88.4, *A*). With the central flattening effect of a myopic laser correction, the corneal contour would be converted to one that was flatter centrally and comparatively steeper in the periphery, a shape referred to as being oblate (Fig. 88.4, *B*). An oblate corneal surface results in decreased focus on the retina, and this effect is especially pronounced with larger pupils, whether inherent to the patient or due to dim illumination, and with larger myopic corrections. Holladay and colleagues suggested that this might be the predominant factor in the functional decrease in visual performance after excimer laser-based keratorefractive surgery.[15,16]

Another mechanism contributing to the asphericity of the cornea and visual quality is due to the laser interaction with the curved cornea. The peripheral cornea receives less laser energy and less tissue ablation than planned. This is due to the greater distance the laser beam has to travel when ablating the peripheral cornea; the curved contour of the cornea means that the central cornea is closest to the laser source and the peripheral cornea furthest away as it curves posteriorly. In addition, the laser beam hits the central cornea orthogonally or perpendicularly to the surface, whereas it hits the peripheral cornea incidentally or at an angle and is partly reflected with some loss of effect (Fig. 88.5).[17] The newer-generation lasers have incorporated a compensation for this phenomenon, a radial compensation function, and this is no longer a significant source of reduced visual quality.

The ablation profiles for myopic corrections have been modified and have evolved to address all these causes of reduced visual quality in an attempt to give the patient the best and most predictable visual result. This evolutionary process has included the refinement of the excimer lasers with each successive generation to create smoother ablations and enhanced beam homogeneity but also to increase optical zone diameters, to minimize oblate corneal contours, and to add transition zone treatments to smooth and improve the peripheral corneal contour.

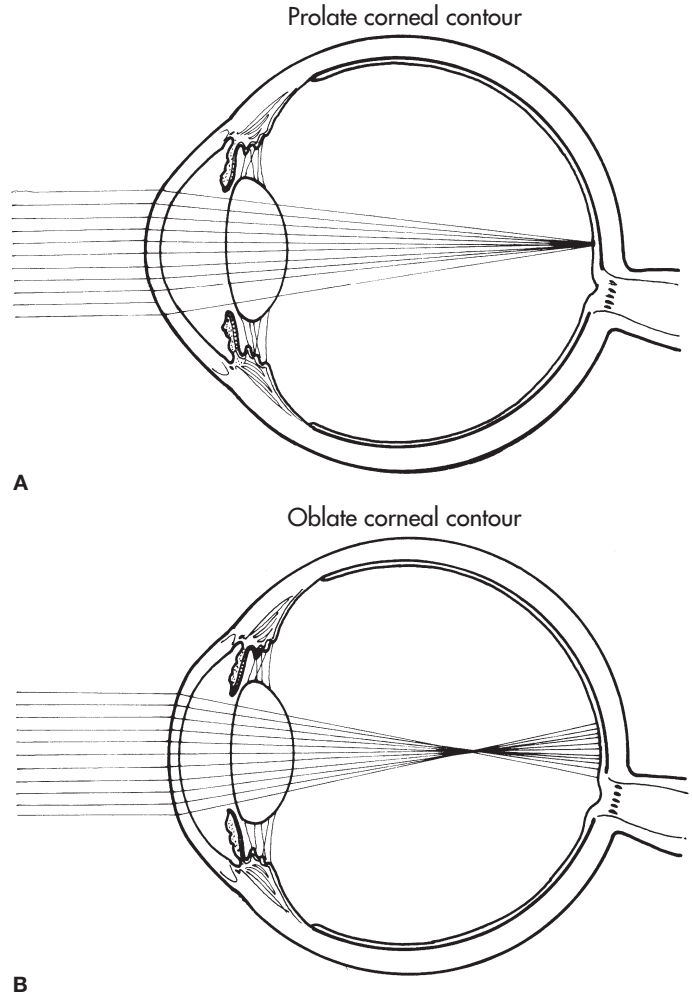

Figure 88.4. *A*, Prolate corneal contour. *B*, Oblate corneal contour.

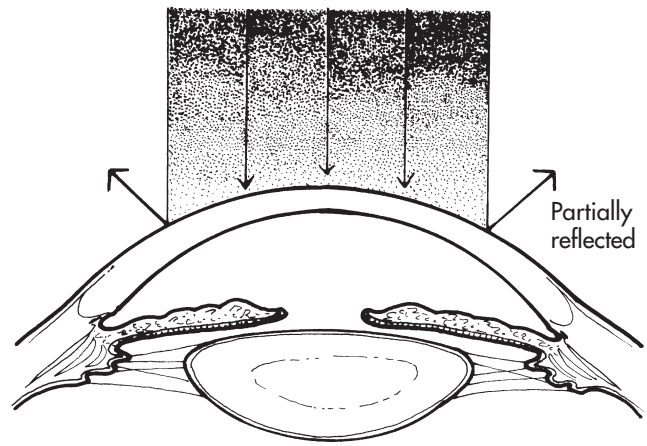

Figure 88.5. Radial ablation efficiency loss causes underablation in the periphery.

PRINCIPLES OF HYPEROPIC ABLATIONS

The correction of spherical hyperopia with the laser requires the removal of a concave lenticule of tissue. Munnerlyn and associates again used the principles that underlie contact lens creation to mathematically describe the dimensions of the lenticule of tissue that would need to be removed in order to accomplish a desired hyperopic correction. The tissue ablation profile was described as a function of initial anterior corneal curvature, corneal refractive index, magnitude of correction desired, and diameter of the lenticule of tissue to be removed, or the ablation zone.[13]

Munnerlyn equation for hyperopic corrections

For the correction of hyperopia, the corneal curvature has to be increased over the ablation zone (or the radius of curvature has to

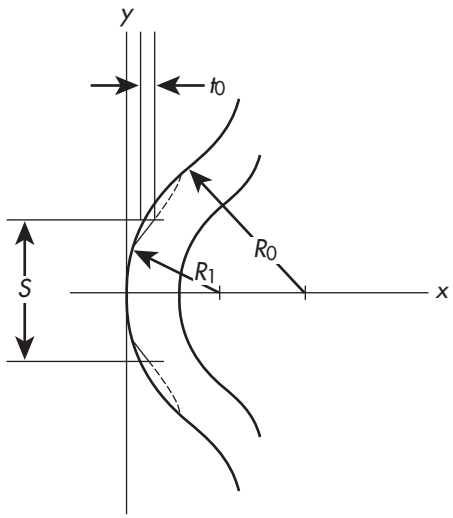

Figure 88.6. Munnerlyn hyperopic ablation.

be decreased). The ablation profile for a hyperopic correction can be calculated by the following equation:

$$t_H(y) = \sqrt{R_0^2 - y^2} - \sqrt{R_1^2 - y^2} + R_1 - R_0$$

where $t_H(y)$ = the depth of tissue removal at a distance y from the optical center

y = the distance radially from the optical center ($y \leq S/2$)

S = the diameter of the treatment zone or the tissue lenticule to be removed

R_0 = the initial anterior radius of curvature of the cornea

R_1 = the final anterior radius of curvature of the cornea.

For hyperopic corrections, the depth of ablation is greatest in the periphery and is negligible centrally and can be determined from Munnerlyn's equations (Fig. 88.6). Again by using binomial expansion, the maximal ablation depth can be approximated as:

$$\text{maximum ablation depth } (\text{mm}^3) = \text{ablation diameter}^2\ (\text{mm}^2) \times \text{diopters of correction (D)}/3$$

Use of the excimer laser to correct hyperopia

With the earliest broad-beam lasers, some of the initial approaches used beam divergers to direct the laser energy to the periphery and masks to control laser energy application. Ablatable masks were made of materials that would photoablate at a known rate. The thinner areas of the mask ablate through quickly and allow passage of the excimer laser energy to the cornea, whereas the thicker areas of the mask shield portions of the cornea from photoablation (Fig. 88.7). Nonablatable masks were also used; these were shaped apertures that allowed passage of laser energy to the cornea and could be rotated to control the ablation pattern applied to the cornea.

With the advent of scanning slit lasers, a slit beam of laser energy could be scanned over the cornea and used with an ablatable mask or a rotating nonablatable mask to ablate the cornea where desired, or the slit beam could be rotated around the periphery obviating the need for a mask. The more recent scanning spot lasers simply apply a greater number of pulses in the periphery than centrally and do not require any masks (Fig. 88.8).

The initial approaches to hyperopic ablations were successful, but again there were reports of regression and poor visual performance. Regression with loss of effect was a greater challenge with

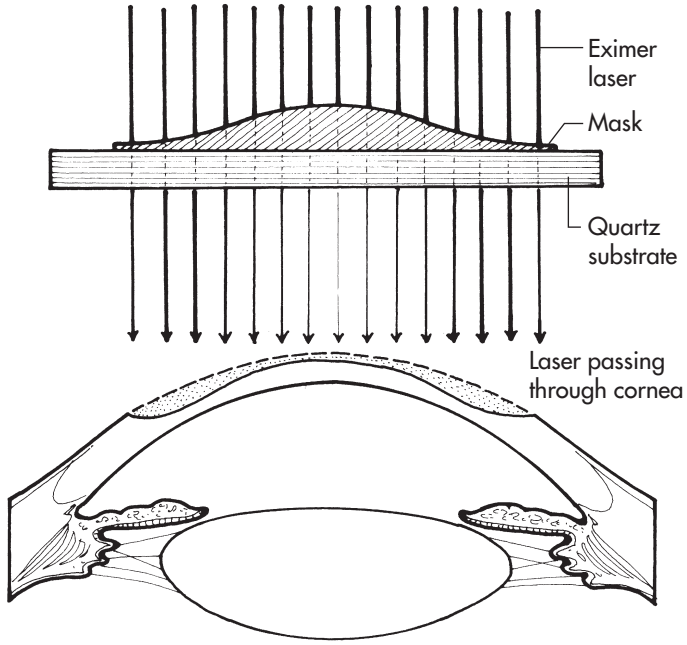

Figure 88.7. Mask for hyperopic ablation.

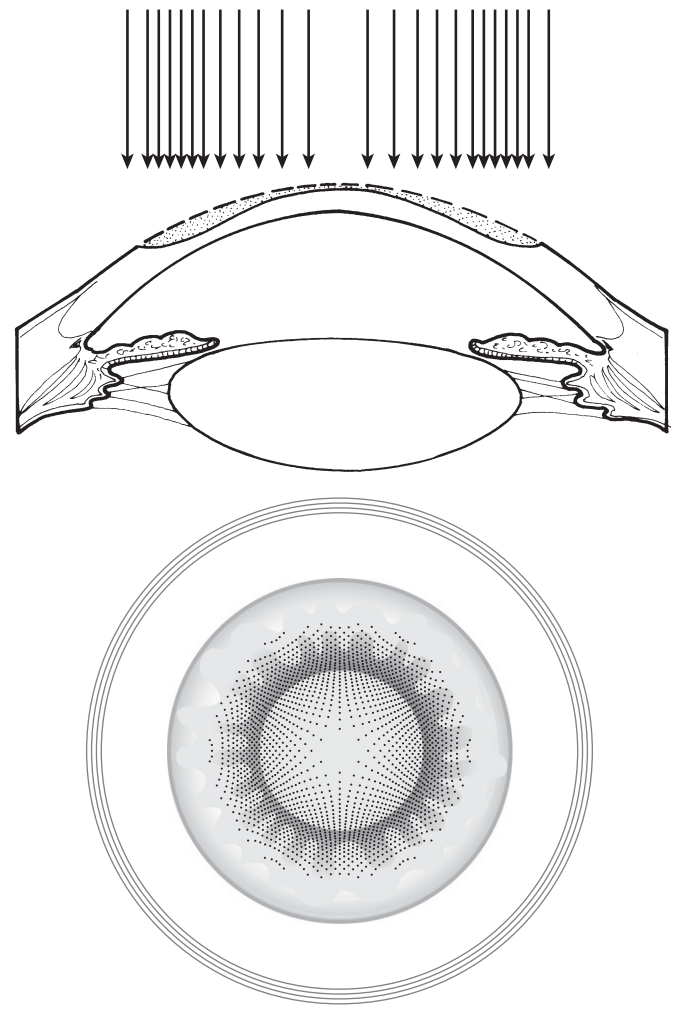

Figure 88.8. Hyperopic ablation scanning spot.

hyperopic ablations compared with myopic ablations. It was physiologically more natural to flatten the corneal center as in myopic corrections, rather than ablate a donut-shaped trough and not have the cornea try to fill the treated areas in with epithelial hyperplasia. Higher hyperopic corrections only required deeper stromal removal with an exaggerated abrupt change in corneal curvature at the edge of the ablation. This was associated with an even more marked healing response with decreased visual acuity under glare conditions.

Similar to earlier myopic correction attempts, the first corrections for hyperopia were done at smaller optical zones. Better visual outcomes and greater stability of result were seen at larger optical zones. In addition, the use of blended transition zones made the recontouring effects more gradual and more stable, and the advent of scanning lasers allowed for smoother ablations.

PRINCIPLES OF ASTIGMATIC ABLATIONS

Astigmatic corrections are more challenging than purely spherical myopic or hyperopic corrections. Astigmatism describes an optical aberration where the refractive power of an optical system varies across different meridians. In stigmatic optical systems, the image of a point source is also a point; in an astigmatic optical system, there are at least two focal points or two focal planes. Conventional laser astigmatic ablations treat regular or symmetric astigmatism, where the two prime meridians of corneal curvature are orthogonal, or 90° apart. Ablation principles for irregular astigmatism will be addressed in the chapters on wavefront- and topography-guided ablations.

Regular astigmatism can be subcategorized as myopic astigmatism, compound myopic astigmatism, hyperopic astigmatism, compound hyperopic astigmatism, and mixed astigmatism. These subcategories describe where the two focal planes created by the astigmatism lie with respect to the retina. This in turn determines the optimal ablation approach to their correction. In myopic astigmatism, one focal plane lies anterior to the retina, and the second focal plane lies on the retina. In compound myopic astigmatism, both focal planes lie anterior to the retina. In hyperopic astigmatism, one focal plane lies on the retina and the second plane lies posterior to the retina. In compound hyperopic astigmatism, both focal planes lie posterior to the retina. Lastly, mixed astigmatism consists of one focal plane anterior to the retina and the second focal plane posterior to the retina (Fig. 88.9, *A–E*).

Use of the excimer laser to correct astigmatism

The goal behind an astigmatic ablation is to resculpt the anterior corneal contour to bring the two focal points to the same plane and then ultimately onto the retina. This requires either selective flattening of the steep meridian or alternatively steepening (or decreasing the radius of curvature) of the flat meridian (Fig. 88.10). The earliest approach with the broad-beam lasers involved flattening the steeper meridian. In 1991, McDonnell and associates proposed passing a large-diameter laser beam between a set of parallel blades.[18] The separation of the blades was controlled by a computer with the slit created gradually increasing in width during the procedure. The mechanical axis (long axis of the slit beam) was rotated and aligned with the astigmatic axis of the patient. No refractive change was intended along the mechanical axis, but the corneal curvature was flattened along the meridian, or 90° opposite of the slit expansion. In a sequential treatment, the cylinder could be treated first and the spherical component next. Elliptical ablations were also employed and were created by having the computer expand both the slit and the iris diaphragms simultaneously; this could treat both myopia and astigmatism concurrently.

Another approach to treating astigmatism was with the use of a mask. The mask was made of an ablatable material and was designed to deliver a graded ablation to the cornea. The thinner areas of the mask would ablate through quickly and allow passage of the excimer laser energy to the cornea, whereas the thicker areas of the mask would shield portions of the cornea from photoablation. The 'steeper' meridian of the corneal surface would receive more treatment and would be flattened.

With the advent of scanning, variable-diameter spot excimer lasers, smaller laser spots could be used to treat astigmatism more directly. Moreover, the laser beam position on the cornea could be altered with scanning mirrors and servo-mechanisms controlled by a computer. The ablation would start with a small-diameter spot along the steep axis, and the spot size would be increased in diameter and continue along the flat axis. This would create a tapered, graded pattern that would flatten the steep meridian (Fig. 88.11, *A* and *B*).

These were appropriate and intuitive approaches to treating myopic astigmatism or compound myopic astigmatism where the steeper meridian could be flattened to the curvature of the flatter meridian, and then the entire cornea could be flattened further with a spherical myopic correction. However, with compound hyperopic astigmatism, this approach meant first flattening the steeper meridian and then attempting to steepen the overall curvature of the cornea with a spherical hyperopic treatment. This required re-steepening of the areas of the cornea that were flattened to treat the astigmatism and thus redundant or excessive removal of tissue was involved. It was a less efficient approach for hyperopic astigmatism.

The more recent scanning-beam lasers use a fixed-diameter spot to rapidly resculpt the cornea as determined by the computer. The beam can be directed to ablate the steep areas more and avoid the flat areas to reshape the myopic astigmatic patient, but can also be used to steepen rather than flatten an axis. The cornea can thus be approached in positive or negative cylinder. This is particularly useful with hyperopic patients with astigmatism where all axes can be steepened but by differing amounts. Not only is it a more direct approach to hyperopic astigmatism and compound hyperopic astigmatism, but it is also much more tissue conserving (Fig. 88.12).

Thus, the most ideal and efficient way to treat any astigmatism is to remove the least amount of tissue and to avoid redundancy. For any myopic astigmatism, this is the minus or negative cylinder format where the steeper meridian is first flattened to create a spherical surface, and then overall corneal surface flattened further to a desired spherical corneal power. In hyperopic astigmatism, it is advantageous to use the plus or positive cylinder ablation approach to first steepen the flatter meridian and then steepen the overall spherical surface further to the desired spherical corneal power.

Mixed astigmatism allows for three possible treatment approaches: minus cylinder format, plus cylinder format, or cross cylinder format. As it turns out, the cross cylinder approach removes the least tissue in mixed astigmatic corrections and is the most ideal and efficient means of achieving the desired refractive and visual outcome. The myopic focal plane in front of the retina is moved posteriorly toward the retina with the minus cylinder ablation, and the hyperopic focal plane is moved anteriorly toward the retina with

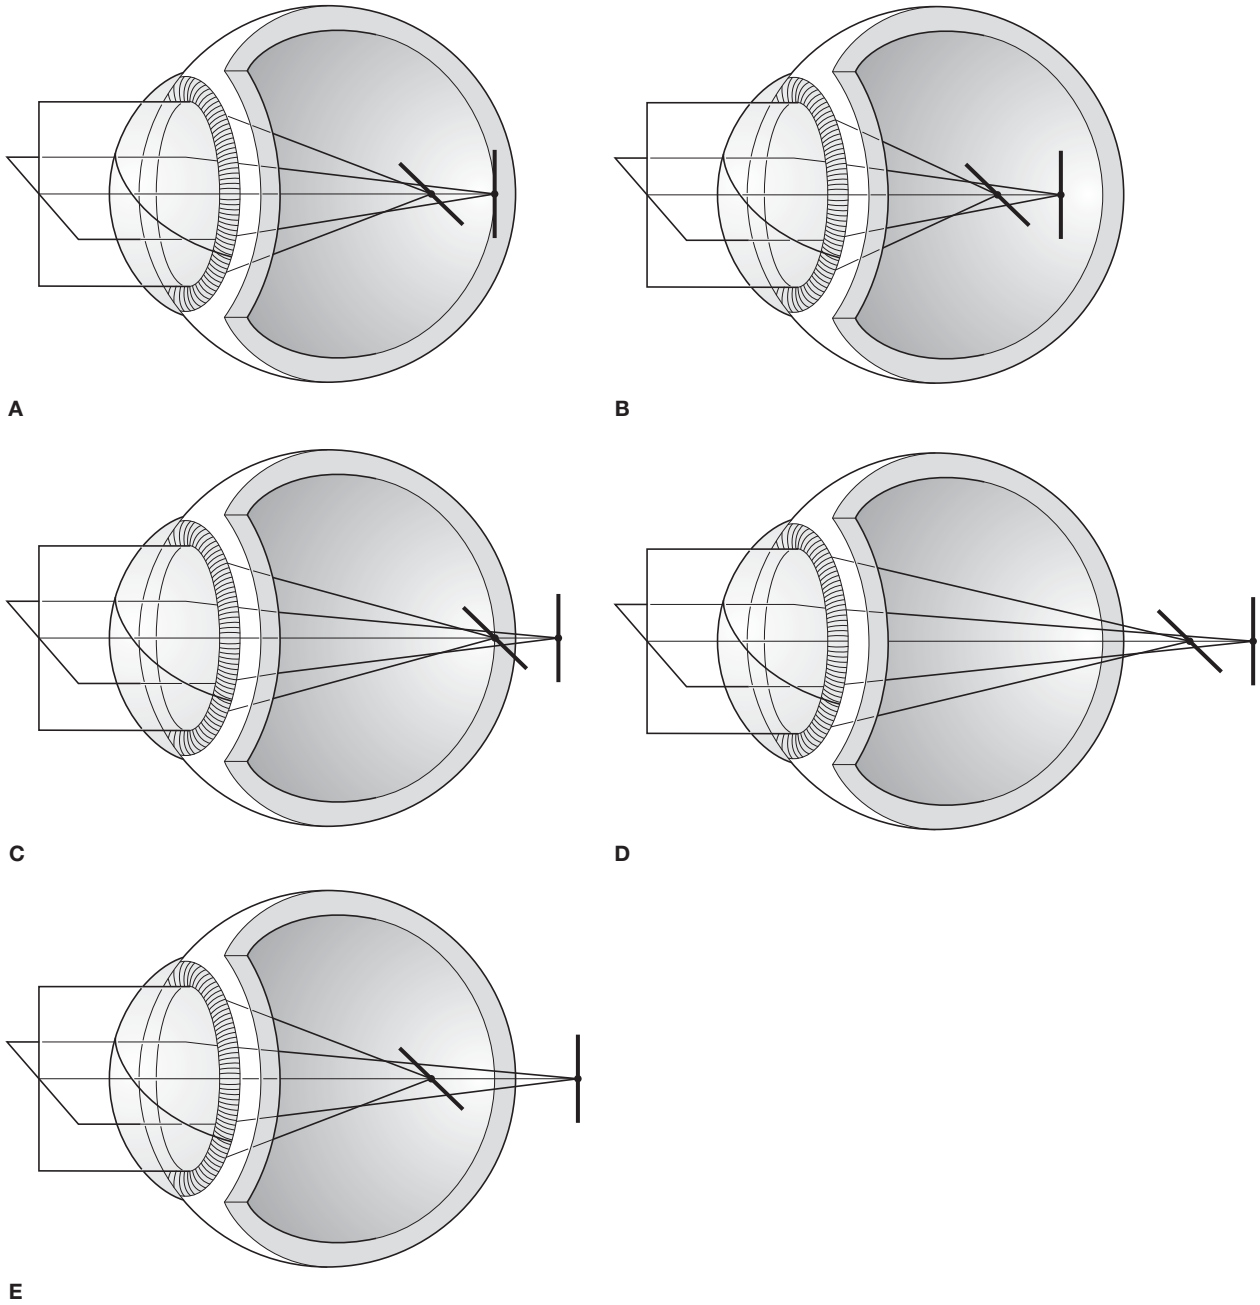

Figure 88.9. *A*, Myopic astigmatism. *B*, Compound myopic astigmatism. *C*, Hyperopic astigmatism. *D*, Compound hyperopic astigmatism. *E*, Mixed astigmatism.

the plus cylinder ablation. No spherical (myopic or hyperopic) ablation is required (Fig. 88.13).

The evolved approach to astigmatic ablation profiles has been increasingly successful, but there are still limits to the degree of correction. Greater regression is still seen with the higher attempted corrections. The regression is perhaps the most common cause of patient complaints of poor visual performance. However, other causes of poor visual outcome include undercorrection seen with any degree of axis misalignment in treating the astigmatism. In addition, as the conventional treatments for astigmatism can only address regular astigmatism, they are not as effective with irregular astigmatism. This requires more customized approaches that will be discussed in subsequent chapters.

BEYOND CONVENTIONAL ABLATIONS FOR MYOPIA, HYPEROPIA, AND ASTIGMATISM

As an introduction to the chapters that will follow, the conventional ablations should be placed into proper context within the spectrum of options that are available and evolving. As stated, conventional laser refractive surgery corrects only myopia, hyperopia, and astigmatism or the lower-order optical aberrations of the eye, and the surgical plan is derived from the patient's manifest and cycloplegic refractions. There are additional optical aberrations or imperfections of the eye that can limit the patient's quality and quantity of vision. These higher-order aberrations can exist before surgery and are typically increased with conventional refractive surgery. And they

are often associated with glare, halos, starbursts, and decreased mesopic or scotopic contrast sensitivity.[19–29]

The current classification of excimer laser ablation profiles can be summarized as follows:

I. Based on the total optical system of the eye:
   A. Conventional ablation profiles: correct lower-order aberrations and are based on the patient's manifest and cycloplegic refractions.
   B. Wavefront-optimized ablation profile: In addition to treating lower-order aberrations, wavefront-optimized treatments attempt to maintain the preoperative prolate shape of the cornea by removing more stromal tissue peripherally than in conventional treatments and adjusts for postoperative biomechanical and biologic effects.[30,31] These extraperipheral laser pulses are derived from the patient's keratometry measurements as well as previous population-averaged preoperative keratometry measurements and postoperative wavefront analyses.[32] The major advantage of this technique compared to wavefront-guided treatment is that the time-consuming wavefront data analysis process is not required. The disadvantages are that it ablates more tissue peripherally than conventional treatments and is perhaps less clinically effective in reducing keratorefractive surgery-induced higher-order aberrations compared to wavefront-guided treatments. One recent randomized prospective study directly compared wavefront-optimized ablations to wavefront-guided ablations using the latest excimer laser platforms. Despite similar keratorefractive surgery-induced increases in spherical aberration (40% increase for wavefront-optimized treatment compared to 46% for wavefront-guided treatment), the total keratorefractive surgery-induced higher-order aberrations were significantly higher after wavefront-optimized treatments (increased by 49%) compared to wavefront-guided treatments (increased by 9%).[33]
   C. Wavefront-guided ablation profile: Wavefront-guided treatments are customized ablations that attempt to reduce the optical aberrations and the total wavefront error of a patient's eye to a reference ideal. The input data are more complex and time consuming to measure as it is derived from objective wavefront sensors (e.g. Hartmann–Shack sensor and Tscherning aberrometer). The wavefront sensor measures the distortion of a planar monochromatic light wave as it is altered by the optics of the eye. Contour irregularities in the cornea or lens typically cause these distortions or aberrations. Although the theoretical advantages of wavefront-guided ablations seem significant compared to conventional ablations, these have only shown marginally better visual results than conventional ablations, particularly in eyes requiring lower degrees of correction or possessing lower preoperative higher-order aberrations.[31,34] Wavefront-guided ablations do generally induce less higher-order aberrations than conventional ablations, and this may correlate to improved visual quality. Since wavefront-guided treatments correct more components of a

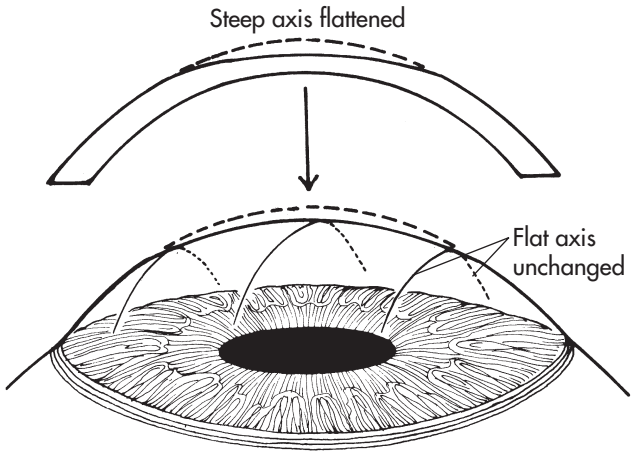

Figure 88.10. Cylindrical ablation.

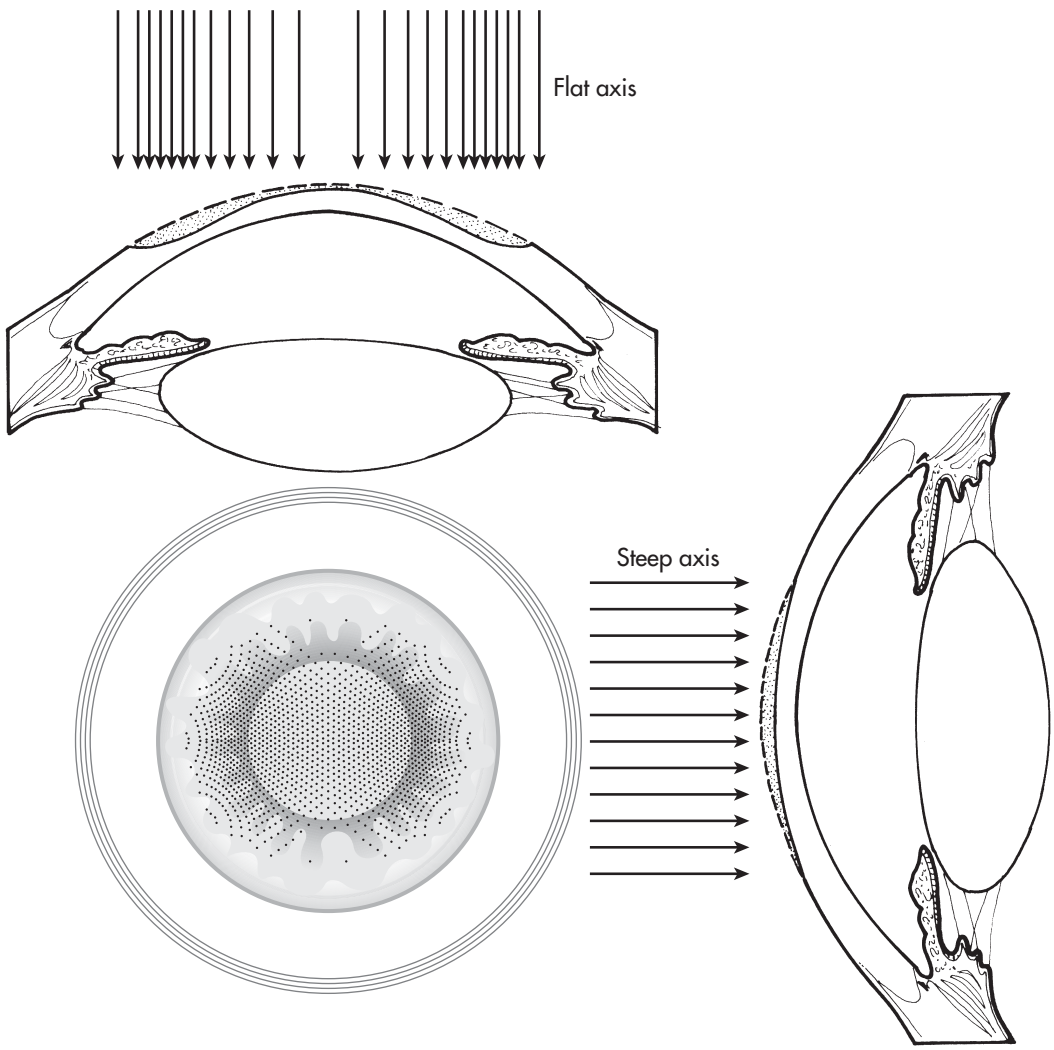

Figure 88.13. Mixed astigmatism ablation—scanning spot.

patient's wavefront error than conventional treatments, it is not surprising that it ablates deeper into the stroma compared to conventional treatments.

II. Based on corneal topography
   A. Topography-guided ablation profile: Topography-guided ablations are an alternative treatment option for patients with irregularities of the corneal surface, particularly those beyond the range of wavefront sensing devices.[35] Input data come from corneal topography measurements, which is then offset to achieve a target asphericity. The major advantage of topographic-guided treatments over wavefront-guided treatments is that they are able to reduce pronounced corneal irregularities that are producing aberrations (e.g. scarring and surgical-induced irregular astigmatism). However, the 'ideal' corneal surface is one that creates balance between corneal and lenticular aberrations, and a one-sided reduction of corneal aberration might even result in an increase of the total aberrations of the entire eye.[31] A major limitation of this technology at this time is that it does not correct refractive spherical error; therefore, a two-stage keratorefractive procedure has been proposed where a topography-guided treatment is followed by a wavefront-guided treatment.[35]
   B. Q-factor adjusted ablation profile: This approach is based on refractive error and corneal topography measurements, and the resultant laser ablation profile corrects the refractive error, while trying to produce a more aspheric corneal shape.[36] The target corneal contour for reducing spherical aberrations is calculated as having a Q-factor of –0.40. The major advantages of this technique compared to wavefront-guided treatments are that it is less time consuming and produces a clinically equivalent reduction in certain postoperative optical aberrations to wavefront-guided ablations.[36] Its disadvantages are that it ablates more tissue centrally than wavefront-guided treatments and does not correct all higher-order aberrations as it predominantly corrects spherical aberrations, similar to wavefront-optimized ablations.

CONCLUSION

Conventional laser ablation treatments with modern fourth-generation scanning-beam excimer laser systems have evolved considerably and are currently sufficient for most keratorefractive surgery candidates. However, patients who have experienced poor outcomes from previous excimer laser or other keratorefractive surgery or who present with greater preoperative optical aberrations would perhaps benefit more from a wavefront-guided treatment. In addition, there are other treatment approaches that are evolving that will be discussed in the chapters to follow.

89 Comparison of lasers for excimer laser vision correction

David R. Hardten, Scott G. Hauswirth

Surgeons have always been extremely dependent on the tools they use, although at no time has this dependency been more obvious than in laser technology. The field of laser refractive surgery has grown immensely from its initial outset in the early 1990s, and increasing popularity of refractive surgery has increased demands from surgeons on equipment that will provide the best outcomes for their patients. Advancements in laser technology and associated software have attempted to keep pace with these demands.

There are now a wide variety of excimer laser platforms that are used for photorefractive and phototherapeutic keratectomy (PRK/PTK), laser in situ keratomileusis (LASIK), laser in situ epithelial keratomileusis (LASEK), and other associated procedures. The basic premise of the laser's function in each of these surgical procedures is to remove corneal tissue in a specific pattern to correct myopia, hyperopia, and astigmatism or, in nonrefractive cases, to remove corneal scar tissue.

The surgeon can become overwhelmed when trying to assess the relative merits of each of these systems. In addition, each laser model is continuously changing as the manufacturers incorporate updates and advancements in the field into their own systems. It is incumbent on the physician to understand the advantages and limitations of their own specific laser before applying them to patient care. It is also important for surgeons to realize the status of each laser in the USA. Some lasers may be approved for certain indications in the USA by the Food and Drug Administration (FDA) but are not yet approved for other indications, and some may not have FDA approval in the USA at all. Surgeons should contact the company directly to get an update on current regulatory status and features.

This chapter addresses the capabilities of the primary lasers used in refractive surgery and may serve as a guide to provide surgeons with information useful in determining which laser may best suit their specific needs.

ENERGY

Laser systems used in refractive surgery are not merely computer-controlled devices that produce perfectly consistent outcomes. There are several variables that must be controlled or taken into account for the optimal surgical results. Among these factors, a primary consideration is energy.

Energy is used to remove corneal tissue during the photoablative process, and the amount of energy present in a given laser beam can be variable. This amount is expressed in terms of laser fluence (mJ/cm^2). Fluence on a standard excimer laser may vary from 50–500 mJ/cm^2, which is too broad a range to give predictable surgical outcomes. Thus, most lasers available have the ability to modify fluence by adding or subtracting additional energy, usually by means of diluting the ArF gas with another molecule (often He), or by varying the voltage across the laser. These methods control fluence to a more acceptable range between 120 and 180 mJ/cm^2. The ablation threshold for cornea stromal tissue is 50 mJ/cm^2. Below this level, only photochemical changes occur. At very high fluence levels, there is an increase in disruption of surrounding tissue by thermal energy, as well as the acoustical shockwave, both of which may produce undesirable results.

Each of the excimer laser systems has a characteristic energy beam profile. This beam profile may have one of several different patterns. A homogeneous or flat beam profile is present when the energy density at every area along the beam is equal. A Gaussian energy beam profile indicates that there is a greater energy density centrally within the beam. A reverse Gaussian profile is present when there is less energy in the center portion compared to peripheral areas of the beam. Identifying these profiles is extremely important in broad-beam lasers, as the beam profile is repeated many times over the same area, and small irregularities in profile may have undesired effects if not identified preoperatively. It is less critical in smaller beam profiles.

All excimer lasers should be maintained and calibrated regularly for best performance. Beam homogeneity and laser fluence should be checked regularly by surgical staff to ensure optimal surgical results.

LASER ENERGY DELIVERY SYSTEM

Most early lasers used a complicated system of optics to attempt to deliver a large homogeneous beam to the surface of the eye. This method of delivery system is termed broad beam. These early deliv-

ery systems provided surgeons with fairly fast surgery times, but surgical outcomes were subject to beam profile.

Another method is a small spot or flying spot, which delivers the laser energy in a smaller spot (typically 0.5–2 mm), which is moved around the cornea, overlapping in a specific pattern to give the desired ablation profile. The homogeneity of the scanning laser beam becomes less important in small-spot lasers than in broad-beam lasers because each of the spots is overlapped by a different spot. Specificity in ablation profile is theoretically increased, but in early models surgical times also increased significantly. There was also some difficulty ensuring proper distribution of the beam profile to the correct area of the cornea, as each treatment took longer and eyes are subject to saccadic movement or rotation during surgery.

A hybrid of the two types is called a variable-spot scanning laser, which allows for a change in the size of the beam delivered to the cornea as well as the ability to move the beam around to generate the ablation profile.

Aside from the beam type, different delivery systems also vary in the rate in which the laser beam is administered to the cornea. This is termed the pulse rate, or Hertz rate (Hz). Typically this will range from 3 to 200 Hz. Low Hz machines take more time and are undesirable in small-spot scanning lasers because no adjacent spots are treated consecutively. At extremely high frequencies, optics tend to degrade faster, and a problem particular to large beam profiles is that thermal effect increases as less time exists between pulses to allow for heat dissipation.

The majority of excimer lasers currently in use today are using small-spot or variable-spot scanning. Development of eye-tracking devices have drastically improved delivery of the beam to the desired location, as it was noted in early delivery systems using small-spot technology that small saccadic eye movements could alter the desired positioning of the beam. Increase in the delivery rate also decreased surgical time.

ABLATION PATTERN

For myopia, it is necessary for the cornea to receive more energy in the central portion of the cornea than it does in the periphery to create an overall flattening effect. This concentration of energy may be done in several different manners. The broad-beam lasers use some type of a masking device to protect the peripheral portion of the cornea from the laser energy while delivering a larger amount of energy to the central portion of the cornea.

Scanning-slit lasers such as the MEL-60 (Jena, Germany) preferentially ablate different areas of the cornea by using a handheld mask (Fig. 89.1). The flying-spot lasers such as the Bausch & Lomb Technolas 217z Zyoptix laser (Bausch & Lomb, San Dimas, CA) or the Allegretto Wave (WaveLight, Benoptinhagen, Germany) use computer control to preferentially place more spots in the center of the cornea than in the periphery for creation of myopic corrections. Comparisons of astigmatic capabilities are covered in another chapter.

The smaller beam lasers require a less powerful laser head as well as fewer optics to homogenize the beam. The scanning lasers, however, are dependent on an eye-tracking or coupling system. Because the surgeon cannot as accurately follow small saccadic eye movements when the laser is rapidly treating small areas on the cornea, computerized tracking of these small movements is more crucial. Also, because the spot size is much smaller, higher pulse rates are necessary to complete the ablation in a reasonable time.

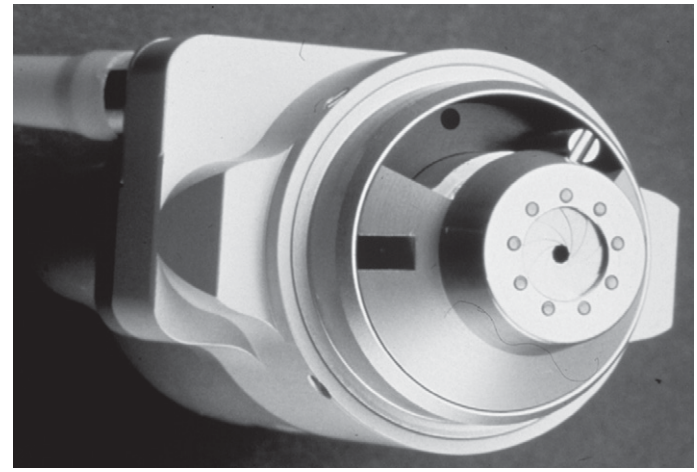

Figure 89.1. Handheld masks used by the Meditec MEL-60 slit scanning excimer laser (Meditec, Jena, Germany). The myopic mask constricts gradually during the treatment to allow more laser treatment to be applied to the central cornea. (Courtesy of Meditec, Jena, Germany.)

Because no one area is treated with two pulses in a row, any thermal energy created is allowed to dissipate between pulses.

VISX STAR LASER

The VISX Star S4 IR excimer laser system (VISX, Santa Clara, CA) is an advancement to the previous models of the VISX excimer lasers (Fig. 89.2). Notably the improvements have come from the integration of a wavefront system and improvements to ensure alignment of the eye-tracking system, which ensures accurate distribution of the laser treatment to the cornea. The Star S4 IR is a variable spot-scanning laser with spot size ranging from 0.65–6.5 mm. Using the WaveScan aberrometer in combination with the laser, surgeons may treat optical zones out to 7 mm using wavefront data and create blend zones as large as 9.5 mm. It also has variable repetition rate (VRR), which allows for variation in delivery times to specific and adjacent sites on the cornea, allowing for improved ejected tissue removal by the vacuum system and thermal dissipation on adjacent sites. The eye-tracking system is a camera-based iris registration (IR) system, which operates on a three-dimensional platform, allowing for adjustment along the *x*–and *y*-axis plus rotation.

The fluence is somewhat in the mid-range of other excimer lasers at 160 mJ/cm^2. The laser operates at speeds up to 20 Hz. A joystick on the control panel allows movement of the patient's bed up, down, to the left, or to the right (Fig. 89.3). The patient fixes on a red flashing He–Ne beam that is coaxial with the excimer laser beam in the standard treatments and aligned with the patient fixation on the WaveScan.

Currently in the USA, the VISX Star S4 IR combined with the WaveScan system is approved to treat up to 11.0 D of myopia, with or without up to 3.0 D of myopic astigmatism, mixed astigmatism up to 5.0 D, and up to 3.0 D of hyperopia with or without 2.0 D of astigmatism. The VISX laser is also being used in a mobile system developed by Laser Vision Centers, Inc. (TLCVision, St Louis, MO).

ALCON LADARVISION LASER

Alcon obtained FDA approval for LASIK with the Apex lasers, and a more recent laser model from Alcon is the LADAR 6000 (Alcon,

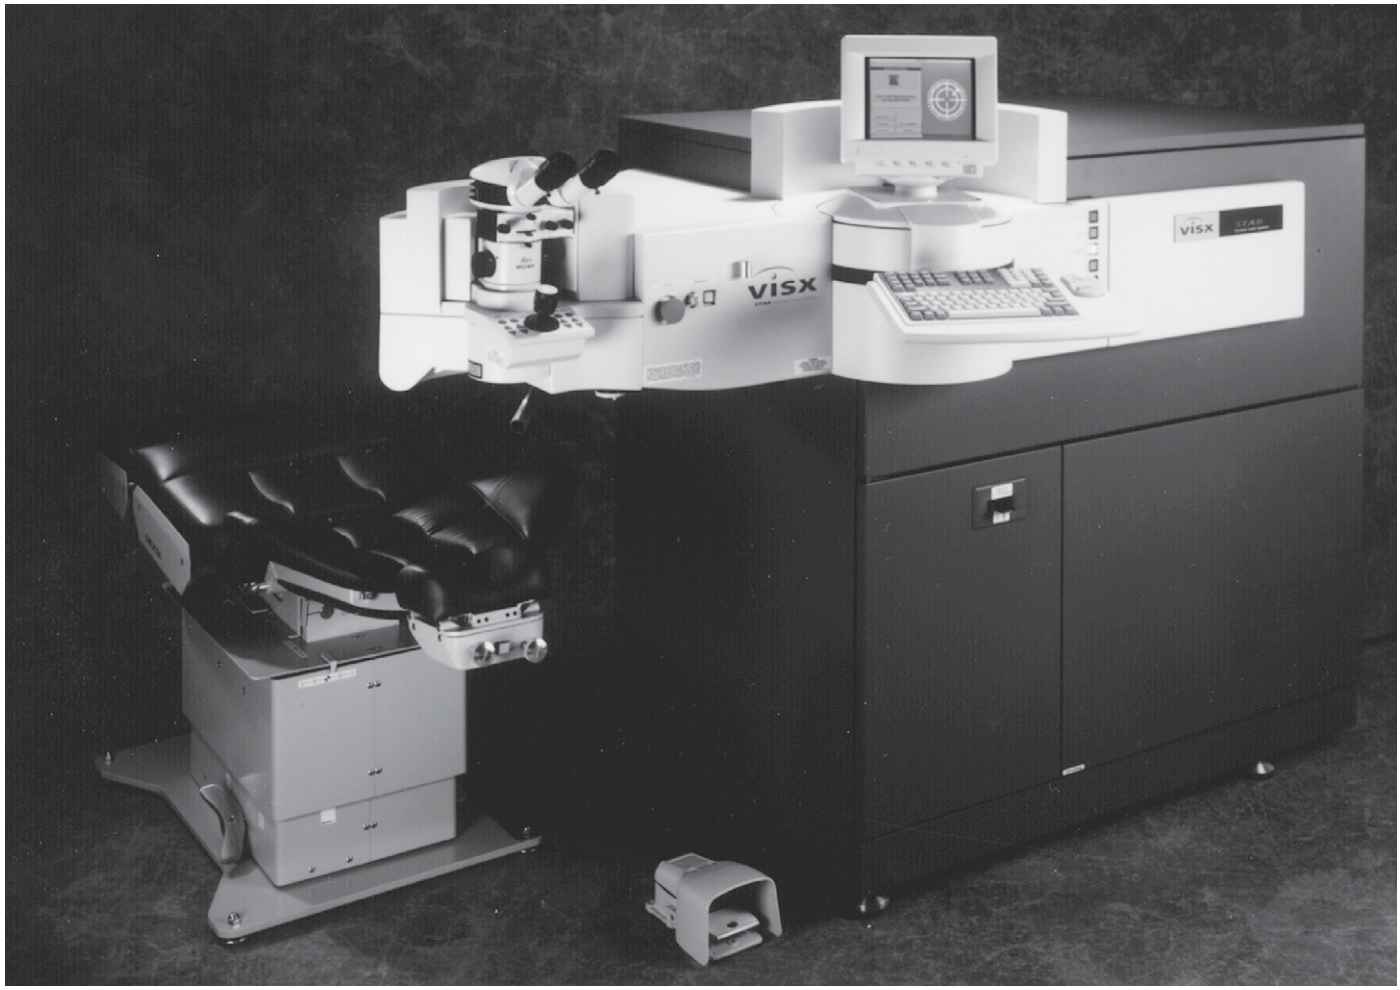

Figure 89.2. The VISX Star laser (VISX, Santa Clara, CA) incorporates a joystick-controlled bed with the excimer laser unit. (Courtesy of VISX, Santa Clara, CA.)

Figure 89.3. The control panel of the VISX Star laser (VISX, Santa Clara, CA) includes a joystick for moving the patient's bed, a Leica Wild microscope (Leica, Inc., Allendale, NJ) and controls for ring and oblique lighting. (Courtesy of VISX, Inc., Santa Clara, CA.)

Figure 89.4. The Alcon LADAR 6000 is a small spot laser with active tracking. (Courtesy of Alcon, Fort Worth, TX.)

Fort Worth, TX), which was developed as a flying small-spot laser (Fig. 89.4). The beam is 0.9 mm wide, has a Gaussian profile, and is fixed in size. It can be used with the CustomCornea software, which allows for wavefront correction. The CustomCornea program also couples the laser delivery with a four-beam infrared eye-tracker functioning at 100 Hz. This makes the tracking system capable of measuring subtle changes in eye position 4000 times/s.

The laser operates at a fluence of 2.7 mJ/cm^2 at the level of the cornea. The treatment rate is 93 Hz with the LADAR 6000 system, an improvement over the 63 Hz found in the LADAR 4000. Optic

zone size is typically 6.5 mm for myopia but can be extended to 9.0 mm (including blend zone) for hyperopia. Blend zone in myopic patients can extend to 11.5 mm.

The FDA has approved the LADAR 4000 and the LADAR 6000 for myopia up to −8.00 D with or without astigmatism up to −4.00 D, hyperopia up to +5.00 D with or without astigmatism of up to −3.00 D, and mixed astigmatism up to 5.00 D of cylinder correction.

ZEISS MEDITEC MEL-80 EXCIMER LASER

Zeiss Meditec (Jena, Germany; Dublin, USA) manufactures the MEL excimer laser. The most recently released model is the MEL-80 laser, which has been approved for use in the USA (Fig. 89.5).

The MEL-80 excimer laser is a small-spot scanning laser with a fixed spot size of 0.7 mm. It operates at a pulse rate of between 10 and 250 Hz. Each pulse duration lasts between 4 and 6 ns. Average fluence level at the cornea is kept in check by diluting the ArF mixture with helium gas. A blend zone can be created out to 10 mm.

A tissue-saving algorithm is used, which results in lower asphericity and preserves more of the corneal tissue for use on thinner corneas. The eye tracker is a high-speed camera-based system combined with an integrated iris-recognition system operating at 250 Hz, which does not require the patient to be dilated.

BAUSCH & LOMB TECHNOLAS EXCIMER LASER

The Technolas 217z with the Zyoptix wavefront system (Bausch & Lomb Surgical, San Dimas, CA) is a small-spot scanning system (Fig. 89.6). It uses a small-size spot with integration of the Zyoptix wavefront software program for treatment of myopia, astigmatism, and hyperopia.

The laser delivery system runs at 50 Hz, with pulse duration of 18 ns. The Technolas 217 laser incorporates an eye tracker with a camera-based iris-recognition system, which runs at 120 Hz. The patient does not need to be dilated to use the eye-tracking system.

The Technolas 217z is approved for myopic LASIK treatments up to −11.00 D with or without astigmatism less than −3.00 D. For hyperopic LASIK, treatments between +1.00 and +4.00 D can be performed with or without astigmatism up to +2.00 D. The 217z incorporates a wavefront system and is approved for myopic LASIK up to −7.00 D with or without astigmatism up to −2.0 D.

NIDEK EC 5000 CX SERIES LASER

The Nidek EC 5000 CX series laser (Nidek, Inc., Fremont, CA) is utilized with the Nidek NAVEX Quest system, which is marketed by

Figure 89.5. The Aesculap-Meditec MEL-80 laser (Aesculap-Meditec, Jena, Germany) has a small flying spot that scans across the cornea for myopic, hyperopic, and astigmatic treatments. (Courtesy of Aesculap-Meditec, Jena, Germany.)

Figure 89.6. The Bausch & Lomb-Technolas 217z Excimer laser with Zyoptix wavefront uses scanning laser technology to treat myopia, hyperopia, and astigmatism. (Courtesy of Bausch & Lomb, Rochester, NY.)

Nidek as a complete refractive surgery package. While the Quest system has not gained approval by the FDA in the USA, the CXII has gained approval status and is available for treatment of myopia and myopic astigmatism. The laser uses a rotating scanning slit to deliver the laser energy. It operates at between 5 and 50 Hz with a pulse duration of 10–25 ns. Fluence averages 360 mJ/cm^2. The laser has an eye-tracking system that operates at 200 Hz and has a torsion control to correct for intraoperative cyclotorsional movement of the eye.

Nidek has FDA approval for the EC 5000, and the CX and CXII systems in the USA but does not have approval for the CXIII as of this writing (Figs. 89.7 and 89.8). Approval for PRK is for treatment of myopia from −0.75 to −13.00 D, and myopic astigmatism from −1.00 to −8.00 spherical equivalents with no more than −4.00 D of cylinder. The FDA has also granted approval for LASIK treatment of myopia from −1.00 to −14.00 D spherical equivalent with no more than −4.00 D of cylinder. Hyperopia has been treated internationally, and the results are still being investigated by the FDA in the USA. This laser is also not yet approved for PTK in the USA.

WAVELIGHT ALLEGRETTO WAVE LASER

WaveLight (Erlangen, Germany) manufactures the Allegretto Wave laser, which is approved in the USA for LASIK treatments of up to −12.00 D of myopia with or without astigmatism up to −6.00 D, and for hyperopic LASIK treatments of up to +6.00 D with or without astigmatism up to +5.00 D. The Allegretto Wave can also treat mixed astigmatism up to 6.00 D. Approved in July 2006 by the FDA is the Wave-Q laser, which is approved for the same parameters of treatment as the Wave, with the exception of mixed astigmatism.

The laser is comprised of a small-spot scanning laser with a fixed spot size of 0.95 mm. Beam profile is Gaussian. The laser operates at a pulse rate of 200 Hz. Fluence at the level of the cornea is measured at 130–140 mJ/cm^2. This system does not use a gas dilution system to control fluence. Instead, the Wave uses a nitrogen-purged optical rail, which reduces the amount of ozone produced during firing of the laser. Optical zones can extend out to 8 mm, with blend zones out to 10 mm.

The eye-tracking system is a camera-based iris-recognition system operating at 200 Hz. Software for the laser also uses a slightly different ablation algorithm, which accounts for normal corneal asphericity, enabling it to minimize spherical aberration and resultant glare or halo.

STUDIES

ALLEGRETTO LIGHT WAVE

FDA clinical trials for myopia and myopic astigmatism were performed with 1-year data available on 780 eyes. Results showed an uncorrected visual acuity of 20/20 or better in 87% of eyes. Loss of two or more lines of best-corrected visual acuity did not occur.

A study appeared in peer-reviewed literature involving 120 patients who were treated for hyperopia or hyperopic astigmatism.[1] They were first divided into three groups based on the degree of refractive error. In the low group (hyperopia 0.00 to +3.00 D and astigmatism <1.00 D; $n = 52$), 92% were within 0.50 D of goal refraction. In the moderate group (hyperopia +3.25 to +5.00 D and astigmatism <1.00 D; $n = 45$), 79% were within 0.50 D of goal refraction. The high hyperopia/toric group (hyperopia >+5.25 D or astigmatism ≥1.25 D) showed 71% of patients achieving within +0.50 D of intended refraction. The high group also noted an increase in higher-order aberrations from 0.47 to 0.94 µm.

In another study, 22 patients underwent LASIK enhancement for residual myopia, hyperopia, mixed astigmatism, or night vision

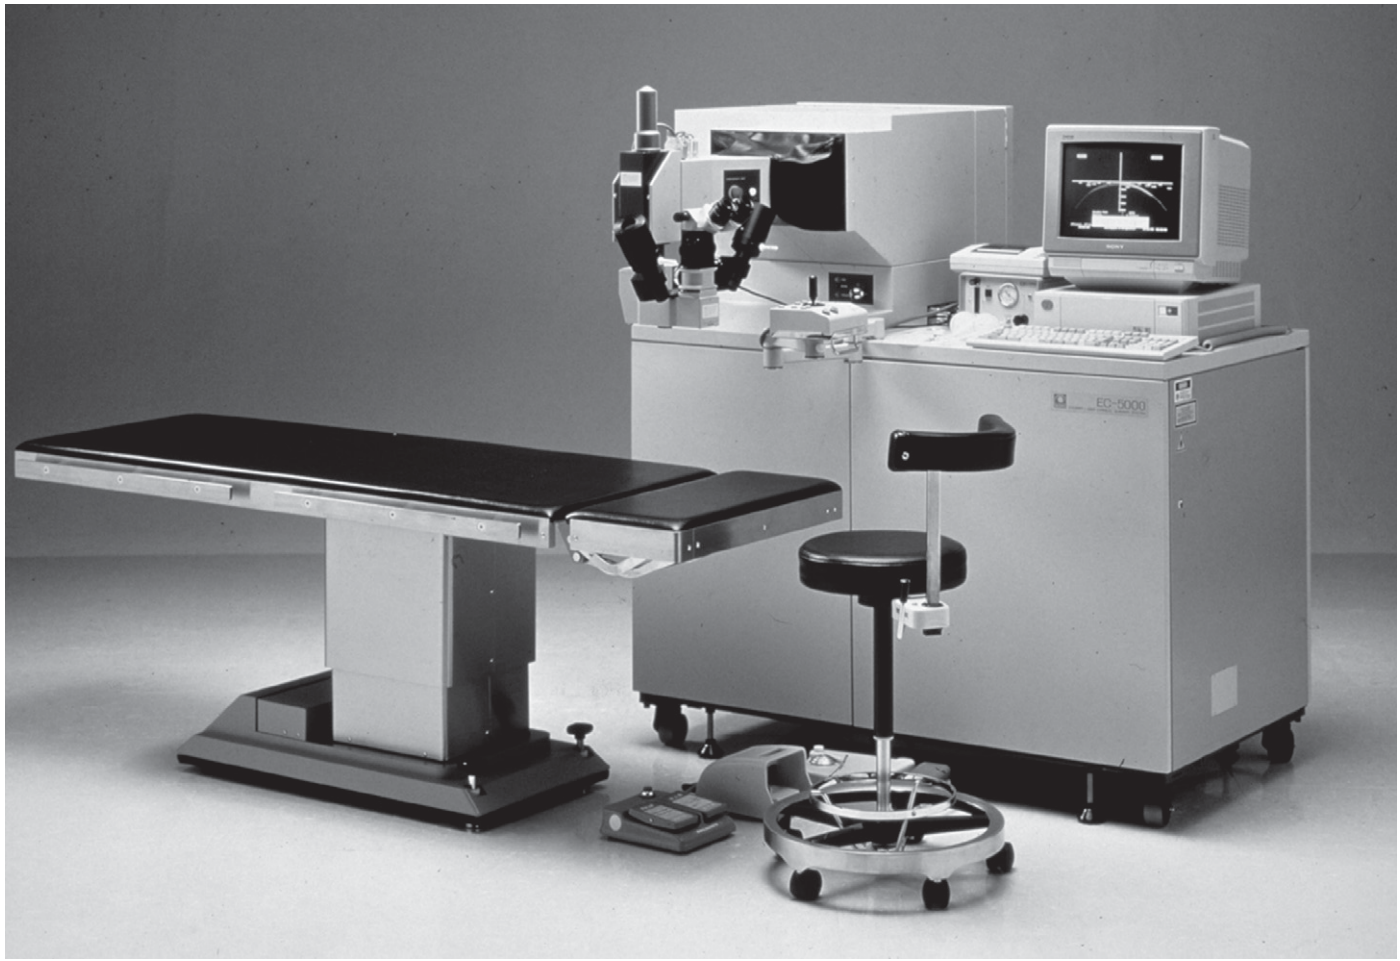

Figure 89.7. The Nidek EC 5000 Excimer laser (Nidek, Japan) uses a scanning slit to create myopic, hyperopic, and astigmatic ablations. (Courtesy of Nidek, Fremont, CA.)

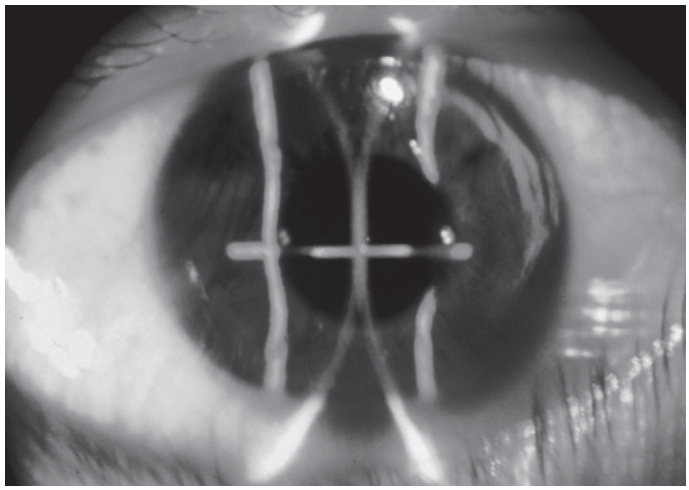

Figure 89.8. The Nidek EC 5000 (Nidek, Fremont, CA.) uses matching projected light images to obtain centration. (Courtesy of Nidek, Fremont, CA.)

problems.[2] All patients postoperatively were within 0.50 D of intended refraction. Mean preoperative BCVA was 20/25 (+0.12), and mean postoperative BCVA was 20/18 (+0.1). No loss of BCVA occurred in any patients. Interestingly, the root mean square (RMS), as an indicator of optical pathways, decreased from 1.04 (+0.22) to 0.46 (+0.14) μm.

VISX STAR S4 WAVESCAN CUSTOMVUE

A retrospective study of 140 eyes that had undergone LASIK for myopia and myopic astigmatism using the VISX CustomVue laser software was performed.[3] Mean preoperative spherical equivalent power improved from −3.89 (+1.48) to −0.21 D (+0.36) at 1 month and to −0.28 D (+0.36 SD) at 3 months. UCVA was measured at 20/20 or better in 84.3% of eyes at 1 month and in 87.9% of eyes at 3 months; 86% of eyes at 1 month and 81% of eyes at 3 months were within +0.50 D of intended goal. RMS values increased slightly from 0.28 (+0.08) to 0.34 (+0.11) μm at 3 months.

Another retrospective study examining the efficacy of the VISX CustomVue treatment for use in enhancements on eyes that had undergone previous keratorefractive surgery was performed.[4] The vast majority (119) of the 120 eyes studied had previously undergone LASIK. Three-month data were obtained. Goal refraction was emmetropia. At 3 months, mean refractive error was −0.20 D, with 100% of eyes being within +0.75 D of intended refraction. RMS values were reduced from 0.39 to 0.34 μm.

In another study, 277 eyes were treated for low to moderate myopia using the VISX S4 laser at six centers around the USA and were available for follow-up at 6 months.[5] UCVA was achieved in 94% of eyes, and 74% of eyes obtained UCVA of 20/16 or better. In this study, 69% of eyes had the same or better postoperative UCVA as their preoperative best spectacle-corrected acuity (BSCVA). Additionally, 90% of eyes were within +0.50 D of intended goal. No

statistically significant ($p < 0.05$) change in higher-order aberrations was noted.

ALCON LADARVISION

A comparison of traditional versus wavefront-guided LASIK was performed on the Alcon LADARVision system.[6] One-hundred forty myopic eyes with maximum level of 7.00 D and maximum astigmatism of less than 2.50 D were assigned to treatment with one of the two systems. At 3 months, 80% of CustomCornea patients had uncorrected vision equal to or better than 20/20, whereas only 45% of the traditionally treated eyes had that level of acuity. In the CustomCornea and traditional treatment groups, 85 and 55% of eyes were within +0.50 D of desired outcome, respectively. Eyes in the CustomCornea group also had statistically significant lower levels of higher-order aberrations ($p < 0.05$).

A recent study examining the results of the LADARVision 6000 for the treatment of myopia and myopic astigmatism was performed.[7] Of the 74 eyes participating, 46 eyes were treated using wavefront-guided software and 28 were treated using conventional methods. At 3 months 93.5 and 89.3% of eyes were within +0.50 D of intended correction in the wavefront-guided and conventional treatment groups, respectively. UCVA of 20/20 or greater was obtained in 97.8 and 92.9% of wavefront-guided and conventional treatment, respectively.

A retrospective, nonrandomized study assessing outcomes on enhancements using the LADARVision 4000 was performed on 97 eyes, which had residual myopia and myopic astigmatism.[8] Conventional LASIK treatment was performed in 74 eyes, and 23 received wavefront-guided treatment with CustomCornea software. Mean pretreatment spherical equivalent was –0.93 D in the conventional treatment group and –0.84 D in CustomCornea group. Post-treatment results (mean follow-up 8.9 months) was –0.19 D in the conventional treatment group and +0.32 D in wavefront-guided group. UCVA of 85 and 35% of eyes was 20/20 or greater in the conventional and wavefront-guided groups, respectively.

ZEISS-MEDITEC MEL-80

Seventy-six eyes with myopia and myopic astigmatism underwent LASIK using the MEL-80 laser.[9] Follow-up data were available to 1 year. Mean uncorrected visual acuity improved from 20/20 preoperatively to 20/18 postoperatively. Ninety-six per cent of eyes were within 0.50 D of intended refractive correction at 1 year. Mean RMS higher-order aberrations increased slightly from 0.20 to 0.28 μm.

Fifty eyes were treated for myopia and myopic astigmatism using aspheric profile PRK on the MEL-80 laser, and 24 eyes were treated using standard PRK ablation profile on the MEL-70.[10] Data were evaluated after 6 months. Postoperatively, there was a greater increase in higher-order aberrations in the traditional PRK group ($p < 0.01$), and a higher percentage of patients in the aspheric treatment group performed better on low-contract visual acuity ($p < 0.05$).

A retrospective study was performed using the MEL-70 laser to examine results of hyperopic correction using PRK and LASIK.[11] One hundred eyes were examined in the PRK group with a mean preoperative correction of +2.85 D, and 100 eyes in the LASIK group with a mean preoperative correction of +4.49 D. Two-year follow-up data were obtained. In the PRK group, mean refractive error was +0.34 D, and 36% of eyes were within +0.50 D of emmetropia. In the LASIK group, mean refractive error was +0.29 D and 70% were within +0.50 D of emmetropia.

NIDEX EC 5000

A retrospective study examining the efficacy of the Nidek EC 5000 CXII system was performed on 100 eyes that had undergone LASIK for myopia and myopic astigmatism. Customized aspheric transition zone profile was used.[12] Preoperative mean correction was –4.70 ± 2.53 D. At 6 months this decreased to 0.12 + 0.53 D. Uncorrected visual acuity was 6/6 or better in 58% of eyes.

Treatment of hyperopia and hyperopic astigmatism using the EC 5000 CXII laser was also performed with three optical zone sizes.[13] A total of 161 eyes, which underwent hyperopic correction with a 7.0 mm optical zone, were examined retrospectively versus control eyes, which used 5.5 and 6.5 mm optical zones. Results showed improved average refractive results and increased stability with increasing optical zone size.

Effectiveness of treatment of mixed and simple myopic astigmatism using the EC 5000 laser was demonstrated using a retrospective study.[14] Forty eyes were examined with data extending to 6 months. Mean postoperative manifest spherical equivalent refraction was +0.30 + 0.46 D. A 77.8% decrease in the magnitude of the cylinder component was present at 6 months, and 50% of eyes were within +0.50 D of intended goal refraction.

COMPARATIVE STUDIES

Several studies comparing laser platforms have been published. Unfortunately, most of these were either not prospective and randomized or utilized older versions of laser hardware or software. These types of studies are difficult to do well because of the rapidly changing technology but are still important.

MEL-70 VS VISX S2 FOR HYPEROPIA AND HYPEROPIC ASTIGMATISM

The right eyes of 43 patients with hyperopia and hyperopic astigmatism were randomly assigned to have LASIK surgery with either the VISX S2 or the Meditec MEL-70 laser, to evaluate increases in corneal aberration.[15] Data were evaluated at 6 months. There were no statistically significant differences in the amount of increase in either group.

LIGHTWAVE VS LADARVISION WITH CUSTOMCORNEA FOR HIGHER-ORDER ABERRATIONS

Thirty patients undergoing bilateral LASIK were randomly assigned to either the Allegretto LightWave laser or to the Alcon LADARVision using CustomCornea software.[16] Of all patients in both groups 90–93% were within ±0.50 D of desired postoperative goal. Subjects who underwent LASIK with the Alcon laser had statistically significant lower amounts of higher-order aberrations ($p < 0.05$).

NIDEK EC5000 VS ALCON LADARVISION4000 FOR LOW TO MODERATE MYOPIA

A retrospective study comparing outcomes on these two lasers was performed on patients who had undergone LASIK for low to

moderate myopia.[17] Results were examined at 6 months. No statistically significant difference in results was obtained with these two systems.

VISX S3 VS TECHNOLAS 217 FOR LOW TO MODERATE MYOPIA

A prospective, randomized trial was performed on patients with low to moderate myopia. Patients were randomized to have surgery on one eye with the VISX laser and on the other with the Technolas.[18] One hundred and forty eyes were enrolled and data were examined at 6 months. No statistical difference was revealed in outcomes on BSCVA or UCVA between groups. RMS of higher-order aberrations was slightly higher in the VISX group (+0.07); however, no subjective difference in satisfaction between eyes was reported by patients.

ALCON LADARVISION 4000 VS VISX STAR S2 FOR BOTH MYOPIA AND HYPEROPIA

A retrospective analysis of 572 sequential LASIK surgeries performed by a single surgeon was performed.[19] The first group consisted of 286 eyes, which were done on the VISX S2 platform. The second group consisted of another 286 eyes, which were performed on the LADARVision 4000. Results were also examined along preoperative ametropia type, and data were evaluated at 3 months. Myopic eyes with uncorrected visual acuity equal to or better than 20/20 were 89% on the LADARVision platform and 63% on the S2. Also for myopia, percentage of patients within +0.50 D of intended correction were 84 and 80% with the LADARVision and S2, respectively. Hyperopic eyes at 3 months showed 74 and 33% for uncorrected visual acuity equal to or better than 20/20 and 69 and 74% were within +0.50 D of intended correction on the LADARVision 4000 and S2, respectively.

DISCUSSION

While there are inherent differences in ergonomics and technical aspects of each laser system, empirically all the excimer laser platforms perform quite well and meet the FDA standards for safety and efficacy. The advances in technology improving ease of use and customization of treatment for each patient seem to be applied in time across most excimer laser systems. It is important for the surgeon to keep up with continued advances and find a system that is flexible and comfortable to use and that provides the best fit for the needs of the surgeon's practice.

90 Tracking and registration

Natasha L. Herz, Li Wang, Douglas D. Koch

Accurate eye tracking and registration are required for optimal results when applying wavefront-guided laser refractive surgery to the cornea. Because the custom ablation profile is highly specific, it must be applied to the cornea only after achieving precise alignment to the area that was mapped. To optimize this, technology is needed that (1) can identify reliable landmarks in order to link the measured wavefront to the corresponding area on the cornea and (2) can track them as the eye continually moves throughout the treatment.

A well-centered treatment ultimately requires good fixation by the patient. However, natural eye movements and improper fixation cannot be avoided during refractive surgery. Active eye tracking systems were introduced to compensate for these movements in order to decrease the incidence of decentered ablations.

With the emergence of wavefront-guided corneal ablation, one more potentially important step, registration, has been introduced. Registration is the process that links the measured wavefront to the treatment ablation profile on the laser platform, thereby facilitating accurate positioning of the ablation pattern on the cornea. Registration can occur initially at the beginning of surgery but ideally would be an active part of the tracking process to compensate for any eye rotation and pupil size changes that might occur during laser ablation.

This chapter discusses eye tracking and registration with wavefront-guided corneal ablation. The status of eye tracking and registration with four major laser systems is reviewed.

EYE TRACKING

EYE MOVEMENTS

The major eye movements that occur physiologically during fixation for refractive surgery are slow drifts, microsaccades, and tremors.[1] Moving the eye to a new fixation location is a voluntary movement called a saccade. The average velocity of saccades is about 200°/s with peaks up to 500°/s and amplitudes up to 15°.[2]

Schwiegerling and Snyder[3] measured eye motion in patients having laser in situ keratomileusis (LASIK) using a video technique and determined centration and variance of the eye position during surgery. They found the mean centration of the pupil center during the surgery to be within 0.25 ± 0.1 mm of the laser axis.

Porter et al[4] studied offsets and eye movements of 10 eyes during laser refractive surgery and computed the temporal power spectrum of the measured eye movements. The temporal power spectrum takes into account the average incidence, velocity, and amplitude of the eye movements during refractive surgery to determine the necessary closed-loop bandwidth required of an eye-tracker to compensate for them during a conventional or customized procedure. Ninety-five percent of the total power spectrum of the eye movements was contained in temporal frequencies up to 1.4 Hz in the horizontal direction and approximately 0.6 Hz in the vertical direction. More than 99% of the total power spectrum was accumulated in temporal frequencies up to 5.1 Hz in both directions. These results indicate that the majority of eye movements that occur during refractive surgery are caused by relatively slow drifts in eye position.

EYE TRACKING TECHNIQUES

Most tracking systems used in excimer lasers are video-based and track the pupillary margin. These systems capture images of the eye at a certain frequency and then process these images to determine where the laser shots need to be fired to compensate for lateral and rotational shifts of the center of the entrance pupil.

A laser radar eye-tracking system is used by the Alcon LADARVision platform (Alcon Surgical Inc., Fort Worth, TX). This system consists of four 905 nm diode laser sensors that are built into the laser head. These four lasers are aimed at the pupillary margin at the 1:30, 4:30, 7:30, and 10:30 positions. Each of these diode lasers fires at 4000 Hz. As movement of the eye is identified, the mirrors that redirect the excimer laser move in order to compensate for any movement of the eye. In order for the tracker to function optimally, the pupillary margin needs to be stable, which is achieved by dilating the eye pharmacologically.

The sampling rate of the required eye tracking system is primarily determined by the repetition rate of the laser. Based on

the findings by Porter et al,[4] an eye-tracking system with a 1.4 Hz closed-loop bandwidth could compensate for most pupil decentrations that occur during a conventional or customized laser refractive surgery. In general, an eye-tracker would have to sample at least 10–20 times faster than this closed-loop bandwidth, or at 15–30 Hz, to have a sufficient latency time to correct for these movements.[4]

The accuracy of the pupil tracking system depends on several factors:

1. **The contrast between the pupil and the iris provided by the illumination.** Taylor et al[5] examined a pupil tracking system and found an accuracy of 0.06 mm for an intact cornea and 0.1 mm for a cornea with a thin flap removed such as occurs in LASIK.
2. **Parallax.** Geometric parallax occurs when the center of the tracking camera, the center of the pupil, and the corneal apex are no longer aligned. Bueeler et al[6] investigated the theoretical limitations derived from parallax and found that pure lateral shifts of the eye under the tracking device can cause localization errors up to 3% of the detected pupil entrance shift. For ocular rotations, the tracking error can be up to 30% of the detected lateral shift in eyes with a high axial length. These results were calculated for a 500 mm distance of the tracker from the eye. Higher tracking errors result as the camera comes closer to the eye and the axial length of the eye increases.
3. **Processing delay or latency time.** The latency time is determined from the point that the eye position is measured to the time that the laser is adjusted. Eye movements could occur during this latency time. For current laser systems, the latency time ranges from 2–90 ms.[7] The magnitude of latency time that is acceptable is dependent on the frequency and magnitude of eye movements during surgery. Minimum processing delay should be achieved to stabilize the laser at the planned ablation position.

REGISTRATION

With wavefront-guided ablations, tracking the pupil alone during the laser ablation is not enough to predictably correct higher-order aberrations. Wavefront-guided procedures require accurate registration of the treatment ablation profile to the area on the cornea over which the wavefront aberrations have been measured. Sources contributing to the registration error include pupil centroid shift and cyclotorsional rotation of the eye.

PUPIL CENTROID SHIFT AND CYCLOTORSIONAL ROTATION

The pupil centroid shifts in different lighting environments.[8,9] This is relevant to excimer laser corneal ablation since, during the wavefront measurement, the lighting is mesopic whereas, during laser treatment, photopic lighting is typically used. Cyclorotational movements of the eye can occur when body orientation changes from seated to supine, such as occurs between wavefront measurement and surgery.

In 64 eyes of 40 patients treated using the Iris Registration (IR) feature of the VISX Star S4 laser system, Koch and Wang in 2005 (unpublished data) found that the pupil centroid shifted by 0.27 ± 0.14 mm (range 0.04–0.51 mm) and cyclotorsional rotation occurred by 2.1 ± 1.5° (range 0.0–6.6°). Similar findings have been reported in the literature[10–13] (Tables 90.1 and 90.2).

Table 90.1 Pupil centroid shift studies: mesopic to photopic lighting

Study	Eyes	Mean Movement (mm)	Other (mm)

IMPACT OF PUPIL CENTROID SHIFT AND CYCLOTORSIONAL ROTATION

Significant reduction in quality of vision occurs when ablation is decentered by 0.2 mm or more[14,15] (Fig. 90.1). The impact of error induced from cyclotorsional movements on the residual point spread function and eye chart letters is shown in Figure 90.2.[16]

Studies by Mrochen et al[17] and Verdon et al[18] showed that decentrations as small as 0.2 mm significantly increase wavefront aberrations and thus decrease the quality of the retinal image. Studies by Bara et al[14] and Guirao et al[15] concluded that lateral displacements begin to be clinically significant when they exceed 0.05–0.1 mm. This agrees with a theoretical study by Bueeler et al[19] where lateral precision of 0.07 mm or better would be necessary to achieve a diffraction-limited retinal image in 95% of normal eyes with a 7 mm pupil. An accuracy of 0.2 mm was required to reach this goal with a 3.0 mm pupil.

To investigate which of these two sources of error had the greatest clinical impact, we evaluated the wavefront aberrations that theoretically would be induced if the ablation was decentered by the mean amount of cyclotorsion and pupil centroid shift found in our study group. To study this, we selected 50 corneal maps of eyes that underwent excimer laser corneal ablation. We used these to do a theoretical ablation with rotation of 2.1° counter-clockwise and a horizontal pupil centroid shift of 0.27 mm, respectively. Using the VOL-CT program (Sarver and Associates), residual wavefront aberrations root-mean-square (RMS) value and Strehl ratio (6 mm pupil) were calculated. In a perfect treatment, the RMS value is 0 and the Strehl ratio is 1. In an imperfect ablation, the RMS value is >0 and the Strehl ratio is <1.

The results of the study showed that total RMS, lower-order RMS, and higher-order RMS values were higher with decentration than with rotational misalignment (Fig. 90.3). The same was true for the

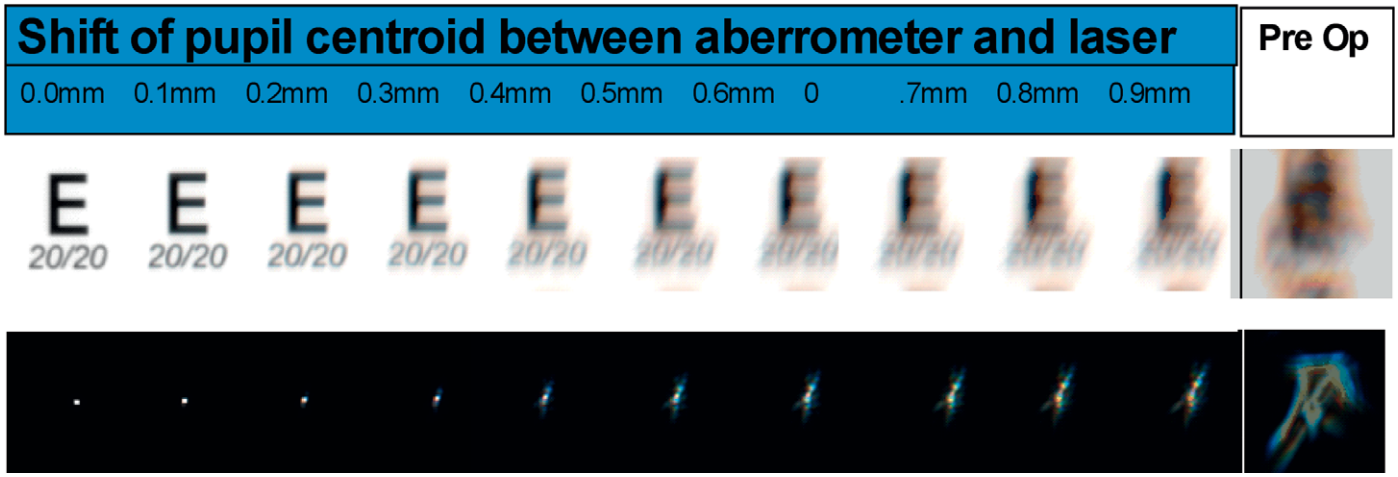

Figure 90.1. The deterioration in the point spread function (PSF) and the appearance of a 20/20 letter 'E' as a function of increasing pupil centroid shift, assuming a 6 mm pupil and using the convolution operation to generate the appearance of the letter chart.[22]

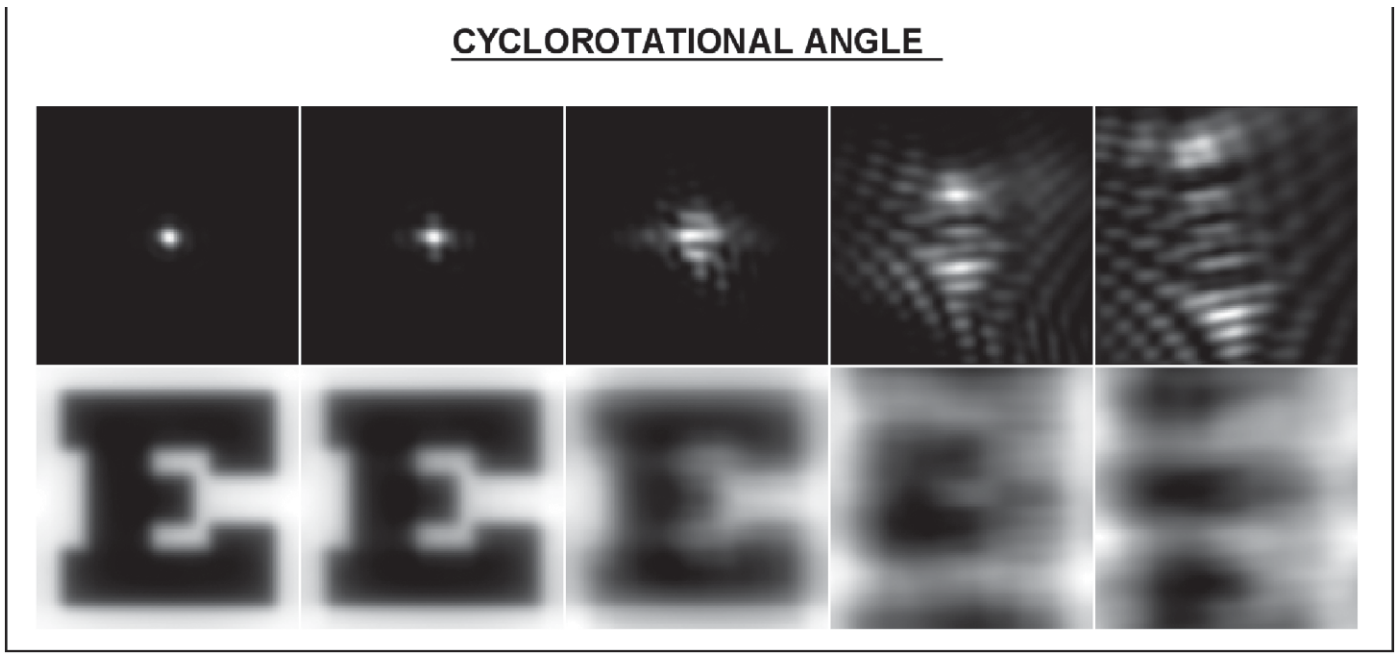

Figure 90.2. Error induced from cyclotorsional movements illustrated by the residual PSF and blurred eye chart letters in an eye with a refractive error of –0.15 DS –1.01 DC × 0°.[22]

Strehl ratio, which was less ideal for pupil centroid shift than it was for rotational misalignment (Table 90.3). Significantly lower Strehl ratio values were induced by decentration of the pupil centroid ($p < 0.001$). This meant the decentered ablations had more aberrations and thus more adverse effect on visual outcome than did the rotational misalignments. With increasing amount of astigmatism, the Strehl ratio values decreased significantly (Fig. 90.4). Once the magnitude of astigmatism was greater than or equal to 2 D, the induced error for rotational misalignment was comparable to that of a decentered ablation.

In another cohort of consecutive cases of 58 eyes treated with the VISX Star S4 IR, based on IR data recorded on the surgical sheet for each eye, residual ocular wavefront aberrations were calculated with cyclorotational error and pupil centroid shift, respectively. Similarly, pupil centroid shift induced significantly higher total RMS and higher-order RMS than did cyclotorsional rotation of the eye. Second-order astigmatism was the largest residual aberration induced by cyclotorsional rotation, whereas coma (third- and fifth-order) was the largest residual aberration induced by pupil centroid shift.

Despite these clear theoretical advantages of compensation for cyclorotational error and pupil centroid shift, we are unaware of clinical studies that validate their importance. However, as laser technology progresses both will almost certainly be essential components of more sophisticated ablation methodologies.

REGISTRATION TECHNIQUES

New technology has been developed to account for pupil centroid shift as well as cyclotorsional rotation. It measures the center of the

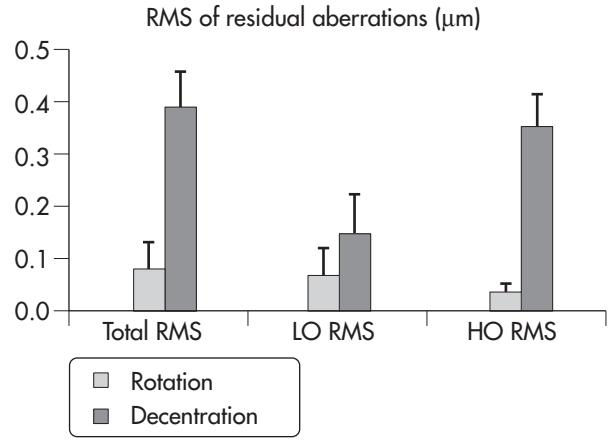

Figure 90.3. In Wang and Koch's study, significantly higher RMS values were induced by decentration of the pupil centroid compared to rotational misalignment (All $p < 0.001$).

Table 90.3 Strehl ratio values induced by rotation and decentration of the pupil centroid in the study by Wang and Koch

	Rotation (2.1°)	Decentration (0.27 mm)
Mean	0.79	0.40
SD	0.17	0.09
Range	0.34–0.98	0.28–0.75

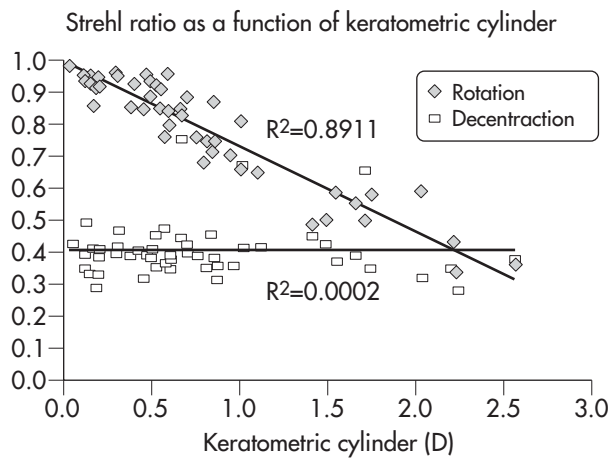

Figure 90.4. In Wang and Koch's study, when astigmatism was greater than or equal to 2 D, the reduction in Strehl ratio was comparable to that induced by pupil centroid shift.

pupil in relation to the limbus or peripheral iris at the time the wavefront measurements are taken and then calculates the adjustment needed at the time of surgery to keep the treatment centered over the original location of the pupil center. It also adjusts for any cyclotorsion that may have occurred during shifting of body orientation from seated to supine. Some systems actively track this during the treatment, while others adjust for it statically before the laser is applied.

REVIEW OF EYE TRACKING AND REGISTRATION WITH DIFFERENT LASER PLATFORMS

AMO-VISX STAR S4 IRIS REGISTRATION EXCIMER LASER SYSTEM

The VISX Star S4 laser system by Advanced Medical Optics has two infrared video-based cameras placed at 90° to each other. Together, they track in the *x*, *y*, and *z* axes. It is an open-loop system that samples at a rate of 60 Hz. Since the laser fires at a rate up to 20 Hz, it acquires a minimum of three consecutive good samples before it allows the laser to fire.

To account for cyclotorsion and pupil centroid shift, the laser uses iris registration software that matches 24 landmarks on the Star S4 IR laser iris image to the 24 landmarks on the WaveScan® iris image (Fig. 90.5, *A–C*). One landmark for each 15° iris sector in each image is identified. A minimum of 21 of the 24 landmarks must match in order to use this feature. The laser also determines the location of the outer iris boundary and determines the centroid of the entrance pupil relative to this landmark. The registration process is typically performed immediately before initiating laser ablation. The laser corrects for cyclotorsional error by internally rotating the ablation. To correct for error introduced by pupil centroid shift (Fig. 90.6, *A–D*), the laser uses the outer iris boundary to shift the center of the ablation from the intraoperative center of the pupil to the centroid of the preoperative WaveScan measurement. Therefore, regardless of location of the pupil centroid at the start of the laser treatment, the ablation pattern is centered over the pupil centroid at the time of wavefront measurement (Courtesy, in part, by Paul Bradford, Technical Support Supervisor-LVC, AMO, Inc.).[12,16,20]

At times, especially with lighter pigmented irides, the software is unable to match the required number of landmarks. It is estimated to occur in less than 10% of eyes.

LADARVISION4000 AND LADAR6000 EXCIMER LASER SYSTEMS

The LADARVision®4000 and LADAR6000™ Systems produced by Alcon use a closed-loop laser radar tracker to track the pupil. Its signal processing time allows minimal latency between acquiring position data and determining where the laser should fire. The tracker samples the position of the eye at 4000 Hz and the system moves to compensate for positional errors at that rate. In order for a closed-loop system to be stable, it must have a sampling rate about 10 times the bandwidth. The LADAR tracker meets this requirement with a sampling rate of 40 : 1.

To register the eye and account for cyclotorsional effects, these systems use the pupil, limbus, and a pair of opposing ink marks on the sclera. For the LADARVision4000 laser, the first step in obtaining an ablation treatment pattern from the LADARWave aberrometer is capturing a photo of the undilated eye. This is used as a reference for the center of the undilated pupil from the limbus. The second step is to obtain five wavefronts of the eye after dilation. This is performed after the ink marks have been placed on the sclera so that the wavefronts can be accurately matched to each other (Fig. 90.7, *A* and *B*). The best three are used to create a composite wavefront for the treatment. This is exported to the laser along with the photo for centration. At the time of surgery, the centration

Figure 90.5. continued

image is used to statically align the eye with the treatment images, accounting for pupil centroid shift and cyclotorsion by using a limbus ring and scleral ink marks as references. This also allows placement of the hinge mask, which can be accurately positioned to provide software-based hinge protection. The tracker is engaged accordingly. Therefore, the treatment is centered over the position of the undilated pupil center even though the pupil is dilated for the procedure.[21,22]

The LADAR6000 laser uses the same method for controlling for pupil centroid shift but has a greatly simplified process of cyclorotational registration (Fig. 90.8). This laser employs a registration system that uses infrared illumination and digital imaging to track blood vessels in the sclera. These are identified during wavefront capture and are registered by the laser prior to surgery to compensate for cyclorotation. This eliminates the need to mark the eye on the day of surgery to control for cyclotorsion. With this new software, the registration process is entirely automated and can be completed four to five times faster than before. (Courtesy of Rick Potvin and John Campin, Alcon Laboratories, Inc.)

TECHNOLAS 217Z LASER SYSTEM

The Technolas 217Z laser system (Bausch & Lomb, Inc., Rochester, NY) contains a pupil tracker that uses an infrared open-loop video to detect the pupil area from which it calculates the pupil center. The video system samples at a rate of 120 Hz to track the *x*, *y*, and z axes, while the laser fires at 100 Hz. The frequency of 120 Hz means there is 8.3 ms between each capture. The dynamic eye tracking software allows 200 µm of movement over the 8.3 ms, which equals 24 µm/ms. If more than 200 µm of movement has occurred, the next laser pulse is interrupted.

The video system uses the whole pupil area in reference to the limbus to statistically compensate for cyclotorsion and pupil centroid shift that occurs between the Zywave aberrometer diagnostic reference and the laser implementation. In addition to this, the most advanced system, the Dynamic Rotational Eye Tracker (DRET), compensates for dynamic eye rotation during the surgery with a sampling rate of 25 Hz. The DRET received USA Food and Drug Administration (FDA) approval in 2007 and will be incorporated into US lasers later that year. (Courtesy of Brendan B. Sheil, Executive Director, US Refractive Business, Bausch & Lomb, Inc., Rochester, NY.)

ALLEGRETTO WAVE EXCIMER LASER SYSTEM

The Allegretto Wave Excimer Laser System (WaveLight, AG, Erlangen, Germany) uses a video-based eye tracker that samples at 200 Hz using infrared illumination. The system calculates the pupil centroid as the intersection of the maximum X and Y diameters and sends this information to the laser. The spot location for each pulse is then adjusted according to the updated location of the pupillary centroid. The total response time of the system, including aiming of the laser pulse, is approximately 6 ms. With a 200 Hz laser, this allows for near pulse to pulse tracking.

The eye tracker detects movement in two ways: magnitude and velocity. Displacement of the pupillary centroid beyond preset limits (typically 2 mm) causes the laser to stop sending pulses, as does eye movement exceeding preset limits. As a result, factoring the maximal saccadic velocity of eye movements, the most a spot can be displaced with the Allegretto is about 13% of the 0.95 mm pulse diameter. Once the eye has slowed movement and returned to the preset zone, the laser automatically resumes pulsing.

The eye tracker sensing threshold can be adjusted to accommodate a range of iris pigmentation. Pupil sizes from 1–8 mm can be tracked. Dilation is not required, nor is registration of the eye with preoperative photographs.

Registration of treatments based on imaging systems such as aberrometry or topography is done using the eye tracker. Calculation of the pupil centroid is performed from the wavefront or topography image using the same method used by the laser tracker.

Torsional registration at both the imaging device and the laser is done manually by matching bony landmarks with alignment guides. Treatments are performed using a pupil diameter within 2 mm of the diameter of the image used to create the treatment. At the laser, pupil size is controlled by adjusting the illumination lights. (Courtesy of Guy M. Kezirian, MD, FACS, President of SurgiVisionR Consultants, Inc., Scottsdale, AZ.)

CONCLUSION

There has been tremendous progress by manufacturers to reduce the error that results from misalignment of the ablation profile to the mapped area. Pupil tracking systems use high sampling rates to decrease latency times and compensate for eye movements during surgery. For cyclorotational registration, laser systems use landmarks on the eye that do not change with lighting conditions, such as the limbus and peripheral iris, as reference points to compensate for pupil centroid shift and cyclotorsional rotation. Currently, at least one manufacturer is attempting to further increase the level of sophistication by providing active cyclorotational tracking.

To provide even greater accuracy in tracking and registration for customized ablations, research and development should focus on several areas, including more robust registration techniques, faster sensor technology, lower latency times, and, perhaps most importantly, a method to track the corneal surface to eliminate parallax error. Clearly, there will be a point of diminishing return where further improvements in the tracking mechanism will provide no discernible increase in clinical results, and determining this point will require both theoretical and clinical studies.

91 Building a personalized LASIK–laser vision correction nomogram

John F. Doane, Randolph T. Jackson

This chapter is intended to demonstrate to the novice surgeon and, possibly, even to the experienced laser refractive surgeon that understanding the specific laser and software version in use, the laser room environment and the surgeon's technique will determine the refractive success and patient's satisfaction after laser vision correction. It is the hope of the authors that experience from surgical results for six different excimer laser manufacturers, nine different laser models, and innumerable software versions for the treatment of myopia, hyperopia, astigmatism, presbyopia, asymmetric ablations, and customized specialty ablations will provide the beginning laser practitioner with a basis for appropriate surgical decision making and respect for the vast complexity of available systems.

INTRAOCULAR LENS 'A-CONSTANT' VERSUS EXCIMER LASER ALGORITHM

Ophthalmic surgeons are extremely fortunate to be able to use advanced intraocular lens formulas when performing small incision phacoemulsification and intraocular lens placement. In uncomplicated cases, either a novice or an experienced surgeon can obtain excellent refractive results. How is this possible? Doesn't experience matter? Yes, experience matters, but well-defined 'A-Constants' for each commercially available intraocular lens have been determined. Once the 'A-Constant' is obtained the refractive result should be near emmetropia.

As an example, let us propose that the average patient with average keratometry values and axial length measurements is examined by an expert technician shared by an experienced and novice surgeon. If the technician obtains high quality, repeatable keratometry, and axial length values and subsequently enters this data into a modern intraocular lens formula to be used by the two surgeons the lens calculated for emmetropia would be identical. If we then assume a standard cataract procedure is performed with intraocular lens placement in the capsular bag after uncomplicated continuous curvilinear capsulorrhexis, the refractive effect should be identical for the two surgeons.

Why is this? The same intraocular lens placed in the given eye as above will achieve identical results, since it is a fixed optic placed at the same location (within the capsular bag) by both surgeons. With intraocular lens placement in small incision cataract surgery, wound healing is not a big factor in surgical results. Hence, the 'A-Constant' is an invaluable reference number to provide transferable refractive predictability and accuracy to any surgeon who would select a given lens model. We will see with laser refractive surgery (photorefractive keratectomy or laser in situ keratomileusis) that an 'A-Constant' or laser algorithm does not necessarily predict excellent refractive results.

Excimer lasers are not manufactured or shipped with an 'A-Constant' per se, but they are built and tested with a manufacturer-supplied algorithm. An algorithm is similar but not synonymous with a tool familiar to incisional keratotomy surgeons called the nomogram. With incisional keratotomy surgery the surgical plan (number, length, and depth of incisions) is based on the patient's age, degree of ametropia, sex, and other factors. Excimer laser algorithms as originally designed dictated for a given degree of refractive error that a specified number of pulses at selected ablation diameters would be applied to the cornea. The laser algorithm is provided to the laser as a software package that is typically encoded on the central processing unit's hard drive or, less commonly, by an optical reader. The algorithm is unique to a given laser model from a specific manufacturer, and the results from a treatment are based upon the laser being utilized within a set temperature, humidity, and particulate matter environment. The algorithm can be different for the same model from a manufacturer if different software versions are downloaded onto the hard drive for use.

If we are dealing with one patient with, for example, 4 D of spherical myopia, why would the algorithm for different laser models or manufacturers have to be different? There are two main reasons: the beam delivery system and the beam fluence. There is a wide variation in beam delivery systems available for use worldwide. With varying maximal treatment zone diameters, there will be a different number of pulses required for any given refractive error. Virtually all newer lasers incorporate scanning beam delivery. There are two aspects of a treatment that need to be selected; the optical zone and the ablation zone. The optical zone's function is to change the refraction of the eye. The ablation zone, which extends peripherally from the optical zone, functions to minimize

regression of effect from epithelial remodeling as well as to minimize night symptoms. For a given refractive error, using the same laser the software will dictate fewer pulses for smaller diameter optical and ablation zones. Likewise, the smaller the zone, the smaller the central depth of the ablation. As the outer zones of the treatments decrease, the scotopic pupil size and its association with unwanted night symptoms must be recognized. A too small optical ablation zone can be associated with night time dysphotopsia.

We have been discussing only spherical myopia. As we move to the treatment of myopic astigmatism, hyperopia, hyperopic astigmatism, bifocal presbyopic ablations and asymmetric ablations, the variance in pulse number, laser beam aperture size, and orientation becomes exponential.

Excimer laser beam fluence is defined as the amount of energy per pulse that is distributed over a defined area (mJ/cm^2). The laser fluence will determine the overall number of pulses for removing a specific micron thickness of tissue to effect a given refractive error or three-dimensional shape. Two different beam profile characteristics (Gaussian, greater energy density centrally than peripherally, versus table top, relatively even energy distribution across the ablation zone diameter) have been described for excimer lasers. It should also be realized that excimer lasers are not static instruments but ever-fluctuating energy sources. This fact requires frequent calibration so the laser energy is released in a controlled fashion. If different fluences exist between lasers, then differing amounts of tissue will be removed per pulse. It is then clear that, with differing fluence between lasers (Table 91.1),[1] the algorithms for specific refractive errors will be quite different.

It should be obvious at this point that production of excimer lasers and software design can and is highly variable among the different manufacturers. There are additional variables that need to be considered when evaluating the overall performance of a given laser. These include inter-model performance variation, laser room environment, geographic profile of the laser center, and surgeon technique. The performance comparison of lasers within the same manufacturer model number is not always identical. To the beginning surgeon this is probably another confusing and confounding factor. Why would the same model lasers not perform in exactly the same way? There may be true variation among lasers of the same model, despite the best efforts of the ablest engineer and design team and also despite consistent instrument setup and calibration. This variation should not be overly concerning since, as we will describe in the ensuing discussion, the surgeon must define the laser performance to obtain the best surgical outcomes.

Table 91.1 Excimer laser fluence levels[1]

Maintenance of the laser room environment is critical for laser refractive surgery success. It is critical not only for performing surgery but also for proper laser maintenance. It is felt and recommended by all laser manufacturers that certain conditions should be maintained for optimal laser performance. The laser room should be a closed environment and not be a multipurpose room with open access. Temperature should be controlled between 18 and 24°C. Humidity should be maintained between 30 and 50%. Low particulate matter filtration should be in effect 24 h per day, 7 days per week. This is done to provide each treatment session with a consistent environment, since laser ablation rates are highly dependent on atmosphere in the optical train to the corneal surface. Additionally, it is done to create the most favorable environment to increase the longevity of the optics within the laser. For instance, if high particulate matter is present in the laser room, this matter can coat the lenses within the optical train. When the laser is next fired the particulate matter can be 'burned' into the lens as an imperfection which will subsequently decrease the homogeneity (i.e. the pattern of energy distribution across the ablation zone) of the laser ablation. If this becomes a chronic situation, the life span of individual optics will be reduced leading to increased laser operational costs. Even more important, this could lead to poor ablation pattern on the cornea with possible visual morbidity. Perfumes, deodorants, scents, alcohol, and other combustible liquid vapors should be prohibited from the laser room since they will coat the lenses and potentially affect the same change as particulate matter. Geography also plays a role in laser performance. The relative humidity and altitude will cause variation in laser performance. On average, a high humidity, sea-level locale will realize less refractive effect than the same treatment entered into the laser compared to a low humidity, high altitude locale.

BUILDING THE NOMOGRAM

With the advent of 'custom' laser in situ keratomileusis (LASIK), nomogram development has become less of an issue but for quality improvement reasons adjustments of the 'surgeon' factor for customized ablations becomes the newest incarnation of an individual surgeon nomogram. That being said, reviewing the historical method of conventional adjustments is required to appreciate customized nomogram adjustments.

Success with LASIK is intimately dependent on two important factors: obtaining an excellent keratectomy and performing an accurate ablation. It has been quoted that LASIK is 90% keratectomy and 10% laser. This might more appropriately be termed the novice surgeon mentality or viewpoint. It has also been our observation that there is a patient viewpoint on this topic: a patient is interested in 100% keratectomy success followed by a 100% successful laser ablation. With experience we believe that the surgeon's viewpoint also changes. As he or she becomes comfortable performing the keratectomy, about 5% of his or her time is spent contemplating and performing the keratectomy and 95% of the effort is spent making certain the laser is operating properly and no human errors have been made by the surgical team. The experienced surgeon's success then comes from having a highly predictable nomogram that has been customized to the laser environment and surgical technique. Without a customized approach to a LASIK nomogram by the surgeon haphazard surgery will likely be performed with less than excellent outcomes. One would do equally well if this approach is taken doing haphazard incisional keratotomy or whatever refractive surgical technique is performed. With this being conceptually understood, the next section will describe

the process by which a surgical team approaches the task of delivering accurate and reproducible results.

The process of developing a LASIK nomogram requires four steps: obtaining patient data, formulating an initial nomogram, entering data into the computer of the laser and evaluating data/outcomes and making adjustments based upon this information.

At first glance obtaining patient refractive data seems mundane and not necessarily where the action is. This is a grave error in refractive surgery and especially laser vision correction. LASIK and surface ablation techniques are incredibly powerful. The laser will ablate whatever is entered into the treatment plan. If inaccurate refractive data is entered, the difference between true refraction and that obtained will be the residual refractive error. It is very important to complete several basic refraction principles. For eyes greater than 5 D of refractive error it is important to have proper vertexing to the spectacle plane (12.5 mm) if this is the convention entered into the laser. This can be completed with trial frame glasses. Significant error in refraction outcome can be realized if patients with large refractive errors are refracted at spectacle plane vertex distance and data is entered at corneal plane. Fogging techniques should be utilized, so the least amount of myopia to see the best spectacle corrected line of vision is the refractive endpoint. This minimizes iatrogenic causes for overcorrection. Cycloplegic refraction can also be done to confirm the fogged manifest refraction. Comparison to old or recent refractions should be noted. If large discrepancies are noted, concern for examination error or refraction instability should be considered. For patients wearing contact lenses special consideration should be given in obtaining this data. Soft contacts should be out at least 3 days prior to examination and topography should be obtained to rule out corneal warpage. Rigid contact lenses should be out at least 3 weeks and stability noted with two separate examinations 3 days apart. Likewise, topography should be obtained to rule out abnormalities.

The initial nomogram used should be based upon available data and not a 'shot in the dark' approach. The novice surgeon should utilize all available information to decide on his or her initial surgeon factor adjustments to the laser algorithm. Knowledge of the specific laser's performance with photorefractive keratectomy should be taken into consideration. If the laser is overcorrecting long term with PRK one could anticipate it would do the same with LASIK. If the laser is undercorrecting long term with PRK it can also be assumed that undercorrection will be obtained with LASIK. The difference between what is entered into the laser and that obtained is typically a set percentage difference at all levels of refractive error. Therefore, the individual surgeon should increase or decrease the planned treatment by a set percentage from the manufacturers' algorithm to achieve the target postoperative refraction.

Entering data into the computer ostensibly seems to be the easiest step in laser refractive procedures but this is not always the case. Typing errors on the computer keyboard, incorrect cylinder convention, vertex distance, cylinder axis, wrong patient, or incorrect eye entry are just a few potential errors that can lead to poor outcomes. Calculation of the treatment to be entered into the laser should be checked multiple times by more than one member of the surgical team. One might ask how can an error happen? If the treatment entered differs from the manifest refraction and, certainly, if a percentage difference must be made for the treatment entered, simple math errors can occur. Hence, multiple calculations and checks should be made for each entry. Is the correct patient chart being used for the next patient to be treated? Is data for the correct eye being entered? Is monovision being treated for the eye? These are but a few of the questions that need to be answered for each data entry. The convention by which data is obtained and entered into the laser should be consistent (Table 91.2). Specifically, if refractions are done in plus cylinder convention they should be entered in plus cylinder. Transposition errors will occur, so if the surgical team can completely avoid this step, it is advisable. It is extremely important to check the axis and the cylinder convention on each case. Minus cylinder can be entered when the patient is refracted in plus cylinder and the surgeon will subsequently induce cylinder on the patient's cornea, typically doubling the pre-existing astigmatism. Proper vertex distance entry should also be made. When treating myopia, if the patient is refracted at 12.5 mm vertex distance and the data is entered at the corneal plane, a percentile overcorrection will occur or vice versa. This will be more significant the higher the refractive error treated leading to visual morbidity in some cases. In summary it is extremely important to use a single cylinder convention and enter data the same every time at the same vertex distance. Multiple checks of the calculated entry should be made by more than one person on the surgical team. No member of the refractive surgery team should feel intimidated to announce they have noted an error that can be corrected prior to patient treatment at whatever stage of the process the error is noted. Overbearing egos should be avoided in the treatment of refractive surgery patients. They will be a hindrance to the best care and correction of avoidable human errors.

Table 91.2 Treatment calculation

Line # 1	Refraction	–6.0 D
Line # 2	Target	–1.0 D
Line # 3	Line # 1 – # 2	–6.0 – (–1.0) = –5.0
Line # 4	Multiply Surgeon Factor* by line # 3 and add or subtract as indicated by the specific laser used	–6.0 – (0.1 × –6.0) = –6.0 – (–0.6) = –5.4 D
Line # 5	Number entered as treatment	–5.4 D

* Addition or subtraction will depend if the specific laser is undercorrecting or overcorrecting in relationship to what the algorithm suggests. In the above example, the laser is overcorrecting compared to the algorithm so a set percentage is taken away from the spherical treatment.

For customized ablations in which high-order aberrations are being addressed the custom treatment table can be adjusted with limitations. A reasonable approach to use for these patient treatments is as follows. It is best to not defer all refraction validation to the wavefront analyzer without a manual manifest and cycloplegic refraction. In fact, all manufacturers have set guidelines when to proceed with a custom ablation. For example, if the wavefront sphere is more plus than +0.75 D, or more minus than –0.50 D, or if the cylinder axis is more than 15° off, the recommendation would be to repeat wavefront analysis. If one is unable to achieve this threshold a standard ablation is recommended. Interestingly, if the higher-order aberration root mean square spot size magnitude is large, it may be impossible to capture a wavefront image that would fulfill the lower-order criteria. Once the manual refraction has been obtained comparison to the wavefront refraction can be undertaken. Most custom ablation platforms will not allow the surgeon to alter the lower-order cylinder axis or magnitude, or to adjust the

higher-order ablation. On the contrary, the sphere amount can be adjusted. Why would a surgeon want to adjust the sphere? Currently, wavefront analyzers do not allow for subjective patient approval of the optical correction, but a manual manifest refraction does allow for this critical component for refractive surgery happiness postoperatively. How does one adjust the custom sphere treatment? One approach is to equalize the treatment to the spherical equivalent of the manifest refraction. Let us say the wavefront refraction is $-5.00 + 1.75 \times 090$ and the fogged manifest refraction is $-4.50 + 1.50 \times 090$. The wavefront spherical equivalent equals -4.13 and the manifest refraction spherical equivalent is -3.75. To equalize the wavefront to the manifest refraction the surgeon would reduce the treatment wavefront sphere by 0.38 D or adjust for a more positive refraction treatment. The next step would be to follow the patients to 3 months and assess any discrepancy from the target outcome to that obtained. If there is a discrepancy the surgeon factor adjustment can be modified with all future treatments.

TECHNIQUE CONSIDERATIONS

After the keratectomy is completed the actual ablation is the key factor in determining the nomogram and is the defining act by the individual surgeon, all other preoperative factors being equal. The time to initiate and complete the ablation and the management of the stromal bed during the ablation will determine the amount of dry stroma removed to effect the refractive change. The dryer the bed during the ablation the more dry weight corneal stromal tissue that will be removed.[2] Ablation technique can range from initiating the ablation and completing the pulse count without interruption to stopping at selected intervals to dry the stromal bed with a cellulose sponge or metal spatula, or alternatively wiping the stromal bed only on the appearance of condensation on the stromal bed surface. How does this affect refractive outcomes and dry corneal tissue removal? The dryer the stroma the more dry weight tissue that will be removed for the same number of pulses and, likewise, the wetter the stromal bed less dry weight tissue will be removed for the same number of pulses and, on average, less refractive change than the 'dry ablation' will be obtained. This technique nuance is the reason each surgeon must define their own nomogram since surgeons using the same laser but markedly different technique will obtain completely different surgical outcomes if they enter the same treatment plan for an identical preoperative refraction. For the individual surgeon the lesson to be taken from this discussion is *consistency in technique*. Consistent time to lift, initiate, and complete a case should be a goal as should the frequency of wiping (every 50 or every 100 pulses, etc.). If one elects to have forced air passed over the stromal bed during the ablation, this can be done as long as it is consistent. Two surgeons using the same laser but markedly different ablation techniques can achieve equal results as long as they both understand the tissue effects of their technique and employ their technique in a consistent fashion.

LASIK NOMOGRAM REFINEMENT

LASIK nomogram refinement begins immediately in the postoperative course. Refraction data should be obtained at each postoperative visit. Quality improvement requires evaluation of the postoperative data with adjustment of the nomogram based upon this data. Not obtaining and utilizing postoperative data for improving the individual surgeon's results is as logical as not obtaining a refraction or topography prior to surgery. It is a necessity for the surgeon to provide optimal care and refractive outcomes. Refractive and topographic stability is obtained by virtually every patient by the 3-month examination for LASIK. Surface ablation takes a bit longer to stabilize, sometimes closer to 6 months for myopia and possibly 12 months for hyperopia. This data that should guide precise refinement of the individual surgeon's nomogram. The surgeon's nomogram becomes more powerful the more eyes treated at any given level of ametropia and the further out the postoperative data is obtained. During nomogram development particular attention should be given to secondary refractive surgeries. For example, an enhancement to correct hyperopia following a myopic LASIK usually requires a decreased nomogram adjustment. The technique of retreatment will require a further adjustment of this nomogram subset.[3] If the retreatment is performed after lifting the flap, the stromal bed is likely to be more dry than if a new flap is cut with a mechanical keratome.

SPHERICAL EFFECTS OF ASTIGMATIC ABLATION

It is important to recognize possible spherical refractive effects of astigmatic correction with the particular laser one uses. Most excimer lasers treating myopic astigmatism operate under minus cylinder convention. The author has noted in all systems used to date (large area ablation lasers or scanning spot) that, for each diopter of cylinder ablated, approximately 0.1–0.2 D of overall central corneal flattening will occur, leading to small amounts of hyperopia. If this is not accounted for by reduction of the spherical ablation plan, unwanted hyperopia may be noted postoperatively. Postoperative refractive data will help the surgeon identify this possibility and be a basis to identify the exact correction for each diopter of cylinder ablated.

In conclusion, laser vision correction nomogram development is an individual process in which every surgeon is in essence an island. There are three important elements in the equation: the laser, the laser room environment, and the surgeon's technique. The excimer laser beam is not a static force but an ever-changing one. Likewise, laser refractive surgery is not a static process and requires the practitioner to be an active flexible participant in the process. The process requires ongoing data acquisition, assimilation, and refinement to provide the highest quality postoperative vision that patients are entitled to and demand in the laser refractive surgery era.

92 Surface ablation: techniques and postoperative management

Leejee H. Suh, Ashley Behrens, Peter J. McDonnell

HISTORY

The history of the excimer laser began in the 1970s when physicists were interested in developing an excited dimer, or 'excimer', from the combination of an excited rare argon gas atom (e.g. argon or krypton) with a diatomic halogen molecule (e.g. fluorine or chlorine).[1] In 1981, Taboada et al used a 193 nm excimer laser to 'indent' the rabbit corneal epithelium.[2] Subsequently, in 1983 Trokel and associates suggested the use of the excimer laser for corneal surgery.[3] The 193 nm excimer laser accurately ablated tissue by a process labeled as 'ablative photodecompensation' while minimizing thermal damage to adjacent tissues. Later, Seiler in Germany and Puliafito in the USA developed optical delivery systems to convert excimer laser radiation into a homogenous beam with precise ablative profiles.[4] Puliafito et al used high-speed photography to image the laser ablation plume created on the cornea with the excimer laser.[5] Seiler and Wollensak used the excimer laser on a human eye to perform astigmatic keratotomy in 1985 and phototherapeutic keratectomy (PTK) in 1986.[6] McDonald et al performed photorefractive keratectomy (PRK) on a myopic, sighted eye in 1987.[7] These initial studies paved the path for subsequent large, multicenter trials of PRK.

INDICATIONS FOR SURFACE ABLATION

PRK can treat refractive errors with satisfactory visual outcome in myopia up to −12 D, astigmatism up to 6 D, and hyperopia up to +5 D.[8] The most predictable and successful results with lowest incidence of complications occur in lower ranges of myopia, astigmatism, and hyperopia. Treatment of low-to-moderate myopia (−1.5 D to −6 D) is associated with success (defined as achieving 20/40 or better uncorrected vision) in more than 90% of eyes.[9–12] Treatment of larger refractive errors has been associated with higher rates of regression, haze formation, and need for retreatment.

Despite being the first widely utilized laser vision correction procedure, PRK has been largely supplanted by laser assisted in situ keratomileusis (LASIK) as the predominant refractive procedure performed in the USA.[13,14] Maintenance of an intact epithelium in LASIK allows for faster visual rehabilitation, less postoperative discomfort, and less risk of undesired excessive postoperative healing and risk of regression. Nevertheless, there remains an important role for surface ablative procedures like PRK in refractive correction. Current indications for surface ablation include thin corneas, anatomic issues providing difficulty for microkeratome use, previous scleral buckling or trabeculectomy surgery, moderate dry eyes, epithelial disease, high or low keratometric readings, and predisposition for contact injury. Insufficient stromal bed has been implicated in post-LASIK instability and increased risk of progressive corneal steepening and ectasia. Most surgeons agree on a minimal residual stromal bed of 250 μm and surface ablation is usually advised for those with corneal thicknesses below 500 μm. Small interpalpebral fissures, deep-set orbits, and corneal or limbal conditions such as pterygia may hinder correct placement of the microkeratome for LASIK. The presence of a filtering bleb and an anteriorly displaced scleral buckle similarly obstruct the placement of the microkeratome suction ring. Some have shown greater worsening of dry eye conditions in LASIK versus PRK.[15] Although significant topographic abnormalities at baseline preclude many patients from candidacy for refractive surgery, those with very high/low central curvatures would benefit more from surface ablation than LASIK, which bodes a greater chance of intraoperative complications.[16] PRK is recommended for those with anterior basement membrane dystrophy, as LASIK may induce/exacerbate epithelial erosions.[17] In these cases, it may be more favorable to choose PRK to improve epithelial basement membrane healing and prevent future erosions. Some authors believe that realization of the full benefits of wavefront-guided laser vision correction requires the use of surface ablation instead of LASIK, due to concern that unpredictable aberrations from LASIK flaps might confound the desired optimization. Finally, those involved in combat or vocations associated with a high risk of trauma to the head, such as military personnel, benefit from PRK versus LASIK where there is a potential for traumatic flap dislocations.

WOUND HEALING IN SURFACE ABLATION

In surface ablation, epithelium is removed with subsequent laser photoablation of Bowman's layer and the anterior stroma. Removal of the epithelial basement membrane exposes the underlying anterior stromal keratocytes to cytokines produced by epithelial injury, such as interleukin (IL)-1.[18] Epithelial injury or surgical trauma induces keratocyte apoptosis, stimulating the migration of inflammatory cells and surrounding keratocytes. One to two weeks after the initial injury or surgery, myofibroblasts appear in the subepithelial stroma. The epithelially derived cytokine, transforming growth factor-β or TGF-beta, has been shown to activate keratocytes into myofibroblasts.[19] Derived from keratocytes, myofibroblasts have relatively reduced transparency and are considered to be a major contributor to corneal haze. In addition, the collagen matrix produced by activated keratocytes is less organized than normal stroma. It has been shown that the corneal wound healing response, such as keratocyte apoptosis, necrosis, and myofibroblast production, is more intense after PRK than LASIK.[20]

PREOPERATIVE EVALUATION

A full preoperative evaluation includes the following: a complete ophthalmic and general medical history, uncorrected and best corrected visual acuity, manifest and cycloplegic refraction in minus cylinder form corrected for vertex distance, keratometry, computed topographic analysis, ocular dominance, pupil diameter in dim illumination, a complete anterior and posterior segment examination, and applanation tonometry. Specific guidelines regarding discontinuation of contact lens wear should be communicated to the patient. Although no determinant clinical trial has demonstrated the optimal time of contact lens discontinuation before refractive surgery evaluation, recommendations have been proposed based on observational data. Often soft contact lens wear should be discontinued at least 3 days prior to evaluation, rigid contact lenses at least 3 weeks prior to evaluation[21] and hard contact lenses at least a month before initial screening. If contact lens warpage is suspected, surgery should be postponed until topography and refractive error are stable at least 2 weeks apart.

PRK INTRAOPERATIVE TECHNIQUE

LASER CALIBRATION

The following technique can be adopted for all excimer laser systems. The refractive surgical day should always begin with proper system calibration and programming. Beam homogeneity, depth per pulse, and beam alignment should be tested with the appropriate calibration films/sensors. In some geographical regions prone to substantial seasonal variations in humidity, the use of dehumidifiers to control the surgical environment may be helpful in minimizing variation in surgical outcomes (Table 92.1).

PREOPERATIVE MEDICATIONS

As patient cooperation is key to surgical success, if there is much apprehension on the part of the patient, mild sedation with oral diazepam (5 mg) is often offered preoperatively. Some surgeons use anxiolytic agents routinely, while others reserve it only for patients whose natural anxiety cannot be managed by supportive feedback from the surgical team. The patient is brought to the laser room and positioned under the microscope on a reclining chair. The nonoperative eye is patched and the head is draped in the usual sterile fashion. Relevant patient data is checked on the computer. Ocular anesthesia is achieved with topical proparacaine HCl 0.5%. Preoperative medications include topical NSAIDs such as ketorolac tromethamine 0.5% (Acular®, Allergan) or diclofenac sodium 0.1% (Voltaren®, Novartis) and a topical fourth-generation fluoroquinolone antibiotic such as moxifloxacin HCl 0.5% (Vigamox®, Alcon)) or gatifloxacin 0.3% (Zymar®, Allergan). A lid speculum is placed in the operative eye and more topical anesthetic is applied.

BEAM CENTRATION AND DATA VERIFICATION

At this point, the surgeon and his/her team perform a 'time out,' verifying the patient's identity and checking all entered data into the system. PRK laser centration is critical to surgical success. Centration over the pupil is preferred to centration over the corneal light reflex.[22,23] The microscope should also be carefully focused onto the corneal surface. The patient is instructed to look at the aiming beam of the laser, usually a blinking light, to ensure adequate centration of the ablation. To familiarize the patient to the laser apparatus and assure the surgeon of the patient's ability to fixate, test shots can be performed. Communication with the patient throughout the process is helpful for ensuring proper fixation, as patients are calmed by knowing the procedure is progressing appropriately and by positive feedback regarding their ability to maintain fixation. Lasers have incorporated sophisticated tracking systems (either passive or active) to ensure appropriate centration of the laser exposure. Some surgeons still prefer the use of passive, low vacuum suction ring to aid in centration.

DELINEATION OF ABLATION OR OPTICAL ZONE

An optical zone mark 1 mm greater than the desired ablation or optical zone (6 mm) is placed on the epithelial surface and centered over the pupil to set up for epithelial removal.

EPITHELIAL REMOVAL

There are three different methods of epithelial removal for PRK employed by refractive surgeons: mechanical debridement with a spatula, blade, or rotary brush; chemical removal with alcohol; and laser-assisted removal. For each method, epithelial removal should be quick and decisive to avoid corneal hydration changes.

In mechanical debridement, a blunt spatula or Beaver blade is used to scrape from the periphery to the center, the area of the epithelium delineated by the marker. Once the lid speculum is placed and the eye opened under the light of the operating microscope, dehydration and resultant corneal thinning will quickly ensue. Mechanical removal should therefore be performed efficiently and in standardized fashion, not taking longer than 2 min. A sponge impregnated with 1% methylcellulose or balanced salt solution can be used to wipe off residual epithelial debris, leaving a smooth surface of Bowman's layer. An alternative tool used to remove epithelium is the Amoils brush (Innova, Toronto, Canada). This brush has fine hairs that provide a smooth corneal surface that does not disturb underlying Bowman's layer.

Alcohol-assisted epithelial removal has been shown to be a simple and safe alternative to mechanical debridement.[24] An 18–25% concentration of absolute alcohol in balanced salt solution or sterile water is applied to the epithelial surface with a sponge for 2–3 min or in a reservoir centered over the optical zone for 20–30 s. The corneal surface is then washed to remove the alcohol. The central epithelium is then peeled with McPherson forceps.[25]

Finally, the excimer laser can be used to remove the epithelium, essentially as in phototherapeutic keratectomy (PTK). This technique is quite dependent on tear film regularity and a smooth preoperative surface, so patients with an uneven tear film are not ideal candidates for this method. A standard depth of approximately 45 μm of tissue can be programmed into the laser for ablation and the residual debris removed with a spatula. Alternatively, epithelial removal can be assured by performing ablation under blue fluorescence—once the epithelial layer is ablated, blue fluorescence disappears.[26] The appeal of this technique for epithelial removal includes uniformity in time and the precise geometry of the epithelium removed, as opposed to manual removal in which removal of excess epithelium (to ensure that the corneal surface to be ablated is free of epithelium) is common.

STROMAL ABLATION

At this point, the ability of the patient to maintain ocular fixation may be checked by placing practice pulses onto the bare stromal bed and communicating to the patient that the ablation is commencing. The programmed correction for stromal ablation is then performed. The stromal bed is then rehydrated with a wet sponge (Fig. 92.1).

POSTOPERATIVE MANAGEMENT

Adjunctive therapy varies among surgeons. Immediately following stromal ablation, chilled balanced salt solution, topical NSAID, antibiotic, and corticosteroid may be applied to the ocular surface, followed by a bandage contact lens. Postoperative instructions (Table 92.2) include reviewing common postoperative symptoms such as blurred vision, glare, and photophobia.

Our recommended medication regimen is as follows: for the first week, a fourth-generation fluoroquinolone four times a day, an unpreserved topical NSAID four times a day, prednisolone acetate 1% four times a day or fluorometholone 0.1% four times a day, and Vicodin® (acetaminophen/hydrocodone) every 4–6 h as needed for pain. In the first week, re-epithelialization is monitored, with complete healing of a 6.5 mm defect often occurring within 48 h. When the epithelial defect is healed, antibiotic use is discontinued. Postoperative management is summarized by time frame: early, intermediate, and late (Table 92.3).

Topical NSAIDs are used regularly in postoperative management of pain, inflammation, and photophobia after surface ablative procedures such as PRK.[27] Effective in postoperative analgesia, NSAIDs work by inhibiting the cyclooxygenase pathway of arachidonate metabolism. Generally, topical NSAIDs are used four times a day after PRK for up to 4–7 days postoperatively. Our routine is to use the NSAID until the epithelial defect is healed, by which time pain control is no longer a concern. Despite the advantages of NSAID use, such as obviating the need for systemic analgesics in most patients, prolonged or frequent use can cause rare complications, such as subepithelial infiltrates, persistent epithelial defects, corneal ulceration, and corneoscleral melting.[28–30]

The efficacy of steroid use remains to be proven in randomized controlled trials.[31] Studies in the low myopic range (less than –6 D) have shown no significant difference in haze development or refractive outcome between eyes treated postoperatively with steroids or artificial tears. Many surgeons believe, however, that steroids are beneficial in those with high myopia or deep ablations. Thus, there are several approaches to the postoperative application of topical steroids. Some start steroids only if there is significant haze or scarring postoperatively. Some prefer a short course of steroids usually over a month with alteration based on haze severity. Others prefer a longer steroid course over a 4-month period with changes accordingly. Our prednisolone acetate regimen is as follows: four times a day for 2 weeks and then two times a day for 2 weeks. Alternatively, our fluorometholone regimen is as follows: four times a day for the first month, three times a day for the second month, twice a day for the third month, once a day for the fourth month, and stopping at the end of 4 months.

In the intermediate phase (second week to 6 months), uncorrected and best corrected visual acuity, corneal clarity, cycloplegic refraction, corneal topography (looking for decentration or central islands), and intraocular pressure are examined. At 6 months the presence of visually significant haze formation and scarring warrants consideration of reoperation.

ROLE OF INTRAOPERATIVE MITOMYCIN-C

Corneal haze may develop as a fine reticular subepithelial pattern about a month after PRK and usually is not visually significant. Haze usually can appear in 1–2 months, reaching peak intensity in

3–6 months, and finally resolving by about 18 months.[32] Haze and scarring after PRK have been attributed to corneal wound healing induced by activation and migration of keratocytes and newly synthesized collagen.

A potentially vision-threatening complication of PRK is the development of significant haze affecting vision. In aggressive ablations, in high myopia (greater than −6 D), and in PRK performed after previous keratorefractive procedures (incisional keratotomy, LASIK) haze formation may especially be dense and visually significant. Most strategies for haze reduction have targeted keratocyte activation after wound healing. Topical steroids have been used to inhibit haze formation after PRK. The mechanism is thought to be inhibition of collagen synthesis. Controlled clinical trials, however, have not demonstrated any significant role of haze prevention with steroids.[33,34] Recently, mitomycin-C (MMC), a popular adjunctive treatment to reduce fibrosis after surgery in certain proliferative ophthalmic conditions such as after trabeculectomy and pterygium excision, has also been used for treatment of postoperative haze.

MMC is an antibiotic derived from *Streptomyces caespitosus* with alkylating properties that allow crosslinking to DNA, thereby inhibiting DNA synthesis. Its antimetabolite properties are particularly effective in rapidly dividing cells, such as proliferating keratocytes during post-laser wound healing. Because it is radiomimetic, the effects are long term and not reversible. Keratocyte apoptosis may be the mechanism by which MMC reduces corneal scarring

Table 92.3 Postoperative management after excimer laser PRK

Postoperative Time	Medications	Factor to Monitor	Restrictions
Early (first week)	4th gen. fluoroquinolone q.i.d. Topical NSAID q.i.d. FML 0.1% q.i.d. or prednisolone acetate 1% q.i.d. Bandage contact lens Vicodin every 4–6 h p.r.n. and haze.[35] In 1991, Talamo et al found decreased haze in rabbit corneas treated with MMC before PRK.[36] Majmudar et al have shown reduction in haze formation with topical application of 0.02% MMC after de-epithelialization in corneas with subepithelial fibrosis.[37] In this study, subepithelial fibrosis was first removed with a Beaver blade. A 6 mm circular sponge (Merocel corneal light shield, Xomed Surgical Products, Jacksonville, FL) soaked in 0.02% MMC was applied on the de-epithelialized surface for 2 min and after removal of the sponge the ocular surface was copiously irrigated with balanced salt solution. With a mean follow-up of 13.8 months, all 8 eyes remained clear with no adverse events. A prospective, randomized, comparative study of 60 eyes which received prophylactic use of MMC showed a statistically significant reduction in haze formation in MMC-treated eyes.[38] A prospective, randomized study on highly myopic eyes (greater than 7 D) prophylactically treated with MMC showed again that intraoperative MMC on highly myopic eyes is safe and effective in preventing haze in high myopes.[39]

With these and other studies, intraoperative MMC is now commonly used in deep ablations (greater than 75 μm) and PRK in high myopia (greater than −6 D). When treatment correction is calculated, one must take into account the tendency of MMC to induce hyperopia. MMC prophylaxis has now also been used in higher-risk surface ablations, such as PRK over previous LASIK, radial keratotomy, and penetrating keratoplasty.[40,41]

Despite this expanding usage, there are dangers of MMC use in high concentration or long exposure times. Although a single application of MMC appears to be safe, there is much evidence of MMC toxicity. Corneal edema, glaucoma, and corneal perforation have been described after prolonged MMC use.[42,43] In an animal model, MMC has been shown to cause corneal endothelial apoptosis and subsequent corneal edema in a dose-dependent manner.[44] Another important consideration is the permanent effects of MMC in inhibiting keratocyte repopulation with subsequent decrease in keratocyte density and collagen production.[45] We believe this agent is best used judiciously while data is gathered regarding the long-term safety and efficacy of mitomycin-C.

ADVANCED SURFACE ABLATIONS

INTRODUCTION

Despite the popularity of LASIK, there has been renewed interest in surface ablative procedures for refractive surgery. The creation of the LASIK flap can be associated with significant intraoperative and postoperative complications with a potential for vision loss.[16] Furthermore, there is evidence that wavefront-guided surface ablation may be more accurate in surface ablative techniques over LASIK, as the flap creation during LASIK may affect the preoperative higher-order aberrations.[46–48] More studies are needed to assess if there is a difference in final higher-order aberrations after surface ablation versus LASIK.

As mentioned, patients who have thin corneas, moderate dry eyes, or who work as military personnel are better candidates for surface ablation. PRK, however, has been associated with greater postoperative discomfort and potential complications such as haze formation and regression, especially in high myopia. These limitations have led to the development of alternative surface ablations, also known as advanced surface ablation, in the form of LASEK and epi-LASIK.

LASEK

Laser subepithelial keratectomy (LASEK)[49] was first performed by Azar in 1996 as 'alcohol-assisted flap PRK' and later renamed LASEK by Camellin.[50] As a hybrid of PRK and LASIK, LASEK tries to combine the advantages of PRK and LASIK while avoiding the disadvantages of both procedures, such as flap complications, prolonged postoperative recovery, and development of corneal haze. In LASEK, diluted alcohol is used to loosen the epithelium and create an 'epithelial flap.' Unlike PRK in which the epithelium is removed, in LASEK the epithelial layer is peeled aside in the form of a flap and repositioned back immediately after stromal ablation. There are several variations on the LASEK technique (Fig. 92.2).

LASEK SURGICAL TECHNIQUES

Azar flap technique (Fig. 92.2, *A*)

Azar describes his technique as follows[51]: the cornea is pretreated with topical 0.5% proparacaine and 4% tetracaine, of which the latter may help loosen the epithelium. The corneal surface is marked with overlapping 3 mm circles around the periphery, simulating a floral pattern. A 7–9 mm well with a semi-sharp marker (ASICO, Westmount, IL) is placed over the epithelium and serves as a reservoir for 18% alcohol. After 25–30 s, the alcohol is absorbed through an aspiration hole. Longer times of alcohol exposure (extra 10–15 s) are recommended for young men, postmenopausal women, and long-time contact lens users, who have thicker epithelium.[52] A jeweler's forceps or modified Vannas scissor (ASICO, Westmount, IL) is inserted under the epithelium and traced around the delineated margin, leaving a hinge of 2–3 clock hours, preferably at the 12 o'clock position. A dry Merocel sponge or modified Vannas scissor is used to peel back the epithelial flap. After stromal ablation, an irrigating cannula is used to hydrate the stroma and epithelial flap with balanced salt solution. The epithelial flap is then repositioned using the cannula and intermittent irrigation, carefully aligning with the prior markings. The flap is allowed to dry for 2–5 min. Topical steroids and antibiotics are placed followed by a bandage contact lens. The bandage contact lens may be removed after complete re-epithelialization (usually on postoperative day 3 or 4).

Camellin technique (Fig. 92.2, *B*)

In this technique,[50] a specialized marking trephine of 8–9 mm is used to create a 270° superficial punch of 80 μm on the epithelium (with a 90° hinge at 12 o'clock) (Janach J2900, Como, Italy). The microtrephine is rotated 10° two or three times with constant pressure. Ethanol (20%) is placed in a specialized well of 8.5 mm (Janach J2905, Como, Italy) for 20 s. Thus in this technique, alcohol can penetrate under the flap prior to lifting. The surface is then irrigated with distilled water or balanced salt solution and then with diclofenac sodium. An epithelial 'micro-hoe' (Janach J2910A, Como, Italy) is used to fold over the epithelial flap toward the 12 o'clock position. If the epithelial edges are difficult to lift, additional alcohol treatment is administered for 15 s. After stromal ablation, a blunt instrument, such as the micro-hoe, Barraquer sweep, or a specialized spatula (Janach J2920A, Como, Italy) is used to gently reposition the flap and allowed to dry for a minute. Some advocate irrigating the stroma with chilled balanced salt solution prior to flap replacement in hopes of reducing postoperative inflammation and pain. The surface is smoothed with a masking solution of 0.25% hyaluronic acid using the algorithm of one second of appli-

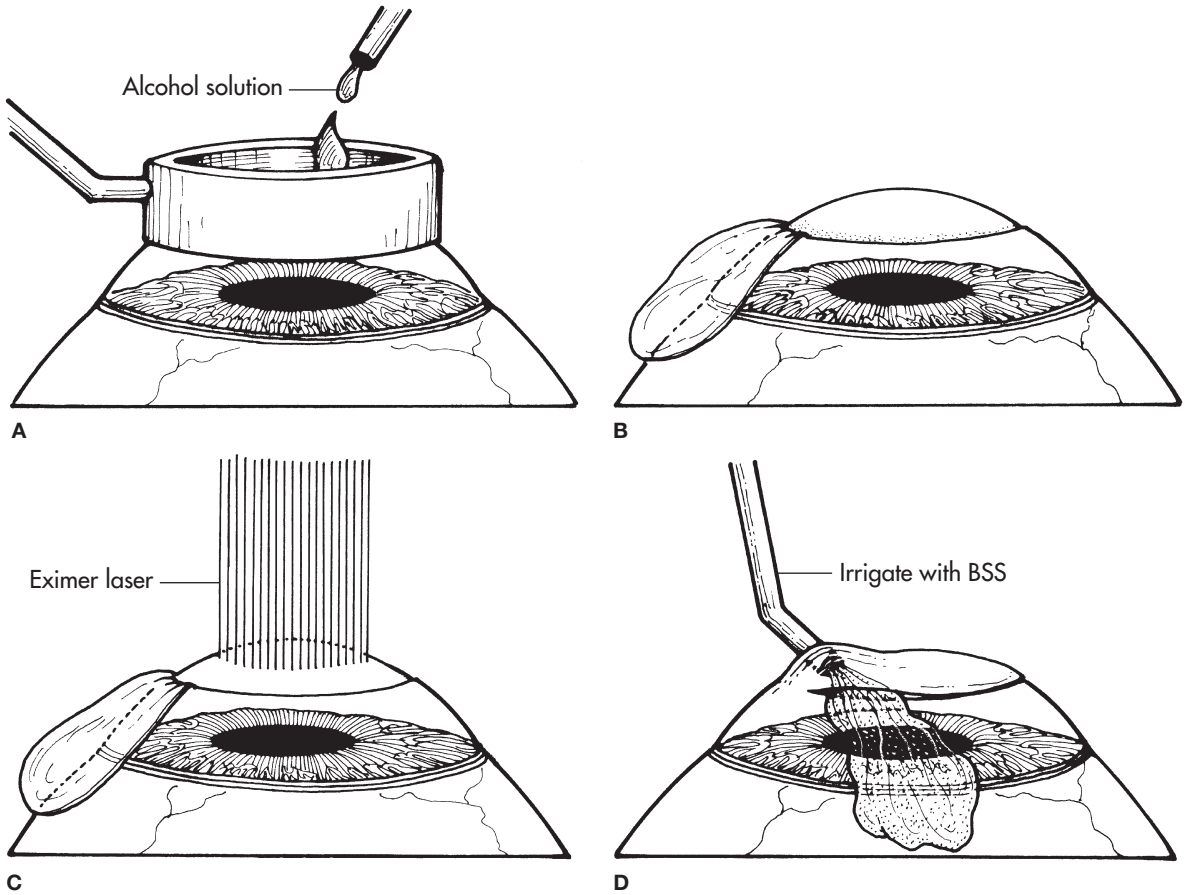

Figure 92.2. LASEK technique. *A*, Azar flap technique. *B*, Camellin technique. *C*, Vinciguerra butterfly technique. *D*, McDonald technique. (Reproduced with permission from Taneri S, Zieske JD, Azar DT. Evolution, techniques, clincial outcomes, and pathophysiology of LASEK: review of the literature. Surv Ophthalmol 2004; 49: 576–602. © 2004 with permission from Elsevier.)

cation for every one diopter of correction. If there is improper flap placement or a nonintact flap, Camellin recommends application of 100% autologous serum, which is continued as a q.i.d. regimen for 1 week postoperatively. A bandage contact lens is then placed and usually can be removed on postoperative day 3 or 4 after re-epithelialization. Topical steroids and antibiotics are also given postoperatively.

Vinciguerra technique (Fig. 92.2, *C*)

In his 'butterfly technique,'[53] Vinciguerra tries to preserve the limbal connection of epithelial stem cells and limbal vasculature. 4% lidocaine drops are instilled on the corneal surface. A thin paracentral line from 8 to 11 o'clock is made with a specialized spatula (Vinciguerra spatula, ASICO, Westmount, IL) and 20% alcohol is placed in a well for 5–30 s. After irrigation with balanced salt solution, the same spatula is used to dissect off the epithelium from Bowman's layer from the center toward the periphery on both sides. The epithelial flap is held in place with a special Vinciguerra LASEK butterfly protector/retractor (ASICO, Westmount, IL). The stromal surface is dried for ablation. A hyaluronic acid solution (Laservis, Chemedica, Munich, Germany) is placed over the stromal surface with a Buratto spatula (ASICO) and further ablation is performed at 30 µm at 10 Hz. The epithelium is repositioned and a bandage contact lens is placed.

McDonald technique (Fig. 92.2, *D*)

Also known as the 'gel-assisted technique,'[54] McDonald uses microkeratome suction and a 3% methylcellulose gel (GenTeal® gel, Novartis Ophthalmics, Duluth, GA) to create the epithelial flap. After topical anesthesia, the cornea is coated with GenTeal gel. The epithelium is marked and is scored down 1–2 mm to Bowman's layer with a 2.25 rounded knife (ASICO). Ten drops of 5% sodium chloride ophthalmic solution are placed to stiffen the epithelium and blotted dry with sponges. A microkeratome suction ring/head is placed and suction applied. A cannula is then slipped under the epithelium and a spatulating motion is made to loosen the epithelium. Suction is released after 30 s and GenTeal gel is injected under the loose epithelium. The raised epithelium is cut in half with Vannas scissors and each half is reflected with a wet sponge. After ablation, the epithelial sheet is repositioned and a bandage contact lens placed.

STATUS OF EPITHELIAL FLAP IN LASEK

Important considerations that arise in LASEK are the viability of epithelial cells in the created flap and the effect of alcohol on epithelial cells. Histological studies of LASEK flaps[49] show an intact epithelial layer with irregularities in basement membrane. No Bowman's layer or stromal cells were present. At the ultrastructural

level, there were normal desmosomes and hemidesmosomes, both of which may help in re-anchoring the epithelium after flap repositioning. The level of separation in LASEK appears to be within the basement membrane.

Chen et al have shown cultured human epithelial cells exposed to alcohol are viable but are significantly reduced in alcohol concentrations above 20% and with exposure times greater than 30 seconds.[55] In rabbit epithelial cells, 20% alcohol exposure caused alteration of surface microvilli, breaks in intercellular junctions, and cellular edema.[56]

CLINICAL RESULTS OF LASEK

With LASEK, there are no microkeratome complications and a reduced chance of epithelial flap complications. The theoretical advantages of LASEK over PRK are less pain, less haze formation, and less regression. Studies have shown reduced formation of TGF-beta in the tear film of LASEK patients compared to PRK patients,[57] thereby reducing the stimulation of haze-causing myofibroblasts. In a rabbit model, Esquenazi et al showed that at higher corrections (–7 D), LASEK-treated eyes had less keratocyte apoptosis and myofibroblast transformation than in PRK-treated eyes.[58]

EPI-LASIK

First described by Pallikaris,[59] 'epipolis' (means 'superficial' in Greek) laser in situ keratomileusis, also known as Epi-LASIK, is an alternative surface ablative procedure to PRK and LASEK. Instead of alcohol, epithelial separation is achieved mechanically with a microkeratome-like instrument with a customized blade design (subepithelial separator). The aim of this method of epithelial removal is to achieve a technique less invasive to epithelial integrity, thereby increasing cell viability and reducing the release of inflammatory cytokines. In contrast to alcohol-treated epithelium, some histological studies show minimal alterations in the epithelial cell layer with areas of intact basement membranes, desmosomes,

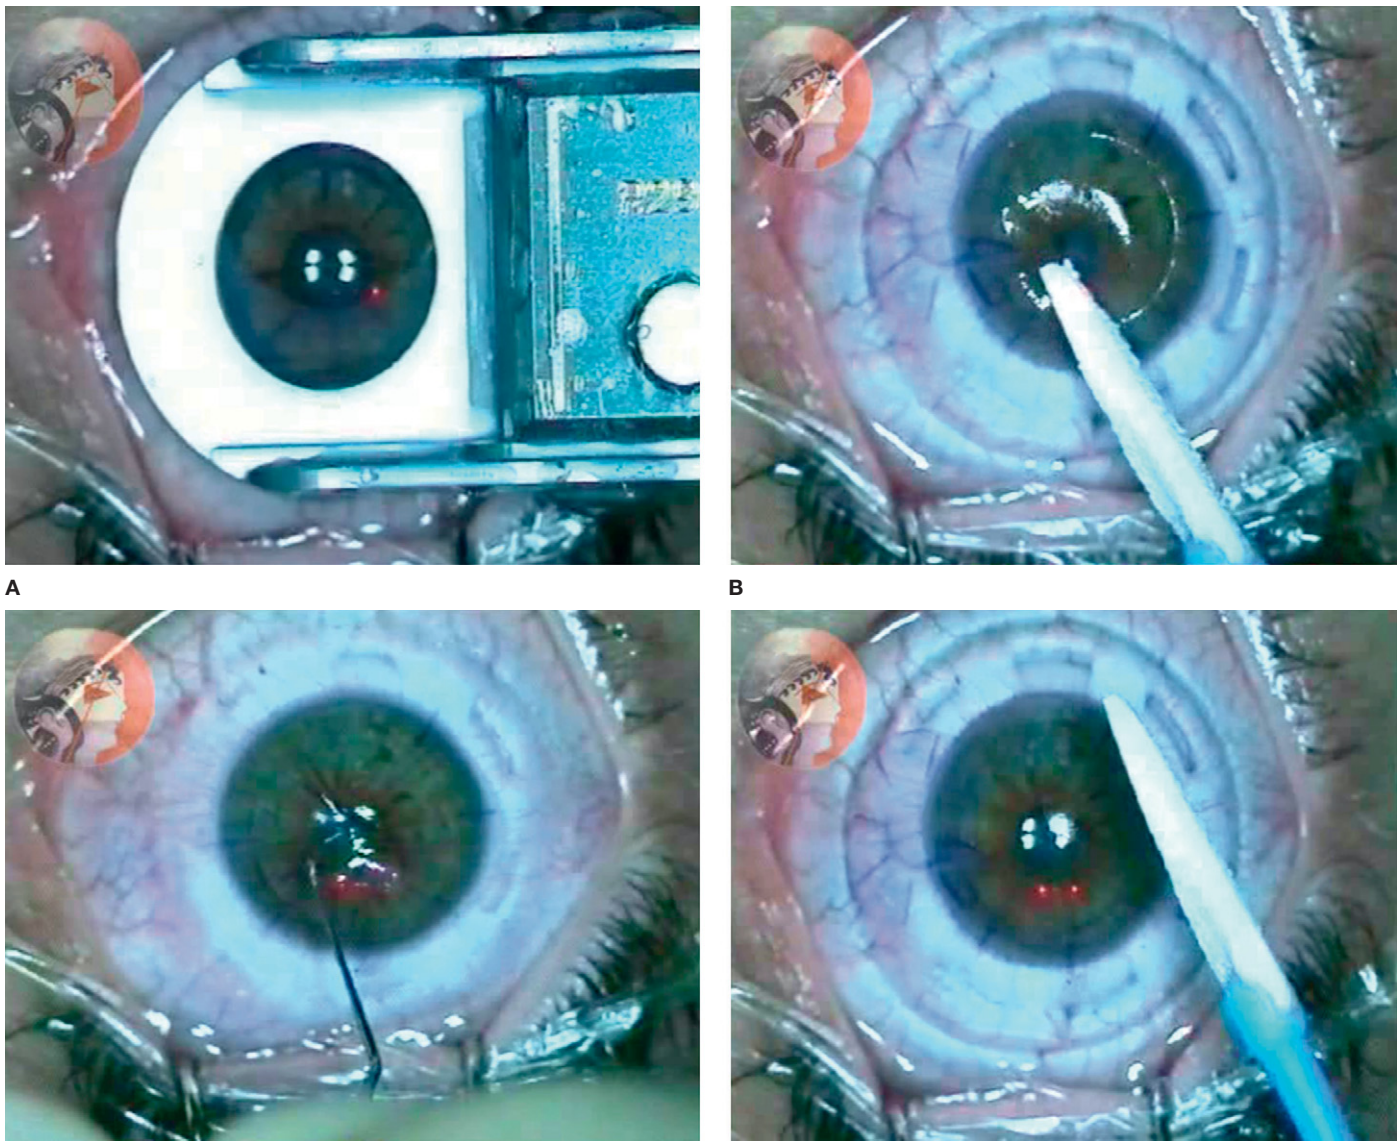

Figure 92.3. Epi-LASIK technique. (Images provided by Dr George Kymionis.) *A*, Microkeratome-like device for Epi-LASIK. *B*, Epithelial flap reflected back with sponge. *C*, Irrigation cannula used to reposition epithelial flap. *D*, Epithelial flap allowed to dry.

and hemidesmosomes.[60] As the basement membrane is believed to provide stability to the epithelial cell layer, preservation of epithelium theoretically can be achieved, if the basement membrane remains entirely intact. Thus, alcohol separation is thought to occur within the basement membrane and mechanical separation in epi-LASIK is thought to be primarily under the basement membrane, but sometimes at other levels.

In this technique, the eye is anesthetized with 0.5% tetracaine hydrochloride. The surface is then irrigated with balanced salt solution and the epithelium is dried with a Merocel sponge. The cornea is marked with a standard LASIK marker. The subepithelial separator is then placed and under suction, an oscillating blade creates an epithelial flap with a 2–3 mm hinge. The flap is reflected back with a wet sponge and the ablation is performed. The stromal bed is then irrigated and an irrigation cannula is used to reposition the flap and flatten any folds or irregularities. The epithelial sheet is allowed to dry for 2–3 min. Topical anti-inflammatory and antibiotic drops are instilled and a bandage contact lens is placed. After re-epithelialization is achieved (usually in 3–4 days), the contact lens is removed and topical steroids are started with tapering over 2 months (Fig. 92.3).

Since the introduction of the epi-LASIK technique, various microkeratome-like devices for epi-LASIK have come on the market such as Centurion SES EpiEdge (Norwood EyeCare, Duluth, GA), Epilift system (Advanced Refractive Technologies, San Clemente, CA), Epi-Blade (Advanced Medical Optics, Santa Ana, CA) for use with the Amadeus II microkeratome, and the Epi-K (Moria USA, Doylestown, PA).

CONCLUSION

The field of surface ablation in refractive surgery has developed significantly since the inception of the excimer laser. Options for patients are ever-expanding within surface ablation, allowing a more tailored procedure for each patient profile. The decision for PRK, LASEK, or epi-LASIK should be determined by the expertise of the surgeon and the needs of the patient, with a thorough discussion of the risks and benefits of each procedure.

93 Outcomes and complications of surface ablation

Tatsuya Onguchi, Dimitri T. Azar

INTRODUCTION

Photorefractive keratectomy (PRK), laser-assisted subepithelial keratectomy (LASEK), and Epi-LASIK are currently the three methods of surface ablation. These procedures employ the excimer laser to ablate the most anterior portion of the corneal stroma (including Bowman's layer), and do not require a partial thickness cut into the stroma.[1] This feature allows greater retention of the biomechanical strength of the cornea in comparison to laser in situ keratomileusis (LASIK).[2–7] The visual rehabilitation after surface ablation is associated with more discomfort during the early postoperative period as compared to LASIK. In addition, the wound healing response after surface ablation is associated with increased halos and glare. With recent improvements in new surface ablation, there is an increasing trend for using these procedures to treat specific cases such as thin corneas, recurrent erosions, and topographical abnormalities in patients predisposed to ocular trauma. LASEK, the method of surface ablation introduced by one of the authors (Azar) and popularized by Camellin, creates an epithelial flap using dilute alcohol.[8–10] The flap is replaced after photorefractive ablation to reduce wound healing. Another method of surface ablation, Epi-LASIK, utilizes an 'Epikeratome' to generate an epithelial sheet without using alcohol.[11–13] Technological and methodological developments in surface ablation, wavefront technology, increased comprehension of laser–tissue interactions, increased predictability, and lower complication rates are likely to improve visual outcomes and patient satisfaction after surface ablation.[14–16]

PRK

PRK was the first ablative refractive surgery approved by the USA Food and Drug Administration (FDA). PRK came into some disfavor during the mid-1990s when laser systems did not have the capabilities of current lasers, including advanced software, accurate eye-tracking and larger ablation zones. Large series of reports on PRK often include older data, making comparison with other procedures difficult.

VISUAL OUTCOMES

Outcomes of PRK vary because it was the first procedure of wide area photoablative refractive surgery, and has a long history. Visual rehabilitation after PRK is recognized to be slower than after LASIK. Danasoury et al[2] demonstrated significantly better uncorrected visual acuity (UCVA) and best-spectacle corrected visual acuity (BSCVA) in LASIK patients than PRK patients at 2 weeks postoperatively. These results were consistent with videokeratographic analysis. After 6 weeks, there was no statistically significant difference in the refractive outcomes between LASIK and PRK.[2–5,17–21] In general, available data suggest that PRK achieves results similar to LASIK. Cumulative data with 6 months or more follow-up are shown below.

SAFETY

The percentage of eyes with a loss of two or more lines of best-spectacle corrected visual acuity (BSCVA) varies from 0.2 to 7%[2–5,18–21] and has been decreasing over the years. The data published after 2000 is almost comparable to LASIK safety.[4,5,19–21]

EFFICACY

Efficacy is defined as the percentage of eyes with UCVA of 20/20 and 20/40 or better. The cumulative data demonstrate UCVA of 20/40 or better in 93%[2,4,17–19] and UCVA of 20/20 or better in 68%[2–4,17–20] after 6 months postoperatively.

PREDICTABILITY

The predictability was indicated by the percentage of manifest refraction spherical equivalent (MRSE) within ±0.50 D and within ±1.0 D. At the 6 month follow-up, 71% of eyes were within ±0.50 D[2–4,17,19,20] and 90%[2,4,17,19] were within ±1.0 D of the desired postoperative refractive error.

COMPLICATIONS

Epithelial problems

Epithelial complications include superficial punctate keratitis (SPK), epithelial defects, and recurrent erosions. Medication toxicity is usually the cause of SPK, and discontinuation of the drops and the use of nonpreserved artificial tears should be considered. Rapid re-epithelialization after surgery is desirable for several reasons, including elimination of pain and discomfort, reduced risk of infection, and more rapid improvement of visual acuity. Re-epithelialization is usually completed within 3–4 days. NSAIDs and topical corticosteroids may inhibit re-epithelialization to a small degree and should be used in the minimal effective dose for the shortest amount of time. Persistent epithelial defects after PRK are associated with a higher incidence of corneal haze and scarring. Autologous serum eye drops may encourage healing. Although excimer laser PTK is an effective treatment for recurrent erosions, PRK may be complicated by recurrent erosion. Patients with pre-existing erosions may benefit from epithelial scraping and laser treatment of PTK. In a large series provided by Thompson et al,[22] only 1 of 2000 patients (0.05%) having PRK developed recurrent erosions postoperatively.

Dry eye

A decrease in tear flow and tear film stability has been reported 6 weeks after PRK, and was reduced up to 6 months later.[23] Tear growth factors (such as HGF, KGF, and EFG) are considerably increased after epithelial injury associated with the wound healing process.[24] The extent and duration of corneal hypesthesia depends on the ablation depth.[25] Dry eye symptoms are less common after PRK than LASIK, partially because LASIK reaches deeper into the stroma damaging more nerves than PRK for the same correction. Reduced corneal sensation causes decreased aqueous tear production, increased tear osmolarity, reduction of goblet cell density, and reduced blinking rate. In a comparative study of tear function changes after PRK and LASIK, Lee et al reported a significant reduction in Schirmer test and break up time (BUT) scores and a significant increase in tear osmolarity after 6 months after both procedures but with a greater decrease in tear film functions in LASIK patients.[23] The frequent use of unpreserved artificial tears may be helpful. Application of cyclosporin eye drops may be a good alternative. Salib et al showed that treatment with 0.05% cyclosporin eye drops provided greater refractive predictability 3 and 6 months after LASIK surgery than unpreserved artificial tears.[26] Placement of temporary collagen punctal plugs are also helpful for patients with moderate to severe dry eye patients.

Halos/glare

Glare and halos are night vision disturbances after refractive surgery. Halos may be associated with an ablation zone that is smaller than a pupil diameter in dim light condition. To avoid these problems, the optical zone diameter should match or exceed pupillary diameter in dim light condition. Aspheric corrections and peripheral blend zones help to create minimized halo effects.

Cental islands

Central islands are areas of localized steepening in the central cornea leading to multifocality.[27,28] Symptoms include ghost imaging, halos, glare, night vision disturbance, monocular diplopia and reduced BSCVA and contrast sensitivity, leading to slow visual rehabilitation.[27,28] Central islands occur in up to 70% of cases 1 week after treatment, but tend to resolve with time to an incidence of 2% at 6 months. Treatment for a central island should be delayed 6 months to 1 year.[27,28] Two hypotheses are thought to be responsible for central island formation. One theory involves ablation shock waves that might induce intrastromal shifts of water, leading to different levels of corneal hydration in the center and the periphery. The other theory is that the laser beam might be blocked centrally by the ejected vortex plume of gaseous and particulate debris generated during surgery. Central island formation is observed in some patients after treatment with broad-beam lasers, but rarely with scanning-slit and flying-spot systems.

Undercorrection and overcorrection

Undercorrection and overcorrection are among the most common complications after PRK. Two wound healing processes, including epithelial hyperplasia and stromal remodeling, affect refractive accuracy and stability.[29] The higher the myopia the higher the incidence of undercorrection. In early studies, small diameters of less than 5 mm were ablated based on evidence that postoperative haze was directly related to the size of the ablation zone. These small ablation zones, however, were associated with halos, glare, and more regression. Increased and long-lasting wound healing processes involving epithelial hyperplasia and possible stromal deposition result in undercorrection. The healing response of the epithelium may increase its thickness so that it changes the corneal curvature and reduces the refractive correction. Topical corticosteroids are sometimes used to correct undercorrection, and such treatments have been reported to reverse the effect of regression.[30] However, the long-term effects of corticosteroid therapy on refractive outcomes are not stable.[31] Undercorrection also adversely affects best-corrected visual acuity and can be accompanied by corneal haze, decentered ablation, and irregular astigmatism. Patients with severe myopia should be advised that they are likely to be undercorrected, take longer to stabilize, and may require a second procedure to achieve their optimal outcome. Over 90% of eyes have an initial slight hyperopic correction and then slight regression toward emmetropia.[29] Initial hyperopic overshoot and/or minimal healing response result in overcorrection. Usually there is no haze with overcorrection. They gradually decrease during a period of 3–4 months. The incidence of overcorrection varies with different lasers, in part because the ablation zones have different diameters. The occurrence of overcorrection depends on the magnitude of the attempted correction, even with greater regression.

Haze

Corneal haze is a very important complication of PRK, typically localized to the subepithelial anterior stroma. Two types of haze are observed after PRK. The more common type of haze is the typical transitory haze that is detected between 1 and 3 months after surgery. This type of haze is rarely associated with clinical symptoms and usually disappears within the first year after the surgery. The other type of haze, 'late onset corneal haze,' is much less common and is usually detected between 2 and 5 months after the surgery. Late onset haze affects corneal transparency and refraction. It resolves over time, but in severe cases several years may be required for full resolution.

Subepithelial haze seen after PRK has been associated with increased growth of collagen and extracellular events in the stroma. Keratocyte apoptosis may be triggered by the release of epithelial cytokines. The subsequent wound healing responses are responsible for a hazy appearance to the corneal stroma after PRK. Disappear-

ance of haze is associated with disappearance of myofibroblasts and remodeling of disorganized stromal collagen. Symptomatic haze is reported to occur in a small percentage of eyes, usually less than 0.5–3%.[32,33] The incidence and severity of haze has been shown to increase with the level of attempted correction.[32–35] Other factors such as atopy,[36] autoimmune conditions,[36] and high UV radiation exposure[37] deteriorate haze formation. Corneal haze is much more common after PRK than LASIK, reflecting the different wound healing.

Efficacy of mitomycin C

Mitomycin C (MMC) prevents haze formation after PRK. PRK-induced haze also can be improved by applying MMC. Carones et al randomized 60 consecutive PRK eyes (preoperative myopia range −6.00 to −10.00 D) into two groups: one received a 2-min intraoperative application of MMC (0.2 mg/mL) and the other did not. They concluded that the prophylactic MMC group had lower haze rates (0% of MMC eyes versus 63% of control eyes with haze higher than +1 at 6 months), better UCVA and BCVA results and more accurate refractive outcomes than those achieved in the control group.[38] Special care has to be taken because epithelial healing after MMC is characterized by prolonged latency and decreased migration rate, depending on exposure time. Permanent effects of MMC should be considered. Late side effects are reported, occurring more than 5 years after treatment.

Infectious keratitis

Infectious keratitis is a rare but potentially vision-threatening complication of PRK. Infection should be considered when corneal infiltrates are present in the first postoperative week after PRK. Many of these infiltrates are sterile, contact lens related, or associated with topical nonsteroidal anti-inflammatory agents or antibiotics. The addition of antibiotics with gram-positive coverage and removal of the soft contact lens is recommended. Central or paracentral infiltrates larger than 2 mm or infiltrates associated with significant pain or anterior chamber reaction are serious and should be smeared, cultured, followed closely, and treated aggressively as a sight-threatening condition. In a retrospective review of 25337 eyes that underwent PRK at 6 Army and Navy refractive services, culture proven or clinically suspected keratitis developed in 5 eyes of 5 patients (0.02%).[39] All cases presented 2–7 days postoperatively. Cultures from four cases grew *Staphylococcus*, including two methicillin-resistant *S. aureus* (MRSA). One case of presumed infectious keratitis was culture negative. Bandage soft contact lens use has been reported to be associated with infectious keratitis. Dantas et al evaluated bacterial contamination after 3 days of soft bandage contact lens-use following PRK in 81 eyes.[40] They found 7.4% positive cultures with normal ocular flora, probably related to topical drops and not related to contact lens-use.

LASEK

The initial enthusiasm regarding LASEK was due to the possibility of combining the advantages and minimizing the disadvantages of PRK and LASIK. In LASIK, dilute alcohol solution is used in the loosening of the corneal epithelium and the creation of an 'epithelial flap.' The loosened epithelium is moved aside from the treatment zone as a hinged sheet. The flap is not discarded but replaced immediately after laser ablation. The advantage of LASEK over LASIK is that it is free from any complication related to the 'stromal flap.' Theoretically, the existence of an 'epithelial flap' can be a barrier preventing lacrimal inflammatory cytokines from increasing stromal wound healing and can provide more comfort postoperatively and faster rehabilitation relative to PRK. If the alcohol dilution were optimal, the procedure could be almost harmless to epithelial viability.

VISUAL OUTCOMES

Slow visual rehabilitation is the major drawback of LASEK (in the same way as PRK). Functional visual acuity is obtainable within a week postoperatively, while it takes more than a month for refractive stability. Early stage post-LASEK status is included in the study of Taneri et al.[9] Most eyes had a UCVA of 20/40 or better at 1 week, and only 25% reached 20/20. At 4 weeks, the eyes with a UCVA of 20/20 stabilized at 69–79% until the 1-year visit. Excellent long-term refractive outcomes for LASEK treated eyes were demonstrated by many studies.[9,11,41–49] Anderson et al[44] conducted the largest study of LASEK treated eyes. They treated and followed 343 eyes for up to 6 months. In this study, the authors reported that 85% of LASEK treated eyes were within ±0.50 D and 94% were within ±1.00 D of the intended correction at 6 months ($n = 115$); 98% of eyes maintained UCVA of at least 20/40 through 6 months ($n = 122$). The longest report was provided by Autrata and Rehurek.[47] They treated 92 patients with low to moderate myopia. At 24 months, 73% of eyes and 92% of eyes had UCVA better than 20/20 and 20/40 respectively, with 62% of eyes within ±0.50 D and 92% of eyes within ±1.00 D. From months 12 to 24, there was almost no change in refraction. The cumulative data for a 6-month period is shown below.

SAFETY

In reports mentioning loss of BSCVA of 2 or more lines, the cumulate percentage rate, excluding retreatments, is 0.8%.[9,11,41–49] Kim et al reported that the main reasons for decreased BSCVA were stromal opacity with myopic regression, irregular astigmatism, and eccentric ablation.[48]

EFFICACY

After 6 months postoperatively, 95% and 71% achieved an uncorrected visual acuity (UCVA) of 20/40[9,11,41,44,45,48,49] and 20/20[9,11,41,43–46,48,49], respectively.

PREDICTABILITY

At 6-months follow-up 78% of eyes were within ±0.50 D[9,41,43–46,48,49] and 88% were within ±1.0 D of the desired postoperative refractive error.[9,43–46,48,49]

COMPLICATIONS

Intraoperative complications

Alcohol leakage

This complication may be decreased with improved surgical skill. The incidence of leakage is 1–3%.[43] Excess pressure on the alcohol solution cone and non-cooperative patients are potential causes. Alcohol leaks should be removed immediately and thorough irrigation of the conjunctiva including fornix is required. Patients often complain of pain for several days after alcohol leakage. No addi-

tional complication such as corneal or limbal erosion and limbal deficiency are reported.

Incomplete epithelial detachment

Incomplete epithelial detachments, such as a tear in the flap, buttonhole, or fragmented flap are possible. The incidence of incomplete epithelial flap is less than 5%.[50] The epithelium of contact lens wearers tends to be more adherent and may increase the risk of an incomplete flap.[50] If necessary, alcohol application may be repeated for an additional 10–15 s. If the flap is torn or otherwise damaged, the surgeon can safely revert to PRK.[50]

Postoperative complications

Epithelial problems

Preservation of the epithelial flap is one of the potential advantages of LASEK over PRK. Intact epithelial sheets will settle and adhere by day 3. In Azar's series, 63% of patients had an epithelial defect on day 1, 9% on day 3, and no defect at 1 week.[8] Whether re-epithelialization is faster after LASEK than after PRK is still controversial. Delayed epithelial stability increases inflammatory responses. Treatment for persistent epithelial defects is the same as PRK.

Undercorrection and overcorrection

Residual myopia is caused by insufficient initial treatment, more commonly observed in high myopia. If there is an undercorrection and the patient is not satisfied with the level of vision, additional treatment may be performed. It can be easily managed with an enhancement procedure by removing the epithelium, sometimes without alcohol, and adding the undercorrected value to the laser. This maneuver must be performed within 1 month after the surgery.

Slight overcorrection is observed more often than PRK. Patients with overcorrection may experience blurred vision when viewing objects up close. Dehydration of the stromal bed (by alcohol application) is thought to be the reason. A nomogram adjustment of 5–10% reduction compared to the PRK computed treatment is recommended.

Haze

Haze formation usually peaks at 3 months postoperatively and resolves by 1 year postoperatively. It is postulated that the LASEK flap can reduce stromal infiltration of cytokines from tears, the release of cytokines from damaged corneal epithelium, and subepithelial keratocyte apoptosis. In animal models, LASEK induced less keratocyte apoptosis and myofibroblast transformation.[51,52] Most reports involving LASEK treatment for low to moderate myopia without MMC describe low levels (0–13%) of haze formation. Series involving the treatment of moderate to high myopia report visually significant haze formation in 8–10% of LASEK treated eyes. Risk factors of haze formation after LASEK procedure are almost the same as PRK. Haze tends to be severe in deeper ablation. Lin et al showed that an ablation depth of 100 µm or deeper increases the risk of haze formation.[53] Superiority of LASEK over PRK in haze formation is reported. Lee et al showed a lower haze rate of LASEK than PRK at 1 month after surgery.[54] Autrata and Rehurek demonstrated less haze in 108 LASEK eyes than in 108 PRK eyes at 1–24 months after the surgery.[47] The mechanisms of lower haze incidence is explained by the lower expression of TGF-beta1 in the tear after LASEK than after PRK[54]; TGF-beta1 is a key regulator of wound healing process after refractive surgery.

Dry eye

Postoperative tear function and ocular surface status is similar to that of PRK. Horwath-Winter et al reported that the BUT value and corneal sensation were decreased up to 1 month postoperatively and vital staining scores increased for up to 1 week after LASEK.[55] These tear function and ocular surface test results after LASEK were better than those of other reported results after PRK. Decreased inflammatory reactions after LASEK than after PRK can explain decreased dry eye symptoms.[54]

Glare and halos

The incidence of glare and halos after LASEK seems to be similar to PRK. Halos occur when either the pupil size in dim light exceeds the effective optical zone size or when there is a de-centered ablation. A halo may be a pronounced form of spherical aberration. Persistent halos are rare and diminish with time, if at all.

Pain

A LASEK flap was expected to reduce the postoperative pain covering the ablated surface of the stroma when compared to PRK. Several studies demonstrated less pain associated with LASEK than with PRK.[47,56,57] Mild discomfort and foreign body sensation are seen in LASEK during the first few days postoperatively. The peak time for pain after LASEK is usually on the second postoperative day because discomfort originates from the contact lens, whereas in PRK it is usually on the first postoperative day. Irregular adhesion of the epithelial flap to the stromal bed and occasional sloughing of the flap can induce more pain than PRK. Most postoperative pain is ameliorated after full epithelialization.[29]

EPI-LASIK

Unlike LASEK, epi-LASIK does not use alcohol to remove the epithelium. Therefore, the potential toxic effects of alcohol to the cornea are avoided. Our review of the literature showed a relatively small number of reports.[6,12,15,16,58–60] Further studies are necessary to evaluate the results of EPI-LASIK in comparison to PRK and LASEK.

VISUAL OUTCOMES

Unlike studies in LASEK, improved visual rehabilitation has not yet been demonstrated in Epi-LASIK. Pallikaris et al reported the visual recovery of 44 eyes that received epi-LASIK.[14] They showed that 38% of the treated eyes had a UCVA of 20/40 or better at day 1, 85% of patients had a UCVA of 20/40 or better, and 34% had a UCVA of 20/25 or better at day 3. At the 1-month postoperative visit, 95% of the patients had a UCVA of 20/40 or better and 65% had a UCVA of 20/25 or better. At the 3-month postoperative visit, 96% had a UCVA of 20/40 or better and 92% had a UCVA of 20/25 or better. No eye lost more than 1 line of BSCVA. Seventy-eight percent of treated eyes were within ±0.50 D, and 100% were within ±1.00 D of the targeted refraction.

COMPLICATIONS

Intraoperative complications

As with LASEK, intraoperative complications of Epi-LASIK are rare and are usually not serious. Kim et al reported inadvertent stromal dissection during mechanical separation of the corneal epithelium

using an epikeratome.[15] The reported incidence of the intraoperative complication is 2 out of 91 eyes (2%). In one case, the stromal flap was dislodged during epithelial removal. This may have resulted in uneven photoablation and postoperative irregular astigmatism, according to the thickness and dimension of stromal loss. These cases were retreated with PRK 8 months after the first surgery. Dai et al reported that one case of stromal tissue remained among 289 eyes (0.3%), and free epithelial flaps were made in 12 eyes (4%).[16]

Epithelial viability

Epi-LASIK was developed to reduce corneal epithelial damage caused by alcohol application in LASEK.[13] However, some studies suggest that correct and consistent usage of alcohol for LASEK is not harmful on epithelial viability.[58,59] The plane of dissection is within the basement membrane in LASEK[8,59] but underneath the basement membrane in Epi-LASIK.[6] It is widely accepted that the adherence of the basement membrane to basal epithelial layer is important for the epithelial integrity.

Postoperative complications

Pain

Epi-LASIK is not a pain-free procedure. Dai et al showed that mild discomfort was reported by 93.4% of his 150 patients and moderate symptoms in 6.6% patients.[16] Pallikaris et al[14] showed five (16%) patients reported burning pain that required medication, and the rest of the patients reported no pain (20 patients, 65%) or mild discomfort (6 patients, 19%). By the third postoperative day, there was no pain or discomfort in the eye treated with Epi-LASIK. There is no improvement from LASEK in this regard.

Haze

In comparison with PRK, the incidence of haze after the surgery is less with Epi-LASIK. Recently, Long et al reported that Epi-LASIK reduced the incident of haze formation and lowered levels of TGF-beta1 in tear fluid, compared to LASEK.[60]

94 LASIK complications

Louis E. Probst

INTRODUCTION

The safety profile of laser in situ keratomileusis (LASIK) has dramatically improved over the last 8 years. LASIK technology has improved with better microkeratomes and scanning excimer lasers that allow for bigger and smoother ablation zones. Surgeon experience has also increased dramatically. These factors have reduced the number of intraoperative contraindications for LASIK. The postoperative complications have also been reduced by the increased awareness of the contraindications for LASIK. LASIK is an elective procedure and, therefore, the complication rate must be low in order for it to be an accepted refractive procedure. Most LASIK complications can be corrected so that no long-term problems persist. However, there are some uncommon complications that can have permanent visual consequences. There are a few LASIK complications that are unique for hyperopic corrections. LASIK complications can be conveniently divided into intraoperative, early postoperative, and late postoperative complications.

INTRAOPERATIVE LASIK COMPLICATIONS

Intraoperative LASIK complications are often preventable with appropriate safeguards of the surgical system. If the equipment is defective or set up incorrectly, a complication is almost certain. Therefore, the key to minimizing LASIK complications is prevention. Proper training and a high degree of focus is essential for both the surgeon and the surgical technicians to minimize operative errors.

A recent retrospective study evaluated the intraoperative flap complications in 84 771 cases of LASIK with the automated corneal shaper (ACS) or the Hansatome.[1] The rate of all flap complications was 0.302%, with failures to achieve intraocular pressure (IOP) in 0.034%, partial flaps in 0.099%, buttonholes in 0.07%, thin or irregular flaps 0.087%, and free flaps in 0.012% of eyes. There were 134 right eye complications and 122 left eye complications. No patient developed an intraoperative flap complication in both eyes. Flap complications have been found to be more common with the ACS as compared to the Hansatome,[2] as success with the ACS is more surgeon experience dependent.

PREVENTION OF INTRAOPERATIVE COMPLICATIONS

Prior to the LASIK procedure, all the equipment should be checked, as any failure of the equipment could result in a flap complication. This is often referred to as the 'preflight checklist.' The microkeratome blade should be checked before every LASIK procedure. The microkeratome blades supplied by the manufacturer can be defective. Nicks or irregularities of the cutting edge will produce a linear ridge through the flap or a split flap.[3] It is difficult to check the microkeratome blade once it is loaded in the microkeratome, as the edge is not well reflected by the light of the microscope. Once the blade is loaded in the microkeratome, it should be checked to make sure it is mobile. It is possible to hear the sound of the microkeratome motor running and have no blade movement if the blade is loaded into the head incorrectly. If a microkeratome pass is made with an immobile blade, a thin irregular flap will result. A test run should then be performed of the microkeratome to ensure that it is running smoothly in the microkeratome track. The resistance level on the Hansatome box gauge should be less than 20. If the gauge is running in the 20–30 range, a drop of proparacaine on the blade and the gears usually causes the resistance to drop into the below 20 range. If the resistance is still in the 20–30 range, the microkeratome should be reassembled as there is excessive blade resistance. Low levels of suction have been experienced when suction tubing was not properly inserted into the suction unit. Therefore, it is important to always check the suction at the beginning of each day to make sure the suction unit is functioning properly. Finally, it is important to confirm the IOP has risen to an adequate level prior to performing the keratectomy. The pressure should be well above 90 mmHg when checked with the 90 mm Barraquer tonometer.

BUTTONHOLE AND IRREGULAR FLAPS

Buttonhole flaps occur when the keratectomy has been performed without adequate suction. The microkeratome produces a meniscus-shaped flap that is thinner in the center so any additional thinning due to the low suction results in a break in the center of the flap creating a buttonhole flap. Although an increased risk of buttonhole

flaps has been suggested with steep corneal keratometry readings (>50 D), this has not been the experience of this author or published in the literature.[4]

Clinical: The buttonhole flap is evident immediately after the microkeratome has completed the reverse pass. The central aspect of the cornea will appear irregular with a 2–3 mm diameter irregular circle in the center representing the buttonhole. If the flap is lifted, it will be thin and difficult to manipulate. The defect through the center of the flap will be obvious (Fig. 94.1). The stromal bed has a clear area in the center about 2–3 mm in size that is slightly elevated representing the uncut area of cornea where the epithelium is still present. After 1 month, haze will form around the edges of the buttonhole (Fig. 94.2).

Management: Performing the laser ablation will result in an irregular astigmatism with central corneal haze. If the buttonhole is identified immediately, the flap should not be lifted. Gentle interface irrigation will allow the flap to be re-floated into position. If the flap has been lifted, the flap should be replaced, and then re-floated into position. This can be difficult as the flap is thin and very unstable. The eye is allowed to heal for at least 3 months. LASIK can be performed again using a deeper plate. Topical steroids are tapered during the healing phase to reduce the risk of haze formation. Although immediate transepithelial photorefractive keratectomy has been reported following flap complications,[5] this technique is not recommended by the majority of refractive surgeons.

Prevention: Buttonhole flaps can be prevented with techniques and precautions discussed above. The keratectomy should never be performed without excellent suction and a perfect blade.

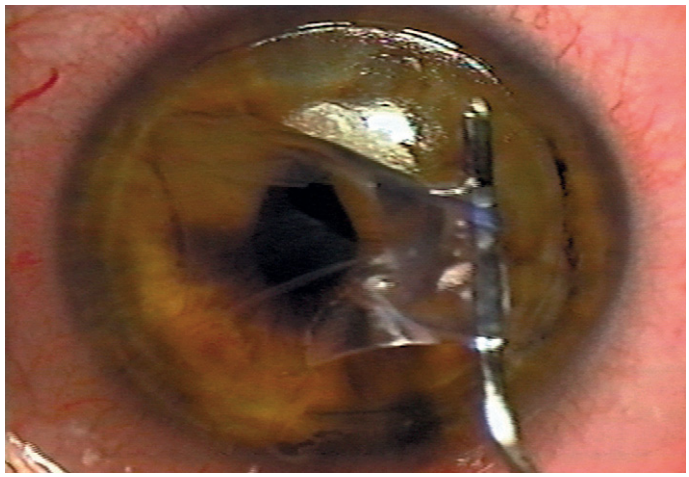

Figure 94.1. Intraoperative view of a buttonhole flap with the cannula protruding through the center of the buttonhole.

THIN FLAPS

The average flap thickness for each microkeratome is variable. The Hansatome generally cuts about 40 μm thinner than the depth indicated on the depth plate. There is also considerable standard deviation in the average cut thickness which is generally about 25 μm.[6,7] Therefore the flap thickness can vary considerably, often between 100 and 200 μm. The Nidek MK-2000 microkeratome also cuts about 20 μm thinner than the depth plate number.[8] Because of this variation, the LASIK surgeon has little room for error if the flap is thin.

Clinical: Thin flaps can be immediately identified after the keratectomy as they tend to role along the distal cut edge. Flaps of 100 μm or more do not demonstrate this pattern. Very thin flaps can be associated with complete buttonhole flaps or partial buttonhole flaps when the central flap is only composed of epithelium. If the suction level was poor or the blade was not moving during the keratectomy the flap and the stromal bed will be irregular. This is best seen with the reflections of the microscope illumination lights. Striae are also more prominent with thin LASIK flaps. The superficial corneal stromal is less hydrated than the deeper stromal so the stromal bed of a thin flap will appear less moist and more reflective. Once a very thin flap has healed a hazy area with irregular striae will form in the center of the cornea (Fig. 94.3).

Management: When a thin flap is achieved the surgeon must evaluate the flap and the stromal bed. If the stromal bed is smooth and the flap itself is smooth, LASIK can still be performed with an excellent outcome. If the stromal bed is not smooth or there are perforations or buttonholes of the flap, then performing the laser ablation will result in irregular astigmatism with central corneal haze.

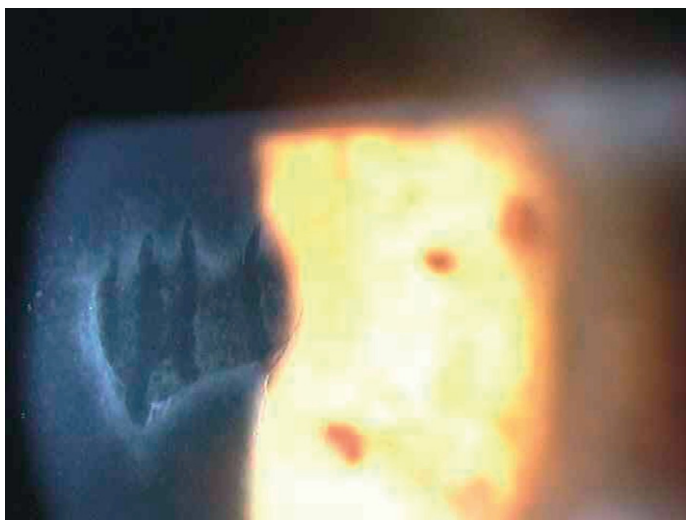

Figure 94.2. One month after a buttonhole with an irregular haze pattern surrounding buttonhole.

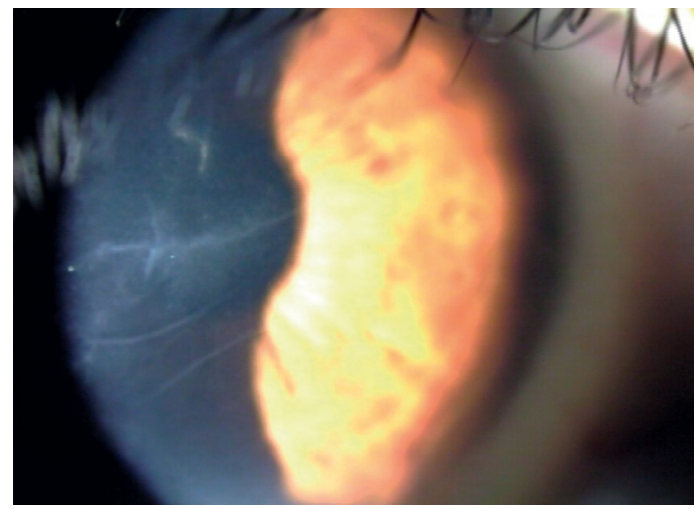

Figure 94.3. Central corneal haze and irregular striae after a thin flap.

In the case of an irregular flap with an irregular stromal bed, the flap should then be replaced and the cornea is allowed to heal for 3 months. LASIK can be performed again using a deeper plate. Topical steroids are tapered during the healing phase to reduce the risk of haze formation.

Prevention: Thin flaps are prevented with the safeguards listed above. The keratectomy should never be performed without excellent suction and a perfect blade.

FREE CAP

A free cap occurs when the microkeratome does not stop to create a hinge but rather continues across the cornea severing the flap from the bed, thereby creating a free cap. Free caps usually occur for two reasons. In eyes with very flat preoperative Ks, a free cap can occur on some microkeratomes such as the ACS when the Ks are less than 41.0 D. A free cap can also occur if there is a very thin flap due to inadequate pressure. This flap would tend to be smaller in diameter, more central in the cornea, with an irregular edge.

Clinical: Free caps are circular and completely separated from the stromal bed. If the free cap is thin, the edges may be irregular and the free cap will fold onto itself when manipulated. If the free cap is of normal thickness, it will maintain rigidity when lifted (Fig. 94.4).

Management: If the suction level was low and the stromal bed is irregular, the flap should be replaced and allowed to heal without performing the excimer laser ablation. If the free cap occurred because of low preoperative keratometry reading, the stromal bed may be smooth and the free cap of normal thickness. In this case, the ablation can be continued with an excellent outcome. The free cap should be carefully placed epithelial side down on a drop of balanced salt solution in the antidesiccation chamber while the ablation is being performed. The antidesiccation chamber should be then covered with a sterile container to ensure that it is not inadvertently knocked off the surgical tray. Once the ablation is performed the free cap can be replaced and aligned using the alignment marks that were placed prior to the keratectomy. It is important to ensure that the epithelial side of the free cap is up and that the epithelial marks are well aligned, otherwise astigmatism will be induced postoperatively because of incorrect flap orientation.

Prevention: In eyes with keratometry readings less than 42.0 D, it is advisable to use the Hansatome or a larger microkeratome head (9.5) on the Nidek Mk-2000. This author has performed LASIK with the Hansatome on Ks less than 37 D and not created a free cap.

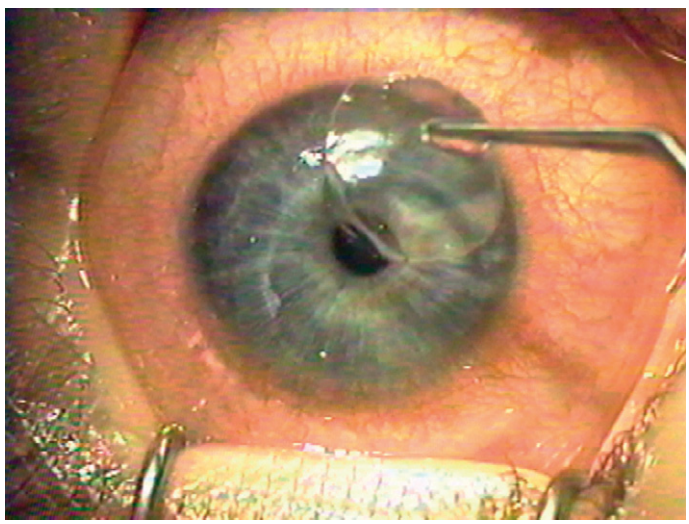

Figure 94.4. This free cap maintains some rigidity as it has a normal thickness.

CORNEAL PERFORATION

Perforation of the cornea during the keratectomy is the most feared and rare complication of LASIK. It was first reported with the ACS microkeratome when the depth plate was not properly screwed into the microkeratome head. Without the depth plate to restrict the cut depth, the blade would cut straight into the cornea causing penetration into the anterior chamber with extrusion of the intraocular contents due to the elevated IOP. When the Hansatome was introduced with a fixed depth plate, this problem was thought to be eliminated. However, this problem was more recently reported during the early introduction of the Nidek MK-2000 microkeratome. Once again, it was the incorrect assembly of the microkeratome that allowed this complication to occur. Nidek has since required that a plastic wedge is placed in the hinge of the MK-2000 that prevents corneal perforation even if the head is not properly assembled.

Clinical: This complication is obvious during the advancement of the microkeratome as there is a sudden release of a jet of fluid as the cornea is penetrated followed by a loss of suction with beeping from the suction pump. The suction should be disengaged immediately. Removal of the microkeratome reveals the penetration which could be associated with extruded iris and/or lens material.

Management: Corneal perforation is managed by preserving as much intraocular tissue as possible, suturing the corneal incision to restore the anterior chamber, and immediate referral for further evaluation/surgery that may be required. An emergency surgical kit that includes a needle driver and sutures should be available in every laser center.

Prevention: Careful microkeratome assembly is critical for successful LASIK. LASIK staff should be well trained for correct assembly as well as the pitfalls of incorrect assembly. The surgeon should always check the microkeratome to insure that it has been properly assembled.

LASER-RELATED COMPLICATIONS

Laser-related complications are perhaps the most frustrating LASIK complication as they are usually completely preventable. The most embarrassing complication is incorrect laser programming. Often this task is left to a technician, who may read a number incorrectly or simply have a typing error. The most insidious programming problems occur with prescription transposition errors. On rare occasions, the excimer laser will actually fail in the middle of a procedure.

Clinical: There is little to warn of incorrect laser programming during the procedure. The result will become obvious postoperatively when the patient does not achieve a good uncorrected visual acuity (UCVA). If there was a transposition error, or an astigmatism axis error the resultant astigmatism may be magnified in a new axis.

Management: Errors in laser programming can be corrected by an enhancement procedure; however the best strategy is prevention with multiple checks. If laser failure occurs, the flap should be replaced and the patient taken from the surgical room. The percentage of the correction performed should be recorded, in case all data

is lost from the laser. The laser company should be called to determine the cause of the failure. Often, with company guidance, steps can be taken that return the laser to full functioning. Most excimer lasers have the procedure in memory so the patient can be brought into the room and the procedure continued from the previous point with no detrimental effect on the outcome. Patient reassurance during this phase is critical to maintain confidence.

Prevention: It is essential to check and double check all programming prior to performing LASIK. One technician can read the programming to the other technician, who verifies the information to ensure that they both have confirmed the numbers. It is very easy to make transposition errors when converting from plus to minus cylinder, therefore the refraction calculations should also be checked. It is helpful to compare the axis and sign of the refractive astigmatism with the astigmatism on the topography to make sure that they are similar. Any discrepancy, particularly those 90° apart may indicate a transposition error.

EPITHELIAL DEFECTS AND ONE-DROP LASIK

Intraoperative epithelial defects (IED) during LASIK can result in a number of highly undesirable complications including prolonged visual recovery, postoperative pain, diffuse lamellar keratitis (DLK), and epithelial ingrowth. Therefore, the LASIK surgeon must strive to avoid this complication in every way possible. A recent study evaluated the risk factors for IEDs during LASIK.[9] IED occurred in 9.7% of 247 eyes. IED significantly increased with older age, preoperative corneal thickness, and maintenance of suction ring vacuum during the reverse pass of the microkeratome. Fewer preoperative drops resulted in fewer IEDs. In patients undergoing bilateral LASIK, the incidence of IED was much higher in the second eye if the first eye developed an IED.

Clinical: IEDs are noted immediately after the keratectomy as irregular areas along the epithelial surface of the cornea. A flap of epithelium can sometimes be seen hanging over the corneal flap (Fig. 94.5). The displaced epithelium is usually edematous and grey in appearance. IEDs can be <1 mm or as large as the entire corneal flap. The flap is usually intact and healthy beneath the defect. IEDs usually occur along the superior edge of the flap where the epithelium is less adherent.

Figure 94.5. Loose flap of epithelium after LASIK.

Management: If an epithelial defect occurs during the treatment of the first eye, the surgeon should continue with the laser treatment, replace the LASIK flap, and place a bandage contact lens over the eye if the defect is greater than 3 mm in size. If the defect is extremely large, it may be elected not to proceed with the treatment of the second eye until the first eye has healed.

The patient must be observed daily for evidence of infection and a prophylactic antibiotic should be used postoperatively at least until the epithelial defect has healed. For small epithelial defects, reassurance that the foreign body sensation will resolve, lubrication, topical NSAIDs to reduce the foreign body sensation, and a topical steroid to control potential interface inflammation may be all that is required. Small epithelial defects will generally heal within 1–3 days. For larger epithelial defects, a bandage contact lens (CTL) should be inserted with care not to disturb the flap. A bandage contact lens with a base curve of 8.4 mm generally fits well. Topical NSAIDs have been associated with sterile corneal infiltrates, therefore they should only be used for 3–4 days.[10,11] Topical steroids should be used at least every few hours as the risk of interface keratitis is higher with larger defects. Oral agents such as sedatives or narcotic agents are required rarely and used only in selective cases as it is far better to have the patient aware of any continued discomfort so that the center can be notified. Pressure patching is contraindicated as patient eye movement against the firmly applied eyelid may create excessive shearing forces and displace the flap. After lubricating drops to hydrate the CTL and topical anesthetic have been instilled into the eye, the bandage CTL can be removed. The ideal technique for CTL removal is to have the patient look up while at the slit-lamp biomicroscope; in this manner the inferior aspect of the CTL is visible and may slide down. Using fine non-toothed forceps, the inferior aspect of the CTL is firmly grasped and the CTL pulled down and away from the eye.

Prevention: One technique that is extremely effective for reducing epithelial defects is 'one drop LASIK'.[12] No preoperative drops are put in the eye prior to LASIK to minimize the toxic keratopathy that greatly increases the risk of epithelial defects. The patient is brought into the laser room and placed under the laser. One drop of topical anesthetic is placed in the eye and then a Murocel sponge soaked in a combination of proparacaine, NSAIDs, steroid, and antibiotic is placed under both lids. In this way we are able to achieve appropriate anesthesia, anti-inflammatory, and antibiotic effect in the eye while reducing the time of exposure so there is limited opportunity for the development of a toxic keratopathy.

Patients that have pre-identified weakness with the epithelium including anterior basement membrane dystrophy or loose epithelium or a skin condition such as acne rosacea are prone to epithelial defects. These patients will be better treated with a nasal hinge flap as the rotary movement of the Hansatome will cause more epithelial friction with a greater incidence of epithelial defects. This author currently uses a nasal hinge flap in approximately 90% of standard myopic LASIK cases and superior hinge flap for hyperopes, wide zone ablations, mixed astigmatism, and large pupils.

LOOSE EPITHELIUM

Loose epithelium may be noted prior to the LASIK procedure or more commonly after the keratectomy. This occurs more commonly in patients over the age of 40 years and those with a history suggesting loose epithelium such as recurrent corneal erosions, previous eye trauma, or obvious anterior basement membrane dystrophy.

Figure 94.6. Loose superior epithelium immediately after LASIK.

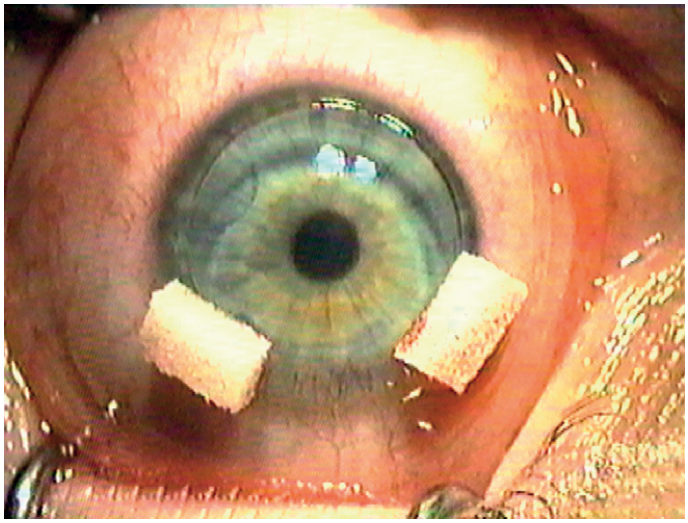

Figure 94.7. Sponges are used to control corneal bleeding during LASIK.

Clinical: Loose epithelium can present in different manners depending on the levels of severity. Mildly loose epithelium will present with a rippled appearance along the cornea surface most commonly seen along the superior flap edge after the keratectomy (Fig. 94.6). Severe loose epithelium can result in large sheets of detached epithelium after the keratectomy with epithelial defects. There is usually some attached epithelium along the inferior flap edge.

Management: Loose epithelium identified after the keratectomy can generally be replaced with gentle pressure along the surface of the flap. Surprisingly, this epithelium will remain in the new replaced position as long as the rest of the epithelium is intact and attached. Large flaps of detached or displaced epithelium are best removed while carefully preserving the remaining attached epithelium. A CTL should then be placed on the eye; this is left in place for 1–3 days to allow the epithelium to attach to the basement membrane of the cornea. Careful removal of the contact lens should reveal healthy attached epithelium.

Prevention: Loose epithelium identified preoperatively should alert the LASIK surgeon to a higher risk of epithelial loss and defects during the LASIK procedure. While the 'one drop LASIK' technique and a careful surgical technique can prevent these complications, photorefractive keratectomy (PRK) or laser assisted subepithelial keratectomy (LASEK) should be considered for low spherical corrections to avoid the risk altogether. If LASIK is still the preferred procedure, a nasal hinged microkeratome will minimize the risk of loose epithelium and epithelial defects.

NEOVASCULAR BLEEDING DURING LASIK

When LASIK was first performed using nasal hinge flaps with the ACS microkeratome, corneal bleeding was not common. The 8.5 mm flap rarely intersected the corneal vessels and if it did, only the superior vessels were involved, which was not a problem to control.

Clinical: With the advent of larger flaps particularly with those created by the Hansatome, it is not uncommon to have corneal neovascular bleeding during the LASIK procedure. Hyperopes tend to have smaller eyes with a greater incidence of neovascular bleeding. Generally, neovascular bleeding occurs immediately after the keratectomy along the superior flap edge. It may be self-limited, lasting for less than a minute or persist for several minutes depending on the size of the vessels cut and the coagulation status of the patient. There are occasions when bleeding occurs 360° around the cornea and can cause difficulties both during the ablation and after the procedure because of bleeding underneath the flap.

Management: Once the flap is cut and it is obvious that there is neovascular bleeding the suction ring can be left in place and downward pressure from the suction ring can tamponade some of the bleeding vessels. The flap is lifted and the bleeding vessels can be dried with a dry Murocel spear.

If there is continued bleeding which could extend into the ablation area then dry rectangles of instrument wipe cut in 2×4 mm segments are placed on the area of bleeding (Fig. 94.7). These are available from Hurricane Medical (Probst LASIK sponge) or can be prepared beforehand by the surgical technician by simply taking an instrument wipe and cutting it into those segments. This allows the ablation to be performed without further interruption. The sponges can be removed and the flap replaced with copious irrigation to make sure there is no further bleeding underneath the flap. The same sponges which have been soaked in Iopidine (apraclonidine HCI) are placed over the areas of bleeding. Iopidine is used as it is an alpha 2 agonist with a vasoconstrictive effect without the pupillary dilation that occurs with phenylephrine. The sponges are left in place for approximately 1 min while the flap is adhering to the stromal bed.

Prevention: There are several maneuvers that can be used to prevent bleeding during the LASIK procedure. When the 9.5 mm suction ring is first placed on the eye, neovascular vessels extending into the exposed cornea will be cut. In this case, the ring can be switched to the 8.5 mm ring so that the neovascular bleeding can be minimized. This author does not use an 8.5 mm ring routinely as this ring more commonly decenters which does not occur to the same degree with the 9.5 mm ring. Pretreatment with Alphagan (brimonidine tartrate) has been suggested to reduce the incidence of intraoperative bleeding; however, this potential benefit must be balanced with the increased width of postoperative slipped flaps.

THE ANXIOUS PATIENT

There is a reasonably high incidence of general anxiety disorder in the population in general which is of course magnified by the normal fears associated with the LASIK procedure. There are also patients who are claustrophobic, who may be fearful if they have had past experience with an MRI. Younger patients are more anxiety prone than the older patients. They have difficulty controlling their anxiety, as well as being extremely sensitive around their eyes, which seems to be a trait particularly common to young males.

Clinical: Anxiety is displayed in countless ways by patients; however, the best measure of identifying the problem is noting increased tension in the surgical suite. As soon as this is noted, the surgeon must make a careful analysis of the source of the problem and address it before further complications arise.

Management: If a patient appears to be anxious, they should be isolated from the other patients so that the anxiety is not propagated throughout the center.

Anxious patients should be evaluated and treated as quickly as possible rather than have them wait while their anxieties build. Preoperative sedation should be used generously whenever someone appears to be anxious. The anxiety prior to LASIK is related to a feeling of helplessness and a loss of control. Patients need to understand that there is no immediate need to do LASIK. Patients should also understand that they can have only one eye treated. Some patients appreciate being able to check their vision with their first eye before continuing with their second eye. Sometimes it is helpful to have the husband, wife, parent, or friend hold the patient's hand during the procedure. If there is any sense of anxiety when the patient is underneath the laser, the procedure should be postponed.

Prevention: Anxiety is demonstrated in many different ways depending on the personality of the patient. Some patients make identification easy by announcing their anxiety as they arrive at the center. Introverted patients will sit quietly in the consultation room; however, they will often leave their coats on, cross their arms and legs, avoid eye contact, and sweaty palms may be noted during the introductory handshake. Extroverted patients will talk in loud tones, pace around the room, make multiple trips to the bathroom, and talk to everyone they can find about the procedure. The challenge for the surgeon and the staff is to identify every anxious patient so they can be appropriately addressed prior to LASIK.

DEEP-SET EYES

Deep-set eyes are more difficult to treat as the palpebral opening is crowded by the prominent orbital bones.

Clinical: Patients with deep-set eyes can be identified preoperatively by their small palpebral fissures, prominent superior orbital rim, and prominent cheek bones. This problem is far more common in men due to a prominent supra-orbital rim but can occur in both sexes. A highly myopic spectacle correction can make the problem appear worse due to the minification effect of the spectacles. Patients with small heads and faces and Asian patients do not generally have deep-set eyes; however, the small palpebral opening introduces similar challenges. Hyperopic patients tend to have small orbits that limit access to the globe for LASIK.

Management: These patients are best avoided until the LASIK surgeon becomes proficient in LASIK. Different techniques can help provide more exposure. Downward pressure on the speculum will often result in slight proptosis. An adjustable wire eyelid speculum usually offers the most exposure with the least interference with the suction ring. Once the speculum has been maximally expanded, a short wait will allow further expansion of a few millimeters. A lateral canthotomy and retrobulbar injection can be performed to increase exposure; however, these aggressive techniques are not well received by the patients. A very effective but technically more difficult technique to perform LASIK in very small orbits is to use the suction ring alone to separate the eyelids without a speculum. Peri-orbital skin can get caught in the microkeratome when LASIK is done without a speculum so caution is required with this technique.

Prevention: If adequate exposure cannot be obtained and the prescription is small, PRK or LASEK may be a safer refractive option in properly informed patients.

EXOPHTHALMIC EYES

Large orbits or exophthalmic eyes are ideal first cases to perform as exposure is maximal. However, there is often considerable orbital fat which allows for a certain amount of spring or ballottement to these eyes when applying the suction ring. This excessive movement can make fixation with the suction ring and the microkeratome pass slightly more difficult as the globe is not stationary. Redundant conjunctiva is often found in exophthalmic eyes which can occlude the suction ring holes without elevation of the true IOP, giving 'pseudo-suction' which is a normal suction pressure reading on the base unit while the IOP remains low.

Management: It is important that the surgeon does not become overconfident and careless because of the excellent exposure. Downward pressure on the speculum can render the eye less mobile in the orbit. Redundant folds of conjunctiva should be pushed away from the limbal region to avoid 'pseudo-suction.' Careful attention to checking the IOP will avoid thin flaps caused by 'pseudo-suction.'

Prevention: In cases when the interaction of the microkeratome and the eye is difficult or the suction level is inadequate, the surgeon should always remember that PRK or LASEK may be safer refractive options in properly informed patients.

EARLY POSTOPERATIVE COMPLICATIONS

FLAP STRIAE

Striae of the LASIK flap occur when it is folded onto itself. Striae generally have three sources: misalignment of the corneal flap after flap replacement, movement of the corneal flap during the first postoperative day, and the 'tenting effect' of the corneal flap over the ablated stromal bed. Obviously, a displaced flap or dislodged flap will also be associated with striae.

Clinical: Normally the striae are oriented horizontally with a nasal hinge and vertically with the superior hinge. Displaced flaps will often have oblique striae. Retroillumination of the fixation light and aiming beam through the dilated pupil provides accurate localization of the flap striae and will help identify striae in cases of unexplained reduction of best corrected visual acuity (BCVA) (Fig. 94.8). Fluorescein staining of the cornea will also assist in identifying subtle striae. If the striae have occurred due to flap movement or displacement after LASIK, the flap may be noted to have shifted 1–2 mm leaving an area of exposed stromal bed. It is helpful to grade striae to assist with the description of their severity and to plan treatment (Table 94.1, Figs 94.9–94.11).

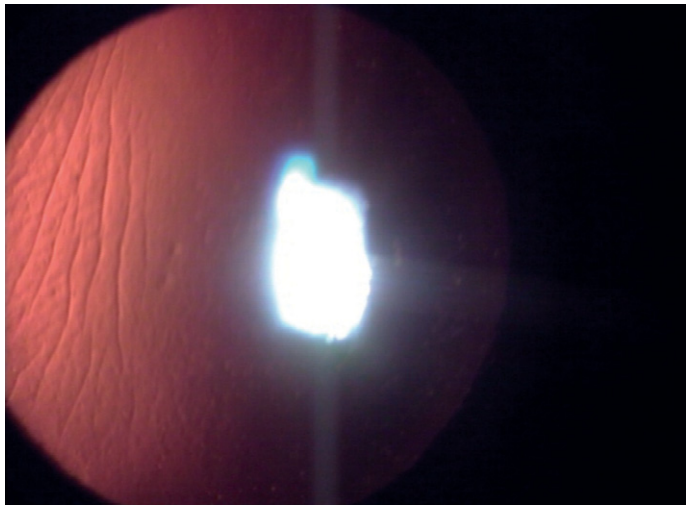

Figure 94.8. Peripheral striae are demonstrated by retroillumination.

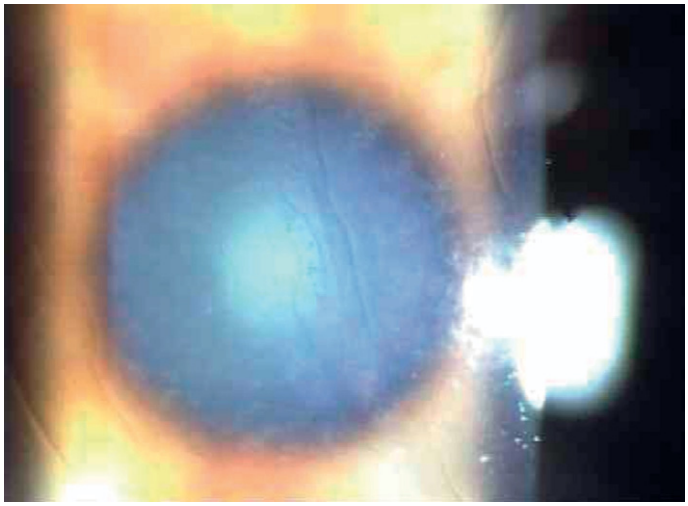

Figure 94.9. Grade 1 mild vertical striae may not affect visual performance.

Table 94.1 Probst classification of flap striae

Grade 1
Fine parallel lines
Difficult to identify
Not in visual axis
No reduction in UCVA or BCVA
No treatment required
Grade 2
Fine parallel lines in flap
Identification obvious
Extent through visual axis
BCVA reduced to 20/25–20/40
Less than one diopter of induced astigmatism
Patient may complain of diplopia
Treatment may be required due to the reduction in the BCVA or the induced astigmatism
Grade 3
Large parallel or 'basket weave' pattern
Identification obvious
Extent through visual axis
BCVA worse than 20/40
One or more diopters of induced astigmatism
Patient may complain of blur, diplopia, and glare
Treatment required to restore BCVA and reduce astigmatism, diplopia, and glare

UCVA = Uncorrected visual acuity.
BCVA = Best corrected visual acuity.

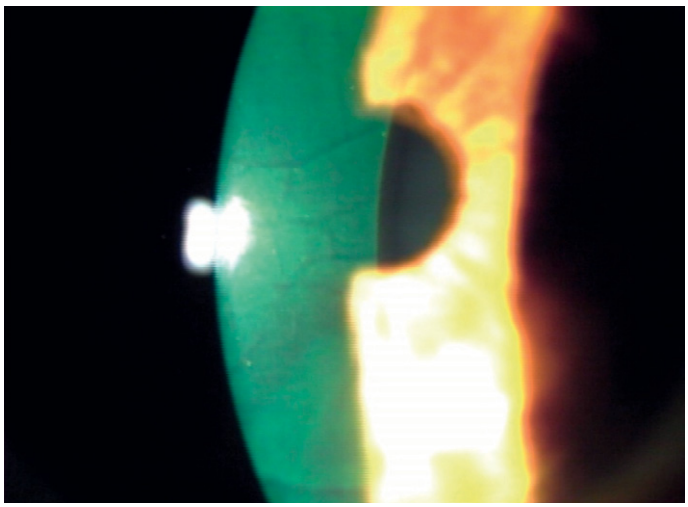

Figure 94.10. Grade 2 striae in a 'basket weave' configuration will reduce the BCVA.

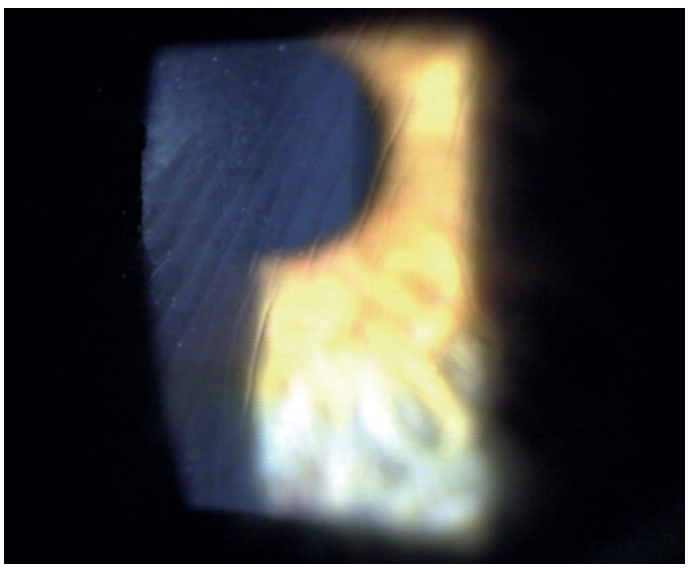

Figure 94.11. Grade 3 severe vertical striae may occur with a displaced flap.

Management: Most flap striae occur within the first hour after LASIK. Flap striae become more difficult to remove as the length of the postoperative course increases, therefore identification of the striae on the first postoperative day is imperative. The indications for the treatment of striae include flap striae that extend through the visual axis, striae causing a decrease in BCVA or diplopia, or striae inducing regular or irregular astigmatism. There have been several techniques described for the removal of flap striae. These include the stretch and smooth technique,[13] flap hydration with hypotonic saline epithelial debridement,[14] flap applanation, photo-therapeutic keratectomy,[15] and flap suturing.[16]

The stretch and smooth technique is the most recognized. The flap edge is first marked at the slit lamp to allow for easy lifting of the flap once the patient is under the microscope. No flap alignment markings are necessary as the flap will be re-aligned in a more correct position when replaced. The flap is then reflected back onto the conjunctiva. The stromal surface of the flap is hydrated with BSS solution for 30–60 s. Some surgeons have suggested the using of a hypotonic irrigation fluid of 80% BSS/20% sterile water mixture to induce flap hydration to assist in flap removal. The flap is replaced in the stromal bed and floated into position with interface irrigation. The flap is left for 5 min to attach to the stromal bed and dry the epithelial surface. The side of blunt forceps is used to stretch the flap perpendicular to the striae for 5–10 min or until epithelial defects start to occur. At the end of the procedure striae will still be visible after stretching; however, will be gone in 24 h. This technique is effective in 90% of striae; however, it can be repeated in 2–4 weeks if necessary.

Prevention: Intraoperative attention to the repositioning of the flap with minimal manipulation once it has been replaced into the correct position. Postoperatively, patients are instructed to avoid rubbing or squeezing the eye. Patients wear eye protection 24 h a day for the first week to prevent any eye trauma while the flaps are healing.

DISLODGED FLAP

A dislodged flap (flap subluxation or dehiscence) occurs when the flap is completely separated from the stromal bed. This most commonly occurs during the first 24 h postoperatively as the flap is still adhering to the stromal bed. Rarely, late dislocation of the flap can occur with corneal trauma.[17,18] With proper LASIK technique and postoperative care, the incidence of flap movement should be less than 1/1000 although an incidence of over 1% has been reported.[19]

Clinical: With nasal flaps, the dislodged flap is found rolled onto the nasal conjunctiva. If the flap has been dislodged for a few hours, it is usually very edematous. The patients are acutely aware of this problem as their vision is extremely blurred (<20/200) and the eye can be painful. With superior hinged flaps, the dislodged flap is usually found 4–5 mm onto the nasal conjunctiva. Epithelium can be seen growing over the area of exposed stromal bed (Fig. 94.12). The flap will have obvious striae and folds; however, they may be disguised by the flap edema.

Management: Patients with dislodged flap should be treated as urgently as possible. Prior to treatment, lubrication and an eye patch can improve the discomfort. Once at the surgical center, the flap is unrolled and smoothed out. The stromal side of the flap and the stromal bed must be thoroughly cleaned of all debris and mucous. The epithelium growing over the area of the exposed stroma should also be removed. The flap is then replaced and allowed to adhere to the stromal bed for at least 5 min because of the edematous state. The flap striae should then be treated as described above. Finally, a CTL should be placed on the eye to safeguard a repeat dislodgement of the flap. When managed properly, the outcome should not be compromised by flap dislodgement.[19]

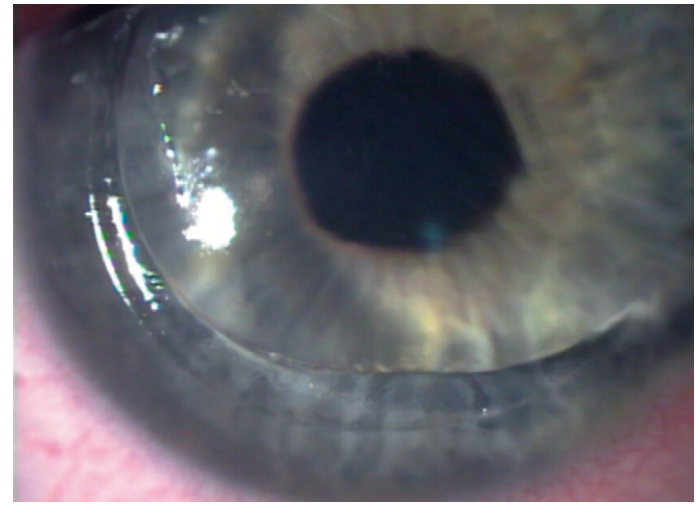

Figure 94.12. Superiorly dislodged flap with exposed stromal bed inferiorly.

Prevention: For the first postoperative day, patients are advised to go home and have a 4 h sleep. This is the critical step to allow their eyes to heal without disturbance immediately after the procedure. For the first postoperative week, patients should be warned not to touch or rub their eyes. Patients should be sent home wearing sunglasses or clear eye shields and instructed to wear these whenever possible. The shields should be worn at night. Patients can participate in any activity that does not involve touching, rubbing, irritating, or squeezing their eyes.

INFECTION

Infections rarely occur after LASIK. However, a recent review of the world literature found that 41 cases have been reported to date.[20] The causative organisms vary from gram positive bacteria to atypical mycobacteria, fungal, and viral pathogens. The infection is usually acquired intraoperatively, but may also be caused by postoperative contamination. While infections are generally unilateral, a bilateral infection after bilateral LASIK has now been reported.[21]

Clinical: The majority of bacterial keratitis patients present within 72 h of the surgery with an acute onset of symptoms.[20] Bacterial infection should be suspected whenever a localized infiltrate is identified either on the surface of the flap or at the flap interface. The infective infiltrate is generally localized, about 1–2 mm in size and white/gray in color with indistinct margins. If located on the surface of the cornea, it may be slightly elevated and associated with an epithelial defect. If allowed to progress without treatment, it will slowly increase in size like an early cornea ulcer. Inflammation of the cornea with surrounding interface keratitis, conjunctival injection, and an anterior chamber reaction may all occur if the infection persists. Reactivation of herpes simplex[22] and zoster[23] viral infections has also been reported after LASIK and presents with corneal dendrites in the postoperative period. Fungal infections after LASIK have a delayed onset and have been related to topical prolonged steroid use after LASIK.[24]

Management: Any suspected corneal infection should be treated immediately. For suspected bacterial infections, hourly topical fluoroquinolones are the obvious first course of treatment. Topical steroids should be discontinued or reduced. Patients should be followed daily. If the infiltrate is larger than 1 mm, increasing in size, or associated with ocular inflammation, a full evaluation by a corneal specialist is recommended. Cultures with microbiological evaluation and fortified antibiotics may be required. If the infiltrate is under the flap, the flap should be lifted, cultures should be taken off the infiltrate from the stromal bed, the infiltrate should be removed, the interface then irrigated, and antibiotics placed in the interface before the flap is replaced. The keratitis can result is some corneal scarring. A BCVA of 20/40 or better can be obtained in the majority of the patients.[20]

Corneal epithelial dendrites that occur in any postoperative LASIK patient, particularly those with a past history of herpes simplex keratitis or herpes zoster, should be treated immediately with the appropriate topical and oral antiviral therapy.

Prevention: Prevention of epithelial defects during and after LASIK should greatly reduce or eliminate the risk of a superficial bacterial corneal infection. Infection at the flap interface is avoided by preventing contamination of the instruments used to treat the interface. Microkeratome heads are sterilized for each patient. New sterile blades are used for each patient. Instruments should also be sterilized. Disposable instruments such as microkeratomes or cannulas ensure the sterility of that step of the procedure. Sterile BSS is used for interface irrigation. While LASIK is not currently a true 'sterile' procedure, all efforts that move in this direction should reduce the risk of infection further.

If a patient had a past history of herpes simplex or zoster infection, a prophylactic course of oral antiviral is recommended 1 week prior and 1 week after the LASIK procedure. Doses of acyclovir from 200–800 mg 5 times per day have been recommended by various LASIK experts. This author treated at least 20 patients with a past history of herpetic keratitis with this regimen and never experienced viral reactivation.

DIFFUSE LAMELLAR KERATITIS (SANDS OF SAHARA)

Diffuse lamellar keratitis (DLK) is referred to by several names, including Sands of Sahara, Sands, nonspecific diffuse interface keratitis, and LASIK interface keratitis (LIK). DLK and Sands are the most common terms. The cause of DLK has remained somewhat of an enigma. Holland et al have demonstrated the risk of DLK from the bacterial cell wall endotoxins that build up in the wet autoclave reservoirs.[25] Epithelial defects have been associated with focal DLK.[26] DLK has been reported months after LASIK associated with ocular inflammation,[27] ocular trauma,[28] and without an obvious etiology.[29] Other causes that have been proposed but remain unproven include cleaning solutions,[30] talc from gloves, Meibomian gland secretions, microkeratome oil, rust on instruments, blade debris, iodine skin cleaners, and carboxymethylcellulose lubrication drops.[31] DLK is a postoperative interface inflammation that occurs in the 24–72 h postoperative period. Late activation of DLK without an identified cause has also been reported.[29] The incidence is thought to be 1:200 to 1:500 cases, but may occur in sequential patients (outbreaks) at a specific location.

Clinical: DLK presents with varying severity, and with patient symptoms ranging from asymptomatic to mild pain, photophobia, and decrease in vision (usually a hyperopic shift). The presentation of DLK can be graded according to the severity of the presentation (Table 94.2, Figs 94.13–94.20).[32] The clinical appearance typically begins in the periphery and is confined to the flap interface without extension into the surrounding stroma. Untreated, this may lead to central inflammation affecting visual acuity secondary to induced hyperopia or irregular astigmatism. It may present with multiple foci, which are diffusely distributed and are often more concentrated around interface debris. Early, subtle DLK may be difficult to differentiate from postoperative superficial punctate keratitis (SPK) or mild interface debris. SPK is always on the corneal surface and will stain with fluorescein. DLK is at the level of the interface and does not stain with fluorescein. There is no anterior chamber reaction in DLK except in the most advanced cases.

Management: Early identification and intervention are the key steps for successful management of DLK. When grades 1 or 2 DLK are identified, the patient should immediately be started on topical steroid every 1–2 h and an antibiotic q.i.d. for prophylaxis against infection.[33] If grade 3 DLK is identified or grade 2 DLK has not resolved after several days of treatment, the flap should be lifted and the interface irrigated. All these measures aim to prevent the progression to grade 4 DLK with central accumulation of cells, central corneal haze and striae, decreased BCVA, and a hyperopic shift. Grade 4 DLK also requires urgent flap irrigation along with flap stretching, and frequent topical steroids after. While PTK has been suggested as another treatment for DLK,[34] this can cause iatrogenic hyperopia.

Prevention: Since epithelial defects have been associated with DLK, the LASIK surgeon should strive to avoid epithelial defects whenever possible. Autoclave reservoirs of wet autoclaves should be drained and cleaned at the end of each day. Instruments should also be cleaned and dried at the end of each day. These maneuvers aim to eliminate the wet environment that could allow the proliferation of gram-negative bacteria that produce the bacterial cell wall endotoxins proposed to be an etiological agent of DLK. Dry autoclaves may offer a safer method of sterilization if DLK becomes recurrent. Disposable instruments offer another method of avoiding a toxic contaminant to the LASIK process. Topical steroids should be used for all patients for a few days after LASIK to suppress any subclinical inflammation.

LATE POSTOPERATIVE LASIK COMPLICATIONS

EPITHELIAL INGROWTH

Carr and coworkers[35] reviewed the risk factors and the incidence of epithelial ingrowth following 1246 consecutive cases of LASIK. Epithelial ingrowth underneath the flap following LASIK was identified in 14.7% of cases. While most of these cases had small amounts of self-limited insignificant ingrowth, 1.7% of all the LASIK cases required flap revision for the removal of significant ingrowth. In another study of 3786 eyes, significant epithelial ingrowth occurred in 0.9% of primary LASIK cases and 1.7% of enhancement cases.[36]

Preoperatively, any factor that contributes to an epithelial defect will increase the risk of epithelial ingrowth. This includes anterior basement membrane dystrophy and a history of recurrent erosions. Helena and colleagues found that ingrowth was associated with some cases of postoperative inflammation.[37] Carr and coworkers[35] found that postoperative epithelial defects, repeat LASIK rather than primary LASIK, postoperative flap slippage within 24 h, and micro-

Table 94.2 Grading of diffuse lamellar keratitis (DLK)

1. Grade 1 DLK

Clinical presentation

- Focal, white to gray, granular material in the LASIK flap interface 1–7 days after LASIK
- No other ocular inflammation/anterior chamber reaction
- Normal visual acuity

Treatment

- Intensive topical steroids every hour with follow-up every 2–3 days to ensure complete resolution

Prognosis

- Excellent after topical steroids and one week for stabilization

2. Grade 2 DLK

Clinical presentation

- Diffuse, white to gray, granular material under the LASIK flap interface 1–7 days after LASIK
- No other ocular inflammation/anterior chamber reaction
- Normal visual acuity

Treatment

- Interface irrigation has an immediate curative effect
- Intensive hourly topical steroids after irrigation
- Follow-up daily to ensure resolution

Prognosis

- Excellent after interface irrigation, topical steroids and 1–2 weeks of stabilization

3. Grade 3 DLK

Clinical presentation

- Diffuse, confluent, white to gray, granular material under the LASIK flap interface 1–7 days after LASIK
- Slight conjunctival injection
- No anterior chamber reaction
- Reduced visual acuity

Treatment

- Interface irrigation has an immediate curative effect
- Intensive hourly topical steroids after irrigation
- Follow-up daily to ensure resolution
- Repeat irrigation in 1–2 days if the inflammation does not resolve
- Topical steroid and antibiotics can been placed on the stromal bed to directly address the area of inflammation

Prognosis

- Excellent after interface irrigation, topical steroids, and several weeks of stabilization

4. Grade 4 DLK

Clinical presentation

- Diffuse, confluent, white to gray, granular material under the LASIK flap interface 1–7 days after LASIK
- Inflammation localized to a 2–4 mm area of intense central inflammation
- Central interface striae in area of inflammation
- Slight conjunctival injection
- No anterior chamber reaction
- Markedly reduced visual acuity

Treatment

- Interface irrigation has an immediate effect
- Wipe the stromal bed with Murocel sponges
- Topical steroid and antibiotics can be placed on the stromal bed to directly address the area of inflammation
- Intensive hourly topical steroids after irrigation
- Follow-up daily to ensure resolution
- Repeat irrigation in 1–2 days if the inflammation does not resolve

Prognosis

- Reduced BCVA and irregular astigmatism with residual hyperopia will persist after the resolution of the inflammation due to the residual interface haze and stromal thinning
- Persistent interface striae may also reduce the final BCVA

BCVA = Best corrected visual acuity.

perforation at the time of simultaneous Arc-T were significant risk factors for epithelial ingrowth after LASIK. Prior surgeon experience was found to be significantly protective against epithelial ingrowth. All of these factors are likely to be related to a disturbance of the epithelial layer during LASIK. Once the epithelium is stimulated to replicate and migrate to heal an epithelial defect, the incidence of epithelial ingrowth will increase.

Clinical: Most commonly, the patient is asymptomatic and the ingrowth is identified on a scheduled postoperative visit as a faint gray line extending less than 2 mm in from the flap edge. The ingrowth can be so discrete that it may be passed over with a quick inspection of the cornea. Epithelial ingrowth can be associated with a mild foreign body sensation that generally indicates an epithelial irregularity along the flap edge associated with the ingrowth. The visual acuity will be unaffected or drop one line of BCVA[37] except in the most severe cases when progression occurs into the visual axis.

The ingrowth is best identified with the direct focal tangential illumination of the slit-lamp biomicroscope. It is generally white to gray in color and can be seen to be located beneath the corneal flap. White to gray areas of stromal haze can occur in areas of previous ingrowth or surrounding an active area of ingrowth. Irregular fluorescein staining and pooling is often identified at the flap edge associated with the ingrowth. Surface irregularities associated with the epithelial ingrowth can be identified with corneal topography.[37] Retroillumination through the dilated pupil can also be useful to delineate the margins of large sheets of ingrowth that have extended near the visual axis. Epithelial ingrowth usually occurs on the superior and inferior regions of the nasal based flap made with the Chiron Vision ACS, although any region of the flap may

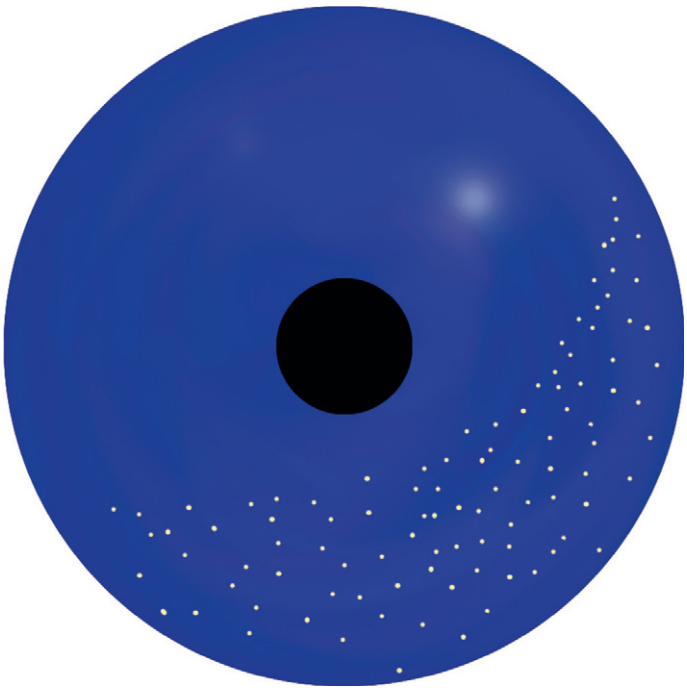

Figure 94.14. Grade 1 DLK illustration. (From Linebarger EJ, Hardten DR, Lindstrom RL. Diffuse lamellar keratitis: diagnosis and management. J Cataract Refract Surg 2000; 26: 1072–1077.)

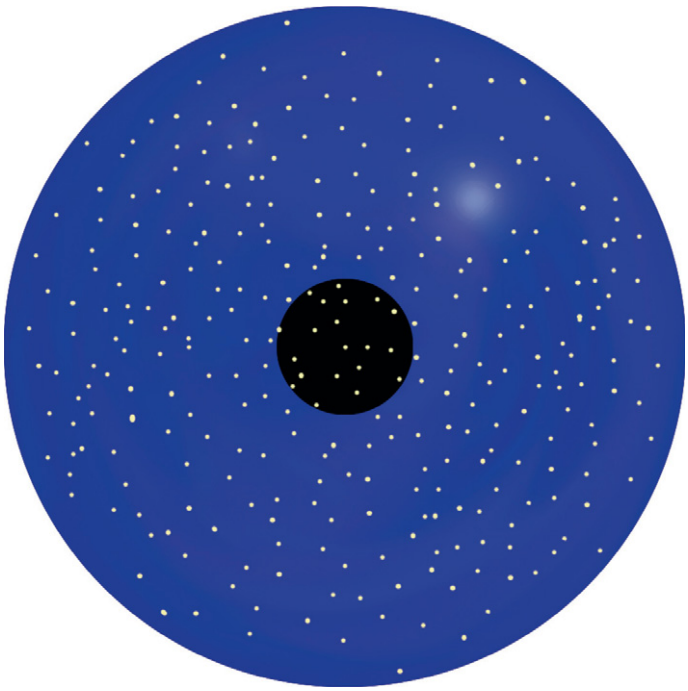

Figure 94.16. Grade 2 DLK illustration. (From Linebarger EJ, Hardten DR, Lindstrom RL. Diffuse lamellar keratitis: diagnosis and management. J Cataract Refract Surg 2000; 26: 1072–1077.)

be affected. The Hansatome tends to be associated with inferior epithelial ingrowth.

Epithelial ingrowth following LASIK can occur in a number of different patterns which can be divided into a classification system of grades that assist with identification and treatment (Table 94.3). Grade 1 is the most common pattern with a fine white line 2 mm inside the flap edge, which is seen in up to 10% of patients (Fig. 94.21). This type of ingrowth generally demonstrates very slow progression that arrests without treatment in a few weeks. Grades 2 and 3 ingrowth are more aggressive forms that tend to be progressive and often require treatment. The affected area should have slit-lamp measurements of the extension of the ingrowth from the flap edge. It can occur in patterns with epithelial pearls or nests, strands, or sheets (Figs 94.22 and 94.23). Grade 4 ingrowth is the most aggressive pattern of ingrowth. It is characterized by strands of epithelial cells streaming underneath the flap toward the visual axis often as early as the first 3 weeks following LASIK. This can be associated with flap edge melting (Fig. 94.24). Obviously, this pattern of epithelial ingrowth requires urgent treatment to prevent further progression.

Management: Indications for treatment of epithelial ingrowth following LASIK include greater than 2 mm of ingrowth from the flap edge, documented progression, associated flap melting, or a disturbance of BCVA which can be attributed to the ingrowth.

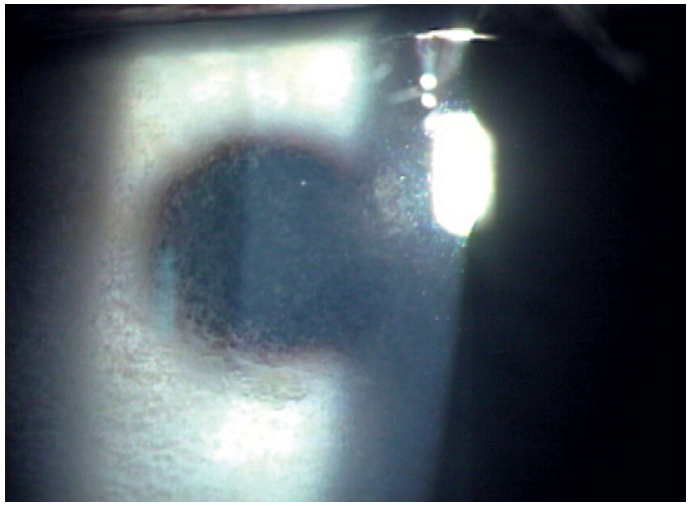

Figure 94.17. Grade 3 DLK with obvious inflammatory diffuse material in the flap interface.

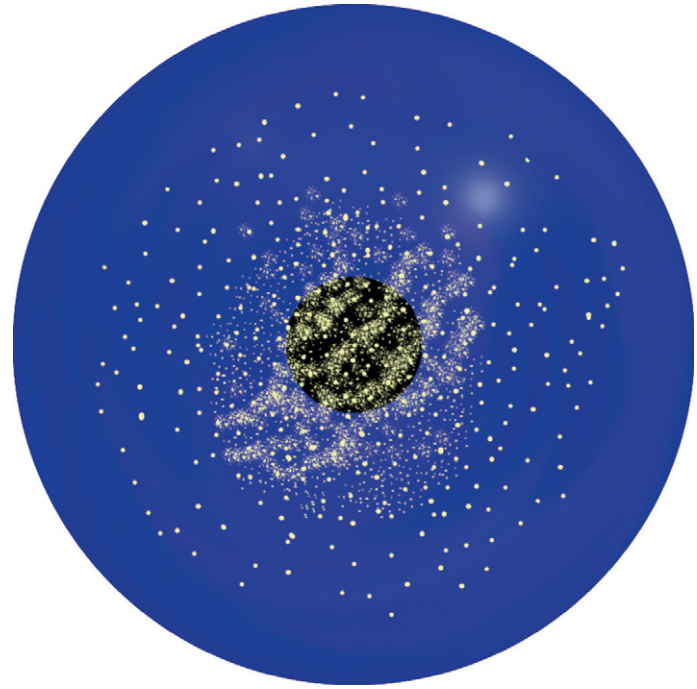

Figure 94.20. Grade 4 DLK illustration. (From Linebarger EJ, Hardten DR, Lindstrom RL. Diffuse lamellar keratitis: diagnosis and management. J Cataract Refract Surg 2000; 26: 1072–1077.)

Epithelial ingrowth removal has been described by several different methods. Generally the flap is lifted and the epithelial ingrowth is removed from the stromal bed and the stromal side of the flap (Fig. 94.25). Since the ingrowth is generally transparent, great care must be used to remove all the ingrowth. Ingrowth that has been present for a short time (<4 weeks) generally slides off the stroma with gentle pressure from a Murocel spear. When the ingrowth has been present for longer, it tends to be more adherent so a dull surgical blade can be used to scrape the ingrowth off the stromal bed. The flap can then be replaced and the interface is generously irrigated to remove any additional epithelial cells. Generally, these two steps are all that is required for complete epithelial removal without recurrence.

Surgeons have suggested that alcohol can be applied to the stromal area of ingrowth to ensure that all the epithelial cells are destroyed.[38] Because alcohol can be toxic to the stroma, this technique should be used sparingly. Phototherapeutic keratectomy of approximately 10 µm has been used by some surgeons to successfully clean the bed after epithelial ingrowth removal.[39] As it may induce a refractive effect, this technique is best reserved for recurrent cases of ingrowth. Suturing of the flap to the stromal bed has also been reported as successful for recurrent cases of epithelial ingrowth.[40] Rarely, epithelial flap removal or corneal transplant may be required.[39]

Prevention: Preoperatively, anterior basement membrane dystrophy, a history of recurrent corneal erosions, advanced age, or a

Table 94.3 Probst/machat epithelial ingrowth classification

Grade 1: thin ingrowth, 1–2 cells thick, limited to within 2 mm of flap edge, transparent, difficult to detect, well-delineated white line along advancing edge, no associated flap changes, nonprogressive
No treatment required
Grade 2: thicker ingrowth, discreet cells evident within nest, at least 2 mm from flap edge, individual cells translucent, easily seen on slit-lamp, no demarcation line along nest, corneal flap edge rolled or gray, no flap edge melting or erosion, usually progressive
Requires non-urgent treatment within 2–3 weeks
Grade 3: pronounced ingrowth, several cells thick, greater than 2 mm from flap edge, ingrowth areas opaque, obvious on slit-lamp, white geographic areas of necrotic epithelial cells with no demarcation line, corneal flap margins rolled with thickened whitish-gray appearance. Progression results in large areas of flap melting from collagenase release from the necrotic epithelium. Confluent haze develops peripheral to the flap edge as flap pulls away leaving exposed stromal bed in contact with surface epithelium
Urgent treatment required with close follow-up, as recurrences are more common due to the altered flap edges

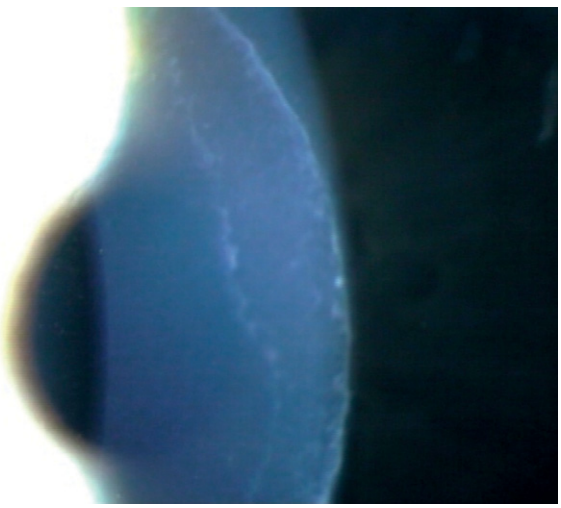

Figure 94.21. Grade 1 epithelial ingrowth with a faint white border inside the flap edge.

history of ingrowth in the other eye would all increase the risk of epithelial ingrowth following LASIK. When one or more of these factors are identified preoperatively, the refractive surgeon must carefully consider whether another refractive option such as PRK would be safer with less potential postoperative complications.

MYOPIC UNDERCORRECTION AND REGRESSION

Ever since LASIK has been performed, enhancements have been required. Due to the normal distribution of LASIK outcomes, some patients will be initially undercorrected. The variability in the corneal healing after LASIK has made LASIK enhancements inevitable. With modern LASIK techniques and excimer lasers the

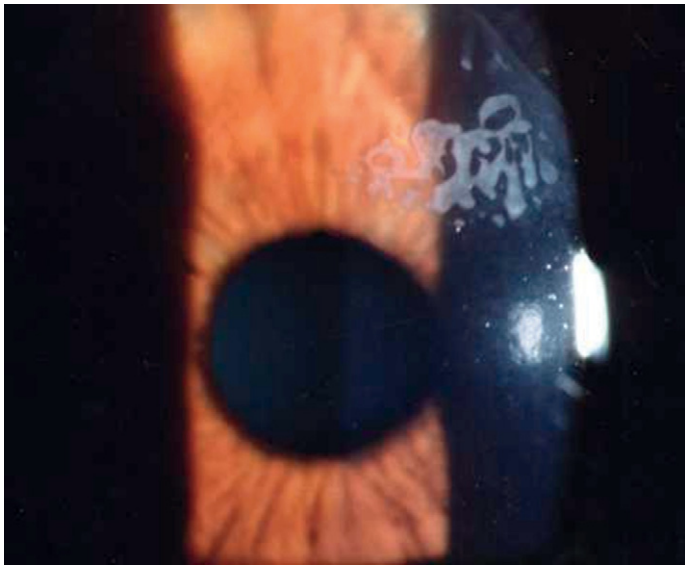

Figure 94.22. Grade 2 epithelial ingrowth with a superior 'grape-like' cluster of epithelium under the flap.

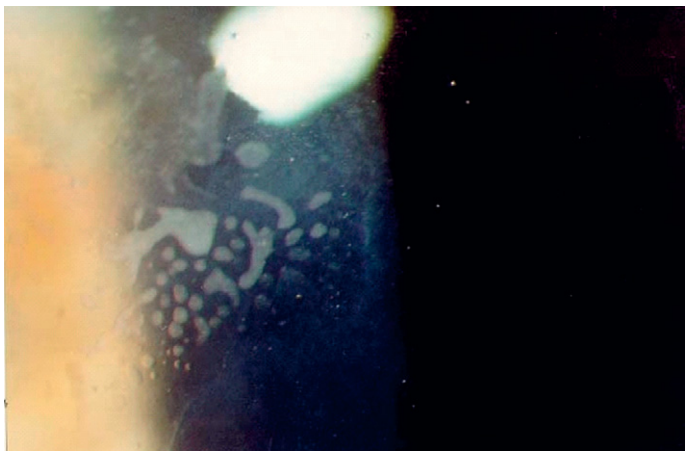

Figure 94.23. Grade 3 epithelial ingrowth with diffuse clusters of epithelial cells extending more than 2 mm from the flap edge.

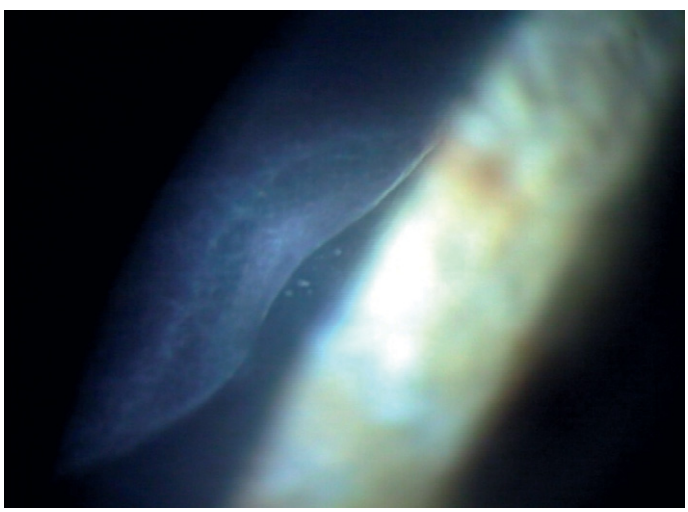

Figure 94.24. Grade 4 epithelial ingrowth is often associated with a flap edge melt.

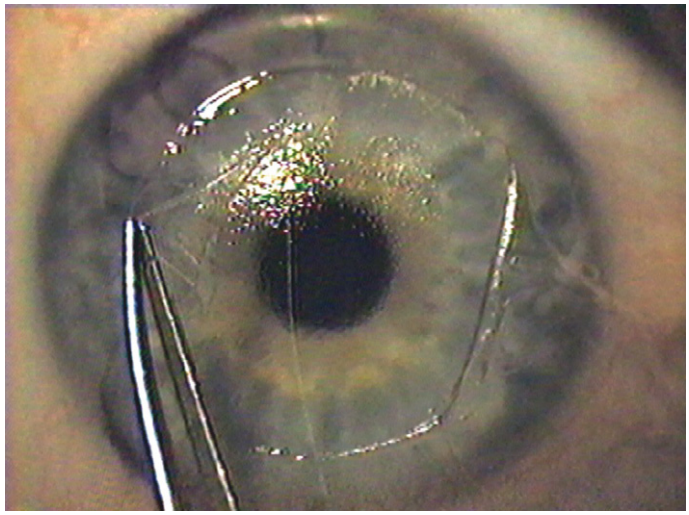

Figure 94.25. The translucent sheet of epithelial ingrowth can be peeled off the stromal bed with forceps.

enhancement rate for myopic LASIK can be generally estimated as 1% per diopter of spherical correction. The enhancement rate for astigmatism is higher at approximately 10% per diopter of astigmatic correction. A patient who has −2.00 D correction would have an enhancement rate of approximately 2% while a patient with −2.00 D of spherical correction and −2.00 D of astigmatic correction would have an enhancement rate of approximately 22%.

Clinical: Myopic LASIK undercorrections are noted immediately as the patient's postoperative UCVA on day 1 will be poor. Regression of the refractive effect usually occurs over the next several months, but rarely can occur years after the primary LASIK. In either case, the patient will be unable to function without glasses or contacts if the undercorrection and regression is significant and bilateral. Patients may also complain of night glare. Presbyopic patients may have their uncorrected near vision restored.

Management: Patients with undercorrections should be prescribed temporary glasses by the end of the first week of surgery or fitted with disposable CTL after 1–2 weeks. Patient symptoms dramatically reduce once some form of temporary correction is obtained pending additional surgical treatment.

Refractive stability should be achieved prior to performing any LASIK enhancement. Generally, it could be estimated that approximately 1 month is required for each diopter of LASIK correction in order to achieve refractive stability. In practice, however, most LASIK enhancements are not performed earlier than the 3–4 month time period, and most large enhancements can be performed at the 6–7 month postoperative LASIK period and achieve excellent results.

Prior to every LASIK enhancement the corneal thickness should be re-measured. The Orbscan will routinely underestimate the thickness of the cornea for LASIK enhancement. This is because this device uses optical pachymetry and will erroneously measure the LASIK flap interface as the posterior edge of the cornea yielding lower corneal pachymetry results. Therefore during LASIK enhancements accurate pachymetry of the cornea is best obtained with ultrasound measurements. As in primary LASIK, at least 250 µm of posterior stroma should be preserved following a LASIK enhancement in order to ensure that the risk of long-term corneal ectasia is minimized. If we assume that the original corneal flap was approximately 160 µm, this means that the minimum corneal thickness that should be preserved after a LASIK enhancement would be approximately 410 µm.

The Orbscan is extremely useful for preoperative evaluation of the LASIK patient as it demonstrates several other conditions that should be monitored prior to performing any additional procedures on the cornea. The anterior flow map of the Orbscan will demonstrate if there are any anterior surface irregularities. More significant, however, is the posterior float map, which can demonstrate any areas of posterior corneal ectasia. If the degree of posterior corneal ectasia on the Orbscan is greater than 50 µm, this indicates that the cornea may be showing some early signs of ectasia and instability as a result of the original LASIK procedure. Furthermore, this ectasia may be contributing to the regressive effect of the cornea. Therefore, large amounts of corneal ectasia, although rarely seen, should be considered a contraindication for a LASIK enhancement procedure. The Orbscan refractive map will demonstrate any irregular topographic patterns. If any irregular patterns are demonstrated on the preoperative LASIK enhancement evaluation the procedure should also be cancelled.

Over the last year and a half, pupil testing has become a standard prior to the preoperative LASIK workup. Prior to this there was really no pupil testing devices available nor was this test regularly performed. It is therefore very important to measure people's pupils prior to the LASIK enhancement to determine whether the original laser settings were indeed appropriate and the feasibility of performing an additional LASIK procedure. The most commonly used device at this time is the Colvard pupillometer. Generally, the blend zone should extend outside the measured pupil size.

For patients who are over the age of 40, the LASIK enhancement often offers an opportunity to revisit the option of monovision. Patients may elect for unilateral LASIK enhancements in order to give monovision a second try. It is important to evaluate older patients with late 'regression' for potential cataract formation because a LASIK enhancement will only temporarily solve their problem, as once the nuclear sclerosis progresses further they will require a cataract procedure.

Prevention: Myopic LASIK undercorrections can be minimized by ensuring a stable refraction preoperatively and careful nomogram adjustment for both the patient's age and the refractive error. The laser room humidity and temperature should also be controlled so the temperature stays between 65°–75° Fahrenheit and the humidity between 30–40%. Although the need for LASIK enhancements cannot be eliminated, the risk can be lowered by careful control of these factors.

ERRORS IN HYPEROPIC REFRACTIVE OUTCOME

The variability in the corneal healing after LASIK has made LASIK enhancements inevitable. With modern hyperopic LASIK techniques and excimer lasers the enhancement rate can be generally estimated as 10% per diopter of spherical correction and 10% per diopter of astigmatic correction. Regression is particularly common with correction over 3.0 D of hyperopia.

Clinical: Hyperopic LASIK undercorrections are noted immediately as the patient's postoperative UCVA on day 1 will be poor. Regression of the refractive effect usually occurs over the next several months, but rarely can occur years after the primary LASIK. In either case, the patient will be unable to function without glasses or contact lenses if the undercorrection and regression is significant and bilateral. Patients may also complain of night glare.

Management: Patients with residual refractive errors should be prescribed temporary glasses by the end of the first week of surgery or fitted with disposable CTL after 1–2 weeks. Patient symptoms dramatically reduce once some form of temporary correction is obtained pending additional surgical treatment. Refractive stability should be achieved prior to performing any LASIK enhancement. Generally, it could be estimated that approximately 1 month is required for each diopter of LASIK correction in order to achieve refractive stability. In practice, however, most LASIK enhancements are not performed earlier than the 3–4 month time period, and most large enhancements can be performed at the 6–7 month postoperative LASIK period and achieve excellent results.

The Orbscan will underestimate the thickness of the cornea for LASIK enhancement; therefore, accurate pachymetry of the cornea is best obtained with ultrasound measurements. As in primary LASIK, at least 250 μm of posterior stroma or a total corneal thickness of 410 μm should be preserved following a LASIK enhancement in order to ensure that the risk of long-term corneal ectasia is minimized. If posterior corneal ectasia on the Orbscan is greater than 50 μm, this indicates that the cornea may be showing some early signs of ectasia and instability as a result of the original LASIK procedure which may be contributing to the refractive regression. Irregular topographic patterns are also a contraindication to LASIK enhancement. The pupil size should be measured to allow for appropriate settings of the ablation zone size.

It is important to evaluate older patients with late 'regression' for potential cataract formation because a LASIK enhancement will only temporarily solve their problem, as once the nuclear sclerosis progresses further they will require a cataract procedure. With eyes less than 410 μm of thickness, the Holmium LTK procedure offers an alternative method of correcting spherical iatrogenic hyperopia for up to 3.0 D.

Lifting the original corneal flap is the preferred technique for enhancement as re-cutting over the original flap can occasionally result in a free wedge of tissue which is difficult to manage.[41] This technique is still effective if a smaller 8.5 mm flap is used as the steepening effective of the hyperopic enhancement is within the treatment optical zone with the blend zone providing no refractive effect.

Prevention: All patients should have a cycloplegic refraction to ensure that accommodation does not occur during the preoperative refraction. Tight control of the operating room environment will improve the consistency of the results. Humidity should be kept in the 30–40% range and the temperature between 65 and 75° Fahrenheit. Low room humidity and high temperatures have been associated with overcorrections. The LASIK nomogram should be set to target slight myopia so that the effect of regression is minimized.

POSTOPERATIVE KERATECTASIA FOLLOWING LASIK

Corneal ectasia following LASIK has been recognized as an uncommon complication of LASIK. In a study of 2873 eyes, 19 eyes (0.66%) developed post-LASIK ectasia.[42] None of the eyes with ectasia had less than 8.00 D of preoperative myopia or a residual corneal bed thickness greater than 325 μm.

Clinical: Corneal ectasia usually presents 1–12 months after the original LASIK procedure.[43–45] The patients often have large LASIK corrections of over 8 D. Most cases involve a final corneal thickness of less than 400 μm associated with the ectasia with less than 250 μm of presumed posterior corneal stroma; however, exceptions to this rule have been reported.[46,47] Ectasia is usually associated with regression of the refractive effect, loss of UCVA and BCVA, and irregular astigmatism. Topography demonstrates irregular astigmatism often with inferior steepening of the cornea. The Orbscan will demonstrate posterior corneal ectasia on the posterior float map with a deep orange to red color in the central area of the cornea with maximum thinning in the same area of the pachymetry map (Fig. 94.26). Furthermore, this ectasia may be contributing to the regressive effect of the cornea.

Management: Any signs of corneal ectasia on the anterior cornea or posterior cornea should preclude any further LASIK as this could exacerbate the ectasia. Patients are best treated with hard CTL if these can be fitted comfortably. Unfortunately, some of these patients must go on to receive corneal transplantation in order to restore functional vision.

Prevention: Patients with keratoconus or other corneal thinning disorders identified on topography should not have LASIK as LASIK will hasten the onset of keratectasia.[48–50] At least 250 μm of posterior stroma should be preserved following LASIK in order to ensure that the risk of long-term corneal ectasia is minimized. If we assume that the original corneal flap was approximately 160 μm, this means that the minimum corneal thickness that should be preserved after a LASIK enhancement would be approximately 410 μm.[51]

LASIK surgeons should carefully calculate the ablation depth per diopter of their excimer laser to determine how many diopters of correction can still be performed while preserving an adequate amount of corneal thickness. Generally, most excimer lasers used at a 6 mm optical zone will remove approximately 13 μm per diopter but as the optical zone or the blend zone are increased this depth can increase to at least 15 μm per diopter and sometimes up to 20 μm per diopter.[51]

NIGHT VISION DISTURBANCES: HALOS AND GLARE

Night vision problems after LASIK have been reported extensively in the media; however, the incidence of significant night vision symptoms is not common. A study of 236 eyes treated on the Bausch & Lomb 217C laser for mild to moderate myopia found that while mild to moderate glare was reported by 10% more patients at the 6 months follow-up, there was no significant increase in marked or severe glare or halos.[52] There were no significant changes in night driving symptoms at any level after LASIK. Hyperopic LASIK tends to be performed on older patients with smaller pupil sizes; however, it also produces a smaller effective optical zone so the incidence of night vision problems is similar.

Clinical: There are two potential night vision problems that occur after LASIK. Halos are the concentric blur circles that surround a point source of light, such as a car headlight, when viewed at night. Halos occur when the optical zone size of the laser treatment are smaller than the mesopic pupil size. Glare is the distortion radiating from light sources at night. Glare occurs because of the optical aberrations of the optical system that are magnified when the pupil dilates at night. Topography can clearly identify the small effective optical zones associated with halos (Fig. 94.27).

Management: Patients who experience night glare postoperatively should be seen immediately as the loss of ability to drive at night can be a very stressful event. Patients are reassured that these symptoms generally abate over 3–6 months. Over the recovery

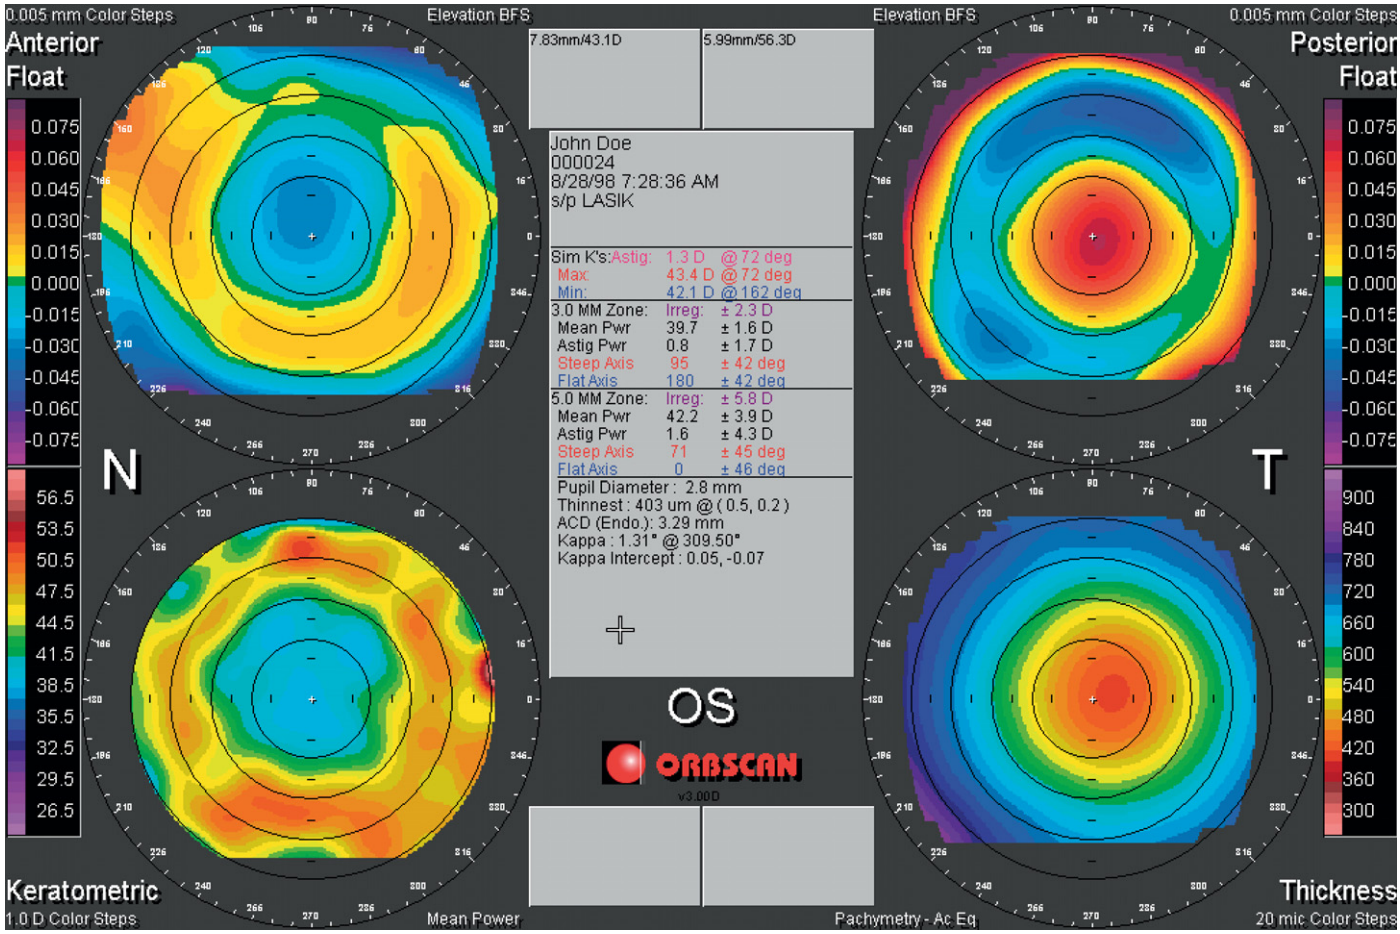

Figure 94.26. Postoperative LASIK Orbscan demonstrating posterior ectasia on the posterior float map.

phase, the treatment of dry eyes and any residual refractive error or monovision often improve the symptoms. For those patients who still have difficulties, night driving glasses, turning on the car dome light when driving, and rarely 1/8% pilocarpine drops just before night driving allow the patients to manage during the recovery phase. Alphagan has recently been found to reduce pupillary dilation at night with far fewer side effects than the pilocarpine.[53] For those rare patients with persistent night glare, custom/wavefront LASIK may offer a more refined method of enlarging the treatment zone.

Prevention: Pupillometry should be performed in all LASIK patients preoperatively to identify those with pupils larger than 6 mm in dim light. While the risks for night glare are multifactorial, the current most accepted treatment is to adjust the blend zone of the treatment correction to cover the measured pupil size.

CENTRAL ISLANDS

The central island is now a rare phenomena after LASIK, which more commonly occurred with broad beam lasers.[54] Central islands occur when the central cornea receives less effect from the excimer pulses than the peripheral cornea. All excimer lasers now use a scanning spot or rotating beam laser delivery system that in effect eliminate the risk of central islands. This author has not had a problem with central islands in the last 4 years with 20 000 LASIK procedures.

Clinical: A central island has been defined as an area of higher refractive power of more than 1.5 D and 2.5 mm or more in diameter[54] or 3.0 D and 1.5 mm in diameter.[55] Postoperative monocular diplopia, visual distortions, and myopia are the main symptoms associated with central islands. Patients with central islands are difficult to refract and have a disproportionately high degree of residual myopia relative to their uncorrected visual acuity. For example, a typical central island patient post-LASIK may have an uncorrected visual acuity of 20/30 with a measured refraction of –2.00 D. Eyes with central islands may also have reduced BCVA, often in the 20/25 or 20/30 range. A central island cannot be identified on slit-lamp examination. Unlike central islands observed with PRK, the topographical abnormalities observed with LASIK do not resolve over time.[56] Topographically, a central island appears as a 2–3 mm area of central steepening, which is red or a lighter shade of blue-green relative to the surrounding area, which is a darker green or more typically blue. The difference in the diopter height of the island compared to the peripheral cornea can range from 3–8 D.

Management: Corneal videokeratography allows the identification of central islands. Central islands are treated by using the Munnerlyn formula (depth of ablation = diameter^2 × diopter correction [height of the island]/3).[57] Computerized videokeratography is used to measure the diameter of the central island, and the height of the island is then calculated by noting the diopter color change between the surrounding ablation and the peak of the island.[55] Central islands

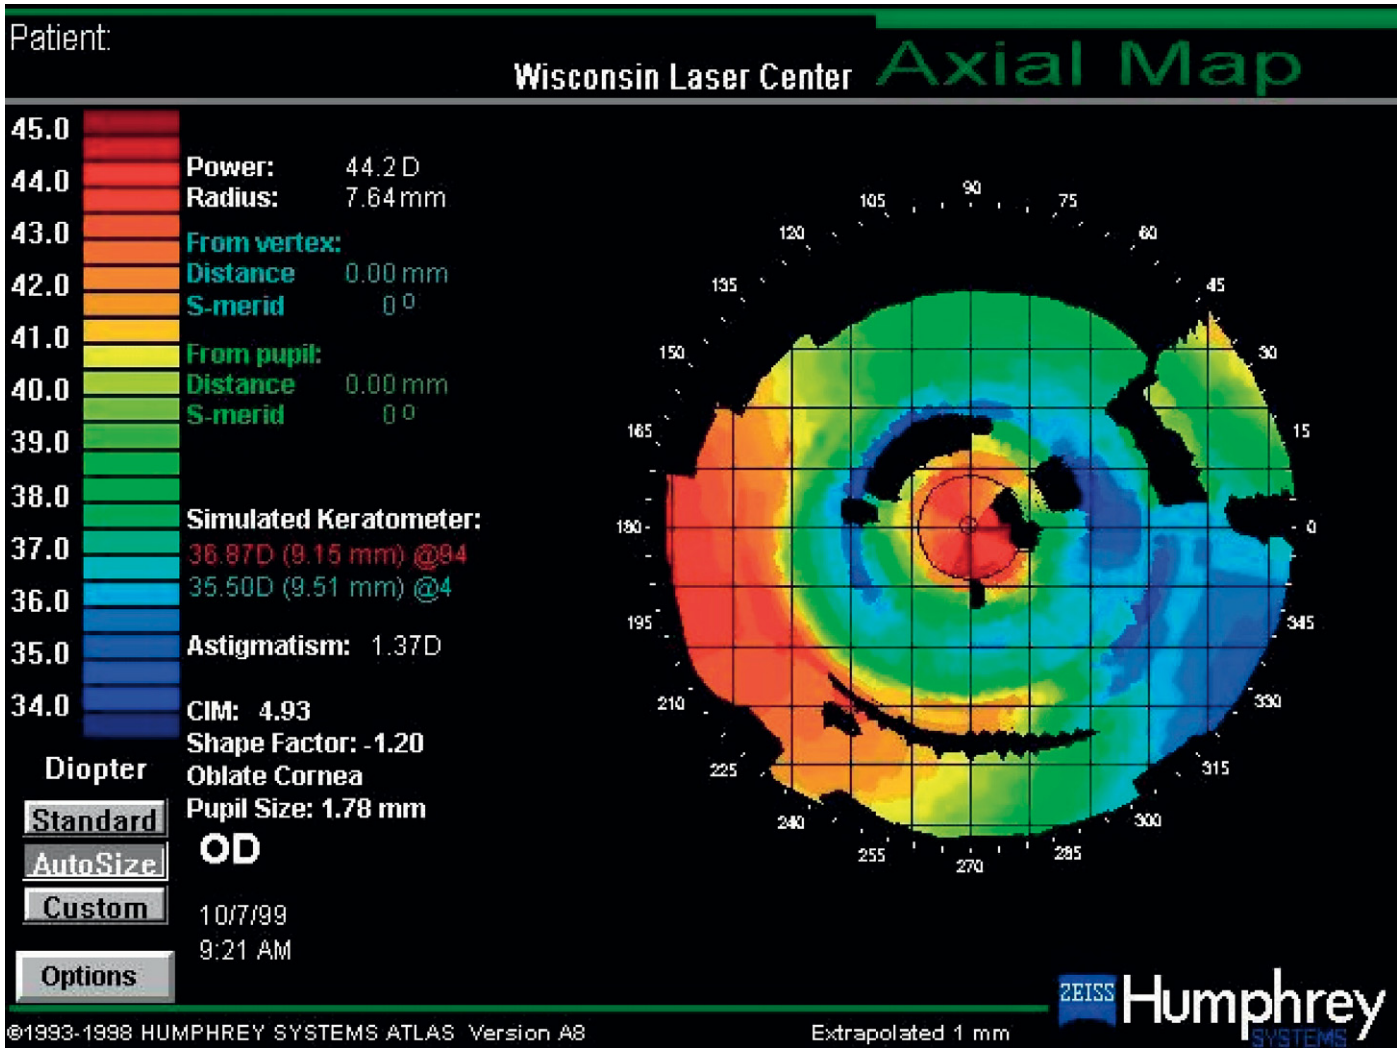

Figure 94.27. Topography after hyperopic LASIK demonstrates relatively small optical effective optical zone.

can be treated using PTK mode of the excimer laser set at the diameter and the height of the central island. Another method involves treating the refractive error with the laser treatment limited to the diameter of the central island. Unfortunately, both these techniques involve estimating the amount of ablation. Too much treatment will result in a central corneal divot with postoperative hyperopia, diplopia, and reduced BCVA. Insufficient treatment will require another re-treatment. With the current advances in customized wavefront laser correction, treatment of patients who are now identified with central islands could be postponed until wavefront technology can accurately identify and treat this problem.

Prevention: The new generation of scanning excimer lasers has effectively eliminated the risk of central islands for standard refractive correction with the excimer laser. However, in the rare circumstance that a central accumulation of stromal hydration is noted during the excimer ablation, this can be removed by wiping the stromal bed during the ablation. Central islands may still occur when performing large (>50 μm) PTK treatments for corneal scars or haze. For these types of treatment, the addition of a small myopic correction of 1–2 D will eliminate the risk for a postoperative central island.

DECENTRATION

Decentration of the excimer laser ablation is much less common now that excimer lasers have eye trackers that allow the center of the laser ablation to be locked onto the center of the pupil. The incidence of decentrations of 0.5 mm or more has been found to occur in 20.8% of eyes after PRK.[58]

Clinical: The patient may be noted to have an undercorrection or induced astigmatism. The patient may complain of diplopia[59] and halos at night. Decentration may produce both a reduction of BCVA secondary to irregular astigmatism and a reduction of uncorrected visual acuity from the associated undercorrection, since the maximally treated area is not aligned. The diagnosis of decentration is made topographically (Fig. 94.28). Nasal decentration is more common with the use of miotics and temporal decentrations with attempts to avoid hitting the nasally hinged flap. Dilatation makes all centration more difficult. When an eye tracker is used most of these difficulties above can be avoided; however, decentrations can still occur when the visual axis of the eye is several millimeters off the center of the pupil. This situation most commonly occurs with a large angle kappa.

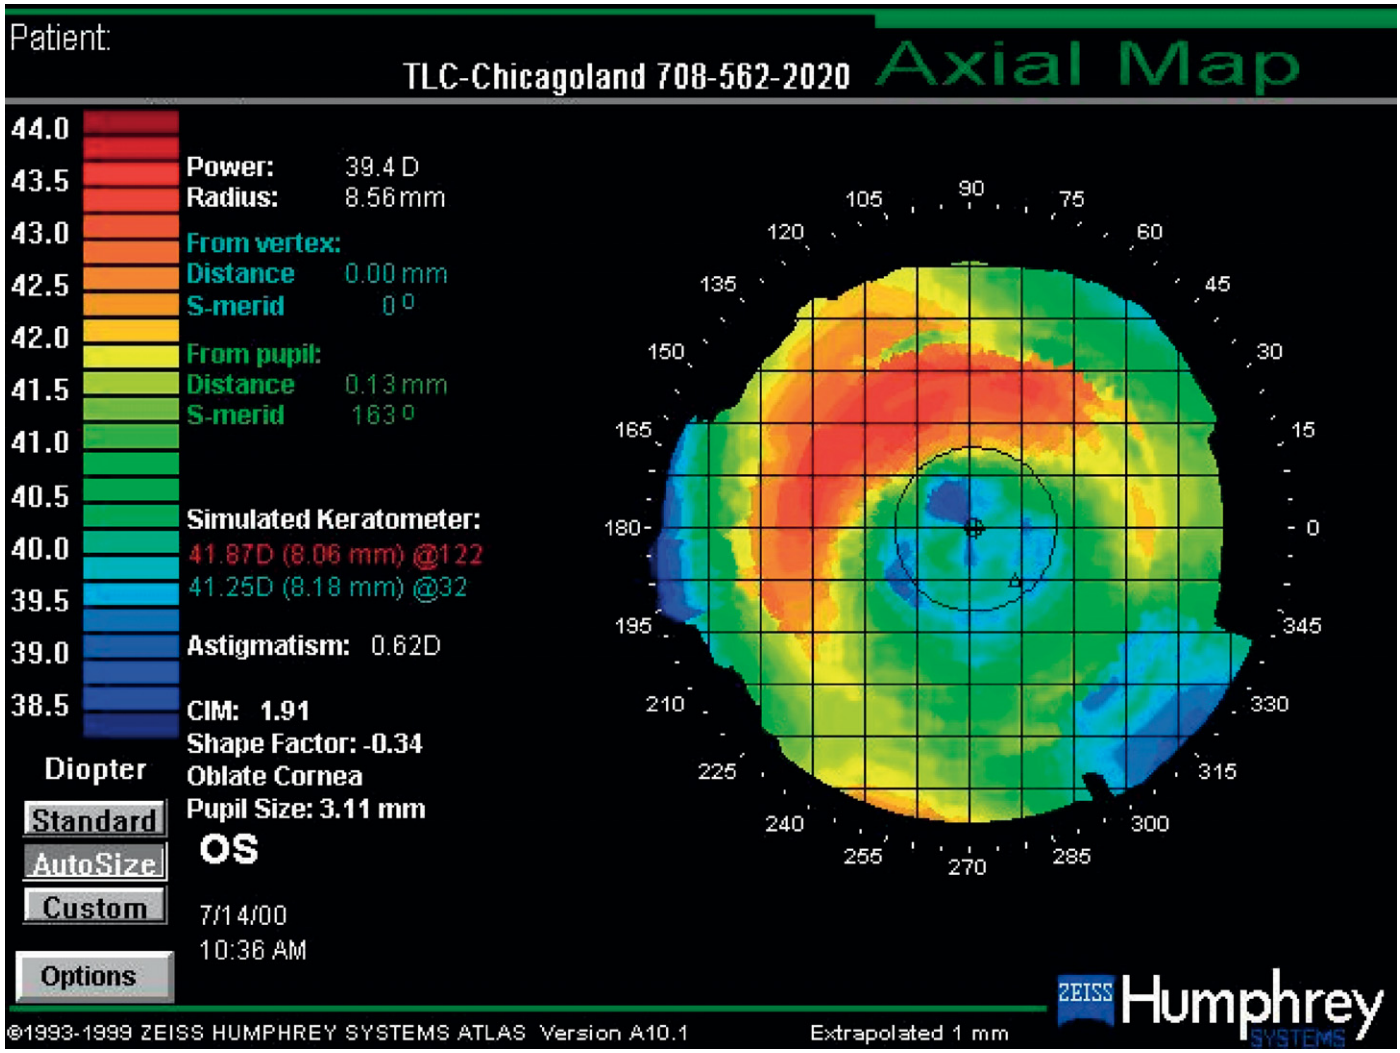

Figure 94.28. Decentered and small zone ablation after hyperopic LASIK will often be associated with night glare.

Management: Various techniques with variable success have been described for the treatment of decentrations including masking techniques to expand the ablation zone, transepithelial ablation opposite to the decentered ablation,[60] or simply correction of the residual refraction with an expanded zone. Custom wavefront LASIK offers the promise of precisely treating the decentered ablation to re-center the ablation and expand the optical zones to improve the night vision problems. Although there is limited experience with this technique at the present time, it offers so much more potential than the previous methods. Therefore, any patient with a decentered ablation at this time should consider waiting for a custom LASIK enhancement.

While patients are waiting for custom LASIK, there are several temporizing measures that can improve the patients' functioning. Although spectacle correction will correct any induced astigmatism, contact lenses will provide better improvement in the quality of the vision. The best improvement will be with a rigid gas permeable contact lens (RGPCTL). Alphagan drops can minimize pupillary dilation at night to reduce night vision symptoms.

Prevention: Decentrations are avoided by appropriate centration of the laser ablation. Generally, the laser ablation should be centered on the center of the pupil unless the patient's fixation, as measured preoperatively or through the operating microscope, is noted to be off the center of the pupil. Most surgeons advise that the laser ablation should then be placed between one half and one third of the distance from the center of the pupil to the visual axis.

IRREGULAR ASTIGMATISM

Irregular astigmatism refers to irregularities identified on corneal topography that do not follow the regular 'bow tie' pattern of astigmatism.

Clinical: Irregular astigmatism can occur alone. However, it usually occurs in association with other LASIK complications such as a flap complication, grade 4 Sands, flaps striae, or a decentered ablation. When irregular astigmatism occurs alone it is often attributed to an asymmetrical healing response of the cornea after LASIK.

Patients will complain of reduced UCVA, blurred vision, diplopia, and glare at night. Irregular astigmatism is often associated with a reduced BCVA. Topography will demonstrate the areas of asymmetrical elevation or depression of the cornea within the visual axis (Fig. 94.29).

If the cause of the lost BCVA after LASIK is unclear, several additional tests can identify the cause. Hard CTL over-refraction will identify subtle corneal pathology. If this over-refraction gives

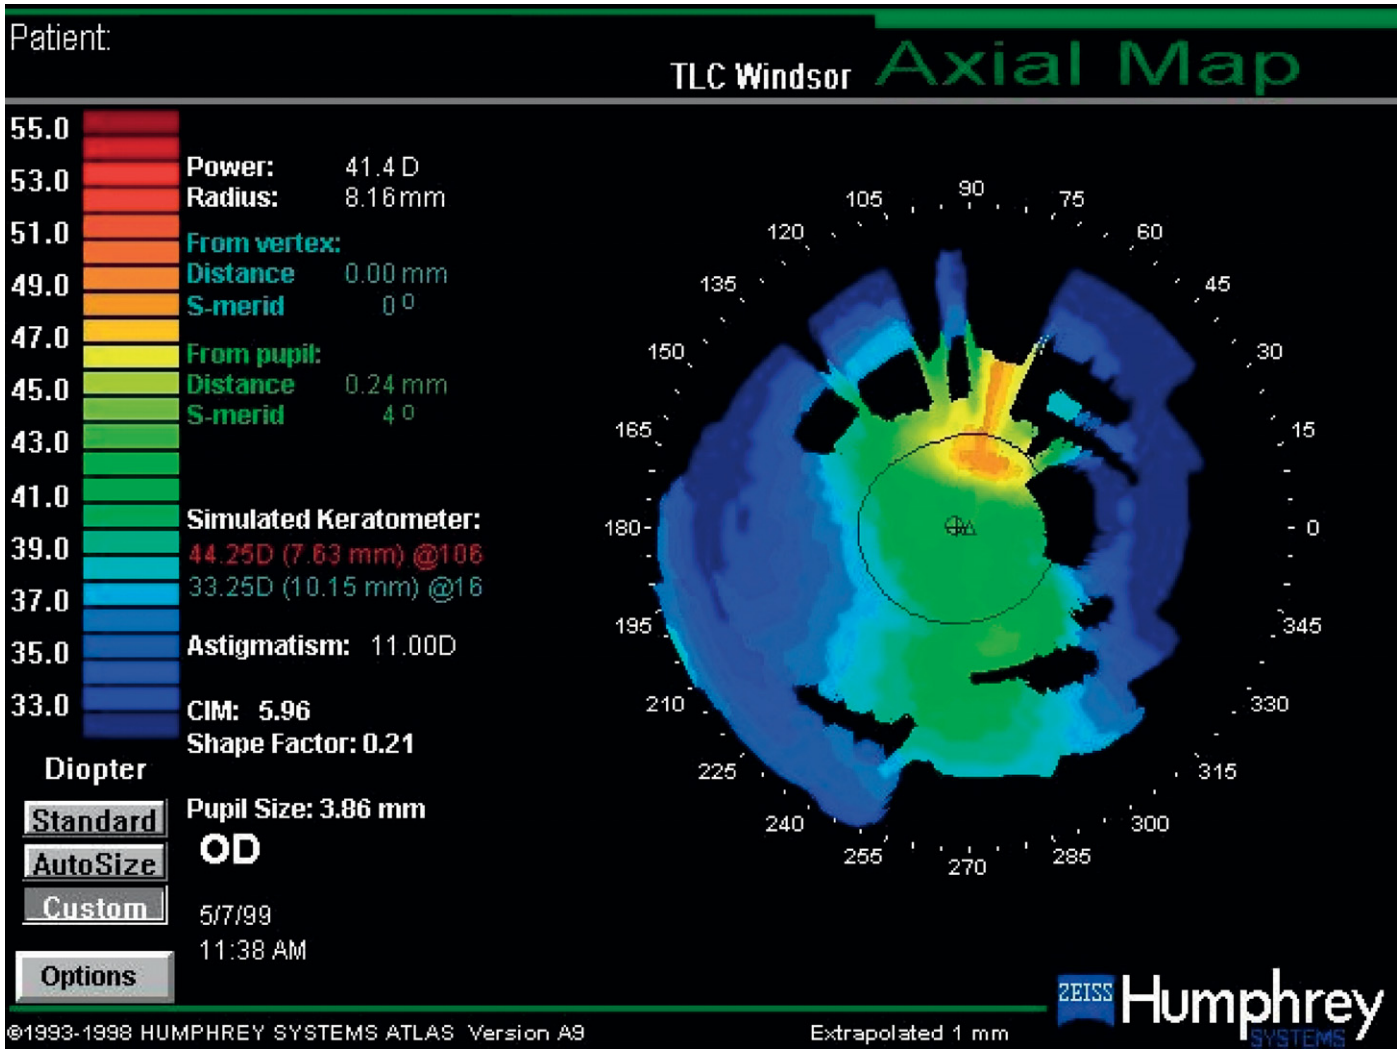

Figure 94.29. Irregular astigmatism on topography 1 year after grade 4 DLK.

a vision of 20/20, the problem is a corneal irregularity. If the BCVA remains reduced, the pathology must involve the lens or the retina. Potential acuity meter (PAM) testing will identify retinal pathology. If the PAM testing is normal, the retinal function is normal and the problem is cornea- or lens-related. If the PAM BCVA is reduced, the problem is retinal. Using these two tests, loss of BCVA related to cornea irregularity can be identified.

Management: Irregular astigmatism associated with other LASIK complications can often be improved or eliminated if the other complication is addressed. Persistent irregular astigmatism or irregular astigmatism that occurs alone is difficult to treat with the current laser systems. Although many techniques have been described using broad beam lasers,[61] they are not recommended. Custom wavefront LASIK offers great promise for the treatment of the few patients with irregular astigmatism. While there has been little experience in this area to date, treatments should be available by this method in the near future.

While patients are waiting for custom LASIK, contact lenses offer the best method for the correction of irregular astigmatism. Soft CTLs will provide up to a 50% improvement in the vision while hard CTLs can offer full improvement if the patient is agreeable to their use.

Prevention: If irregular astigmatism is identified prior to the primary LASIK procedure, it is usually considered a contraindication for standard LASIK as the standard laser ablation pattern cannot correct the irregular pattern. Irregular astigmatism associated with a history of prior hard CTL use may resolve after the contacts have been out for several weeks to months. Irregular astigmatism also occurs with forme fruste keratoconus.

Prior to using the excimer laser, the quality of the laser beam should be tested to ensure that there are no beam irregularities. The LASIK technique should be performed in a manner that allows even application of the laser treatment to avoid irregular astigmatism.

POST-LASIK DRY EYES

Dry eye after LASIK is due to the creation of a temporary neurotrophic cornea by the severing of corneal nerves during creation of the LASIK flap.[62,63] Neurotrophic dry eye is caused by decreased corneal sensation with decreased feedback to the lacrimal gland and reduced tear production.[64] Confocal microscopy has demonstrated that the number of stromal nerve fiber bundles decreases by 90% immediately after LASIK.[65] During the first year after LASIK, the nerve fiber bundles gradually return, although by 1 year their

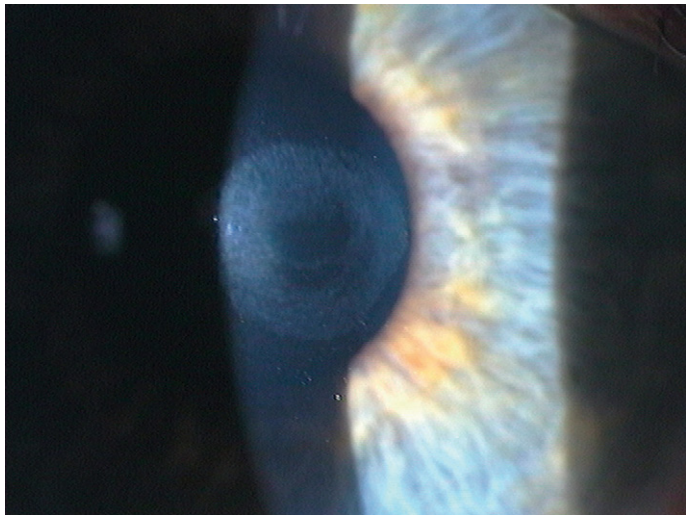

Figure 94.30. Central superficial punctate keratitis after a large hyperopic LASIK correction associated with a reduction in the UCVA and the BCVA.

number remains less than half of that before LASIK. Nasal hinge flaps have been shown by Eric Donnenfeld, MD to sever fewer of these nerves because it preserves the nasal nerves and hence dry eyes are less of a risk because the neurotrophic cornea is less severe.[66]

Clinical: The post-LASIK dry eye presents immediately after the procedure. The patient experiences the 'burning' sensation of the classic dry eye and the vision is often reduced if a dry eye keratopathy affects the central cornea. The symptoms are resolved temporarily with topical lubrication but may return less than 1 h after application. Generally, the symptoms resolve over the first postoperative month but can rarely persist for up to 1 year. Post-LASIK patients are often very frustrated by the dry eye problem as they have usually not experienced it prior to LASIK. After hyperopic LASIK, the dry eye can be caused by both the neutrotrophic cornea and the reduced tear film of the steeper central cornea. This can cause a central SPK that can dramatically affect both the UCVA and BCVA (Fig. 94.30).

Management: The post-LASIK dry eye should be assessed with the same approach used with the classic dry eye patient. Decreased tear secretion can be due to the post-LASIK neurotrophic cornea, but it also can be exacerbated by pre-existing lacrimal gland disease. Large palpebral fissures and Meibomian gland dysfunction can increase the evaporative loss of tears. LASIK patients with dry eyes should be evaluated for all these conditions for the most effective treatment and patient education.

After the LASIK procedure, frequent lubrication is suggested every hour even in normal patients to ensure good healing of the cornea. Punctal plugs are put in the lower punctum if symptoms persist. If the dry eye problems persist after 1 month, silicone plugs should be inserted in the upper punctum. Lubrication should be continued at least 4–6 times a day with nonpreserved viscous artificial tears. Rarely, ointment can be used at bedtime each night. Topical steroid may be useful for treating the inflammatory component of the dry eye as well as any associated eye allergy. Loteprednol etabonate 0.5% is particularly useful, as it is not associated with increased risk of cataract or elevated IOP. In rare instances, bandage contact lenses may be required. Environmental controls for dry eyes, including bedroom humidifiers and protective sunglasses, may also be useful for patients who have chronic dry eye problems. It is important to continue to see the dry eye patient to continue to provide reassurance that the corneal signs and symptoms are resolving.

Prevention: During the preoperative process, it is important to identify patients with dry eyes. If the patient has a history of dry eyes or has evidence of dry eyes, including a small tear meniscus or superficial punctate keratitis, it is helpful to heal their epithelium with lubricating drops prior to the procedure. Dry eyes should be suspected in patients who are already using topical lubrication prior to LASIK or that have skin conditions such as acne rosacea. Another group of patients prone to dry eyes are premenopausal women who tend to have the most complaints with dry eyes after LASIK. Schirmer testing is useful in all patients suspected of dry eyes. Punctal plugs should be used quite liberally in order to minimize the postoperative dry eye. This author prefers to use silicone punctal plugs because they are effective for 1–12 months after the procedure. Collagen plugs are only effective for 1–2 weeks and frequently need replacement.

During the LASIK procedure it is best to use a nasal hinge flap for dry eye patients in order to avoid as much as possible the neurotrophic keratopathy. During the LASIK procedure, every effort should be made to preserve the epithelium as epithelial defects will prolong healing and exacerbate the post-LASIK dry eye symptoms. Other procedures could also be considered such as PRK or LASEK which preserve more corneal sensation and create less neurotrophic keratopathy. These two procedures involve surface ablation of the cornea and therefore should not be performed for corrections greater than −6.00 D, as they would have a greater incidence of corneal haze.

VITREORETINAL COMPLICATIONS AFTER LASIK

There has been a increased theoretical risk of retinal detachment after LASIK caused by alteration of the anterior retina from the suction ring. While the myopic population is already at an increased risk of detachment, no direct relationship has been identified.[67] A recent retrospective review of a large number of LASIK cases (38 823), found that the rate of retinal detachment was 0.08%.[68] Other complications noted to occur at a low frequency after LASIK include lattice degeneration (0.3%), posterior vitreous detachment (0.1%), macular hemorrhage (0.1%), retinal tear without retinal detachment (0.1%),[67] and choroidal neovascularization (0.1%).[69] Although the incidence of vitreo-retinal pathologic conditions in myopic eyes after LASIK is low, it remains important to screen pre- and post-LASIK eyes for complications of lattice degeneration.[67]

COMPLICATIONS UNIQUE TO FEMTOSECOND FLAP CREATION

Opaque bubble layer (OBL)

The bubbles produced during the Intralase flap creation are deposited in the posterior and peripheral stroma.

Clinical: White areas develop during flap creations that vary in size from 1–8 mm in diameter (Fig. 94.31). They have fluffy and almost crystalline borders. The OBL will enlarge and expand as the flap is being created. OBL can make pupil visualization and eye tracking difficult. OBL can make patient fixation on the fixation

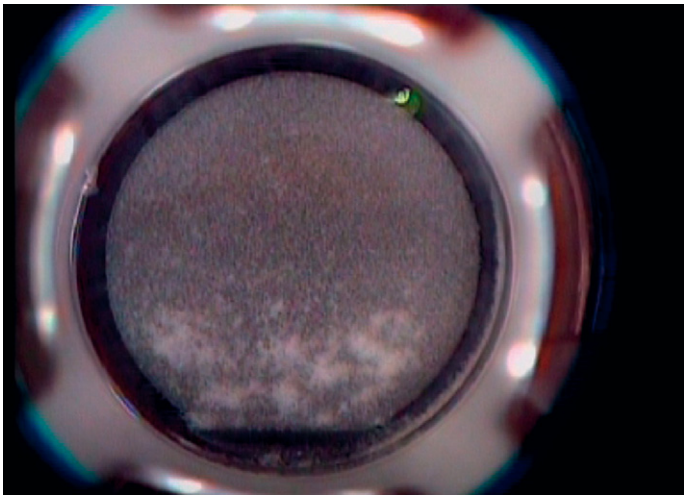

Figure 94.31. White fluffy areas are visible forming during and after flap creation.

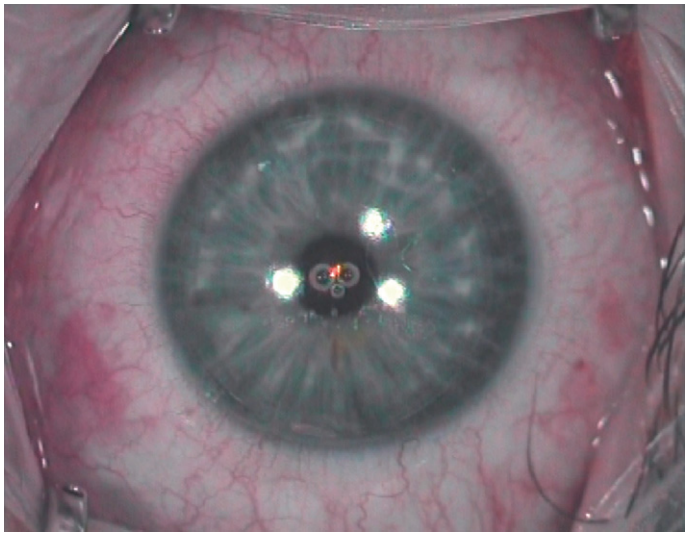

Figure 94.33. Gas bubble in the anterior chamber after Intralase flap creation. This will absorb without treatment over 1–3 h.

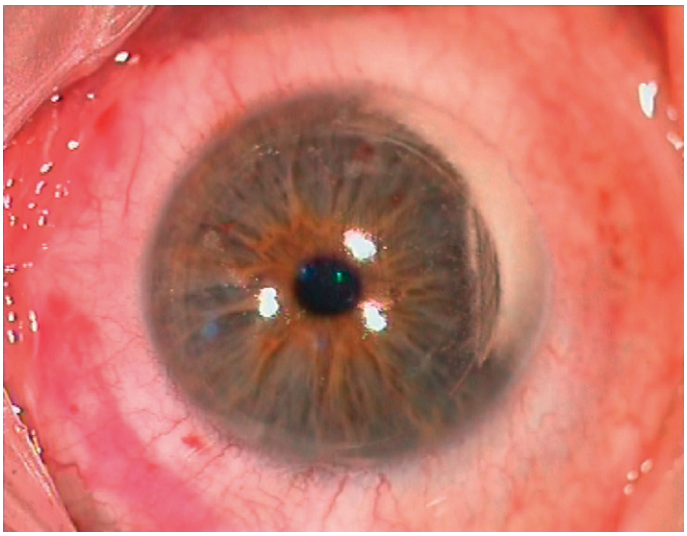

Figure 94.32. Peripheral opaque bubble layer (OBL) can be seen as a white area along the limbus. This is the ideal area for OBL formation as it does not affect the tracker.

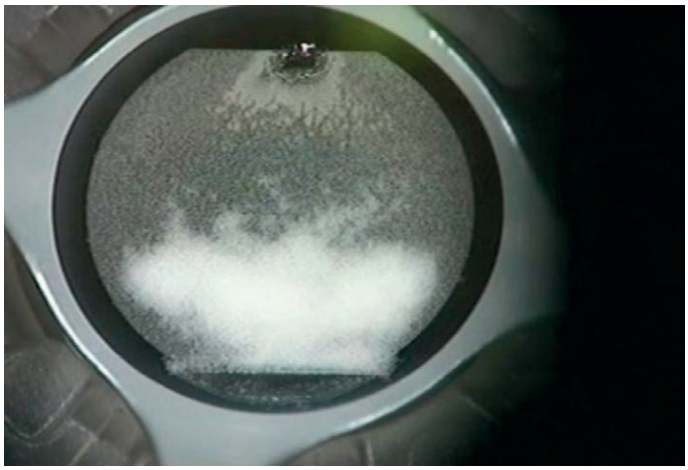

Figure 94.34. Gas breakthrough occurs rarely with Intralase. It appears as a bubble underneath the applanation cone during the flap creation.

target difficult. OBL more commonly occurs in the peripheral stroma (Fig. 94.32).

Management: Mild OBL is common and this degree of OBL can usually be wiped away with a Merocel sponge. Denser OBL will absorb in 20–30 min and the surgeon may wish to wait for resolution of the OBL prior to treatment. OBL does not seem to have an adverse outcome on the results of LASIK, even when the ablation is performed with OBL visible in the stromal bed.

Prevention: OBL is reduced by the faster pulse rate of the 60 KHz laser which allows for reduced energy levels, a denser grid pattern of laser treatment, and less gas production. The technique of 'soft docking' is essential to reduce the incidence of OBL. In this technique, a meniscus is left around the cone edge rather than complete applanation of the cornea. This meniscus is ideally in contact with the area where the 'pocket' of the Intralase flap is created. This meniscus will provide an easier route for the gas to escape so it does not deposit in the posterior stromal bed. Regular laser maintenance also will reduce the incidence of OBL.

Gas breakthrough

Gas created during the flap creation process can be deposited in the stromal bed where it produces the OBL; the peripheral stroma where it produces peripheral OBL; into the anterior chamber where it produces gas bubbles that can disrupt the eye tracker during treatment (Fig. 94.33); or through the flap and under the epithelium or Bowman's layer which is called gas breakthrough.

Clinical: Patients at the greatest risk for gas breakthrough include those with loose epithelium and those who have thin flaps created with the Intralase (<100 μm). Bubbles 1–3 mm in size can be seen forming during flap creation under the applanation cone at the surface of the cornea (Fig. 94.34). They are most often solitary but several bubbles can occur. They are generally small (<1 mm), but (<1/1000) large bubbles can occur. If the bubble is large, the flap cannot be lifted, since the lameller plane is incomplete underneath the bubble.

Management: Small amounts of gas breakthrough do not effect the lifting of the flap or treatment. Large bubbles can make the flap difficult or impossible to lift. If the flap cannot be lifted, the flap

should be replaced and the eye allowed to stabilize for a few weeks. At that time, the flap can be re-cut at a 40 µm greater depth or PRK can be performed with mitomycin C.

Prevention: Maintaining a flap depth of 120 µm considerably reduces the risk of gas breakthrough. The reduced spot size and the higher pulse rate of the 60 KHz laser has allowed for a denser 8 × 8 spot/line separation of the Intralase that has reduced the risk of gas breakthrough.

Transient light sensitivity (TLS)

TLS is thought to be related to higher side-cut energy levels used for flap creation or possibly a higher bed energy used for flap creation.

Clinical: Photosensitivity at day and at night starts 1 month after LASIK with the Intralase laser. There are no ocular abnormalities noted on examination. The uncorrected visual acuity is unaffected.

Management: The patient is prescribed topical steroids on a tapering schedule starting at four times a day over 1 month. This treatment results in resolution of the TLS.

Prevention: The 60 KHz laser allows lower energy levels to be used for flap creation and seems to reduce the incidence of TLS.

95 Comparative analysis of mechanical and laser microkeratomes

John F. Doane, Randolph T. Jackson, Stephen G. Slade

This is an exciting time for laser in situ keratomileusis (LASIK), with microkeratome modifications making flap creation safer and more predictable. To explore these improvements, this chapter reviews advances in the traditional mechanized microkeratome and the development of a newer alternative, the femtosecond laser, for flap creation. For the patient seeking refractive surgery, the goal is to have excellent vision without spectacles. This consists of two important considerations. Foremost is safety with maintenance or improvement of best spectacle corrected visual acuity, while at the same time having a highly accurate refractive outcome with optimization of uncorrected vision. Advances in both the mechanical keratome and the femtosecond laser seek to meet these criteria.

The original Barraquer microkeratome was an innovative device where the oscillating blade slid over a nongeared suction ring. Many small improvements since then have reduced complications for both the novice and experienced surgeon, so that buttonhole formation, free caps, corneal abrasions, and incomplete flaps are far less common. With the application of the femtosecond laser to create corneal flaps, there is the potential to further reduce complications, improve visual results, and develop new forms of subepithelial, intrastromal, and lamellar corneal refractive surgery. With the evolution of mechanical keratomes corneal refractive surgery has undergone tremendous advances in the past 50 years. The trend toward an increasingly automated process has provided more reproducible results with less dependence on individual surgical technique.

In the early 1960s, Professor Jose I. Barraquer of Santefe de Bogotá, Colombia, was hand-dissecting free caps from the anterior cornea, followed by free-hand dissection of the stromal bed. The first automated microkeratome was developed by Professor Barraquer in the first half of the 1960s.[1] To ensure a uniform flap, the eye needed to be held firmly and the intraocular pressure increased. Professor Barraquer achieved this by developing the suction fixation ring. Even today, the Barraquer tonometer, which is used to quickly check for adequate intraocular pressure during the keratectomy procedure, is still in widespread use.

The basic components of the Barraquer keratome are still present in today's models. These components include the keratome head, blade, depth plate, and vacuum suction ring. The sagittal height of the suction ring and the diameter of the orifice that receives the cornea affect the diameter of the flap. To a beginning surgeon, it would appear that the flap thickness would be controlled solely by the depth plate of the microkeratome and the suction ring parameters would determine the diameter of the flap. While this is valid there are a few other direct correlates to this initial assumption. The steepness of the cornea and the central thickness correlate directly to the end flap thickness. The steepness of the cornea directly influences flap diameter with applanating microkeratomes. The steeper the cornea the larger the resultant flap diameter and likewise the flatter the cornea the smaller the resultant diameter. Steep corneas, for example greater than 47 D, provide a longer arc length of exposed cornea for the microkeratome to engage and, therefore, a larger diameter flap will be created. Conversely, flat corneas (i.e. <42 D) provide a shorter arc length of exposed cornea for the microkeratome to engage and will lead to smaller diameter flaps, and if extremely flat, can lead to free-cap formation.

There are various guidelines for suction ring size based on keratometry and type of ablation. An unusually small corneal diameter or orbital opening can limit the suction ring size that can be used. Regarding flap thickness, the microkeratome depth plate is the starting point, but a few other factors are directly related to outcomes when using an applanating microkeratome. Steeper and thinner corneas tend to produce thinner central flaps, while flatter and thicker corneas tend to produce thicker central flaps, despite using the same depth plate. New blades tend to produce thicker flaps than blades that are sterilized and reused. Low intraocular pressure, or pseudosuction, will lead to thin flaps, while loss of suction during the keratectomy will lead to truncated or free caps.

SHORT-PULSED LASER DEVELOPMENT FOR FLAP CREATION

The term 'photodisruption' was coined by Martin Mainster, MD, PhD in 1983 in an article in which he also described the plasma physics foundations of lasers in the picosecond and nanosecond range.[2] The process involves focusing a large amount of energy into a focused spot in a very short time interval. A key element of this technology is that the laser light must be perfectly focused. If the laser is not

focused, there will be no tissue effect. This is unlike CO_2, argon, or excimer laser delivery systems, which will have tissue effects, albeit suboptimal, even if not focused precisely.

A well-focused short-pulse laser causes an extremely localized temperature increase and electron configuration changes that convert tissue into a matter called plasma. Plasma occurs in nature only under conditions of extreme high temperature, such as lightning strikes, and in the atmosphere of a star such as the sun. The temperatures involved to create plasma are in the range of 10–15 000°C. Amazingly, this is 2–3 times the temperature on the surface of the sun.[2,3] Depending on the time duration or the pulse width, the power created can vary with short-pulsed lasers. The power generated relates to the equation, power = energy/time. For a given amount of energy, decreasing the pulse width increases the power per pulse. Conversely, if you are using ever shorter pulse widths, the amount of energy required to achieve a certain power declines precipitously. With short-pulsed lasers, a microplasma is created and this will vaporize a given sphere of corneal tissue. When photodisruption occurs, there is a plasma expansion followed by a shock wave and the creation of a resultant cavitation bubble (Fig. 95.1). The entire process happens in a very small area and during a very short time period, thus avoiding significant thermal damage to the eye.

This process has been used to great effect with the YAG laser. The YAG laser pulse width is in the nanosecond range. As noted above, by decreasing the time duration of the pulses even further, less energy can be used and the resultant spot size is of smaller diameter with less collateral damage to neighboring tissue (Fig. 95.2).

For corneal surgery, the short-pulsed laser is focused precisely to create the microplasma and cavitation bubble. Microplasma creation vaporizes corneal tissue and creates a bubble of CO_2 gas and water that effectively separates the corneal lamellae. The gas and water are reabsorbed by the endothelial pump with a resultant cleavage plane in the cornea. When thousands of these pulses are connected together, a distinct cleavage plane can be achieved. These spots can be placed horizontally or vertically to achieve desired dissection planes (Fig. 95.3).

The pattern of the cleavage plane is literally at the discretion and creativity of the surgeon and the software written for the specific short-pulse laser system. The wide cavitation spacing of nanosecond short-pulse lasers precluded their use for precise corneal dissection. The subsequent evolution of short-pulsed lasers involved picosecond- and then femtosecond-pulse widths. Two companies produced picosecond lasers designed for intrastromal ablation: Phoenix Lasers, Inc (Phoenix, Arizona). and Intelligent Surgical Lasers, Inc (San Diego, California).[3] Owing to technical difficulties they did not make their way into clinical practice. Notably, the cavitation spacing with the picosecond laser, although closer than with nanosecond lasers, was still not close enough to create

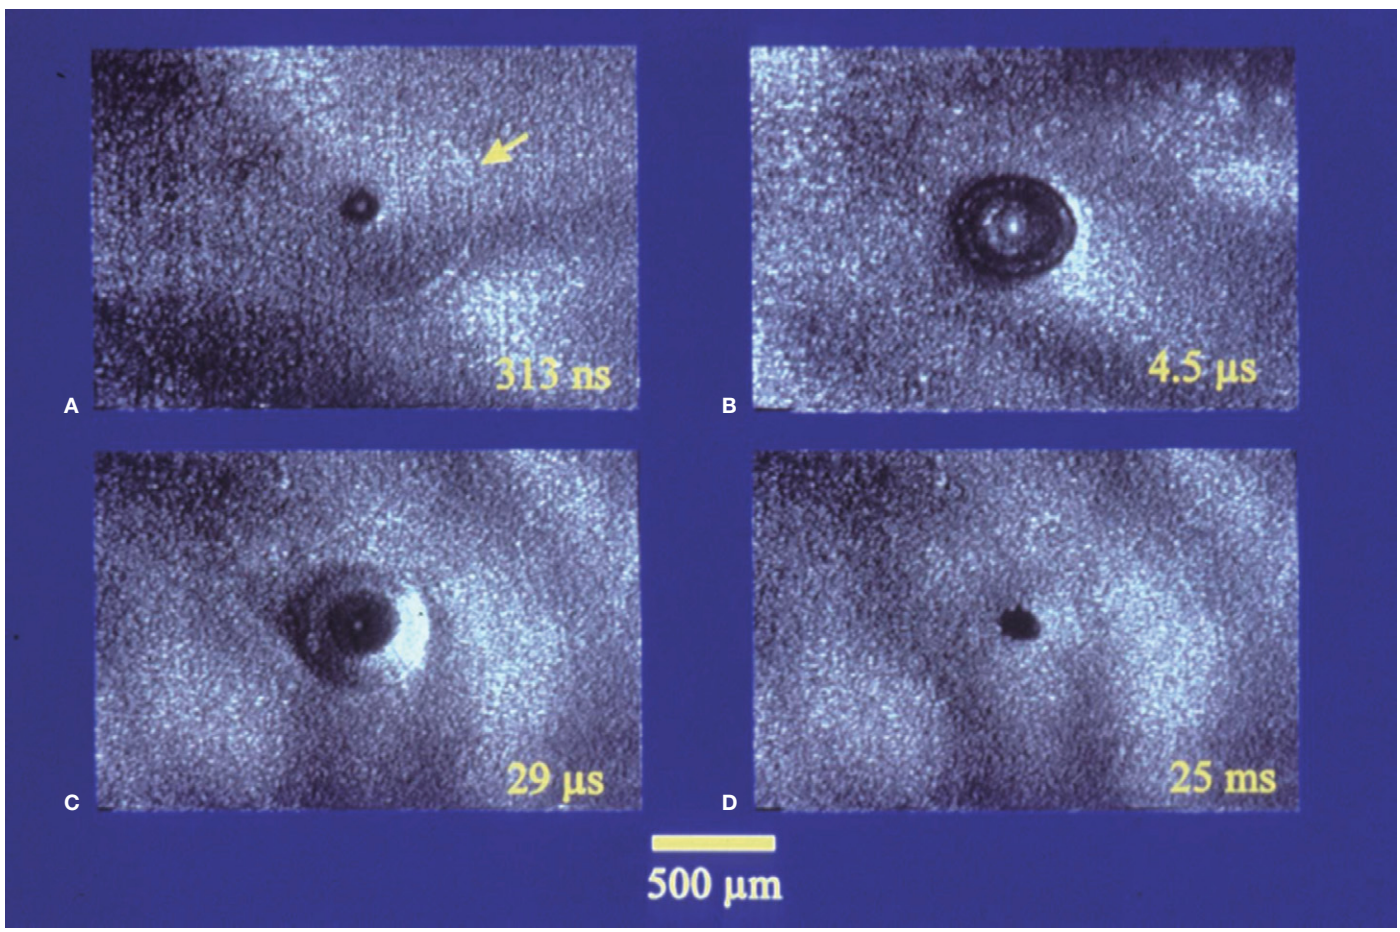

Figure 95.1. Time elapsed photography of short-pulse photodisruption (nanosecond) with three phases of the process. Plasma expansion, shock wave progression, and cavitation bubble creation are evident in this photo series. Photograph courtesy of Intralase®.

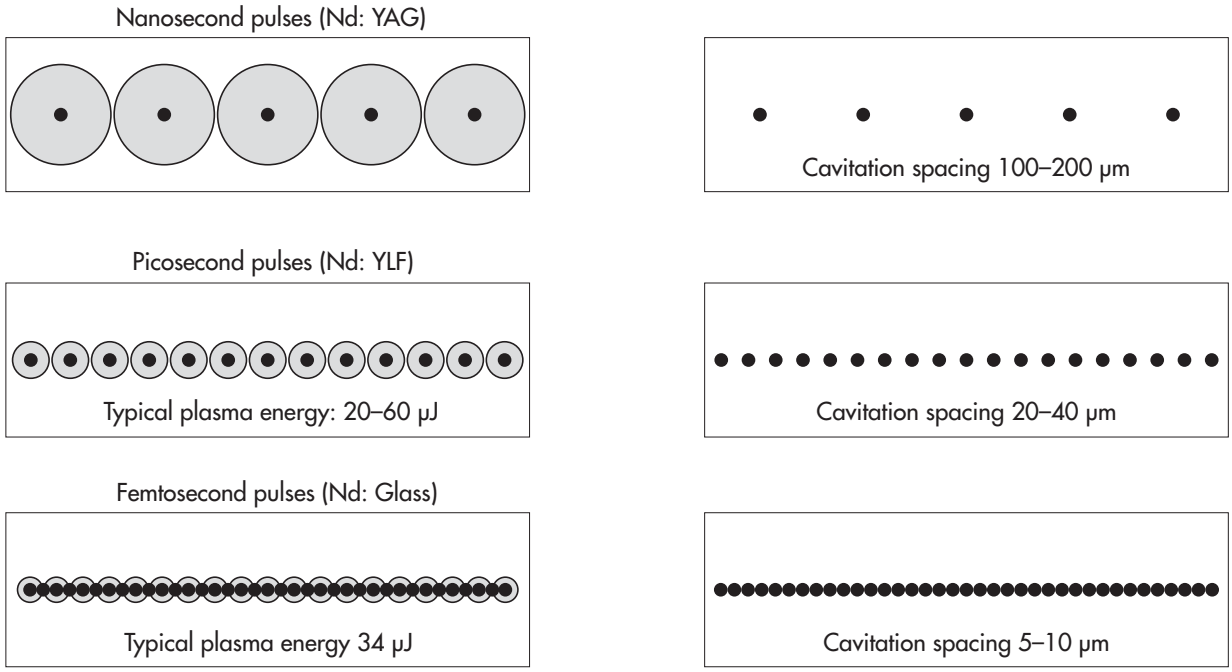

Figure 95.2. Spot energy, spot size, and cavitation spacing for the nanosecond, picosecond, and femtosecond pulsed lasers, respectively. With the nano- and picosecond lasers, the cavitation spacing is so wide that accurate cleavage plane development within corneal tissue is not close enough to create contiguous dissection. With the femtosecond lasers, the cavitation spacing is ideal to create a dissection plane. Note: nanosecond laser energy is in the range of milliJoules whereas picosecond and femtosecond energies are in the microJoule range. Based on photograph courtesy of Intralase®.

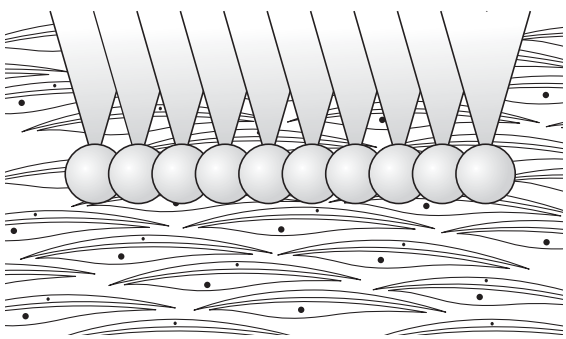

Figure 95.3. Femtosecond pulses connecting to make a horizontal dissection plane. Based on photograph courtesy of Intralase®.

adequate lamellar tissue separation. Research from the University of Michigan published in 1997 found lasers with a pulse duration in the 100 femtosecond range to be well suited for making corneal incisions.[4] One femtosecond is 1×10^{-15} s. To put it in perspective, in 1 second light travels 7.5 times around the globe, while in 1 femtosecond light can travel 30 μm and in 100 femtoseconds light barely has time to make it across the width of a human hair. It was not long after the Michigan researchers developed a laser that worked effectively for corneal dissections that these lasers found their way into clinical ophthalmology practice.

The IntraLase® Pulsion FS (femtosecond) laser was the first commercially available surgical femtosecond laser in 2001. In 2004, the FemTec™ laser from 20/10 Perfect Vision® received US Food and Drug Administration (FDA) approval for LASIK flap creation. The patient–glass interface for the FemTec™ laser is spherical in shape to match the corneal curvature and reducing suction and intraocular pressure requirements, whereas the Intralase Pulsion glass–plate interface is flat. While available in Europe, the FemTec™ laser is not yet being marketed in the USA. More recently, in March 2006, the DA VINCI™ femtosecond laser from Ziemer Ophthalmics© also received FDA approval for use in LASIK. Carl Zeiss Meditec® and WaveLight® are both working on a femtosecond laser and FDA approvals are anticipated in the near future. These instruments are also FDA approved for treatments requiring an initial lamellar resection of the cornea. Corneal transplantation, endothelial transplantation, and insertion of intrastromal rings are other areas where the femtosecond lasers are beginning to prove their effectiveness.

The process of flap cutting with a femtosecond laser is different from the mechanical microkeratome process in a number of ways. A suction ring is still used but with lower pressure. The intraocular pressure increase is reportedly closer to 40 mmHg, instead of the 70 mmHg or slightly more used with the mechanical microkeratome.[5] Note that when the femtosecond flat applanation lens contacts the cornea the intraocular pressure will increase beyond that created with the negative suction created with the syringe system. This reduces the percentage of patients experiencing transient loss of vision during the flap creation. A disposable patient interface which consists of a metal cone with a clear glass applantion lens is used to flatten the corneal dome after the suction ring vacuum is initiated (Fig. 95.4). This glass lens provides a reference plane from which a distance can be chosen where the short pulse laser is to be perfectly focused for maximal photodisruption effects and cleavage plane dissection (Fig. 95.5). A plastic syringe system fashioned after the Hessburg–Barron corneal transplantation suction trephination system is used to create vacuum with a suction ring assembly that acts as the coupler of the cornea to the applanation lens. The applanation lens is lowered over the cornea to achieve the

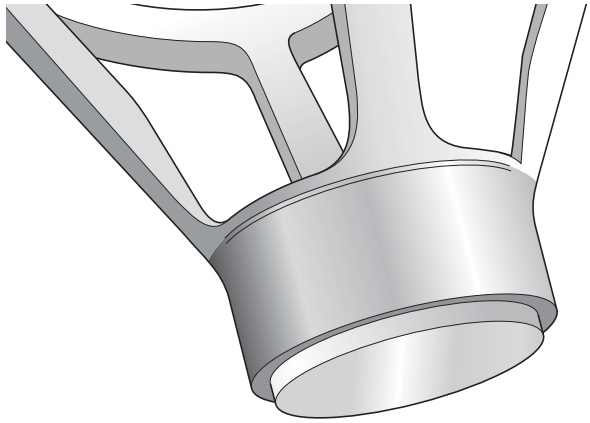

Figure 95.4. IntraLase® disposable patient interface. Based on photograph courtesy of Intralase®.

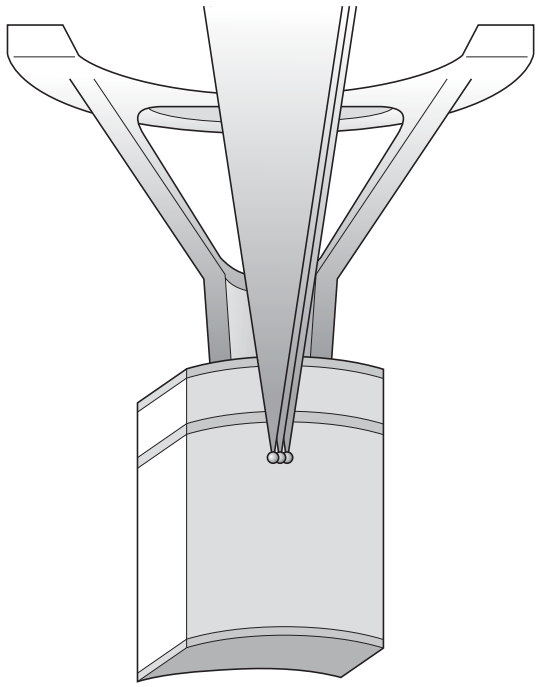

Figure 95.5. The glass lens applanates the cornea to form a reference plane for the laser. Based on photograph courtesy of Intralase®.

exact diameter desired for the corneal flap. The patient's keratometry values are essentially irrelevant compared to mechanical keratome devices. The laser creates the flap by starting at one edge with 1 µm spot placement that expands to create a 2–3 µm cavitation bubble. More bursts create a string of cavitation bubbles back and forth in a raster pattern (or alternatively a spiral pattern) until the base of the flap has been created. The laser then forms the flap edges at an angle selected by the surgeon (Fig. 95.6). The flap diameter and thickness and hinge position are all user adjustable via a graphic user interface (Fig. 95.7). Side-cut angle can be optimized to balance easy repositioning (steep angle) with ease of entry for initial lifting (shallow angle). The width of the hinge is also adjustable to allow the surgeon to balance flap security with exposure for the excimer laser near the flap.

COMPARISON TO THE COMPLICATIONS POSSIBLE WITH THE MECHANICAL MICROKERATOME

FLAP ANATOMY: MECHANICAL VERSUS LASER KERATOMES

Is the flap anatomy for mechanical and femtosecond lasers the same? From subtraction pachymetry data, our findings suggest that mechanical microkeratomes create a minus meniscus flap[6] (Fig. 95.8). Femtosecond lasers have the capability to create near planar flaps (Fig. 95.9). With steeper and thinner corneas as noted above, mechanical microkeratomes will cut an ever thinner flap. If one checks subtraction pachymetry either at 3 or 5 points on the cornea (one central and four peripherally), the data will be similar to that found in Figs. 95.10 and 95.11. This begs the question as to why mechanical microkeratome flaps are of a meniscus shape. Owing to the 'conservation of arc-length', there has to be central dimpling of the cornea with a microkeratome functioning by applanating the cornea in advance of a cutting blade. With a fixed chord length and compression of the arc to meet this chord length, the cornea has to dimple toward the iris (RJ Sherin, Personal communication). The steeper the cornea the more this dimpling will be, and the worst case scenario would be a buttonhole formation of the flap (Figs 95.12–95.14).[6]

A meta-analysis of studies that include over 1000 eyes reveals that mechanical flap cutting complications such as free caps, buttonhole formation, partial flaps, flap decentration, and epithelial defects occur in 0.3–5.7% of cases.[7] Loss of two or more lines of best spectacle-corrected visual acuity (BSCVA) occurs in 0.5–2% of cases.[8,9] Owing to a learning curve, beginning surgeons have higher rates of complications when compared to experienced surgeons. However, complications occur even in the hands of experienced surgeons.[10] Free caps are a rare occurrence with mechanical microkeratomes. Moreover, the cap normally can be reposited without incident if correct alignment is obtained. If the original alignment is not obtained, regular and irregular astigmatism can occur. The femtosecond laser by design will not create a free cap, and none has been reported to date. Nonetheless, there is still some risk of a torn or free cap following lifting of the flap. If the femtosecond laser does not have near perfect confluence of the bubble layer, adhesions may be present that make flap elevation

Figure 95.7. Graphical user interface of IntraLase® FS laser. Based on photograph courtesy of Intralase®.

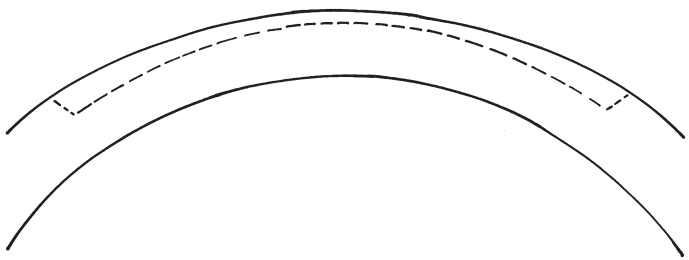

Figure 95.8. Illustration of meniscus shape flap made by a mechanical microkeratome. (Stechschulte SU, Doane JF, Motes S. Mechanical microkeratomes create a meniscus, not a planar flap. ASCRS presentation. San Diego, CA; April 29, 2001.)

difficult. If significant force is required, flap and/or hinge tearing has been reported.

Avoiding partial flaps and buttonholes is arguably the greatest advantage of the femtosecond laser. With mechanical microkeratomes, if there is a laceration through Bowman's layer over the pupillary axis, corneal opacity and/or irregular astigmatism may occur. If a partial flap was created leading to loss of best spectacle corrected vision, the flap can be repositioned, and after 3 months, a new flap can be cut or surface ablation can be performed. The scar may be permanent and can affect best spectacle corrected vision. Suction loss can occur with the femtosecond laser during flap creation. Management of these cases requires the patient to remain at the surgery facility until the opaque bubble layer resorbs in 30–60 min. The patient can then be brought back, and the femtosecond laser can be programmed as if the patient had never had a prior flap formation attempt. In one study, the flaps of four eyes were recut without problems between 5 and 45 min after the initial attempt.[11]

Defects of the epithelium during LASIK are the most common intraoperative complication and these tend to be uncomfortable for the patient at the very least. A study comparing the Carriazo–Barraquer and standard compression Hansatome™ with the IntraLase® included over 100 eyes in each group and found loose epithelium in 9.6% of eyes with the Carriazo–Barraquer, 7.7% with the Hansatome™, and none in the IntraLase® group. Epithelial defects increase the risk of bacterial keratitis and recurrent erosions. Diffuse lamellar keratitis (DLK) has been shown to be 24 times more likely in the presence of an epithelial defect.[12] Epithelial ingrowth, flap

melts, and treatment regression all have shown an association with epithelial defects. With the femtosecond laser, no moving parts come in contact with the cornea, greatly reducing the chances of creating an epithelial defect during the cutting of the flap. With the increased effort required to lift a femtosecond-created flap, there is an opportunity to cause epithelial defects during this stage of the

procedure. Avoiding an epithelial defect, probably the most common intraoperative complication, is important, since it is uncomfortable for the patient, and increases the risk of epithelial ingrowth, DLK, and bacterial keratitis.

Late LASIK complications—ectasia

As discussed above, there is a degree of variability in the depth of corneal flaps created with a mechanical microkeratome. The factors of pachymetry, intraocular pressure, and corneal curvature are variable from case to case. The standard deviation of the Hansatome™ and Moria™ microkeratome has been found to be in the 26–29 µm range, but there are clinicians reporting first standard deviation at 10 µm. The femtosecond laser gives a highly precise flap depth with a standard deviation of 14 µm in one comparative study.[13] This precision of the femtosecond laser may eventually decrease the need for intraoperative pachymetry on corneas where there is a concern for adequate residual corneal stromal bed thickness. With a less precise and accurate system, the surgeon has to be ready to abort the case if the residual corneal stromal bed thickness is insufficient. Keratectasia appears to be multifactorial, with some relation to residual corneal stromal bed thickness. Being able to better predict the residual bed depth may help guide the treatment of borderline LASIK candidates.

Corneal sensitivity

There is some evidence that the return of corneal sensitivity may occur more quickly in patients treated with femtosecond created flaps.[14] The mechanical keratome cuts a flap that is meniscus shaped and thus deeper near the edges, thereby cutting more nerve fibers in the peripheral cornea. This explanation for the faster return of corneal sensitivity needs to be confirmed with larger clinical studies, as well as with histologic studies.

The photograph on the right was made with the Hansatome™ and has a diameter of 9.5 mm. Note the larger hinge angle on the right reduces the area available for excimer photoablation. Photograph courtesy of IntraLase®.

Transient light sensitivity syndrome

One complication that is peculiar to the femtosecond patient is the syndrome of transient light sensitivity also known as GAPS (good acuity photosensitivity syndrome). This consists of complaints of severe light sensitivity occurring around 2 to 6 weeks after LASIK. Even low levels of light from television or computer use can be quite uncomfortable for these patients. Visual acuity is generally not affected and the slit-lamp examination does not reveal inflammation. Topical steroid treatment brings resolution without long-term sequelae. Decreasing the laser energy settings appears to greatly reduce the occurrence of light sensitivity.[15]

KERATITIS

Both infectious keratitis and DLK can occur following use of the mechanical microkeratome or the femtosecond laser. Early reports revealed that there may be an increased incidence of DLK following use of the femtosecond laser. This has not been borne out in larger studies to date but most surgeons using femtosecond lasers for flap creation do use topical corticosteroids at a higher frequency and longer duration on average than cases being done with a mechanical microkeratome. There is some advantage to the femtosecond laser in regard to infectious keratitis as it eliminates the keratome and blade as sources of infection.

Visual outcomes

There are some obvious reasons why better vision could be expected when LASIK is performed with a femtosecond flap rather than a mechanical microkeratome flap. The femtosecond flap is highly uniform in thickness (Fig. 95.9). In contrast, mechanical keratome flaps tend to be more meniscus shaped as discussed above. Undercutting of the hinge in femtosecond flaps may contribute to a more uniform mechanical stability.[16] Despite theoretical advantages, research on visual outcomes to this point is mixed.[13,17] The most important measure, uncorrected visual acuity appears to be equal in both groups in most studies to date. Contrast sensitivity appears to be slightly better in the femtosecond group at the 3-month visit.[14] There also appears to be less induced astigmatic refractive error after femtosecond surgery.[5] There are two possible reasons for this. The first reason is that the hinge is undercut on the femtosecond laser, perhaps giving a more uniform, spherical, biomechanical stability of the cornea.[18] The other reason is that the hinge can be made smaller with the femtosecond laser providing more room for ablation near the flap[19] (Fig. 95.14).

Mechanical microkeratomes and femtosecond lasers both appear to be safe and effective for generating LASIK flaps. The femtosecond laser currently holds an edge in appearing to give similar visual results while eliminating or reducing certain types of flap complications. Improved predictability with uniform flap shape may help in patients with thin corneas where residual stromal bed thickness may be inadequate if the flap is inadvertently too thick. It is still controversial whether the femtosecond laser has optical advantages, such as improved contrast sensitivity or better uncorrected distance visual acuity. While not consistently shown in clinical research, there are theoretical visual outcome advantages to having such features as a uniformly dry stromal bed upon flap lifting and an undercut hinge with a small arc length.[20]

In conclusion, for any new device to displace prior technology, typically one or more hurdles need to be overcome. One could look at a comparison of which technology is better, cheaper, and faster as an initial filter. It is not universally believed that laser flap creation is better but this may change with time. At present it is substantially more expensive to use femtosecond technology than mechanical microkeratomes and it is certainly slower although this may eventually be overcome. The last concept to understand is safety. There is substantial controversy regarding safety as there are certainly risks with either technology that are not present with the other. Yet, with technology sometimes you do not have to universally and definitively beat the prior technology to gain traction in the market. It is likely that femtosecond technology will continue to gain market share and utility among ophthalmic surgeons. The time frame to obsolescence of mechanical microkeratomes is not certain as the cost for femtosecond laser technology is prohibitive in many regions of the world currently. But as with most technological evolutions, costs will come down and the technology will find greater geographic adoption.

96 Femtosecond laser-assisted corneal surgery

Qais A. Farjo, Ayad A. Farjo

INTRODUCTION

The development of femtosecond laser technology has created new opportunities to advance corneal surgery, where the technology can take advantage of the unique anatomy and accessibility of the cornea. These lasers work by creating an extremely short, focused pulse of energy, causing formation of a cavitation bubble.[1,2] As the energy can be focused at a desired depth, even through mild opacities, creation of numerous adjacent cavitation bubbles in a specified pattern provides a precise and powerful tool for tissue dissection. In the cornea, automated planar dissections can be readily created and lamellar flaps are now commonly made with these lasers. With the desire for minimally invasive procedures and predictable outcomes, it is possible this technology will advance the standard of care in corneal surgery in coming years.

CLINICAL APPLICATIONS

LASER-ASSISTED IN SITU KERATOMILEUSIS SURGERY (LASIK)

The primary advantage for the use of femtosecond lasers in corneal refractive surgery is the improved safety over microkeratomes in creation of the lamellar flap.[3] Additional advantages include increased precision,[4,5] customization, and ease of surgery. The chief disadvantage is the cost of purchasing and maintaining the complex equipment. Likewise, it is unclear whether there is a visual advantage to the patient.[6,7] In LASIK, the procedure has also traditionally taken longer to perform than blade-based microkeratome flaps, although increases in laser speed have diminished this difference with the approximate cutting time being 15–20 s for a 60 kHz laser engine.

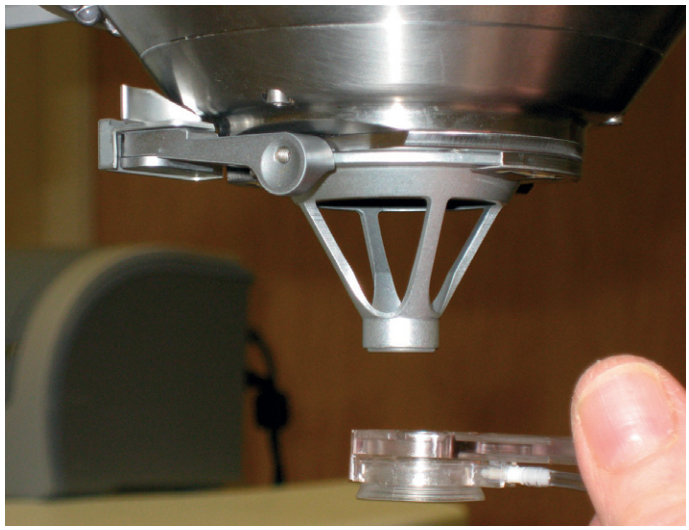
Since the introduction and widespread dissemination of LASIK, the most concerning complications of the procedure involve problems inherent in the creation of LASIK flaps. Although microkeratomes are generally safe with low complication rates,[8,9] most sight-threatening problems associated with LASIK occur as a result of flap complications.[10] The driving force behind the adoption of femtosecond lasers has been to minimize these complications.

The safety and precision of laser-based flap creation results in generally lower standard deviations of the flap thickness relative to those of blade-based flaps,[3–5] although this advantage may be less prominent when compared with newer microkeratomes. Lower degrees of suction are necessary for creation of femtosecond laser-based flaps, with only a spring-loaded syringe necessary to generate adequate suction (Fig. 96.1, *A* and *B*). Additionally, as the flap is cut optically, the entire procedure can be visualized. The ability to focus within the corneal stroma allows the creation of the internal aspect of the flap prior to cutting of the edges (Fig. 96.2, *A–C*). This 'inside-out' cutting approach reduces the concern for problems such as free caps or buttonholes. If a problem is encountered while the cavitation bubbles are being formed, the procedure can be aborted or restarted without concern because the edges have not been cut and the tissue is not displaced. Furthermore, as the flap is often adherent at points between the laser spots, it is not truly free until an instrument is used to bluntly complete the dissection also allowing the procedure to be aborted without fear of visual consequence.

Femtosecond lasers allow for customization of the flap for each patient. In addition to producing reliable flap thicknesses, the flap diameter can be selected to one-tenth of a millimeter. This consistency can be achieved because variations in suction, speed of cutting, and corneal steepness do not affect flap diameter as observed with blade microkeratomes. Flap hinge position can be placed in any axis desired, including temporally hinged flaps that may better preserve corneal nerves and provide improved surgical exposure. The width and angle of the hinge can also be reduced if needed to further enhance surgical exposure. Such hinges allow the LASIK flap to be completely reflected during the excimer procedure, providing protection for the hinge during ablation and placement of the entire excimer treatment within the flap bed. Finally, flap centration is also customizable allowing for precise localization over the patient's pupil, effectively eliminating problems associated with decentered LASIK flaps.

One factor that may also lead to improved accuracy when using femtosecond lasers is the creation of a more consistently hydrated

A



B

Figure 96.1. *A*, The ring is placed on the eye and a spring-loaded syringe is used to generate suction. *B*, The applanation cone is then docked to the ring, which allows for precise delivery of the laser energy to the eye. A side view of the Intralase applanation cone attached to the laser and how the suction ring can be docked is shown.

LASIK bed. Microkeratome blades will generally track moisture and debris from patient tears or from sterile water used to lubricate them into the LASIK bed. This alteration of hydration can have unpredictable effects on the absorption of excimer laser energy. While such effects are generally minimal, they can occasionally result in undercorrections or irregular astigmatism, especially when treating large refractive errors. Because no fluid is generally brought into the interface by the femtosecond laser, a more consistent level of hydration is obtained between procedures, possibly improving the predictability of the excimer ablation.

Technique

The authors use standard LASIK instrumentation, but add an instrument for blunt dissection (e.g. Barraquer spatula), a Sinskey hook, and a nontoothed forceps for flap reflection. In the authors' practice the femtosecond laser is in the same room as the excimer laser, although in other practices these are sometimes in separate rooms. The latter allows the surgeon to create a flap then perform an excimer ablation on another patient while the cavitation bubbles dissipate on the first patient. Generally, the preferred laser settings for the author are a 9.0 mm flap diameter and 120 μm depth, which create a flap that is similar to a 'manhole cover' and allows for better reseating after the excimer ablation, minimizing flap striae.

The general technique is similar to standard LASIK procedures. Anesthetic drops are applied followed by placement of the suction ring with care to center over the pupil. The cornea is applanated and the cone centered on the pupil. Centration of the suction ring on the pupil is important for creation of consistently large and centered flaps. Although the flap can be centered in real time by software, a grossly decentered suction ring may necessitate excessive recentering by this method and results in a reduction of flap diameter. With experience, centration becomes simpler and less software manipulation is required. During the procedure, it is best to encourage patients to raise their eyebrows and avoid head movement to prevent loss of suction. Cavitation gas bubbles can occasionally travel retrograde through Schlemm's canal into the anterior chamber[11] and are of little consequence, though they may require waiting for excimer ablation as they may interfere with pupil tracking. Leaving a small crescent of cornea superiorly that is not applanated may be helpful to allow accumulation of gas bubbles as the flap is cut. For bilateral cases, it is generally easiest to cut flaps on both eyes before performing excimer ablation. After flap creation, it is not necessary to wait for the cavitation bubbles to clear before lifting the flap.

The eye is then prepared in the standard fashion for LASIK. Lifting the flap is generally more difficult than standard microkeratome flaps. The Sinskey hook is used to localize the edge of the flap, followed by insertion and sweeping by the Barraquer spatula. As the flap is thinner than most microkeratome flaps and the underlying adhesion is greater, care should be taken to avoid damaging the flap while sweeping and lifting. The undersurface of the flap tends to appear slightly more irregular than microkeratome-based flaps, but this does not appear to have any detrimental effect on vision (Fig. 96.3). In areas of opaque bubble layer (OBL) formation, the adhesion of the flap tends to be greater and somewhat greater force is required to free the flap. The flap is then reflected and the excimer ablation is performed. After replacing the flap, it is massaged away from the hinge and the gutter margin is inspected for even width to verify proper re-positioning.

Occasionally, suction loss during creation of the flap will occur and, depending on the degree of completion, the procedure can be either repeated or aborted (Fig. 96.4, *A–C*). When attempting a re-cut at the same depth as previously desired, the laser usually will create cavitation bubbles in the plane that was previously intended. However, extra care must be taken during lifting of the flap to avoid entering the incorrect plane. Recognition of the cause of suction loss is important in prevention of recurrence. It is also possible to perform a 'side cut' only procedure, without re-cutting the entire bed, if the procedure aborted during this final phase of flap creation. Recentration of the flap is important and it is recommended to reduce the flap diameter by 0.2 mm to assure that the side cut will fall within the diameter of the previously cut bed. The flap edges can also be cut manually using a surgical blade or curved corneal scissors. When cutting with corneal scissors, it is advisable to cut with a slight pressure radially to ensure the largest possible flap is created.

If the procedure is aborted, the flap can be reattempted once the cavitation bubbles have cleared after several minutes. It may,

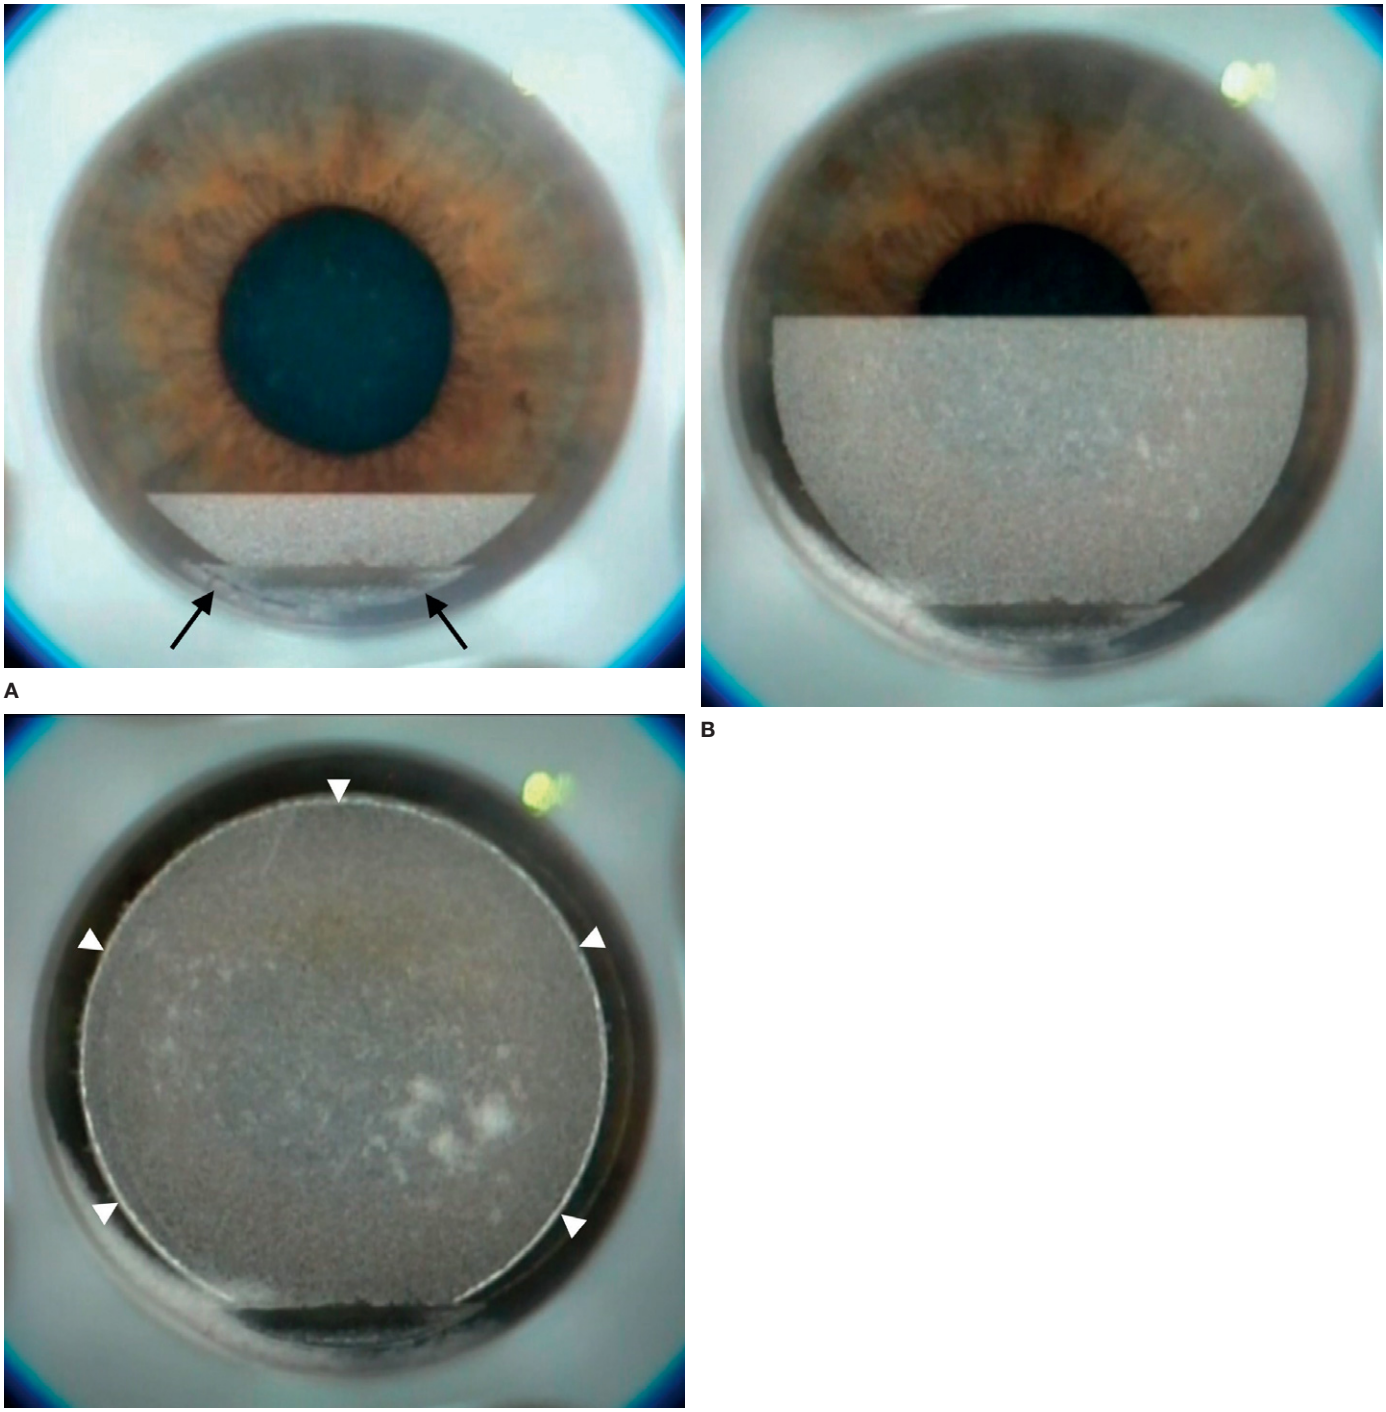


Figure 96.2. *A*, The internal portion of the LASIK flap is cut before the edges. Note the 'pocket' which is created prior to the planar cut in order to act as a reservoir for intrastromal gas (black arrows). Leaving a small meniscus of unapplanated cornea superiorly is recommended to facilitate transit of accumulated gas into the pocket. *B*, A raster pattern of cavitation bubbles creates the lamellar dissection. *C*, The arc of ablation can be seen performing the side-cutting of the flap edges anteriorly (white arrowheads).

however, be advisable to have the patient return in 2–4 weeks to avoid creating multiple planes. Addressing the underlying cause for the aborted procedure is important. For example, if a patient was squeezing excessively during the procedure they should be coached in relaxation of their eyelids or eye brows. Occasionally, injection of local anesthetic into the brows can be helpful for patients who have difficulty relaxing them. Unlike blade-based microkeratomes where head movement will generally not affect suction, subtle head movement can cause a loss of suction and necessitate aborting the procedure. Comfortable and stable head positioning is therefore important before initiating the procedure. As the laser cone may come into contact with the nose, it is recommended that the head be turned slightly in the opposite direction from the eye that is being worked on to reduce this possibility.

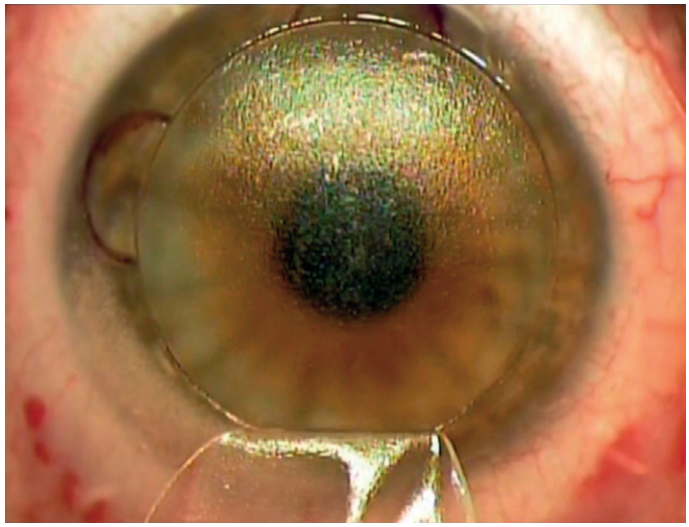

Figure 96.3. Lifting of femtosecond-assisted LASIK flap. Note that the narrow hinge angle allows near total reflection of the flap, allowing complete placement of the ablation. Also note the somewhat more irregular surface of the flap bed compared with blade-based microkeratomes.

Postoperative care

Femtosecond lasers tend to create a greater amount of intracorneal inflammation than microkeratomes. This can lead to more intense postoperative pain and irritation, for which patients should be prepared in advance. Initiation of prednisolone acetate 1% drops and a topical antibiotic immediately after surgery is helpful in controlling this. An oral analgesic may also be necessary for pain control. The pain typically lasts less than 6 h and can be alleviated with application of topical steroids and artificial tears as well as oral analgesics. Oral nonsteroidal anti-inflammatory drugs (NSAIDs) are often useful in treating both the inflammation and pain, although narcotics are certainly more effective in treating the pain. Transient light sensitivity syndrome (TLSS), a condition in which patients suffer significant postoperative photophobia, has been reported to have an incidence of 1.3% after femtosecond laser flap creation and is thought to be related to higher pulse energy settings. The problem is unpredictable but generally self-limited and responsive to early institution of topical steroids.[12,13]

Because of the design of the planar flap with vertical flap edges, healing tends to occur faster and more vigorously than with traditional blade-based microkeratomes. This improved healing is generally advantageous, but it can make lifting flaps for repositioning or enhancement more difficult. Not surprisingly, the longer the time that is allowed to pass the more difficulty there will be in lifting the flap. Although the flap lift procedure does not differ significantly, extra care must be taken to avoid traumatizing the flap which could allow epithelial ingrowth subsequently. Performing enhancements between 3 and 6 months is generally accomplished without too much difficulty. Afterwards, it may be more advantageous to re-cut the flap rather than lift it.

INTRACORNEAL RING SEGMENT IMPLANTATION

Intracorneal ring segments such as Intacs are an accepted treatment for low degrees of myopia[14] and in recent years, they have become recognized as a valuable surgical treatment of ectatic disorders of the cornea such as keratoconus[15–19] and post-LASIK ectasia.[20,21] Insertion of the segments results in central flattening by taking advantage of corneal biomechanical properties. Although manual systems exist for the implantation of intracorneal ring segments, the use of femtosecond lasers offers distinct advantages. These include customization of the axis, depth, and width of the channels, uniform depth of the channels for 360°, and increased speed and safety of the procedure. On the other hand, some disadvantages compared to manual dissection exist in addition to cost. Chiefly, the uniform depth of the channels does not necessarily follow a path between corneal lamellae. Even by increasing the laser ring energy to assure that the dissection is complete, this factor as well as the presence of microadhesions within the channel, can make insertion of the ring segments more problematic.

In the author's and other's experience,[22] intracorneal ring segments have greatest effect in treatment of early keratoconus. In many cases the cone will persist, but will be flattened and centered postoperatively. In patients with advanced keratoconus, distortion and high astigmatism may remain, requiring continued use of contact lenses. Most patients experience improvement in contact lens tolerance associated with the improved corneal contour.[23] With thinner preoperative corneas and central cones, the refractive effect of the segments can be quite dramatic. With diseases such as pellucid marginal degeneration where peripheral thinning can be significant, or with greatly decentered cones, use of a femtosecond laser may not be possible without cutting more at a more shallow depth. In such cases, it may be best to use a manual dissection system to avoid perforation.

Technique

The instrumentation required is less extensive than that needed for manual insertion and include a Sinskey hook, symmetric glide, Intacs insertion forceps, needle driver, and tying forceps. The first step is centration and, although the manufacturer recommends insertion of Intacs on the geometric center of the cornea, the authors advise centration on the pupil. This reduces patient complaints of glare and night vision disturbances and does not seem to have any adverse effect on procedure efficacy. Placement of the Intacs so that the incision is along the steep refractive axis of astigmatism is also recommended. Although this will usually coincide with the topographic incision, occasionally they will be different. In rare cases where the topographic axis is 90° away from the refractive axis, it is best to follow the topographic landmarks to determine optimal placement of incision axis.[24] If a ring illuminating light source is available (as with the VISX laser), the steep axis can often be confirmed by using this as a qualitative keratometer (Fig. 96.5, *A–C*).

Nomograms have been published by the manufacturer for selection of ring sizes in myopia with normal corneas as well in keratoconus (Table 96.1).[24] In considering segment selection for keratoconus, choice of segment thickness is dependent on the severity of the patient cone and patient refractive error preoperatively. Asymmetric implantation with placement of a thicker segment inferiorly and thinner segment superiorly has been generally reported to be effective in treatment of keratoconus.[17,18] Additional reports exist describing implantation of only a single segment inferiorly or adjustment of the procedure by removal of a superior segment.[18,25,26] The authors have found that symmetric segment implantation is generally effective and tends to produce the most flattening of the cone (Table 96.2). Symmetric segment implantation is also effective in recentering the cone. As would be expected,

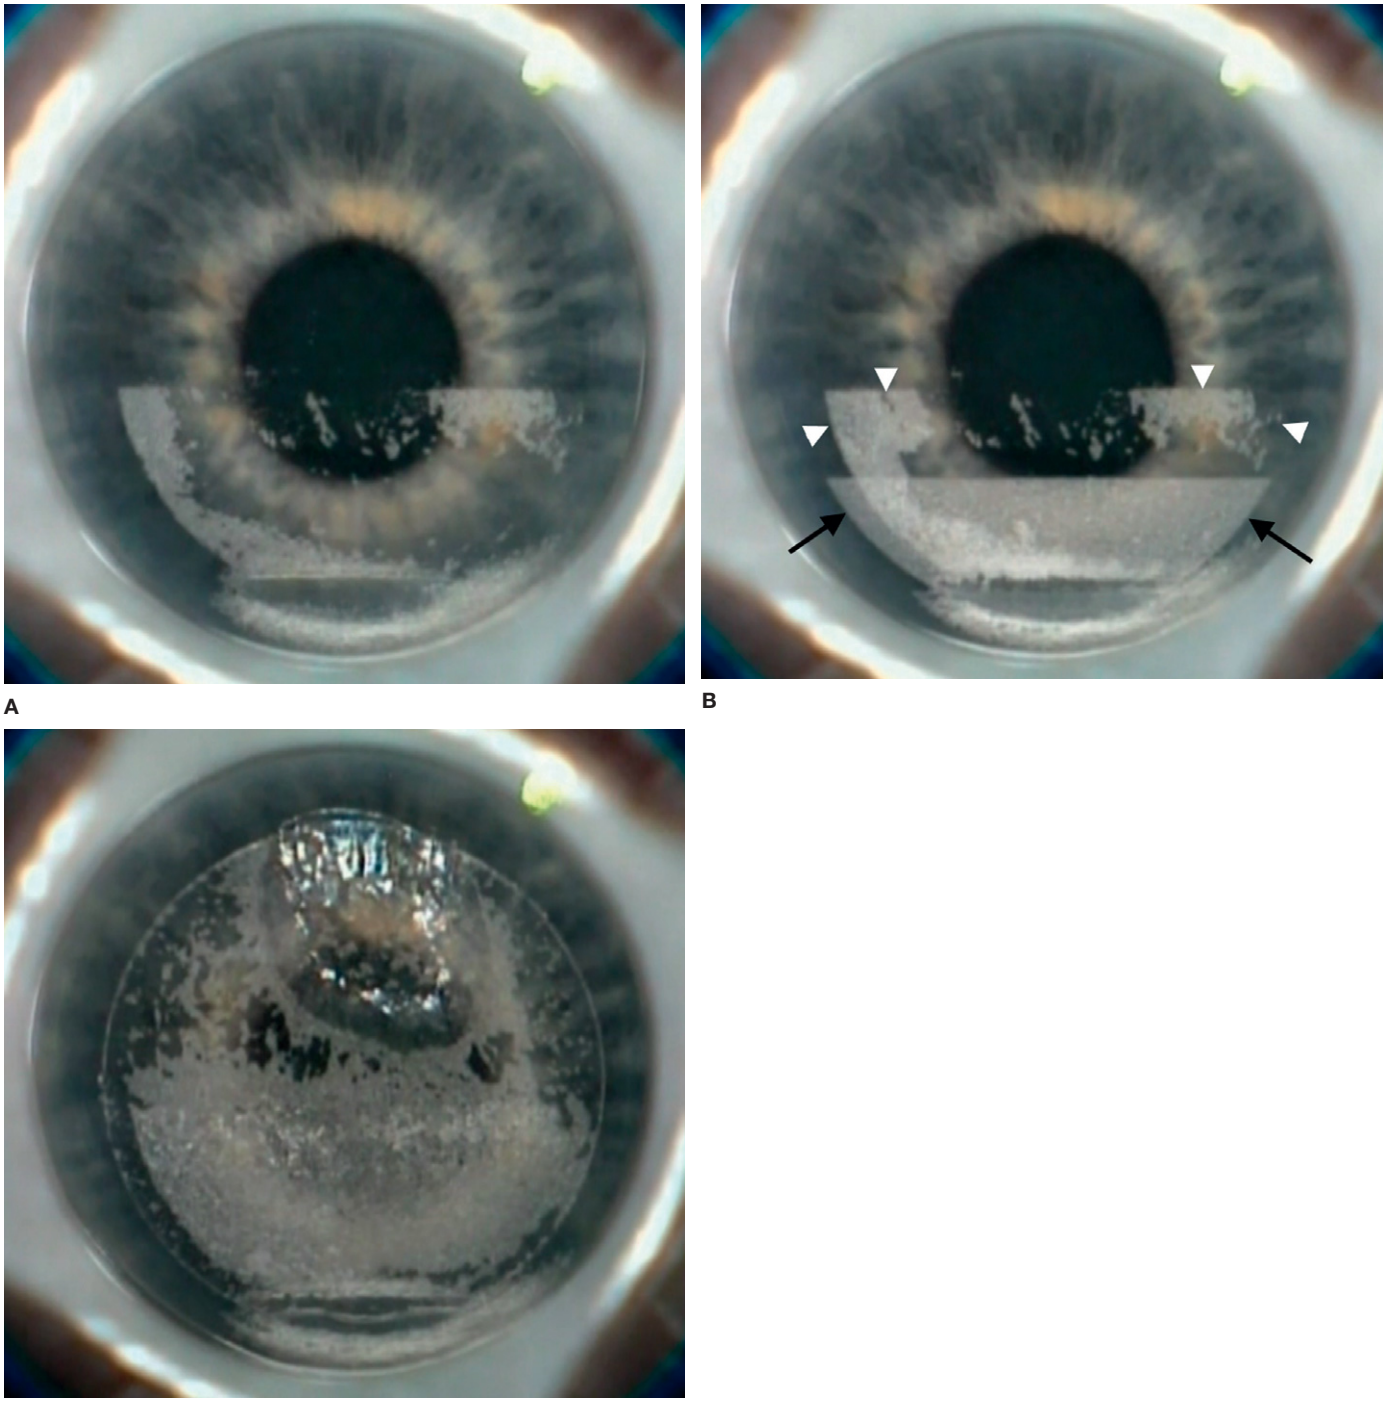

Figure 96.4. *A*, Immediate re-cut of LASIK flap after procedure interruption due to suction loss. *B*, The edges of the previous flap (white arrowheads) are visible during re-cutting of the new flap (black arrows). *B*, Successful re-cut of the flap. Note that the re-cut diameter was slightly larger than the original flap. This may indicate that the original flap attempt may have had poor ring centration, which resulted in software reduction of the flap diameter, and may have been contributed to initial suction loss.

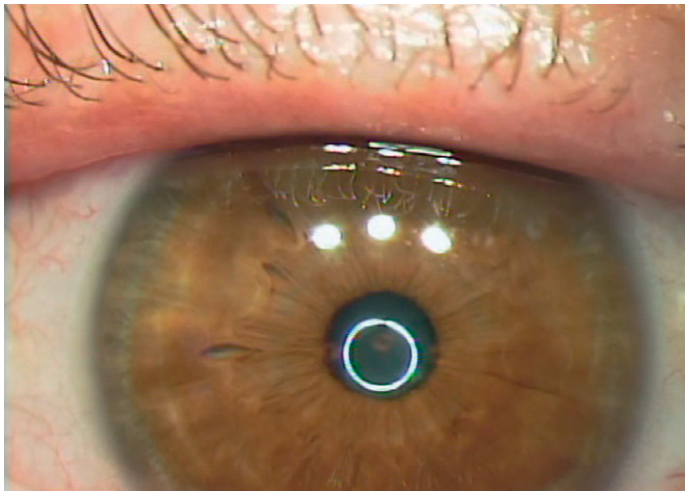
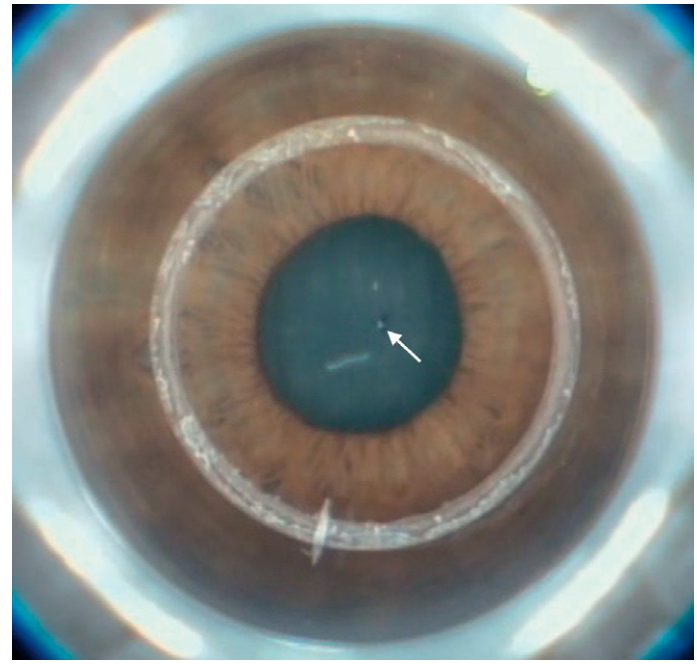
implantation of the thickest segments (0.35 mm in the USA at time of this writing) results in the greatest flattening of the cone and greatest refractive effect.

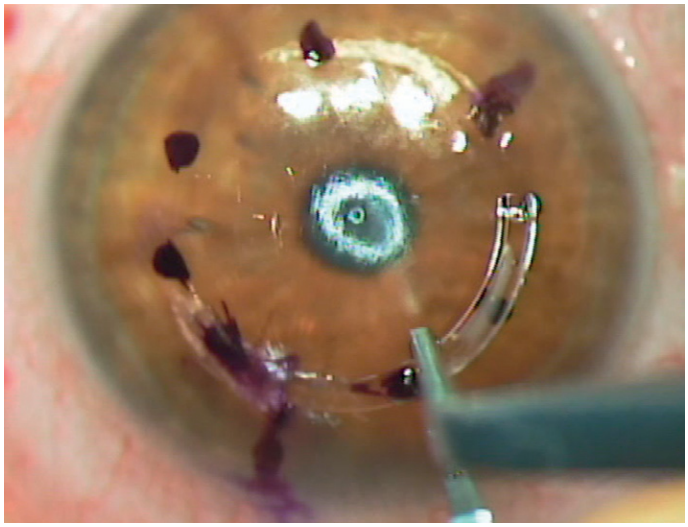
The more narrow the channels, the more difficult the insertion of the segments will be. However, with more narrow channels, the effect of the segments is greatest in the authors' experience. As this can be customized, it is recommended that the channels be made wider for initial cases and gradually decreased as surgeon experience allows. Inner tunnel diameter can vary between 6.6–6.8 mm and the outer diameter can vary from 7.4–7.6 mm. For initial cases, a combination of 6.6 mm inner diameter and 7.6 mm outer diameter is recommended with reduction of the outer diameter with experience. The authors finds the best balance of efficacy with ease of insertion by setting the inner diameter to 6.6 mm and the outer diameter to 7.5 mm, especially when the 0.35 mm segment sizes are used. To insure easiest insertion, the difference between outer and



A



B



C

Figure 96.5. *A*, Ring illumination confirms the steep astigmatic axis on the cornea. *B*, Femtosecond laser channels are created with placement of the entrance incision on the steep topographic axis. Note that channel is centered on the pupil rather than the geometric center of the cornea marked in blue (arrow). *C*, It is recommended that the ring segments be grasped at the midpoint of the exposed segment to maximize insertion force and reduce the chance of fracturing the segment. Direct marking of the segment channels as depicted is not advised as this tends to collapse the channel, making insertion more difficult.

Table 96.1 Intacs manufacturer recommended Intacs nomogram in keratoconus

Preoperative SE	<3 D	>3 D
Intacs size	0.25 superior/0.30 inferior	0.25 superior/ 0.35 inferior

SE = Spherical equivalent.

D = Diopter.

Rapuano CJ, Sugar A, Koch DD, et al. Intrastromal corneal ring segments for low myopia: a report by the American Academy of Ophthalmology. Ophthalmology 2001; 10: 1922–1928.

Table 96.2 Authors' suggested Intacs nomogram in keratoconus (symmetric segments)

Preoperative SE	<1.5 D	1.5–2 D	2–2.5 D	2.5–3 D	>3 D
Intacs size	0.25	0.275	0.30	0.325	0.35

SE = Spherical equivalent.

D = Diopter.

inner diameter should be double the segment size (e.g. 0.6 mm difference for 0.30 mm segment size).

The depth of the cornea should be measured along the path which the Intacs are expected to take. The depths of the channels should be set to approximately $^{2}/_{3}$ of this depth. For standard, healthy corneas, this depth can be approximated by subtracting 90 µm from the central corneal thickness. The manufacturer advises against implantation of ring segments into corneas thinner than 450 µm at the incision site. When inserting the segments, one should be careful

to locate the full depth of the channels in order to avoid creating a false passage. As noted above, insertion of Intacs segments into channels created by femtosecond lasers can be more challenging than implantation into channels created manually. Floating the Intacs in a drop of antibiotic solution makes removal from their protective case easier. In general, if one grasps the midpoint of the segment that is not within the channel and exerts a small rotational force, the segments can be most easily advanced. Other options include increasing ring energy to assure complete dissection, slow insertion of the Intacs, and insertion of a semicircular guide. In most cases, resistance can be overcome with slow and steady pressure and counter pressure with a dry sponge will help open up the incisions. Attention should be paid to try to follow the semicircular pattern of the channels with a small rotational effort. Sometimes removing the segment and reinsertion with emphasis paid to maintaining momentum of insertion also can prove helpful. A dry technique is recommended as hydration of the incision site or channels creates stromal swelling that can make it more difficult to insert the segments. The segments should never be forced into the channel as a false passage may be created and, if the implantation is excessively difficult, the channel should be re-cut. Finally, care should be taken to avoid tracking of epithelium into the channels during insertion and the channels should be checked to be free of epithelium at the end of the procedure, with no gaping of the incision, to reduce the potential of postoperative epithelial ingrowth.

For bilateral cases, although it can be more time efficient to cut the channels in each eye followed by insertion of the segments, the authors advise that each eye be done individually. The primary reason for this is that visualization of the channels, which are filled with air bubbles, is easiest immediately after cutting and that the channels tend to close, if left too long making insertion of the segments more difficult. Although marking of the channels with ink on the corneal surface after cutting can improve visualization, it is advised to avoid this if possible as this can also tend to cause the channels to close at the points of marking (Fig. 96.5, *C*). If implantation is complicated, it allows the surgeon and patient the option of reconsideration of proceeding with the second eye. At the conclusion of the procedure, suturing of the incision is recommended as it can prevent epithelial ingrowth, segment migration, and infection and assure good healing. The suture will generally loosen within 3–6 months and can be removed when this occurs.

Postoperative care

Inflammation following Intacs implantation is moderate with both manual and femtosecond approaches and oral analgesics are recommended. Prednisolone acetate 1% drops and a topical antibiotic are recommended to be used four times daily for 1 week. The drops can be discontinued without taper. Photophobia is not unusual following intracorneal ring segment implantation and may persist for 1–2 weeks in some patients. In rare circumstances, one or both of the segments may need to be explanted.[27] If unsuccessful in improving the patient's visual function, keratoplasty can be performed subsequently. Finally, it is important to counsel patients that the ring segments are used to delay keratoplasty and do not cure keratoconus with likely progression of the disease in the long-term.[28]

FEMTOSECOND LASER-ASSISTED KERATOPLASTY

Femtosecond lasers are also being used for optical lamellar,[29] endokeratoplasty,[30–33] and penetrating keratoplasty.[34–36] At the time of this writing, these techniques are being refined and there is sparse literature on outcomes of these procedures, especially relative to standard manual techniques.

Optical lamellar keratoplasty

The best candidates for femtosecond laser-assisted optical lamellar keratoplasty are those patients with corneal scarring but minimal thinning and generally uniform corneal thickness. The procedure may be especially useful for patients with focal anterior corneal scarring or those with anterior stromal dystrophies who fail therapy with phototherapeutic or superficial keratectomy. The technique and management is similar to standard lamellar keratoplasty except that oversizing of the corneal donor relative to recipient is generally not necessary. An exception is in cases involving severe recipient scarring extending to the limbus, oversizing by 0.25–0.5 mm may be helpful in reducing postoperative astigmatism and induced hyperopia. The procedure can also be performed under topical anesthesia.

Harvesting of the donor is most readily accomplished using a donor globe but, because of hypotony and the fact that the conjunctiva is generally absent, obtaining adequate suction and applanation can be difficult while harvesting the donor. It is important to apply a slight but steady pressure on the posterior aspect of the globe while cutting the tissue. Determining adequate corneal depth for dissection of the host and donor is essential. Estimation of depth of the opacity, coupled with ultrasonic corneal pachymetry measurements can be used to arrive at a setting for recipient dissection. Cutting a donor lenticule 50–100 μm deeper than the recipient can compensate for edema of the donor. One must also consider that if the epithelium is removed from the donor prior to harvesting, this tends to increase effective donor stromal depth by 50–60 μm. Preoperative recipient corneal thinning might also be a factor in determining to create a thicker donor button than that which is excised.

In general, energy settings need to be increased as the laser cuts deeper within the cornea. Because variation in laser energy output exists between lasers, the optimized energy settings for standard femtosecond-assisted LASIK flaps should be used and then adjusted upwards. For every 20 μm over 160 μm depth, the raster pattern needs to be increased by 0.1 J over the LASIK settings. If the laser is focused through a dense scar, the total energy should be increased by 0.2 J in order to create an effective plane of dissection (Fig. 96.6, *A–C*). Side cut energy is generally set 0.5 J greater than the raster energy. Energy adjustments for the harvesting of the donor lenticule are also advised. The settings tend to be similar to the host settings when similar depths are used. After allowing the donor disc to adhere to the corneal bed, placement of a single continuous suture is recommended to secure the graft and reduce induced astigmatism.

Inflammation following lamellar keratoplasty is generally well controlled with topical prednisolone acetate 1% which can be continued for 1–2 weeks. A topical antibiotic is recommended for 1 week. As the procedure can be performed under topical anesthesia, the drops can be initiated immediately postoperatively. Removal of sutures can be completed by 3 months or as the suture loosens.

ENDOKERATOPLASTY AND LASER-ASSISTED PENETRATING KERATOPLASTY

Deep lamellar endothelial keratoplasty (DLEK), posterior lamellar keratoplasty (PLK), and Descemet's stripping endothelial

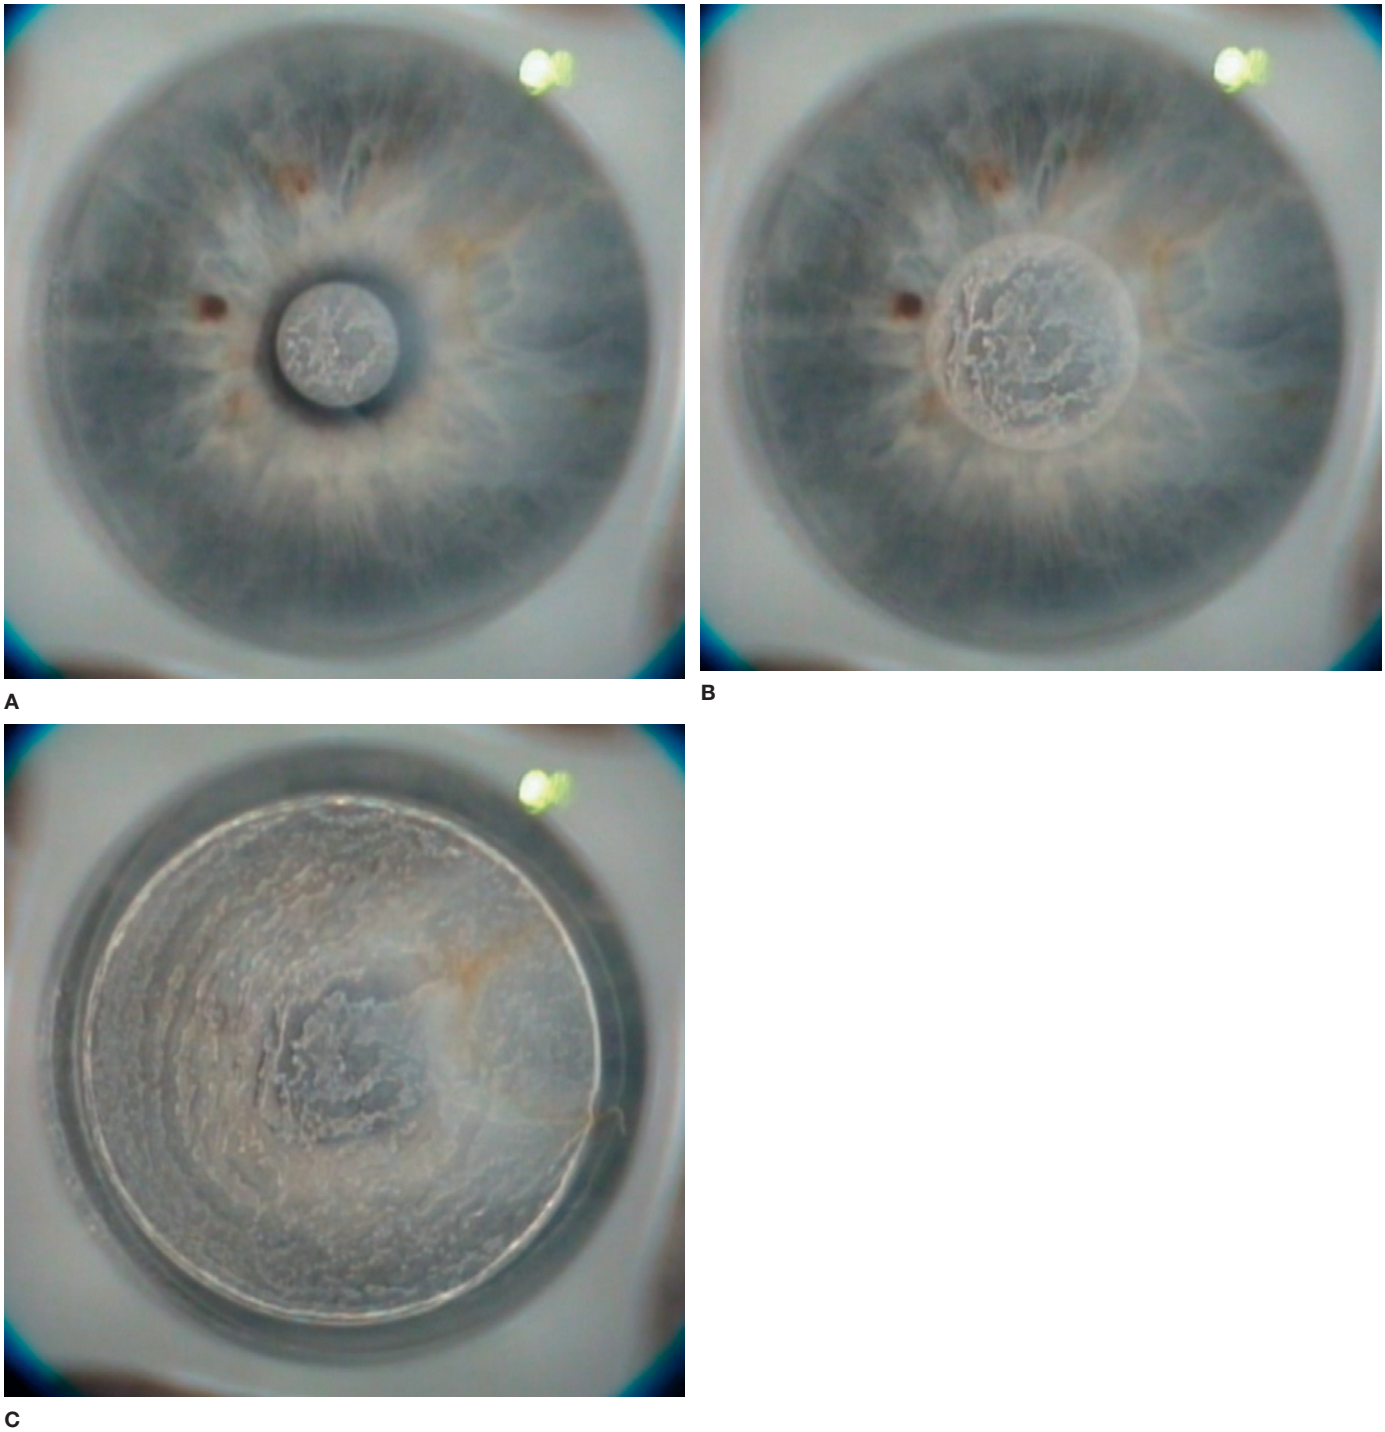


Figure 96.6. *A–C*, A spiral pattern is used to create the lamellar dissection for anterior lamellar keratoplasty in an eye with an arcuate scar bisecting the pupil.

keratoplasty (DSEK) have become more popular alternatives for the replacement of abnormal corneal endothelium. Creation of a posterior lamellar dissection plane in order to remove an endothelial button can be achieved with a femtosecond laser.[31–33] The lamellar button can then be removed through a limbal penetrating corneal incision. Such dissection can be more consistently and reliably achieved with a femtosecond laser than with manual methods and eliminates the risk of anterior or posterior perforation during dissection.

Even with procedures that do not involve significant resection of the host such as DSEK, femtosecond lasers offer potential to improve surgical time and outcomes through more precise creation of donor buttons. Precut donor tissue is now available from many eye banks and more precise depth of dissection may be possible with use of femtosecond lasers.[37,38] There may be improved sterility over a microkeratome given that a blade does not pass through the interface. Microadhesions between the donor disc and the anterior stroma also offer the advantage of prevention of dislocation during

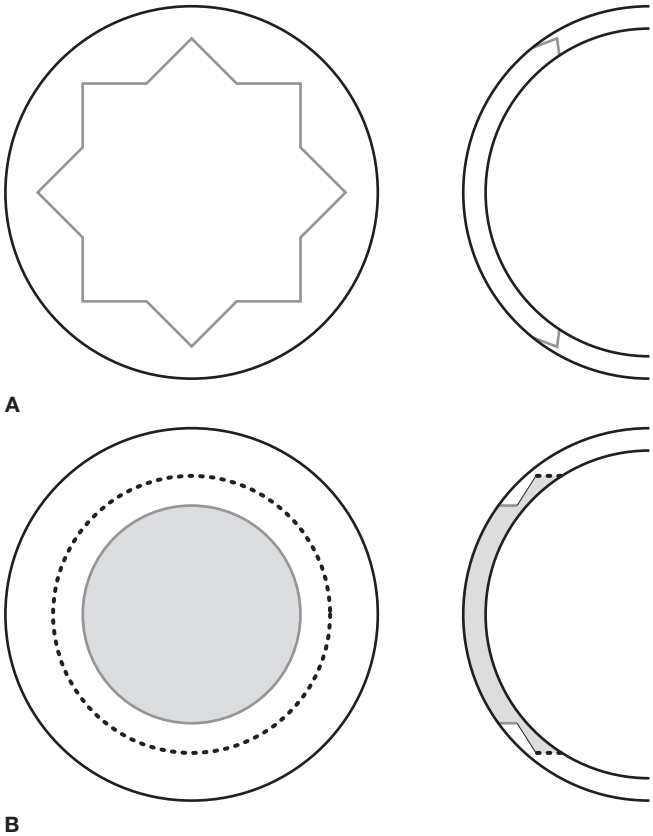

Figure 96.7. *A*, Geometric-shaped penetrating grafts can be fashioned so as to improve wound strength, tissue distribution, and possible postsurgical astigmatism. *B*, 'Top hat' shaped configurations may allow for improved wound strength.

transportation. The bed may not be as smooth as one cut with a microkeratome, which may have an unclear impact on donor adhesion, and intraoperative separation of the donor disc from the donor stroma might be more difficult with this method.

Penetrating keratoplasty with dissection of both donor and recipient by the femtosecond laser has a number of attractions. With the ability to fashion unusually shaped donor lenticules that 'dovetail' with the recipient, the femtosecond laser has the potential of improving healing time and induced astigmatism (Fig. 96.7, *A* and *B*). Inverse-mushroom or 'top-hat' shaped grafts theoretically should be better secured and more resistant to traumatic wound dehiscence. Conical incisions and positional spikes may allow better tissue distribution and wound strength. Fewer sutures would likely be necessary to secure such grafts, reducing operative time and suture-related complications. Likewise, with better healing, the sutures would be able to be removed earlier than with traditional penetrating keratoplasty.

Limitations, however, remain as far as application of this technology to all patients requiring penetrating keratoplasty. Patients with severe disorganization of the cornea or anterior segment may neither see any benefit nor be safe candidates for host dissection. Patients with rupture or corneal perforation of the eye would also not be good candidates given the suction currently required to create dissection planes. It is also unclear whether increased surface area contact with the host would increase the chance of rejection. Notwithstanding this, femtosecond lasers may further refine this procedure which, though currently successful, suffers from numerous technical limitations and unpredictability.

SUMMARY

Femtosecond lasers are instruments that offer more surgical precision than current manual techniques. As time progresses, it will become apparent whether this advantage results in better patient outcomes and offsets the additional cost of the devices. In the meantime, new applications for the lasers continue to appear including glaucoma surgery,[39] wedge resection for high astigmatism,[40] and keratoprosthesis implantation.[41] With time, it would be expected that portability and reduced equipment costs will further expand the application of this technology, perhaps beyond ophthalmic surgery.

The authors do not have a financial interest in any products mentioned.

97 Excimer laser enhancements

Frederick S. Brightbill

The decision to 'enhance' or further treat the corneal bed after laser assisted in situ keratomileusis (LASIK), laser assisted subepithelial keratectomy (LASEK), and epithelial laser assisted in situ keratomileusis (EPILASIK), or to enhance the corneal surface after photorefractive keratectomy (PRK), is nearly as important as the initial doctor–patient agreement to undertake the first refractive procedure. Enhancement is a mutual endeavor fostered by the ophthalmologist's knowledge and experience, coupled with the patient's desire for the best possible visual outcome.

Modern day refractive surgery with lasers has most certainly received widespread physician and patient approval. Improved procedures over the past 10 years often, but not always, result in 20/20 distance acuity. Immediate factors influencing the degree of improvement in acuity include: (1) the amount of spherical and astigmatic error; (2) the methods of locating and treating both the astigmatic axis and power; (3) tracking devices; and (4) patient cooperation in the laser room. Regression of the ablation effect with time and/or progression of refractive error may lead to a less than ideal result.

DURATION OF EFFECT

With current follow-up of radial keratotomy and both PRK and LASIK eyes reaching more than 10 years, it appears that the majority of patients having either PRK or LASIK with or without early enhancement remain relatively stable, but that stability certainly cannot be guaranteed. In the 10-year progressive evaluation of radial keratotomy (PERK) study,[1] 43% of eyes were changed in the hyperopic direction by 1.00 D or more between 6 months and 10 years after surgery. With care taken not to offer refractive surgery to younger patients who demonstrate progressive myopia >0.50 D within the previous year, this author's late enhancement rate (greater than 2 years) is 2%. These late enhancement procedures most often are performed with a 150 μm microkeratome rather than the 130 μm initial cut using the Moria CB system (Moria, Inc., Doylestown, PA; Antony, France).

For myopic eyes, the greater the amount of spherical error the more difficult it is to achieve 20/20 vision, as there appears to be greater loss of initial effect than in eyes with lower amounts of myopia. If this author limits the LASIK procedure to patients having −3.00 D or less, experience over 10 years indicates a highly successful procedure outcome in 95% of eyes at 20/20. Those with −9.00 D or higher amounts of myopia, given the standard precaution of not exceeding the 50% rule, the incidence of enhancement in this author's practice climbs to between 10 and 30%.

Careful documentation of progressive refractive error in younger myopic patients at the time of screening is useful to protect against operating too soon, although it is never possible to predict future myopic progression. In my own case while editing the second edition of this text, at age 42 and wearing spectacles, I gained −0.50 D of myopia.

The Kleins' Beaver Dam Eye study[2] in adults with 15 years follow-up found that the direction and amount of change in refraction was related to age and that the spherical equivalent became more positive in the youngest participants in the study and more negative in the oldest. This finding would suggest that refractive patients between ages 43 and 59 with an initial plano result could progress to hyperopia via the aging process. This issue raises the question of whether to limit enhancements in mildly undercorrected myopic patients in their late 30s, to avoid inducing early presbyopia.

PRESBYOPIC EYES AND LASIK

Currently, we have no technology to treat bilateral myopia and presbyopia with excellent visual results at both distance and near, but there are encouraging results in managing hyperopic eyes with presbyopia.[3] This can be modified, however, if the patient is willing to have mild undercorrection in a myopic eye or mild overcorrection in a hyperopic eye, so-called monovision. Conductive keratoplasty (CK)[4] can induce corneal steepening with functional corneal multifocality in an emmetropic eye and, if stable, provides temporary improvement at near. Its downside includes repeated applications with time, as presbyopia worsens with progressive distance blurring in the treated eye. In this author's practice, following preoperative discussions of alternatives, 90% of patients either decline monovision or have progressive complaints of monovision intolerance as they approach ages 50–55, because of the increasing blur at distance.

Most postrefractive patients under this author's care want nothing to do with contact lens wear again, especially since the purpose of surgery is to be rid of them. Alternatively, many patients, especially those who complain of glare and starbursting in the undercorrected eye, are willing to accept spectacles for short periods of time; for example, while driving at night, particularly if it is raining, or while attending a sporting event or concert.

For the postrefractive patient with mild residual myopia (–0.50 to –1.25 D) in one eye and good distance acuity in the opposite eye, so that daylight driving with miotic pupils is easily tolerated, spectacle correction in the undercorrected eye combined with a plano opposite lens is an excellent solution that appeals to both patient and doctor for near acuity preservation. Enhancement is thus avoided.

NUMBER OF ENHANCEMENTS

Initial ablation depth, corneal thickness, ease of lifting the flap, and elapsed time since the previous LASIK procedure must all be evaluated prior to enhancement. There is general agreement for LASIK surgery that either 250 μm or one-half of the initial corneal thickness should be preserved to avoid the potential for corneal ectasia, although initial corneal depth alone[5] most likely is not the only factor in its occurrence. Flapless procedures such as PRK obviously allow for more frequent enhancements due to increased residual bed thickness but suffer from the requirement that the entire procedure must be repeated, in addition to the attendant discomfort.

COMPLICATIONS

Complications are somewhat dependent on surgical technique. Preexistent blepharitis is treated appropriately following the screening evaluation prior to LASIK. This author instills fluoroquinolone drops, 1drop hourly times four, given 24 h preoperatively and 72 h postoperatively; and in the laser room use two 4 s surface irrigation rinses with cooled balanced salt solution. Using this treatment protocol, together with betadine lid skin preparation, there have been no instances of infection in 10 years.

Epithelial abrasions always occur at the site at which the flap is lifted. Care must be taken to locate the plane of the bed rather than only epithelium, which results in 'skidding' across the surface and inducing irregular abrasions, causing added discomfort. By far the most bothersome complication of enhancement is that of epithelial ingrowth. Probst and Machat[6] have classified epithelial ingrowth into four stages, ranging from mild cell growth 2–3 mm from the limbus, which becomes inactive but is always visible on slit lamp examination, yet has no apparent effect on visual acuity; to active epithelial proliferation with progressive astigmatism 90° perpendicular to the growth and with significant increasing blurred vision requiring a flap lift and removal of the ingrowth.

AVOIDING ABLATION WITH SIMULTANEOUS INGROWTH REMOVAL

The ophthalmologist should not perform ablation along with ingrowth removal as it is rarely an undercorrection but rather the growth itself that induces myopic astigmatism. One may simply check the initial first postoperative day acuity, which nearly always is good but which deteriorates in subsequent weeks as the ingrowth becomes clinically apparent. Residual epithelial sheets of cells with a gray jelly-like consistency are easily removed, but individual cells are impossible to identify. Laser ablation of the bed, undoubtedly littered with cells, could lead to even further cell proliferation.

WHEN TO ENHANCE

As in strabismus and cataract surgery, in which a subsequent procedure (e.g. suture adjustment or capsulotomy) is not uncommonly required for a better result, patients having LASIK must understand during the evaluation and workup that enhancements are a part of the process rather than a complication. This is usually reflected in the initial global fee quoted to them. When an enhancement is recommended, it is reassuring for patients to understand that it is not only a quicker but a more comfortable event than the primary encounter and that visual recovery occurs more rapidly than following the primary procedure.

Timing the enhancement procedure is quite important for the final outcome and can never come soon enough for the patient. It therefore requires patience from both parties. When the visual acuity at first seems good but at 4–8 weeks has regressed, the ophthalmologist must be on the lookout for a stable postoperative refraction, with the return of the best-corrected acuity to 20/20 or to the best-preoperative acuity. Higher amounts of preoperative refractive error generally require more time to stabilize than lesser errors. LASIK-induced dryness must be monitored and treated and in fact may partially account for postsurgical regression.[7]

For patients with significant regression that affects their ability to drive or read, spectacles should be provided. When possible, conversion to spherical equivalent and the use of old frames, coupled with limiting coatings and bifocals to reduce cost, results in a happier patient. For some patients who exhibit anxiety while waiting for the enhancement, the ophthalmologist may want to consider paying for the interim glasses as a goodwill gesture.

Repeat topography and 'K' readings should be reviewed to rule out early ectasia.

In general, this author prefers never enhancing a patient earlier than 2 months postoperatively and more recently prefer waiting 3 months with two consecutive stable refractions before proceeding.

THE ENHANCEMENT PROCEDURE

Needed equipment includes:

1. Sterile fine-tipped ink marker.
2. Topical anesthetic (0.5% proparacaine is less likely to induce abrasion than tetracaine).
3. Slit lamp microscope.
4. Sharp instrument for locating base of flap potential space (e.g. Storz golf club foreign body spud with triangulated tip #E084).
5. Flap lifting forceps (e.g. Guell LASIK forceps AISCO #AE4358).
6. Speculum.
7. Cheyet drain with long arm removed.

Procedure:

1. At the slit lamp, dry and mark the limbus at 6 o'clock or at 6 and 12 o'clock axes with a sterile ink pen (Fig. 97.1).
2. Then, using both direct and retroillumination of the thin wound scar, reapply the ink pen without drying just distal to the inferior 150° to 180° edge of the flap (Fig. 97.1).
3. Usual lid/skin prep.

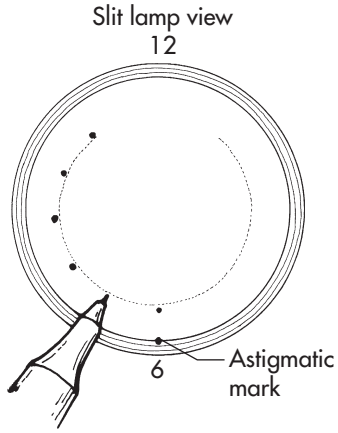

Figure 97.1. At the slit lamp, a sterile ink marker is used to mark the 6 o'clock position for astigmatic alignment and multiple marks over the faint scar at the flap edge using retro and scleral scatter illumination.

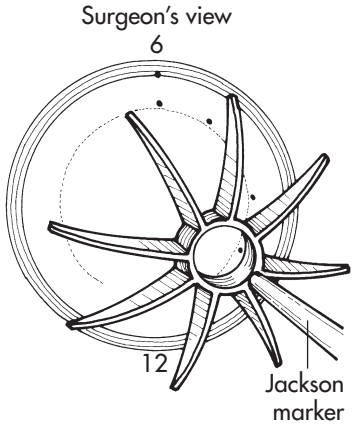

Figure 97.2. At the microscope, the corneal marker is placed overlapping the limbus for flap realignment.

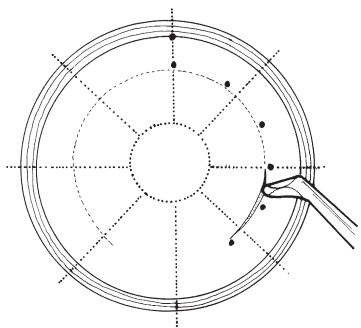

Figure 97.3. Right-handed surgeon's view of 30° angle with slight continuous distal pressure seeking flap 'pocket' with clean, sharp instrument.

4. In the laser room, hold the sharp spud tip at about a 30° angle just distal to flap edge and apply mild inferior pressure, while moving along the wound margin as the tip seeks an opening into the flap space. Care must be taken to angle below the epithelium to avoid large abrasions (Fig. 97.3).
5. Lift 20–25° degrees of the flap edge to facilitate lift with the forceps.

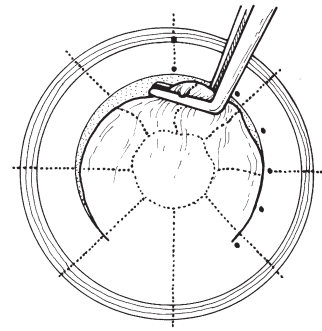

Figure 97.4. Grasp inferior flap edge with forceps pulling towards the superior hinge.

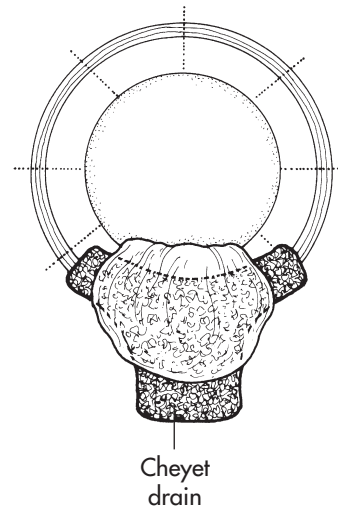

Figure 97.5. Fully expose residual bed up to the edges of the hinge and rest epithelial side down on moistened Cheyet drain.

6. Grasp flap edge gently with forceps and pull towards the flap hinge until the original flap width is reached (video) (Fig. 97.4).
7. Lay flap onto fully moistened partial Cheyet drain to prevent epithelial damage (Fig. 97.5).
8. Check flap edge over all 300° to insure no epithelium overhangs the tear. If present, using a dry cellulose sponge, move distally away from the flap edge so as not to trap it beneath the flap as it is repositioned.
9. Perform laser enhancement and replace flap with usual technique for balanced salt solution irrigation and 'ironing out' epithelial striae with a moistened methylcellulose sponge (Fig. 97.6).
10. Brush distally placed epithelium back across bared Bowman's membrane.

Caution: It is very easy for loose epithelial cells to become trapped beneath the flap, leading to cellular ingrowth. Irrigate copiously beneath the flap; take care to avoid contacting the epithelium with the irrigation tip. Intermittent washing the barrel of the irrigation

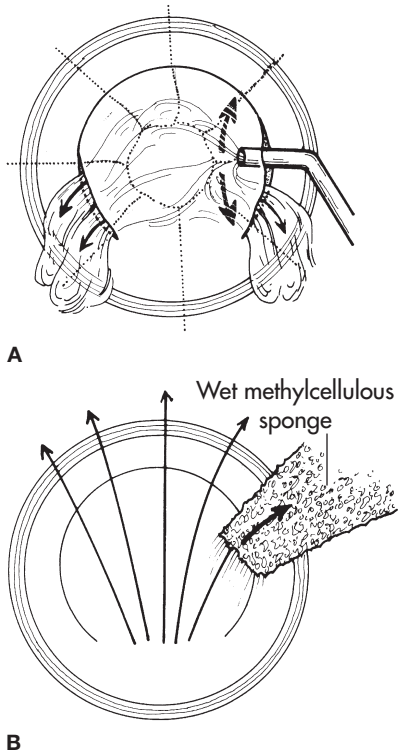

Figure 97.6. Replace aligned flap onto moistened bed and irrigate with balanced salt solution. Care must be taken to avoid excessive rubbing of cannula at flap edge leading to epithelial ingrowth.

tip while operating and careful ultrasonic cleaning with copious irrigation are preventative measures to limit ingrowth*.

**Suggestion*:
A reasonable alternative to post ablation flap-down irrigation is 'flap-up' gentle irrigation of the stromal bed with absorption of the balanced salt solution irrigant using methylcellulose sponges to avoid debris and bacterial contamination.

METHODS FOR INGROWTH REMOVAL

RELIFTING THE FLAP

Active epithelial ingrowth is easily noted on slit lamp biomicroscopy as an amorphous, pearly white, irregular subepithelial opacity that usually, but not always, originates from the flap edge. The ingrowth should be measured in height and width and photographed for comparison several weeks later. A baseline refraction to document astigmatic progression with loss of best-corrected vision is essential for future comparison and for deciding whether to intervene with a second flap lift.

The primary surgical focus with active ingrowth is to avoid stimulating more ingrowth through incomplete removal or inadvertent epithelial cell spreading by instruments placed under the flap. Prior to lifting the flap, the borders of the ingrowth are marked on the epithelial surface with a sterile ink pen at the slit lamp. It is recommended leaving 1.0 mm of clear border from the ingrowth edge. This facilitates visualization of the ingrowth following lifting (and inverting) the flap. The surgeon must remember to mark the flap for enhancements just as in the initial LASIK procedure.

It is prudent to build a platform on which to place the inverted flap, as its removal requires downward pressure to engage the gelatinous clumps of cells. For a superior flap, two stacked, moistened partial Cheyet drains are placed on the superior bulbar conjunctiva. Two sharp #64, #69 or #57 Beaver disposable blades are applied: the first to the inner inverted flap superiorly and the second to remove cells in the stromal bed. Reapplication of the blades is not performed unless they are copiously irrigated and wiped to clean off cellular debris. Both scraped areas are rubbed with non-moistened sterile sponges to remove more cells, but one can never be certain as to how many residual cells remain. The flap is refloated using copious irrigation and smoothed with a wet methylcellulose sponge.

Careful postoperative follow-up, observing for recurrence, is important. It is extremely rare that a second flap lift is necessary; much more commonly, minimal Stage I ingrowth is visible but inactive without progressive astigmatism.

Other methods for removing epithelial cells beneath the flap include: using the YAG laser and flushing cells beneath the flap with irrigation through previously placed flap openings; or flap-up flushing prior to flap replacement.

98 Intraocular lens calculation

Kenneth J. Hoffer

INTRODUCTION

Since Sir Harold Ridley experienced a 21 D 'surprise' in lens power calculation on his first two cases in 1949–50, we have been seeking ways to calculate intraocular lens (IOL) power with greater accuracy (Fig. 98.1). The science is rather dry and does not stimulate great interest on the part of the majority of cataract surgeons. To make the subject more understandable, it would be advantageous to break it down into its component parts.

The three major components of IOL power calculation are biometry, formulas, and clinical variables. *Biometry* can be divided into its components needed to calculate IOL power: the *axial length*, the *corneal power,* and the *IOL position*. The subject of *formulas* can be divided into their *generations*, their *usage,* and their *personalization*. *Clinical variables* are divided into the topics *patient needs and desires*, *special circumstances,* and *problems and errors*.

When the human lens is replaced with an IOL, the optical status becomes a two-lens system (cornea and IOL) projecting an image onto the fovea. The distance (X) between the two lenses affects the refraction as does the distance (Y) between the two-lens system and the fovea. X is defined as the distance from the anterior surface (vertex) of the cornea to the effective principle plane of the IOL in the visual axis. Y is defined as the distance from the principal plane of the IOL to the photoreceptors of the fovea in the visual axis. It is easy to see that X + Y is equal to the visual axis axial length of the eye (A). Therefore, knowing X and A will allow the calculation of Y (Y = A – X).

Also, to calculate the IOL power (P) we must know the vergence of the light rays entering the cornea (K) (refractive error (R)). For emmetropia, R is zero. The relationship of these factors (X, Y (A – X), P, K, R) are such that a formula can be written to describe it. Knowing the values of any four of these variables will allow for the calculation of the fifth.

BIOMETRY

AXIAL LENGTH

If the crystalline lens (cataract) is to be removed, obtaining an accurate axial length (AL) is mandatory. If the lens has already been removed (aphakia/pseudophakia) or will not be removed (phakic IOL), an AL is not always necessary because the correct implant lens power can be calculated using a refraction formula (see below). Because this formula requires an accurate vertex distance, it is not dependable in cases of aphakia where errors in the vertex distance of a high-powered refraction can have a significant effect.

The important considerations for obtaining accurate ultrasound AL are listed in Table 98.1.

Axial length instruments

Up to 1999, all axial length measuring instruments have been A-scan ultrasound units. There are many A-scan instruments available and it is important to make sure the unit that you are using has been calibrated and is capable of accurate measurements. It is important to be sure that the instrument has a true analog screen such that true echo spikes are observed in determining axiality. Instruments that merely report a numerical reading of the AL ('black box' or spike simulation) do not allow clinical decision making during the examination and are fraught with potential errors. A major step in improving accuracy would be to replace such an instrument with one that has an oscilloscope screen.

A newer methodology for axial length was introduced in 1999 by Carl Zeiss Meditec, Jena, Germany (Fig. 98.2, *A* and *B*.) It uses laser coherent interferometry to measure AL. The instrument, called the IOLMaster® performs four functions: (1) it measures the AL, (2) the corneal power (K or r), (3) the anterior chamber depth (ACD) (the latter two by optical means), and (4) performs the formula IOL power calculations using four modern third generation theoretic formulas. The author has performed side-by-side analysis of the accuracy of this instrument compared to our standard immersion A-scan technique and found the instrument to be comparable to immersion ultrasound. A multitude of reports in the literature con-

clude that the IOLMaster® cannot obtain results in 10–17% of eyes because of either posterior subcapsular cataract (PSC), the density of a cataract, or the patient's inability to fixate. Our results are similar. We have so far noticed considerable difficulty obtaining an AL measurement in eyes with PSC cataracts but have been impressed with the results up to this point and especially its ease of use and repeatability.

Warning: Be sure the Index of Refraction in the IOLMaster is set to 1.3375 in the Setup screen of the computer for the Hoffer Q formula to operate accurately.

Immersion ultrasound technique

The immersion technique of Ossoinig[1] has been shown to be more accurate than the standard applanation contact technique in several studies[2,3] over the past 15 years. They report a mean average shortening of the AL of 0.25–0.33 mm using applanation compared to immersion. If this shortening error by applanation were a consistent one it could be compensated for by the addition of a correction constant or by IOL power formula personalization. Unfortunately, this is not possible since the error varies from eye to eye.

Arguments against using the immersion technique are that it is time-consuming, more expensive, messy, and requires the patient to be totally supine. On the contrary, the examination can be performed in a standard ophthalmic examination chair reclined back at a 45° angle with the headrest set back so that the patient's AL is perpendicular to the floor (Fig. 98.3). To maintain a non-leaking

fluid bath in the Ossoinig scleral shell (Hansen Ophthalmic Development Labs, Coralville, IA), we use a 50/50 dilution of 2.5% hydroxypropyl methylcellulose (Goniosol®) in Dacriose® solution. Once the eye is anesthetized topically, the scleral shell is gently placed between the lids and filled 3/4 full with the solution. Any air bubbles should be vacuumed with a short silicone tube attached to a syringe. The latter can also be used to remove the solution at the completion of the procedure. The ultrasound probe is placed into the solution and positioned parallel to the axis of the eye (Fig. 98.4). Axiality is judged by watching for the correct spike patterns on the oscilloscope screen as the probe position is adjusted. First the corneal and retinal spikes must be identified and 'equally' maximized. An undilated pupil aids the examiner by the fact that eliminating the iris spikes improves the chances of being more axial; a dilated pupil eliminates this advantage.

Many find the Prager Shell (ESI, Inc., Plymouth, MN) easier to use for immersion, and studies appear to indicate it being accurate. The author has no experience with it.

Warning: Measuring the AL of *both* eyes is prudent and customary.

Warning: If the AL is very difficult to obtain and the eye appears to have a length greater than 25 mm, suspect a *staphyloma*. Use the IOLMaster or the Shammas method: By direct ophthalmoscopy (with patient fixating on the cross-hair target), measure the distance from the target (macula) to the edge of the optic nerve (in disc diameters). A B-scan exam is then performed to measure the AL at that distance from the edge of the optic nerve shadow (Fig. 98.5).

Warning: When measuring an eye containing an IOL, ignore multiple reduplication echoes caused by the IOL seen in the vitreous space.

Warning: If planning silicone oil injection into the vitreous space, perform an accurate AL measurement before doing so and make this information available to the patient. It is practically impossible to measure a silicone oil eye (try using a velocity of 1000 m/s). The Zeiss IOLMaster is the only way to get an accurate measurement in silicone oil-filled eyes. Alternatively, consider performing a secondary IOL after the aphakic refraction is obtained.

Always measure AL to the nearest hundredth of a millimeter and record it carefully. Errors in AL are the most significant and amount to approximately 2.5 D/mm in IOL power but it is important to be aware that this error drops to approximately 1.75 D/mm in very long eyes (30 mm) but jumps to approximately 3.75 D/mm in very short eyes (20 mm). Greater care must be taken in measuring short eyes.

Ultrasound velocities

The ultrasound velocity[4,5] for the various parts of the eye, IOL materials, and average pseudophakic velocities that the author has calculated are shown in Table 98.2.

Warning: Measuring an eye containing a silicone IOL with standard phakic velocity (1555 m/s) can amount to an error of 3–4 D.

The nominal average velocity for the normal range AL eye is 1555 m/s. Because of the inversely proportional change in the axial ratio of solid to liquid as the eye increases in length, the average phakic velocity of a short 20 mm eye is 1560 m/s and that of a long 30 mm eye is 1550 m/s (Fig. 98.6). This factor only amounts to a small (0.25 D) error in the extremes of AL, but it can be corrected for. The inversely proportional relationship is greater in pseudophakic eyes but is not a factor at all in aphakic eyes (1534 m/s).

Table 98.2 Ultrasound velocities[4,5] (at body temperature)

A. From the following sound velocity values[4,5]

• Cornea and lens	1641 m/s
• Aqueous and vitreous	1532 m/s
• PMMA IOL	2660 m/s
• Silicone IOL	980 m/s
• Acrylic IOL	2026 m/s
• Glass IOL	6040 m/s
• Silicone oil	987 m/s

B. The author calculated average sound speeds[4] *for various conditions of a 23.5 mm eye*

• Phakic eye	1555 m/s
• Aphakic eye	1534 m/s
• PMMA pseudophakic	1556 m/s
• Silicone pseudophakic	1476 m/s
• Acrylic pseudophakic	1549 m/s
• Glass pseudophakic	1549 m/s
• Phakic silicone oil	1139 m/s
• Aphakic silicone oil	1052 m/s

PMMA = polymethylmethacrylate.

If an eye has been measured using the wrong velocity, it can be easily corrected without re-measuring the eye by using Formula 98.1:

$$AL_{CORRECTED} = (AL_{MEASURED}) \times (V_{CORRECTED}) \div V_{MEASURED}$$

where V = ultrasound velocity.

This is because the instrument does not measure length or distance (d) directly. Instead it measures the time (t) it takes the sound to traverse the eye and converts it to a linear value using the velocity (V) formula where $d = V \times t$.

Optional corrected AL factor (CALF) method

Holladay[6,7] has offered an optional method to measure the AL which attempts to decrease the error inherent in changes in average velocity due to the length of the eye. The reasoning behind this method is that, if an 'average' eye velocity is incorrect, it affects the entire AL measurement. However, if the estimate of the CALF value is wrong, it only affects a small percentage of the overall AL, i.e. only the lens portion. The method involves measuring all eyes, regardless of status, at a sound velocity of 1532 m/s (as if the eye was a bag of water) and to this value is added the CALF. The CALF value represents the thickness of a lens in the eye whether it is the crystalline lens or IOL(s). Formula 98.2 gives the CALF value of any lens (including the cornea or IOL):

$$CALF = T_L \times (1 - 1532/V_L)$$

where T_L = the axial thickness of the lens and V_L = the sound velocity through that lens.

Holladay computes the thickness of the human cataractous lens using Formula 98.3:

$$T_L = 4 + age/100$$

and the sound velocity through the cataract using Formula 98.4:

$$V_L = 1659 - [(age - 10)/2]$$

Substituting the above two formulas into the CALF formula above, the CALF formula for the crystalline lens yields (Formula 98.5):

$$CALF = \left[4 + \frac{age}{100}\right] \times \left[1 - \frac{1532}{\left(1659 - \left(\frac{age - 10}{2}\right)\right)}\right]$$

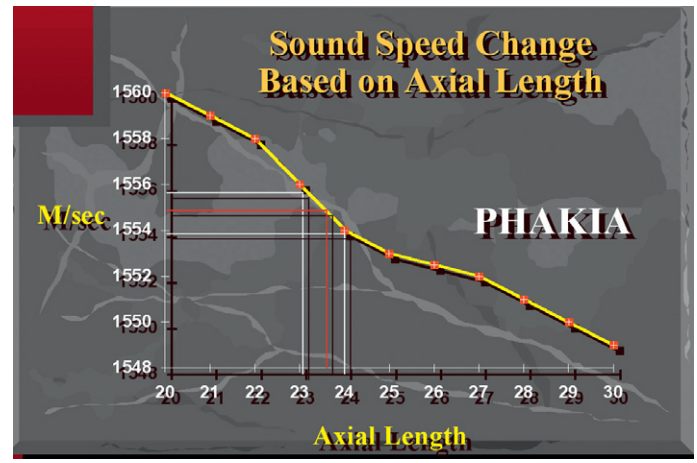

Figure 98.6. Phakic velocity. Graph of decline in average sound velocity of a phakic eye as the axial length increases.

The CALF for the cataractous lens is therefore calculated using only the age of the patient. Holladay recommends using a CALF value of 0.28 (value for 70-year-old) for all ages because the value for a 1-year-old is 0.306 and that for a 100-year-old is 0.224. The maximum error in CALF for those younger than 70 is 0.026 (0.07 D) and for those older than 70 is 0.056 (0.14 D).

His formulation, however, ignores the factor of the corneal thickness (0.55 mm). To correct this, this author recommends using a CALF of 0.32 (0.28 + 0.037). The correction for the cornea is calculated in Table 98.3B. A similar method can be used for pseudophakic eyes using CALF = $T_L \times (1 - 1532/V_L)$ and the known V_L for each IOL material (Table 98.3A). Knowing the thickness of the implanted IOL, the formulas in Table 98.3C can be used. If the IOL thickness cannot be obtained, Holladay[7] has published a table to use. The AL of an eye containing two IOLs of different materials can be obtained using the formula in Table 98.3C.

Biphakic eyes (phakic eye with a phakic IOL)

The problem here is eliminating the effect of the sound velocity through the phakic lens when measuring the AL using ultrasound. This author published a method[8] to correct for this potential error by using Formula 98.6:

Table 98.3 Formulas for calculating biometric parameters

A. CALF factors for pseudophakic eyes (using $CALF = T_L \times (1 - 1532/V_L)$

where V_L = the sound velocity for the IOL material in the eye:

- $CALF_{PMMA} = T_L \times (1 - 1532/2660) = +0.424 \times T_L$
- $CALF_{Silicone} = T_L \times (1 - 1532/980) = -0.563 \times T_L$
- $CALF_{Acrylic} = T_L \times (1 - 1532/2026) = +0.243 \times T_L$

B. The correction for the cornea:

- $CALF_{Cornea} = T_C \times (1 - 1532/1641) = 0.55 \times (0.066423) = 0.037$

C. Knowing the thickness of the implanted IOL, the following formulas can be used:*

- PMMA eye $AL = AL_{1532} + 0.424 \times T_L + 0.037$
- Silicone eye $AL = AL_{1532} - 0.563 \times T_L + 0.037$
- Acrylic eye $AL = AL_{1532} + 0.243 \times T_L + 0.037$
- Piggyback IOLs $AL = AL_{1532} + T_1 \times (1 - 1532/V_1) + T_2 \times (1 - 1532/V_2) + 0.037$

where T_1 and T_2 are the thickness and V_1 and V_2 are the velocity of each IOL.

*The IOL thickness can be obtained from the manufacturer.

PMMA = polymethylmethacrylate.

$$AL_{CORRECTED} = AL_{1555} + (C \times T)$$

where AL_{1555} = the measured AL of the eye at sound velocity of 1555 m/s, T = central thickness of the phakic IOL and C = the material specific correction factor of +0.42 for PMMA, –0.59 for silicone, +0.11 for collamer and +0.23 for acrylic.

The publication[7,7a] contain tables showing the phakic IOL central thickness for each dioptric power for each phakic IOL on the market today.

Retinal thickness factor

Some formula writers add a value to the ultrasonic AL measurement to take into account the additional distance from the surface of the retina to the level of the receptive end of the retinal cones. This value has been estimated to be 0.20–0.25 mm and is automatically added to the AL in some formulas (Binkhorst, Holladay) and not used at all in others (Colenbrander, Hoffer Q).

CORNEAL POWER

The first lens in the eye's optical system is the cornea. We usually think of corneal power in terms of diopters of optical power but really we are measuring the radius of curvature of the anterior surface and making assumptions regarding the curvature of the back surface based on the Gullstrand eye. As newer instrumentation evolves, such as the Pentacam (Oculus, Inc USA, Woodenville, WA), we may be able to use Scheimpflug photography to measure the posterior surface of the cornea and thus the true total optical effect of the cornea. It has been proposed by many that we should convert to using the radius of curvature (*r*) rather than diopters (D) but that may take a long time, especially in the USA.

The important factors to consider in obtaining accurate corneal power are listed in Table 98.1B.

Instrumentation

A manual keratometer measures only the front surface of the cornea and converts the radius (*r*) of curvature obtained to diopters (K) using an index of refraction (IR) of 1.3375 (some units use a different IR). The formula to change from D to *r* is $r = 337.5/D$ and from *r* to D is $D = 337.5/r$. Many postulate that this index is too high and Holladay[6] recommends using 4/3 instead. To make this correction, one can simply multiply the K reading obtained (in D) by the factor 0.98765431. This will result in approximately 0.54 D decrease in corneal power (range; 0.43 D for 35 D cornea to 0.62 D for 50 D cornea). Use the formula $1/3/(IR - 1$ if your keratometer uses a different index of refraction (IR.)

Warning: Before using this refractive index correction factor clinically, test it on a series of previously operated eyes to see what effect it would have had on your accuracy.

To assure accuracy it is important to calibrate all keratometers (including the IOLMaster) on a regular schedule.

Warning: Be sure the index of refraction is set to 1.3375 in the Setup screen of the computer on the IOLMaster for the Hoffer Q formula to operate properly.

Corneal topography units also supply simulated corneal power values. This author performed a prospective comparison study of the manual keratometer (Bausch & Lomb, Rochester, NY) with one such unit (TechnoMed C-Scan, Tubinger, Germany) on 172 cataract eyes. The mean of the central (3 mm zone) readings was 0.24 D flatter with the topography unit (43.55 D vs. 43.79 D), which may be explained by the index of refraction discussed above. When personalization was performed on both instrument data sets, however, IOL power calculation accuracy was statistically equal.

Warning: Hard contact lenses (including gas permeable) should be removed permanently for at least 2 weeks prior to measuring corneal power for IOL power calculation.

Astigmatism

Regular astigmatism is not a factor in IOL power calculation because the goal is to predict the postoperative spherical equivalent refractive error. Therefore, the average of the two K readings is the only value used and should result in mixed astigmatism. If a myopic cylinder were desired, the flattest K reading could be used instead of the average. If astigmatism is surgically corrected at the time of lens implantation, it would be important to know the effect of this surgery on the final average corneal power and adjust the K reading used to calculate the IOL power accordingly. Due to the coupling ratio, this effect is usually zero but an analysis of ones previous cases would be useful. Some have reported higher errors in eyes with severe astigmatism.

Keratoconus eyes

Because a cornea with keratoconus can become very steep, it is important to consider the fact that formulas that use the K reading to estimate the IOL position i.e. the Effective Lens Position (ELP) may overestimate this actual postoperative (PO) position. One should be aware that the K reading has less of this effect in the Hoffer Q formula than the other modern theoretic formulas. It is not a factor at all with the Haigis formula since it does not use the K reading at all in estimating the ELP.

Previous corneal refractive surgery

Previous corneal refractive surgery changes the architecture of the cornea such that standard methods of measuring the corneal power cause it to be underestimated (myopia) and overestimated

(hyperopia). This was first reported by Koch et al[9] in 1989. Radial keratotomy (RK) causes a relatively proportional equal flattening of both the front and back surface of the cornea leaving the index of refraction relationship the same. On the other hand, photorefractive keratectomy (PRK), laser-assisted intrastromal keratomileusis (LASIK), and laser-assisted epithelial keratomileusis (LASEK) flatten only the front surface. In myopic eyes, this changes the refractive index calculation creating an underestimation of the corneal power by about 1 D for every 7 D of refractive surgery correction obtained.

The major cause of error is the fact that most keratometers measure at the 3.2 mm zone of the central cornea, which often misses the central flatter zone of effective corneal power; the flatter the cornea, the larger the zone of measurement. There are at least 22 methods to more accurately estimate the corneal power or adjust the target IOL power in these refractive surgery eyes. To calculate the target IOL power P_{TARG} many of these methods require knowledge of some of the following biometric information:

- Obviously the planned postoperative refractive error desired—Rx_{TARG}
- Refractive surgery preoperative corneal power (K readings)—K_{PRE}
- Refractive surgery preoperative refractive error (spherical equivalent)—R_{PRE}
- Refractive surgery postoperative refractive error (spherical equivalent)—R_{PO}

Methods to estimate true PO corneal power

Clinical history method[10–16]

This method is based on the fact that the final change in refractive error the eye obtains from corneal surgery was due only to a change in the effective corneal power. If this refractive change is added to the presurgical corneal power, we will obtain the effective corneal power the eye has now.

Warning: All patients having corneal refractive surgery should be given the following data to maintain in their personal health records: (1) Preoperative corneal power, (2) preoperative refractive error, (3) postoperative healed refractive error (before lens changes effect it).

They should be told to give it to anyone planning to perform cataract/IOL surgery on them. All attempts should be made to obtain the above information from the refractive surgeon's records. Odenthal et al[17] in 2002 discovered that, though it is optically correct, it is not beneficial to vertex correct the spectacle refraction as was originally recommended. Most recommend not vertexing the refractions because it causes underestimation of the K reading.

For this method, the estimated effective corneal power (K) can be calculated using Formula 98.7:

$$K = K_{PREOP} + R_{PREOP} - R_{PO}$$

where R = refractive error, PREOP = preoperative, PO = postoperative.

Contact lens method[10–19]

The contact lens method was first described in 1948 by Frederick Ridley[18] of England (the inventor of NaOH IOL sterilization), taught by Joseph Soper[19] in 1974, and popularized by Holladay in the 1990s. This method is based on the principle that if a hard PMMA (not rigid gas permeable) contact lens (CL) of plano power (P) and a base curve (B) equal to the effective power of the cornea, is placed on the eye it will not change the refractive error of the eye. That is, the difference between the manifest refraction with the contact lens (R_{CL}) and without it (R_{NoCL}) is zero. To calculate the estimated corneal power use Formula 98.8:

$$K = B + P + R_{CL} - R_{NoCL}$$

where B = base curve, CL = contact lens, P = power of CL, R = refractive error, NoCL = bare refraction.

Again, it is not currently recommended to vertex correct the refractive errors to the corneal plane. Several computer IOL power calculation programs calculate these two methods automatically when needed (Hoffer® Programs and Holladay® IOL Consultant). There are commercially available hard PMMA CL sets in plano powers with appropriate base curves from Ocusoft (Fig. 98.7, *A*) and Eye Scan Consulting (Fig. 98.7, *B*) (Decatur, GA).

Maloney corneal topography method[20]

Based on his analysis of corneal topography central Ks (Kt) on LASIK eyes, Robert Maloney[20] developed a formulation in 1998 to predict true corneal power using only the Kt (Formula 98.9):

$$K = Kt \times (376/337.5) - 5.5 \text{ or}$$
$$K = 1.1141 \times Kt - 5.5$$

where Kt = postoperative topography single central K.

Koch modification of Maloney method[21]

In 2003, Douglas Koch[21] analyzed several of these methods and obtained the best results using the Maloney method but only after increasing the constant from 5.5 to 6.1 (Formula 98.10):

$$K = Kt \times (376/337.5) - 6.1 \text{ or}$$
$$K = 1.1141 \times Kt - 6.1$$

where Kt = postoperative topography central K.

He reported on series of eyes that the best results were obtained using this K estimation and the Aramberri Double-K method with a third generation formula. He also offered a second method to calculate estimated corneal power if the change in refractive error (RC) the patient received is known (Formula 98.11):

$$K = Kt - (0.19 \times RC)$$

where Kt = central average K from corneal topography, RC = refractive change in refractive error from the surgery.

Ronje method[22]

The Ronje[22] method proposes that the corneal power can be estimated by simply adjusting the flattest postoperative manual keratometry (K_{POFLAT}) by 25% of the change in the spherical equivalent refractive error (RC) that occurred from the corneal refractive surgery.

For example (Formula 98.12):

$$R_{PRE} - 5.00, R_{PO} = \text{plano; (thus RC} = -5.00), \text{and } K_{POFLAT} = 42.00$$
$$K = K_{POFLAT} + 0.25 \times RC$$
$$= 42.00 + 0.25 \times (-5.00)$$
$$= 42.00 - 1.25$$
$$= 40.75$$

where R_{PRE} = prerefractive surgery spherical equivalent, R_{PO} = post refractive surgery spherical equivalent, and K_{POFLAT} = flattest measured postoperative manual keratometry.

C

Figure 98.7. Hard PMMA CL kits in plano powers for the CL method: *A*, Ocusoft kit, *B*, Ocusoft contact lenses and remover, *C*, Eye Scan Consulting kit hard PMMA CL kit in plano powers for the CL method.

Shammas No History Method[23]

Another interesting proposal is by Shammas,[23] who studied a series of eyes that have had LASIK. His results led him to propose a formula, in 2003, to predict the effective power of the cornea without needing any of the patient's clinical history, only the post-operative K reading obtained with manual keratometry (Formula 98.13):

$$K = 1.14 \times K_{PO} - 6.8$$

where K = predicted corneal power, K_{PO} = the average corneal power obtained with manual keratometry after corneal refractive surgery.

Instruments: topographers and pentacam

The first instruments to measure corneal power by topography were the Eyesys, Technomed C-Scan, and Humphrey units. Holladay developed the 'diagnostic summary' for the Eyesys unit (Fig. 98.8) but still most of these measurements fall down in postrefractive surgery eyes.

That brings us to the latest and most promising technology, the Oculus Pentacam, which images the anterior segment of the eye using a rotating Scheimpflug camera measurement providing three-dimensional images (Fig. 98.10, *A–C*). These images provide a topographic analysis of the corneal thickness, its front surface and most importantly its back surface curvature. In conjunction with software provided by Holladay, the Pentacam is touted to have the ability to generate what they call a 'TrueNetPower' map of the cornea and measure the power of the postrefractive surgery cornea within ±0.55 D. This may provide a better estimation of the true corneal power but it has not yet been tested in a large randomized clinical trial.

With consultation from Holladay, the Pentacam produces a 'Holladay Report' which is based on the 4.5 mm zone reading. This was an update from the previous one using the 4.0 zone which was not proven accurate. Many studies using this report have shown the inaccuracy of this report as well and future improvements are expected before this report can be trusted for clinical use in LASIK eyes.

Corneal power estimation summary

In summary, if the results of the above K estimation methods differ, use the lowest estimated corneal power (highest for hyperopic refractive eyes). Rarely are such eyes myopic after IOL surgery. Obviously, some methods cannot be used if the historical data is not available, and the CL method is impossible if the cataract precludes performing a refraction. In such cases, it might be wise to delay the IOL implantation and calculate the secondary IOL power using the aphakic refractive error in the refraction formula or use a piggyback lens or phakic refractive lens to correct any deficiency. However, there are other methods available; some attempt to calculate the true corneal power while the others fudge the calculated IOL.

Methods to adjust/calculate the target IOL power

Aramberri double K method[27]

Once you have decided on the 'best' estimated pre-op K, there is one more consideration. It is the Double-K method, one of the most important developments to improve the prediction of corneal power in eyes that have had refractive surgery. It was proposed in 2001 by Aramberri[27] of San Sebastian, Spain. His proposal makes eminent sense. The modern theoretic formulas (except the Haigis) use the corneal power for two purposes: the first is to predict the ultimate position of the IOL (ACD or ELP) and the second (along with AL, target refraction and ELP) is to calculate the power of the IOL. The formulations and algorithms used to predict the ELP are based on the anatomy of the anterior segment which has not been changed by corneal refractive surgery (only the center is flattened and thinned). Therefore, if the PO refractive surgery K reading (which is significantly flatter) is used to calculate the ELP it will produce an erroneous ELP value. Since the anatomy has not changed, Aramberri recommends the use of the preoperative K reading to calculate the ELP. The IOL power is then calculated using the PO K reading, thus the 'Double-K.' His analysis of a small series of eyes proved the benefit of this idea. This method is available for the SRK/T, Holladay and Hoffer Q formulas on the Hoffer® Programs computer system (see Fig. 98.12.)

Feiz method[28,29]

This method was first described in 2001 by Feiz et al.[28] Their formula was developed by comparing manual keratometry values after LASIK and using the SRK/T formula, the IOL power calculated using the historical method, and what they termed the vertexed IOL power method. In this method two assumptions were made. The first was that to achieve emmetropia, the change in spherical equivalent induced by keratorefractive surgery had to be balanced by the change in IOL power. The second assumption was that for every diopter of change in IOL power, only 0.7 D of change will be seen at the spectacle plane.

Performing a linear regression analysis of the vertex IOL power compared to standard keratometry, they developed two linear regression formulas: one for myopic LASIK corneas and the second

BOX 98.1 FEIZ

MYOPIC EYE	HYPEROPIC EYE
SRK/T calculates 16.0 D IOL	Hoffer Q calculates 22.0 D
Change in Rx = –6.0 D	Change in Rx = +3.0 D
$-0.595 \times (-6) - 0.231 = +3.34$	$-0.862 \times (+3) + 0.751 = -1.84$
P = 16.0 + 3.34 = 19.34 D	P = 22.0 – 1.84 = 20.16 D

for hyperopic LASIK corneas (Formulas 98.14 and 98.15):
For myopic LASIK corneas:

$$P = P_{TRx} - 0.595 \times RC - 0.231$$

For hyperopic LASIK corneas:

$$P = P_{TRx} - 0.862 \times RC + 0.751$$

where P = required IOL Power, P_{TRx} = the IOL power calculated for the desired PO Target Rx using the AL and measured (unadjusted) K reading, and RC = the change in refraction (spherical equivalent) caused by the refractive surgery.

In 2005, they reported a comparison of all three methods for IOL calculation[29] in 19 eyes after myopic LASIK or PRK which resulted in consistently higher IOL powers using their formula compared to using the post-LASIK measurements and the historical method. It still resulted in 16% of eyes either moderately over- or under-corrected. The hyperopic formula has not had any reported study demonstrating its validity.

Below are example calculations (Box 98.1).

From their formulas, they produced a nomogram for both types of eyes which might be easier for those without a calculator handy (Box 98.2).

Latkany method[30]

The first proposal by Latkany's group[30] uses the manually measured flattest K of the postoperative cornea in the SRK/T formula. The resulting IOL power is then adjusted by Formula 98.16:

BOX 98.2

FEIZ[29] NOMOGRAM	ADJUSTMENT TO TARGET IOL POWER	
D change in Rx from LASIK (X)	Myopic Eye [–0.595 × –0.231]	Hyperopic Eye [–0.862 × +0.751]
1.00	+0.36	0.00
2.00	+0.96	–0.97
3.00	+1.55	–1.84
4.00	+2.15	–2.70
5.00	+2.74	–3.56
6.00	+3.34	–4.42
7.00	+3.93	–5.28
8.00	+4.53	–6.15
9.00	+5.12	–7.00
10.00	+5.72	–7.87

$$P = P_{FlatK} - (0.47 \times PRx + 0.85)$$

where P = required IOL power, P_{FlatK} = the IOL power calculated by SRK/T for desired PO Rx using the AL and the measured flattest K reading (unadjusted), and PRx = the preoperative refractive surgery spherical equivalent.

The study reported this method to be equal to the historical method for calculation of corneal power. Below is an example calculation (Box 98.3).

Masket refractive history method[31]

In 2005, Sam Masket[31] proposed yet another method which adjusts the power of the IOL calculated using the measured data. Formula 98.17 is used to adjust the IOL power:

$$P = P_{EMM} - 0.323 \times RC + 0.138$$

BOX 98.3 LATKANY

MYOPIC EYE

SRK/T calculates 22.91 D IOL using Flattest K 42.00 D

Pre-LASIK Rx = –5.0 D

–((0.47 × –5) + 0.85)) = +1.50

P = 22.91 + 1.50 = 24.41 D

BOX 98.4 MASKET

MYOPIC EYE	HYPEROPIC EYE
SRK/T calculates 16.0 D IOL	Hoffer Q calculates 22.0 D
Change in Rx = –6.0 D	Change in Rx = +3.0 D
–0.323 × (–6) + 0.138 = +2.076	–0.323 × (+3) + 0.138 = –0.82
P = 16.0 + 2.0 = 18.0 D	P = 22.0 – 1.0 = 21.0 D

where P = required IOL power, P_{EMM} = the IOL power calculated for emmetropia using the AL and measured (unadjusted) K reading, and RC = the change in refraction (spherical equivalent) caused by the refractive surgery.

He recommends using the SRK/T formula for myopic ALs and the Hoffer Q for hyperopic ALs. Here are example calculations (Box 98.4).

In a series of 28 post-LASIK eyes, he reported 43% of the eyes obtaining a postoperative refractive error of plano, 95% being within ±0.50 D of prediction and a total error range from –0.75 D to +0.50 D. These early results in a small series by the author of the method are quite impressive.

Wake Forest method[32]

In 2005, Michael Gagnon[32] presented an alternative calculation method by the group at Wake Forest University, which has been discussed by others over the years. This method simply uses the patient's preoperative refraction before LASIK as the target or 'desired' PO refraction in the calculation and the measured AL and K readings without modification.

Ianchulev intraoperative aphakic refraction method[33]

In 2003, Sean Ianchulev[33] proposed calculating IOL power by performing aphakic refraction on the operating table immediately after the cataract has been removed using a handheld automated refractor. The resultant refraction is modified by Formula 98.18:

$$P = 2.02 \times AR + (A - 118.4)$$

where P = emmetropic IOL power, AR = automated refraction, and A = IOL A constant.

His early results are quite promising. This method would completely eliminate the need for axial length and corneal power measurements and the problems with LASIK and silicone oil-filled eyes. However, it would require a large inventory of IOL powers available in the OR.

Following on this idea, in 2006, Mackool[34] published a small series of patients who had cataract extraction without IOL implantation under topical anesthesia. An aphakic manifest refraction was performed 30 min after the surgery at a vertex distance of 12 mm. The following formula was then used to calculate IOL power (Formula 98.19):

$$P = 1.75 \times AR + (A - 118.84)$$

where P = emmetropic IOL power, AR = aphakic refraction, and A = IOL A constant.

After the IOL calculation, the patient was immediately returned to the operating room for IOL implantation using the calculated power. Using the above formula in 12 eyes, he reported a mean absolute refractive error of 0.30 D, and an average refractive error of –0.18 D. Having two separate surgeries would seem inconvenient.

Hoffer/Savini LASIK IOL Power Tool

In 2006, it became obvious that there were so many methods to perform these calculations that it was becoming very confusing. This author, collaborating with Giacomo Savini of Bologna, Italy, decided to place all the various calculations on one Microsoft Excel spreadsheet so it would be easy to see what data needed to be collected (Fig. 98.11). Once all or most of the data are entered into the appropriate cells, the calculations are performed automatically. Then the results of all the methods are displayed side by side allowing the surgeon to select the most appropriate calculation. Anecdotally, the first use of this spreadsheet (Fig. 98.12) led to a 2 month PO refractive error of –0.25 D (SE) when the target R*x* was –0.50 D (UCVA 20/25; BCVA 20/20). The Tool can be downloaded for free at www.EyeLab.com

Retinal detachment eyes: Hoffer Double-AL method

Just as the Double-K method uses two K readings because the formulas use the K reading to predict the ELP, this method, proposed by the author in 2000, instead uses two ALs. The PO retinal detachment (RD) AL of the eye is used to calculate the IOL power. Since most post-encircling band RD eyes have a 1.0 mm increase in AL, and the ACD is not affected by the encircling band, it would be best to use the AL-1 in the part of the formula that calculates the predicted ELP. This amounts to making the IOL a little weaker than would be predicted using all the modern formulas. Alternatively, one would just lower the power of the recommended IOL power in such RD eyes.

Corneal transplant eyes

A problem also arises when attempting to predict what the corneal power will be after corneal transplantation. Some have suggested using the corneal power of the other eye (if it is available) or using an average of one's post-transplant corneal powers, but published reports show a very large range of prediction and refractive errors using these attempts. Performing the IOL implantation after the corneal transplant has settled down was suggested by this author[35] in 1986, and in 1990 Geggel[36] reported excellent refractive results (Fig. 98.13) using this two-stepped approach (66%, 20/40 or better acuity without correction). A toric phakic IOL or a secondary piggyback toric IOL is another alternative to correct residual ametropia.

Corneal scar eyes

The problem of getting an accurate corneal power measurement in eyes with corneal scarring and irregular astigmatism has not received much attention. Cua et al[37] studied this in two eyes needing IOL exchange due to large 'IOL surprises' of +5 and –7.5 D. They compared six methods to ascertain the corneal power and found

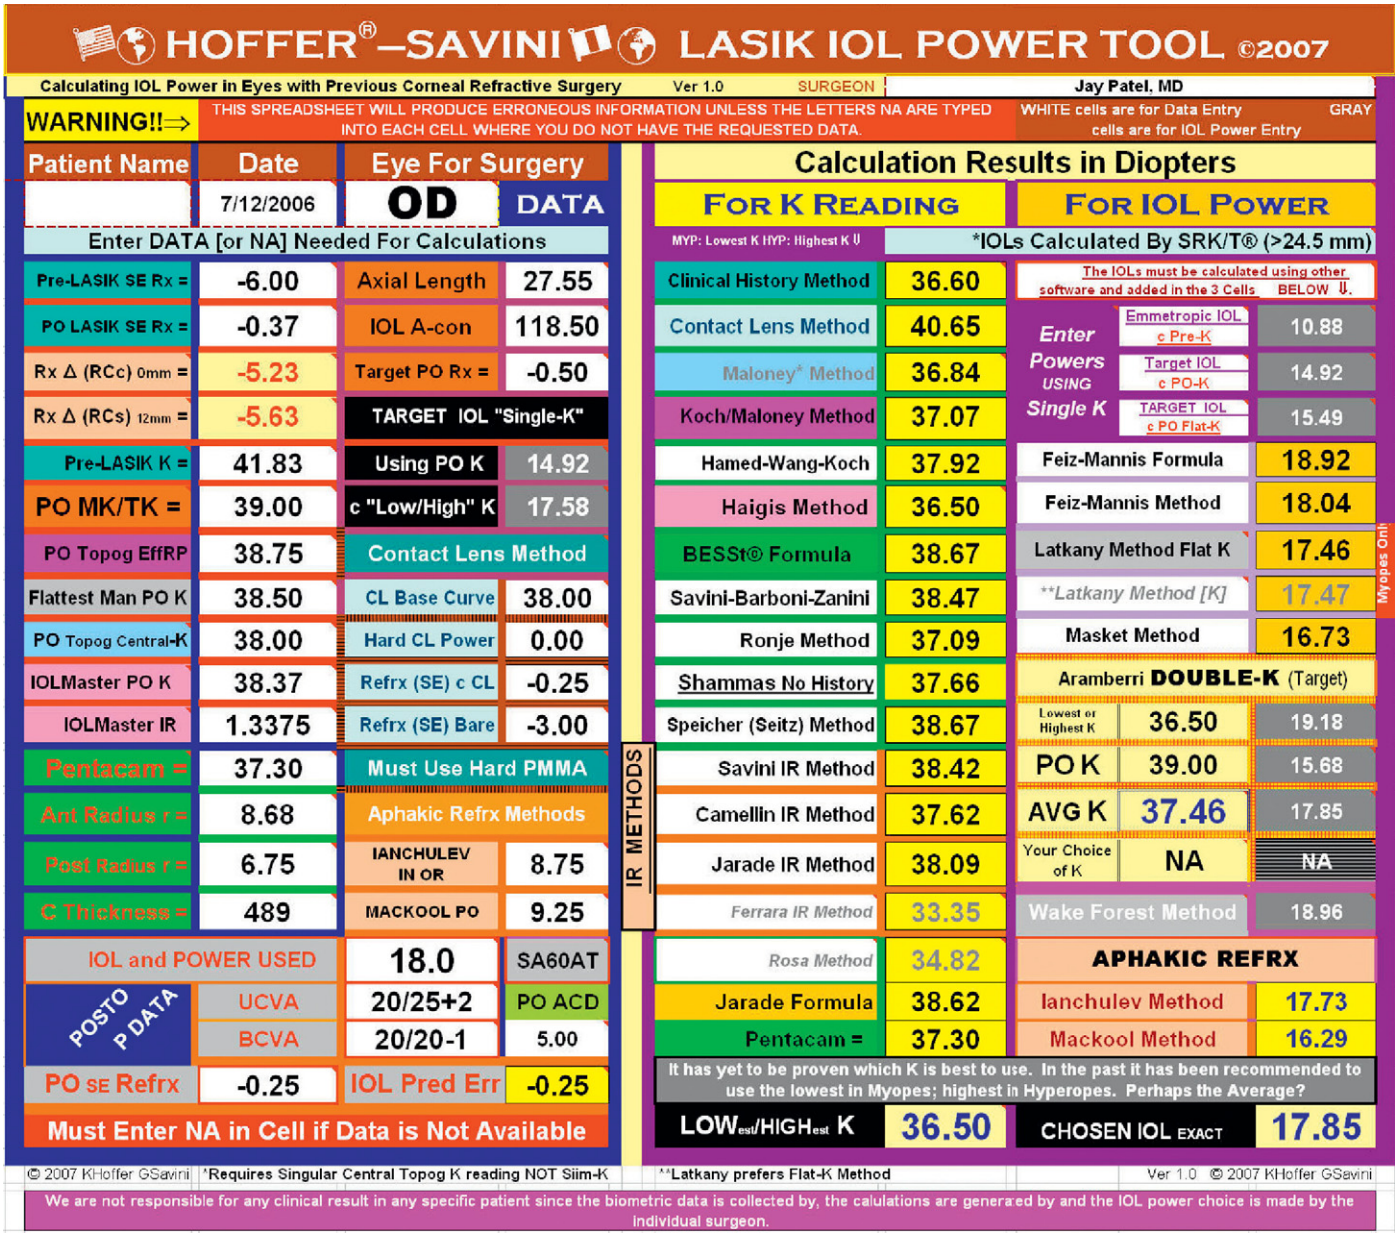

Figure 98.11. Hoffer/Savini LASIK IOL power calculation spreadsheet Tool. Areas for input of biometric data and calculations.

the hard contact lens over refraction method to be the most accurate; decreasing the error they would have obtained with the manual keratometer of +4 to −5 D to −0.4 to −1.6 D. This may be a useful clinical tool in such cases.

IOL AXIAL POSITION

This factor was historically referred to as the anterior chamber depth (ACD) because the optic of all IOLs in the early era was positioned in front of the iris, in the anterior chamber. Because most IOLs today are positioned behind the iris, new terminology has been offered such as ELP by Holladay[6] and Actual Lens Position (ALP) by the US Food and Drug Administration (FDA).

ACD is defined as the axial distance between the two lenses (cornea and lens or IOL) or, more exactly, the distance from the central front surface (anterior vertex) of the cornea to the effective principal plane of the IOL (or front surface of the crystalline lens). This value is required for all formulas and it is incorporated into the A constant specific to each IOL style for regression formulas or as an ACD, both supplied by the manufacturer. Some have proposed that it would be useful to measure the preoperative anatomic ACD (corneal epithelium to anterior capsule) either with an A-scan unit or by optical pachymetry. The author performed such a comparison study on 44 eyes and showed that the optical method resulted in a mean 0.20 mm (±0.35 mm) deeper ACD than obtained by ultrasound using 1548 m/s (3.14 vs. 2.93 mm).

The IOL position has been considered the least important of the three variables as a cause of IOL power error but in 1998, the author saw an early PO IOL patient with a shallowed ACD and myopia of −2.50. After 3 days, the chamber deepened by 2.0 mm and the refractive error changed to plano. IOL position has received the most attention from formula writers over the

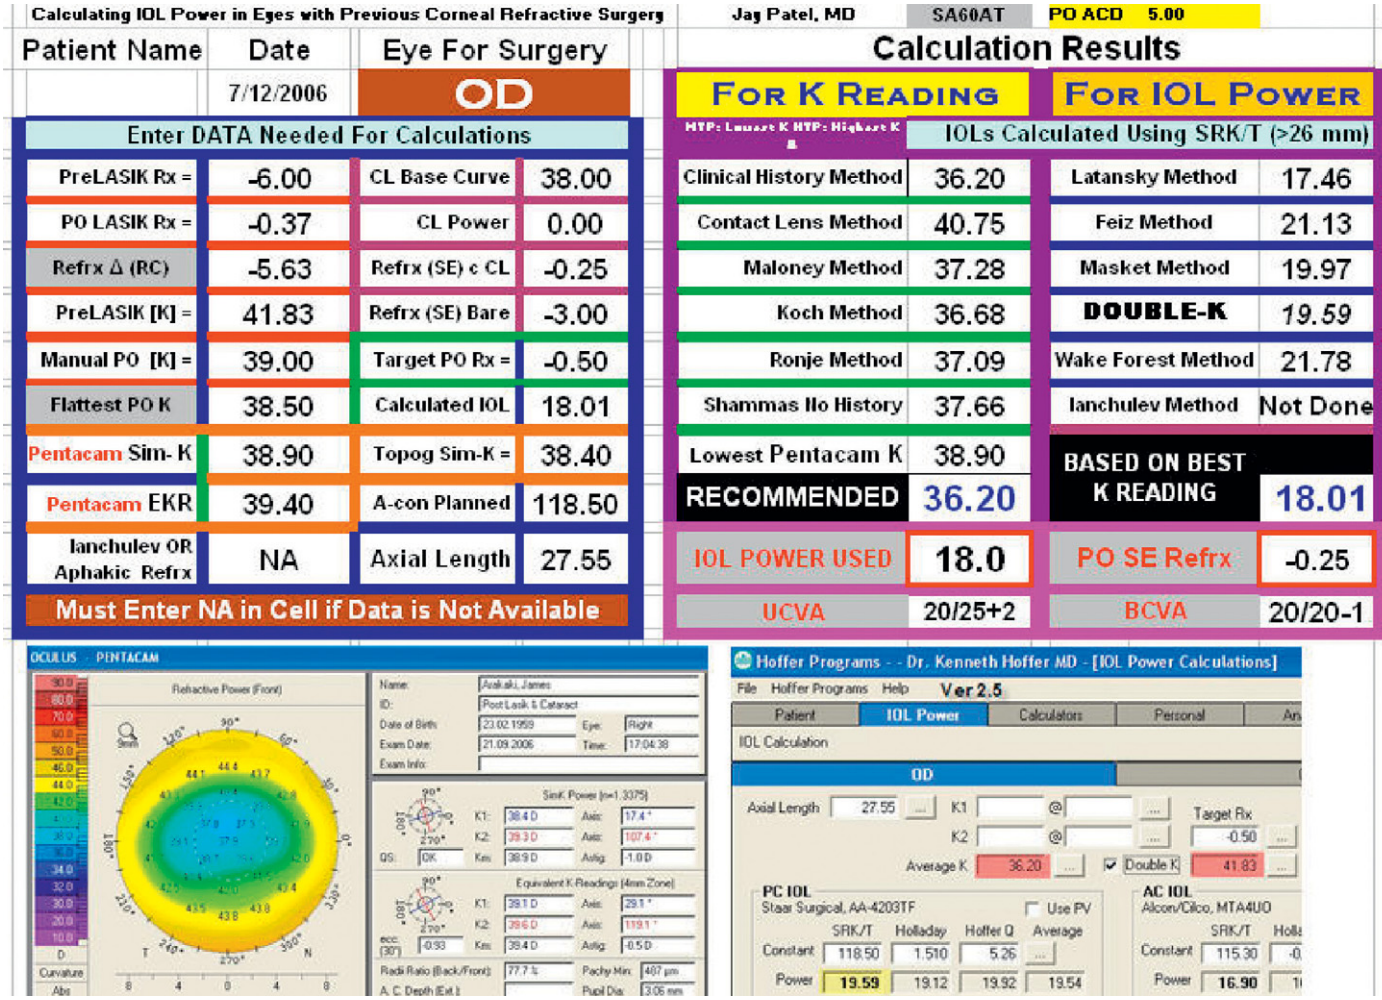

Figure 98.12. Hoffer LASIK IOL power calculation spreadsheet organizer showing all data and PO results.

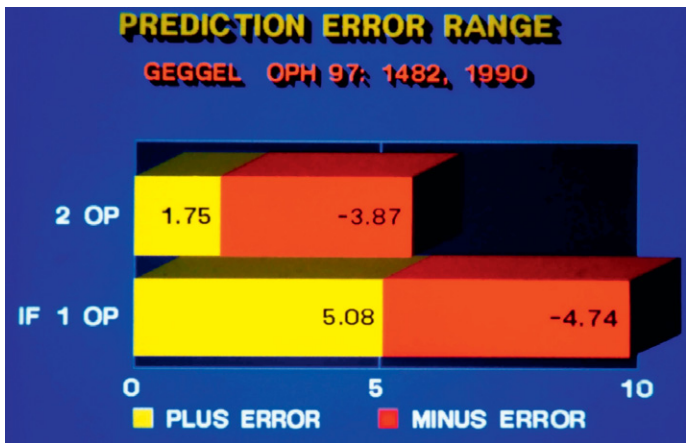

Figure 98.13. Corneal transplants. Dramatic decrease in range of IOL prediction error when IOL is implanted secondarily after transplant heals (5.62 D) vs. a triple procedure (9.82 D).

past 10 years. The major effort has been toward better prediction of where the IOL will ultimately rest. A recent study by the author on a series of 270 eyes receiving a silicone plate haptic lens showed that the IOL shifted a mean of 0.06 mm posteriorly (ACD deepened) at 3 months, compared to its position on the first day after surgery. This was commensurate with a mean 0.21 D shift toward hyperopia.

Warning: An IOL intended for capsular bag placement should be decreased by 0.75–1.00 D (depending upon the IOL power) when placed in the ciliary sulcus.

FORMULAS

GENERATIONS

First generation

The first IOL power formula was published by Fyodorov[38] in 1967. Colenbrander[39] wrote his in 1972 followed by the Hoffer[40] formula in 1974. Binkhorst[41] published his formula in 1975, which became widely used in America. In 1978, first Lloyd and Gills,[42,43] followed by Retzlaff[44] and later Sanders and Kraff,[45] each developed a regression formula based on analysis of their previous IOL cases. This work was amalgamated in 1980 to yield the SRK I formula.[46] All these formulas depended on a single constant for each lens that represented the predicted IOL position (ACD).

Second generation

In 1982, at the Welsh Cataract Congress in Houston, the author[47,48] showed a direct relationship between the position of a PMMA posterior chamber IOL and the axial length, and presented a formula (ACD = 0.282 × AL + 2.83) to better predict ACD. Others (Binkhorst,[49] SRK II[50] (1988)) developed different mechanisms to

apply this predictive relationship which Holladay defined as the second generation.

Third generation

In 1988, Holladay[51] proposed a direct relationship between the steepness of the cornea and the position of the IOL. He modified the Binkhorst formula to incorporate this as well as the axial length relationship. Instead of ACD input, the formula would calculate the predicted distance from the cornea to the iris plane (using a corneal height formula by Fyodorov) and add to it the distance from the iris plane to the IOL. The latter he called the surgeon factor (SF) and it is specific to each lens. Retzlaff[52] followed suit and modified the Holladay I formula to allow use of A constants calling it the SRK/T theoretic formula in 1990. It was intended to replace the previous SRK regression formulas, but some American surgeons still use them. In 1992, Hoffer developed the Q formula[53] using a tangent function of the K to accomplish the same effect.

Fourth generation

In 1990, Olsen[54] proposed using the preoperative ACD and other factors to better estimate the postoperative IOL position and published algorithms for this. After several studies showed the Holladay I formula not as accurate as the Hoffer Q in eyes shorter than 22 mm, Holladay used the preoperative ACD measurement as well as corneal diameter, lens thickness, refractive error, and age to calculate an estimated scaling factor (ESF) that multiplies the IOL-specific ACD. This Holladay 2 formula has been promulgated since 1996 but has yet to be published.

Fifth generation

In 1999, Wolfgang Haigis[55] proposed using three constants to predict the position of the IOL based on the characteristics of the eye and the IOL. The formula calculates the predicted PO ELP by Formula 98.20:

$$ELP = a_0 + a_1 \times ACD + a_2 \times AL$$

where ELP = predicted IOL position, a_0 = a lens-specific constant, a_1 = a constant to be effected by the measured preoperative ACD, and a_2 = a lens-specific constant to be effected by the measured preoperative axial length, ACD = the measured axial distance from the corneal apex to the front surface of the lens and AL = axial length.

As in the Holladay formula, the constants must be optimized (personalized) to each IOL style and surgeon. Single optimization only optimizes the a_0 and creates accuracy equal to the Hoffer Q and Holladay, but triple optimization of all three constants creates additional accuracy. The problem is that triple optimization requires a series of 500–1000 cases of one lens style and the eyes in the series must statistically cover all axial lengths from very short to very long. This may be quite difficult to achieve for the average surgeon.

Refraction formula

Holladay[56] published a formula in 1993 to calculate the power of an IOL for an aphakic eye or ametropic pseudophakic eye (piggyback IOL) or a refractive lens (PRL) for a phakic eye. It does not need the AL but requires the corneal power, preoperative refractive error, and desired postoperative refractive error as well as the vertex distance of both. I do not recommend its use in aphakic eyes because the vertex distance is difficult to measure accurately and due to the high power of their refractive error, greater errors can result. It is, however, a good check against the AL formula calculation.

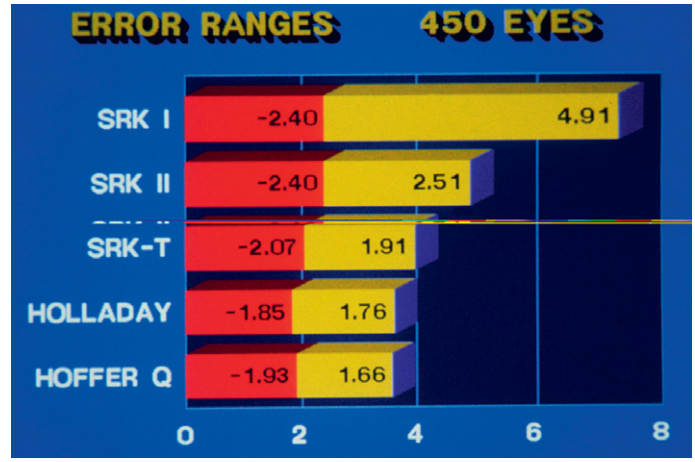

Figure 98.14. Error range. Range of IOL power error in 450 eye study using regression formulas compared to modern theoretic formulas.

USAGE

Based on axial length

This author's study[53] of 450 eyes (by one surgeon using one IOL style) (Fig. 98.14) showed that in the normal range (72%) of axial length (22.0–24.5 mm) almost all formulas function adequately, but that the SRK I formula is the leading cause of poor refractive results in eyes outside this range. It also showed that the Holladay I formula was the most accurate in medium long eyes (24.5–26.0 mm) (15%) and the SRK/T was more accurate in very long eyes (>26.0 mm) (5%). In short eyes (<22.0 mm) (8%) the Hoffer Q formula was most accurate and this was confirmed ($p > 0.0001$) in an additional large study of 830 short eyes as well as in a multiple-surgeon study by Holladay. Holladay has postulated that the other formulas overestimate the shallowing of the effective lens position (ELP) in these very short eyes.

A more recent study[57] this author performed on 317 eyes showed that the Holladay 2 formula equaled the Hoffer Q in short eyes but was not as accurate as the Holladay I or Hoffer Q in average and medium long eyes (Table 98.4). Eyes shorter than 19 mm are extremely rare (0.1%) and may well be benefited by using the Holladay 2 formula. It appears that in attempting to improve the accuracy of the Holladay formula, the addition of more biometric data input has improved the Holladay 2 formula in the extremes of axial length but deteriorated its excellent performance in the normal and medium long range of eyes (22.0–26.0 mm), which is 82% of the population.

Methodology

There are several means by which to use these newer formulas including A-scan instruments, handheld calculators, and computer programs that run on DOS, Windows, and Macintosh systems as well as for the handheld Palm personal digital assistant (PDA) operating system (Fig. 98.15, *A–F*). You can also program the published ones yourself on a spreadsheet program. It is important to check the errata in references 41 and 42. The most popular commercial programs are the Hoffer Programs System* (the first computer program for IOL power in 1994) and the Holladay IOL Consultant* (1997), which

include several formulas and the ability to personalize them as well as routines to deal with odd clinical situations.

(*Available from EyeLab, Inc., Santa Monica, CA)

PERSONALIZATION

The concept of personalizing a formula based on a surgeon's past experience and data was introduced by Retzlaff[52,58] using the A constant to refine the formula. Holladay incorporated this concept into backsolving for the surgeon factor, and Hoffer backsolved for his personalized ACD. Several studies have proved that formula personalization definitely improves formula accuracy significantly.

The following parameters are required from postoperative eyes:

1. axial length (pre-op)
2. corneal power (pre-op)
3. IOL power
4. postoperative refractive error (stable).

The eyes should all contain the same lens style by one manufacturer implanted by one surgeon. The same biometry instruments and technician should also have been used. Eyes with postoperative surprises or acuity worse than 20/40 should not be included in the analysis due to poor accuracy in obtaining refractive error. Personalization involves backsolving for the exact IOL position that would produce the resultant refractive error with that IOL power, AL, and K. Then all the 'ideal' IOL positions are averaged to arrive at the personalized value to use in the future. Personalization can be easily performed using the Hoffer® Programs or Holladay® IOL consultant computer programs.

CLINICAL VARIABLES

PATIENT NEEDS AND DESIRES

Most surgeons have developed their own plan for deciding on the clinical needs of their patients. It has often been recommended to aim patients for mild postoperative myopia (–0.5 to –1.5 D) so if the error is on the plus side, they will be emmetropic and if on the minus side, they will have reading vision. This is necessary because of the larger range of IOL power errors generally experienced. When the bell-shaped curve of prediction error is squeezed down to 67% within ±0.50 D, it is then possible to aim most patients for emmetropia. This is even more important when implanting a multifocal IOL. Senior citizens are much more active today than in the past and in emergency situations it would be a lot safer if they were emmetropic than seeking for their myopic correction to escape to safety.

There are several exceptions, however. Patients who have been life-long myopes are never happy being hyperopes postoperatively. Patients who would wind up with a large anisometropia should be stimulated to be fitted with a contact lens in the other eye prior to deciding on an emmetropic IOL. Monocular CL wearers are more successful than binocular. It is wise to document all discussions regarding unusual situations.

SPECIAL CIRCUMSTANCES

Monocular cataract in bilateral high ametropia

The dilemma is to make the surgical eye emmetropic or match the large ametropia of the other eye, which may never need surgery. Up to now, this author has convinced most patients to accept a monocular CL or ignore the other eye and go for the 'brass ring' of emmetropia. In the future, those who cannot tolerate CLs could have a phakic IOL either placed in the other eye or placed over the IOL to eliminate aneisikonia and have it removed if the other eye ultimately has surgery.

Pediatric eyes

Children have always posed a dilemma[59] in IOL power selection in that the eye will grow in length and become more myopic if a fixed emmetropic power is implanted. The study of pediatric eyes by Gordon and Donzis[60] shows a steep axial length growth rate from premature babies to age 2, increasing by 6 mm (approximately 20 D), while corneal power drops from 54 D to 44 D offsetting 10 D. If IOLs are used in this age group it might be best to place piggyback lenses with the more posterior IOL having the average adult emmetropic power and the anterior IOL being the added power needed to reach emmetropia now. As the children grow, they can be corrected with myopic glasses until they are old enough to have the anterior IOL removed.

Between the ages of 2–5 years, growth slows to about 0.4 mm per year and only increases another 1 mm from age 5–10 while corneal power remains stable. From age 2–10, it might be wise to aim for 1.5–2 D of hyperopia postoperatively which allows for reasonable uncorrected vision and light spectacle correction in amblyopia treatment. When they mature, they will wind up emmetropic or mildly myopic, depending on age at implantation. Growth

slows after age 10–15 and emmetropia can be the aim. Future use of implantable phakic refractive lenses over the top of IOLs may be very helpful in these children since they can easily be exchanged as the eye grows, keeping them emmetropic throughout life.

Plager et al[61] reported on 38 eyes of 27 subjects receiving an IOL in childhood. Based on their results they recommend the following scheme for the refractive goal for children depending upon their age (Box 98.5).

Multifocal IOL

In 1991, the author[62] reported that to obtain –2.75 D myopia (reading at 14″–16″) the IOL power in the near vision region must be about 3.75–4.00 D stronger than the emmetropic power. It was also shown that the amount of this additional power in a bifocal IOL is not affected at all by the axial length and very little by the corneal power. It is affected, however, by the IOL position and an AC lens needs less add power than a PC lens. Obviously, to negate the need for any glasses, it is important to aim for emmetropia, but mild

Age	3	4	5	6	7	8	10	13
Goal	+5.00	+4.00	+3.00	+2.25	+1.50	+1.00	+0.50	Plano

postoperative hyperopia is far better than even the mildest myopia. The distance vision will be reasonable in the former (they can easily obtain readers if necessary); while in the latter it will not. Bifocal IOL patients with myopia are not happy and everything should be done to avoid this situation since minus power 'readers' are not readily available. In the future, a phakic IOL could be implanted over the top of the bifocal to make the eye emmetropic.

Silicone oil refractive effect

The second problem that arises when the vitreous is replaced with silicone oil is that the refractive index of the oil is much less than that of the vitreous and it acts as a negative lens in the eye which must be offset with more power in the IOL. This effect is dependent upon the shape factor of the back surface of the IOL such that a biconvex IOL creates the worst problem and a concave posterior lens (no longer commercially available) causes practically no effect. In between the two is the plano-posterior lens, which is recommended in these cases. With a plano-convex lens, 2–3 D must be added to the IOL power to compensate for this silicone effect.

Piggyback lenses

Either piggyback lenses can be placed primarily or the second lens placed secondarily over a previously healed IOL. In the former, the anterior IOL forces the posterior IOL more posteriorly a distance equal to the central thickness of the anterior lens. This causes the posterior lens (whose focal point is moved more posteriorly) to require more power to maintain the same focus. This effect diminishes the thinner (lower power) the anterior lens is and a thinner lens is easier to remove if that should be necessary. Primary piggyback lenses need special calculations to adjust for the posterior lens shift. One can simply add one-half the central thickness of the anterior IOL to the ACD being used by the formula.

Secondary lenses can be calculated using the refraction formula or by a more simple formulation based on the fact that the healed primary IOL is more stable. Due to the different effect on vertex power changes between plus and minus lenses, the following formulation works well (Formula 98.21).

$$\text{Hyperopic: piggyback IOL} = 1.5 \times \text{Rx}_{\text{ERROR}}$$
$$\text{Hyperopic error: piggyback IOL} = 1.0 \times \text{Rx}_{\text{ERROR}}$$

where Rx = PO spherical equivalent refractive error.

PROBLEMS AND ERRORS

The major problem is an unacceptable postoperative refractive error. The sooner it is discovered, the sooner it can be corrected and the patient made happy. Therefore, it is wise to perform K readings and a manifest refraction on the first postoperative day. The author has long recommended immediate surgical correction[63] (24–48 h). This allows easy access to the incision and the capsular bag, one postoperative period, and excellent uncorrected vision. The majority of medicolegal cases today are due to a delay in diagnosis and treatment of this iatrogenic problem. Up to now, we could only correct this problem by lens exchange which creates the dilemma of determining which factor created the IOL power error: axial length, corneal power, mislabeled IOL, or a combination of all three. Today, with the advent of low-powered IOLs, the best remedy may be a piggyback IOL. When using a piggyback IOL, it is not necessary to determine what caused the error or to

re-measure the axial length of the freshly operated pseudophakic eye. It is possible to confirm the power of an explanted IOL by using the McReynolds lens analyzer (Vision & Hearing Center, Quincy, IL).

It is important to remember that a shallow AC can lead to as much as 3 D of myopia (depending on the power of the IOL) which will disappear when the AC reforms. An RK eye has a propensity for the cornea to flatten postoperatively causing large hyperopic surprises. It may take up to 3 or 4 months for the cornea to re-steepen; therefore, surgical correction should not be attempted until then.

Handling the IOL power surprise

An inappropriate PO refractive result is disappointing to both the patient and the surgeon. It is often difficult to determine what caused this prediction error.

A. According to most studies, the most common cause is an error in measuring *axial length*.

I. This is most commonly seen in eyes longer than 25 mm that have a higher incidence of *staphyloma*. The problem with staphylomas is that they can vary in size and position. If the macula is located at the deepest end of the staphyloma the anatomical AL will equal the visual AL. Most often the macula lies somewhere else along the slope of the staphyloma and the ultrasound measures the anatomical AL which is longer than the true visual AL. Usually these errors are ones of too long AL and too weak an IOL power (hyperopic error).

II. Contact applanation ultrasound artificially shortens the AL and this built-in variable error is worse as the AL becomes shorter. Though this fact has been well accepted, still 70% of clinicians use this procedure and add a fudge factor to correct for it. This would be acceptable if the amount of artificial shortening was approximately the same for every eye, but it is not. Some eyes are shortened by as much as a 1 mm and others are not shortened at all. This shortening leads to a too short AL and too strong IOL power (myopic errors).

III. Technician inexperience or just plain error is another cause for incorrect AL measurements.

IV. Using the wrong average ultrasound velocity is another cause for measurement errors. Many use an average velocity of 1550 m/s which is incorrect. As proven by Hoffer,[42] the correct value to be used for an average phakic cataractous eye is 1555 m/s. The problem is that the average speed for a short 20 mm eye is 1560 m/s and it is 1550 m/s for a long 30 mm eye.

V. Poor IOLMaster readings that are not recognized by the examiner are also a cause of error in AL and are more common as the cataract is more dense or the patient is not able to fixate properly.

VI. Silicone oil-filled eyes are an especially vexing problem since the ultrasound wave is so slowed down crossing the posterior segment that it is often impossible to get a reading at all. It is also difficult to determine what percentage of the vitreous body is filled and what parts the beam is going through.

VII. Lastly there is the problem of the eye that 'just can't be measured'! This situation is rare but unfortunately real. No one has offered a complete explanation for this.

B. Incorrect measurement of the *corneal power* is the second most common reason for IOL power error.

I. Overestimation of the corneal power (K) is the rule in eyes that have had previous corneal refractive surgery. This is due to the fact that there has not yet been a keratometer or keratometer attachment that will allow the measurement of the true central effective corneal power in these eyes. Two factors are at play here. The first is the fact that most keratometers measure at the central 3.2 mm (wider if the cornea is flatter) of the cornea and not able to get the more central flat area that is being used by the eye. The second is the change in the refractive index of the cornea that is difficult to correct for in any individual eye because it is dependent upon the amount that the cornea has been thinned.

II. It is important to have a schedule of calibrating all keratometers to prevent errors in measurement.

III. The IOLMaster has a setup screen that allows the operator to change the index of refraction (IR). Most users are unaware of this. The manufacturer did this to allow the instrument to produce K readings equivalent to that obtained by the manual keratometer used in the clinician's office. American keratometers are set at an IR of 1.3375 and European ones at 1.336. Hoffer recently discovered that if the IOLMaster IR is not set for 1.3375, the Hoffer Q formula will be in error. He has not tested the Holladay 1 and 2 or the SRK/T formulas.

IV. In cataract patients who wear contact lenses, there is a corneal warping factor that produces incorrect K readings compared to what they would be without the CLs (the state the eye will probably be after IOL surgery). This is especially true in eyes wearing hard CLs. Ten years ago a medicolegal case was lost in Louisiana because the judge ruled that the CLs should have been kept out for a minimum of 2 weeks prior to the keratometry examination.

V. Corneal scarring, especially in the center, can cause a great problem in measuring the corneal power.

VI. Eyes that will need corneal transplantation also pose a problem in predicting preoperatively what the ultimate healed corneal power will be.

C. The third and least effective factor in prediction error is the healed *effective position of the IOL* in the eye. This is referred to as the A constant, the surgeon factor (SF), or the Hoffer anterior chamber depth (ACD). Holladay instituted the replacement term, effective lens position (ELP), since most IOLs today are not in the anterior chamber.

I. Errors may occur if the IOL settles in a deeper or shallower position than that predicted by the formula or what would be expected in an eye with that particular IOL, AL, and K. Sometimes this can be a temporary situation in the early PO period.

II. Another cause of error is when the ACD constants have not been personalized to the individual IOL style, surgeon, and clinic.

D. *Formulas* are a cause of IOL power error especially for those using regression formulas and most definitely with those using the SRK I regression formula in eyes outside the normal AL range of 22–24.5 mm. This has been shown in so many studies[14] over the past 12 years it would be impossible to reference them all here.

E. There are other *miscellaneous* causes for IOL power errors that can be just as serious as those mentioned above. A rare manufacturer labeling error can be very serious and very difficult to pick up before the patient is discharged from the facility. If the operating room staff nurse hands the surgeon the wrong IOL power during the surgery this may not be easily recognized in time to correct the error. Lastly, transcription mistakes can cause some of the largest errors seen.

Prevention of common errors:

- Use the IOLMaster or immersion A-scan to measure the AL.
- Suspect a staphyloma in eyes >25 mm: use IOLMaster and/or Shammas A/B-scan technique.

- Use CALF method: measure eye using 1532 m/s and add 0.32 mm to the result to correct for any error in sound velocity.
- Employ a well-trained, experienced technician.
- Regularly calibrate manual keratometers.
- Carefully evaluate the IOLMaster scan for reliability.
- Keep CL out for 2 weeks prior to keratometry (at least in one eye.)
- Silicone oil eyes need the IOLMaster if possible or ultrasound AL multiplied by 0.71.
- Use the Hoffer® Q formula in eyes <22 mm and in post-refractive surgery eyes.
- Use the Holladay® 1 formula in eyes 24.5–26 mm in length.
- Use the SRK/T formula in eyes longer than 26 mm.
- Never use the SRK regression formulas (SRK I or II).
- Personalize your ELP factors in the formulas.
- Surgeon should personally select the IOL power for the individual patient.
- Prepare a sheet with all IOL powers that may be needed and place it on the wall and also on the microscope in the operating room for the surgeon and nurse to verify the correct IOL power. Use red paper for right eyes and yellow paper for left eyes.
- Be sure to set the IR to 1.3375 in the setup screen of the IOLMaster.
- Use the clinical history and contact lens methods (have PMMA CLs in the clinic) for post-refractive surgery corneas and use the lowest calculated K (highest for hyperopes).
  - Consider the Shammas 'No History' Formula: $K = 1.14*K_{PO} - 6.8$ or the Maloney or Koch Corneal topography methods.
  - Use the Aramberri Double K: calculate the ELP using the preoperative K and the IOL power using the PO K.
- Download and use the free Hoffer/Savini LASIK IOL Power Tool www.EyeLab.com.
- Consider delaying the IOL implantation until the cornea has healed after a penetrating keratoplasty rather than performing a triple procedure.

Suggestions for diagnosing and treating IOL power surprises

- Make it a routine to perform a manifest refraction on PO day 1 so as to discover the problem early enough to take the patient back to the operating room and correct the problem in the first 48 h. The patient is immediately pleased and medicolegal actions are completely eliminated.
- Consider the use of a piggyback IOL or phakic IOL if the eye has healed beautifully and removal of the errant IOL would be more traumatic to the eye. For myopic error use 1 multiplied by the error and for hyperopic errors use 1.5 multiplied by the error (or the Shammas formula).
- Consider a minimal 4-incision RK if repeat intraocular surgery is not possible.
- Measure the power of a removed IOL using the McReynolds Analyzer (William McReynolds 217-222-6656) or ask a manufacturer to be present in the operating room to do it.

CONCLUSION

Simple steps and attention to detail can be very useful in preventing IOL power errors, and recent advances in IOL power range availability has made this problem more easily corrected. Since performing the first American ultrasound IOL power calculation[64] in 1974, the past 34 years have seen great improvements in the accuracy of postoperative refractive prediction. Future improvements may someday eliminate the problems we have left.

99 Anterior chamber phakic intraocular lens

James Lee, Lisa Herrygers

INTRODUCTION

The field of excimer laser refractive surgery has expanded dramatically over the past decade. Laser-assisted in situ karatomileusis (LASIK); photorefractive keratectomy (PRK); and laser subepithelial keratomileusis (LASEK) have been the most popular. Other modalities include corneal inserts, conductive keratoplasty, clear lens extraction with or without intraocular lens insertion, and phakic intraocular lens implants. Corneal refractive procedures account for the vast majority of cases but can be associated with many potential complications including corneal ectasia; diffuse lamellar keratitis; epithelial ingrowth; corneal haze and regression, as well as infection.[1] Excimer laser refractive surgery is capable of inducing irreversible change in cornea shape, inducing optical aberrations resulting in visual disturbances such as glare, halos, starbursting, and loss of contrast sensitivity.[2] In addition, there is also a limit to the amount of refractive correction possible, primarily determined by corneal thickness and high astigmatism.

Phakic intraocular lenses provide certain advantages in refractive surgery. Most of the potential problems associated with corneal procedures are alleviated because the cornea is left mostly undisturbed.[3,4] It is reversible and a greater range of refractive corrections can be treated since it is not dependent on corneal thickness. The amounts of postoperative higher order optical aberrations may be lower than those seen after LASIK. This may result in fewer visual complaints such as glare, halo, and starbursts. However, as with all surgical procedures phakic intraocular lenses can be associated with surgical complications including endophthalmitis, corneal endothelial damage, retinal detachment, glaucoma, and cataract.

LENSES

Phakic intraocular lenses can be placed in the anterior chamber, posterior chamber, or fixated on the iris. Anterior chamber phakic intraocular lens are either angle-supported or iris-fixated.[5] Angle supported models include Vivarte (IOL Tech/Ciba Vision, Atlanta, Georgia), NuVita (Bausch & Lomb, Rochester, New York); Acrys of phakic IOL (Alcon Laboratories, Fort Worth, Texas); whereas the Artisan/Verisyse (Worst-Fechner/Artisan Lens [Ophthtec/AMO, Santa Ana, California]) is iris fixated. These lenses are made using either acrylic or polymethylmethacrylate (PMMA) materials which have been used successfully as intraocular implants in cataract surgery and have been proven to be well tolerated and safe within the eye.

The NuVita is a single-piece angle-supported design with a nonfolding 5 mm optic size diameter. This lens can be used for treating refractive errors in the range of –7.00 to –20.00 D but is only available in Europe. Bausch & Lomb is currently working on a new anterior chamber angle-supported hydrogel foldable lens for the USA market. The Vivarte lens is a single-piece hydrophilic acrylic with angle support. It is foldable and can be inserted into the eye through a small self-sealing corneal incision. It has an optic diameter of 5.5 mm and is supplied in different diameters from 12.00–13.00 mm. The refractive range is from –6.5 to –31.00 D in 0.5 D increments. The Acrys of angle-supported phakic IOL is an acrylic foldable design. It is available in a 5.5 mm or 6.0 mm diameter optics with an overall length of 12.5–14.0 mm. It has a refractive range of –6.00 to –16.5 D in 0.50 D powers. The Artisan/Verisyse lens is made from PMMA material and has an overall length of 8.5 mm and an optic diameter of 5 or 6 mm (Fig. 99.1). It is an iris-fixated lens that attaches to the midperipheral iris. Because PMMA is inflexible, a large incision is required to insert this lens. The lens is available in the myopic refractive range from –5.00 to –20.00 D using a 5 mm optical zone diameter and from –5.00 to –15.00 D using a 6 mm optical zone diameter. Currently, the Artisan/Verisyse lens is the only USA Food and Drug Administraton approved anterior chamber phakic intraocular lens in the USA. There is a foldable version of the Artisan/Verisyse that is currently undergoing clinical trials.

PREOPERATIVE EVALUATION

The Artisan/Verisyse lens is the only phakic anterior chamber intraocular lens currently approved in the USA, and the FDA[6,7] has set specific guidelines for its use. A patient must be at least 21 years old and not pregnant or breastfeeding. The patient's anterior chamber depth must be greater than 3.2 mm and iris configuration

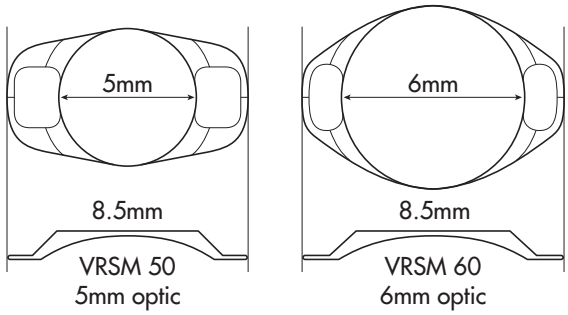

Figure 99.1. Verisyse™myopic phakic lenses.

must be normal. There is also an endothelial cell density requirement that varies depending on age.

CONTRAINDICATIONS

- Cataract
- Retinal detachment or a family history
- Abnormal pupil
- Abnormal cornea
- Endothelial cell count <2000 cells/mm^2
- Anterior chamber depth too shallow
- IOP >21 mmHg

The Artisan lens is approved for a myopic treatment range of −5.00 to −20.00 D with less than or equal to +2.50 D of astigmatism at the spectacle plane. Patients must also document manifest refraction stability for the prior 6 months as defined by a spherical equivalent change of less than 0.50 D.

A careful and thorough patient selection is critical to obtain successful outcomes with phakic intraocular lens. Patient counseling is crucial, as in all refractive surgical procedures. The patient must have realistic expectations and understand that the Artisan lens will not correct astigmatism. The patient must also understand the need for a possible second procedure to correct any residual over- or undercorrection of the refractive error. The preoperative evaluation includes a comprehensive examination including anterior segment evaluation, dilated fundus examination, manifest refraction, cycloplegic refraction, and pupil diameter measurement. Ancillary testing must include measuring anterior chamber depth and the corneal endothelial cell count.[8]

SURGICAL TECHNIQUE

The implantation of the Artisan lens into the anterior chamber is typically performed under topical or peribulbar anesthesia. Preoperative miosis is obtained with topical pilocarpine. Two paracenteses are made at the 10 and 2 o'clock positions. The anterior chamber is then filled with cohesive viscoelastic taking care to avoid injection under the iris. The dispersive and supercohesive viscoelastic materials should not be used. A longer incision is then made at the 12 o'clock position. The length of the incision depends on the lens optic size (5 or 6 mm). The incision can be made corneal, limbal, or scleral, depending on a surgeon's preference. A specialized lens forceps is used to insert the lens. The Artisan lens is attached to the midperipheral iris with an enclavation needle. The needle is inserted through the paracentesis openings and a fold of iris is carefully tucked in between the split haptics. This process, called enclavation, is performed at the 3 and 9 o'clock positions (Figs 99.2–99.6). The wound is then closed using 10-0 nylon or absorbable sutures. The cohesive viscoelastic is completely removed from the eye to reduce the potential for postoperative intraocular pressure elevation. A laser peripheral iridotomy is performed preoperatively or a surgical peripheral iridotomy is made intraoperatively to prevent pupillary block glaucoma. Postoperative medical management consists of a combination of a topical antibiotic, a nonsteroid medication, and a topical steroid. Sutures are removed after 1–2 months or when appropriate as judged clinically by the surgeon. Surgery for the second eye is performed 2 weeks later.

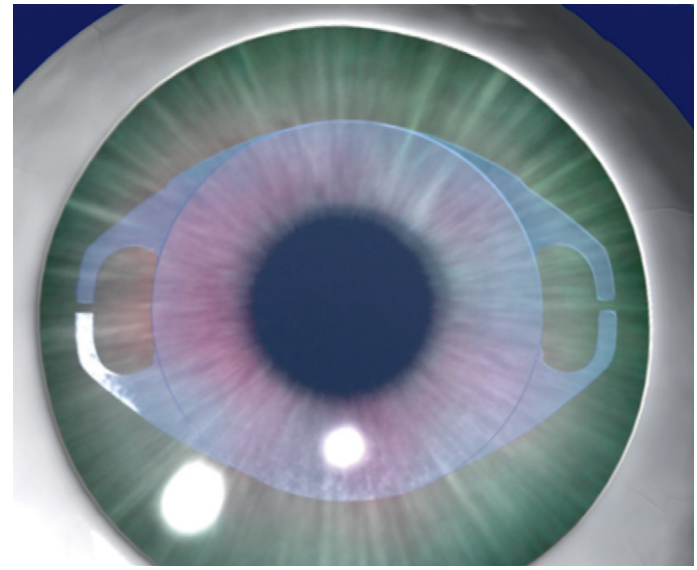

Figure 99.2. Lens positioned in the anterior chamber & aligned with vertical & longitudinal pupillary axis.

RESULTS

The FDA submission data for the Artisan phakic intraocular lens shows very positive clinical results.[9] The procedure is accurate and predictable. Sixty-three per cent of eyes achieved correction within 0.5 D of the target and 87% achieved correction within 1.0 D of the target (Table 99.1). Patients maintained stable correction at 3 years with 96% of patients having less than ±1.0 D of shift.[10] Also at 3 years, 92% had 20/40 or better uncorrected distance visual acuity and 44% had 20/20 or better uncorrected distance visual acuity. Patient satisfaction surveys showed that the majority of the patients did not experience night visual symptom changes such as glare, halo, and starburst (Table 99.2). Contrast sensitivity study showed no loss of contrast sensitivity under mesopic and photopic conditions after Artisan lens implantation.

COMPLICATIONS

During the Artisan phakic clinical study there were several incidences of adverse events (Table 99.3). The incidence rates of three major adverse events were found to be higher or the same when compared to the historical control population. Adverse events included IOL dislocation (0.8%), retinal detachment (0.6%), and surgical reintervention (4.2%), which included lens explants, lens

Table 99.1 Uncorrected visual acuity of the patient population

	% Each Visit			
Uncorrected Visual Acuity	6 Month	1 Year	2 Years	3 Years
20/20 or better	33.2	35.1	34.6	31.2
20/40 or better	86.7	86.6	87.1	84
20/80 or better	97.9	97.8	98.3	95.2
Worse than 20/80	2.1	2.1	1.7	4.8
No. of patients	581	493	356	231

exchange, lens reattachment, and retinal detachment. The rates of other clinical complications were lower than the incidence reported in the historical control population. These include hyphema, iritis, and wound leak. Complications such as endophthalmitis, cystoid macular edema, pupillary block, corneal decompensation,[11] and elevated intraocular pressure were not observed during the trial. However, other surgeons implanting the same lens in different clinical studies[12] have reported some of these same complications.[11] Treatment-induced astigmatism[13] occurred in 2–3% which was within the study's safety target of less than 5%. In the clinical trial, the incidence of lens opacity was 4.5%, and of these, four were determined to be visually significant and three required cataract extraction. One of the patients lost 2 lines of best uncorrected visual acuity following surgery.

The potential for damaging the corneal endothelium was carefully studied during the trial since anterior chamber intraocular lenses

Table 99.4 Percent cumulative endothelial cell loss for various anterior chamber depths from 6 months to 3 years

Anterior Chamber Depth	Cumulative Cell Loss (%)	Number of Patients
3.0–3.1 mm	9	7
>3.2–3.4 mm	2.9	22
>3.4–3.9 mm	4.1	51
>3.9 mm	6.3	31

have been associated with corneal edema following cataract surgery (Table 99.4). Eyes with anterior chamber depths less than 3.2 mm displayed the greatest endothelial cell loss at 3 years (9.0%), while those with anterior chamber depths greater than 3.2 mm experienced significantly lower endothelial cell loss. The rate of endothelial cell loss was greatest between the second and the third year. The loss rate was lowest during the first 6 months. The rate of endothelial cell density loss in implanted eyes is 1.8% per year based on a regression analysis. If the rate of endothelial cell loss remains the same over years then 25 years after the implantation 39% of patients can be expected to lose 50% of their corneal endothelial cells. At this time there is uncertainty as to the long-term implications associated with this degree of endothelial cell loss. Because the trial was only 3 years in duration, there remains an important need for a study to determine the seriousness of the endothelial cell loss. Meanwhile, it is prudent to regularly assess patients' corneal endothelial cells following implantation of Artisan lenses.

Since FDA approval, numerous papers have been published regarding the efficacy and safety of the Artisan/Verisyse lens. It appears to be very effective in providing a safe and accurate method for correcting myopic refractive error. Early results from hyperopic and astigmatic treatments using Artisan lenses appear promising.[14] Furthermore, patient satisfaction rate following lens implantation appears to be very high.

CONCLUSION

The anterior chamber phakic intraocular lens technology offers many advantages in refractive surgery. It is reversible, accurate, predictable, and patient satisfaction appears to be high. However, it is also associated with certain adverse events that can be potentially serious including endophthalmitis, corneal decompensation, and retinal detachment. Successful clinical outcomes require careful preoperative screening, counseling, and examination as well as diligent postoperative follow-up examinations.

100 Phakic posterior chamber lens (pPIOL)

Michael A. Lawless, Christopher Hodge

INTRODUCTION

Phakic intraocular lenses offer a number of advantages over competing refractive surgical techniques, spectacles, and contact lenses. Waring,[1] in an editorial in 1991, spoke of the long history of phakic intraocular lenses within ophthalmology, and two papers from as far back as 1990[2,3] both demonstrate the refractive accuracy of phakic intraocular lenses and show their superiority over myopic epikeratoplasty and myopic keratomileusis at that time.

Specifically a phakic intraocular lens has four potential advantages over alternative refractive techniques:[4]

1. The crystalline lens is retained allowing accommodative function in younger patients and protecting against the vitreoretinal side effects of clear lens extraction.
2. There is no disturbance to the natural prolate corneal shape, which has evolved over millennia to provide the best anterior refractive surface of the eye.
3. The phakic intraocular lens is potentially removable and exchangeable.
4. As wound healing is not a variable the refractive result tends to be predictable, and if the desired endpoint is not achieved, it is fairly easily adjustable with modern corneal refractive surgery as a bioptics procedure.

The disadvantages of phakic intraocular lenses relate to the risks of an intraocular operative procedure. In addition there are specific risks and issues related to where the phakic intraocular lens is placed; whether it be the anterior chamber, the iris plane, or behind the iris. One of the advantages of posterior chamber phakic intraocular lenses is that they remain behind the pupil eliminating edge effects as a source of optical aberration. This chapter concentrates specifically on phakic posterior chamber intraocular lenses (pPIOL).

HISTORY TO THE PRESENT DAY

Fyodorov began work in the 1980s at the Moscow Eye Institute, and by 1990 the collar button lens, which was designed to protrude through the iris, was altered so that it could be placed entirely within the posterior chamber.[5] The most frequent complication was decentration because the overall length of 10–11 mm was too short for stable positioning. There were also limitations related to surgical technique at that time with minimal or no ophthalmic viscosurgical device (OVD) used.

Fechner used the Adatomed (Chiron-Adatomed, Munich, Germany) lens entirely within the posterior chamber. The lens had a wide range of powers, an overall length of 12.5 mm and a 5.5 mm optic. This model fell into disuse because of anterior fibrotic damage in the crystalline lens at the contact zones with the thick edges of the pPIOL.[6]

There are three pPIOLs currently in use around the world in any number. These are the phakic refractive lens (PRL), STAAR implantable collamer lens (now known as the Visian ICL), and the Stick lens.

The PRL is made of ultra thin hydrophobic silicone with a refractive index of 1.46. The diameter of the optic is 4.5–5.5 mm depending on the lens power. The posterior base curve aims to mimic the anterior surface of the crystalline lens (10.0 mm of curvature). The front surface curvature varies with correction. The central thickness is less than 0.5 mm, is constant for myopic lenses, and varies with hyperopic lenses. The edge thickness is always less than 0.2 mm. The edge thickness is constant in hyperopic lenses and varies in myopic lenses. The company claims the lens has no anatomical fixation site and floats on a layer of aqueous humor inside the posterior chamber exerting no pressure on the ciliary structures, and without coming into contact with the anterior capsule or the crystalline lens. Generally one single size is used, 11.3 mm for myopic eyes and 10.6 mm overall length for hyperopic eyes. The PRL lens, distributed by Zeiss-Meditec (Carl Zeiss Meditec AG, Dublin, CA), was formally marketed by Ciba Vision (Ciba Vision Corporation, Duluth, GA) after the commercial rights were purchased in 2000 from the developer, Medennium International Vision (Medennium Inc, Irvine, CA).[7]

In the early 1990s, STAAR (STAAR Surgical, Monrovia, CA) patented a material made of 60% poly-HEMA, water (36%), benzophenone (3.8%), and called it a collamer (collagen-copolymer).[8] The lens was called the ICL (implantable contact lens) as initially it was thought that it would come into contact with the anterior surface of the crystalline lens.[9]

In 1993 the first ICL prototypes were implanted.[10] The optic was small (3.5–4.5 mm) and a significant minority of patients developed early glaucoma leading to the subsequent use of two peripheral iridotomies.[11] In 1994 a new version became available with an overall length of 11.5 mm and an optic of 4.5 mm. Decentration was an issue, but the main problem was undercorrection. These early ICL designs had no markings and version 2 (V2) was produced in 1996 with orientation markings on the haptics. Versions V2 and V3 resulted in an unacceptable number of anterior subcapsular lens opacities (9.2% of the US Food and Drug Administration (FDA) cohort V3 series).[12]

The current model is the Visian ICL V4, a rectangular one piece lens 7.5–8.0 mm wide, available in four overall lengths (11.5 mm, 12.0 mm, 12.5 mm, and 13.5 mm for myopia, and 11.0 mm, 11.5 mm, 12.0 mm, and 12.5 mm for hyperopia). The optic diameter ranges from 4.65 mm to 5.5 mm in myopic lenses, depending on the dioptric power, and is always 5.5 mm for hyperopia. The design change has been in the vaulting. The V4 has an additional 0.13–0.21 mm of anterior vault due to the steeper radius of curvature of the base curve which varies depending on the dioptric power. Myopic lenses are plano concave with the plano surface facing anteriorly, and hyperopic lenses are meniscus shaped, being convex on the anterior surface.

The Stick lens (IOL Tech, La Rochelle, France) is the newest of the pPIOLs. It is a single piece lens made of hydrophilic 28% water, soft acrylic material. Its feature is that it sticks firmly to the anterior surface of the crystalline lens, hence the name. The anterior radius of curvature varies, and the overall length of 11.5 mm, posterior shape, and curvature are fixed to match the anterior surface of the crystalline lens. There are four closed loop haptics with large apertures, which it is claimed to allow the maintenance of supply of nutrients to the crystalline lens from aqueous flow, and it is also claimed that this means that vaulting is not necessary to prevent cataract formation.[13]

RESULTS: EFFICACY

The most powerful data comes from the ICL myopia study published in 2004.[14] The efficacy variables are shown in Table 100.1. This study examined 526 eyes of 294 patients with a follow up retention of 77.2% at 3 years. All eyes received the V4 ICL lens design between November 1998 and December 2002. At 3 years 59.3% of eyes had 20/20 or better unaided and 94.7% achieved 20/40 (if best spectacle corrected acuity was 20/20 or better preoperatively and emmetropia had been targeted). A total of 67.5% of patients were within 0.5 D and 88.2% were within 1 D of intended correction. As Table 100.1 shows, for the 7–10 D preoperative myopia level, which would be the commonest range where the lens would be considered as an alternative to corneal refractive surgery, 54.2% achieved 20/20 or better unaided, and 86.9% were 20/40 or better, with 94.3% very or extremely satisfied and no patients unsatisfied.

Figure 100.1 shows the stratified uncorrected acuity for those with less than 7 D of myopia, 7–10 D and greater than 10 D of preoperative myopia where a targeted endpoint was within 0.5 D of emmetropia and preoperative best spectacle corrected acuity was 20/20.

Contrast sensitivity was analyzed at two study sites using the stereo-optical Optec X1600F2 vision tester, performed with best spectacle correction using light levels of 3 candella/m^2 after 10 min of dark adaptation with and without a glare source of 10 lux. Testing was performed at 1.5, 3, 6, 12, and 18 cycles per degree

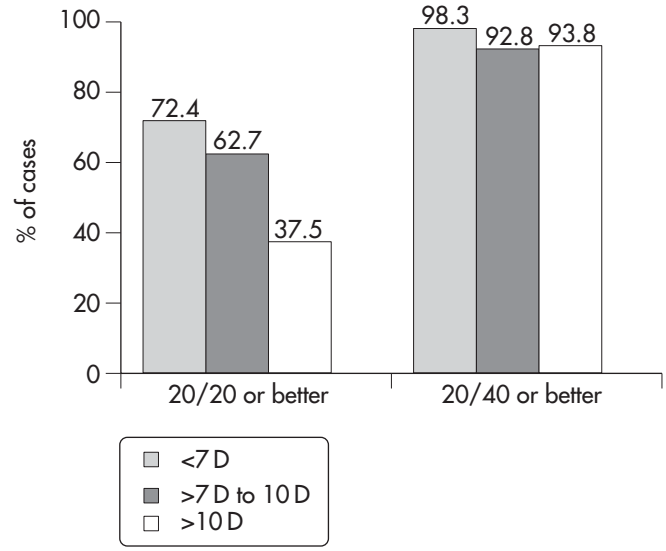

Figure 100.1. Three-year postoperative uncorrected visual acuity stratified by preoperative myopia in the subset of patients with preoperative best spectacle-corrected visual acuity of 20/20 or better and in those targeted to within 0.5 D of emmetropia. Reprinted from Sanders et al. US FDA clinical trial of the implantable collamer lens (ICL) for moderate to high myopia. Three-year follow-up. Ophthalmology 2004; 111: 1683–1692, ©2004 with permission from the American Academy of Ophthalmology.

(cpd). The results are shown in Figures 100.2 (without glare sources) and 100.3 (with glare sources). Under mesopic conditions there was no loss of contrast sensitivity at any spatial frequency, and a statistically significant improvement in contrast at 6 and 18 cpd. When a glare source was used, there was a significant improvement in contrast sensitivity at all spatial frequencies except 1.5 cpd. These excellent contrast sensitivity results are in keeping with clinical observations of others, and are to be expected with the good quality optics of the ICL and the retention of normal corneal asphericity.

Table 100.2 shows the change in subjective patient symptoms before and 3 years after surgery. Across five categories of glare, halo, double vision, night vision, and night driving, the most common subjective response was that there was no change, ranging from a low of 76% for night driving up to 97% for double vision. There was a fairly even spread between improvement and worsening of the five subjective areas.

A comparative multi-center study comparing the ICL with LASIK in eyes with moderate to high myopia (8–12 D) showed the ICL to be superior in both uncorrected visual acuity and best spectacle corrected acuity. The ICL had significantly fewer eyes losing two or more lines of BCVA and significantly more eyes gaining two or more lines of BCVA.[15]

Accurate correction of myopia and hyperopia with the ICL has been confirmed in a study published by Lackner et al, detailed in Figure 100.4.[16] The preservation of excellent visual quality was also confirmed by Jiménez-Alfaro et al[17] in 2001 in a contrast sensitivity study after implantation of 20 eyes in 10 patients with the ICL with a mean preoperative myopia of 14.10 D. The CSV 1000 (Vector Vision Inc, Dayton, OH) was used and showed contrast sensitivity improved after surgery at all spatial frequencies (3, 6, 12, and 18 cpd).

The PRL has shown excellent efficacy data. For uncorrected visual acuity within the range −7.00 to −20 D, 71.2% of eyes were within ±1 D of emmetropia, and 88.5% were within ±1.5 D of emmetropia.

Table 100.1 Summary of key efficacy variables stratified by preoperative spherical equivalent (SE*)

		Preoperative SE			
		≤7 D Myopia (%)	>7–10 D Myopia (%)	>10 D Myopia (%)	TOTAL (3–20 D)

The preoperative vs. postoperative spherical equivalent is shown in Figure 100.5.[18]

RESULTS: COMPLICATIONS

Making sense of complications of pPIOLs first requires an understanding that the natural history of the average candidates for these lenses, that is the high myopes, have an increased risk of sight-threatening problems during their lifetime even without intraocular surgery. In highly myopic eyes the incidence of retinal detachment is increased, with an increased rate of posterior staphyloma, atrophic thinning of the choroid and sclera with variable degrees of vitreous syneresis and posterior vitreous detachment.[19,20] Highly myopic eyes are also more likely to develop chronic open angle glaucoma and pigmentary glaucoma, and age-related cataract appears earlier than in the normal population.

Highly hyperopic eyes are more at risk of angle closure glaucoma. A list of complications from a meta-analysis of the literature for

various pPIOLs is shown in Table 100.3. For reliable data with reasonable follow up, the ICL myopia study group gives the most comprehensive analysis. The key safety variables are shown in Table 100.4. In general, the higher the degree of preoperative myopia the greater the incidence of complication or adverse event. In this study all five of the eyes with persistent loss equal to two lines of best spectacle corrected visual acuity occurred in those with greater than 10 D of myopia. All of the subsequent cataract extractions and three of four of the ICL repositioning occurred in those with greater than 10 D of myopia.

The induction of lens opacities or clinically significant cataract is of considerable interest because of the close proximity of these

lenses to the natural crystalline lens. Anterior lens opacities (not necessarily clinically significant) were observed in six (2.5%) eyes in the greater than 10 D group, seven eyes (4%) in the 7–10 D group, and only one eye (0.9%) in the less than 7 D group. Of those lens opacities considered clinically significant, both nuclear and anterior subcapsular, all occurred (seven of seven eyes) in the greater than 10 D myopic group. The average age of the study population was 36.5 years (range 22–45) and development of lens opacities may differ in an older population. The three eyes which suffered retinal detachment in this series had preoperative myopia of −9.50, −16.25, and −17.75 D. Perkins[21] has estimated that the expected risk of retinal detachment in phakic myopes is as high as 0.68% per year. Given the follow up in this FDA series of high myopes, as many as nine retinal detachments would be expected, whereas only three were observed. Retinal detachment in one eye produced the only severe nonreversible visual loss in the entire FDA study.

An endothelial cell sub-study was performed in over 200 eyes at each of the preoperative, 3 month, 1 year, 2 year, and 3 year postoperative visits. Sixty-seven eyes were also evaluated 4 years postoperatively. Cumulative cell loss over the first 3 years was 8.4–9.7% depending on the method of analysis. Fifty-seven eyes were examined at both 3 and 4 years postoperatively and the mean endothelial

cell densities were 2354 cells/mm^2 and 2355 cells/mm^2 respectively. The 3–4 year percentage cell change was a 0.1% gain (90% confidence interval, 1.4–1.6%). There was no decrease in percentage hexagonality or increase in co-efficient variation at any interval studied.

Endothelial cell analysis is a relatively controversial issue. It is expected that there will be a small and hopefully insignificant cell loss at the time of surgery, but the area of concern is the possibility of further ongoing cell loss through a patient's life. If this mechanism was due to intermittent mechanical contact, then clearly a lens in the posterior chamber is safer than any other. Dejaco-Ruhswurn and colleagues have suggested in a small study that there may be other mechanisms, specifically a noncontact inflammatory mechanism for ongoing endothelial cell damage.[22] They reported an aggressive loss with rates changing from 5.5% at 1 year, 7.9% at 2 years, 12.9% at 3 years, and 12.3% at 4 years. Only the first year data was statistically significant and the cell morphology indices remained stable. Unpublished data by Reinstein et al[8] on 12 eyes implanted with the ICL in one eye and evaluated for 8 years, with the fellow eye used as control, showed an endothelial cell loss rate similar to that of physiological aging (about 0.7%) per year in the ICL eyes. A complication specific to the PRL was described by Donoso et al.[18] In a series of 53 eyes of 39 patients, there were two cases of inferotemporal subluxation of the PRL through the zonules with no iatrogenic or predisposing factors. Both lenses were explanted through the original clear corneal incision. The authors note that in a personal communication seven PRL dislocations into the vitreous and six PRL subluxations into the anterior chamber were noted in Italy and Spain, and their suggestion was 'until the causes of subluxation are explained, we believe it is prudent to use the STAAR Surgical ICL rather than the PRL IOL.'

Intermittent ICL contact with the crystalline lens during accommodation has been addressed.[23,24] As the sulcus retracts with accommodation no significant changes in distance between the ICL and crystalline lens were found. The ICL vaulting increases as necessary, compensating the 200–600 μm forward movement of the anterior lens surface. Behavior of ICLs in relation to the crystalline lens during accommodation varies with age. The position shift is dependent on the initial vault and the ability of the anterior lens surface to bulge forward. In contrast under photopic environmental conditions or after application of pilocarpine, pupil constriction reduces the vault height, forcing the ICL against the crystalline lens.

ANATOMIC CONSIDERATIONS

Compared with traditional intraocular lenses used with cataract surgery, phakic intraocular lenses have a relatively small anatomic space in which to be placed.[4] Accurate sizing of the pPIOLs is essential for a successful long-term result. Limbal measurements of white to white distance, particularly in the horizontal axis, are commonly used to predict the anterior chamber diameter and ciliary sulcus diameter. This external measure correlates poorly. Werner et al[25] compared vertical and horizontal white to white measurements with direct anatomic measurements in phakic human eye bank eyes and found a positive correlation only between the vertical white to white distance and the anterior chamber angle diameter. There was no correlation between the horizontal white to white distance and the anterior chamber angle diameter; nor was there correlation between either technique of external measurement and the ciliary sulcus diameter.

There are five methods for gaining information about anterior chamber depth and anterior segment configuration:

1. Traditional A-scans ultrasound with an immersion technique giving an excellent measurement of anterior chamber depth.
2. Partial coherence inferometry (PCI) using the Zeiss IOL master for anterior chamber depth.
3. Very high frequency digital ultrasound, which was developed from ultrasound biomicroscopy (UBM). The newest device is the Artemis II, which gives the most useful information regarding anterior segment anatomy.
4. Scheimpflug imaging using the Pentacam system.
5. Anterior segment optical coherence tomography (OCT) using the Zeiss Visante system, which is limited by its inability to directly image behind the iris.

The five modalities are compared in Table 100.5.

Table 100.5 Summary table of methods for measuring anterior chamber anatomy

	Company	Method	Resolution	Imaging Ability
A Scan	Various	Ultrasound	±100 μm	ACD
IOLMaster	Carl Zeiss	Partial coherence interferometry	±10 μm	ACD White to white
Visante	Carl Zeiss	Ocular coherence tomography	Axial ±18 μm Transverse ±60 μm	ACD AC angle Iris and lens position (through pupil)
Artemis 2	Ultralink	Arc Scanning VHF Ultrasound with digital signaling processing	Approx. ±1.2 μm	ACD AC angle Vault Sulcus to sulcus diameter
Pentacam	Oculus	Scheimpflug principle for slit image photography	±39 μm	ACD AC angle Vault

ACD = anterior chamber depth.

Table 100.6 Widely accepted criteria for implanting phakic IOLs

• Ages 21 to 50
• General good health
• Stable manifest refraction (±0.50 D 6 months apart)
• Ammetropia not correctable with excimer laser surgery
• Unsatisfactory vision with intolerance of contact lenses or spectacles
• ACD (endothelium to anterior crystalline central distance) ≥2.8 mm Note: ≥2.5 mm for PRL
• Irido-corneal aperture ≥30° (Shaffer grade 3 and 4 or Scheie grade 0 and 1)
• Endothelial cell count >2500 cells/mm^2 at 20 years of age
• Endothelial cell count >2000 cells/mm^2 at 40 years of age
• No ocular pathology (corneal disorders, glaucoma, uveitis, cataract, maculopathy, etc.)
• No previous ocular surgery

PATIENT SELECTION

The FDA has approved the Visian ICL for adults 21–45 years of age to correct myopia from −3.00 to −15.00 D with less than or equal to 2.5 D of astigmatism, and to reduce myopia greater than 15 D and up to 20 D with less than or equal to 2.5 D of astigmatism, both with an anterior chamber depth of 3.0 mm or greater and a stable refractive history (within 0.5 D) for 1 year prior to implantation. The generally accepted criteria are shown in Table 100.6. The impact of the rapidly evolving anterior segment imaging techniques is yet to be established in regular clinical practice.

To summarise, ideal candidates are mature young patients, able to make full advantage of the accommodation potential of their natural lens, but having high ametropia not accurately or safely correctable with excimer laser surgery.

SURGICAL TECHNIQUE

The patient is prepped and draped as for routine cataract and lens surgery. Topical anesthesia, with or without sedation, is the standard method, and wide dilatation is required. A week prior to intraocular surgery, two laser peripheral iridotomies at the 11 and 1o'clock positions should be performed.

The lens is placed via an injection technique through a 3.0 mm clear corneal temporal incision. The correct loading of the ICL in the cartridge injector is essential. Using a modified McPherson forceps with long blunt curved tips, the lens is grasped and checked under the microscope. The ICL has two tiny holes on the footplates at the distal right and proximal left to indicate the anterior side. The current PRL has no landmarks. The cartridge is partially filled and lubricated with saline and OVD, and the lens is normally loaded dome up. A piece of soft material (foam tip) is positioned to protect the lens from contact with the plunger of the shooter.

Two side port incisions of 1.0 mm are created and a cohesive OVD substance, such as Ocucoat, is normally used. The cartridge is inserted bevel down. The tip of the injector should only just penetrate the wound. The lens is injected and moves along the funnel in a cylindrical fashion gradually unfolding as it enters the chamber. Retro-pupillary positioning of the footplates involves maneuvering the haptics through the side ports with a sand-blasted 'tucker.' Only a very small degree of dialing is acceptable and manipulations must be smooth and gentle to avoid damage to the crystalline lens and iris.

Once positioned correctly the OVD must be removed as completely as possible using a bimanual irrigation aspiration technique particularly to reach the OVD trapped beneath the ICL. Usually, acetylcholine is injected intraocularly to constrict the pupil, and the wound hydrated.

SPECIAL CLINICAL CONSIDERATIONS WITH THE PHAKIC POSTERIOR CHAMBER INTRAOCULAR LENS

BIOPTICS

Bioptics means combining a phakic intraocular lens with corneal refractive surgery. This is particularly appealing in high ametropia because it combines both a corneal tissue sparing approach with the ability to maximize the effective optical zone. It may be part of a planned procedure, particularly with preoperative astigmatism, or it may be unplanned where there is a residual refractive error after phakic intraocular lens implantation.

Three issues are worth considering. If corneal refractive surgery follows phakic posterior lens implantation, when is the 3.0 mm temporal corneal incision stable enough to withstand the application of a microkeratome or femtosecond suction device? When is the refractive error stable to allow an accurate correction? Thirdly, is the application of a microkeratome with raised intraocular pressure likely to cause damage to the corneal endothelium because of the phakic lens, or is it possible to dislocate the lens?

If bioptics is a planned approach some clinicians suggest the creation of a LASIK flap prior to phakic IOL surgery. We personally do not do this routinely but prefer to wait 2–3 months following surgery and perform corneal refractive surgery on its merits. Two to three months assures both refractive stability and tectonic security of the wound. Often relatively small residual refractive errors need to be dealt with, and surface ablation may be considered as a preferred technique.

ASTIGMATISM

Astigmatism is able to be treated with the Visian ICL but there are no reported cases in the literature. The astigmatic range of treatment is 1–4 D. The surgery is identical to routine ICL implantation but in addition the lens needs to be orientated to the appropriate axis. There are anecdotal good reports but it is reasonable to assume that the ICL will rotate in a significant minority of eyes to make this a less than ideal mechanism for dealing with astigmatism. It is probable that astigmatism, where clinically relevant, will continue to need to be treated with a bioptics corneal refractive approach.

CATARACT AND INTRAOCULAR LENS SURGERY AFTER PHAKIC POSTERIOR INTRAOCULAR LENS SURGERY

It may be the fate of all posterior chamber phakic intraocular lenses to be removed, and/or removed in conjunction with cataract and lens surgery. The largest study in the literature so far is by Morales et al.[26]

Of 215 patients (370 eyes with ICL implantation between 1997 and 2002) 56 eyes (15%) of 45 patients were found to have lens opacities of which 14 eyes (3.8%) of 12 patients had symptoms that required cataract and intraocular lens surgery. Of the 14 eyes 12 had original high myopia and 2 had hyperopia. Axial length was measured using the Sonogauge A scan, and the Hoffer Q formula was used for IOL calculations modified according to the desired postoperative refractive targets. No difficulties were encountered measuring the axial length in any way. The patients were prepped in the normal manner, and following injection of OVD the proximal haptics of the ICL were dislocated into the anterior chamber using a Bechert lens manipulator. The ICL was then grasped with forceps and extracted from the anterior chamber through a 3.2 mm incision. The anterior chamber was refilled with OVD and cataract surgery completed in a routine manner. No adverse events were observed. One eye had a tear in the posterior capsule unrelated to the ICL manipulation. The final manifest spherical equivalent was 0.30 D (standard deviation 1.07) and a range of +2.38 to −2.00 D. Ten eyes (71%) were within ±1 D of the calculated target. Since the speed of sound through the various materials of phakic intraocular lenses is widely different, and is not the same as the average velocity used to measure the eye, a variable but definite error occurs. Hoffer[27] concluded that the greatest effective error will occur with a silicone IOL in an eye with very high hyperopia, and the least effect will occur with a collamer lens (Visian ICL) in an eye with very high myopia.

CONCLUSION

Phakic posterior chamber intraocular lenses are approved for use within the USA, and will be part of the refractive surgery portfolio. They bridge the gap between corneal refractive surgery and cataract and lens surgery, requiring skills from both subspecialties. Specifically the highly developed surgical skills, which are an essential component of cataract and lens surgery, and also the perioperative decision making, most often associated with corneal refractive surgery. Given the success both in efficacy and safety of corneal refractive surgery (but also its definite limits) phakic intraocular lenses will form a minority of refractive surgical procedures in adults below the age of 50 years. The placement of a phakic intraocular lens in the posterior chamber is particularly appealing esthetically and from the viewpoint of protecting the endothelium and anterior chamber angle, and the main complication is cataract development. At least this is a complication that is amenable to effective treatment. Issues of particular lens design, and better methods of optimizing a lens size and shape to an individual anterior segment anatomy, will improve both the accuracy and safety, and therefore the popularity of this type of surgery over the next few years.

101 Multifocal, pseudo-accommodative, and accommodative intraocular lenses

Jesse Chew, Liliana Werner, Randall J. Olson

Intraocular lenses (IOLs) are a standard part of cataract surgery and their rapid evolution over the last few decades has led to significant advances in their design. Today they not only restore the refractive power of the eye after surgery but also may provide special features to address presbyopia.

Presbyopia is an age-related process that can be described as a decrease in amplitude and speed of accommodation.[1] Accommodation occurs by contraction of the ciliary body and subsequent relaxation of the lens zonules resulting in increased lens curvature and hence optical power. Physiologic changes in the lens capsule, lens, ciliary muscle, and zonules have all been implicated as factors causing presbyopia.[2]

One means of achieving good distance and near vision after cataract surgery is with multifocal IOLs which use simultaneous vision. Separate near and distance images are superimposed on the retina. In this setting the optical power of the eye is not changed but the brain must interpret the images as separate, selecting the one related to the object of regard and suppress the other.[3] The other mechanism to achieve good distance and near vision in the eyes is to actually change the optical power of the eye, true accommodation, by having an IOL that moves or changes shape during contraction and relaxation of the ciliary muscle.

Accurate biometry is essential to obtain appropriate visual results for all types of IOL implantation. Axial length can be measured with immersion A-scan ultrasonography or laser interferometry. Contact A-scan ultrasonography should be avoided as it is prone to compression errors with resulting underestimation of true axial length. Similarly, manual keratometry is recommended as automated keratometers often lack the accuracy desired. Topography derived keratometry also lacks the accuracy of manual keratometry and is not recommended.

Previous corneal laser refractive surgery is not a contraindication to multifocal or accommodative IOL implantation. However, because of greater potential error in the keratometry readings, patients should be warned there is a higher chance of missing the target refraction and needing a secondary procedure to achieve emmetropia.

Patients with macular pathology and limited potential acuity after cataract surgery are not likely to gain sufficient benefit from a multifocal or accommodative IOL compared to a monofocal IOL. Patients who are at risk of having retina surgery/silicone oil should obviously not be implanted with any of the new lenses manufactured from silicone-based materials. All the pseudophakic lenses mentioned in this segment require precise centration and capsular bag support. They are not recommended for use without an intact capsulorrhexis and posterior capsule.

In this text, we describe some of the new IOLs currently available or under development, which are designed to relieve patients of presbyopia. It should be noted that none of the IOLs mentioned correct pre-existing astigmatism, which should be addressed with some form of refractive procedure for optimal visual results.

MULTIFOCAL INTRAOCULAR LENSES

Multifocal IOLs have multiple optical foci (typically two: one distance and one near) and thus even under the best of conditions one image will be in sharp focus, and one image will be blurred by a defocus aberration. By their very design, this lower optical quality as compared with monofocal IOLs is measured as lower contrast sensitivity in patients.[4] However, most published studies confirm that multifocal IOLs lead to good near visual acuity with distance correction. Still, they often fail to satisfy highly demanding patients, with an explantation rate of up to 7% for the Array IOL.[5] The presence of halos around image borders could outweigh the advantages of spectacle independence. As the strength of these halos depends on the luminance of the defocused image, multifocal IOLs can be distance dominant or near dominant, or even change dominance with pupil size.

Current multifocal optics address distance and near, but this may not meet the visual needs of all patients. An intermediate focal length is desired by some. Adding an intermediate distance to current diffractive designs would add greater complexity to an already complex manufacturing process that may degrade the optical quality of the lens.

Before choosing a multifocal IOL, precise biometry as well as careful patient selection are required. This is especially important because of concerns related to the possibility of higher incidence of decreased contrast sensitivity and glare with these lenses. Success

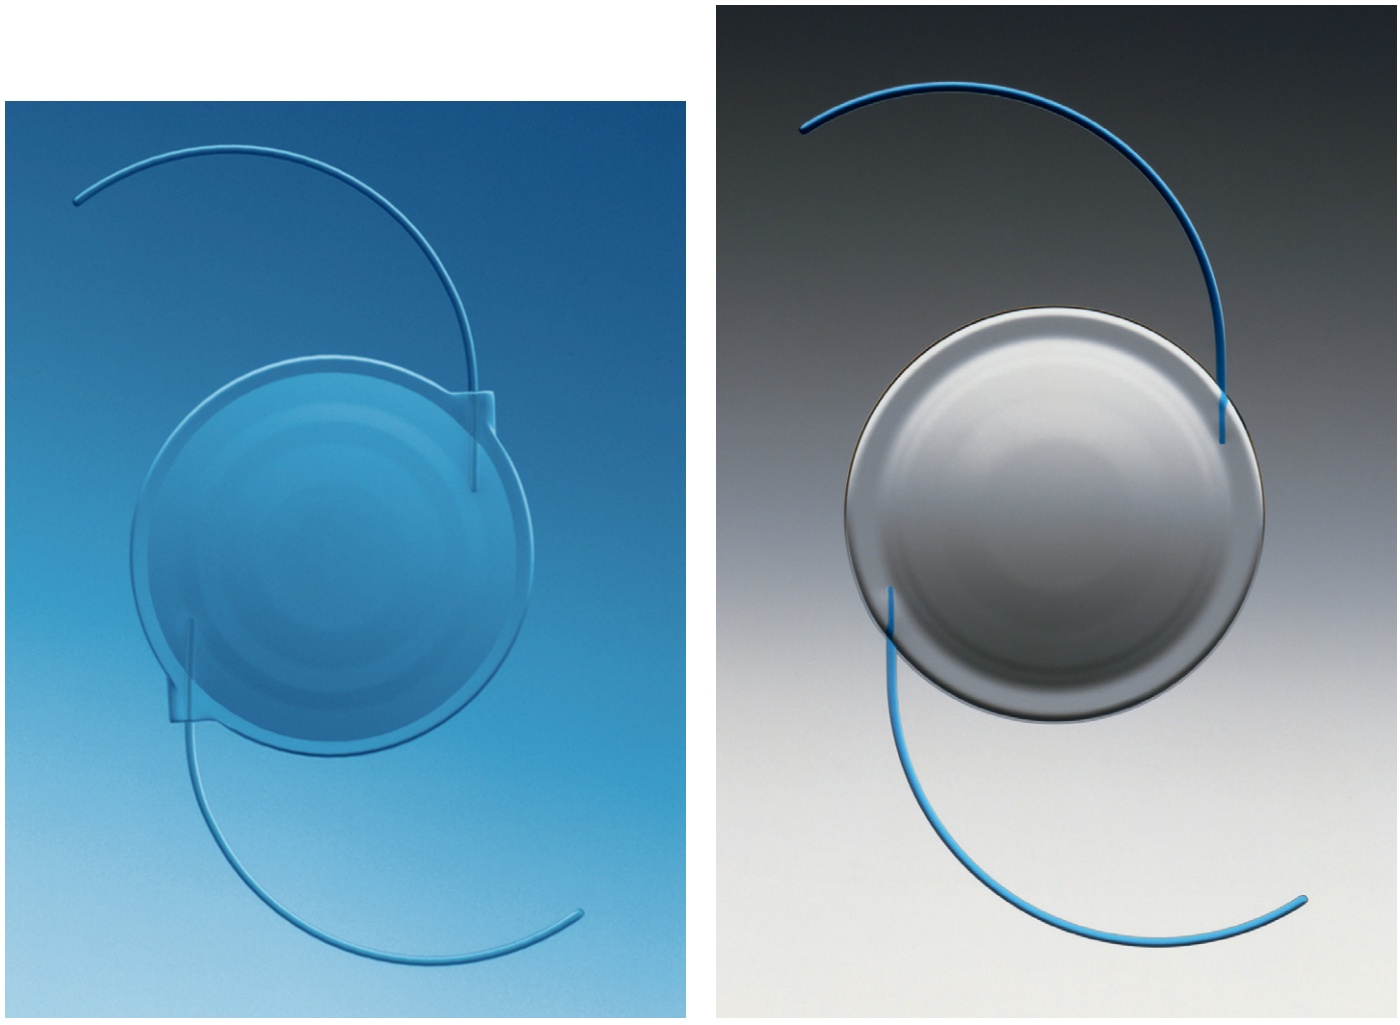
is also dependent on surgical technique: in-the-bag implantation and appropriate capsulorrhexis are necessary to ensure good centration, avoid myopic shift, and reduce posterior capsule opacification (PCO).[6] It is generally recommended by all manufacturers that multifocal IOLs be implanted bilaterally for better patient satisfaction.

PSEUDOPHAKIC MULTIFOCAL IOLs

The Array lens (Advanced Medical Optics, AMO, Santa Ana, CA) is a three-piece multifocal IOL manufactured from a silicone material having a refractive index of 1.46 (Fig. 101.1, *A*). It has angulated 'C' haptics made of extruded polymethylmethacrylate (PMMA). The optic is 6.0 mm in diameter with total length of the lens measuring 13.0 mm. It is the first multifocal IOL approved by the Food and Drug Administration (FDA). The optical design of this lens is a zonal-progressive multifocal optic with five concentric zones. The center of the lens is primarily for distance. All the other zones have distance and near in different proportions—approximately 50% of the light at distance, 37% at near, and approximately 13% for intermediate vision. The optical zone is 4.7 mm in diameter. No available light is lost as the optic is refractive and not diffractive. The addition power is +3.5 D at the lens plane and it is available from +6.0 to +30.0 D in 0.5 D steps.

Javitt et al compared bilateral implantation of the Array lens versus a monofocal lens with respect to visual function, patient satisfaction, and quality of life.[7] They found that those patients who had bilateral implantation of the Array obtained better uncorrected and distance-corrected near visual acuities and reported better overall vision, less limitation in visual function, and less spectacle dependency than patients with bilateral monofocal lenses. In the study by Schmitz et al reduced contrast sensitivity was found in the multifocal group (also implanted with the Array) only at the lowest spatial frequency without halogen glare.[8] The monofocal and multifocal groups of patients studied by them had no statistically significant differences in contrast sensitivity with moderate and strong glare. Their results suggest no difference in glare disability induced by halogen light similar to oncoming vehicle headlights for patients implanted with monofocal and multifocal IOLs.

More recently, AMO launched the ReZoom lens (Fig. 101.1, *B*). This is a second-generation, refractive, multifocal IOL, manufactured from a hydrophobic acrylic material with a refractive index of 1.47. It has angulated (5°) modified 'C' haptics made of 60% blue core PMMA monofilament. The overall diameter of the lens is 13.0 mm, with an optic diameter of 6.0 mm. The optical design of this lens features the Balanced View Optics Technology, with five concentric zones modified from the Array design to enhance func-



A B

Figure 101.1. Multifocal intraocular lenses manufactured by Advanced Medical Optics: *A*, Array. *B*, ReZoom.

tion and decrease glare (Fig. 101.2, *A* and *B*). Zones 1, 3, and 5 are distance dominant, while zones 2 and 4 are near dominant. The latter provide +3.5 D near add power at the IOL plane translating to +2.57 D add power in the spectacle plane and a near point of 39 cm or 16 inches. There is an aspheric transition between the different zones. The area of zone 4 was decreased by 55%, zone 3 was increased by 80%, and zone 2 was increased by 2% in relation to the Array™. The IOL is also available from +6.0 to +30.0 D in 0.5 D steps. It incorporates the new OptiEdge design, which combines three elements: a rounded anterior edge, a sloping side edge that is frosted, and a sharp, vertical posterior edge. The rounded anterior edge and frosted sloping edge were designed to minimize glare. It spreads out rays that pass through its surface and disperses light rays reflected from the edge. This is especially important with IOLs manufactured from hydrophobic acrylic materials, which have a higher refractive index than silicone materials. The frosted sloping side edge is designed to reduce the area of the surface that can cause internal reflections and to scatter internal reflections away from the retina. The squared posterior optic rim design has proven to be effective in the prevention of PCO. FDA approval came in March 2005. Clinical experience suggests that emmetropia should be targeted; however, any error in the refractive target that must occur should be on the side of hyperopia (±0.25 D) to provide good near vision as well as good distance vision for driving.[9]

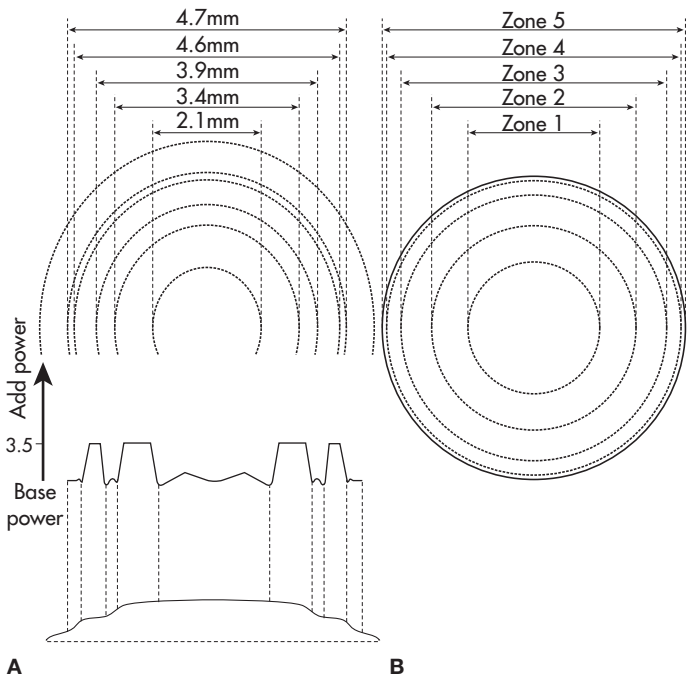


Figure 101.2. Schematic drawings showing the distribution of refractive power in the Array (*A*) and the ReZoom (*B*) lenses according to the different zones.

Clinical trials showed significantly better mean binocular and monocular distance corrected intermediate visual acuity in subjects with bilateral multifocal IOLs when compared with subjects with bilateral monofocal IOLs. A recent study by Longhena and associates compared the ReZoom IOL with the Array IOL.[10] Thirty patients (60 eyes) received a ReZoom or an Array after cataract surgery. Six month data showed 80% of ReZoom patients were spectacle independent compared to 60% of Array patients. No glare or halos were reported by 80% of ReZoom patients compared to 40% of Array patients.

Dick, in a study, compared visual acuity, photic phenomena, and defocus acuity curves of the ReZoom IOL and the Array IOL. Similar defocus curves were noted with both lenses, indicating good near and excellent intermediate vision. ReZoom patients reported spectacle independence 100% of the time for distance, 95% for intermediate, and 71% for near vision. There was also a lower incidence of photic phenomena with the ReZoom when compared to the Array IOL.[11]

Another currently available multifocal IOL is the ReSTOR lens (Alcon Laboratories, Fort Worth, TX). This apodized, diffractive IOL received FDA approval in March 2005, and is manufactured by using the platform of the hydrophobic acrylic single-piece AcrySof lens (Fig. 101.3, *A*). The lens has a length of 13.0 mm and the optic is 6.0 mm in diameter. The design incorporates 12 diffractive grating zones present on the anterior surface in the central 3.6 mm of the optic. Apodization is the gradual tapering of the diffractive steps from the center to the periphery. The largest diffractive step is at

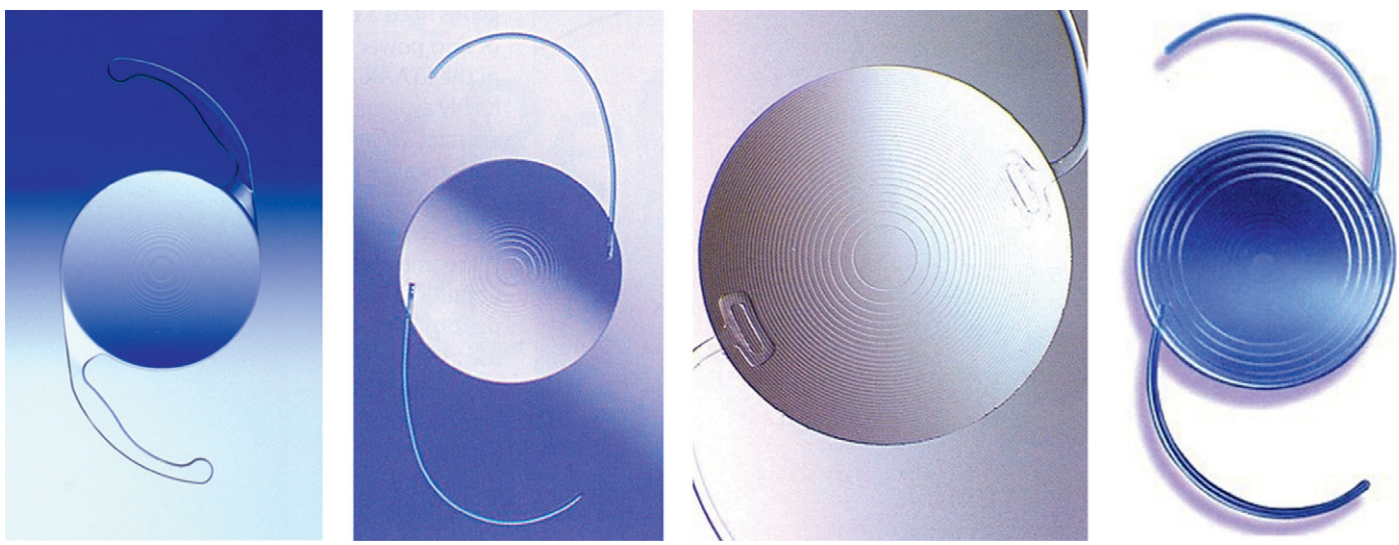

Figure 101.3. Photographs showing other currently available (or under evaluation) multifocal lenses. *A* and *B*, single-piece and three-piece ReSTOR lenses (Alcon). *C*, Multifocal Tecnis lens (AMO). *D*, Acri-Twin (Acri.Tec).

the lens center (about 1.3 μm) and sends most of the light to a near focus. As the steps move away from the center, they gradually decrease in size, blending into the periphery, and sending a decreasing proportion of light to a near focus. As a result of this design, when the pupil is small, such as during reading tasks, the lens provides appropriate near and distance vision (the Array multifocal IOL provides no near image if the pupil is approximately 2.5 mm or smaller). However, in large pupil situations, such as at night, the ReSTOR lens becomes a distant-dominant lens, providing appropriate distance vision while reducing unwanted visual phenomena, as the defocused near image has less signal strength. The add power is +4.0 D at the lens plane, which provides approximately 3.2 D of add power at the spectacle plane. It should be noted that with a diffractive approach there is a resultant 15–17% of the light being lost attributable to random scatter.[12]

In FDA clinical trials, bilateral implantation of the AcrySof ReSTOR IOL into 566 patients provided uncorrected visual acuity of 20/40 or better throughout the distance to near visual range with no restrictions on pupil size.[9] Following cataract surgery 80% of patients with bilateral implantation achieved total spectacle independence and 17% reported only occasional use of spectacles. There were significantly more glare, night vision problems, and halos for subjects implanted with the ReSTOR lenses when compared to a monofocal IOL control group. However, this was observed only in the 'mild' or 'moderate' symptoms category whereas no significant differences were noted in the 'severe' symptoms when compared to the control group.

A study by Rocha et al compared the visual acuity, total and high order wavefront aberrations (coma, spherical aberrations, and other high-order aberrations), and contrast sensitivity in 105 eyes implanted with four different lenses: the ReSTOR, 3-piece and single-piece monofocal AcrySof lenses, and a single-piece hydrophilic acrylic monofocal lens.[13] They observed that the ReSTOR induced significantly less spherical aberration compared to the monofocal lenses, but the contrast sensitivity was better with the monofocal AcrySof lenses.

More recently Alcon has produced the ReSTOR, model MA60D3, which is a three-piece multifocal hydrophobic acrylic lens, with PMMA haptics (Fig. 101.3, *B*). The optic has the same apodization design as its predecessor. Early clinical trials have shown 88.0 and 84.6% spectacle independence for distance and near vision. Unwanted photic phenomena has been described as clinically acceptable.[14]

The Tecnis lens with the Z-Sharp Optic Technology (AMO) has an anterior aspheric surface that compensates for the natural positive aberration of the cornea. The manufacturer is also working on a multifocal lens, which incorporates a diffractive posterior surface to the Tecnis design (model ZM001). In theory, the Tecnis multifocal lens would compensate for the decrease in contrast sensitivity that may be associated with multifocal lenses, by an increase in contrast sensitivity due to the aspheric characteristics of the lens. Peer-reviewed articles on the Tecnis multifocal IOLs are not yet available in the literature (Fig. 101.3, *C*).

Different clinical studies on the three above-mentioned multifocal designs have been presented at the latest annual symposiums and meetings of the European and American Societies of Cataract and Refractive Surgeons, as well as the American Academy of Ophthalmology. The three designs were generally associated with appropriate near, intermediate, and distance vision, as well as spectacle independence. To date, superiority of one design over the other is yet to be determined. Many have presented using a refractive multifocal in one eye and a diffractive in the second to optimize the best features of both. Peer-reviewed studies are currently being carried out.

The newly developed Acri.Twin (Acri.Tec, Hennigsdorf, Germany) bifocal diffractive 3-piece lens has a 6.0 mm silicone optic and PMMA monofilament haptics with 5° angulation (Fig. 101.3, *D*). The overall diameter is 12.0 mm. The central thickness of the IOL is reduced by peripheral fresnel structures. These structures are not responsible for near focus. The two focal points are created by central diffractive steps on the anterior surface of the IOL. There are two models: the Acri.Tec 733D and the Acri.Tec 737D. The Acri.Tec 733D has a 30% to 70% light distribution between distance and near focus while the Acri.Tec 737D has a 70% to 30% light distribution between distance and near focus. The IOLs are designed to be implanted binocularly (one model in one eye, the other model in the fellow eye). According to the manufacturer, both IOLs have a near addition of +4.0 D in the lens plane. A recent study by Schmidinger et al suggests that binocular implantation of the Acri.Twin system may be beneficial for visual acuity, near contrast sensitivity function, and distance contrast sensitivity function compared with a diffractive bifocal IOL.[15] Currently, this system is available in Europe but has yet to be approved for use in the USA.

PHAKIC MULTIFOCAL IOLs

IOL technology encompasses not only pseudophakic patients but phakic patients as well. Most degrees of myopia, hyperopia, and astigmatism, can be corrected with refractive surgery. Available techniques include excimer laser treatment, phakic IOLs, and clear lens exchange. The development of phakic multifocal IOLs give refractive surgeons yet another tool to add to their armamentarium for treating refractive errors, including presbyopia. The obvious advantage of a phakic multifocal IOL is, of course, the reversibility.

The bifocal refractive phakic IOL, known to most as the Baikoff IOL, is marketed under the trade names of Newlife (IOLtech, La Rochelle, France) and Vivarte Presbyopic (Ciba Vision, Duluth, GA). This is a hydrophilic acrylic lens manufactured through a process named selective polymerization, which allows the manufacture of a one-piece IOL with flexible and rigid areas anywhere needed to optimize the mechanical properties of the lens (Fig. 101.4, *A*). The lens thus has soft hydrophilic acrylic (38% water content) optic and footplates, while the haptics have a rigidity similar to that of PMMA lenses. This foldable angle supported lens has a 5.5 mm diameter optic which is divided into three concentric zones. The center and periphery are for distance vision and the middle periphery is for near vision. The central zone diameter is 1.5 mm, the intermediate zone is 1.1 mm wide, and the remaining 2.9 mm makes up the peripheral zone. The haptic is shaped like the number '2' and is available in overall diameters of 12.0 mm, 12.5 mm, and 13.0 mm. The lens comes in powers between −5.00 D and +5.00 D for distance vision with an addition of +2.50 D for near vision.

In the first trial study of phakic multifocal IOLs, Baikoff and his associates looked at 55 eyes of 33 patients with this lens implanted.[16] Although the results were satisfactory with fewer than 10% needing glasses in mesopic conditions, there were some findings which should be addressed. Slight pupil ovalization was seen in 10% of eyes under high light conditions, with fewer being noted in normal light conditions. Endothelial cell loss was not significant. No cataract or ocular hypertension was observed although the follow up time in the study was limited to only one year. In general, patients who reported halos tolerated them well. The authors suggested strict anatomic and psychological inclusion criteria for patient selection. The lens requires an anterior chamber depth (ACD) of 3.0 mm or

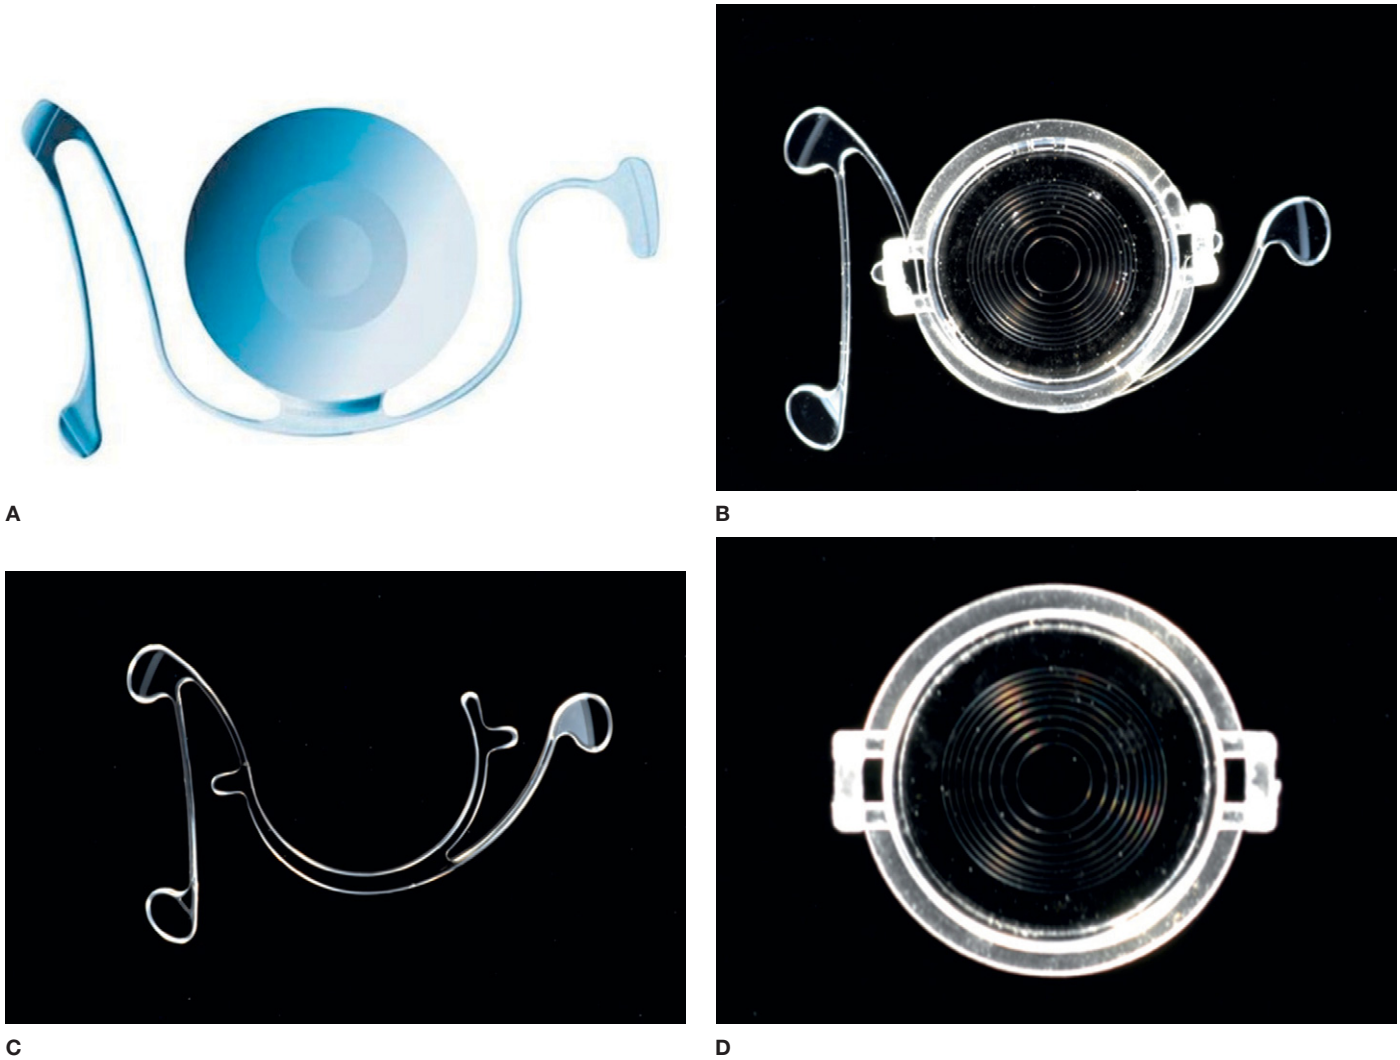

Figure 101.4. Examples of phakic, multifocal intraocular lenses. *A*, Newlife lens (Ioltech). *B–D*, Presbyopic phakic multifocal version of the Kelman Duet lens (Tekia). The two components of this lens are shown separately in *C* and *D* (haptic and optic, respectively).

deeper, an open angle, healthy endothelium, and no anterior segment or retinal disorders. Any astigmatism must be corrected before or after implantation of the phakic IOL. Patients who are too demanding and those whose profession require them to drive at night must be excluded.

In another pilot study, this one by Alio and Mulet, a multifocal phakic IOL prototype by Advanced Medical Optics was implanted into 34 eyes of 17 patients.[17] This one piece, angle supported, PMMA anterior chamber IOL is designed to maximize the physical distance from the IOL to both the cornea and the iris. The lens has a meniscus shape with a diameter of 12.5 mm and an optic diameter varying between 5.8 mm (myopic) and 6.0 mm (hyperopic), depending on the implant power. The anterior surface includes a multifocal design similar to that of the Array lens, with an add power of +1.75 D at the lens plane. This low power add was chosen apparently to minimize postoperative night vision photic phenomena. The design has five concentric zones: 1, 3, and 5 being distance dominant, and zones 2 and 4 being near dominant. The lens is available in powers ranging from +5.0 D to −15.0 D in 0.5 D increments. Because it is not foldable, a larger incision is necessary for implantation. In this study, wounds were 6.5 mm wide. Results showed that 65% of patients did not require reading glasses after surgery. However, the lens did not always allow comfortable extended reading or the ability to read small print clearly without spectacles for more than 20 min without visual fatigue. Findings concerning endothelial cell count and anterior segment complications correlate with previously published data on other angle-supported phakic IOLs.[16,18] As with the Newlife/Vivarte Presbyopic IOL, there were several cases of pupil ovalization but these resolved after 1 month of miotic treatment. No cases of ocular hypertension or cataract were noted although follow-up time was once again only for 1 year.

The very nature of multifocal lenses makes patient selection extremely important no matter what lens is chosen. There will almost undoubtedly be some compromise in visual quality when compared to best spectacle corrected vision. Patients must be made aware that spectacle independence may come at the cost of excellent preoperative vision for good postoperative vision.

Another multifocal phakic IOL being developed uses the platform of the Kelman Duet implant (Tekia, Inc., Irvine, CA). This is a foldable, phakic, angle-fixated anterior chamber IOL (Figs 101.4, *B–D*). The lens has two components: an independent Kelman tripod PMMA haptic, with an overall diameter of 12.0, 12.5, or 13.0 mm, and a 6.3 mm silicone optic, with an incorporated glare shield. The haptic of this lens is implanted first into the anterior chamber through an incision inferior to 2.0 mm. The multifocal optic is then inserted using an injector onto the previously implanted haptic, and then

fixated to it by the means of the optic eyelets and haptic tabs using a Sinskey type hook. The optic can be exchanged as the refraction of the patients evolves, e.g. in case of progressive presbyopia.

The last phakic multifocal IOL has a slightly different approach to the correction of ametropia and presbyopia. The Vision Membrane (Vision Membrane Technologies Inc., Carlsbad, CA, Apollo Optical Systems LLC, Rochester, NY, and Millennium Biomedical Inc., Pomona, CA) is a thin, vaulted, angle fixated diffractive IOL with a 6.0 mm optic. Its thickness ranges from 450 to 600 μm compared to 800 to 1200 μm for a standard refractive IOL. According to Lane et al it can be implanted through a 2.60 mm wide incision.[9] With an optic of 6.0 mm there should be less halos and glare effect when compared to anterior chamber IOLs of lesser diameter. No peripheral iridotomy is necessary because of the very flexible vaulted design which optimizes distance away from both the pupil and the corneal endothelium. Currently, the lens is manufactured from a silicone material.

Conventional diffractive optic lenses use a single diffraction order in which the optical power of the lens is directly proportional to the wavelength of light. A white light will project as different wavelengths focusing at different distances from the lens. The Vision Membrane is described as having multi-order diffraction (MOD) designed to bring multiple wavelengths to a common focus. This principle allows the IOL to be of a constant thickness for all refractive powers, and eliminate chromatic aberrations.

There are two forms of the Vision Membrane lens available. One is intended for correction of near or farsightedness (single power). The other is for the correction of near or farsightedness plus presbyopia. These are available in powers from −15.0 D to −1.0 D, and from +1.0 D to +6.0 D in 0.5 D increments. Patients are recommended to be over the age of 18 years, with stable refraction. Previous posterior chamber IOL implantation is not a contraindication.

ACCOMMODATIVE INTRAOCULAR LENSES

In the past few years there have been several accommodative IOLs developed. Some have single optics designed to move along the visual axis during accommodative efforts, thus changing the effective power of the eye. Others have a dual optic design where the contraction and relaxation of the ciliary muscle causes change in the separation distance between the two lenses.

When evaluating near vision for any accommodative IOL, remember that beyond movement, pseudoaccommodative factors such as increased depth of focus from small pupil size, residual myopia and astigmatism, and high contrast settings can contribute to improved near vision.

SINGLE OPTIC

The Eyeonics Inc. (Aliso Viejo, CA) CrystaLens (model AT-45) is a modified plate haptic lens manufactured from a third generation silicone material (Biosil) with a refractive index of 1.43 and has an integrated UV-absorbing chromophore (Fig. 101.5, *A*).[19] It is the first accommodative IOL based upon movement in the capsular bag secondary to accommodative effort and has been FDA approved for use in the USA since November 2003. It is hinged adjacent to the optic and has looped polyimide haptics. Grooves, which run across the plates adjacent to the optic, make the optic–haptic junction flexible. The overall length of the lens is 11.5 mm, corner to corner, while the straight length is 10.5 mm. The biconvex square-edged optic has a diameter of 4.5 mm and a manufacturer's recommended A-constant of 119.24 when placed in the capsular bag. Theoretically, when there is accommodative effort by the ciliary body mass, there is increased vitreous pressure which will move the optic forward along the visual axis creating increased effective lens power. It has been recommended that one drop of atropine be administered at the time of surgery and one drop the first day after surgery to allow the lens to remain in the most posterior possible position within the capsular bag and prevent forward movement until a certain amount of fibrosis surrounds and stabilizes the haptics. This should result in greater potential forward movement upon ciliary muscle contraction. The hinges are intended to facilitate forward movement of the optic by minimizing the resistance to the pressure exerted on the lens by the forward movement of the vitreous body during accommodative effort.

This IOL is intended for placement in the capsular bag only. The recommended capsulorrhexis size is 5.5 mm. This allows the plate haptics to be posteriorly vaulted in the right position. A large capsulorrhexis or a wound leak at the end of the surgery potentially allows the lens to vault anteriorly. This position inhibits movement of the lens and would likely require surgical repositioning.

Unfolded, the lens can be inserted through a 3.2 mm incision, and slightly less than 3.0 mm with the injector system. Uniplanar clear corneal incisions are not recommended because of potential early postoperative wound leakage.

The lens is claimed to give 1 D of additional power during accommodation. In the investigational FDA clinical trials, 497 implantations were done with the CrystaLens allowing approximately 73% of subjects to remain essentially free of spectacles. However, other studies have not been able to show good correlation between the objective measurement of the anterior shift of the lens and the reported near vision of the patients.[20,21] In some cases posterior movement was actually observed. Therefore, it is likely that pseudoaccommodation or IOL arching inducing added power may play a role in the reading performances of patients implanted with this lens design.[22]

There is some concern with regards to patients with large pupils. The scotopic results achieved in clinical trials were excellent; however, the average age of the patients was approximately 70 years. Dysphotopsias, because of a comparatively small optic measuring only 4.5 mm in diameter, may be of concern when using such a lens on younger patients with larger pupils.

The CrystaLens is very flexible and can bend more easily than a standard IOL in response to capsular contraction. Because of unpredictable capsular contraction in pseudoexfoliation patients, manufacturers recommend the lens not be used in patients with this condition.

Other concerns about the CrystaLens include the accommodative potential after Nd:YAG capsulotomy. Over 50 eyes in the USA clinical trial have undergone laser capsulotomy and their accommodative abilities have not diminished. If needed, posterior capsulotomies are recommended to be small, approximately 3 mm or less, to avoid vitreous herniation around the optic and to preserve the mechanism responsible for accommodation in this lens. Capsular fibrosis syndrome has also been discussed with dislocation of the IOL or induced 'Z' syndrome (one haptic up and one back). Some have recommended 100% prophylactic laser capsulotomy, which raises concerns about retinal detachment and cystoid macular edema.

Three year data for the eyes in the USA clinical trials demonstrate no loss of accommodative performance over time, which suggests IOL movement is probably not important for near vision even after

Figure 101.5. Examples of mono-optic, accommodative intraocular lenses. *A*, CrystaLens (Eyeonics). *B*, Earlier BioComFold design (Morcher). *C*, Akkommodative 1CU (HumanOptics). *D*, Tek-Clear (Tekia).

typical capsular fibrosis. Similar findings have been observed in longer-term follow-up in overseas trials.[23]

Other single optic accommodative IOLs have been more popular in the European market. The first was a ring-haptic IOL designed by Payer (Fig. 101.5, *B*).[24,25] Models BioComFold 43A and 43E were marketed in the 1990s. This is a foldable hydrophilic acrylic single piece lens, which has a disk-like shape with a peripheral ring. The ring is connected to the central optic by an intermediate forward angled perforated ring section. The optic sits anterior to the ring haptic plane to allow forward shift of the optic during ciliary muscle contraction and hence ring haptic compression. Available now is the Biocomfold 43S which is an accommodative IOL with refractive multifocal optic.

Yet another accommodative IOL is the Akkommodative 1CU made by HumanOptics (Erlangen, Germany). This is also a hydrophilic acrylic single optic posterior chamber lens (Fig. 101.5, *C*). The optic is 5.5 mm in diameter with biconvex shape and an ultraviolet filter incorporated. There are four haptics tapering at the optic–haptic junction, which act as hinges, giving the lens an overall diameter of 9.8 mm. The refractive index is 1.46 with a recommended A-constant of 118.1. The lens is available in powers between +16.0 to +26.0 in 0.5 D increments. The design is often assumed to function similar to the CrystaLens. This is actually not the case. Relaxation of lens zonules during ciliary body contraction leads to relaxation of the capsular bag and forward movement of the IOL at the hinges of the four haptics.[26] This would suggest that the flexibility of the capsular bag is critical to its performance, which has yet to be proven in large peer-reviewed studies. It has been suggested that an IOL of this design characteristically moves less than 1 mm anteriorly on accommodative effort as determined by ultrasound biomicroscopy.[3] As with all accommodative IOLs that are intended to shift position with accommodative effort, the effective lens power increase varies with the power of the lens. High-powered lenses typically used for hyperopes will show greater change in diopter power when compared to weaker powered lenses of the same design. For high myopes who generally have

lower-powered IOLs implanted, the potential add will be more limited.

The Tek-Clear (Tekia, Inc., Irvine, CA) accommodative IOL was also designed to take advantage of the natural accommodating process of the human eye (Fig. 101.5, *D*). This is a single-piece, disk-shaped lens, with an overall diameter of 10.0 to 11.5 mm, manufactured from a hydrophilic acrylic material, which can be fully injected through an incision of 3.2 mm. The lens design incorporates a 'bending-beam' approach, to optimize the IOL movement as the ciliary muscle contracts during the accommodation process. Its full bag haptic design incorporates a square edge for PCO prevention.

DUAL OPTIC SYSTEMS

Theoretical studies using model eyes demonstrate that dual-optic IOL systems may have an advantage over single piece accommodative lenses in terms of amplitude of optical power gained with optic movement during ciliary muscle contraction.[3,27] This is particularly true if there is anterior movement of the anterior optic with an unchanged position of the posterior optic. The Synchrony IOL (Visiogen Inc., Irvine, CA) is a one-piece, dual optic lens manufactured from silicone (Figs 101.6, *A–C*).[28] The optics have a general design of a plate haptic silicone lens and they are connected by a bridge through the haptics, which act like a spring. The 6.0 mm posterior aspect of the lens has a larger surface area than the 5.5 mm anterior, which allows better stability within the capsular bag during contraction and relaxation of the ciliary muscle. The anterior optic has two expansions oriented parallel to the haptic component that lift the capsulorrhexis edge and prevent complete contact of the anterior capsule with the anterior surface of the lens. The anterior optic has high +32.0 D power while the posterior lens has a patient-dependent minus power to return the eye to emmetropia. Theoretical accommodation is 3.3 D, with 1.5 mm of anterior

Sarfarazi, currently being developed by Bausch & Lomb.

lens movement. The lens is designed to work within the capsular bag according to Helmhotz's theory of accommodation. The distance between the two optics is stated to be at a minimum in the unaccommodated state and at a maximum in the accommodated state, with the anterior optic displaced forward. Stoppers are incorporated to maintain a minimum separation of the lenses which sets the resting distance refraction at emmetropia. With accommodative effort and zonule relaxation, the tension of the capsular bag is released, which allows the interoptic spring-like articulations to displace the anterior optic forward. Rabbit studies by Werner et al demonstrated that significantly less anterior capsule opacification and PCO were observed in eyes implanted with the Synchrony™ lens when compared to eyes implanted with plate haptic silicone lenses.[29,30] They also demonstrated that interlenticular opacification (ILO) was significantly associated with pairs of hydrophobic acrylic lenses implanted in the bag, but not with the Synchrony. The Synchrony is currently under clinical trials. Since the last quarter of 2005, it is being implanted through a 3.6–3.8 mm incision, by using a preloaded injector that only requires balanced salt solution for IOL lubrication. The suggested continuous curvilinear capsulorrhexis size is between 4.5 and 5.0 mm. A recently reported series of 24 patients implanted with this lens showed 100% distance corrected visual acuity of greater than or equal to 20/40. Defocus curve analysis showed a mean accommodative range of 2.83 ± 0.16 D.[31] Actual anterior lens movement has been documented by ultrasound analysis.

Another dual-optic accommodative IOL system is now being developed by Bausch & Lomb (Rochester, NY). It was invented by Dr Faezeh M. Sarfarazi and is composed of a single-piece molded silicone lens (Fig. 101.6, *D*). There are two optics connected by three haptic components. The design also uses a high-powered positive anterior lens and a low-powered posterior lens. It has Bausch & Lomb's patented Aspheric Advanced Optics platform, which reduces aberrations and makes the lens system less prone to optic–optic decentration and tilting. The haptics act to center the lens as well as provide the spring-like resistance that separates the two optics. The posterior surface of the posterior lens has a square edge to reduce PCO. The continuous silicone lens is designed to match the size and characteristics of the human eye to achieve accommodation through the natural contraction/relaxation of the capsule by the ciliary muscle. According to its inventor, measured accommodation closely matches the theoretical optical design of 2.2 D per mm of lens translation for a total accommodation of 4.0 D. Clinical trials show the lens can be inserted through a 4.0–4.5 mm incision and into the capsular bag with good centration. It is currently under clinical studies being conducted by Bausch & Lomb. So far safety has clearly been demonstrated with good patient acceptance.[32]

NEWER CONCEPTS

With such huge efforts being put forth toward designing an IOL that 'cures' presbyopia, we are bound to come across some innovative ideas, which take a different approach to addressing the problem. What if instead of a multifocal IOL, or an IOL that moves with accommodative effort, we could have an IOL which mimicked the natural crystalline lens during ciliary muscle contraction?

One approach may be to place a malleable material inside the capsule to produce a situation very close to our pre-presbyopic state. At Medennium Inc. an IOL with such potential capabilities is being developed. This lens uses a thermodynamic hydrophobic acrylic material that is packaged as a solid rod approximately 30 mm long and 2 mm wide.[6] The refractive index of the material is 1.47, and the softening temperature is 20–30°C. When implanted through a small incision, body temperature transforms the rod into a soft gel-like material, which has the shape of a full-size biconvex lens that completely fills the capsule. The entire transformation takes about 30 s and the result is a 9.5 mm wide lens having 2–4 mm thickness at the center depending on thickness (Fig. 101.7, *A–D*).

Besides being implanted through a very small incision, another potential advantage is to restore accommodation. By combining a full-sized optic with a flexible material, the hope is that the lens will be able to mimic the accommodative action of a young, natural lens. Complete filling of the capsular bag may eliminate the space for cell growth (Fig. 101.8). The hydrophobic material of this lens exhibits a tackiness, which might promote its attachment to the capsular bag, enhancing PCO prevention. A new design of this lens is being developed, which is a three-piece lens with PVDF haptics. This potentially will eliminate problems related to varying capsular bag sizes in different eyes. Dealing with after-cataract formation, refractive precision, and whether or not the anterior capsule needs to be largely intact to transmit accommodative effort are still unresolved issues. It is also not clear how well accommodative forces can act on such a lens with the anterior capsule open due to capsulorrhexis.

Yet another design for an accommodative lens originates from the thought that when a flexible material is pressed between two hard planes, one of which has a central aperture, the flexible material will follow the path of least resistance through that aperture. If that flexible material is transparent, this bulge acts as a lens that changes in radius and power according to the pressure applied. This is the concept of the NuLens (NuLens Ltd, Herzelia Pituach, Israel). In theory, the IOL power would change with ciliary body action and generate an add power of up to at least 8.0 D by manipulation of a flexible material between a sulcus-fixated rigid plate and a ciliary muscle operated capsular diaphragm.[33] This diaphragm would consist of the collapsed capsular bag, zonules, and ciliary processes. It would provide the force transfer from the ciliary muscle to the diopter-generating device placed adjacent to it.

To complete the concept, there would be a need for a stable reference plane in front of the diaphragm to turn those forces into physical changes in curvature of a flexible lens material. Once the rigid reference plane is fixated, a contained flexible material could be placed between the rigid plane and the capsular diaphragm. Movements of the diaphragm would then deform that flexible material through a hole in the rigid anterior reference plane or through a posterior pushing piston to create a secondary lens.

The original design used accommodation effort for distance vision, which raises issues of patient acceptance and induced esotropia due to the accommodative convergence mechanism. Another design gets around this issue if it were to prove to be a problem. Thus far a second generation lens has been developed, which is designed to be fixated in the ciliary sulcus via micropins, and the dynamic surface is in the posterior part of the lens near the nodal point of the eye. Ongoing development for safe insertion and fixation techniques into the ciliary sulcus are being tested for structural assessment and further modification of the lens components (Fig. 101.9, *A* and *B*).

Early laboratory studies, including in primates have been done with promising results. The feasibility of the concept has been demonstrated; however, further analysis along with the continuing development of this lens is necessary before any clinical conclusions can be made about the future use of this IOL in humans.

H = haptics; E = end plates with micropins; P = piston (from Ben-Nun J, Alio JL. Feasibility and development of a high-power real accommodating intraocular lens. J Cataract Refract Surg 2005; 31: 1802–1808). *B*, Experimental implantation of the NuLens in a human eye obtained postmortem (posterior view of the anterior segment).

In summary, we have been witnessing an incredible evolution in the world of IOLs, much of it driven by the quest to treat presbyopia. The interest in this field continues to grow as manufacturers aim to meet the visual needs of patients while maintaining high standards of safety and quality. Whether it will be pseudoaccommodative or accommodative, the innovative designs of IOLs are a trend sure to expand. Which design will provide the best patient satisfaction is not clear at this time.
