Notice
Medical knowledge is constantly changing. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the author assume any liability for any injury and/or damage to persons or property arising from this publication.

PREFACE

The 'face' and 'faces' of this Fourth Edition text for 2008 have changed as the reader will note immediately on viewing our front cover. In the hope of appealing to a broader international readership, we are joined by Olivia Serdarevic (Paris and New York) and Charles McGhee (Auckland, New Zealand). Peter McDonnell (Baltimore) and Ayad Farjo (Ann Arbor) complement our editorship, which seemed an increasingly daunting task involving three continents and our book publisher across the Atlantic. Add in the mix of an older editor (FSB) trying to keep up with the world of multiple contributors, frequently changing e-mail addresses, along with on-line manuscript corrections, and the task seemed overwhelming.

This book arose 22 years ago from an Eye Bank Association of America meeting in San Diego when keratoplasty began to flourish and eye banks created more stringent standards and were led by fellowship-trained corneal surgeons. We trained and were mentored by outstanding corneal surgeons and influenced directly by the likes of Dohlman, Kaufman, Laibson, Fine, Peyton, Polack, Troutman, Maumenee, Castroviejo and indirectly by Paufique and Rycroft among others.

The publication of Krachmer, Mannis and Holland's first and second editions of Cornea stands as a monument to absolutely the best of our current generation of corneal specialists with much to tell us about both the medical and surgical aspects of the diagnosis and treatment of corneal disease. Our mutual publishing company Elsevier suggested that this text should accentuate the surgical aspects of the cornea, and we have achieved this. In doing so we have strived to retain appropriate research chapters which aide our understanding of corneal anatomy and physiology.

This Fourth Edition again utilizes marvelous additional illustrations of Laurel Cook Lhowe to emphasize surgical technique and there is a return to color figures throughout the text. The refractive surgery portion of Cornea Surgery has been extensively revised and lengthened with Section Four reviewing 'Endothelial keratoplasty' and Part Six providing in-depth coverage of 'Surgical Correction of Refractive Errors'. The reader will note the retention of previous edition upgraded chapters such as 'Penetrating Keratoplasty' but the loss of all but one eye-banking chapter. Eye banks under the direction of the Eye Bank Association of America in fact have not disappeared—to the contrary we use them more than ever as they take on additional roles such as processing tissue for lamellar keratoplasty.

So as to not forget the lessons of the past; Peter Laibson, both in his lecture in Chicago two years ago, and in Chapter One of this text, has provided historical perspective on modern day corneal surgery.

Frederick S. Brightbill, MD
Madison, Wisconsin, U.S.A.
July, 2008

LIST OF CONTRIBUTORS

Juan C. Abad MD
Cornea, Anterior Segment and Refractive Surgery
Clinica Oftalmologica de Medellin (COM)
Medellin
Colombia

Richard L. Abbott MD
Thomas W Boyden Endowed Chair in Ophthalmology
Health Sciences Professor
Cornea and External Diseases
UCSF Department of Ophthalmology
Research Associate
Francis I. Proctor Foundation
San Francisco, California

Omar Ahmad MD
Ophthalmology, Resident Physician
University of Michigan
Ann Arbor, Michigan

Tracy L. Aigner OD

Esen Karamürsel Akpek MD
Associate Professor of Ophthalmology
Director of Ocular Surface Diseases and Dry Eye Clinic
Wilmer Eye Institute
Johns Hopkins University
Baltimore, Maryland

Daniel M. Albert MD, MS
Director of the UW Eye Research Institute
F.A. Davis Professor and Lorenz E. Zimmerman Professor and Chair Emeritus
Department of Ophthalmology & Visual Sciences
University of Wisconsin School of Medicine and Public Health

ACKNOWLEDGMENTS

FSB: I want to thank Wanda Jones-Madison for her assistance and perseverance in organizing the Fourth Edition; Ayad Farjo for his extensive knowledge of current ophthalmic literature and help with the new Table of Contents; Courtney Moffatt Brightbill for her loving support and keeping me on track with the computer age; Sharon Nash, Emma Riley and Russell Gabbedy among others at Elsevier; and the editors and contributors to Corneal Surgery for their time and devotion.

AF: It is not often that I have the opportunity to publically acknowledge those who have supported and encouraged me. First of all it has been a distinct pleasure working with Fred Brightbill and the other distinguished editors on this edition. I am deeply grateful to my wife Karin and sons Zayd and Kai for their patience and tolerance and to my brother Qais for his insight and critical commentary. My parents, Anastas and Muna and brothers Laith and Rafal have been a mountain of support. I also wish to thank my mother-in-law, Diane Sletten who left us too soon and husband Rolf Sletten. I have been fortunate to be associated with the Universities of Michigan, Iowa and Wisconsin. My particular thanks goes to my mentors at Michigan: Roger Mayer, Kaz Soong and Alan Sugar; and to my colleagues on the Cornea service at the University of Iowa: John Sutphin and Michael Wagoner.

PM: In my personal and professional development, I have been fortunate to have friends, family and colleagues who have helped me immeasurably. Thanks for Jan, Laura, Peter and Emma for being understanding of the demands of an academic career. Arnall Patz and Stephen Ryan were excellent role models and patient mentors. Arun Patel, Chris Muller, David Pyott, William May, James Mazzo and Bob Butchofsky exemplified effective leadership, and are also people in the field of Ophthalmology that I admire greatly.

CNJM: On a large, wide-ranging endeavor such as this fourth edition one always gratefully recalls the knowledge and skills passed on by mentors, peers and junior staff. I am particularly indebted to my early mentors in ocular pathology, Professor William Lee in Glasgow and Professor Dan Albert in Boston who taught me much about research and academic writing. My clinical career in ophthalmology owes a huge debt to far too many to name individually, but my clinical and surgical skills were molded at key stages by Dr John Williamson and Dr Jeffrey Jay in Scotland and Dr Geoffrey Crawford in Western Australia. Of course many corneal fellows have kept me up to date and have been enthusiastically involved in my various projects over the years and I often feel I have learned as much as I have given on this two way street. Finally, my career and my contribution to this book and other academic activities would have been absolutely impossible without the understanding and loving support of my dear wife Jane.

OS: I want to thank Fred Brightbill for his excellent previous editions; his stamina to complete this edition; and his invitation to include me in this most worthy project.

I also thank my mother and late father whose courage, fortitude, determination, integrity, wisdom and kindness inspired me to both pursue and foster knowledge and innovations for improving life.

DEDICATION

To the researchers, clinicians, teachers and patients—past and present—who have clarified our understanding of cornea and anterior segment function, leading us to remarkable new surgeries for treating disease and improving vision.

1 History of corneal transplantation

Peter R. Laibson

The first visually successful human corneal transplant was performed 101 years ago, on December 7, 1905, in Olmutz, a small Moravian city near Prague in Slovakia, formerly Czechoslovakia. It was performed by Dr Eduard Zirm on Alois Golgar, who was blind bilaterally from a lime injury.[1] Both corneas were severely scarred centrally, leaving some peripheral clarity. His vision was hand motions in both eyes.

Karl Braur, an 11-year-old boy, was the donor. He had lost vision following an intraocular metallic foreign body injury in July 1905. Zirm enucleated the blind eye and used the donor's clear cornea to form two 5.0-mm donor corneas. He removed the corneas with a 5.0-mm von Hippel trephine, which was first used by von Hippel in 1888 (Fig. 1.1). The same principle of using round trephines to remove the donor button and cut the host cornea is used today. Zirm kept the transplants in place with a bridge of conjunctiva sutured over the corneas. The patient's left corneal transplant was trephined from a more central part of Braur's donated cornea. The right corneal transplant failed and had to be removed but the left transplant cleared and Golgar was sent home 15 weeks after the operation. A year afterward an ophthalmologist checking Golgar's visual acuity found it to be 6/36 with a stenopeic disc. He could read J-4 with glasses[2] (Fig. 1.2). Zirm died in March 1944 without recording any other corneal transplants in his 45 publications. Golgar lived for 3 years after the operation.

The successful corneal transplant performed by Eduard Zirm, even though a single case, followed a century of keratoplasty investigation and failure. Keratoplasty in the 19th century was doomed to failure because of a total lack of knowledge concerning many basic concepts that would prevent failure, such as the germ theory and sepsis, immunology and tissue biology, anatomy and physiology of the cornea, and anesthesia. Even today immunologic rejection is not clearly understood, although it is successfully treated in most instances, usually with topical corticosteroids.

The concept of removing a clouded cornea was discussed by Charles Darwin's grandfather, Erasmus Darwin, in 1796. He felt that after an ulcer of the cornea perhaps the scar could be cut out and have it heal with a transparent scar. He recommended this 'strongly to some ingenious surgeon or oculist.' In 1824, Franz Reisinger coined the term 'keratoplasty' and it is he who is credited with this term, although controversy surrounds this attribution.[3] In those years it was felt that the human cornea could be replaced with an animal cornea from another species. The history of corneal transplantation in the 19th century has been reviewed by Castroviejo,[4] Paton,[5] and particularly Sir Benjamin Rycroft[6] in his Doyne Memorial Lecture of 1966. An outstanding book on the history of corneal transplantation was written by Manus and Manus in 1999.[7]

Sir Benjamin Rycroft in his Doyne lecture divided keratoplasty evolution into four periods:

I. Inspiration (1789–1824)
II. Trials and Frustration (1825–1872)
III. Conviction (1873–1905)
IV. Achievement (1906–1965)

I suggest a fifth category, V. Refinement and Innovation (1966–present).

At the start of the Inspiration period, from 1789 to 1824, a French surgeon, Pellier de Quengsy, in 1789 actually suggested that a glass cornea could be used to replace the human cornea. He illustrated what was perhaps the first keratoprosthesis but this was never done (Fig. 1.3). Erasmus Darwin in 1797 suggested that by surgically removing corneal pathology the scar might grow back clear. This, of course, was wishful thinking.

In the first part of the 19th century little was done in transplantation until Reisinger suggested that living tissue grafts might be used to perform a corneal transplant. This, of course, was doomed to failure as, among other things, different species were used for the transplantation. Wilhelmus Thome, in 1834, was the first to use the term 'corneal transplantation', although he did not do one. Perhaps the first successful transplant was done by James Bigger, who when captured by Sahara Bedouins was able to achieve his freedom, it is thought, by transplanting the opaque cornea of the pet gazelle of the head sheik using another gazelle's cornea.[8] Most attempts at transplantation in the 19th century used corneas of different species or heterografts and they failed. Kissam, in 1844, discussed guidelines for keratoplasty which although written 165 years ago are actually accurate for current keratoplasty techniques.[9] He suggested the donor and recipient should be of the same size. There should

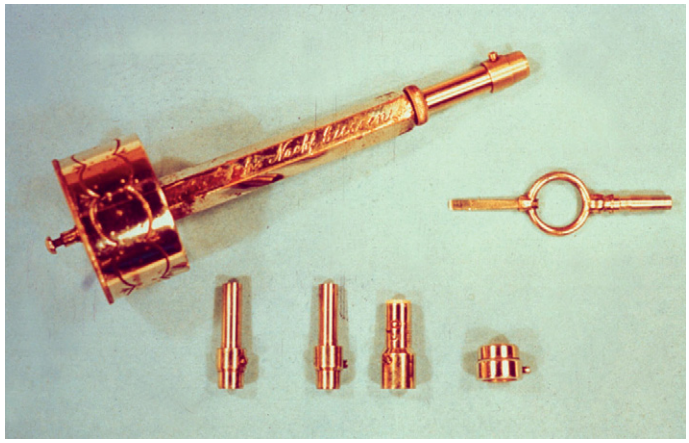

Figure 1.1. Round corneal trephine first used by Arthur von Hippel in 1888. This was a mechanical trephine with a key wind-up utilizing a spring mechanism, which rotated the trephine to remove corneal tissue. This gold-plated trephine photograph provided courtesy of Berthold Seitz, MD.

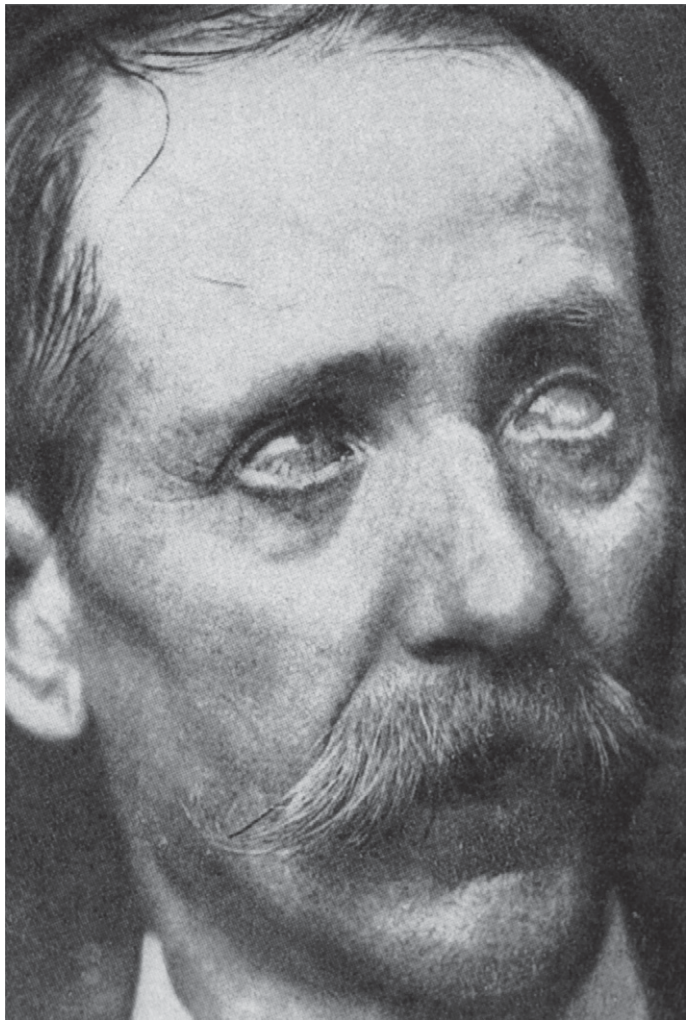

Figure 1.2. Alois Golgar, the first patient with a successful penetrating corneal transplant in 1905. His left eye shows a small clear corneal transplant, 4 mm in diameter. The corneal scarring in the right eye is from an alkali burn with corneal transplant failure in that eye.

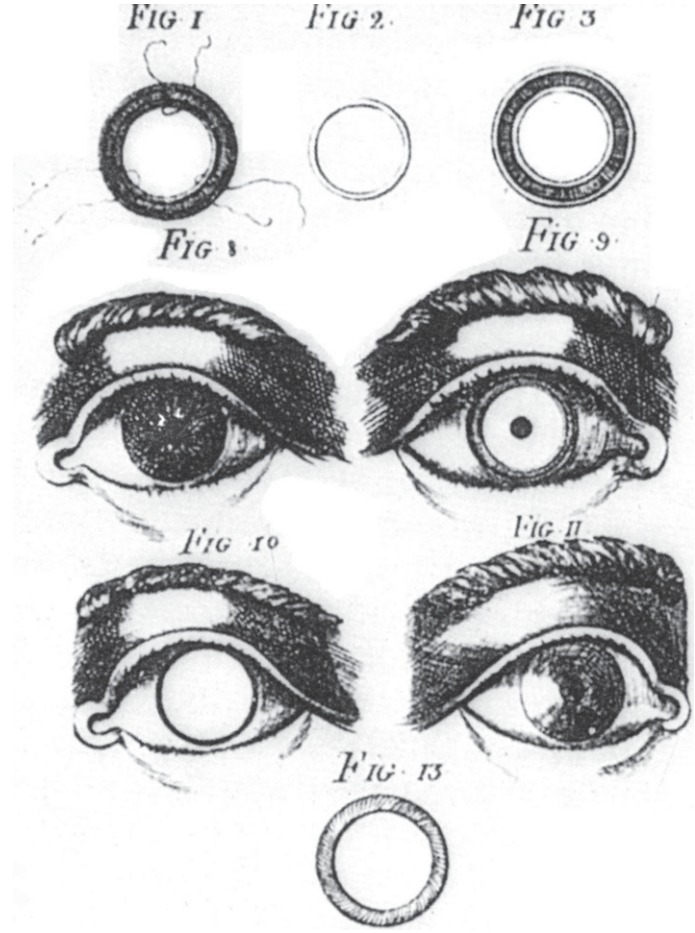

Figure 1.3. Illustration from Pellier de Quengsy's article in 1789 suggesting that a glass cornea might be used to replace a clouded human cornea.

be a rapid and atraumatic transfer of donor tissue with minimal tissue damage and there should be careful corneal fixation and protection of the intraocular contents, such as the lens, iris, and vitreous. It is significant that these concepts are all important today.

The third period, that of Conviction, from 1873 to 1905, saw Henry Power recommend transplantation within the same species.[10] In 1877, von Hippel started publishing his studies using circular mechanical trephines to remove the donor and recipient corneas. This principle is the same for keratoplasty today (Fig. 1.4). He did, however, set back keratoplasty for a time, as he recommended heteroplastic over homoplastic tissue. Other factors leading to success of corneal transplantation included the development of general anesthesia. Ether was first used in 1846, in the etherdome at Massachusetts General Hospital, chloroform in 1847, and in 1867 Lister first brought our attention to an aseptic setting for successful surgery. Topical cocaine was discovered by Kohler in 1884. Without anesthesia and asepsis, keratoplasty was unsuccessful even if done within the same species.

The period of Achievement, from 1906 to 1965, was actually started with Edward Zirm's successful transplantation of Alois Golgar's cornea. Despite Zirm's success with a single penetrating keratoplasty, this operation was not accepted in the first two decades of the 20th century. The lamellar graft was more often used, if any graft was done at all. Direct suturing was years away and penetrating grafts almost always failed. Most research into keratoplasty was

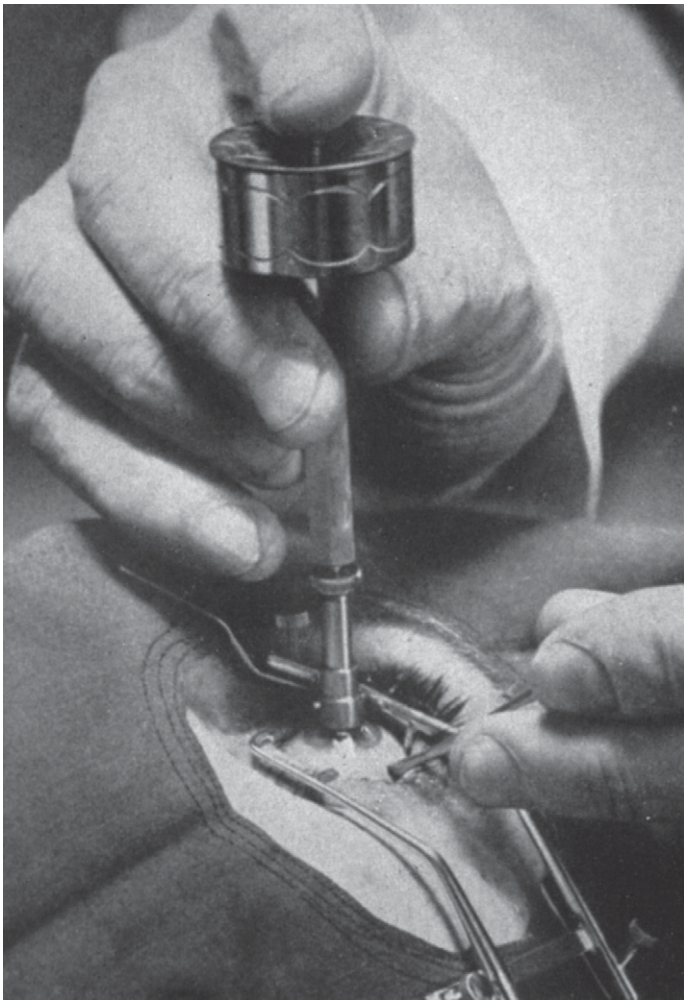

Figure 1.4. von Hippel trephine vertically in place over an eye being used to trephine the donor cornea.

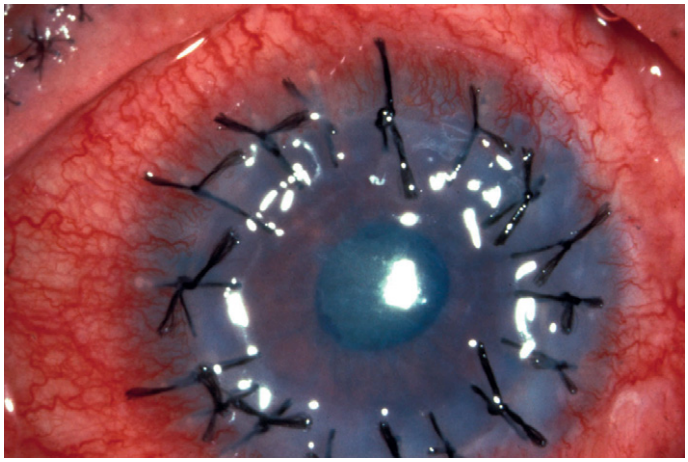

Figure 1.5. Edge to edge appositional sutures using 8–0 silk. Notice the extreme inflammation in this eye. The knots were tied on the surface and long ends left in place for 3 weeks.

carried out in Europe by the giants of that time, including Magitot,[11] in 1912, who first used preserved human corneas, and by Elschnig[12] in Prague. By 1930 his clinic had done 170 corneal transplants, with an amazing 22% success rate without the use of topical antibiotics or steroids! In these years most of the corneal transplants were small, about 4.0 mm, and were kept in place either by conjunctival flaps, with lid closure, or by fixation sutures placed across the cornea as had been done by Zirm.

Harry Gradle published one of the first articles in the US literature on the present status of keratoplasty in the *American Journal of Ophthalmology* in 1921.[13] He found that keratoplasty results were uniformly dismal up to that time. Only single case reports were published and in only one instance were two cases published. No patient had good vision and he concluded that a transplantation from another species is a biologic impossibility (whether or not transplants could be done successfully within the same species was not completely agreed upon). He did not refer to Elschnig's work in Prague, where corneal transplants in humans had been done for at least 10 years with some modicum of success. In those years, of course, US ophthalmology looked toward Europe, and many US ophthalmologists who were interested in furthering their careers studied there.

Sir Tudor Thomas, a leading figure working in England in the 1930s, experimented with corneal transplantation. He felt that it was premature to operate on humans when the results were so dismal.[14] In the early years of the 20th century, Elschnig was the leading advocate for corneal transplantation. In 1930, Elschnig and Vorisek[12] reported their 20 years of corneal transplantation experience in humans. They believed that the only successful method was that of a partial penetrating corneal transplant, where full-thickness human corneal tissue was used. This tissue was usually 4.0–5.0 mm in diameter and was removed from the donor with the von Hippel round trephine. A bridle suture from limbus to limbus in a double-arm fashion was used to maintain the cornea in position until healing occurred. Elschnig's clinic and laboratory results were remarkable considering he was still using techniques from the 19th century. His scrupulous concern in cleaning the cul-de-sac to prevent infection was important, as was his care with proper corneal alignment using overlying sutures, even if this suture was cut 2 days after the operation. The final bandage was removed at 3 weeks and one can imagine the suffering these helpless patients underwent with double patching and bed rest for that period of time. It is interesting to note that even in the early 1950s and 1960s, when edge to edge 8–0 silk sutures were used, 8–12 of these sutures were placed (Fig. 1.5), with a 5.0–7.0-mm-sized transplant. Patients were maintained on bed rest for 3 weeks with their head sandbagged so they would not move. At the end of 3 weeks, all sutures were removed (Fig. 1.6). Even in the 1960s, only about 50–60% of these transplants remained clear.

Although Magitot[11] had successfully transplanted preserved human corneas as early as 1911, freshly enucleated nonpreserved human corneas from eyes with pathology were the source for the corneal transplant donor in most cases. By the middle of the 1930s, when transplantation became more successful, there were not enough diseased eyes with clear corneas that required enucleation to satisfy the needs of the corneal transplant surgeons, who had many cases of bilaterally blind patients on their lists. Elschnig did support the use of cadaver corneas but it was Vladimir Filatov who was primarily responsible for popularizing the use of cadaver corneas for corneal transplant purposes. Filatov, in a review of corneal transplantation, mentions the use of cadaver corneas stored in an ice chest at 4°C.[15] The eyes were enucleated 'within 2–3 h before the body was taken to the morgue, or while in the morgue, certainly within just a few hours of death.' The corneas were used within 20–56 h after death. These early principles of cadaver

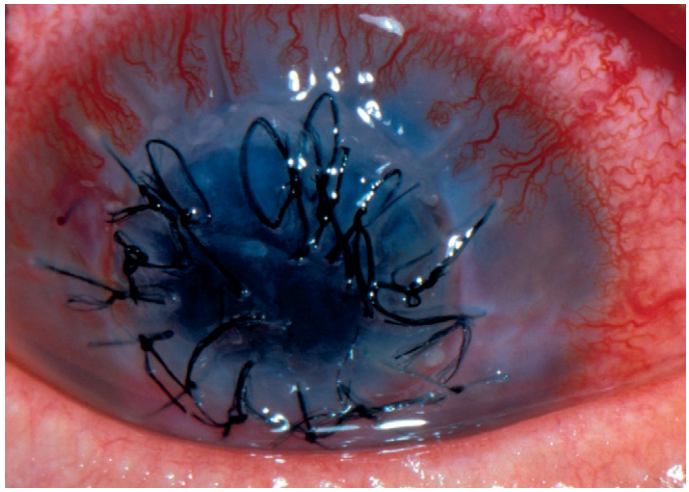

Figure 1.6. Three weeks after the silk appositional sutures were placed in a penetrating graft. There is marked vascularization and suture loosening, requiring all sutures to be removed at the same sitting 3 weeks after the initial surgery.

enucleations are techniques still used today in many countries. Other corneal surgeons preceded Filatov with individual case reports of cadaver cornea use but it is Filatov who was credited with popularizing cadaver corneas for corneal transplantation.

Equally important in the outcome of corneal transplantation is the fixation technique. Many methods have been used to ensure the proper alignment of the donor cornea, beginning with just conjunctival flaps and crossed sutures over the cornea. In the beginning only small grafts, less than 4.0 mm, were used. With these small grafts, overlay sutures were satisfactory for stabilization when the best suture material was probably equivalent to 4–0 or 5–0 silk. Numerous techniques were described in literature[15a] a for fixating corneas (Fig. 1.7). Most of these fixation techniques preceded edge to edge appositional sutures. The sutures were anchored in the sclera beyond the cornea and were removed soon after corneal transplantation because of loosening and vascularization. Ramon Castroviejo's unusual technique of square corneal transplants created with a parallel razorblade was utilized until the 1960s, mostly for keratoconus. He felt that a square graft, with one point directed toward 6 o'clock provided better stability in keratoconus (Figs 1.8 and 1.9). Castroviejo's investigations of keratoplasty, his design of unique instruments and his exquisite skill almost single-handedly improved our techniques and popularized corneal transplants in the 1940s and 1950s[16,17] (Fig. 1.10). Aside from Ramon Castroviejo, few ophthalmologists in the USA were performing corneal transplantation, either experimentally or on humans, before World War II.

A corneal transplant symposium, sponsored by the American Academy of Ophthalmology, occurred for the first time at Palmer House in Chicago in October 1947. A panel of physicians, including R Townley Paton, John M McLean, Ramon Castroviejo, and Edward Maumenee, presented at this symposium. Paton[18] wrote about patient selection while McLean[19] discussed keratoplasty technique, quoting liberally from Castroviejo's work, which dated back to 1932. Castroviejo[20] reviewed complications and illustrated the overlay suture for fixation in his article. Complications of keratoplasty included significant anterior synechiae, iris prolapse, infections (penicillin was the only antibiotic in use), glaucoma, vascularization, inflammation, edema, and deformity due to the protruding edges of the transplant during the postoperative period.

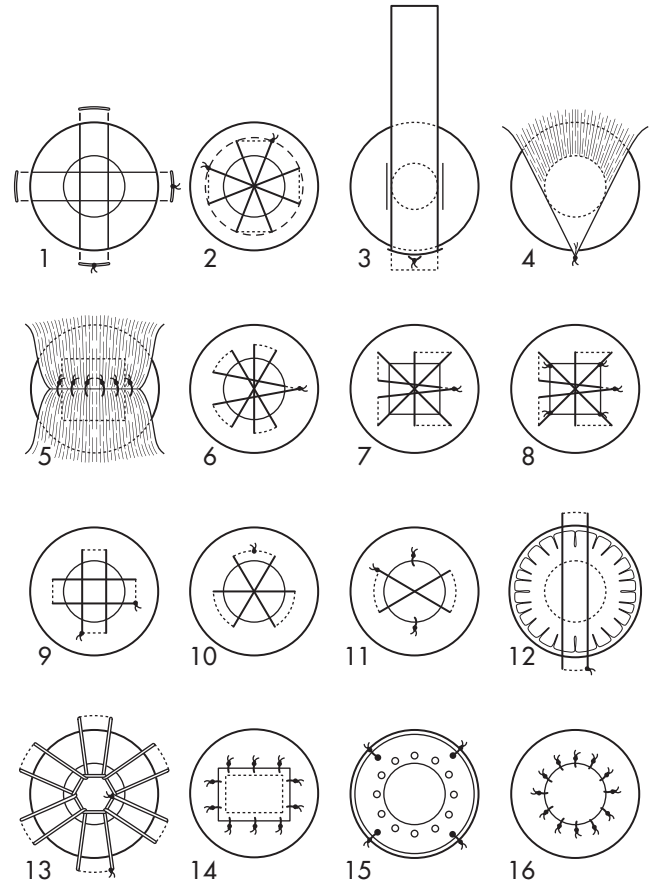

Figure 1.7. Various ways of fixing a corneal transplant with overlay sutures, conjunctival flaps, and in the bottom row eventually edge to edge appositional sutures.

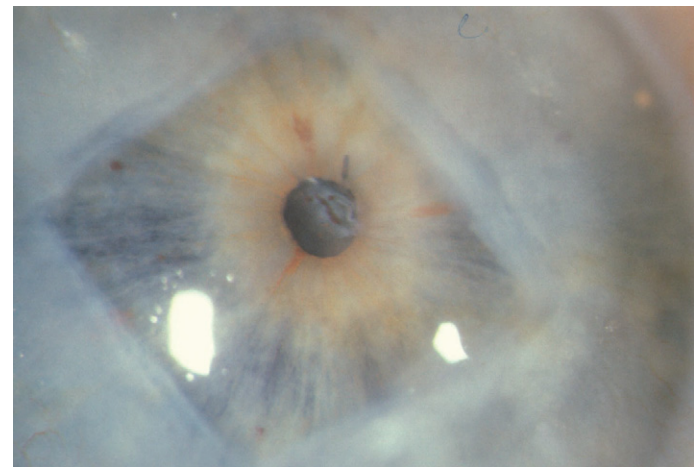

Figure 1.8. A Castroviejo square corneal transplant 30 years after this procedure was done in a patient with keratoconus. The cornea was moderately clear centrally and the patient still had 20/70 vision.

Maumenee and Kornblueth[21] discussed the physiopathology of corneal transplants. In 1948, it was not clear whether the new graft was merely a framework for ingrowth of recipient cells or if the donor stromal cells and endothelium persisted. The importance of the corneal endothelium in maintaining corneal hydration was still not appreciated. It was Stocker's[22] work in 1952 that called our attention to the donor endothelium in keratoplasty. Davson in

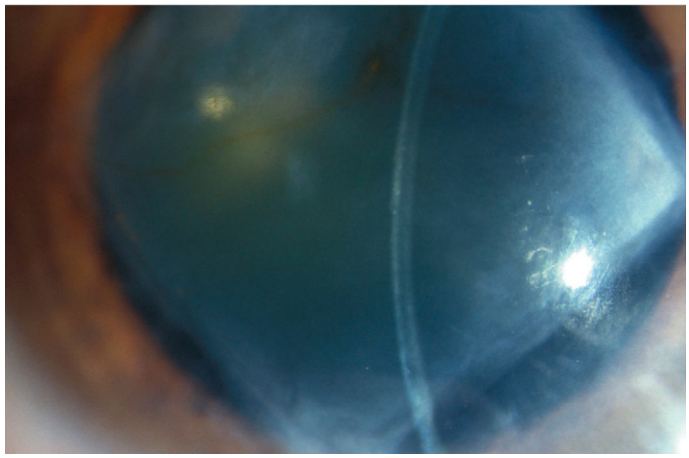

Figure 1.9. Slit view to show the clarity of another square corneal graft done for keratoconus, 28 years after keratoplasty by Ramon Castroviejo.

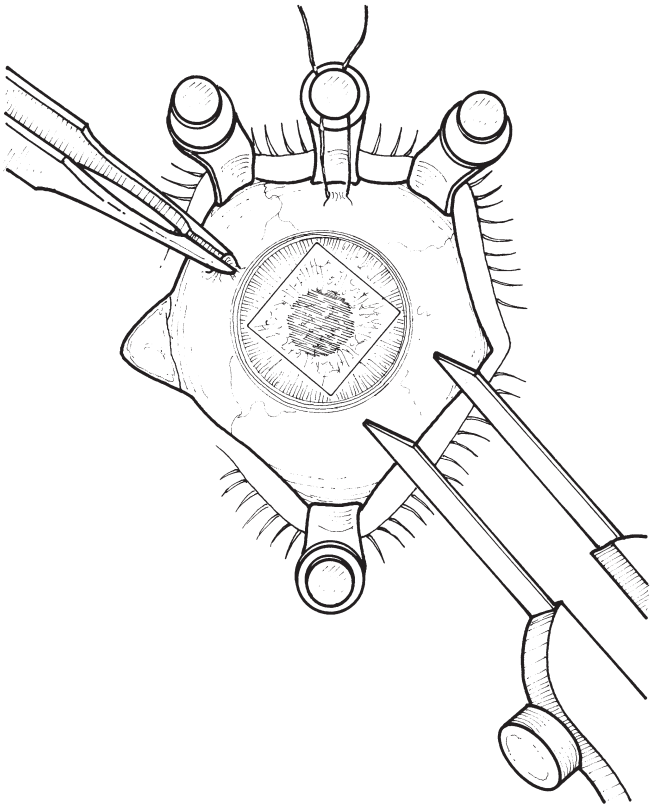

Figure 1.10. Castroviejo's parallel razor blade cutting knife to produce a square cornea. This is just one of many instruments designed by Castroviejo to make keratoplasty a better procedure in the years before microsurgery.

England, Harris and Nordquist, Mishima and Hedbys and Dohlman, as well as Morris, all in the USA, were to make major contributions concerning our understanding of the importance of the corneal endothelium. Specular microscopy was not done until the mid-1960s, and the longevity of the endothelium in keratoplasty is still being looked at, particularly by Bourne.[23]

In Europe, Paufique, Sourdille, and Offret in Paris, Billingham and Boswell in England, and Pollack in New York, as well as Khodadoust and Silverstein in Baltimore were working on graft

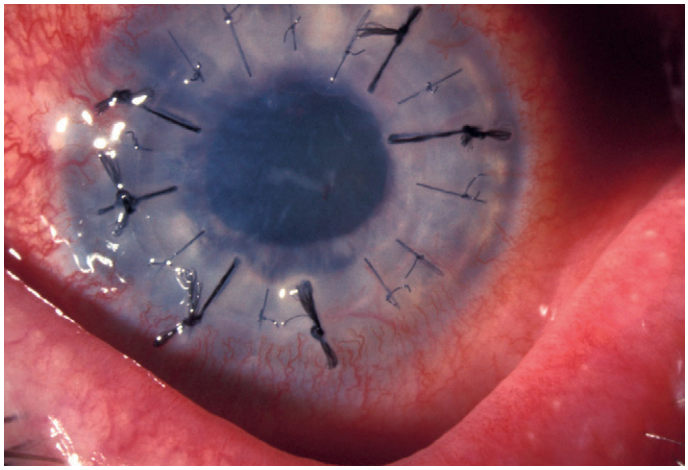

Figure 1.11. Beginning of nylon suture use. These sutures were not entirely trusted initially so there are some silk sutures tied on the surface and some nylon sutures, also with the knots tied on the surface.

rejection. The endothelial rejection line was named after Ali Khodadoust, an ophthalmologist still working in Connecticut today.[24] In the results section of this first American Academy of Ophthalmology Symposium on corneal transplantation, Owens[25] discussed a study of 417 grafts where 36.5% remained clear. The best results were with keratoconus, where 66% were clear, and hereditary dystrophies, 59%. There were no clear grafts obtained in patients who had Fuchs' corneal dystrophy. Max Fine,[26] in San Francisco, was the first corneal surgeon to do a transplant west of the Mississippi and to advocate keratoplasty for Fuchs' dystrophy and aphakic bullous keratopathy.

The surgical techniques for keratoplasty were slowly changing due to better instrumentation and suture material. By 1950, José Barraquer, a pioneer in keratoplasty in Barcelona, Spain, was using donor tissue up to 6.5 mm in diameter and utilized direct suturing with fine silk sutures, using very sharp Grieshaber needles (Grieshaber, Schaffhausen, Switzerland).[27] Mackensen and Harms at the University of Tubingen, in West Germany, in the late 1950s and early 1960s, initiated the use of nylon sutures. They were among the first to change from silk to nylon for direct appositional suturing. Richard Troutman, in 1963, introduced these sutures to the USA, along with the microscope, for keratoplasty.[28] In 1968, 10–0 nylon for keratoplasty was introduced commercially by Ethicon (Johnson & Johnson) (Figs 1.11 and 1.12).

As corneal transplantation grew to be more successful, the need for corneas from cadavers became greater. Eye banking began in the 1940s, when Paton established the first eye bank in the USA. This was the Eye Bank for Sight Restoration founded in New York in 1944. In 1961, the Eye Bank Association of America was established. Statistics for corneal transplants compiled by the Eye Bank Association of America, in their first year, showed that approximately 2000 transplants were done in 1961. In 2005, approximately 36 000 transplants were done in the USA from tissue obtained from the Eye Bank Association of America collaborating eye banks, while another 9000 corneas were sent overseas for transplantation.

In the era of cadaver cornea usage from whole eyes it was necessary to operate within 48 h of death to preserve the donor endothelium. This was inconvenient for the patient, the surgeon, and the operating room staff, as well as marginally healthy for the corneal endothelium bathed in aging aqueous fluid, which usually began

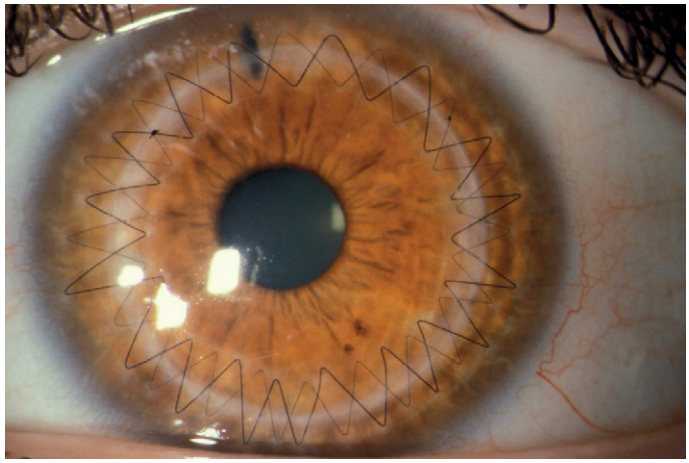

Figure 1.12. Modern corneal transplant with a double running 10-0 nylon buried suture, and an 11-0 running nylon buried suture.

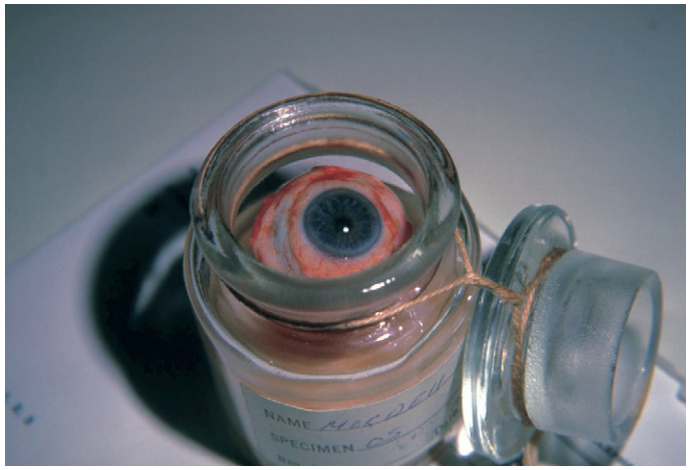

Figure 1.13. Glass jar storage of whole enucleated eye placed on a moist cotton sponge in the bottom of the jar. These eyes were kept refrigerated and had to be used within 48 h, as the endothelium of the donor was bathed by stagnant aqueous.

Figure 1.14. The tissue culture media on the left was first developed by McCarey and Kaufman.[29] This was sterile tissue culture media which allowed the cornea, with a small scleral rim, to be preserved for 3–4 days. On the right is later media known as K-Sol, which stretched the preservation period to 5–6 days. The currently available media, Optisol, allows use of the cornea for 7 days and beyond with excellent preservation of the endothelium.

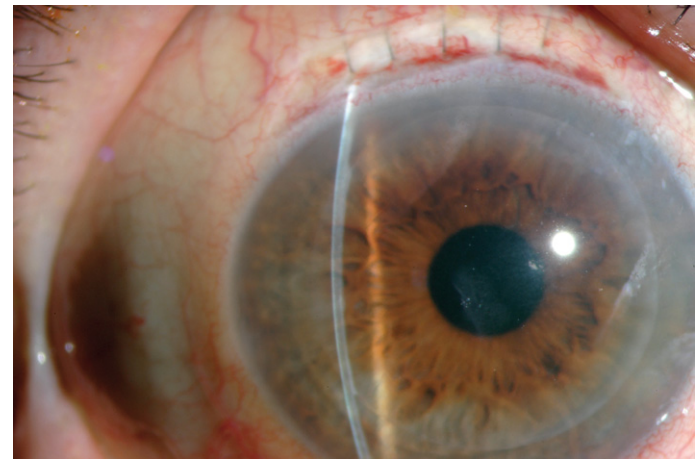

Figure 1.15. Cornea several days after a DSAEK procedure for Fuchs' dystrophy where Descemet's membrane and endothelium is peeled away from the host cornea and replaced by donor Descemet's and endothelium. to fail if the corneas were not used within 48–60 h of death (Fig. 1.13). The concept of corneal storage in artificial media was introduced by McCarey and Kaufman[29] in the early 1970s (Fig. 1.14). They employed tissue culture media and various enhancements to maintain the endothelium, and later antibiotics were added to prevent infection. Almost all corneal transplants in the USA are performed today using corneas that have been stored at 4°C in corneal storage media. In the UK and Europe organ culture is the storage method of choice.

Cornea storage media have improved continually so that corneas now may be stored for at least a week, maintaining excellent corneal endothelial physiology. The endothelium continues to be an important subject of research, as even 15 years after keratoplasty, endothelial failure is a major cause of graft failure.[30] New surgical techniques are now looking toward just transplanting endothelium and Descemet's membrane (Fig. 1.15).

In the *100-Year Review of the Cornea*, by Laibson and Rapuano, published in 1996[31] for the 100th anniversary of the American Academy of Ophthalmology Surgery, corneal transplantation was well accepted with a success rate in the 90% range for keratoconus, Fuchs' dystrophy, and pseudophakic bullous keratopathy, the three most important diseases requiring keratoplasty. Just 10 years later, in 2006, there is a very exciting new field in corneal transplantation. There are of course several problems with penetrating corneal transplants. The length of time for best corrected vision after penetrating keratoplasty can be 18 months or longer because of selective suture removal. Although fine nylon sutures ushered in the fifth period of keratoplasty, that of Refinement and Innovation (1966 to present), these nylon sutures did alter the rate of wound healing. With silk sutures knotted on the surface healing was usually complete by 21 days, after which the sutures were removed. With nylon sutures, which quickly bury beneath the surface, the healing period of a corneal transplant is much longer. It is now routine for surgeons to leave interrupted and running sutures in place for at least a year, and if vision is good with or without cor-

rection and with little astigmatism the sutures are left in even longer. One of the problems with the nylon suture is that it can break and breakage is relatively unpredictable. Also, astigmatism after corneal transplantation has been one of the main problems leading to unsatisfactory vision even though the graft may be clear.

Endothelial transplantation with posterior lamellar keratoplasty was first discussed many years ago by Polack[32] and brought to our attention more recently by Ko et al[33] and Melles et al.[34] The field of endothelial keratoplasty has recently been reviewed by Mark Terry[35] and is the most exciting new surgical technique since the introduction of nylon sutures and microsurgery. Surgical techniques for endothelial keratoplasty are still in evolution, including the use of lasers for the lamellar dissection. It has been very exciting to witness the changes in penetrating keratoplasty from the 1960s and even more exciting to see the current explosion of ideas in the field dealing with endothelial transplantation and anterior lamellar transplantation.

Our skill with corneal transplantation has greatly improved the visual prognosis for patients with corneal disease. Hopefully, in the years to come with further refinement of these new surgical techniques along with a better understanding of corneal transplantation rejection and wound healing, corneal endothelial replacement will prove even better for our patients than current penetrating keratoplasty techniques.

2 Eyelid malpositions: entropion, ectropion, and trichiasis

Jeremy Van Buren, Cat Nguyen Burkat

INTRODUCTION

Maintenance of corneal surface integrity requires proper eyelid position and functioning. Precise apposition of the eyelid margin to the cornea is essential to distribute the tear film evenly, to maintain an appropriate tear lake, and to remove debris. With entropion, inward rotation of the eyelid margin may result in ocular irritation and severe abrasion by offending lashes. Conversely, in ectropion, outward rotation of the margin leads to breakdown of tear film protection with subsequent exposure keratopathy. Lastly, trichiasis and distichiasis are conditions where misdirected or abnormal lashes lead to abrasion and compromised corneal integrity.

The pathophysiology of these common eyelid disorders is best understood by considering the eyelid anatomy. The posterior lamella refers to the tarsus and tarsal conjunctiva, and the anterior lamella refers to the skin with the underlying orbicularis oculi muscle. The eyelash follicles and associated glandular appendages are located in the anterior lamella. The posterior border of the anterior lamella is the gray line, which corresponds to the orbicularis muscle of Riolan. The mucocutaneous junction is located on the margin, posterior to the meibomian gland orifices.

The vast majority of ectropion and entropion cases involve the lower eyelid. The inferior retractor complex of the lower eyelid is composed of aponeurotic expansions from the inferior rectus muscle.[1] These expansions form the capsulopalpebral head, which divides to envelop the inferior oblique muscle, before fusing anteriorly with Lockwood's ligament to form the capsulopalpebral fascia. The fascia connects Lockwood's ligament to the inferior fornix, to the inferior border of the tarsus, and to the preseptal orbicularis muscle and skin at the level of the eyelid crease. The inferior orbital septum joins with the capsulopalpebral fascia 4–5 mm below the inferior tarsal border, and then inserts onto the inferior tarsus (Fig. 2.1). Abnormalities of the precise anatomic interrelationships of these structures can result in the aforementioned eyelid malpositions.

ENTROPION

Entropion refers to an inward rotation of the eyelid in such a way that the eyelid margin, skin, and eyelashes directly rub against the globe. If untreated, entropion can lead to surface irritation, tearing, keratoconjunctivitis, corneal ulceration, and vision loss.[2]

EVALUATION

The clinical examination of entropion is aimed at classification, assessment of eyelid laxity, cicatricial changes, and secondary effects on surrounding structures.[3] Proper assessment begins with a detailed history, which will help distinguish between the major entropion etiologies (involutional, congenital, acute spastic, and cicatricial).

Initial physical evaluation begins with assessing eyelid laxity. Laxity comprises three components: medial canthal tendon laxity, lateral canthal tendon laxity, and tarsal degeneration. The medial canthal tendon normally does not allow the inferior punctum to be pulled laterally more than approximately 2 mm. Lateral displacement of greater than 5–6 mm, or punctal distraction to medial limbus or pupil, are indications for surgical correction (Fig. 2.2, *A* and *B*). Likewise, lateral canthal tendon tone should not allow the lateral canthal angle to be pulled medially over the lateral limbus. The snapback test is performed by pulling the eyelid anteriorly and measuring the distance of displacement. One should not be able to pull the eyelid more than 6 mm away from the cornea. When released, the eyelid should return sharply to its former apposition against the globe. Failure to do so indicates tarsal attenuation or lateral canthal tendon laxity (Fig. 2.2, *C* and *D*). Lastly, the inferior fornix should also be examined for inferior retractor dehiscence.

Cicatricial entropion may be due to scar tissue contracture within the posterior lamella. The tarsal conjunctival surface and fornices should be evaluated for subepithelial fibrosis and tarsal deformation. Eyelid retraction refers to the amount of scleral show seen when the eyelid margin is not located at its normal height (1 mm inferior to the superior limbus for the upper eyelid, or at the level of the inferior limbus for the lower eyelid). In retraction, the eyelid margin itself is correctly apposed to the globe without anterior or posterior rotation. The anterior lamella should be evaluated for hypertrophy or orbicularis muscle spasms.

The entropic eyelid and lashes can result in corneal abrasions, ulcers, scarring, and chronic inflammation. Therefore, a thorough

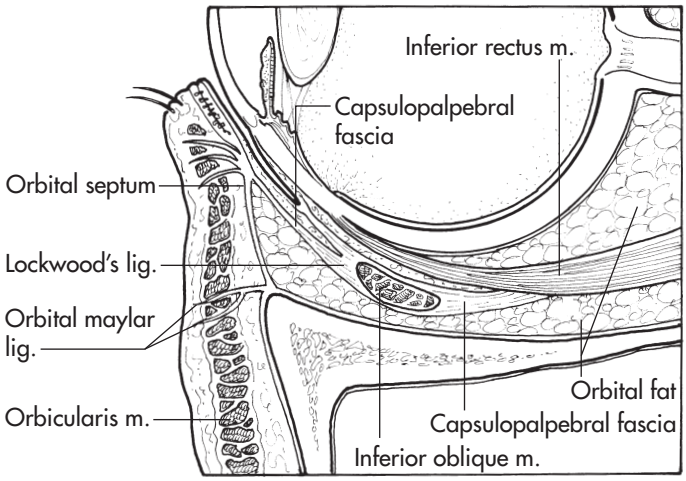

Figure 2.1. Normal anatomy of the lower eyelid in cross section.

evaluation of the cornea, including fluorescein staining, is required in all patients.

CLASSIFICATION

Involutional entropion

The most common type of entropion, involutional entropion, usually affects elderly persons and involves mainly the lower eyelids (Fig. 2.3, *A*). In the upper eyelid, eyelash ptosis may cause chronic irritation and keratopathy, and be confused with entropion. Three main factors contribute to development of involutional entropion: horizontal laxity, retractor complex disinsertion, and orbicularis muscle override. Others have suggested age-related enophthalmos and the 'hammer effect' of orbicularis contraction as less significant factors.[4,5]

Disinsertion or attenuation of the retractor complex allows the lower tarsus to move anterior and superior, causing the lid margin to turn inward. Dehiscence of the inferior retractors from the inferior tarsal edge may be seen as a white horizontal line deep in the fornix, corresponding to the leading edge of the disinserted retractor

layer. The pinkish-red tissue seen between the tarsus and white line is the preseptal orbicularis muscle now visible through the conjunctiva (Fig. 2.3, *B*). Because the attachment of the capsulopalpebral fascia to the inferior fornix remains intact, the inferior fornix may appear deepened when compared to the normal eye. The affected eyelid may also fail to retract fully during downgaze.

Figure 2.4. Epiblepharon of the lower eyelid with fine eyelashes oriented toward the cornea, but a normally apposed eyelid margin.

These anatomic findings can also cause ectropion. A factor that contributes to whether the unstable lower lid is going to turn inward is the preseptal fibers of the orbicularis muscle overriding the pretarsal fibers (Fig. 2.3, *C*). When this occurs, inward pressure is applied to the margin. The exact cause of this phenomenon is still speculative. Interestingly, Asians may be more predisposed to involutional entropion due to a more anterior and superior protruding position of orbital fat within the eyelid.[6]

Congenital entropion

This rare condition can affect both lower and upper eyelids.[7] Mechanisms are complex and involve tarsal dysgenesis (kinked tarsus) or disinsertion of the lower lid retractors. As opposed to epiblepharon in which a fold of skin pushes the lashes inward toward the globe, this condition does not improve spontaneously. Anomalies of the eye can also be present.

Epiblepharon is a congenital condition that occurs most commonly in Asians.[8] A horizontal fold of lower eyelid skin and underlying orbicularis muscle override the margin in such a way that the eyelashes are flipped backward toward the cornea and assume a vertical or posterior orientation (Fig. 2.4). In contrast to congenital entropion, the tarsus and posterior margin remain in their normal positions. The contact of the eyelashes with the cornea can be present all the time or only in downgaze, resulting in recurrent, bilateral ocular irritation or chronic epiphora of unclear etiology. Fortunately, eyelashes in children are fine and soft, so the problem is usually well tolerated. With growth of the facial bones, spontaneous resolution is common, more so in Caucasians than in Asians. Treatment is reserved for cases with significant threat to corneal integrity.

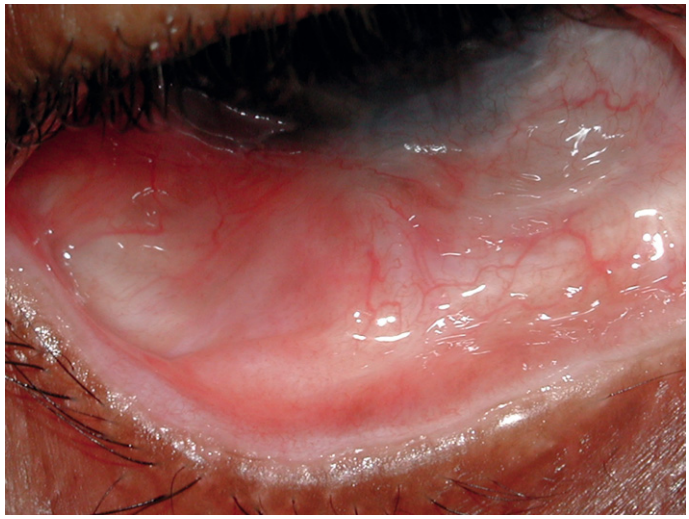
Acute spastic entropion

Any ocular irritation (e.g. after cataract surgery, corneal transplantation, or infection) can induce significant blepharospasm and subsequent entropion.[2,3] The eyelids are squeezed so tightly that the orbicularis muscle causes an inward rotation of the margin. This condition can affect any age group and lasts up to 6 weeks. In older patients it may be a manifestation of latent involutional entropion that may require subsequent surgical intervention.

Cicatricial entropion

Many conditions cause contracture of the posterior lamella and subsequent entropion[9] (Fig. 2.5, *A* and *B*). It is important to carefully

A



B

review the patient history and past examinations for conditions such as surgical or trauma-related scarring, chemical burns, and inflammatory entities such as trachoma, Stevens–Johnson syndrome, ocular cicatricial pemphigoid, acne rosacea, atopic conjunctivitis, and chronic meibomitis. Any long-standing irritation can induce an added cicatricial component to prior eyelid malposition. In contrast to other forms of entropion, cicatricial entropion commonly affects the upper and lower eyelids.

MANAGEMENT

Involutional entropion

The nonincisional suture technique described by Quickert et al[7] and modified by Feldstein[10] is a valuable temporizing measure that can be performed in the office setting. Three or four absorbable sutures (i.e. 4–0 mild chromic) are passed through the eyelid and left in place until spontaneously resorbed. One needle of a double-armed suture is passed deep into the fornix, picking up the disinserted retractors, continues adjacent to the lower border of tarsus, and exits through the skin at the level of mid-tarsal height. The second needle is then similarly passed 3–5 mm lateral to the first. The knot is tied with such tension that a slight ectropion appears (Fig. 2.6, *A*). Typically, three sutures are placed along the lower eyelid in this fashion. This procedure should be considered temporary due to a high recurrence rate.

Definitive treatment addresses each factor causing eyelid laxity.[11] Anterior and posterior approaches have been advocated. The advantage of the anterior approach is a good success rate but involves more dissection.[5] The posterior approach through the conjunctiva avoids a visible scar.[12] Meticulous correction of the three main factors (horizontal laxity, inferior retractor disinsertion, and orbicularis override) results in a very low recurrence rate.

Medial canthal tendon laxity, if present, must also be addressed. Many techniques have been advocated with variable success. An important consideration is to properly tighten the posterior limb of the medial canthal tendon to the posterior lacrimal crest, in order to avoid iatrogenic anterior distraction of the medial eyelid and punctum away from the globe. Next, residual horizontal laxity can be corrected with a lateral tarsal strip procedure.[13,14] A strip of tarsus is exposed and denuded of eyelid margin, skin, and eyelashes (Fig. 2.6, *B*). The tarsal strip is anchored to the periorbita at the level of Whitnall's orbital tubercle inside the lateral orbital rim. Disinserted lower eyelid retractors are reattached to the inferior tarsal border, and a horizontal strip of preseptal orbicularis muscle can be carefully excised (Fig. 2.6, *C*).

Congenital entropion

Techniques have included cauterization, everting sutures, skin and muscle excision, blepharotomy, tarsal incision or splitting, excision of the kinked area with margin rotation, and tarsal fracture with reanastomosis of the retractor complex to achieve better margin apposition. Anatomically, there may be lack of cutaneous-capsulopalpebral fascia attachment as in congenital epiblepharon, but intraoperative findings also suggest dehiscence of normal tarsal-capsulopalpebral fascia attachment. Repair has been advocated to include attaching the retractors to tarsus, as well as attaching skin to tarsus and the retractors to correct the lid malposition and create a normal eyelid crease.[15]

Spastic entropion

Medical management may be helpful by breaking a cycle in spastic entropion with lubricating ointments, bandage contact lenses, or taping of the eyelid. Tape is applied to pull the eyelid down and away from the eye, or horizontally and superiorly to mimic a lateral tarsal strip procedure. Injection of botulinum toxin into orbicularis muscle treats the spastic entropion component in essential blepharospasm or hemifacial spasm. However, injection of botulinum could turn an involutional entropion into a flaccid ectropion if initially mistaken for spastic entropion, or if significant lower eyelid laxity is also present.

Cicatricial entropion

Every attempt must first be made to control any inflammatory conditions before surgery is performed. The severity and extent of posterior lamellar involvement guide the surgical planning.[9] Surgical repair may be considered in three broad categories: margin rotation procedures with a partial or full-thickness tarsal plate incision, eyelid margin splitting procedures with anterior lamellar recession with or without mucous membrane grafting to the margin, and spacer grafts to elongate the posterior lamella. Mild cases may require only marginal rotation procedures. A transverse blepharot-

Surgical repair of involutional entropion. *A,* Quickert suture technique for repair of involutional entropion. *B,* Lateral tarsal strip procedure with exposed tarsus being reattached to lateral periosteum. *C,* Disinserted inferior retractors are reattached to the inferior tarsal border.

omy and margin rotation described by Weis can be effective in repairing a cicatricial entropion.[16] In effect, this procedure creates a full-thickness blepharotomy scar between the retractors, the tarsus, and the anterior lamella.

Full-thickness tarsal margin rotation with super-advancement of the posterior lamella 2–3 mm past the new rotated margin may allow for contraction to occur without recurrence of the entropion.[17] A horizontal V-wedge resection of anterior tarsus has been described to correct the abnormal tarsal shape while avoiding surgery on the conjunctiva and subsequent reactivation of inflammatory disease.[18] An additional effect can be achieved with shortening or repositioning of the anterior lamella with a lid splitting procedure or tarsoconjunctival advancement.[19] Graft materials, such as tarsus, hard palate, ear cartilage, acellular dermis, and buccal mucous membrane, can be used for severe scarring or retraction of the posterior lamella.[20]

ECTROPION

In ectropion, the lid margin is everted from its normal apposition to the globe.[21] If left untreated, ectropion can lead to chronic epiphora, chronic conjunctivitis, exposure keratitis, corneal scarring, ulceration, and perforation. The epiphora, conjunctivitis, and keratitis may accompany eyelid laxity before frank ectropion becomes manifest.

EVALUATION

Evaluation should include assessment of eyelid laxity by snapback test, medial or lateral canthal tendon laxity, disinsertion of the lower lid retractors, punctal ectropion, inferior scleral show, retraction, lagophthalmos, and corneal surface integrity. Cicatricial vertical shortening of the anterior lamella from past trauma, burns, dermal inflammatory conditions, or chronic eyelid rubbing from eye irritation or epiphora should be noted.[22] In eyelid retraction, the orientation of the tarsal plate and eyelid margin are normal, but the resting height of the margin is retracted beyond the limbus, usually with evidence of scleral show. Eyelid retraction is a common finding in Graves' ophthalmopathy. Lagophthalmos is present when normal contraction of the orbicularis muscle fails to close the eyelids.

CLASSIFICATION

Congenital ectropion

This rare condition can present alone or in combination with other malformations, including blepharophimosis, euryblepharon, ocular anomalies, and systemic pathology such as trisomy.[21] The eyelid ectropion may appear minimal at rest. However, the condition is accentuated on upgaze, lid closure, or when opening the mouth due to a shortage of midfacial skin. Treatment involves graft techniques to compensate for a short anterior lamella. Congenital ectropion must be differentiated from total bilateral eversion of the upper eyelids in the newborn (Fig. 2.7). If total bilateral eversion is present, conservative treatment with lubrication and patching is usually sufficient.

Involutional ectropion

This condition is encountered frequently in elderly persons.[22–24] Similar to entropion, eyelid instability is a key factor and can be caused by horizontal laxity, vertical laxity with dehiscence of the

Figure 2.7. Total eversion of the upper eyelids, bilateral, in a newborn.

A

B

Figure 2.8. Cicatricial ectropion with vertical shortage of the anterior lamella due to chronic allergic dermatitis (*A*) and aggressive chemical peeling of the midface (*B*).

retractors, tarsal thinning, and age-related enophthalmos. Without adequate support, the lower lid is stretched further by gravity and the natural descent of the midface with age. Moreover, constant eye wiping from surface irritation or epiphora stretches the tissues further and leads to worsened malposition. In ectropion, orbicularis overriding is absent, thus allowing the unstable eyelid to turn outward. Histopathologically, focal degeneration of the orbicularis muscle with arteriosclerotic changes of the marginal artery can be found, suggesting chronic muscle ischemia.[23]

Cicatricial ectropion

Cicatricial ectropion occurs when there is a shortening of the anterior lamella due to cutaneous or subcutaneous scarring.[21] Trauma, burns, sun damage, inflammatory skin disease, herpes zoster, skin contraction as a result of chronic ectropion, maceration from epiphora and rubbing, excessive skin resection from blepharoplasty, and aggressive chemical peeling and cosmetic laser procedures are common causes (Fig. 2.8, *A* and *B*). The presence of vertical skin striae may suggest existing cicatricial changes. The ectropion may also worsen in upgaze and when the mouth is opened widely.

Paralytic, mechanical, and inflammatory ectropion

Paralytic ectropion results from orbicularis oculi paresis or paralysis secondary to facial nerve palsy (Fig. 2.9). More than 80 etiologies

Figure 2.9. Paralytic ectropion following Bell's palsy, illustrating an ectropic atonic lower eyelid, lagophthalmos, midfacial ptosis, and paralytic brow ptosis.

of seventh nerve palsy have been described, the most common being trauma, infection, idiopathic Bell's palsy, and tumor.[25] An atonic lower eyelid is particularly susceptible to gravitational forces and will exacerbate any previous eyelid malposition, and result in eventual ectropion and eyelid retraction with time. Loss of orbicularis tone can lead to retraction of the skin, adding a cicatricial component to the ectropion. Mechanical ectropion is caused by the effect of gravity from a large lesion or tumor of the eyelid or cheek, pendulous edema, or by heavy glasses resting on the cheek. Inflammatory ectropion can result from many causes of inflammation or allergy of the eyelids, as well as from a long-standing ectropion.[21] Inflammatory ectropion will typically have an anterior cicatricial component as well.

MANAGEMENT

Medical management

Cicatricial, inflammatory, and paralytic ectropion have medical components to their management. In cicatricial and allergic ectropion, cosmetics and ointments or eye drops may be potential causes of chronic inflammation or allergy. In the presence of a chronic hypertrophic conjunctivitis, antibiotic-steroid ointment can be used to reduce inflammation. Surgery should be delayed until the inflammation improves. In ectropion, the lacrimal pump is incapacitated, thus disrupting the normal maintenance of a healthy tear film. Aggressive lubricating drops and ointments are essential. In paralytic ectropion, taping the eyelids at night or wearing moisture chambers may provide additional relief if there is a poor Bell's phenomenon. In idiopathic facial nerve palsy, the orbicularis paresis frequently resolves over a few months, therefore conservative treatment is indicated as long as corneal exposure is minimal. However, when significant eyelid laxity precedes the paresis, the ectropion is usually permanent and surgical management is generally necessary.

Surgical management

Involutional ectropion

When present, medial canthal tendon laxity is corrected first by a tucking or suspension procedure to the posterior lacrimal crest as described for entropion repair. Punctal position is next evaluated. If reposition is indicated, an elliptical incision is made in the conjunctiva and eyelid retractors.[26] Buried sutures are placed to close the defect, which rotates the punctum inward. Lower eyelid medial ectropion is repaired by medial canthal tendon tightening and/or reinsertion of inferior retractors.[27] Whether the approach is transcutaneous or transcaruncular,[27,28] the medial edge of the tarsus or

the medial canthal tendon itself is secured to the posterior lacrimal crest, taking care to avoid injury to the nasolacrimal sac. This provides vertical support of the lid while maintaining the medial canthal angle posteriorly on the globe. Residual horizontal laxity is then reduced by performing a tarsal strip procedure or canthus-sparing canthopexy,[13,14] in which the lateral canthoplasty has been modified to avoid a lateral canthotomy and cantholysis.[29]

Any long-standing malposition of the eyelid can induce additional scarring, resulting in shortening of the anterior lamella and thus secondary cicatricial ectropion. Vertical tightness of the lid skin can be subtle and not immediately detected. An early sign can be disappearance of the horizontal wrinkles. Asking the patient to open the mouth widely can also help reveal any eyelid skin deficit. A shortened anterior lamella requires correction with a skin graft or flap.

Congenital ectropion

Shortening of the anterior lamella is corrected with skin grafts, and any concomitant horizontal laxity is reduced by aforementioned horizontal lid-shortening techniques.

Paralytic ectropion

Conservative treatment with a temporary tarsorrhaphy using non-absorbable suture over bolsters can protect the cornea for days to weeks. The suture may be tied in a fashion that allows opening for repeated eye drops or examinations. A lateral tarsorrhaphy may be appropriate and simple to perform. The adjacent eyelid margins of the lateral upper and lower eyelids are excised and the lids sutured together through the gray line. A medial tarsorrhaphy can be performed if lagophthalmos is prominent medially, with care to avoid injury to the canaliculi. Permanent adhesion can be achieved through transposition of a tarsal segment from one lid to the other. The adjacent upper and lower lateral lid margins are split along the gray line for the desired length of closure to a depth of approximately 3 mm. A flap of upper lid tarsus and conjunctiva is created laterally and a smaller matching area is resected from the lower lid tarsus. A double-armed suture is then passed through the upper lid tarsal flap to exit the edge, then through the lower lid defect and tied over the skin, resulting in a tongue-in-groove apposition. Thus, the cut edges of the upper tarsal flap appose the lower tarsal defect for a stronger effect.

Implantation of a gold weight under the pretarsal orbicularis muscle of the upper eyelid can help upper eyelid closure.[30] Different weights are tested preoperatively in the office to ensure adequate closure while minimizing ptosis. When permanent surgical solutions are needed, horizontal laxity often must be treated with eyelid tightening or shortening laterally.[25] A fascia lata or temporalis fascia sling, or a midface lift may also lessen the gravitational pull on the atonic lower eyelid.[25,31]

Cicatricial ectropion

Depending on the extent of cicatricial involvement, treatment incorporates scar revision with excision of scar, complete release of superficial or deeper layer cicatrix, geometric Z-, W-, M-plasties, and horizontal eyelid tightening. Once the cicatrix is released and the anterior lamella allowed to recess to its relaxed position, the amount of anterior lamellar shortage can be determined. Anterior lamellar deficits can be addressed with a combination of pedicle flaps, advancement or rotational flaps, or free skin grafts from the upper eyelid, preauricular, retroauricular, or supraclavicular areas.[32] Any flaps should avoid vertical tension, while maximizing horizontal tension. Z-plasties lessen the effect of scars and redirect tension along more natural skin tension lines. The lower eyelid may be bolstered superiorly with a temporary tarsorrhaphy or Frost suture through the eyebrow for several weeks to minimize postoperative eyelid retraction or graft contraction.

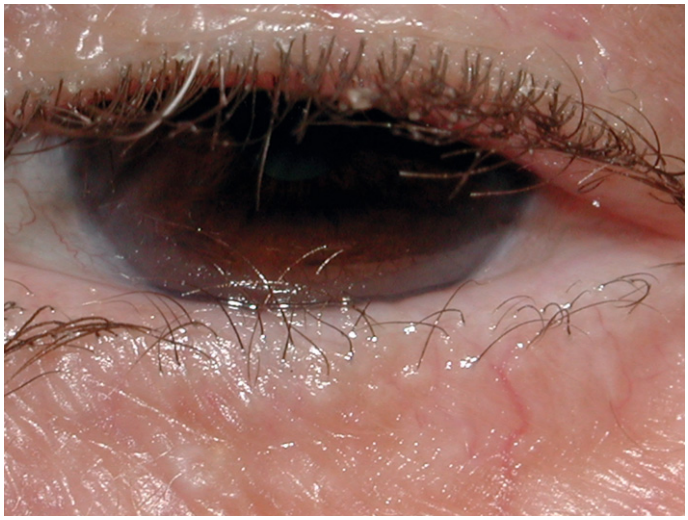

Figure 2.10. Trichiasis, central right lower eyelid.

TRICHIASIS AND DISTICHIASIS

Trichiasis refers to a condition in which eyelashes emerging from their normal anterior origin are misdirected backward toward the cornea, while the tarsal plate maintains a normal apposition to the globe (Fig. 2.10).[2] It is distinguished from an entropion by assessing the eyelash orientation when the eyelid is in proper position. Trichiasis can be idiopathic or secondary to chronic inflammatory conditions such as trachoma, ocular cicatricial pemphigoid, Stevens–Johnson syndrome, blepharitis, chronic conjunctivitis, or chemical burns.

Distichiasis is a congenital or acquired condition in which an extra row of eyelashes emerges from the ducts of the Meibomian glands.[2] In this typically autosomal dominant condition, embryonic common pilosebaceous units differentiate into hair follicles rather than Meibomian glands. These eyelashes can be fine and well-tolerated, or coarser and a threat to corneal integrity. Trauma and chronic inflammatory conditions of the eyelids or conjunctiva as mentioned previously are frequent causes of acquired distichiasis.

MANAGEMENT OF TRICHIASIS

A few misdirected eyelashes can be treated first by epilation and observed. They will usually grow back within 4–6 weeks. Electrolysis is another option that treats several eyelashes at a time.[2] The eyelid is first anesthetized with local infiltration. The tip of the electrolysis fine-wire needle is inserted adjacent and parallel to the hairshaft down to the eyelash follicle, and the current is applied until a small bubble can be observed at the surface beside the hairshaft. The eyelash is then easily wiped or pulled away without resistance. If the eyelashes recur, treatment can be repeated, although frequent retreatment may eventually result in eyelid notching.

Cryotherapy is effective for groups of abnormal eyelashes.[33,34] Following infiltration of local anesthesia, a nitrous oxide-cooled probe covered with water-soluble petroleum jelly is applied to the

involved eyelid margin until a temperature of −20°C is reached. After allowing for thawing, a second cycle is applied, and the eyelashes are epilated. Cryotherapy induces more loss of normal adjacent eyelashes than electrolysis, and is associated with possible complications such as eyelid notching, necrosis, skin depigmentation, and recurrence. Postoperative edema and erythema can be expected for up to 1 week following treatment.

Argon laser ablation has been used more widely to treat trichiasis, although with variable results.[35,36] Complications are few but may include mild hypopigmentation, eyelid notching, and recurrence. In a study of trachomatous trichiasis, argon laser ablation was successful in 55.5% of lids after one session, with an increase in success rate to 89% after several sessions.[37] Several treatments will often be necessary to completely ablate the abnormal follicles. Segmental areas of trichiatic eyelashes can be treated definitively with a full-thickness wedge resection, which offers good cosmesis and minimal complications.

MANAGEMENT OF DISTICHIASIS

Focal areas may be treated by simple epilation or electrolysis. Cryotherapy applied to the posterior lamella or electrolysis also can be used for a few eyelashes. In the case of more extensive distichiasis, the affected eyelid margin can be split along the gray line, and the posterior lamella treated with cryotherapy or focal hyfrecation, or the posterior margin and tarsal plate containing the distichiatic hair follicles can be excised.[2] Splitting the eyelid margin minimizes injury to the normal eyelashes in the anterior lamella, while effectively treating the distichiatic eyelashes emerging from the Meibomian gland orifices posteriorly. Revision of the anterior lamella or mucous membrane grafting may also be indicated in some instances; therefore, treatment should be individualized for each patient.

3 Conjunctiva and tear film

Ilya M. Leyngold, Roy S. Chuck

The crucial role of the preocular tear film in the maintenance of healthy corneal and conjunctival surfaces has been well established. Conversely, a healthy ocular surface is necessary to ensure the integrity of the tear film. Proper functioning of the tear film is dependent upon its adequate production, distribution, and preservation. Thus, a disruption in any of these processes may result in ocular surface damage with associated clinical symptoms. Tear film abnormalities are intimately related to the conjunctival topography and function in addition to the proper function of many other periocular structures. This chapter focuses on the conjunctival structural and functional components, and their role in the renewal of the preocular tear film. Also, other factors that are salient to the maintenance and formation of the tear film are discussed. Finally, abnormalities of the tear film and secondary ocular surface damage with their respective causes are explained.

CONJUNCTIVAL ANATOMY, STRUCTURE, AND FUNCTION

ANATOMY

The conjunctiva is a thin, translucent mucous membrane overlying the anterior portion of the sclera and the inner surface of the eyelids.[1] It is divided into the palpebral conjunctiva, the bulbar conjunctiva, and the superior and inferior fornices.

The palpebral conjunctiva consists of orbital and marginal tarsal components.[1] The orbital portion forms a convoluted structure with many folds in contrast to the tarsal component, which is smoother and closely adherent to the tarsal plate. Bulbar and palpebral conjunctiva come together at the superior and inferior fornices, forming a loose attachment to the underlying tissues. The bulbar conjunctiva lines the anterior sclera, or the 'white' of the eye. This structure has loose attachments to the orbital septum in the fornices, Tenon's capsule (except at the limbus), and the underlying sclera.[2] It also contains multiple folds, which increase the surface area for secretion.

Each eye contains specialized conjunctival structures called semilunar folds (plica semilunaris) and the lacrimal caruncle located in the medial canthi. The plica semilunaris is a delicate and movable fold divided from the bulbar conjunctiva by a 2-mm-deep concavity.[1] Upon lateral rotation of the eye, the lacrimal caruncle is conspicuous directly medial to the semilunar fold. Superficially, it is lined by a nonkeratinized stratified epithelium and contains meibomian-like sebaceous glands similar to the glands of Zeis.[1]

STRUCTURE AND FUNCTION

Conjunctiva is covered by both stratified columnar and nonkeratinized stratified squamous epithelium. Two to five layers of stratified epithelial cells, superficial and basal, cover the largest conjunctival surface area. Structures lined by the stratified squamous epithelium include the limbus, caruncle, and the areas of the mucocutaneous junctions at lid margins.[2] Mucus-secreting goblet cells are dispersed throughout the superficial and middle epithelial cells, especially in the semilunar fold and fornices,[3] playing an important role in the maintenance of the preocular tear film. Langerhan's cells are also found in the conjunctival epithelium.

Numerous other glands are found within the conjunctival epithelium in addition to the mucin-secreting goblet cells. These are also important in maintaining moisture of the ocular surface and the proper physiological composition of the tear film. The glands histologically similar to the main lacrimal gland proper, accessory lacrimal glands of Krause, secrete the minor component of the tear film aqueous layer. They are mostly located in the temporal conjunctiva. Glands found less frequently, Manz and Wolfring, secrete mucinous substance resembling that of the goblet cells.[1] Superiorly and inferiorly to the tarsal plate, the crypts of Henle create a papillary pattern at the conjunctival surface.

The area underlying the epithelial layers is substantia propria. It is composed of the fibrovascular connective tissue connecting the epithelium and the tarsus together in the palpebral region.[3] The structure is infiltrated by fibroblasts and inflammatory cells. Lymphatic follicles with germinal centers may arise during childhood and/or in response to ocular inflammation; however, true lymphatic follicles are generally not found in a healthy adult conjunctiva.[1]

Conjunctiva is a very vascular structure. The extensive vascular network is formed primarily from the anastomoses of the anterior

ciliary and palpebral arteries, and abundance of conjunctival veins. Lymphatics arise from both the deep and superficial layers of the conjunctiva, eventually draining into the lymphatics of the eyelid, creating a rich lymphatic plexus.[2] Conjunctiva is innervated by both sensory and sympathetic nerve fibers. Sensory innervation of the conjunctiva is by branches of the ophthalmic and maxillary divisions of the cranial nerve V (CN V) and the long ciliary nerve.[1]

STRUCTURE AND FUNCTION OF THE TEAR FILM

The milieu of the preocular tear film ensures normal function and structure of the ocular surface epithelium.[4] The tear film is also important as a refracting surface of the eye, contributing to a sharper visual image. This phenomenon is due to its ability to fill and flatten the microscopic depressions of the corneal surface created by the reticulations (0.5 µm high and 0.3 µm wide) on the epithelial surface.[5] The preocular tear film is formed by three individual layers measuring a total of about 7 µm in thickness. The outermost layer is composed of lipid compounds produced by the meibomian glands. The intermediate layer is mostly formed by the aqueous secretions of the main and accessory lacrimal glands. The innermost layer of the tear film is thought to consist of two components: the inner, glycocalyx, and the outer, mucin. The former is secreted by the surface epithelium and the latter, more loosely associated layer, produced by the conjunctival goblet cells.[6]

THE LIPID LAYER

The hydrophobic moieties secreted by the meibomian glands of the lids comprise the lipid layer of the tear film. Around 20 meibomian glands are found in each upper and lower lid.[7] Although mechanisms responsible for meibomian gland secretion rates are still poorly understood, Cermak et al demonstrated that patients with primary and secondary Sjogren's syndromes, conditions with poor meibomian gland function, have low levels of androgens.[8] This finding led the investigators to hypothesize that this hormonal imbalance contributes to meibomian gland dysfunction, leading to tear film instability and evaporative dry eye, common features of this autoimmune disorder. They showed that androgens control production of commonly secreted lipids by meibomian gland such as nonpolar sterols, wax esters, and phospholipids, in turn promoting production of the lipid layer. Secreted lipids spread uniformly on the aqueous portion of the tear film forming a two-layered structure. The resultant duplex film is quite stable and allows the lipid layer to undergo significant compression and decompression during blinking without the loss of its integrity. In addition to reducing evaporative losses from the tear film, the lipid phase prevents contamination of the tear film by the sebaceous gland excreta of the eyelids,[7] and facilitates thickening of the aqueous layer by lowering the surface tension of tears.[9]

THE AQUEOUS LAYER

The aqueous phase forms an intermediate layer of the tear film, providing close to 90% of the total tear film thickness.[10] The isotonic or slightly hypotonic aqueous component is secreted at a rate of approximately 1.2 µL/min.[11] Both main and accessory lacrimal gland secretions are mostly reflex dependent and appear to be identical.[12] Following the tear vesicle fusion with the inner portion of the lacrimal acinar cell plasma membrane, the tears are released and flow through the ductular openings of the main and accessory lacrimal glands. The flow continues through the forniceal spaces into lacrimal rivers and over the exposed ocular surface.[7] Contraction of the orbicularis oculi muscle drives the fluid in the temporal-to-medial direction. Upon relaxation of the muscle, immediately following the blink, most of the tears are drawn into the two punctal openings located near the medial canthus. The fluid then flows into the lacrimal canaliculi, the lacrimal sac, the nasolacrimal duct, and finally into the inferior meatus of the nasal cavity.[13,14] As the tears flow through the nasolacrimal duct, a significant portion of the fluid is reabsorbed across the mucosal surface.[7] Aqueous fluid that fails to exit through the nasolacrimal system is either evaporated or reabsorbed through the conjunctiva.

THE MUCIN LAYER

The mucin layer is a thin structure measuring approximately 0.5 µm in thickness.[15] The glycocalyx-based innermost component of the mucin layer is secreted by the subsurface epithelial vesicles,[6,16] forming a strong bond with the epithelial surface. Overlying the glycocalyx is a loosely adherent mucous layer derived from the conjunctival goblet cells. The stimulus for mucous secretion is not fully understood; however, there is evidence that 15(*S*)-hydroxyeicosatetraenoic acid (15(*S*)-HETE) serves as a potent mucin secretagogue in the goblet cells of the ocular surface epithelium.[17] The outer component is thought to impart a fragile covering over epithelial cells, in turn enabling the aqueous layer to provide continuous covering.[7] Therefore, the presence of the outer component is essential for the stability of the aqueous phase. On the other hand, the importance of the interaction between the outer and inner portions of the mucin layer is still under investigation.

MAINTENANCE OF THE TEAR FILM

Action of the lids plays a vital role in the formation and maintenance of the preocular tear film. Lid closure or blinking allows a uniform distribution of the tear film over the ocular surface. The upper lid is mostly responsible for this function as it sweeps three-quarters of the corneal surface and has considerably more force compared with the lower lid.[7] Blinking re-establishes a smooth and evenly distributed tear film after evaporative losses create disruptions and thinning of the tear film. Evaporation of the aqueous phase occurs if blinking is absent or incomplete, causing the lipid layer to invade and contaminate the mucin layer. The interaction between the outermost and innermost layers of the tear film causes further breakup of the tear film and increased drying of the epithelium.[18] Tear film maintenance is dependent on adequate tear production and distribution. Dysfunction of the variables responsible for these actions may result in the ocular surface disease.

TEAR FILM ABNORMALITIES

Dry eye is a prevalent disease affecting up to 15% of individuals 65 years or older.[19] It is commonly seen in patients with low androgen levels, including those with autoimmune diseases, peri- or post-menopausal women, and the elderly.[20,21] Dry eye has been classified by the National Eye Institute into two major categories based on the mechanism of preocular tear film disturbance: tear insufficiency and evaporative tear loss.[22] Although this classifica-

tion is very useful in the initial evaluation of the dry eye patient, there is often a significant overlap between the two categories such as seen, for example, in Sjogren's syndrome.[22] For organizational purpose, the discussion of dry eye conditions will be based on the aforementioned classifications. Major ocular conditions classically associated with tear-deficient dry eye addressed in this chapter include those of Sjogren's and non-Sjogren's type. Dry eye pathologies associated with evaporative tear loss such as meibomian gland dysfunction, abnormalities of the conjunctival mucin secretion, lid closure defects, and abnormal ocular surfaces are also discussed in detail.

AQUEOUS TEAR-DEFICIENT DRY EYE

Aqueous tear deficiency represents one of the most common causes of dry eye.[7] If severe enough, it may lead to ocular irritation and ocular surface disease, also called keratoconjunctivitis sicca (KCS). Most individuals experience decrease in tear secretion with age, but only a fraction of those are affected significantly enough to develop KCS. Thus, even though lacrimal gland function diminishes with age, ocular surface disease is not a normal part of the aging process as previously believed. Generally, patients with clinically significant aqueous tear deficiency complain of foreign body sensation, burning, and ocular surface pain. This condition is more frequent among women. Both history and clinical findings are used to diagnose KCS. Physical examination features suggestive of the disorder include tear film mucous threads and debris, decreased tear meniscus height, wetting length of Shirmer test strips, and tear breakup time (i.e. under 5 s). Interpalpebral surface supravital staining with fluorescein, rose bengal, and/or lissamine green are also used to diagnose KCS.[7,22]

It is important to diagnose and initiate treatment early to prevent complications of KCS such as filamentary keratitis and corneal ulcerations. Deficiency in aqueous tear production leads to decrease in nonspecific immune mechanisms of the ocular surface. For example, lysozyme and lactoferrin, protective enzymes of the tear film, were found to be significantly lower in the tears of patients with dry eye.[23,24] In addition to decreased immune defenses, ocular surface flushing is impaired, leading to even greater pathogen susceptibility.[7] Thus, frequent ocular infections develop, leading to blepharitis with secondary development of conjunctivitis and keratitis.

Sjogren's syndrome tear deficiency

Connective tissue disorders are frequent systemic causes of KCS. These represent a subset of autoimmune disorders that are generally linked by diffuse vasculopathy and characterized by inflammatory damage to multiple vital organs including the eye. For example, up to 15% of patients with rheumatoid arthritis develop KCS.[7] Within the variety of rheumatologic disorders KCS has been divided into two categories—primary and secondary Sjogren's syndromes—that can both cause severe ocular surface disease. Primary Sjogren's syndrome is characterized by exocrine gland dysfunction with prominent involvement of salivary and lacrimal glands. In addition, patients with this disease may manifest inflammatory damage to musculoskeletal, gastrointestinal, urogenital, integumentary, and respiratory systems.[25] When there is an association with a specific autoimmune disease such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma, polymyositis, or polyarteritis nodosa a diagnosis of secondary Sjogren's syndrome is given. Tear deficiency can be quite severe among these patients. This is thought to result from an immunologically mediated inflammatory damage to the lacrimal gland and the ocular surface. Those with Sjogren's syndrome and poorly controlled KCS may develop severe complications, including peripheral ulcerative keratitis (sometimes leading to perforation), scleritis, and rheumatoid scleral nodules.[7] It has been shown that patients with Sjogren's disease have decreased serum levels of circulating androgens[8] linking androgenic activity to the presence of ocular surface damage.

Non-Sjogren's syndrome tear deficiency

Multiple studies have demonstrated that maintenance of the healthy ocular surface with adequate quantity and quality of aqueous tear secretion is dependent upon sufficient hormonal balance.[26–29] Just like in Sjogren's syndrome, decreased serum concentrations of androgens have been associated with the development of aqueous tear deficiency in some non-Sjogren's patients.[30] This phenomenon explains the increased prevalence of dry eye disease in women, particularly those in postmenopausal age groups, elderly, and any of the individuals with low endogenous androgen levels. Animal studies have shown the dependence of normal lacrimal gland secretion on hormonal levels. For example, androgen deficiency following orchiectomy has been demonstrated to increase the volume of secreted tear fluid, while reducing the concentration of secretory component and of IgA in the tear fluid.[31,32] Testosterone administration reverses these changes. However, pituitary gland removal prevents this reversal. Mechanistically, androgens appear to downregulate lacrimal gland lymphocytes, thereby suppressing the inflammatory ocular surface damage.[33]

Aqueous tear deficiency may occur with other systemic conditions such as HIV and sarcoidosis. These can also be viewed as a relative imbalance between immunologic and hormonal activities. Other causes of non-Sjogren's tear-deficient dry eye include those secondary to lacrimal gland obstruction (secondary aqueous deficiency) such as occurs in trachoma, ocular cicatricial pemphigoid, Stevens–Johnson syndrome, and burns.[34,35] Also, patients with reflex abnormalities tend to develop tear-deficiency dry eye such as seen in cranial nerve VII palsy. Although both Sjogren's and non-Sjogren's dry eye syndromes are described here under classification of aqueous tear deficiency, they can be further complicated by evaporative loss arising from overlapping pathogenic mechanisms.

EVAPORATIVE DRY EYE

Tear film stability is in large part determined by the composition and interactions of the lipids covering the surface of the aqueous layer and the mucin-rich inner layer of the tear film. Increased evaporation of tears with resultant tear film instability arises from a variety of abnormalities affecting the structures that serve to protect the tear film. Structural and functional defects in the meibomian gland, conjunctiva, cornea, or lids may result in evaporative dry eye. Increased tear evaporation secondary to these abnormalities commonly exacerbates aqueous deficient dry eye because the diseases are often concurrent.[36,37] In addition, similar to tear deficiency dry eye, disturbances in androgenic and estrogenic regulation appear to play a pivotal role in pathogenesis of the most common etiology of evaporative dry eye, meibomian gland dysfunction.

Meibomian gland dysfunction

Meibomian gland dysfunction more often results from the acquired disease of glandular tissue rather than intrinsic paucity of

meibomian acinar cells. There are conditions such as congenital anhidrotic ectodermal dysplasia that are associated with hypoplasia of meibomian glandular epithelium, but those are quite rare. More commonly, it is the abnormality of the composition and volume of meibomian gland excreta that results in KCS. Studies have demonstrated that in similarity to the lacrimal gland, the meibomian gland also contains estrogen and androgen receptors responsible for its proper function.[38–40] For example, in androgen-deficient states, such as congenital androgen insensitivity disease, menopause, or Sjogren's syndrome, there is an alteration in synthesis and type of lipid molecules in the meibomian gland, resulting in abnormalities in chemical composition of the lipid layer.[8] In severe cases, where an obstructive meibomian gland dysfunction occurs, there is a dramatic increase in tear film osmolality, resulting in accelerated evaporative tear loss.

Secondary infection of the meibomian gland, such as occurs in blepharitis, may also change the lipid content of the tear film causing symptomatic dry eye. Upregulation of tissue and bacterial lipases during infection results in increased concentrations of liberated diacylglycerides and free fatty acids. This alteration in chemical composition of the lipid layer contributes to the instability of the tear film.[41,42]

Abnormalities of conjunctival mucin secretion

Changes in conjunctival morphology leading to a paucity of goblet cells and their secretions may also result in instability of the tear film similar to that seen in meibomian gland disease. Conjunctival surface and consequently goblet cell populations are affected by a number of conditions including trachoma, vitamin A deficiency, ocular cicatricial pemphigoid, erythema multiforme, and chemical burns.[7]

A classic condition associated with mucin deficiency is hypovitaminosis A. Characteristic goblet cell destruction, and keratinization of the conjunctiva and cornea are seen. Keratinomalacia and foamy gray triangular areas on the conjunctival surface of poor wettability (Bitot's spots) eventually develop. Despite initially normal lacrimal and meibomian gland functions, the tear break-up time and clearance decrease, resulting in symptomatic evaporative dry eye. Ultimately, however, increased scarring develops leading to obstruction of main and accessory lacrimal gland ductules with subsequent secondary aqueous tear deficiency.[34,35]

Lid closure defects

Tear film stability is in large part dependent upon normal blink function. If there is blinking impairment or lid incongruity with ocular surface the tear film cannot be properly reformed. This results in nonuniform layering of the tear film with discrete areas of poor wettability, leading to localized drying secondary to evaporative losses. Keratinization occurs in these areas, resulting in even greater desiccation. This creates a vicious cycle that leads to severe dry eye signs and symptoms.

Lesions to the seventh cranial nerve such as those seen in patients with strokes or Bell's palsy impair proper lid closure with resultant exposure keratitis. Adhesions between the tarsal and bulbar conjunctiva (symblepharons) commonly seen in patients with severe chemical burns, erythema multiforme, and cicatrizing ocular pemphigoid may restrict lid movement compromising the stability of the tear film.

Lid-globe incongruity such as occurs with ectropion or lid inflammation may cause a nonuniform distribution and improper surfacing of the pre-ocular tear film. Moreover, poor congruity of lids with ocular surface may lead to punctual mal-apposition with consequent decreased removal of contaminated tear film.

Abnormal ocular surfaces

Primary abnormality of the ocular surface arising from the alteration of the morphologic characteristics of the corneal epithelium can compromise the stability of the tear film. These surface irregularities prevent the normal adsorption of tear mucin to the multiple microvillous projections of the corneal epithelium.[7] This leads to abnormal tear surfacing, resulting in evaporative tear loss, epithelial abrasions, and ulcerations. As in the other causes of dry eye, corneal surface damage from primary ocular surface abnormality may lead to impairment of sensory corneal innervation. The resultant corneal anesthesia often leads to further epithelial abnormalities ranging anywhere from punctate keratopathy to corneal perforation.[7]

PATHOGENESIS OF DRY EYE

Over the past decade much progress has been made in understanding the pathophysiologic mechanisms leading to KCS. It has been recognized that the normal tear homeostasis is dependent upon an intact communication within the specialized unit consisting of the ocular surface, the main and accessory lacrimal glands, lids with their associated structures, and the interconnecting enervation.[43]

A disruption of this unit from the damage to either of its constituents leads to the signs and symptoms of KCS. Extensive research through animal models and immunomodulatory therapies with topical corticosteroids and steroid sparing agents has shown that the key mechanism leading to the disruption of the tear film and resultant KCS is inflammation.[44–50] In both evaporative and aqueous tear-deficient dry eye the presence of proinflammatory markers in tears and conjunctiva underscores the role of inflammation in pathogenesis of dry eye. Abundance of inflammatory mediators in tears and epithelium of aqueous tear deficiency and rosacea-associated meibomian gland dysfunction implicates the role of matrix metalloproteinase-9 as an activator of various cytokines, including interleukin-1, contributing to the cellular damage of the ocular surface.[51,52] Other findings suggesting the pivotal role of inflammation include increased concentrations of other proteases such as plasmin, in the tear fluid,[53,54] and increased conjunctival expression of immune activation markers such as HLA-DR, CD-40, and intercellular adhesion molecule (ICAM)-1.[55–57] A positive correlation has also been demonstrated between the levels of conjunctival inflammatory markers and the degree of conjunctival squamous metaplasia, severity of dry eye symptoms, and corneal fluorescein staining.[58,59]

The exact mechanisms triggering the inflammatory response at the ocular surface and lacrimal glands are unknown, but several possible explanations have been proposed. As detailed previously, patients with low levels of androgens such as postmenopausal women, the elderly, those undergoing anti-androgen therapies, and those with Sjogren's disease are especially prone to dry eye. Animal studies have suggested that androgen suppresses ocular surface inflammation in both aqueous deficient and meibomian gland dysfunction associated dry eye, and its reduction leads to inflammation that precipitates dry eye.[30,60] T-lymphocytes continuously migrating through the lacrimal glands and associated structures normally

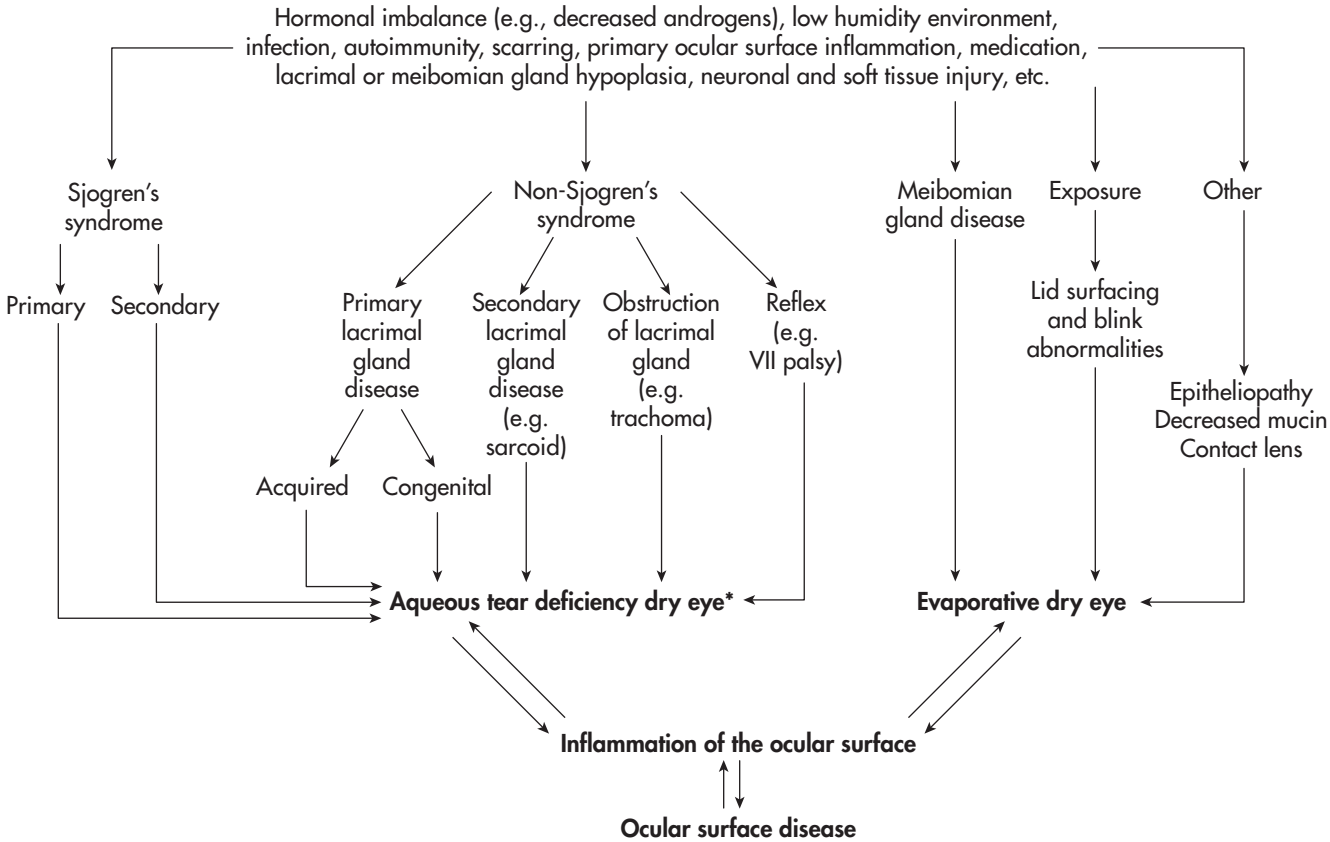

Figure 3.1. Pathogenesis of keratoconjunctivitis sicca. *For simplicity, Sjogren's and non-Sjogren's syndromes are shown in association with aqueous tear deficiency only. In reality, many patients with aqueous tear deficiency also exhibit evaporative dry eye. Double errors indicate the interchangeable relationship between cause and effect. (Modified from Lemp MA. Report of the NEI/industry workshop on clinical trials in dry eye. CLAO J 1995; 21: 221–232; permission pending.)

undergo apoptosis as they leave the ocular surface. In androgen-deficient states, there is increased trafficking of lymphocytes through the neural-epithelial junction in the lacrimal glands and ocular surface with concurrent expression of lymphocyte-activating antigens on the cellular membranes of lacrimal and ocular surface epithelia.[61] As lymphocytes undergo activation, their apoptotic pathway becomes inhibited, and they continue to secrete more proinflammatory cytokines, further upregulating cell surface lymphocyte-activating antigens. This creates a self-perpetuating cycle of ocular surface inflammation with resultant ocular surface damage.

Inflammation of the ocular surface is also sustained by decreased ocular surface sensitivity. It has been shown that as tear clearance and production decreases ocular sensitivity becomes depressed.[22] Consequently, there is a decrease in sensory-stimulated reflex tearing, leading to poor tear response to ocular surface damage. Injury to the ocular surface exacerbates the inflammatory response, resulting in increased ocular surface and lacrimal gland lymphocytic infiltration, further depressing sensory-stimulated reflex tearing. Through this vicious cycle inflammation is perpetuated leading to KCS.

Although numerous experiments have demonstrated the inflammatory nature of dry eye with similar histopathological and immunological findings,[58] the origins of KCS are diverse. In fact, many cases of KCS are probably multifactorial. Commonly, the presence of both aqueous deficiency and evaporative dry eye exists reflecting similar etiological factors. Figure 3.1 is a schematic representing the complex pathogenesis of KCS.

4 Corneal epithelium and stem cells

Murat Dogru, Min Chen, Shigeto Shimmura, Kazuo Tsubota

CORNEAL EPITHELIUM

The cornea is a transparent avascular tissue that is highly specialized to refract and transmit light and is essential for ideal visual function.[1]

MACROSCOPIC FEATURES OF THE CORNEA AND ITS PHYSIOLOGIC PROPERTIES

Optical properties

The adult human cornea measures 11–12 mm horizontally and 9–11 mm vertically. It is approximately 0.5 mm thick at the center, and its thickness is about 0.7 mm at the periphery.[2] The anterior corneal surface is convex and aspheric, with the radius of curvature measuring between 7.5 and 8.0 mm at the central 3 mm optical zone of the cornea, giving the cornea a refractive power of 40–44 D.[1]

Corneal transparency mainly depends on the special anatomic arrangement of collagen fibers in the stroma, which is responsible for the cancellation of interference of scattering of an incident light ray by a collagen fiber from other scattered light, allowing light to pass through the cornea.[3] The corneal epithelium and tear film help to maintain the smooth epithelial surface, which has been reported to be very important for the attainment of good functional visual acuity, a new technology thought to reflect the visual function related to daily activities.[4,5] The total refractive index of the cornea reflects the sum of refraction at the anterior and posterior corneal interfaces as well as the transmission properties of the tissue. The refractive indices of air, tear fluid, corneal tissue, and aqueous humor are 1.000, 1.336, 1.376, and 1.336, respectively.[1]

Innervation

Sensory nerves in the cornea are mainly derived from the ciliary nerves of the ophthalmic branch of the trigeminal nerve, which can be detected as thin fibers with a slit lamp microscope or with confocal microscopy (Fig. 4.1).[1,6]

Vascular system

The anterior ciliary artery, which is derived from the ophthalmic artery, forms a vascular arcade in the limbal region anastomosing with vessels derived from the facial branch of the external carotid artery, providing nutrients and factors that play important roles in corneal metabolism and wound healing.[1]

MICROSCOPIC ANATOMY AND PHYSIOLOGY OF THE CORNEAL EPITHELIUM

The cornea consists of five layers: the epithelium (Fig. 4.1), Bowman's layer, the stroma, Descemet's membrane, and the endothelium. It has three major functions: (1) it acts as a mechanical barrier to debris and microorganisms and, via Langerhans cells; (2) it creates a transparent optical surface by adsorption of the tear film; and (3) it maintains a barrier to the diffusion of water, solutes, and drugs.[1,7–9]

Microscopic anatomy

The human corneal epithelium is a stratified, squamous nonkeratinized epithelium consisting of five to seven layers of cells, including two to three layers of terminally differentiated superficial cells, two to three layers of wing cells, and a single layer of columnar basal cells (Fig. 4.3).[7–9]

Superficial cells: The superficial cells are flat and polygonal (diameter: approximately 40–60 μm), the surfaces of which are covered with numerous microvilli and glycocalyx coat interacting with, and stabilizing, the precorneal tear film.[7–10] Superficial cells are joined laterally to the adjacent cells with tight junctional complexes, which with the very low permeability of the membranes of the superficial cells form the barrier property of the corneal epithelium.[10]

Wing cells: Wing cells have lateral, thin, wing-like extensions from a more rounded cell body,[1,6] and they are interconnected by desmosomal junctions and gap junctions that serve as electrochemical conduits.[9]

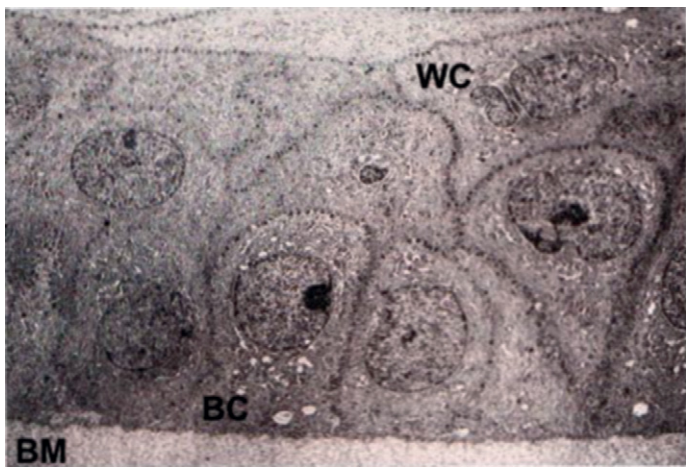

Figure 4.3. Scanning electron micrograph of the wing cells (WC) and basal cells (BC) sitting on the Bowman's membrane (BM).

Basal cells: The basal cells are the mitotically active cells of the epithelium containing ribosomes, rough endoplasmic reticulum, mitochondria, centrioles, microfilaments, microtubules, and glycogen granules.[1,8]

Basal cells of the corneal epithelium adhere to the basement membrane via hemidesmosomes that are linked to anchoring fibrils of type VII collagen.[11] The basal cells secrete type VII collagen, which aggregate to form[12] the anchoring fibrils penetrating the basement membrane, where they form anchoring plaques with type I collagen. E-cadherins, a component of zonula adherens, are present at the lateral surfaces of the basal cells of the corneal epithelium and mediate cell–cell interaction.[1,13]

EPITHELIAL CELL TURNOVER

The corneal epithelium renews itself within approximately 5–7 days, with the superficial cells being constantly shed into the tear pool. Terminal differentiation of cells, coupled with cell death by apoptosis, prompts the cell loss via desquamation, which is aided by blinking.[7,8,14,15] The maintenance of the corneal epithelium is thought to be achieved by the unipotent stem cells (SC) located in the basal epithelium of the corneoscleral limbus.[16–19]

LIMBAL STEM CELLS

LIMBUS

The corneal limbus is a highly vascularized, innervated, and pigmented zone between the cornea, conjunctiva, and the sclera. The zone has pigmented spikes called the Palisades of Vogt which are thought to bear the limbal stem cells (Fig. 4.4).[20]

LIMBAL STEM CELLS

At present, the general criteria for defining stem cells are: (A) slow cycling during homeostasis in vivo; (B) poor differentiation with

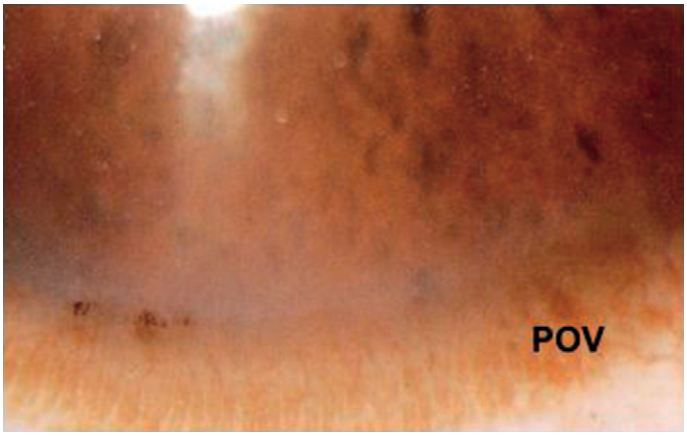

Figure 4.4. Palisades of Vogt (POV) at the corneal limbus thought to harbor the limbal stem cells.

primitive cytoplasm; (C) high capacity for error-free self renewal; and (D) activation to proliferate by wounding or replacement in culture.[21–24] Stem cells can mitose to generate transient amplifying cells (TAC) that are short-lived and function primarily to amplify cell numbers. The transient amplifying cells finally differentiate into postmitotic cells that are committed to cellular differentiation.

The current evidence of the limbal location of corneal stem cells may be summarized as follows:

1. The limbal basal epithelium lacks the corneal epithelial differentiation-associated keratin pair keratin 3 (K3) and keratin 12 (K12),[17,23,25] which led to the hypothesis that the limbal basal epithelium harbors the stem cells.
2. Limbal basal epithelium cells have a higher proliferative potential in culture than central and peripheral cornea epithelium cells.[26,27] Cotsarelis et al[28] found that tritiated thymidine was incorporated for long time intervals only into limbal basal cells, suggesting that the limbal basal epithelium contains slow-cycling cells identified as the 'label-retaining cells'.[28,29] These cells are also resistant to the induction of differentiation.[28,30–32]
3. Abnormal corneal wound healing with conjunctivalization, vascularization, and chronic inflammation occurs when the limbal epithelium is partially or completely removed.[33–36] The effectiveness of limbal transplantation for the treatment of experimentally induced stem cell deficiency, confirmed in rabbits by Tsai and coworkers, further supported the limbal location of corneal epithelial stem cells.[37]
4. The limbal location of corneal epithelial stem cells can account for the relative preponderance of limbal neoplasms and the scarcity of corneal epithelial tumors, assuming that neoplasms arise mainly from relatively 'undifferentiated cells'.[38]
5. A mathematical analysis of the kinetics of maintenance of the corneal epithelial mass confirms that the corneal epithelium can be maintained by cellular proliferation originating from limbal stem cells without contribution of the adjacent conjunctiva.[39]

Collectively, these data leave little doubt that corneal epithelial stem cells reside in the limbus.

IDENTIFICATION OF LIMBAL STEM CELLS

The major molecular markers proposed for limbal stem cells in ocular or nonocular tissues in the past decade can be categorized into the following groups.[40]

Cytokeratins

Cytokeratins are a group of cytoskeletal proteins that forms intermediate filaments in epithelial cells and are expressed in distinct patterns during epithelial development and differentiation. The subfamily comprises at least 20 different polypeptides, which are expressed in paired combination of acidic and basic molecules according to the type of epithelium and its state of differentiation.[40,41]

K3/K12: The keratin pair K3/K12 is specially expressed in corneal epithelial cells and is regarded as markers of corneal epithelial differentiation.[40,42–44] When specific antibodies are used, epithelial cells in the basal layer of the limbus are devoid of these two cornea-specific keratins, underlining their undifferentiated nature.[17,23,25,40,45,46]

K5/K14: Basal cells of both corneal and limbal epithelia express the keratin pair K5/K14.[47]

K15: It has recently been discovered that K15 is expressed in superior and basal limbal epithelial cells with lack of expression in central corneal epithelium.

K19: No significant difference in K19 staining could be found between limbal and corneal epithelia in two studies.[23,48]

The expression patterns of K12, K14, K15 and K19 are shown in Figs 4.5 and 4.6.

Cytosolic proteins

Several proteins, including enzymes such as cytochrome oxidase, Na/K-ATPase, and carbonic anhydrase, have been identified and found in higher concentration in basal cells of the limbal epithelium than that of central corneal epithelium.[49,50]

a-enolase: Recent reports of Chen et al[23] and Schrehardt et al[40] showed that a-enolase was not only expressed by basal but also by suprabasal epithelial cells at the limbus and occasionally by basal corneal epithelial cells, indicating mitotically or metabolically active cells, rather than a limbal SC localization.

PKC: PKC-gamma has been identified as specific to the limbus, whereas all other subtypes can be found both in the central and limbal epithelium.[51]

Cyclins: Cell-cycle associated proteins, such as cyclins D, E, and A, have been also identified as proteins preferentially localized to basal epithelial cells at the human limbus.[52] Calcium-linked protein, associated with early epithelial differentiation, and protein S100A12, which is involved in Ca^{2+}-dependent signal transduction processes in differentiated cells, is expressed in corneal epithelial basal cells but not in limbal calls.[40,53]

Nuclear proteins

P63: Transcription factor p63, involved in tumor suppression and morphogenesis, is expressed by basal epithelial cells that have the ability to proliferate, and is a nuclear marker for corneal epithelial SC.[40]

Cell surface proteins

Cx43: In the corneal epithelium, only two gap junction proteins have been identified so far: connexin 43 (Cx43) and connexin 50 (Cx50). Connexin 43 has been reported to be absent from the basal layer of the human limbal epithelium, whereas suprabasal limbal cells showed slightly positive staining.[23,54,55]

E-cadherin: In human cornea, negative staining was observed in basal layers and positive staining was observed in suprabasal layers at the limbus.[25] Recent reports[40] reveal a weak reaction

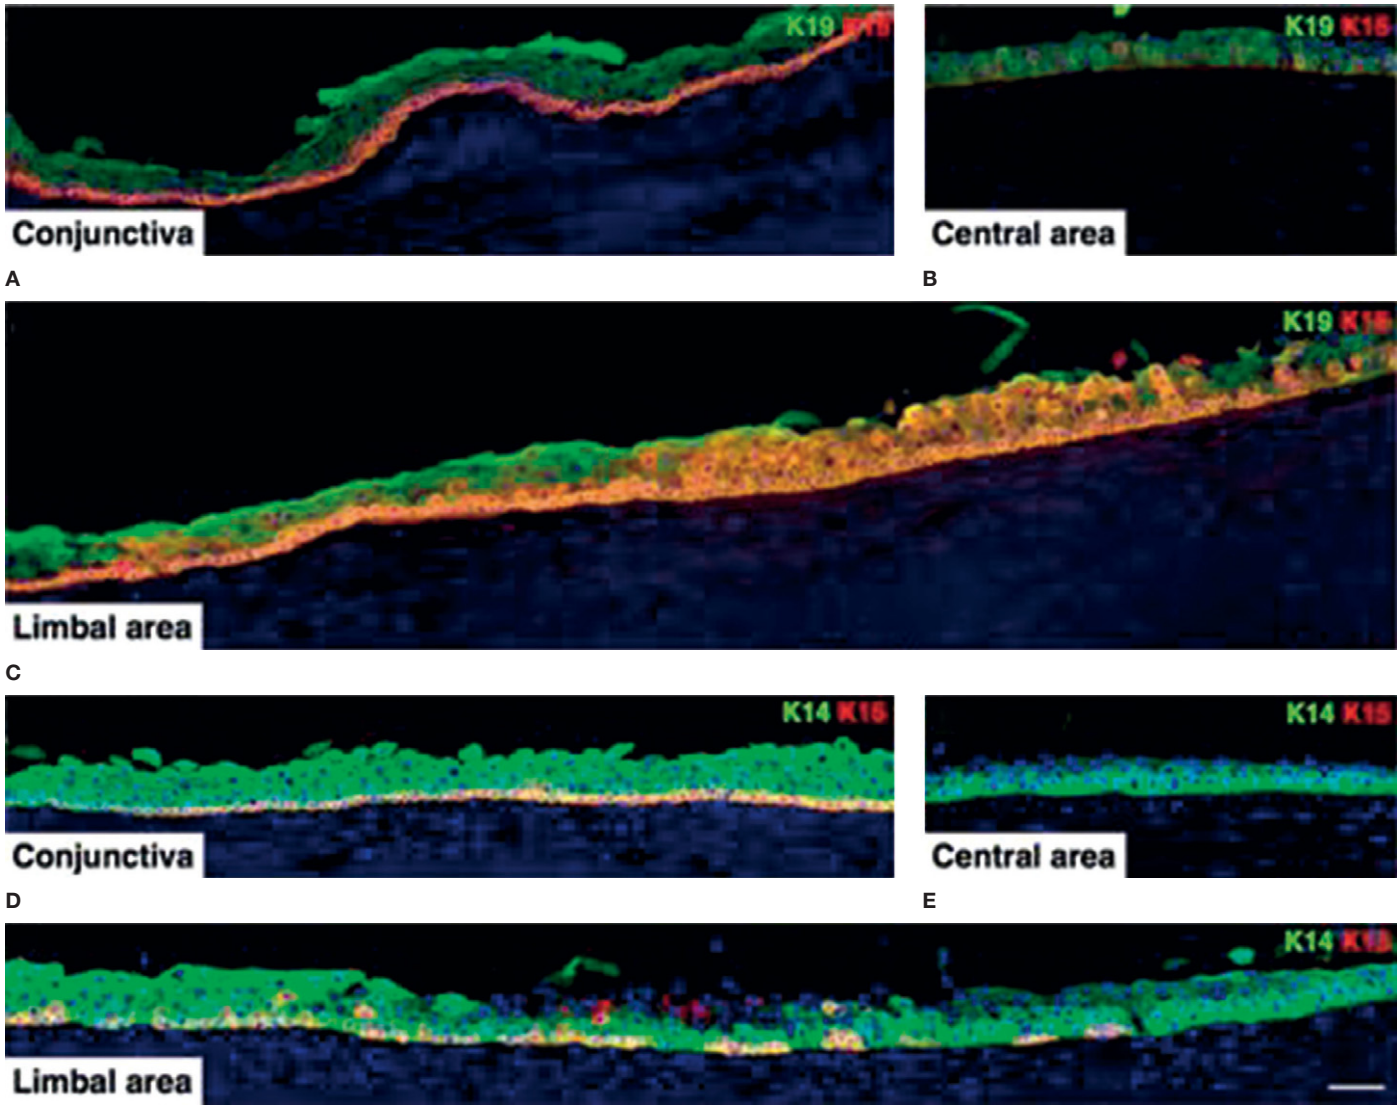

Figure 4.5. Expression pattern of K15, 19 and K14 in human corneal and conjunctival epithelium. Images of serial sections stained with anti-K19 (green, FITC) and anti-K15 (red, Cy3) antibodies (*A–C*) and with anti-K14 (green) and anti-K15 (red) antibodies (*D–F*) Conjunctiva (*A* and *D*) and central (*B* and *E*) or limbal area (*C* and *F*) of the cornea. Together with the expression of K15, a strong expression of K19 was observed in the basal and suprabasal layers of the conjunctival and limbal epitheliae. (*A, C, D* and *F*) Cells weakly positive for K19 were also found in the central area (*B*). K14 was observed in the conjunctiva and in the basal and suprabasal layers of the limbus and central corneal epithelium. Published with permission of the copyright holder The Association for Research in Vision and Ophthalmology, Fig. 4.1 in Yoshida S, Shimmura S, Kawakita T, et al. Cytokeratin 15 can be used to identify the limbal phenotype in normal and diseased ocular surfaces. Invest Ophthalmol Vis Sci 2006; 47: 4780–4786.

in all limbal basal cells and throughout the conjunctival epithelium.

Beta-catenin: Uniform labeling of all cell membranes throughout ocular surface epithelia without any differences in staining pattern of the basal limbal cornea has been reported.[40]

Integrins: In human cornea, integrin β1 is uniformly expressed by basal cells of both limbus and cornea and lacks any real specificity in distinguishing human limbal from corneal basal cells.[19,23]

EGF-R: Growth factor receptors are proteins that preferentially localize to the cell membranes of limbal basal cells. The presence of high levels of growth factor receptors may allow limbal basal cells to be differentially stimulated by fibroblast- or blood-derived growth factors to maintain their undifferentiated nature or to undergo proliferation upon wounding.[40] Although a strong expression of EGF-R in limbal basal cells was also confirmed in human cornea, there was no clear difference in staining intensity between the basal cells of the limbus, corneal, and conjunctiva.[23,40,56]

ABCG2: ATP-binding cassette subfamily G, member 2 (ABCG2), has been identified as a molecular determinant for hematopoietic stem cells, and has been proposed as a universal marker of stem cells. Chen et al demonstrated that this protein is immunolocalized to the cell membrane and cytoplasm of some human limbal basal epithelial cells, but not in most limbal suprabasal cells and corneal epithelial cells.[23]

5 Shape, structure, and biomechanical properties

Pierre Fournié, Gabriel M. Gordon, Dolena R. Ledee, Cynthia J. Roberts, M. Elizabeth Fini

Biomechanics is the study of the mechanics of living systems. The cornea is not mechanically inert. Biomechanical changes can manifest clinically as an immediate reduction in corneal transparency, changes in corneal shape, shape instability over time, and increased sensitivity to shape changes caused by altered hydration, hypoxia, and subsequent injury or surgery. The cornea is similar in tissue organization to skin, but it is simpler, being avascular and lacking appendages. However, it is also more complex, as corneal tissues have many unique structural features. Understanding the biomechanical properties of the cornea is confounded by this, its layered structure, and its molecular heterogeneity. The corneal stroma comprises approximately 90% of the corneal thickness. It provides the cornea with its mechanical properties via its unique structure of interlacing layers of collagen fibrils embedded in a hydrated matrix or 'ground substance' rich in proteoglycans, glycoproteins, other soluble proteins and inorganic salts. Cells called keratocytes scattered sparsely through the stroma form an interconnected network that contributes to the maintenance of corneal structure. The microscopic properties of the corneal stroma are responsible for corneal transparency, whereas the macroscopic arrangement of the collagen lamellae is the basis of shape and physical strength.

MICROSCOPIC ORGANIZATION

THEORY OF CORNEAL TRANSPARENCY

Investigation into the mechanics underlying corneal transparency has occupied scientists for many decades.[1–10] Despite considerable advances in our understanding, there is still no universally accepted explanation. As summarized by Farrell and McCally,[11] all currently viable transparency theories have three common factors:

1. Individual collagen fibrils inefficiently scatter light.
2. The large number of fibrils, however, requires destructive interference of scattered light.
3. Light scattering is directly proportional to thickness, and the cornea is thin.

EXTRACELLULAR MATRICES

Collagens are a family of extracellular matrix proteins found throughout the body. They function in the extracellular space in a variety of ways, from architectural support to filtering of debris, to cell signaling. The majority (~68%) of the collagen comprising the dry weight of the stroma is type I,[12] which is intertwined with collagen V into heterotypic fibrils.[13] X-ray diffraction techniques have shown that these heterotypic fibrils are a constant 31–34 nm wide throughout the central stroma (fibrils thicken toward the limbus) (Fig. 5.1, *A* and *B*) and are organized into orthogonally layered, parallel arrays called lamellae. These layers span the entire cornea like thin laths. At the limbus—the transitional zone between cornea and sclera—they merge with the limbal lamellae.[14] The interfibrillar distance within each lamella varies depending on where the fibril is located. The interfibrillar space in the center of the cornea is about 57 nm, which increases to about 62 nm toward the limbus[15] (Fig. 5.1, *A* and *B*). The fibrils are also packed together more densely in the posterior stroma.[16] While the diameter of individual fibrils does not vary with stromal depth, each lamella is composed of various number of collagen fibrils that does vary depending on the stromal depth. The lamellae in the anterior third of the stroma are about 0.5–30 μm wide and 0.2–1.2 μm thick and are much more disorganized compared to the posterior lamellae, which can grow to about 100–200 μm wide and 1–2.5 μm thick.[17]

Maurice proposed that the collagen fibrils within the stromal lamellae are arranged in a perfect crystalline lattice and that corneal transparency results from the phenomenon that light scattered by individual fibers is canceled by destructive interference from scattered light of neighboring fibers; therefore, light is transmitted only in the forward direction.[1] Although subsequent studies revealed a high degree of order, the lattice structure is not perfect.[6,18,19] Nevertheless, a lattice-like structure may be sufficient (Fig. 5.1, *A* and *B*). Refractive elements in tissues whose dimensions are small (<200 nm) compared with the wavelength of light (~500 nm) should not scatter very much light on the basis of the interference effects

proposed by Maurice.[5,20] Consequently, the normal stroma only minimally scatters incident light because of the regular distribution and size of the collagen fibrils. The heterotypic pairing of type I with type V collagen in the corneal fibrils results in a uniquely narrow fibril diameter, which is thought to aid transparency.[21]

The mechanisms that govern assembly of the stromal architecture are not well understood. Besides the unique heterotypic collagen fibrils, many of the other constituents of the stroma may also act to establish and maintain this design. Collagen III seems to have a similar distribution as collagen I, although its exact role is undefined.[22] Collagen VI has been shown to be present in the interfibrillar space where it binds the collagen I/V fibrils laterally to help maintain fibril spacing.[23] Collagen XII has been localized to Bowman's layer as well as the entire stroma, where it seems to contribute to proper fibril spacing as well as playing a role in structural stability, connecting Bowman's layer to both the underlying stroma and the epithelial basement membrane.[24] Collagen XIII was unassociated with the extracellular matrix alone but has been localized to the plasma membranes of stromal cells in the posterior two-thirds of the stroma,[25] perhaps indicating a role in lamellar organization. Collagens XV and XVIII have anti-angiogenic properties attributed to their carboxy terminal domains which can be cleaved to form angiogenesis inhibitors (endostatins and neostatins); thus they may help to maintain the avascular status of the cornea. Collagen XV has shown a diffuse immunolocalization throughout the adult stroma,[26] while collagen XVIII seems to be localized to the posterior stroma adjacent to Descemet's membrane.[27]

After collagens, proteoglycans are the next major component of the corneal stroma. Proteoglycans function in diverse processes throughout the body. They are composed of a core protein covalently bound to anywhere from 1 to over 100 carbohydrate chains. There are seven types of these carbohydrate chains, called glycosaminoglycans (GAGs), which can be attached during intracellular processing and help determine their function. The two main types of proteoglycans found in the corneal stroma are the keratan sulfate-containing proteoglycans keratocan, lumican, and mimecan, and a chondroitin/dermatan sulfate-containing proteoglycan called decorin. The specific proteoglycan profile of the corneal stroma is linked to transparency. These molecules bind collagen fibrils and may act as mediators of fibril and lamellar assembly.[28] They also are likely to contribute to the control of corneal hydration (and thus swelling) through their specific abilities to bind water. Lumican has been localized to the entire corneal stroma although it is much more heavily expressed in the posterior two-thirds. Lumican-deficient mice develop cloudy corneas at 3 months of age, which persists into adulthood. Transmission electron microscopy imaging has shown that the posterior stroma in mice lacking lumican contains fibrils with significantly larger diameters as well as large fibril aggregates, improper interfibrillar spacing, and much more disorganized lamellae.[29] Interestingly, no such abnormalities are detected in the anterior stroma of these mice, implying a different mechanism for maintaining the fibrillar arrangement. Similarly, X-ray diffraction has shown that keratocan-deficient mice possess a thinner corneal stroma with collagen fibrils of increased diameter and larger interfibrillar spacing.[30] Unlike lumican-deficient mice, however, keratocan-deficient mice do not show any stromal cloudiness. Mutation of the keratocan gene in humans has recently been shown to cause cornea plana, which is characterized by a flattened corneal surface.[31,32] Mimecan-deficient mice seem to have no corneal defects. Corneas are clear with fibril diameters and interfibrillar spacing showing no difference from wild-type littermates.[33] Decorin

has been localized throughout the corneal stroma, including strong expression in Bowman's layer, bound to collagen I/V heterodimers as well as the laterally connecting collagen VI.[34] While the cornea has not been examined in detail in decorin-deficient mice, the skin of these mice is very fragile with irregular collagen fibril diameters as well as abnormal interfibrillar spacing.[35]

Bowman's layer is an 8–12 μm region located between the stroma and the epithelial basement membrane. Bowman's layer lacks lamellae and is instead a densely interwoven but unorganized array of collagen types I, III, V, VI, and XII composed of three or four stratified layers in the center which blend together toward the limbal region.[36] Unlike stromal fibrils, however, which have a 31–34 nm diameter, fibrils in Bowman's layer can be as small as 20 nm in diameter. Bowman's layer is even more acellular than the stroma, the only cells being nerve bundles which pass perpendicularly from the stroma into the epithelial basement membrane where they enervate the cornea epithelium. Bowman's layer is, however, relatively transparent, presumably because spatial fluctuations in the refractive index are small, collagen fibers are small, and this layer is thin.

STROMAL CELLS

Keratocytes are the major cellular components of the human corneal stroma. The origin of these cells is controversial, with either neural crest or mesenchymal origin being possible. Hayashi et al identified the presence of both neuronal and mesenchymal cell markers in immunostained keratocytes and concluded that keratocytes originate from neural crest cells and differentiate into mesenchymal cells.[37] In the adult cornea, keratocytes exhibit a slow turnover: approximately every 2–3 years. They appear as a sparse population of flattened cells located between the collagen lamellae of the corneal stroma. The major function of keratocytes in the normal cornea is to maintain the collagen scaffold and extracellular matrix of the stroma. The keratocytes synthesize new collagens and proteoglycans, while also secreting collagenases and other enzymes to degrade the old stromal matrix. Although each stromal cell scatters light, the total light scattered is small because of the low cellular density. The keratocytes occupy 2–3% of the volume of the stroma.

While appearing scattered and disconnected in corneal cross-sections, keratocytes can be seen in en face views to form an interconnected cellular network by extension of dendritic processes (Fig. 5.2). Gap junctions at the tips of the cellular processes allow for communication between the cells.[38] There is clear evidence that this extensive and highly coupled stromal keratocyte network is much more dynamic than previously thought. In this avascular tissue, the keratocyte network provides a means by which nutrients and metabolites are passed into the central regions of the stroma and waste products are excreted. Advances in corneal and refractive surgery have highlighted the importance of understanding keratocyte function.

Recent studies report the presence of additional cell types in the adult corneal stroma that express stem cell markers and have the ability to divide extensively and generate differentiated keratocytes.[39] These progenitor cells express the ocular development gene PAX6, which is not expressed by the resident stromal keratocytes.[40] The origin of these cells in the corneal stroma is not yet determined. An understanding of their properties might have important implications for cell-based corneal therapy or for the development of bioengineered corneas.

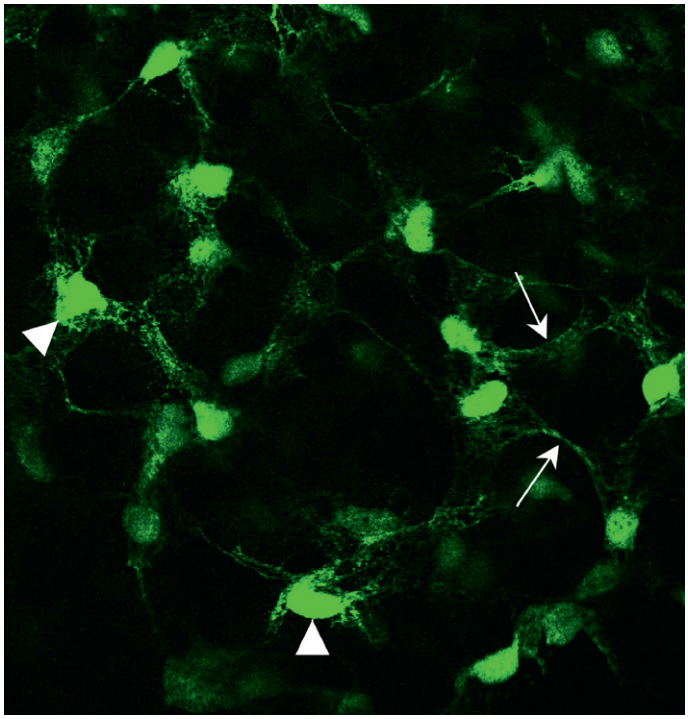

Figure 5.2. Confocal microscopy (×400) of the corneal stroma of a transgenic mouse carrying the Green Fluorescent Protein. Green cells indicate keratocytes with their cell body (arrowheads) and dendritic processes (arrows) forming a three-dimensional interconnected cellular network.

Finally, it was recently demonstrated that bone marrow-derived stem cells are normal components of the corneal stroma in most or all corneas, even in the absence of inflammation (Fig. 5.3).[41–43] As a result, the consensus that the cornea is devoid of resident antigen-presenting cells was profoundly revised. The usual explanation for the extraordinary success of orthotopic corneal allografts, either in humans or in experimental animals, is related to the phenomenon termed 'immune privilege.' This immune privilege concerns both the site of engraftment and the corneal tissue. This notion has lost favor since the demonstration of a large number of resident bone marrow-derived antigen-presenting cells from different lineages—such as dendritic cells and monocytes or macrophages—in both the epithelium and stroma of the normal cornea.[41–43] The immune-privilege of corneal allografts, however, does not rely on a single mechanism for evading immune destruction and the function of these 'wandering cells' in the corneal graft rejection process remains to be investigated. Most of these cells have an immature phenotype lacking major histocompatibility complex class II expression and are extremely inefficient at activating T lymphocytes.[42] They are capable of expressing class II antigens after trauma and surgery.[44]

There are also important functional differences between dendritic cells and macrophages that should be emphasized. Dendritic cells are found in small numbers in the peripheral parts of the cornea and they are not detected in the central parts under normal conditions. Macrophages are found in both parts, but mostly in the periphery.[45] Dendritic cells are much more potent at initiating and expanding secondary immune responses involved in corneal rejection than macrophages, which have a high phagocytic and a low T-cell stimulatory capacity. Macrophages thus seem to have a pivotal role as effector cells and are less likely to trigger an immune rejection reaction. The exact roles of resident tissue macrophages

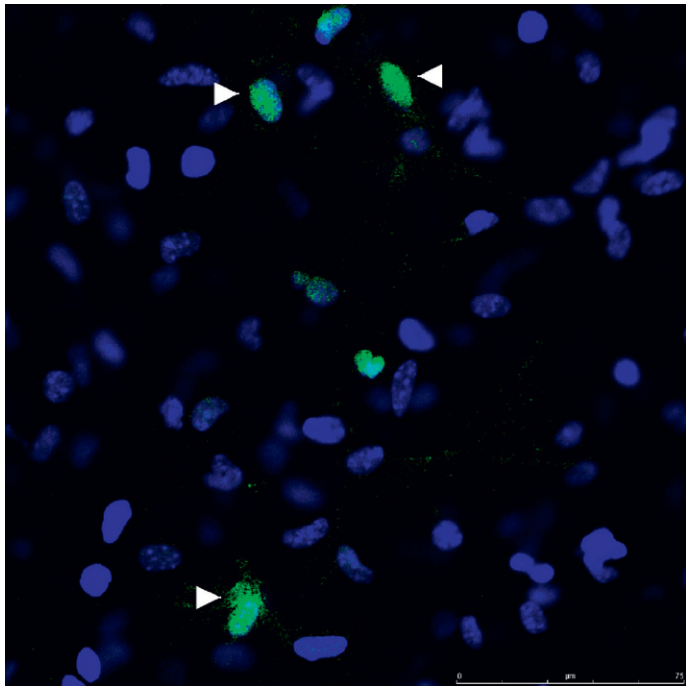

Figure 5.3. Confocal microscopy (×400) of the corneal stroma of a chimeric mouse. A lethally irradiated wild-type mouse has been transplanted with bone marrow-derived cells from a Green Fluorescent Protein transgenic mouse. Green cells (arrowheads) indicate bone marrow-derived cells and blue cells indicate the nuclei of keratocytes.

are not well defined. They are highly phagocytic, facilitating their role in clearing tissue of damaged, infected, or senescent cells. Macrophages also perform essential tasks in wound healing via tissue remodeling through the secretion of appropriate enzymes and growth factors. Their immunologic function remains to be determined. Whereas the macrophages might provide a critical first line of defense against pathogens that breach the epithelial barrier by producing antimicrobial substances and other inflammatory cytokines and chemokines, their role as antigen-presenting cells is unclear. Instead of activating T cells, macrophages in the stroma that are exposed to transforming growth factor-β might, on the contrary, contribute to the immune-privileged status of the cornea by downregulating the T-cell response and inducing tolerance to antigens acquired within the tissue.[46]

NERVES

Electron microscopy images of the corneal stroma show up to 30 sensory nerve fiber bundles of up to 20 μm in diameter with individual fiber diameters ranging from 0.5 to 2.5 μm which enter the stroma from the periphery in a radial pattern. These bundles, found mostly in the anterior stroma, run parallel to the collagen lamellae.[47] While Schwann cell cytoplasm has been localized along the nerve bundles, the individual nerve fibers are not myelinated, implying that the Schwann cells play a role in stromal nervous system survival rather than conduction of the electrical impulse. In addition to being surrounded by Schwann cells, nerve bundles are also embedded in amorphous extracellular matrix structure. Nerve bundles toward the central anterior of the stroma are usually arrayed in the superior to inferior direction while those in the periphery seem to prefer a nasal-temporal pattern.[48] Some nerve fibers in the stroma have been shown to come in direct contact with keratocytes before the bundles make a 90° turn and pass through pores in Bowman's layer to enervate the corneal epithelium.

STROMAL RESPONSE TO STRESS OR INJURY

Any disturbance in the uniformity of collagenous fiber spacing, fibril composition, or proteoglycan content can result in a loss of corneal transparency. This can result from corneal edema, physical damage to the stroma, or deposition of fibrotic tissue in the stroma subsequent to acute damage or as part of a chronic wound healing situation.

The limiting layers of the cornea are sites of active ion transport that regulate the hydration of the hydrophilic stroma.[49,50] The ideal physiologic corneal hydration is approximately 78% in humans. Reduced corneal metabolism (i.e. due to hypoxia or lowered temperature) adversely affects the barrier properties and transport functions of both the epithelium and endothelium, resulting in an increase in corneal thickness and a loss of transparency.[49,51] Corneal edema also results from damage to the corneal endothelium, disrupting the pumping action of its Na/K ATPase ion channels.[52]

In edematous corneas, the diameter of the collagen fibrils remains essentially constant; swelling occurs in the ground substance and leads to increased spatial separation of the collagen fibrils.[53] Those regions that are devoid of collagen fibers are often referred to as stromal 'lakes' (Fig. 5.1, *C*). It is theorized that if a stromal lake reaches a size comparable to half the wavelength of light, scattering increases markedly, leading to a loss of corneal transparency.[20] Loss of light transmittance increases with the amount of corneal swelling.

Following debridement of the overlying epithelium during refractive surgical procedures, keratocytes in the underlying corneal stroma are stimulated to undergo programmed cell death or 'apoptosis.'[54] Keratocyte apoptosis seems to be a benign response thought to have evolved to protect the cornea from further inflammation and the subsequent loss of transparency. These cells are simply replaced following re-epithelialization, probably by replication and migration of keratocytes from the debridement margin.[55,56] There is little or no expression of fibrotic markers.[57]

The cornea is remarkably resistant to stimuli that would initiate a fibrotic repair response in other tissues. These features of cornea may have evolved to limit undesirable changes in tissue structure due to normal renewal or repair processes, much as corneal immune privilege protects it against damaging inflammatory reactions.[58] These phenomena have collectively been termed 'corneal constancy.'[59]

When damage to the cornea penetrates the basement membrane and into the stroma, stromal cells transition into repair phenotypes under the influence of cytokines released by the corneal epithelium.[57,59,60] Keratocytes transformed to the repair or 'activated' phenotype exhibit many morphologic characteristics of fibroblasts, including a fusiform shape, multiple nucleoli, and a lack of cytoplasmic granules. A battery of new genes is activated, including genes that encode cell:matrix adhesion molecules, repair-type extracellular matrix components, and proteinases such as the matrix metalloproteinases.[61,62] As wound healing progresses, a subset of repair fibroblasts assumes properties that are characteristic of myofibroblasts, defined by their larger appearance and expression of alpha-smooth muscle actin.[60,63] Corneal myofibroblasts are responsible for wound contraction as well as for extracellular matrix deposition and organization during corneal repair.

Much of the synthetic activity of the repair cell is involved with the production of an opaque, repair-type extracellular matrix. The composition of this matrix is very different from that of the normal, uninjured stroma. This difference in composition, as well as the disorganized manner of repair tissue deposition, contributes to its opacity.[64] A major change is the appearance of fibronectin, much of which is synthesized by the repair fibroblast.[65] Tenascin is also synthesized in the repair tissue, but not in normal stroma.[66] The ratio of collagen types synthesized by the repair fibroblast is different from the types found in the normal stromal extracellular matrix.[67] Synthesis of keratan sulfate proteoglycan is downregulated, while synthesis of decorin sulfate proteoglycan is induced.[68] The reason for this change is not known, but might represent an alternation in the biosynthetic pathway, possibly through new expression of a specific glycosyltransferase enzyme.

Because of the opacity of repair tissue, refractive surgical procedures aim to limit the wound healing response.[69] Laser surface ablation procedures accomplish this by minimizing the amount of tissue damage. Flap-creating procedures such as LASIK minimize the epithelial-stromal interaction that mediates fibrosis. In such minimal wound healing situations, repair tissue deposition is very low and does not appear to be a major factor in the subsequent 'haze' or translucency that can develop in the cornea following surgery. In this case, cells may be the most important reason for loss of transparency. Indeed, the cells that migrate into the wound bed in corneal wounds are highly reflective when viewed by in vivo confocal microscopy.[70] The molecular changes responsible for this acquisition of light-scattering properties are not known. Possible molecular contributors are the repair-type cytoskeleton with its highly developed stress fibers, or the pericellular extracellular matrix. Another mechanism might lie in reduction in the levels of a newly discovered class of molecules called 'corneal crystallins.' These are taxon-specific, multifunctional proteins that accumulate to very high levels in corneal cells.[71] Aldehyde dehydrogenase 3 (ALDH3) and transketolase (TKT) are the main water-soluble proteins in the corneal stromal keratocytes of most mammals.[72] These proteins at high concentrations may contribute to the transparent state of the cornea by destructively interfering with scattered light through short-range physical interactions, similar to the lens crystallins.[73] Transformation of keratocytes to the repair phenotype in culture is accompanied by loss of crystallins in cell culture.[74,75] In a rabbit wound healing model, crystallin loss correlates with loss of cell transparency.[60] However, ALDH3A1-deficient mice appear indistinguishable from wild-type corneas, and are transparent as determined by light and slit-lamp microscopy.[76] It remains to be seen whether subtle changes in clarity occur that are difficult to measure and perhaps more likely to be manifest in stress conditions. However, the corneal crystallins may probably serve other functions that could preserve corneal clarity, for example protecting tissue against oxidative stress, as occurs in the lens.[77] In fact, a recent publication indicates that ALDH promotes survival of corneal epithelial cells in the face of reactive oxygen species (ROS) and DNA damaging agents.[78]

Recently, a role was proposed for bone marrow-derived stem cells in tissue regeneration. It was suggested that these cells have the potential to form new tissue cells, especially after injury.[79,80] Bone marrow-derived stem cells might either transdifferentiate into corneal cells (such as corneal keratocytes) or, more likely, fuse with existing cells to form a multinucleated cell. Studies are currently ongoing in multiple laboratories to examine their hypotheses and the results promise to be very interesting.

MACROSCOPIC ORGANIZATION

EMBRYONIC DEVELOPMENT

Between the fifth and seventh week of human embryogenesis a series of important developmental events in the corneal stroma occur. By this time the lens vesicle has pinched away from the surface ectoderm and cells of the limbal periocular mesenchyme, a secondary mesenchyme (i.e. a mesodermal area infiltrated by neural crest cells), begin to migrate anteriorly and inward in three waves to fill the void. There are two somewhat contradictory theories on the order of the migration of cells. Both theories concur that the first wave of cells migrates between the surface ectoderm and the lens to form the corneal and trabecular endothelium. They, however, differ on the destiny of the second and third wave of cells. In one theory the second wave of cells migrates between the primitive corneal epithelium and endothelium to give rise to the keratocytes with the third wave giving rise to the stroma of the iris between the endothelium and lens.[81–83] Tripathi and Tripathi proposed the reverse.[84] The presence of the lens appears to be essential during the migration of these periocular mesenchymal cells in the differentiation of the corneal stroma.[85,86]

From the second and into the third month, differentiation of the corneal stroma continues. The stroma increases from ~5 to 8 rows of cells to 15 and now contains collagen fibers, particularly type I and type III. The stroma spreads toward the sclera and the central stroma is more attenuated compared to the more confluent peripheral posterior layers. Lying in parallel to the corneal epithelium, the anterior stromal cells tend to be more round in shape compared to the spindle-shaped posterior cells.[87–89] The arrangement of the fibroblast (predecessors of the keratocytes) coincides with the synthesis of glycosaminoglycans, such as keratan sulfate, which regulates the spacing of the collagen fibers,[90] hence transparency. At this stage the cornea is hydrophilic and translucent due to the high water content.[88] Sensory nerve fibers can be observed, with innervation beginning at 3 months reaching into the epithelium by 5 months of age.[91]

At 4 months the cornea continues to differentiate and mature. Although the stromal region is greater than 15 layers thick and of equal thickness throughout, the corneal diameter has increased due to longer collagen fibrils, and the demarcation between the stroma and sclera is more distinct. There are fewer mesenchymal cells and more flattened keratocyte type cells and an abundance of parallel collagen lamellae.[88,89] From here on the differentiation of the cornea continues at a slower rate. Into the fifth month the Bowman's layer abutting the corneal basement membrane becomes visible at the ultrastructural level. The keratocytes at this stage of development also exhibit an increased level of lysosomal enzyme activity indicative of a potential involvement in collagen and glycosaminoglycans turnover rate.[92]

The eyelids open at about 6 months and morphological changes involving stromal thickness and cellularity occur. As observed in many vertebrate animals, the stroma increases in thickness just prior to eyelid opening with thinning after opening. Also, the density of stromal cells appears to decrease.[93,94] It is uncertain if the number of cell decreases or if the density shift is due to the shift in volume. This swelling and thinning may be related to sulfation of lumican, a major keratan sulfate proteoglycan in the stroma. Synthesis of keratan sulfate increases water absorption and consequently swelling and maturation of the endothelium, the corneal pumping station, leads to a thinning. It should also be noted that

between the period of eye opening and birth the number of proliferating cells in the stroma drops precipitously. The remaining stromal cells express little or no cyclins or cyclin-dependent kinase inhibitors, suggesting an exit from the cell cycle into G0, which is supported by the ability to stimulate these cells to proliferate.[55,95]

By the seventh month the cornea is well developed. The diameter of the cornea will have increased from 4.2 mm at 4 months to 9.3 mm at term. After birth in the first postnatal month the cornea has a steep curvature which decreases over the next 6 months until finally stabilizing.[96]

SHAPE

The cornea has a dual role of providing protection to trauma and infection as well as maintaining transparency and structural integrity to refract light into the eye and to maintain the eyeball's shape under the action of the intraocular pressure. The bulk of the cornea is formed by the lamellar stroma, which in the human adult is approximately 450–550 μm thick centrally and consists predominantly of flattened, stacked, collagenous lamellae (200–250 layers) oriented parallel to the corneal surface. The stroma is considerably thicker in the periphery (550–750 μm). Because of its features, the stroma is the layer that provides the cornea with its shape and mechanical properties. The adult human cornea is smaller in the vertical diameter (9–11 mm) than in the horizontal diameter (11–12 mm). The shape of the anterior corneal surface is convex and aspheric. The central 3-mm optical zone radius where the surface is almost spherical is between 7.5 and 8.0 mm, with the peripheral corneal curvature being less marked. The posterior surface overall has a shorter radius of curvature. Corneal shape varies between individuals. An interesting side note is that right and left corneas are structurally distinct, although both seem to exhibit a degree of midline symmetry that might help to explain the topographical enantiomorphism exhibited by fellow corneas.[97]

PHYSICAL STRENGTH

Human corneal tissue is a complex viscoelastic structure. The cornea is able to recover its original shape after stress is removed, but the relaxation path is different from the deformation path. This property is referred to as hysteresis and is due to the ability of the tissue to absorb and dissipate energy. The tensile strength of the cornea is dependent on its collagen content. The stroma thus provides the majority of the cornea's tensile strength. The exact mechanism responsible for the maintenance of the corneal shape, however, is not known.

The orientation of successive fibril layers throughout the entire cornea is an important factor determining the mechanical properties of the cornea. There is a difference between the arrangement of the lamellae in the anterior third of the cornea and that in the posterior two-thirds.[98] In the mid- and posterior stroma, collagen lamellae tend to be arranged parallel to the surface, and fibrils in one lamella run at approximately right angles to those in the adjacent lamellae in the superior–inferior and nasal–temporal directions preferentially (Figs 5.4, *A* and *C* and 5.5).[99,100] It has been suggested that these collagen lamellae patterns exist to withstand the stress exerted on the cornea by the ocular motor muscles, thereby helping to preserve corneal shape.[99,100] In the anterior one-third of the stroma, collagen lamellae run in more random directions and branching of the lamellae in this superficial region (100–120 μm thick) has been described in both the vertical and horizontal planes with fibrils interdigitating from one lamella to the next, sometimes weaving between three lamellar layers (Fig. 5.4, *B* and *C*).[98] Some stromal interweaving in the horizontal plane also occurs in the deeper lamellae.

In corneal edema, swelling is lowest in the most anterior part of the stroma and even extreme swelling has little effect on corneal curvature. The proteoglycan ratio in the corneal stroma is related to stromal hydration and water distribution. In the posterior part keratan sulfate, a more hydrophilic proteoglycan, is prevalent; whereas in the anterior part dermatan sulfate, a much less hydrophilic proteoglycan, is prevalent. Müller et al suggest that the tightly interwoven anterior lamellae, which restrain corneal swelling, might also account for the maintenance of corneal curvature.[101] Given the importance of this site, a question about corneal stability arises concerning excimer laser refractive surgery in which this part of the stroma is either ablated (photorefractive keratectomy) or intersected (keratomileusis). Furthermore, a proportion of the anterior lamellae inserts into Bowman's layer. Interestingly, Bowman's layer is not present in all animals[102] and its removal does not measurably alter the mechanical properties of the cornea.[103] Thus, while there are speculations as to the purpose for Bowman's layer, its function remains unclear.

The physical strength can be compromised in different corneal diseases, which results in anomalies of corneal shape, and thereby on the eye's refractive status (Table 5.1). Corneal thinning is a hallmark of noninflammatory ectatic disorders. The orthogonal arrangement of the collagen fibrils is profoundly altered in keratoconus with a loss, rather than a compaction, of collagen, which is responsible for the clinical thinning.[104] Both the thinning and altered collagen arrangement can account for the biomechanical instability of the tissue, and lead to corneal protrusion.

BIOMECHANICAL RESPONSE TO EXCIMER LASER REFRACTIVE SURGERY

Although thinning of the cornea is associated with protrusion and consequent increase in curvature in noninflammatory ectatic disorders such as keratoconus, the opposite response occurs when the normal cornea is intentionally thinned by removing tissue in a specific pattern via laser refractive surgery. In this case, the central cornea flattens biomechanically due to alteration of the structure by ablation of central portions of tension-bearing lamellae. Preoperatively, the normal cornea can be considered analogous to a series of rubber bands, stacked one on top of the next, with water-soaked sponges in between each layer. The rubber bands represent corneal lamellae, and the sponges represent ground substance or matrix. The rubber bands are stretched due to loading by the intraocular pressure, and the water held in the sponges is 'squeezed' out by the

constant tension in the rubber bands. Thus, the normal corneal state of relative dehydration is enhanced by the tension carried in the lamellae, unless the swelling forces are altered by pathology or surgery (Fig. 5.6, *A*). In laser refractive surgery, the lamellae are severed in a circumferential pattern, with the deepest ablation in the center for a myopic procedure and deepest ablation in the paracentral region for a hyperopic procedure. Once the central lamellae are ablated, the tension in the remaining peripheral lamellar segments is dramatically reduced, much like cutting through layers of rubber bands in the analogous model. The relaxed rubber bands can no longer hold the water out of the sponges, and the sponges expand as they imbibe water. However, unlike the stacked rubber bands, the cornea has a complex interweaving collagen microstructure. As the lamellar segments remaining in the peripheral cornea relax when the central cornea is ablated, the swelling forces are regionally altered, causing the peripheral cornea to swell and thicken.[105] This is illustrated schematically in Fig. 5.6, *B*. This is a similar mechanism to that which causes the central cornea to flatten between opposing arcuate incisions in the peripheral cornea, which are used to treat astigmatism. The incisions are placed 180° apart in the meridian of greatest curvature, causing that meridian to flatten, even without the removal of tissue. Thus, any procedure which severs corneal lamellae in an arcuate or circumferential pattern will cause the central cornea to flatten and the peripheral cornea to thicken. The biomechanical central flattening is in synchrony with the ablation pattern in a myopic procedure, and opposes it in a hyperopic procedure where the goal is to increase central curvature. Figure 5.7 is a series of topographic maps from a patient who received a myopic LASIK procedure. The preoperative pachymetry and tangential curvature are given in Fig. 5.7, *A* and *B*. The corresponding postoperative maps are given in Fig. 5.7, *C* and *D*, which illustrates the typical paracentral steepening that is characteristic of myopic refractive surgery. The pachymetric and tangential curvature difference maps are given in Fig. 5.7, *E* and *F*. The central cornea shows a reduction in thickness in the pachymetric difference map, which is expected in a myopic procedure. However,

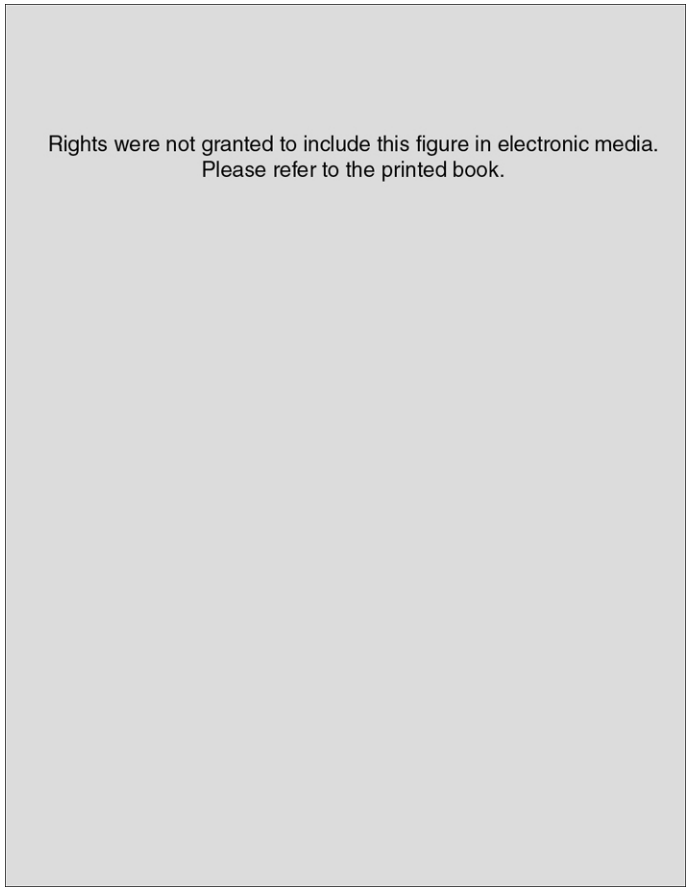

Figure 5.5. Electron micrograph (×32 000) of the posterior stroma shows strictly alternating cross-sectioned and longitudinal sectioned collagen bundles. (K, keratocyte). (This figure is also taken from Komai Y, Ushiki T. The three-dimensional organization of collagen fibrils in the human cornea and sclera. Invest Ophthalmol Vis Sci 1991 July; 32(8): 2244–2258.)

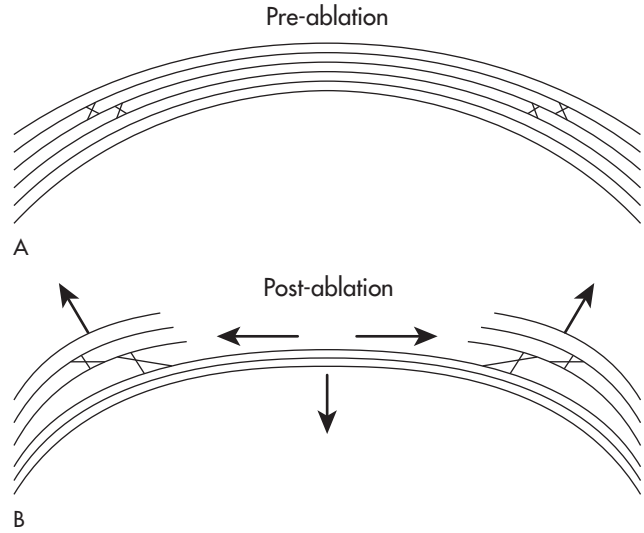

Figure 5.6. Schematic illustration of the change in corneal structure between the preoperative normal state (*A*) and the postablative state (*B*). Once the central portions of the tension-bearing lamellae are removed via ablation, the remaining peripheral lamellar segments relax and the peripheral cornea imbibes water causing it to expand. Due to the complex interweaving microstructure, the peripheral swelling generates a force on the underlying layers causing the central cornea to flatten.

the peripheral cornea shows an increase in thickness within the transition zone, where tissue was actually ablated. This is consistent with the model presented in Fig. 5.6, *B*. The peripheral thickening in laser refractive surgery is associated with an increase in curvature, which is evident in the tangential difference map. This paracentral steepening contributes to biomechanical spherical aberration induction after myopic excimer refractive surgery.

In rare cases, loss of structural stability may occur following laser refractive surgery. This results in further corneal thinning and consequent steepening, characteristic features of iatrogenic ectasia. This biomechanical decompensation response is similar to that seen in keratoconus. Iatrogenic ectasia has been reported more often in LASIK than in PRK, and greater risk has been associated with enhancements, low residual stromal bed thickness, and preoperative curvature anomalies, as well as other factors.[106,107] However, postoperative ectasia has also occurred in the absence of these risk factors. The exact mechanism remains unknown. The widely accepted threshold for residual stromal bed thickness after the creation of a flap and subsequent ablation is 250–300 μm in LASIK, and 400 μm of total corneal thickness in surface ablation. Yet, a series of 'ultrathin' corneas after surface ablation has been reported with a final total corneal thickness less than the accepted threshold without the occurrence of ectasia over 5 years of follow-up.[108] Some of these eyes had a total corneal thickness of less than 300 μm without the occurrence of ectasia. The hypothesis for the long-term stability of these ultrathin corneas was that a wide 10 mm ablation zone was used in a phototherapeutic pattern, which more evenly distributed the stress in the cornea and avoided the stress concentration of a small diameter, thin zone. Therefore, the risk for developing iatrogenic ectasia is multidimensional. It is also possible that an as yet unidentified risk factor exists related to preoperative biomechanical properties that might indicate a weaker cornea. The ability to readily measure biomechanical properties in vivo would allow further study of this rare complication.

MEASUREMENT OF CORNEAL BIOMECHANICAL PROPERTIES IN VIVO

Until the introduction of the ocular response analyzer (ORA) in 2005,[109] no clinical technique existed to measure corneal biomechanical properties in the living eye. The ORA is similar to a noncontact tonometer in that a controlled stream of air is used to rapidly deform the cornea to a flattened state of applanation. This inward applanation event is detected by an electro-optical system composed of an infrared emitter aligned with the cornea such that when applanation occurs, the light becomes focused on an infrared detector creating a spike in the measured signal. The air stream produced by the ORA, however, continues to increase past applanation to a state of corneal concavity where the air pressure peaks. As the air pressure subsequently decreases, the cornea passes through a second applanation event in the outward direction, as the cornea recovers its original shape. If the cornea were purely elastic, the air pressure at which both the inward and outward applanation events occur would be equal. However, due to the viscoelastic nature of the cornea, some of the energy is absorbed or dissipated, and the air pressure at which the second applanation event occurs is less than that of the first applanation event. The difference between the two air pressures is termed 'corneal hysteresis', and is a marker for the viscoelastic properties of the cornea.

In an elastic material, the response of the material is dependent only on the magnitude of the applied force. In a viscous substance,

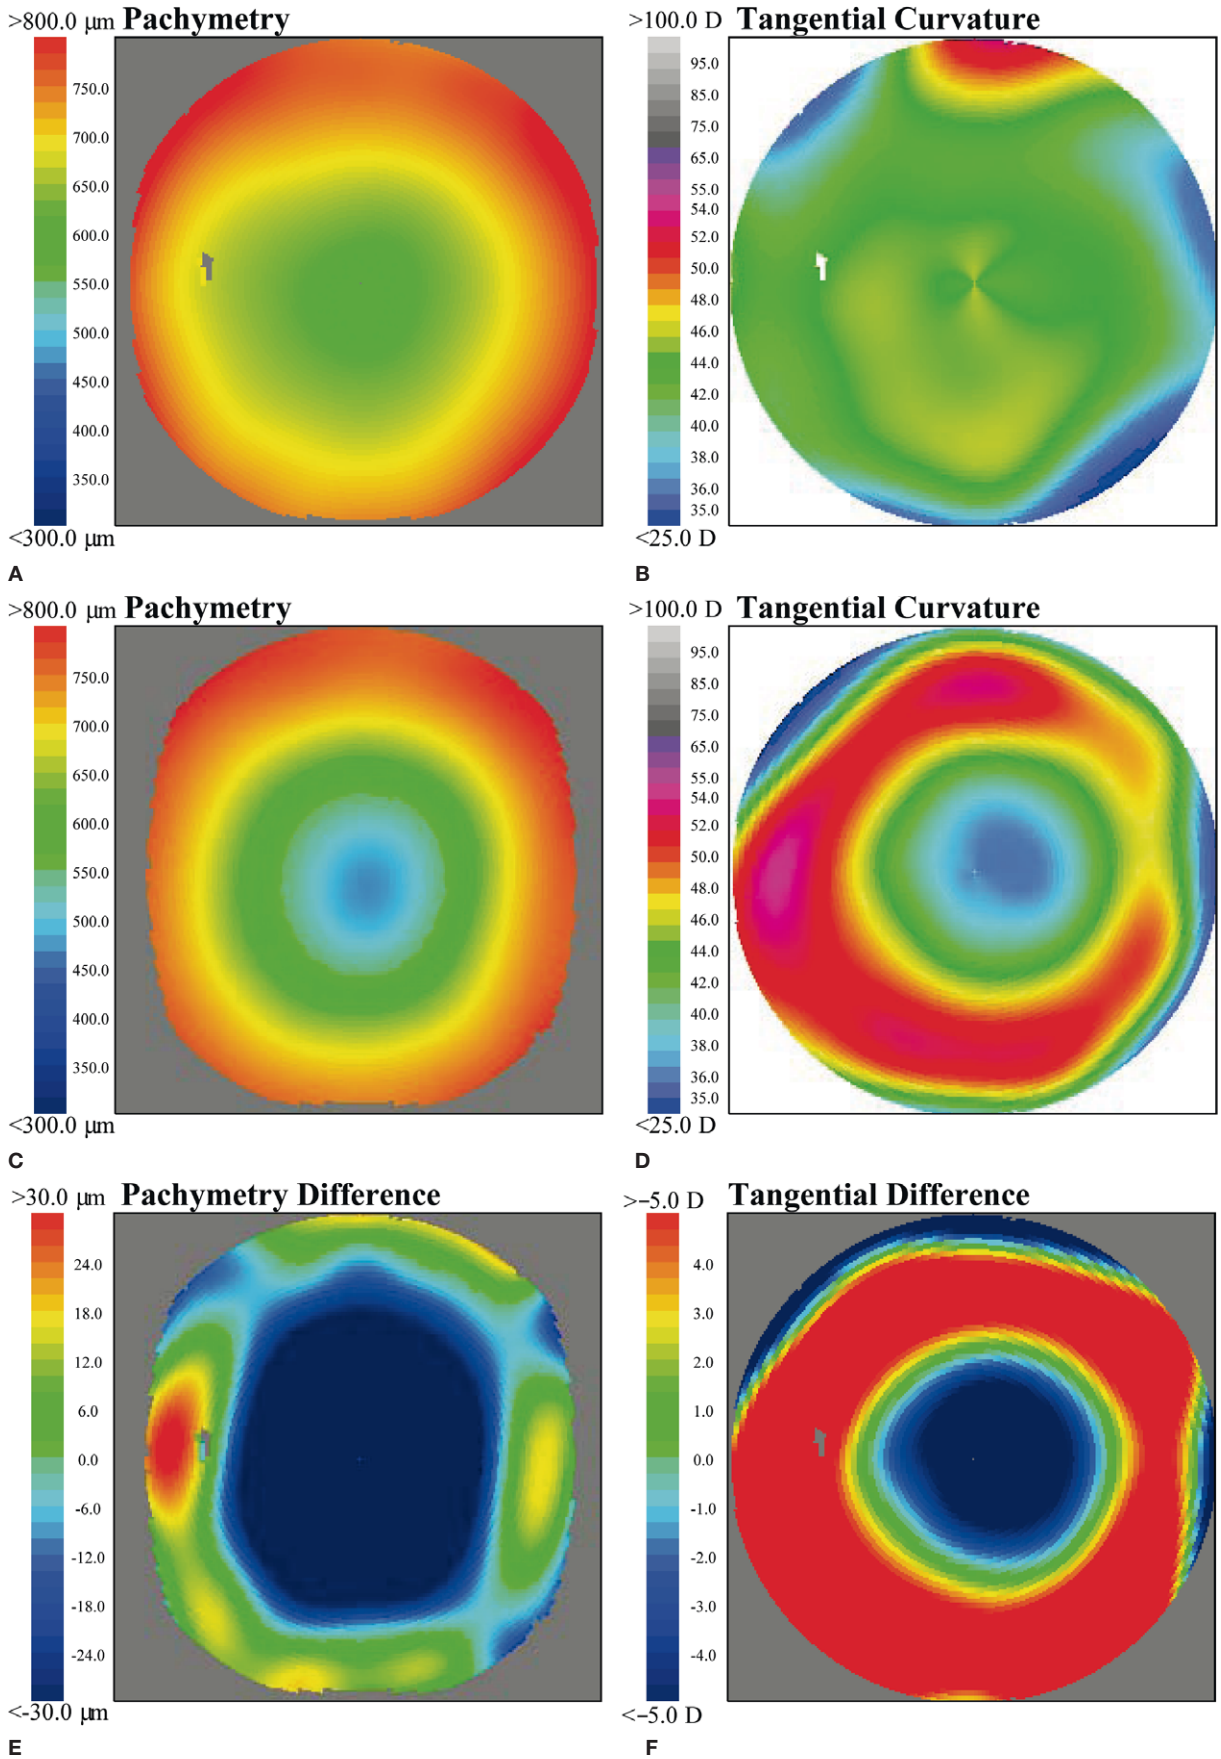

Figure 5.7. Topographic maps from a patient who received a conventional myopic LASIK procedure. The full diameter of the maps is 9 mm. *A,* Preoperative pachymetry map. *B,* Preoperative tangential curvature map. *C,* Postoperative pachymetry map. *D,* Postoperative tangential curvature map. *E,* Pachymetric difference map which shows a central decrease in thickness across the optical zone and a peripheral increase in thickness within the transition zone where ablation occurred. *F,* Tangential curvature difference map that shows a central decrease in curvature, along with biomechanically driven paracentral and peripheral increases in curvature (From Cynthia Roberts).

the response is dependent not only on the magnitude of the applied force, but also on the rate at which the force is applied. In other words, viscosity implies a delayed or time-dependent response. However, it is important to remember that in a viscoelastic material like the cornea, the resulting hysteresis is influenced by both the viscous and elastic components. Two corneas with the same level of hysteresis may be different in terms of elasticity and viscosity.

Corneal hysteresis is positively correlated with corneal thickness,[110] which indicates that a thicker cornea dissipates or absorbs more energy than a thinner cornea. This may be due to increased collagen content in a thicker cornea. However, the viscoelastic response of the cornea may be altered by pathology or surgery. Patients with keratoconus or Fuchs' dystrophy have been reported to have corneal hysteresis lower than that of normal eyes,[109] despite the vastly different corneal states. Keratoconic eyes are thinner than normal due to loss of collagen, and corneas with Fuchs' dystrophy are thicker than normal due to edema. It is interesting to note that thick normal corneas tend to have higher hysteresis, and thick edematous corneas tend to have lower than normal hysteresis. It is unlikely that the elastic and viscous components in keratoconic and Fuchs' corneas are similar, even with similar values of low hysteresis, due to the distinct structural characteristics. Further research is needed.

Excimer laser refractive surgery not only alters corneal thickness and curvature, it also modifies corneal biomechanical properties. Corneal hysteresis is significantly reduced after both surface ablation and LASIK.[111] The reduction in hysteresis is not predicted by the change in corneal thickness, and therefore may be attributed to a fundamental change in viscoelastic properties. The long-term effects of this modification in corneal properties are not yet known.

Early evidence indicates that corneal hysteresis correlates with visual field loss in glaucoma.[112] However, the nature of the association between properties of the cornea and damage at the back of the eye is not yet known. Understanding the importance of corneal biomechanical properties for diagnosis and treatment in disease states is in its infancy, due to recent development of the ability to measure corneal biomechanical properties in vivo.

Mechanical properties of the stroma account for the transparency, shape, and physical strength of the cornea. Corneal biomechanics can be altered in corneal diseases injury, and corneal surgery. Whereas most medical and surgical treatments of the cornea are geared toward the restoration of corneal transparency or shape, refractive surgery for the transparent cornea designed to change its shape has recently been introduced. The long-term stability and predictability of corneal refractive procedures have now become more prominent concerns. A better understanding of the corneal biomechanical response is essential, in addition to corneal pathology, for screening potential refractive surgery candidates, predicting corneal behavior, and achieving optimal visual performance.

6 Stromal wound healing

Trevor Sherwin, Colin R. Green

The cornea has been described as an evolutionary compromise due to the diversity of the functional demands placed upon it. In order to fulfill these demands the cornea must remain transparent, refract light, contain the intraocular pressure, and act as a barrier to protect the eye from the surrounding environs, with each of these functions being provided by the highly specialized substructural organization.[1]

The stroma or substantia propria forms approximately 90% of the 600-μm thick cornea and is predominantly composed of an extracellular matrix arranged in lamellae running parallel to the corneal surface (Fig. 6.1). Interlaced within the matrix lamellae are layers of keratocytes whose primary role is to maintain the stroma. These cells are critical in the process of wound healing.

THE CORNEAL STROMA IN HOMEOSTASIS

MATRIX COMPONENTS

The cornea is mainly composed of an extracellular matrix with the two major constituents being collagen and proteoglycan. There are 19 known collagen types and the cornea expresses 10 of these plus some spliced variants[2] with type I collagen and type V collagen being the most abundant.[3] Two classes of proteoglycan are found within the stroma, those with keratan sulfate side chains (lumican, keratocan, and mimecan) and those with dermatan sulfate side chains (decorin).[2] The normally acellular Bowman's layer is a specialized condensation of the anterior stroma that contains type III collagen in addition to types I and V.[4]

KERATOCYTES

The keratocytes within the stroma appear sparse when examined within anteroposterior sections[3] (Fig. 6.1). However, labeling the cells of the cornea with a fixable live cell dye enables the cellular components of the stroma to be seen more clearly even within anteroposterior sections[5] (Fig. 6.2). 'En face' images of keratocytes reveal the highly connected nature of the cell syncitium and there are differences in cellular appearance depending upon their position in the anterior, mid-, or posterior stroma. These differences between the three keratocyte subpopulations identified are clearly illustrated in comparable high-resolution three-dimensional reconstructions of cells from each region (Fig. 6.3). Large, variably shaped, and orientated cell bodies and numerous short cell processes characterize anterior keratocytes. Together they form a variety of cell process to cell process, cell process to cell body, and cell body to cell body contacts that dominate the anterior stroma. In the central stroma, where cell density is clearly lower, cell bodies also show variable shape and orientation, and maintain some cell body to cell body contacts. However, continuity with adjacent keratocytes is largely maintained through an attenuated network of cell process to cell process contacts. The cell bodies of posterior keratocytes appear 'swollen' when compared to anterior and central keratocytes. They are fringed by a number of short cell processes and flat extensions of cytoplasm, which form thin fenestrated areas adjacent to parts of the cell body.[5]

NERVE ARCHITECTURE

The cornea is densely innervated by sensory fibers from the ophthalmic branch of the trigeminal nerve, which responds to mechanical, thermal, and chemical stimulation of the cornea. Individual nerve cells communicate via a range of both classical and peptidergic neurotransmitters. In the human cornea, many radially oriented nerve bundles enter the cornea via the sclera in the 9–3 h direction, bend 90° and pass through Bowman's layer (Fig. 6.4, *A*), then bend 90° again, before ramifying and ending within the epithelium as free nerve endings (mostly C-fibers). Corneal nerve architecture in humans has been studied using light and electron microscopy.[6–8] As elegant as these studies were, the intrinsic limitations of corneal tissue obtained from cadavers or enucleated eyes and the fragile nature of corneal nerves was illustrated by the fact that significant degeneration of sub-basal nerve bundles occurred within 13.5 h of death.[7] However, the advent of the in vivo confocal microscope led to the visualization of stromal and sub-basal nerves in living subjects (Fig. 6.4, *B* and *C*). Most recently, this technique has been utilized to map large areas of the sub-basal nerve plexus of the central and mid-peripheral human cornea in health[9] (Fig. 6.5) and disease.[10]

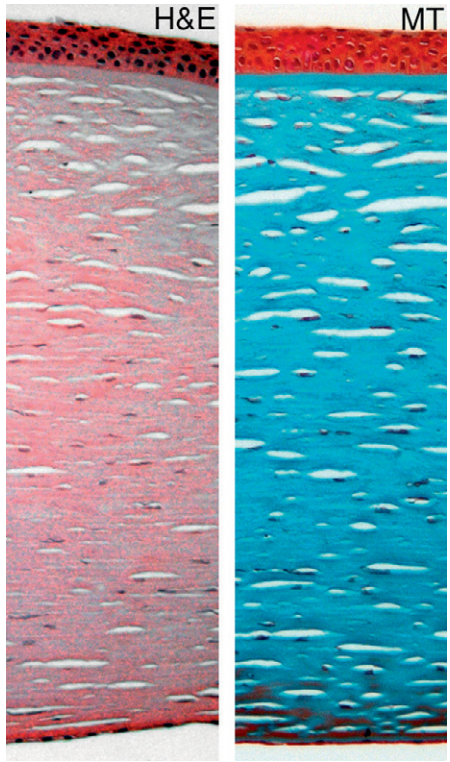

Figure 6.1. Classical hematoxylin and eosin stain (H&E) of an anteroposterior section of the human cornea showing the distinct layers that comprise this tissue. The epithelium consists of five to seven cell layers. The stroma, between Bowman's layer underlying the epithelium and Descemet's membrane above the single cell layer endothelium, makes up about 90% of the 600-mm thick cornea. Masson's trichrome (MT) illustrates that the blue stained stroma is predominantly composed of collagen. Stromal keratocyte density is seen to be greatest in the anterior stroma. The spaces evident within the stroma are a preparation artifact, but serve to illustrate the layered structure of the collagen lamellae.

STROMAL HEALING

CELLULAR RESPONSE

The response to any injury, which includes corneal surgery, involves four phases: (1) the removal of damaged tissue, (2) a proliferative and migratory phase, (3) a phase of repair and replacement, and (4) termination of the wound-healing process. The primary cellular change in response to injury or a surgical incision is the spreading death of keratocytes immediately adjacent to the wound site through apoptosis. Apoptosis is the programmed death of cells occurring without significant release of intracellular components that might damage the surrounding tissue. Apoptosis of keratocytes peaks at about 4 h but the effects may last up to 1 week after the incision. The loss of keratocytes from the stroma by these two processes can lead to an acellular zone that extends 200–300 μm from the incision.[3]

The subsequent cellular response is the appearance of inflammatory cells at the anterior end of the incision. These inflammatory cells, in or near vascular regions of the cornea, include macrophages, T cells, and polymorphonuclear cells that migrate into the corneal stroma from the limbal vessels, or it has been proposed possibly from the tear film.[11] Author citations differ as to the timing of the appearance of the inflammatory cells varying from 3.5 to 12 h.[3,11] However, infiltration already begins to resolve by 48 h.[3] These cells probably function in clearing the stroma of the apoptotic bodies and other cellular material left behind by the die back of keratocytes.[11]

Within 6 h after injury subtle changes are occurring in the keratocytes which border the acellular zone. The cells appear to increase in size mirrored by an increase in the number of phagosomes and vesicles and both the number and size of the nucleoli.[3] Most ribosomal RNA genes are located in specialized regions of chromosomes associated with the nucleolus, thus these changes are consistent with increased protein translation. The cytoskeleton is remodeled as the keratocytes appear to transform into fibroblasts with stress fibers containing actin (Fig. 6.6), nonmuscle myosin, and α-actinin becoming visible and the cell morphology changes into a more fusiform shape.[12,13] These repair cells migrate into the acellular zone within 24 h after insult and reach the edge of the incision by day 2. At approximately 72 h after injury the fibroblasts that have reached the wound edge begin to proliferate such that a fibrotic network of cells form parallel to the cut surface.[3]

Depending on the type of wound, myofibroblasts may appear characterized by the expression of α smooth muscle actin (α-SMA) and increased levels of cadherins and transforming growth factor β (TGF-beta) receptors. These cells are usually larger and contain more stress fibers and focal adhesions than fibroblasts.[14] The appearance of α-SMA is thought to impart greater contractile properties on the myofibroblast cells[15] and expression of α-SMA is concurrent with wound contraction. Myofibroblasts appear first under the epithelium[13,15] and then spread backwards to engulf the whole region under repair, tending to occur in highly fibrotic wound types associated with significant extracellular matrix deposition and extensive tissue contraction (Fig. 6.7).[16] The appearance of myofibroblasts within the cornea and their subsequent contraction are associated with opacity during repair.[17,18] As the wound is resolved the loss of myofibroblast markers within stromal cells is seen, followed by the loss of fibroblast markers. Cell numbers begin to decline and return to normal between 3 and 6 days post injury and gradually the cells at the wound site return to normal morphology and number.[3] From this point remodeling of the cornea begins to produce a mature and more functional scar.[14]

CYTOKINES

The cytokine family comprises several subclasses, including growth factors, interleukins, colony-stimulating factors, and interferons, and is responsible for a variety of biological responses, including cell growth, differentiation, inflammation, and wound healing. Cytokines are expressed by a mixture of diverse immune and non-immune cell types. These factors are ubiquitous throughout the human body tissues and have a plethora of roles that include extracellular matrix production, extracellular matrix degradation, and chemotaxis.[19]

The release of cytokines in response to a corneal wound is detected within minutes with the key regulator being interleukin-1 (IL-1). The release of IL-1 and tissue necrosis factor α (TNF-α) from compromised epithelial cells after injury has been implicated in the keratocyte apoptosis that follows.[20,11] However, the interactions are complex as IL-1 has also been shown to initiate increased keratinocyte growth factor (KGF) and hepatocyte growth factor (HGF) in the stroma and the keratocytes, now competent for IL-1 production, enter a self-perpetuating loop modulating this growth factor production.[3,20]

The response of the keratocytes at the periphery of the acellular zone following apoptosis, to transform and migrate and then to

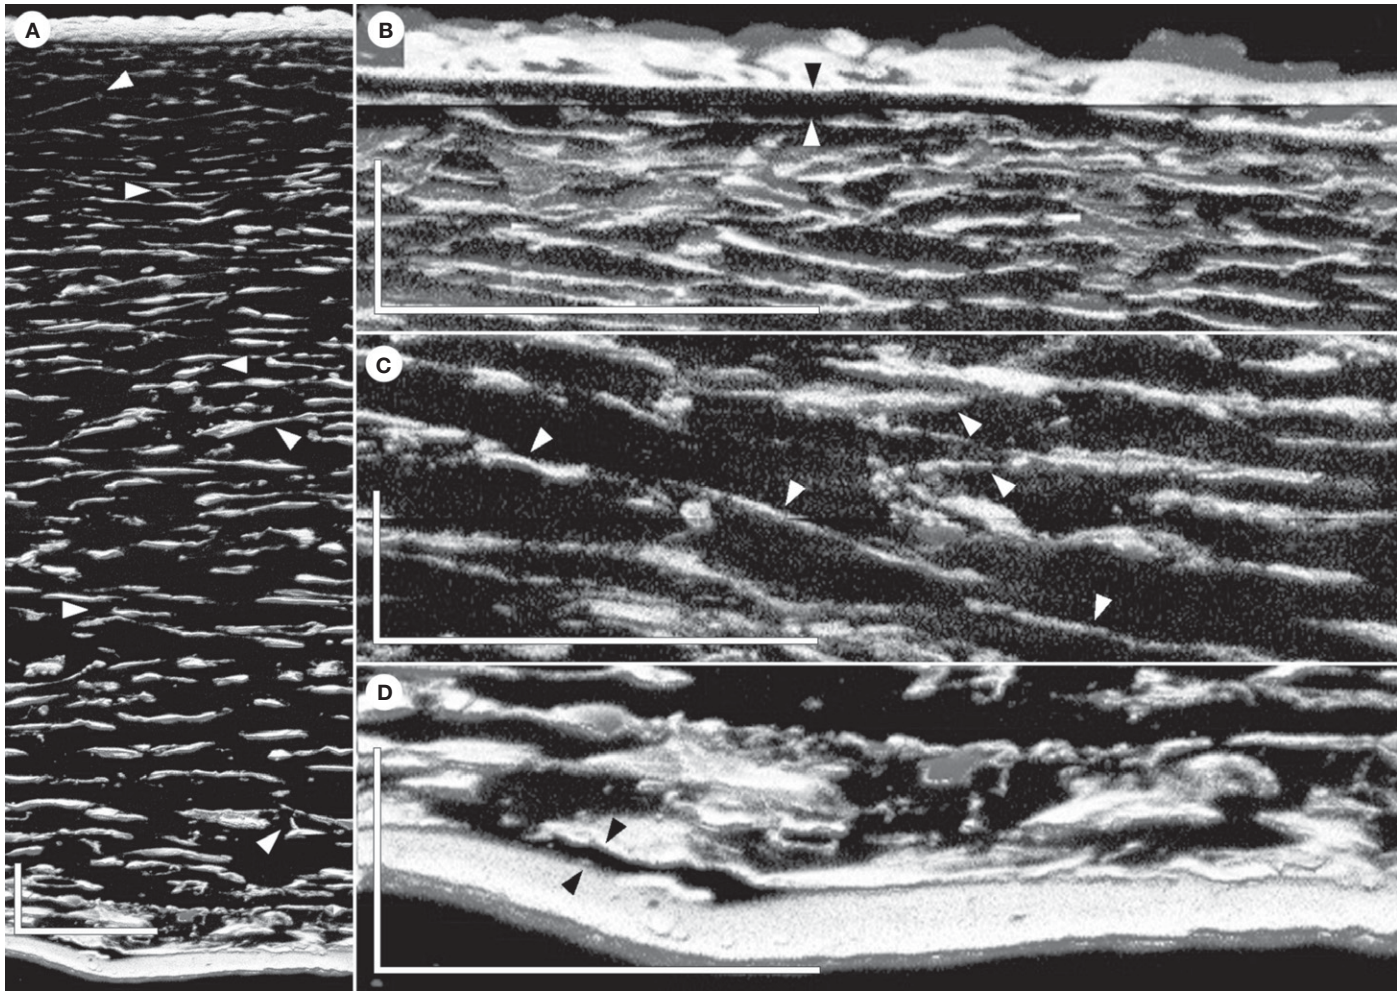

Figure 6.2. *A,* Human cornea visualized using a live cell tracker dye (CMFDA) in an anteroposterior direction. The light colored cells appear in layers interspersed with extracellular matrix (unstained), but processes appear to run between layers linking them (arrow heads). *B, C,* and *D:* higher magnification images at the anterior (*B*), mid (*C*), and posterior (*D*) levels of the stroma. Cell density is higher at the anterior level but the keratocytes here are finer in structure. Arrow heads in *B* indicate Bowman's layer. Arrow heads in *C* indicate cell to cell contacts between keratocytes and arrow heads in *D* indicate an extracellular matrix between a stromal keratocyte and Descemet's membrane. Note that Descemet's membrane shows positively with the cell tracker dye but is an acellular structure.[5] (Reprinted courtesy of Clinical and Experimental Ophthalmology.)

proliferate, is stimulated by the release of platelet-derived growth factor (PDGF) and transforming growth factor β (TGF-beta) from the epithelium into the stroma.[3,11] PDGF along with epidermal growth factor (EGF) and insulin-like growth factor (IGF) have been implicated in the inhibition of apoptosis once healing is under way.[20,21] A significant increase in TGF-beta binding is initially observed at the wound margin, playing an important role in modulating the inflammatory response and in providing the stimulus for fibroblasts at low cell density to transform into myofibroblasts.[22] This latter transformation is enhanced with the interaction of PDGF.[23] Later in the healing cascade, fibroblast growth factor (FGF) has been observed to play a role in the latter stages of wound closure. In culture FGF has been shown to induce the conversion of myofibroblasts to fibroblasts,[22] a function seemingly supported by the fact that FGF inhibits TGF-beta expression,[24] which drives the transformation in the reverse direction. Whilst the above data seem to indicate specific roles for specific cytokines in corneal wound healing, the interactions between growth factors and cell, and growth factor to growth factor inevitably means that the right combination of factors needs to be expressed with spatial and temporal coordination to ensure correct wound healing.

Several trophic factors have been identified within the human cornea, the most prominent of which is nerve growth factor (NGF), which has been shown to be essential in neuronal regeneration after injury.[25,26] However, NGF has also been shown to play roles in cell proliferation, migration, and differentiation in non-neural cells.[27–29] Indeed, topical NGF has been applied with success in human chronic corneal epithelial defects such as immune or neurotrophic ulcers[30,31] and been shown to accelerate the healing at the surgical incision site after cataract surgery.[32] Whilst this indicates a direct role for NGF in corneal wound healing by exerting an effect upon the non-neuronal cells, the relationship between the abundant corneal nerves, the non-neuronal cells with which they interact and NGF remains to be elucidated.

REMODELING OF EXTRACELLULAR MATRIX

Corneal wounds that enter the stroma require not only deposition of new matrix components but also the removal of old damaged matrix components and then extensive remodeling of corneal repair tissue. Initial phases of wound healing which involve the removal of damaged stroma is orchestrated by the plasminogen-activator/

Figure 6.3. A detailed view of keratocytes in anterior (*A*), mid (*B*), and posterior (*C*) stroma shown using live cell tracker dye (CMFDA). Arrow heads in *A* clearly show fine cellular processes linking keratocytes and indicating that the tissue behaves as a syncitium. In *B* the mid-stroma is seen to be more sparsely populated. In *C* stromal keratocytes appear to form more cell body to cell body contacts, with arrow heads indicating fine fenestrae on the cell bodies.[5] (Reprinted courtesy of Clinical and Experimental Ophthalmology.)

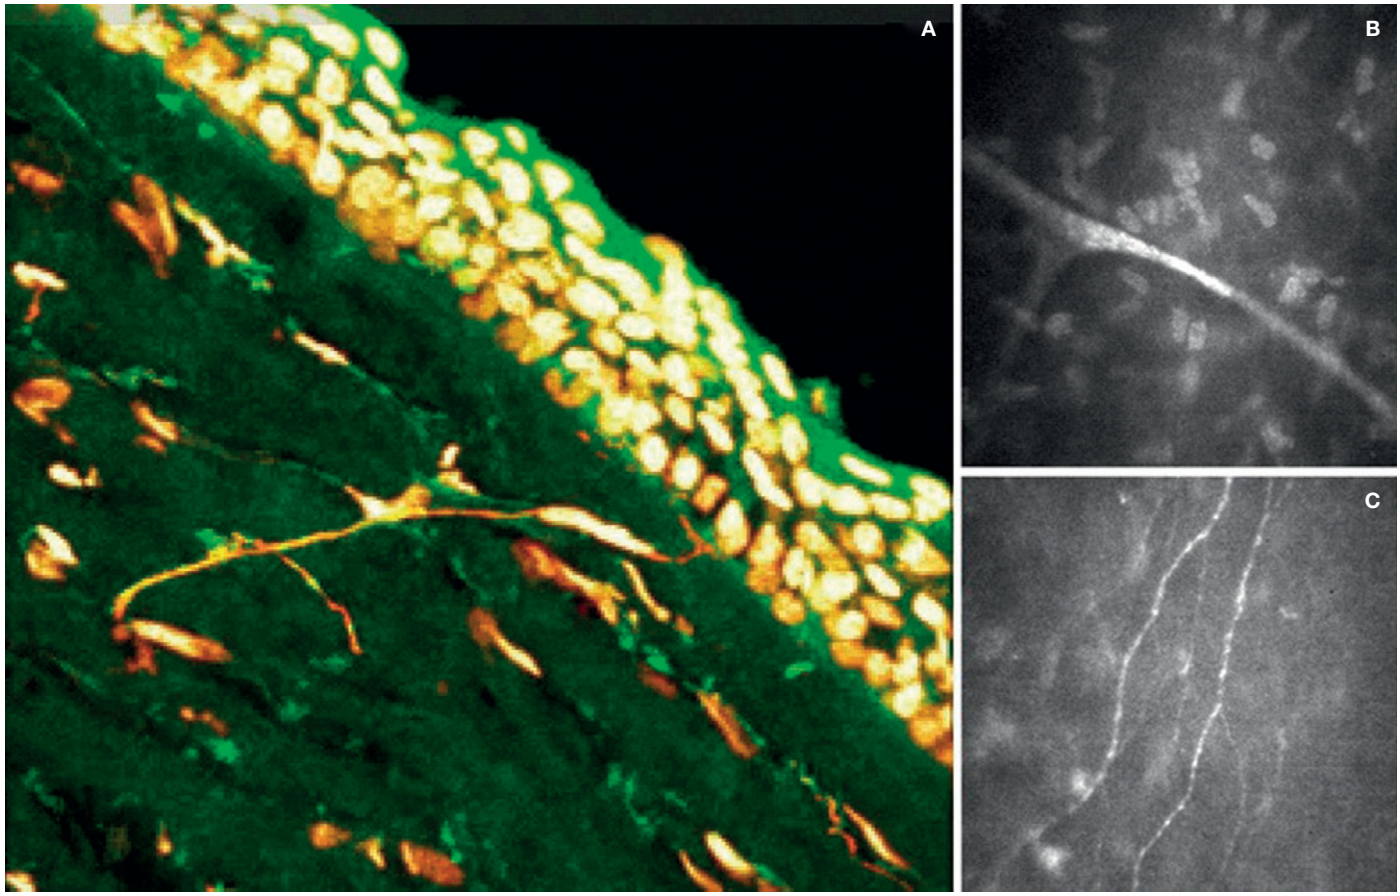

Figure 6.4. *A,* Immunofluorescence detection of stromal nerves and cell nuclei shows a nerve approaching and crossing Bowman's membrane before spreading along the basal layers of the epithelium. The nuclei of several stromal keratocytes can be seen in association with the nerve before it contacts the epithelium. Stromal nerves may provide a direct route of communication between keratocytes and epithelium. *B,* In vivo confocal microscopy of stromal nerves also shows association of keratocytes with the nerve axons. These axons give rise to the nerve fibers which form the sub-basal nerve plexus shown by in vivo confocal microscopy (*C*).

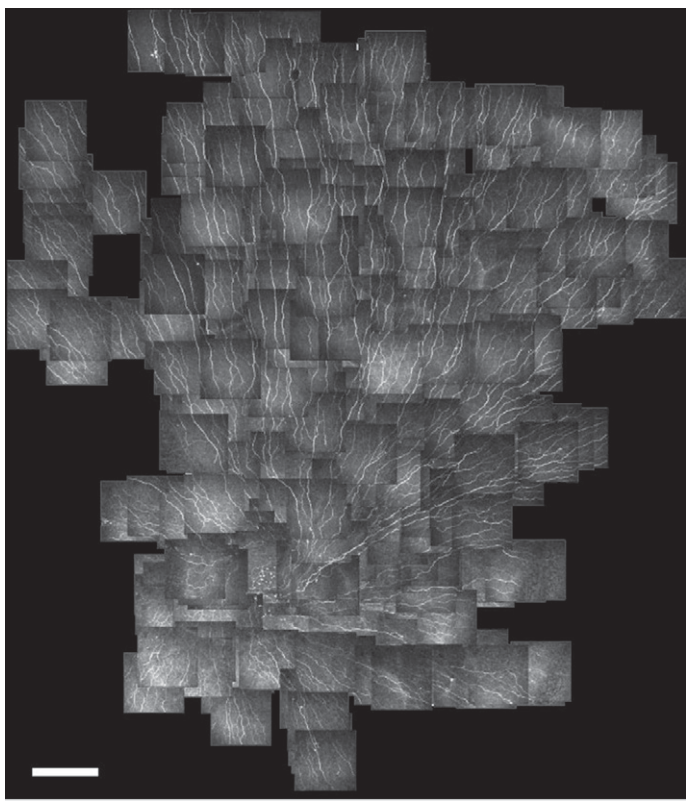

Figure 6.5. A montage of 315 in vivo confocal images depicting the architecture of the sub-basal nerve plexus of a single subject over the central and near peripheral cornea. Images were captured using the HRT II fitted with the Rostock corneal module. Scale bar, 400 μm.

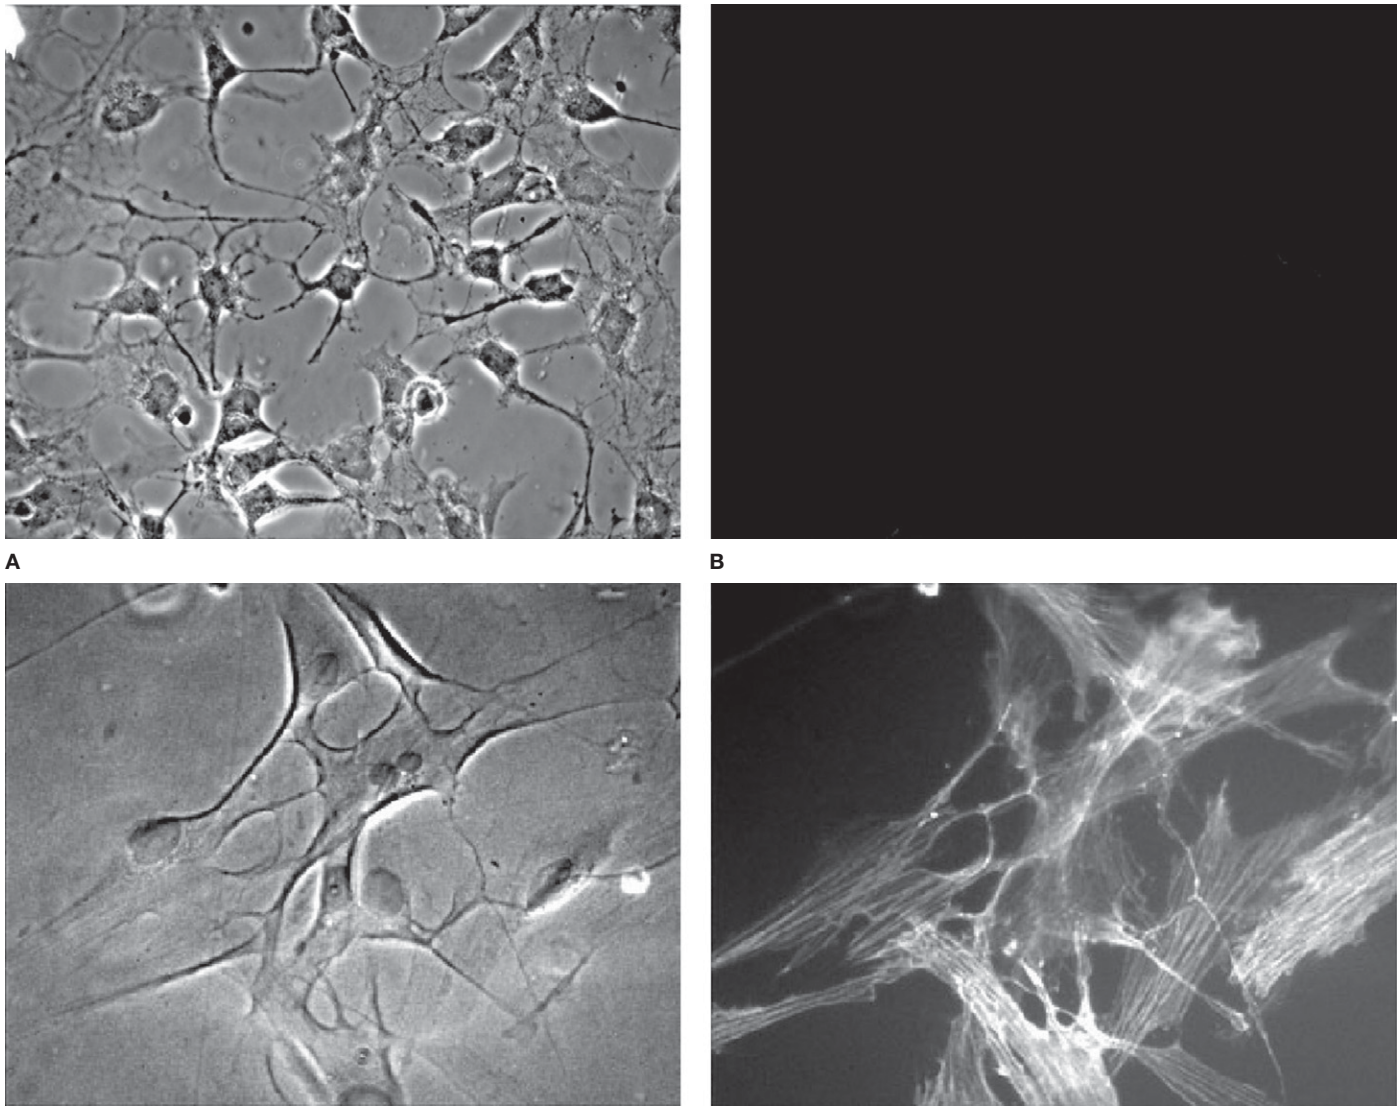

Figure 6.6. *A,* Human stromal keratocytes in culture retain their in vivo morphology with fine processes linking cells. *B,* Immunohistochemical labeling indicates that these cells are devoid of filamentous actin. Upon insult (serum addition) the keratocytes undertake a fibroblastic morphology (*C*) and have now assembled actin stress filaments in their cytoplasm (*D*).

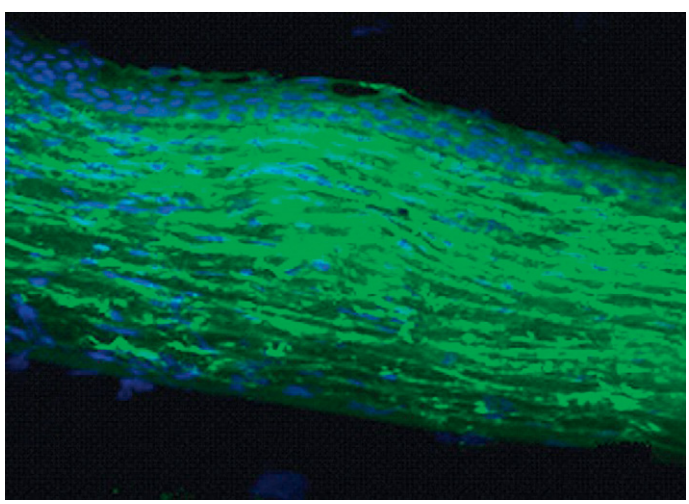

Figure 6.7. Alpha smooth muscle actin labeling myofibroblasts in the peripheral stroma of a laser-ablated rat cornea. The smooth muscle actin appears green with cell nuclei highlighted in blue. Even though the PRK ablation was in the central region of the cornea, keratocyte differentiation has occurred though the full thickness of the cornea peripheral to the wound site and the cornea has swollen to double its normal thickness.

plasmin system[33,34] and by matrix metalloproteinases.[35] Members of the family of zinc-containing endo-peptidases, the matrix metalloproteinases (MMPs), which are expressed at very low levels in normal tissue, have been implicated in the turnover of matrix components in corneal wound healing. The expression of MMPs is upregulated in response to inflammation and during remodeling of tissues in response to cytokines and growth factors.[36]

Only one MMP has been shown to be present in the intact normal cornea, namely MMP2, also known as gelatinase A, as these proteolytic enzymes were first named after the substrates that they cleaved. This enzyme is capable of cleaving fibronectin, denatured collagens, and basement membrane components, and has been detected in normal human corneal stroma. The origin of MMP2 in the stroma appears to occur in the most part by diffusion from the aqueous humor[37] but as little tissue remodeling is required in the quiet cornea the metalloproteinase is in its pro-enzyme form and associated with a specific inhibitor for MMP2, namely tissue inhibitor metalloproteinase 2 (TIMP2).

Studies comparing expression of MMPs in the stroma of corneal wound models compared with unwounded cornea found MMP 1 (collagenase), MMP3 (stromelysin-1), and MMP9 (gelatinase B) were all present 24 h after the wound was created but still absent from the unwounded cornea. MMP2 levels had significantly increased and now the enzyme was in an active form. Other studies have demonstrated MMP expression during the time course of repair tissue deposition and subsequent long-term remodeling.[38,39] The expression pattern of all four MMPs follows similar kinetics. For example, MMP1 increases 1.4-fold between 1 and 4 weeks after insult while cell numbers rise 4.5-fold. Between 4 and 8 weeks after injury, the MMP1 level drops 4.2-fold while cell number decreases by only 1.8-fold up to week 10. This shows that MMP1 levels are not related to stromal cell numbers but are being regulated temporally. Of interest is the fact that nonsteroidal anti-inflammatory drugs (NSAIDs) do not downregulate MMP gene expression, with MMPs 1 and 8 being expressed in increasing amounts in ulcerative keratolysis from topical NSAID use.[40] In photorefractive keratectomy (PRK) treatment, a fast wound-healing process was found to be associated with very high levels of MMP8 and membrane type 1-MMP (MT1-MMP)[36] and their activation, suggesting a role for MMP8 and MT1-MMP in the corneal wound healing cascade. In skin wounds the activation of MMP2 has been correlated with the expression of MT1-MMP,[41] which could signal a joint role in corneal wound healing.

EXTRACELLULAR MATRIX MOLECULES

The stromal fibroblasts and myofibroblasts are responsible for stromal remodeling after wounding through the production and resorption of collagen and the production of glycosaminoglycans.[2,36] The provisional corneal wound matrix produced is rich in fibronectin and chondroitin sulfate, which enhances the migration of repair fibroblasts into the wound area.[42] In contrast to the upregulation of chondroitin sulfate proteoglycan is the decrease seen in the levels of keratan sulfate proteoglycan in the wounded stroma.[43] The deposition of fibronectin in the provisional matrix is mirrored by the repair fibroblasts turning on the synthesis of the $\alpha 5$ integrin chain to form the $\alpha 5\beta 1$ integrin heterodimer, classically defined as the fibronectin receptor. It has been proposed that acquisition of this receptor allows focal adhesions to fibronectin and thus may contribute to the ability of the fibroblast to migrate on the fibronectin-rich provisional matrix.[44] Using in vitro models of human corneal fibroblasts in collagen gels, it has also been demonstrated that the presence of fibronectin or vitronectin was required for contraction of the collagen gels.[45] Molecules which are normally present only in the basement membrane also seem to be deposited within the provisional stromal matrix, including type IV collagen, type VII collagen, and laminin.[2] After formation of the provisional matrix the remodeling phase begins as the initial provisional matrix that results in scarring is gradually replaced with matrix that will be more functional in terms of optical quality. This matrix contains type I and type III collagen that were not part of the provisional matrix. Thus, it is suggested that the provisional matrix, which is rich in fibronectin and chondroitin, promotes the entry of migrating repair fibroblasts into the wound site and also may promote the contractile functions of the myofibroblast aiding in pulling wound edges together. Upon reversion to normal keratocyte phenotype the scar tissue is gradually remodeled over a period of years in an attempt to restore optical quality.

COMPARISON WITH SKIN WOUND HEALING

The tissue model used for many wound-healing studies has been the skin. Due to the similarities between skin and cornea—both are composed of a collagenous stroma with the corneal stroma being the equivalent of the dermis in skin, and both are overlaid with a squamous epithelium—it is not surprising that the knowledge gained from skin wound healing has largely proved directly transferable to the cornea, the most significant difference being the limited number of cell layers (five to seven) in the corneal epithelium. The corneal keratocytes and skin fibroblasts play similar roles, and undergo similar phenotypic changes during wound repair to close the wound (differentiating into myofibroblasts) or to lay down scar tissue. Many of the cytokines involved in wound repair are duplicated, such as TGF-beta3 which has been the focus of therapeutic intervention in both tissues. However, there are also differences in the wound healing process that exist both due to anatomical differences and also probably due to the need to maintain the function of the cornea, especially its transparency. One major factor contributing to corneal transparency is the precision with which the stromal matrix is ordered. First, the collagen fibrils are composed of heterodimers of type I and type V collagens, which allows a very narrow fiber diameter. Second, type VI collagen is present within the cornea at unprecedented levels. This type of collagen is not located within the fibrils themselves, but instead forms thin filaments with a 100-nm periodicity.[46,47] These type VI collagen filaments have been shown to run alongside and between the collagen fibrils[48] and are thought to interact with stromal proteoglycans within the interfibrillar matrix to determine the interfibrillar distance of the collagen fibrils.[49] The emergence of new collagen types such as type XII collagen that has been shown to be present in the quiescent stroma may play a role in the arrangement and assembly of the collagen fibrils.

SURGICAL WOUNDS: HEALING AND VISUAL OUTCOMES

SUTURED AND UNSUTURED WOUNDS

Penetrating keratoplasty is historically the oldest, the most common, and the most successful form of transplant procedure performed

worldwide. Two forms of suturing are used to secure the tissue in place, continuous and interrupted, and surgeons variously use one or both. The presence of sutures within a surgical corneal wound provides several beneficial functions. Firstly, the suture brings together the edges of the wound, eliminating empty space, thus minimizing the distance that repopulating cells (fibroblasts) must travel. Secondly, the suture limits epithelial ingrowth and thirdly it provides immediate tensile strength. Finally, sutures act as an inflammatory stimulus for leucocytes and macrophages which assist healing and also provide substrata along which these cells may move.[50] Modern cataract surgery now routinely uses the corneal step method, which uses intraocular pressure to seal the unsutured wound and the corneal flap created during LASIK refractive surgery also remains unsutured.

Comparative studies on deep sutured and unsutured wounds in a primate corneal model and observation of human tissue postmortem that had undergone previous surgery revealed some interesting findings.

Sutured wounds were found to (1) lack epithelial plugs, (2) exhibit more complete healing, (3) display substantial sub-epithelial fibroplasia with a hypertrophic scar, and (4) display fibroblasts and lamellae that spanned across the wound. Similar wounds that were left unsutured displayed (1) prominent, chronic epithelial plugs (Fig. 6.8), (2) less complete healing, (3) a lack of sub-epithelial fibroplasia, and (4) fibroblasts and lamellae that ran parallel to the wound edge.[51]

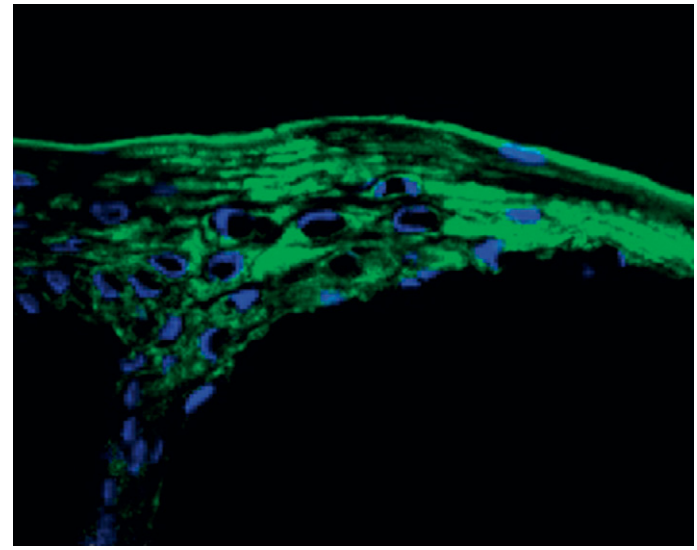

Figure 6.8. The formation of an epithelial plug, which serves to fill unwanted tissue gaps and provide a smooth ocular surface, is a common postsurgical occurrence of unsutured corneal wounds. The figure depicts an in vitro model of unsutured corneal wounds that forms perfect epithelial plugs, seen here immunolabeled for keratins 3 and 12 (green) and counterstained with DAPI to show nuclei (blue).

PENETRATING KERATOPLASTY

The healing of a human corneal wound does not occur by the reanastomosing of the cut ends of collagen lamellae within the stroma. Rather, healing occurs by the deposition of a provisional matrix within the wound site, which intercalates with the existing lamellae.[2] Thus the physical architecture of the wound in penetrating keratoplasty (or any other incision for that matter) will play a role in the healing process. Often the donor and recipient corneas are not cut so that the edges lie at 90° to the cut surface but rather to form a trapezoid with the longer of the parallel sides at the corneal surface (Fig. 6.9). The recovery of tensile strength within the wound has been shown to be slow in animal models, with tensile strength being 8, 36, and 50% of normal at days 10, 40, and 100, respectively. However, in humans the recovery is even slower with 50% of normal corneal tensile strength being reached between 2 and 3 years postoperatively.[52]

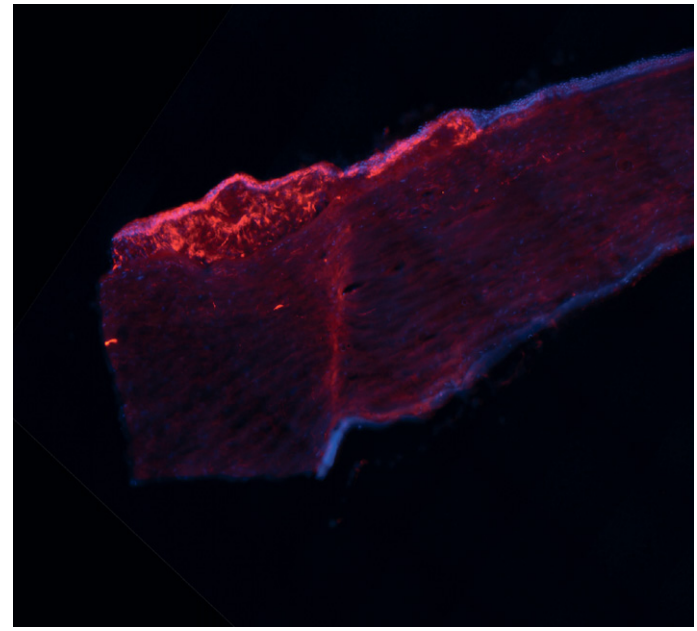

Figure 6.9. The host–graft junction of a cornea from a 70-year-old female grafted 10 years previously for keratoconus, and now being regrafted for progressive astigmatism. The graft had no previous history of rejection and exhibited no vascularization. The grafted cornea, fixed, frozen, and crysectioned, has been stained for actin and counterstained with DAPI to show the nuclei. Of interest is (1) the host–graft junction interface which is not perpendicular to the corneal surface, (2) the presence of actin positive cells (fibroblasts) at the interface 10 years post-graft, and (3) the disrupted nature of the epithelium from the recipient spilling across the junction to involve the epithelium on the graft.

REFRACTIVE SURGERY

The cellular response to refractive surgical techniques, PRK and LASIK have been analyzed in a rabbit model.[53] This study found that there was increased keratocyte apoptosis, keratocyte proliferation, and myofibroblast generation in PRK for high myopia in comparison with LASIK for high myopia or PRK for moderate myopia. In LASIK eyes, keratocyte apoptosis and proliferation occurred within the stroma above and below the lamellar interface of the flap. In contrast, in corneas after PRK procedures, keratocyte apoptosis was observed in the anterior stroma with proliferation occurring in the posterior and peripheral stroma. No generation of myofibroblasts was observed in the central cornea of eyes after LASIK for high myopia or PRK for moderate myopia. The authors suggested that the proximity of the stromal cellular processes to the overlying epithelium in PRK treatment facilitates the generation of

myofibroblasts and other healing processes. Further noted was the agreement of the above rabbit data with the low incidence of haze noted in LASIK or low myopia PRK treated human corneas.[54–56]

A recent study examined corneal wound healing after LASIK where the corneal flap was created using a conventional mechanical microkeratome versus a femtosecond laser.[57] The study found no difference in keratocyte activation or migration between the two techniques, but the authors did note a modulation of wound healing at the flap edge. It was noted that the flap edge produced by the femtosecond laser was more defined than the edge produced by the mechanical microtome, the latter of which also showed epithelial cell invasion rather than the epithelial plug seen in the femtosecond laser flap. At the 2-month examination of the microkeratome group, the epithelial cells had disappeared, leaving an irregular zone of fibrotic wound healing. In the femtosecond laser group at the 2-month examination, the stroma adjacent to the flap was hyperreflective, suggestive of a wound healing process, but no activated or abnormally large keratocytes were present. The authors suggested that the more abundant fibrotic tissue in the femtosecond laser group was due to the precision cutting of the laser. In the microkeratome flap the cut edge resembles an incision wound, producing tighter fitting edges on contact, whereas the femtosecond laser flap produces a gap which is filled by an epithelial plug producing a greater interaction between epithelium and stroma, thus producing greater scarring. The femtosecond laser is said to create greater corneal stromal inflammation than the mechanical microtome up to 24 h postoperative, but a stronger flap adhesion.[58]

EMERGING AND FUTURE TECHNOLOGIES

STEM CELLS FOR STROMAL REPAIR

Pluripotent stem cells provide a source of cells for corneal stroma repair and engineering in vivo. They undergo asymmetric differentiation to reproduce themselves and progenitor cell offspring with high fidelity and potency. They usually reside in protective niches such as hematopoietic stem cells in the bone marrow, or limbal epithelial stem cells in the palisades of Vogt at the limbal rim (see Ch. 12.6 for further details on epithelial stem cells). Although still poorly understood, both limbal epithelial stem cells[59] and stromal stem cells[60] express putative stem cell markers such as ABCG2, p63, and PAX6, and lower levels of the gap junction protein connexin.[43] Stromal stem cells have only recently been identified,[60] residing near the highly vascularized limbal rim. As with limbal epithelial stem cells, they are label retaining owing to a slow cell cycle time and can therefore be isolated in a fluorescent activated cell sorter as a specific side population.

Autologous stem cell transplantation has proven to be a very effective surgical procedure for the restoration of badly damaged ocular surfaces.[61] Harvesting sufficient numbers of cells can result in deficiency in the donor eye[62] but may in the future be overcome by culturing holoclone balls providing a source of pluripotent cells for transplantation. The success rate for allogenic transplantation for bilateral injury or disease remains low despite the administration of immunosuppressants[63,64] but provides promise for the future, not only the cornea, but also for other tissues. Limbal epithelial stem cells transplanted into damaged retina are able to differentiate into a neuronal phenotype[65] and may play a role in stromal repair where epithelial–keratocyte interactions are important.[20] Stromal stem cells are also pluripotent, for example expressing cartilage-specific markers such as cartilage-oligomatrix protein, aggrecan and type II collagen under chondrogenic conditions, and glial fibrillary acidic protein, neurofilament protein and beta-tubulin II when grown in neurogenic culture medium.[60] Although hematopoietic stem cells may provide a source of keratocytes for stromal repair,[66] the stromal stem cells appear to be the first to be identified with truly keratocyte progenitor potential providing a possible resource for stroma cell-based therapy and tissue engineering.

GENE THERAPY AND GENE REGULATION

By 2005 technological advances had enabled more than 300 phase I and II gene-based clinical trials, but few have been applied to the cornea.[67] Yet the cornea is ideally suited for gene regulation, being readily accessible and immune-privileged. Wound healing with growth factors, for example, has had limited benefit owing to the vast soup of factors involved (over 3500 genes are significantly altered when a tissue is damaged[68]). The length of delivery, timing of application, and expense of production are important, but an overriding factor is the effective delivery of factors with sufficient bioavailability. Gene therapy and gene regulation protocols (ranging from transient antisense or RNAi strategies to stable viral transfections) offer a possible solution. Originally developed to correct heritable gene defects,[69,70] gene therapy is defined as a treatment based upon introduction of genetic material to provide therapeutic benefit, directly by the expression of a gene product, or indirectly by inducing translation of an antagonist or modifier product. In its wider sense, 'gene therapy' may include regulation of gene products at the mRNA level (antisense genes, RNAi, siRNA, antisense oligonucleotides, morpholinos, deoxyribozymes) although most of these do not necessarily involve stable transfection of genetic material. Methods of gene delivery may involve liposomes, electroporation, direct injection, coated particle bombardment, or viral techniques (such as viral vectors, recombinant adenoviruses, and retroviruses—for full review see ref. 71). Gene therapy has the potential to reverse myofibroblast differentiation using FGF-1 or FGF-2[22] or to inhibit the expression of TGF-beta to reduce postoperative scarring and PRK-induced corneal haze.[72] A plasmid vector-encoding tissue plasminogen activator (tPA) has shown promise in reducing fibrin formation, the biologically active tPA being detected for 4 days after vector application[73] and gene transfer of a TGF-beta type II receptor to block TGF-beta activity has inhibited corneal opacification, edema, and angiogenesis.[74] For disease conditions such as keratoconus, a strong increase in the Sp3 short isoform and a lack of the Sp3 activator long isoform causes a total absence of the nerve growth factor (NGF) receptor TrkA (and decreased levels of NGF itself along with reduced p75 neurotrophic receptor levels).[75] The possibility exists for future gene therapy for diseases of this type.

COMPONENT SURGERY AND CORNEAL ENGINEERING

Penetrating keratoplasty is the current treatment of choice for irreparably damaged corneas. The success rate is high owing to the low incidence of immunogenic rejection although once rejection does occur, secondary procedures are inevitably less successful. Furthermore, with alkali burns, immunological disorders, severe dry eye, stem cell deficiency, vascularization, ocular diseases such as Stevens–Johnson syndrome or neurotrophic scars secondary to herpes zoster ophthalmicus, penetrating keratoplasty may not be tolerated. Recent trends to replace only the essential tissues or cells, termed 'component surgery', help to reduce the risk of rejection and

may yield better refractive outcomes. Where surgery is required to repair stromal dystrophies, damage to the endothelium can be avoided reducing the risk of complications. Component surgery may include the epithelium, epithelial or stromal stem cells, portions of the stroma itself, or the endothelium. Tissue components may be transplanted as sheets using carriers or scaffolds, or as lamella sections (for review see ref. 76). Several procedures such as amniotic membrane carriers for the epithelium, endothelial lamella keratoplasty, and deep lamella keratoplasty are already in clinical practice. Epithelial sheet transplant has proven successful for burns, ocular surface diseases such as Stevens–Johnson syndrome, and ocular cicatricial pemphigoid.[77] Epithelial sheets are most commonly grown on amniotic membranes in air–liquid interface cultures using 3T3 feeder cells and are then applied to provide stromal covering and repair. These epithelia become multilayered and show differentiation through the layers, including expression of epithelial markers such as keratins 3 and 12.[78,79] Polymers and extracellular matrices have also been used; whether all of these cultured epithelial sheets contain cells with stem-like properties remains unresolved. In lamellar keratoplasties irregularities in the surface being grafted onto can leave haze, and keratomes that create lamellar flaps or caps are favored. Deep lamellar excisions to the level of Descemet's membrane is a relatively newer procedure[80] although perforation of Descemet's membrane remains the most common complication, occurring in approximately 30% of cases.[76] For endokeratoplasty, inclusion of Descemet's membrane and some deep stroma preserves the anterior corneal curvature reducing changes in astigmatism or refraction. Again, use of a microkeratome to prepare both host and donor tissues creates a smooth interface with better outcomes.[81]

Penetrating keratoplasty or component surgery are, however, both limited by the availability of suitable donor tissue with waiting lists exceeding 2 years now common in the USA.[82] This issue is further exacerbated by diseases such as HIV and hepatitis C, and by the increased use of LASIK corrective surgery, which renders the cornea unsuitable for grafting.[83] The development of keratoprostheses and tissue-engineered corneas has been rapid, especially since 2000.[84] The highly organized stroma, with over 300 highly ordered layers, represents a special challenge if the transparency of the cornea is to be maintained. Synthetic materials are readily available, have good optical properties, reduce the risk of disease transfer, and no postoperative remodeling is required.[85] However, biodegradable polymers are generally not suitable if they are to retain transparency,[86] and artificial materials must also be nontoxic, oxygen and nutrient permeable, and must avoid triggering an immune or inflammatory response that could lead to biodegradation, calcification or tissue melting.[85,87] Some keratoprostheses have now been in use since the 1990s (such as the Dohlman–Doane keratoprosthesis[88]) but complications are not unusual with artificial devices, including glaucoma, retroprosthetic membrane, melting, retinal detachment, and endophthalmitis.[89] As a result, there is a growing interest in cell-based engineered tissue replacements that mimic the structure and functions of the natural cornea. It is expected that cell-based engineering will ultimately lead to corneal substitutes that will play an important role in corneal healing and stromal repair. As noted above, the recent discovery of stromal stem cells[60] and the pluripotency of limbal epithelial stem cells offers numerous possibilities for tissue engineering, including autologous tissue engineering, provided the correct substrate and medium is provided. The multiple use of limbal rims returned from transplant surgery is especially appealing provided suitable matrices can be identified for cell population from the limbal rim. Currently, natural biopolymer hydrogels such as those based upon alginate, chitosan, agarose, and collagen are favored and have been shown to support three-dimensional growth of cells.[84] Since 85% of the stroma is extracellular matrix, the majority of studies have used gels based upon these components (primarily type I collagen, chondroitin sulfate, and heparin sulfate). One of the limiting factors has been the mechanical properties of the matrices used, with higher collagen concentrations and cross-linking techniques used to improve these.[82] Possibly owing to the poor mechanical properties of bioengineered corneas or corneal tissue for stromal wound repair, few tissue-engineered cornea research groups are seeking clinical application.[84] However, the potential of stem cell research coupled with advances in gene therapy, tissue engineering, and advanced corneal surgery provides a positive future for the corneal surgeon.

7 Corneal endothelium: structure and function in health and disease

Daniel G. Dawson, Dayle H. Geroski, Henry F. Edelhauser

Supported in part by NEI grants: EY-00933, P30-EY06360, an unrestricted departmental grant from Research to Prevent Blindness.

INTRODUCTION

The cornea covers the anterior one-sixth of the circumference of the globe. It is a clear, transparent, avascular structure richly supplied with sensory nerves in the anterior third of the corneal stroma. In fact, the corneal sensory nerve endings are found in the epithelium and they subserve touch and pain sensations. There are no lymph vessels or other channels for bulk fluid flow. The interface between the corneal tear film and the ambient atmosphere provides roughly two-thirds of the refractive power of the human eye. It, therefore, is a common point where medical (e.g. contact lenses) or surgical (e.g. laser in situ keratomileusis (LASIK) or surface ablation) interventions are performed to improve refractive errors. Much of its oxygen requirement for metabolic activities comes from the atmospheric oxygen dissolved in the tear film.[1] When the eyelids are closed, oxygen can also enter the tear film from the superficial conjunctival capillaries. Most nutrients such as carbohydrates, vitamins, amino acids, and other substrates are primarily delivered to the cornea through the leaky corneal endothelial barrier with a minor contribution from the vascular arcades of the limbus. Certain growth factors, immune constituents, or other substrates, like retinol (prevents epithelial keratinization), are secreted by the lacrimal gland and delivered to the cornea by the tears. Carbon dioxide and other metabolic end products are removed across the corneal endothelium to the aqueous humor, by the tear film, or through the limbal capillaries. The cornea itself is resilient, yet is described as viscoelastic in its response to stretching forces. Due to its avascular nature, the human cornea heals in a limited primitive fashion to injury,[2] albeit epithelial–stromal interactions and fibrous metaplasia of the corneal endothelial cells will result in localized areas of stronger fibrotic wound healing.

Although other cell types do exist in the cornea, like Langerhans and dendritic bone marrow-derived immune cells, trigeminal nerve dendrites, Schwann cells, and histiocytes, the human cornea is primarily composed of three cell types: epithelial cells, stromal keratocytes, and endothelial cells.[1] They all can replicate under mitosis, but they vary significantly in their in vivo self-mitotic capacity (proliferative capacity) with epithelial cells being the most renewable, stromal keratocytes being in the middle, and endothelial cells being the least renewable. This fact is seen clinically when epithelial cells can completely regenerate after injury (e.g. corneal abrasions) or can develop into cancer (e.g. squamous cell cancers that originate from limbal progenitor cells, or stem cells, at the Pallisades of Vogt), while endothelial cells are most commonly involved in age-related (e.g. Fuchs' dystrophy) or injury-related disease (e.g. pseudophakic bullous keratopathy), ultimately resulting in corneal edema and bullous keratopathy.

The limited proliferative capacity of human corneal endothelial cells apparently is only an in vivo phenomenon as endothelial cells can proliferate quite well in ex vivo cell culture conditions.[3–5] The in vivo mitotic quiescence of human corneal endothelium has been found to be predominantly due to cell contact inhibition, in part through the activity of p27.[3] This results in corneal endothelial cells being arrested in the G1-phase of the cell cycle.[4] High aqueous humor concentrations of TGF-beta2 along with age-related cellular senescence and lack of an injury-inducible cytokine-stimulating pathway are secondary fail-safe mechanisms that also suppress in vivo endothelial cell proliferation if cell-to-cell contact is compromised (e.g. endothelial cell damage).[3,4]

The purpose of this chapter is to describe the structure and function of the corneal endothelium in health and disease. Moreover, common potential endothelial stressors will be discussed, such as contact lenses and commonly practiced surgical procedures.

MICROSCOPIC ANATOMY, ULTRASTRUCTURE, AND PHYSIOLOGY

EMBRYOLOGY TO BIRTH

Although embryologic eye development begins at 4–5 weeks of gestation (27–36 days) during lens vesicle formation, the development of the corneal endothelium only occurs by the end of this time period when the first wave of neural crest-derived mesodermal cells begin to extend beneath the corneal epithelial cells from the

limbus at around 5 weeks of gestation (33 days). These cells form the primitive endothelium, which is initially composed of two-cell layers. By 8 weeks of gestation, a monolayer of cells is formed that starts to produce Descemet's membrane. The epithelium and endothelium remain closely opposed until 7 weeks of gestation (49 days) when a second wave of mesoderm begins to grow centrally from the limbus between the epithelium and endothelium producing the corneal stroma. By the third month of gestation, Descemet's membrane can be clearly recognized on histologic sections. By the seventh month of gestation, the cornea resembles that of the adult in most structural characteristics other than size. At birth in the full-term infant, the horizontal diameter of the cornea is only around 9.8 mm (surface area 102 mm^2), or approximately 75–80% of that of an adult human cornea (note that the posterior segment is <50% of adult size at birth). Additionally, at birth, the cross-sectional thickness of the epithelium averages 50 μm, the Bowman's layer averages 10 μm, the central cellular corneal stroma averages 450 μm, Descemet's membrane averages 4 μm, and the endothelium averages 5 μm thick.

INFANCY TO ADULTHOOD

The endothelium of the infant cornea is composed of a single layer of approximately 500 000 neural crest-derived cells, each measuring around 5 μm in thickness by 20 μm in diameter, covering a surface area of 250 μm^2.[6,7] The cells lie on the posterior surface of the cornea and form an irregular polygonal mosaic. The tangential appearance of each corneal endothelial cell is uniquely irregular, usually uniform in size to one another, and typically six-sided hexagons (which is the most energy efficient and optimal shape to cover a surface without leaving gaps).[8] They abut one another in an interdigitating fashion with a 2–4-nm wide extracellular space between each other. The extracellular space is known to contain discontinuous apical tight junctions (macula occludens) and lateral gap junctions (Fig. 7.1), thereby forming an incomplete barrier to the diffusion of small molecules. As corneal endothelial cells have numerous cytoplasmic organelles, particularly mitochondria, they have been studied and found to have the second highest aerobic metabolic rate of all cells in the eye next to retinal photoreceptors.[6] At birth, the central endothelial cell density of the cornea is around 5000 cells/mm^2.[7] Because the corneal endothelium has a very limited in vivo regenerative capacity (endothelial cells are currently hypothesized to proliferate—particularly in the corneal periphery near Schwalbe's line—at too low a rate to adequately replace dying cells) and because aging results in progressive cellular senescence, particularly in the central regions of the cornea in part through the activity of the cyclin-dependent kinase inhibitor p21, there is a well-documented decline in central endothelial cell density with age that typically involves two phases: a rapid and a slow component (Fig. 7.2).[4,5,7–9] During infancy, the cornea continues to grow over the first 2 years of life reaching adult size at 2 years of age with an average horizontal diameter of 11.7 mm (surface area 138 mm^2). It changes very little in size, shape, and optical properties thereafter. The only significant structure in the cornea that continues to grow after age 2 is Descemet's membrane as it gradually increases an additional 6–11 μm in thickness from birth to death. Due to corneal growth and age-related or developmentally selective cell death, during the fast component, the central endothelial cell density decreases exponentially to about 3500 cells/mm^2 by age 5 and 3000 cells/mm^2 by age 14–20.[8,9] Thereafter, a slow component occurs where central endothelial cell density decreases to a linear steady rate of 0.3–0.6% per year, resulting in cell density measurement around 2500 cells/mm^2 in late adulthood.[7–9] Because the corneal endothelium maintains its continuity by migration and expansion of surviving cells, it is not surprising that the percentage of hexagonal cells decreases (pleomorphism) and the coefficient of variation of cell area increases (polymegathism) with age.[8]

It is important when reviewing this information to realize that these are average central corneal endothelial cell counts from predominantly Caucasian US populations. Several studies reveal that important racial and geographic differences exist as Japanese, Filipino, and Chinese corneas have been found to have higher cell density measurements than Caucasians, while Indian corneas have lower cell densities (Table 7.1).[10–13] It is hypothesized that this range of central cell densities may be predominantly due to differences in corneal diameter and endothelial surface area between these groups (e.g. Japanese, Caucasian, and Indian horizontal corneal diameters averaged 11.2, 11.7, and 12.0 mm, respectively), but genetic and environmental factors are also a possibility. Additionally, this data applies only to central corneal endothelial counts

Table 7.1 Comparison of Endothelial Cell Density in Indian, American, Chinese, Filipino, and Japanese Populations

since recent work has shown that higher endothelial cell densities can typically be found in more peripheral aspects of the cornea (Fig. 7.3).[14] Therefore, it appears that corneal endothelial cell numbers decrease on average about 50% from birth to death in normal subjects. Because corneal decompensation typically doesn't occur until central density values approach 500 cells/mm^2 (90% decrease in endothelium from birth or 80% decrease from healthy adulthood level), there appears to be plenty of cellular reserve potential remaining after an average human lifespan of 75–80 years of life.[8,9] Estimates suggest that healthy, normal human corneal endothelium should maintain corneal clarity up to a minimum of 224–277 years of life, if humans lived that long.[9]

The primary function of the corneal endothelium is to maintain the deturgescence and clarity of the cornea through a barrier function and a pump-leak mechanism first described by David Maurice.[15] Secondarily, it is also known to secrete an anteriorly located basement membrane called Descemet's membrane and a posterior located glycocalyx layer.[1]

BARRIER FUNCTION

The barrier function of the endothelium is dependent upon having a sufficient number of corneal endothelial cells to cover the posterior surface of the cornea and having integrity of endothelial cellular tight junctions, which are present in the extracellular spaces between endothelial cells (Fig. 7.4). Clinically, the barrier function of the cornea can be assessed by the use of the specular microscope or the confocal microscope (endothelial cell density), and fluorophotometry (permeability). In healthy human corneas, this barrier prevents the bulk flow of fluid from the aqueous humor to the corneal stroma, but does allow moderate diffusion of nutrients, water, and other metabolites to cross into the stroma through the 2–4-nm wide extracellular spaces. The leaky endothelial barrier may initially seem inefficient, but when one considers that most nutrients for all layers of the cornea come from the aqueous humor, some limited leakiness of the monolayer is reasonable. Additionally, despite the normal loss of endothelial cells that occurs with age,

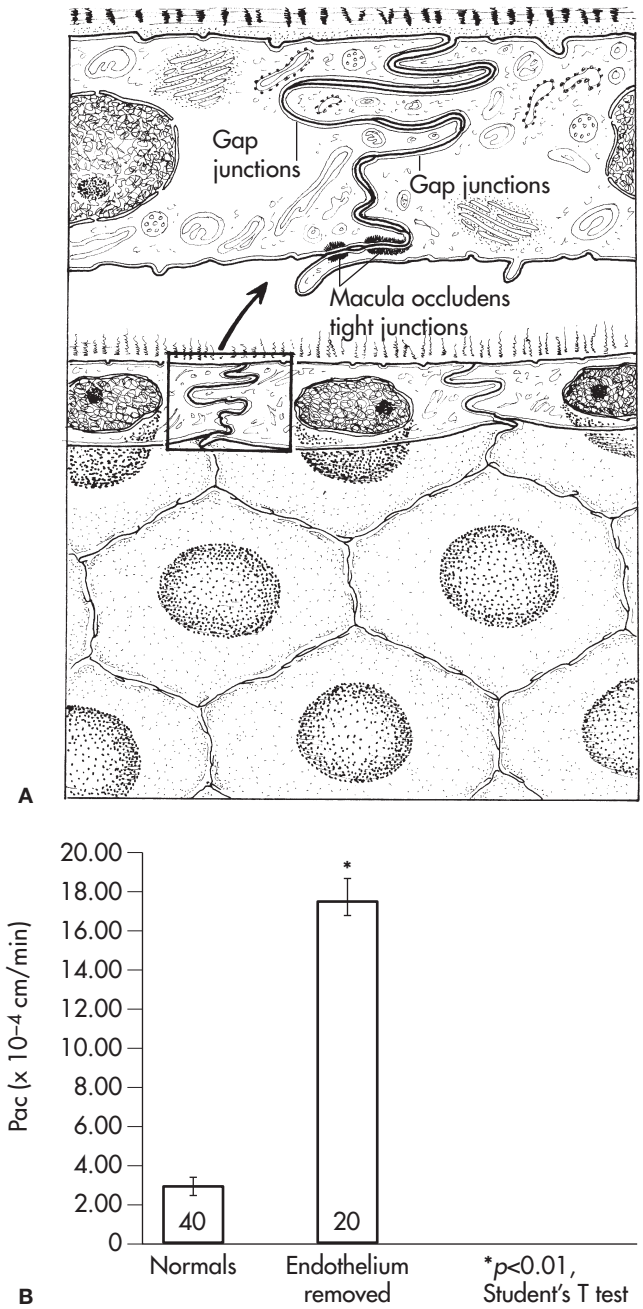

Figure 7.4. Diagram (*A*) and graph (*B*) illustrating the normal barrier function of corneal endothelium, which is due to endothelial cells covering the posterior corneal surface without gaps and the focal, tight junctions (macula occludens). The bar graph in *B* shows the normal permeability of human endothelial monolayer to carboxyfluorescein compared to that without endothelium, which resulted in a six-fold increase in permeability. (From Watsky MA, McDermott ML, Edelhauser HF. In vitro corneal endothelial permeability in rabbit and human: the effects of age, cataract surgery, and diabetes. Exp Eye Res 1989; 49: 751–767 with permission from Elsevier.)

there appears to be no appreciable increase in the permeability of normal, healthy aged corneas.[16] Only when the endothelium is severely reduced in cell density (central endothelial cell density = 2000 cells/mm^2), is acutely damaged, and/or has disrupted cell junctions, does its permeability increase (up to a maximum six-fold increase in permeability to carboxyfluorescein (12.85×10^{-4} cm/min) compared to normal (2.26×10^{-4} cm/min)).[16] Studies have inferred that during the fifth month of gestation the tight junctions completely form and the endothelial barrier is established.[17]

A number of factors have been known to acutely affect the barrier function of the endothelium, including the following: reversible disruption of cell junctions (calcium-free solutions or glutathione-restricted solutions); mechanical damage (e.g. trauma, IOL insertion); surgical instrument trauma; or chemical injury (e.g. non-physiologic or toxic intraocular solutions, preservatives). Fortunately, the remaining viable cells are able to migrate, re-cover the posterior corneal surface by spreading out over a larger surface area, and re-establish the intercellular cell junctions. Thus, the barrier function of the corneal endothelium is efficiently restored.

PUMP-LEAK MECHANISM

The classic temperature reversal studies provided the first evidence that the maintenance of corneal transparency was metabolically dependent.[18] Corneal thickness was found to increase when intact eyes were refrigerated. This effect was observed to reverse (i.e. the tissue thinned) when the tissue was re-warmed (temperature reversal). Subsequent in vitro corneal perfusion studies demonstrated that temperature reversal still occurred in the absence of the corneal epithelium, implicating active metabolically dependent processes in the corneal endothelium as mediating corneal deturgescence.[1] Subsequent studies demonstrated that transporters, located primarily in the endothelial cell's lateral cell membrane, effected the transport of ions—principally sodium (NA^+) and bicarbonate (HCO^{3-})—out of the stroma and into the aqueous humor. An osmotic gradient is created and water is thus osmotically drawn from the stroma into the aqueous humor.[19] It is important to note that this osmotic gradient occurs only if the endothelial barrier is maintained. A transport protein found to be essential to endothelial 'pump function' is Na^+/K^+-ATPase (Fig. 7.5).[20,21] Subsequently, the number and density of Na^+/K^+-ATPase sites have also been quantified using [3H]-ouabain.[21] These studies have shown that approximately 3 million Na^+/K^+-ATPase sites are present in the lateral membrane of a single endothelial cell. This corresponds to an average pump site density of 4.4 trillion sites/mm^2 along the lateral plasma membrane wall of an intact endothelium.[22] In rabbit corneas, studies have demonstrated that only by 5–7 months of gestation does the density of Na^+/K^+-ATPase sites increase to adult levels so that the cornea becomes dehydrated and transparent.[23] Clinically, the metabolic pump of the corneal endothelium can be assessed in vivo using pachymetry to measure how quickly the corneal thickness recovers after being purposefully swollen by wearing an oxygen-impermeable contact lens. A number of factors are known to alter endothelial pump function: pharmacologic inhibition of Na/K-ATPase (e.g. ouabain), decreased temperature, lack of bicarbonate or carbonic anhydrase inhibitors, and a chronic reduction in endothelial cell numbers from mechanical injury, chemical injury, or disease states. Fortunately, with regard to the latter, physiologic compensatory mechanisms prevent corneal edema from occurring to a certain degree when central endothelial cell densities are between 2000 and 750 cells/mm^2. This occurs by either increasing the activity of pump sites already present, which requires more ATP production by the cell, and/or by increasing the total number and density of pump sites on the lateral membranes of endothelial cells (Fig. 7.6).[22] A similar phenomenon occurs in the proximal tubule cells of the human kidney to adjust for an increased salt load. In Fuchs' endothelial dystrophy, for example, the cornea has been found to remain clear

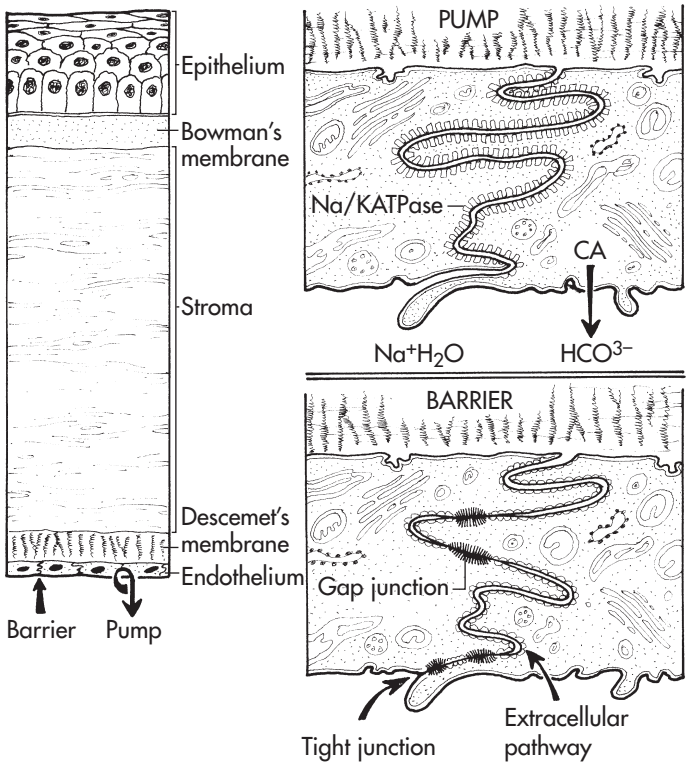

Figure 7.5. Diagram illustrating the opposing forces of the corneal endothelial barrier and metabolic pump. When the leak rate equals metabolic pump rate, the corneal stroma is 78% hydrated and the corneal thickness is maintained. (From Waring GO, et al. The corneal endothelium. Normal and pathologic structure and function. Ophthalmology 1982; 89: 531 © Elsevier 1982.)

and of normal thickness despite having very low endothelial cell counts and increased endothelial monolayer permeability to fluorescein (5.30×10^{-4} cm/min).[21] Apparently, this occurs because the metabolic activity and density of the Na^+/K^+ pump sites increase to compensate for the increased permeability.[24] The point at which compensatory mechanisms appear to ultimately fail is when the central endothelial cell density reaches 500 cells/mm^2 or less (range of 750–250 cells/mm^2) (Fig. 7.6).[7,25] At this low cell count, the permeability has greatly increased to such a point that the endothelial cells, which are spread so thin, do not have enough room on their lateral cell membranes for more metabolic pump sites and all the current pumps are maximally active. Therefore, the metabolic pump fails to balance the leak and corneal edema results. A summary of the entire corneal endothelial cell transport system was most recently reviewed by Bonanno.[26]

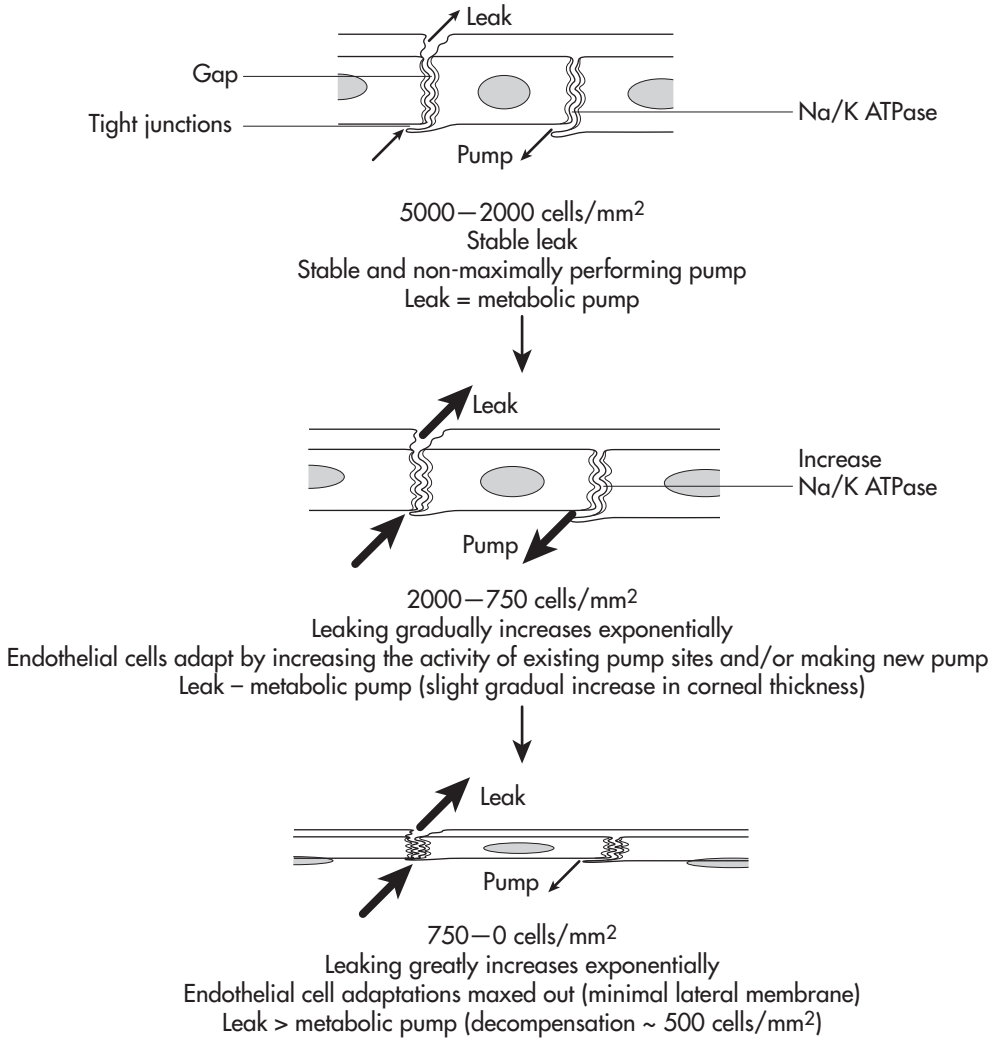
When the corneal endothelial barrier and metabolic pump are functioning normally, the corneal stroma has a total Na^+ concentration of 179 mEq/L (134.4 mEq/L free and 44.6 mEq/L bound to stromal PGs), while the aqueous humor has a total Na^+ concentration of 142.9 mEq/L (all free).[27] Therefore, after accounting for chloride activity and stromal imbibition pressure, an osmotic gradient of +30.4 mmHg exists causing water to diffuse from the stroma to the aqueous humor (Fig. 7.7). Additionally, the corneal endothelial cells contain high concentrations of carbonic anhydrase, which forms HCO^{3-} (bicarbonate) from metabolic CO^{2-}. The HCO^{3-} diffuses down its concentration gradient into the extracellular space or across the membrane to the aqueous humor via the Cl^-/HCO^{3-} exchanger[28] or through Cl^- (anion) channels.[29,30] Bicarbonate can also enter the cells via a Na^+/HCO^{3-} co-transporter,[31] and the intracellular pH can be regulated, at least in part, by a basal Na^+/H^+ exchanger.[32] Endothelial Cl^- transport occurs through both transporters and channels, with Cl^- entering the cell from the stroma via a basal $Na^+/K^+/2Cl^-$ transporter and the HCO^{3-}/Cl^- exchanger, and exiting into the aqueous humor via apical anion channels.[31–33]

ENDOTHELIAL CELL BASEMENT MEMBRANE AND GLYCOCALYX

A secondary function of endothelium is its ability to secrete an extracellular matrix. The secreted and deposited extracellular matrix along the basal surface of the endothelium forms Descemet's membrane (Fig. 7.1, *B*) and is essentially a life-long accumulated basement membrane of the endothelial cells. Although some collagen fibrils from the posterior stroma are embedded in the Descemet's membrane, it really has no major junctional or adhesional complexes to the posterior stroma other than a small 0.5 μm thick layer of fibronectin. Descemet's membrane is highly elastic and relatively strong since it is primarily composed of collagen (type IV and VIII) and glycoproteins (fibronectin, laminin, thrombospondin). At birth, it averages 4 μm thick. On electron microscopy, the fetal Descemet's membrane is composed of many wide-spaced, 110-nm banded collagen fibrils.[34] After birth, collagen is gradually added to this initial fetal layer throughout life, being notably different from the fetal layer as it is nonbanded and contains small diameter collagen fibrils that arrange into a lattice matrix.[34] Typically, the Descemet's membrane at the end of a normal human lifespan (75–80 years of age) measures around 10–15 μm thick (4-μm thick banded layer and a 6–11-μm thick nonbanded layer). With disease (e.g. Fuchs' dystrophy) or injury (e.g. trauma or surgery), the Descemet's membrane may become focally or diffusely thicker than normal from abnormal collagen deposition. This newly deposited abnormal collagen is called the posterior collagenous layer of the Descemet's membrane and is classified into one of three types: banded, fibrillar, or fibrocellular.[35] Presumably, this posterior collagenous layer is deposited because endothelial cells become stressed. Finally, the endothelium is also known to secrete a 0.72 ± 0.02 μm (mean ± SE) thick glycocalyx layer on its apical surface (Fig. 7.8).[7] Functionally, the glycocalyx layer appears to protect the endothelium, particularly in regard to anterior segment surgery.

WOUND HEALING

Because the primary role of the corneal endothelium is to maintain proper stromal hydration, the recovery of an intact and functional endothelial cell monolayer is essential to the maintenance of corneal transparency. As mentioned previously, corneal endothelial wound healing occurs predominantly by cell migration and enlargement rather than by cellular proliferation because of in vivo mitotic quiescent mechanisms.[5] Thus, injury to the central endothelium results in decreased cell densities, both in the central and the peripheral cornea.[36–38] The percentage of endothelial cells that are hexagonal (pleomorphism) is reduced (normal is >50%) and the coefficient of variation in cell size (polymegathism) is increased (normal is less than 45%).[36–38] In the rabbit, where wound healing is accompanied by both endothelial cell migration and near complete cellular reconstitution (i.e. proliferation), these parameters shift toward preoperative values during the time course of wound healing. In cat corneas, where minimal cell division occurs following endothelial wounding, cell density remains depressed; a similar situation occurs in the human cornea.



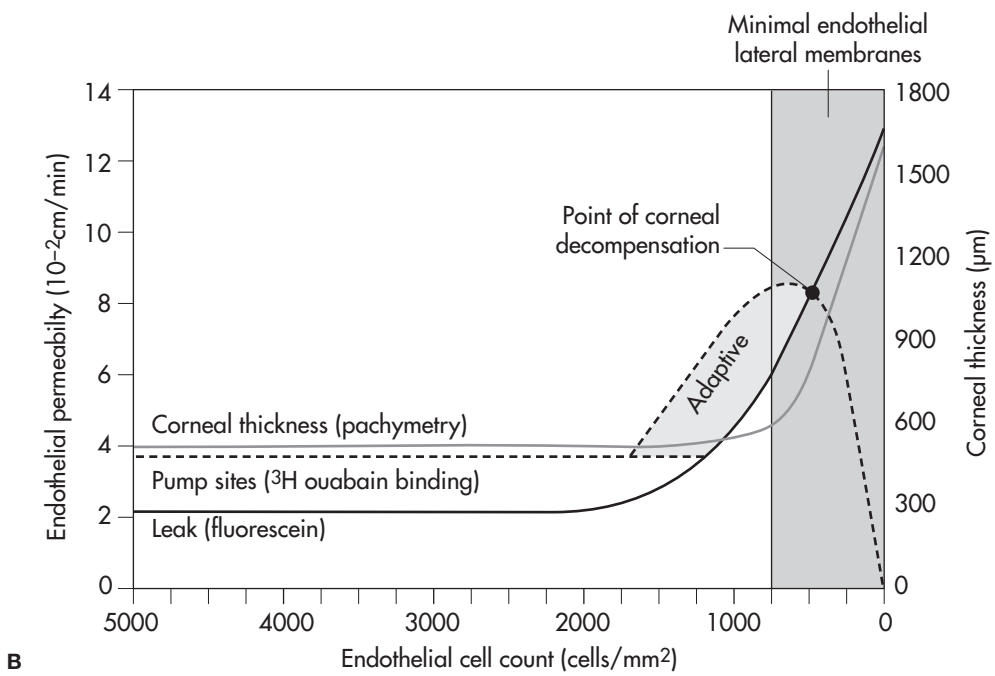


Figure 7.6. Diagram (*A*) and graph (*B*) illustrating the relationship between central endothelial cell density, barrier function, pump sites, and pachymetry. Note that the number of pump sites are not all maximally used in the normal state (5000–2000 cells/mm^2). With increased leaking (2000–750 cells/mm^2), there is an adaptive phase in which the endothelial cells can maximally use all the pump sites or form more pump sites to offset the leak up to a point. When the surface area of the lateral membranes of endothelial cells progressively becomes too small (750–0 cells/mm^2), these adaptations max out and eventually decline. The point where endothelial cell pump site adaptations crosses permeability (500 cells/mm^2) is typically when corneal decompensation occurs. (From Dawson DG, et al. Physiology of the eye and visual system: cornea and sclera. In: Duane's Foundation of Clinical Ophthalmology on CD-ROM. 2006; vol. 2c. 4: 1–76.)

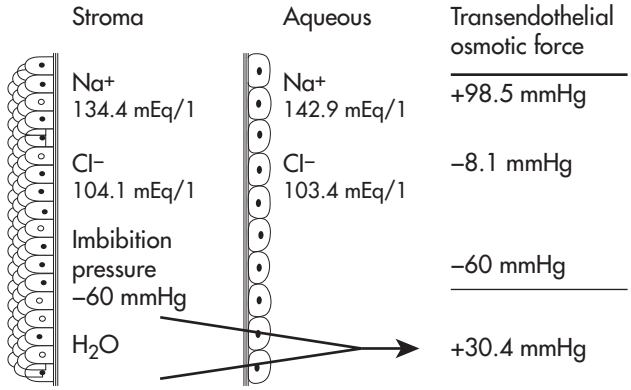

Figure 7.7. Diagram illustrating the total transendothelial osmotic force due to Na^+ activity, Cl^- activity, and imbibition pressure. Although the Na^+ activity within the aqueous humor is greater than that within the stroma (142.9 vs 134.4 mEq/L, $p < 0.05$), using a reflection coefficient of 0.6, the calculated osmotic force due to Na^+ is 98.5 mmHg. Similar calculations for Cl^- and imbibition pressure result in osmotic forces of –8.1 and –60 mmHg, respectively. The sum of these forces results in a total osmotic force of +30.4 mmHg, which ultimately results in deturgescence of the cornea. (From Stiemke MM, et al. Na^+ activity in the aqueous humor and corneal stroma of the rabbit. J Exp Eye Res 1992; 55: 425–433 with permission from Elsevier.)

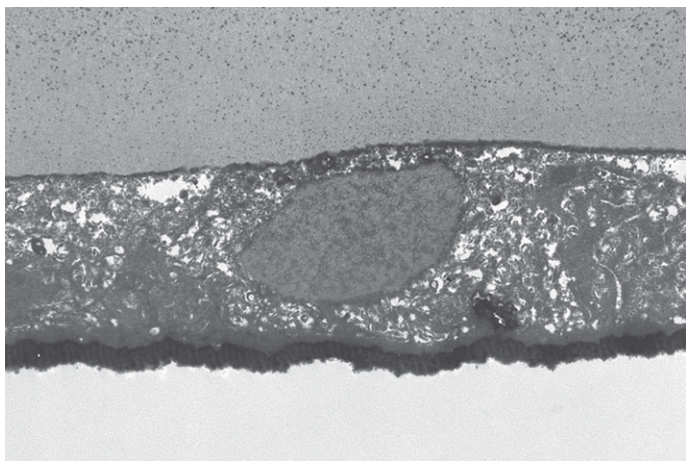

Figure 7.8. Transmission electron micrograph (×7300) using a special mucin preserving stain (2.5% glutaraldehyde with 0.1 M sodium cacodylate HCl and 0.5% cetylpyridinium chloride) demonstrates the natural 0.72 μm thick glycocalyx layer covering the apical surface of human endothelial cells. (From Deepta Ghate, MD.)

Several studies have examined endothelial cell function following wound healing. Yee and co-workers examined the permeability characteristics of the endothelium over the time course of wound healing, while incorporating a ouabain binding analysis to quantitate endothelial Na^+/K^+ ATPase pump site densities.[38] Based on these studies, it was concluded that the rabbit corneal endothelium following a transcorneal freeze injury heals in three stages. Stage one (0–3 days) is characterized by an initial coverage of the wound by pleomorphic spindle-shaped cells that form a functional, but incomplete barrier that have minimal pump site densities. In stage two (4–7 days), the endothelial cells assume a flattened configuration, have an irregular polygonal shape, and establish normal pump site density and barrier function. During this stage, corneal thickness was observed to show its most rapid rate of normalization. Stage three (8–30 days) is characterized by a remodeling of the endothelial cell monolayer. During the final stages of wound healing, cell rearrangement can occur (exchange of neighbors among cells by sliding past one another).

Endothelial wound healing in the cat cornea is slower and less complete in terms of returning to preoperative values than rabbits. Ling and co-workers found that removal of the central 6 mm of cat corneal endothelium resulted in stromal swelling that returned to preoperative values only by 35 days after wounding.[39] Central endothelial cell density decreased 25% at 4 weeks after wounding, and the coefficient of variation increased to 60%. In a separate study, it was found that permanent stromal swelling occurred in the cat when cell density was reduced to below 40–45% of control values.[40]

Human corneal endothelium appears to heal even slower and to a less complete extent compared to that of both the cat and rabbit. With aging, the number of replication-competent endothelial cells decreases and the number of senescent cells increases, particularly in the center of the cornea.[5] It is hypothesized that this increased central cellular senescence explains why age-related endothelial cell disease is primarily found in humans. Fortunately, humans can also tolerate more total cell loss than animals as chronic stromal swelling only occurs when cell density is reduced around approximately 80% of normal.

CORNEAL EDEMA

The Donnan effect states that the swelling pressure in a charged gel, like the corneal stroma, results from ionic imbalances. The fixed negative, or anionic, charges on corneal stromal proteoglycan GAG side-chains (one carboxylic acid and one sulfate ester side chain per disaccharide repeat on a dermatan sulfate GAG polymer, and one or two sulfate ester side chains per disaccharide repeat on a keratan sulfate GAG polymer) have a central role in this effect. The anti-parallel GAG duplexes (tertiary structure) produce long-range electrostatic repulsive forces that induce an expansive force termed swelling pressure (SP). Because the corneal stroma also has cohesive and tensile strengths that resist expansion, the normal SP of the non-edematous corneal stroma is around 55 mmHg.[41,42] If the stroma is further compressed (e.g. increasing IOP or mechanical applanation) or expanded (e.g. corneal edema), the SP will correspondingly increase or decrease. Conversely, the negatively charged GAG side-chains also form a double-folded helix in aqueous solution (secondary structure) that attracts and binds Na^+ cations, which results in an osmotic effect leading to the diffusion and subsequent absorption of water by proteoglycans via bound Na^+ cations. Thus, the central corneal thickness is maintained around its average value of 540 to 550 μm (based on ultrasound pachymetry) because the fixed negatively charged proteoglycans induce a constant swelling pressure through anionic repulsive forces, and because the hydration level of corneal stroma is constantly maintained at 78% water because corneal stromal proteoglycans imbibe water through cationic attractive forces.[43] Under normal circumstances, the negative pressure drawing fluid into the cornea, called the imbibition pressure (IP) of the corneal stroma, is approximately –40 mmHg.[44] This implies that the negative charges on corneal proteoglycans are only about one-quarter (~27 %) saturated, or bound, with Na^+ and water, and that the remaining unbound proportion is still available to bind more Na^+ and absorb more water if given either a compromised endothelium or epithelium, or both. Normally, the highly impermeable epithelium and mildly impermeable endothelium keep the diffusion of electrolytes and fluid flow in the stroma to such a low level (resistance to diffusion of electrolytes and fluid flow = epithelium (2000) >> endothelium (10) > stroma (1)) that the endothelial

cell metabolic pump can maintain stromal hydration in the normal range of 78%. Although IP = SP when corneas are in the ex vivo state, IP is actually lower than SP in the in vivo state because of the hydrostatic pressure induced by intraocular pressure (IOP), which now must be accounted for. This is best represented by the equation IP = IOP − SP[44] and explains why the hydration level of a patient's cornea is not only dependent on having normal barrier functions, but also on having a normal IOP. Therefore, a loss of corneal barrier function, an IOP ≥55 mmHg, or a combination of the two results in corneal edema.[45]

Corneal edema is a term often used loosely and nonspecifically by clinicians, but literally refers to a cornea that is more hydrated than normal, or >78% water. The topic of corneal edema is important for clinicians to understand because it affects the architecture and function of the corneal epithelium and stroma. Epithelial edema clinically causes a hazy microcystic appearance to occur in the epithelium in mild to moderate cases, significantly decreasing vision and increasing glare. It also can cause the development of large painful, sub-epithelial bullae in severe cases. These changes correlate histopathologically with hydropic basal epithelial cell degenerative changes and the development of extracellular subepithelial fluid filled spaces (e.g. cysts and bullae). Interestingly, if bullae are chronically present, a fibrocollagenous degenerative pannus often times will form in the subepithelial space, decreasing vision further but markedly reducing the pain. In comparison, corneal stromal edema clinically appears as a painless, hazy, thickening of the corneal stroma, resulting in a mild to moderate reduction in visual acuity and an increase in glare. At the same time, Descemet's membrane folds commonly appear on the posterior surface of the cornea. Histopathologically, these changes correlate with the light microscopic findings of thickening of the corneal stroma in the posterior cross-sectional direction with loss of the normally present artifacteous stromal clefting.[46] Ultrastructural and biochemical studies have further shown that stromal edema causes an increase in the distance and disruption of spatial order between collagen fibrils,[45] a decrease in the refractive index of the extracellular matrix,[47] hydropic degenerative changes or cell lysis in the resident keratocyte population,[48] and a loss of proteoglycans.[49] Although various proportions of the two types of negatively charged proteoglycan may account for the higher hydration levels in the posterior stroma compared to the anterior stroma,[50,51] it appears that the directional orientation of the collagen fibrils and degree of lamellar interweaving has the greatest influence on the amount of regional stromal thickening, or swelling, as a result of increased hydration levels. Because the collagenous architecture of the corneal stroma (i.e. limbus to limbus directional orientation of collagen fibrils) highly resists circumferential expansion, only anterior–posterior expansion occurs in the human cornea, mostly in the posterior direction. This occurs because most of the collagen fibrils in the anterior third of the corneal stroma are obliquely oriented and, perhaps most importantly, extensive lamellar interweaving occurs in the anterior third of the corneal stroma, whereas weak bridging filaments (i.e. type VI and FACIT collagens) occur diffusely throughout the entire corneal stroma. Furthermore, the lamellar interweaving explains why the anterior third of the cornea mildly swells and actually maintains the anterior corneal curvature even when the remaining stroma swells up to three times its normal thickness.[48] Because fibrotic corneal scars have random directionally oriented collagen fibrils, they also have been found to resist swelling under edematous conditions.[52]

Therefore, although it is commonly stated that corneal thickness and interfibrillar spacing increase in a linear fashion to the hydration level of the corneal stroma,[42,46] one needs to know that this relationship mainly applies to the posterior two-thirds of the corneal stroma. Finally, while both epithelial and stromal edema commonly co-exist together, there are two notable exceptions. As the epithelium lacks fixed negatively charged proteoglycans and has much weaker cohesive and tensile strength values than the corneal stroma, its state of hydration is mainly dictated by IOP levels.[53] Conversely, because collagen fibrils in corneal stroma are anchored at the limbus for 360°, they exert increasing or decreasing cohesive strength on the corneal stroma (i.e. compression of stromal tissue) as the IOP elevates above or decreases below normal, respectively. This results in the transmission of stromal edema to the epithelial surface in cases of high IOP or to the stroma in cases of low IOP. Therefore, if IOP is ≥55 mmHg with normal endothelial barrier and pump function, epithelial edema usually occurs by itself, or if endothelial cell dysfunction and hypotony (IOP ~0 mmHg) occur together, then stromal edema occurs alone (Fig. 7.9).

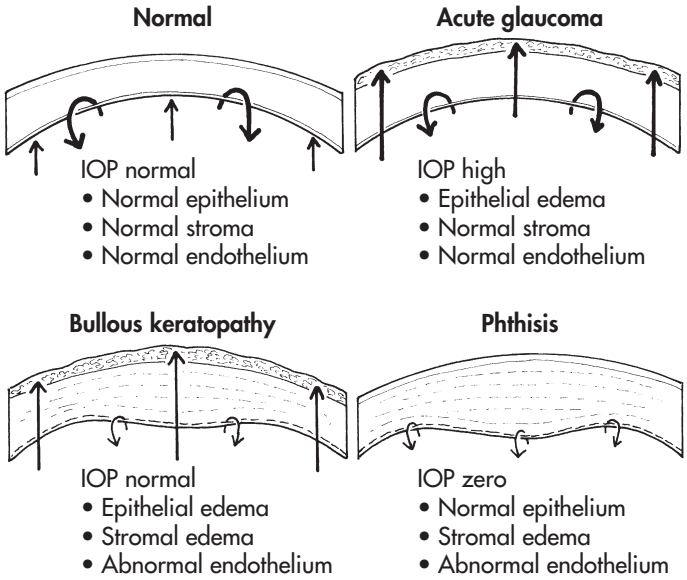

Figure 7.9. Diagram demonstrating the delicate balance between stromal swelling pressure, endothelial pump function, and intraocular pressure. Usually if endothelial cell pump function fails and IOP remains normal, both stromal and epithelial edema occurs (lower left). Only when IOP increases above the swelling pressure of the stroma and the endothelium functions normally do we see epithelial cell edema alone (upper right) and only when IOP is zero and the endothelium functions abnormally do we see stromal edema alone (lower right). (From Hatton MP, et al. Corneal oedema in ocular hypotony. Exp Eye Res 2004; 78: 549–552 with permission from Elsevier.)

INJURY

There are many exogenous stresses that could potentially damage the corneal endothelium over a person's lifetime (Fig. 7.10). Perhaps the most common interventions that might stress a person's cornea are contact lens wear, excimer laser-based keratorefractive surgery (LASIK, PRK), and intraocular surgery (cataract surgery, refractive IOL surgery, corneal transplantation).

CONTACT LENSES

Contact lens wear does not cause loss of endothelial cell density, but it can cause acute reversible corneal edema and can also potentially cause chronic signs of endothelial cell stress (increased polymegathism and decreased pleomorphism).[6,54] The corneal endothelium

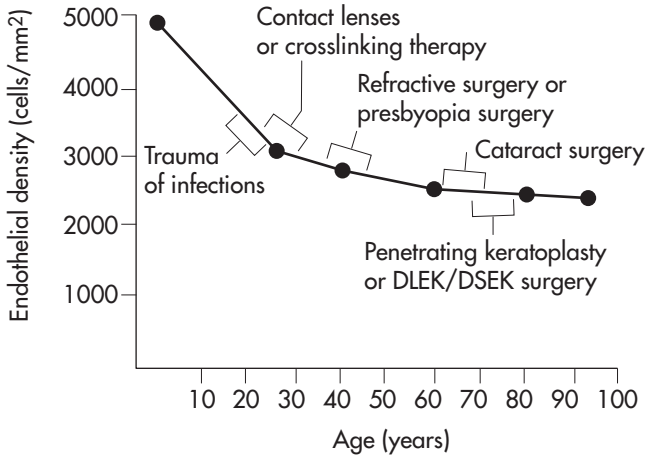

Figure 7.10. Graph demonstrating the normal decrease in endothelial cell density that occurs with aging. Located along the line graph are major endothelial cell stressors that commonly may occur in a person's lifetime, which may decrease the cell density loss greater than normal.

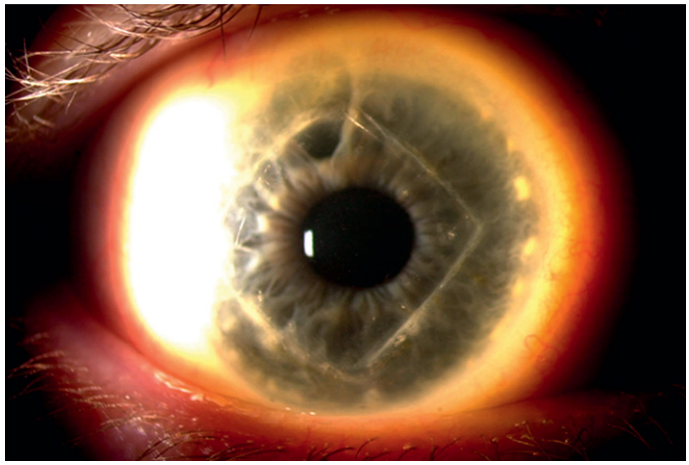
utilizes the same carbohydrate metabolic pathways as the corneal epithelium. However, the transport function of the endothelial cell requires oxidative activity that is five to six times that of epithelial cell.[55] Atmospheric oxygen is the primary source of oxygen to the endothelium. Interruption of this oxygen supply by low oxygen transmissibility contact lenses or a low oxygen environment will result in a shift to anaerobic metabolism, a concurrent increase in stromal lactic acid and CO_2, and a drop in stromal pH.[56] In addition, hypoxia can stimulate epithelial production of 12(R)HETE, a potent inhibitor of the endothelial Na^+/K^+ ATPase.[57,58] Acute reversible clinical changes observed with hypoxia include stromal swelling, endothelial dysfunction, and endothelial blebbing. Chronic hypoxia can eventually lead to irreversible endothelial polymegathism and pleomorphism. In fact, Polse and co-workers have shown that chronic corneal hypoxia in humans alters the endothelium's ability to reverse induced swelling.[59]

SURGICAL INJURY

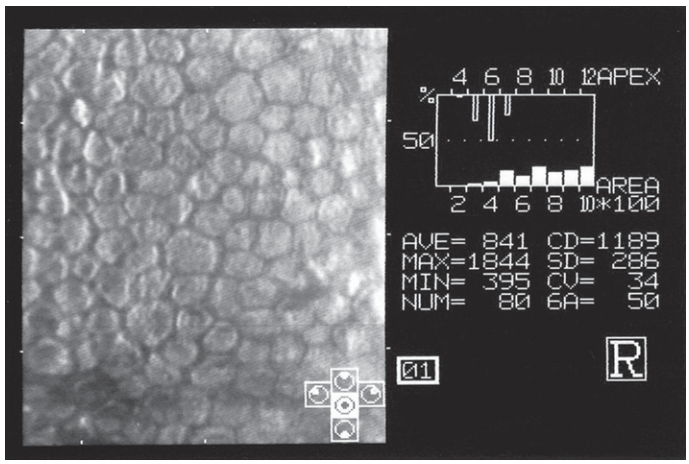
Excimer laser-based keratorefractive surgery has been found to induce acute, temporary endothelial cell stress (increased polymegathism and decreased pleomorphism) and loss of barrier function if performed on a cornea with a residual corneal thickness of 200 μm, presumably because of the shockwave produced by the laser ablation.[7] Otherwise, no long-term endothelial cell effects have been linked to laser refractive surgery.[7]

By comparison, all intraocular surgeries have been found to cause varying degrees of both acute and, more importantly, long-term damage to corneal endothelium. Modern small incision cataract surgery (Kelman phacoemulsification (KPE) + various foldable IOLs) is the preferred technique in the USA, Europe, and other more developed countries as randomized studies have shown that it results in better clinical outcomes compared to larger incision techniques, like extracapsular cataract extraction.[60] However, KPE does cause significant endothelial cell injury due to a number of factors, such as corneal distortion, ricocheting of nuclear fragments, intraocular lens or intraocular instrument contact, and release of free radicals.[61] A recent randomized controlled trial showed that KPE caused an exponential reduction in central endothelial cell density up to 1 year after surgery with endothelial cell density loss averaging 10.5%.[61] However, no significant changes in polymegathism or pleomorphism were found.[61] This fast component period of cell loss is statistically similar to that observed following extracapsular cataract extraction (ECCE), another common alternative technique used for performing cataract surgery (particularly in third world countries), which results in a 9.1% reduction in endothelial cell density at 1 year after surgery.[61] Capsule rupture with vitreous loss, hard cataracts, and age at the time of surgery are factors that have been shown to significantly increase endothelial cell loss rates (Fig. 7.10).[61] Long-term slow component cell loss data is currently unknown for KPE, whereas ECCE data shows that a 2.5% per year linear rate of cell loss occurs from 1 to 10 years after surgery.[9,54,61,62] Recent data on the two phakic refractive IOL procedures commercially available in the USA, Verisyse (Ophthec, distributed by Advanced Medical Optics) and the foldable Visian ICL (Staar Surgical), show less acute component damage than standard cataract surgery (Verisyse causes around 7% cell density loss and Visian ICL around 3% cell density loss at 1 year after surgery).[63] However, just like with ECCE, a chronic, slow component that is four- to nine-fold higher than normal cell loss has been observed over a 5-year postoperative time point (Verisyse causes on average 2.7% cell density loss per year and Visian ICL 2.5% cell density loss per year between 1 and 5 years after surgery).[63]

Corneal transplantation surgery, or penetrating keratoplasties (PK), has been found to cause the greatest long-term decrease in central endothelial cell densities of all the commonly performed intraocular anterior segment surgical procedures (Fig. 7.11), perhaps because of the peripheral loss of stem-like cells or the loss of the peripheral storage zone of higher cell densities.[64] Long-term longitudinal studies up to 20 years after surgery show that endothelial cell loss after corneal transplantation occurs in two phases: a fast and a slow component.[65] During the fast component, the central endothelial cell density decreases exponentially with 36.7% cell loss at 1 year and 8.4% cell loss per year up to 5 years after surgery.[60] Thereafter, a slow component occurs where central endothelial cell density decreases at a linear steady rate of 4.2% per year.[65] Concurrently, polymegathism gradually increases and pleomorphism gradually decreases throughout the longitudinal follow-up period. Over the last 9 years, corneal transplantation surgical procedures have significantly changed the way most clinicians manage corneal endothelial cell disorders as posterior lamellar keratoplasty techniques have evolved to selectively replace the corneal endothelium. Posterior lamellar keratoplasty (PLK), deep lamellar endothelial keratoplasty (DLEK), Descemet's stripping endothelial keratoplasty (DSEK), and Descemet's membrane endothelial keratoplasty (DMEK) are the current options in this group of surgeries being performed to date.[66,67] Currently, the simplest and most effective technique is DSEK surgery, which seems to be preferred by patients compared to more traditional full-thickness PK surgery.[68,69] It is important to mention that the preferred approach of DSEK may be supplanted soon by another technique, so this chapter may not be up to date by the time it is published. Despite this possibility, one of the major concerns with DSEK surgery, probably second only to the high dislocation rate found with this surgery, is how the endothelium survives long term in these grafts. The fact that surgeons commonly fold the DSEK grafts and insert them through small incisions using various grasping forceps, and that air is used to keep the graft in place for 1 hour to 1–2 days in duration after the surgery would make one think that it damages the corneal endothelium much more than routine PK surgery (Fig. 7.12). In fact, many posters studying corneal endothelial cell loss after foldable posterior lamellar keratoplasty techniques including DSEK surgery at the 2006 and 2007



A



B

Figure 7.11. Slit-lamp photograph (*A*) and specular micrograph (*B*) of one of Dr Castroviejo's patients 42 years after his square penetrating keratoplasty surgery. The central endothelial cell density is 1189, CV is 34, and the percentage of hexagons is 50.

ARVO meetings showed greater rates of cell loss than that observed after penetrating keratoplasty.[70–73] A recent published study from one experienced surgeon's practice also supports this as the acute endothelial cell density decrease one year after DSEK was 40%.[74]

Finally, there are other surgical adjuvants or new procedures on the horizon that could affect the corneal endothelium. The surgical adjuvant that is most concerning is that of topical mitomycin C (MMC), which is applied after excimer laser-based keratorefractive surface surgery to prevent or treat subepithelial scarring. Currently, there appears to be no evidence of endothelial cell toxicity if a single local application of MMC is used at a concentration of 0.02–0.002% for an exposure duration of 12 s to 2 min.[75,76] The newest procedure that is most concerning is that of corneal collagen crosslinking with riboflavin and UVA light, which is one of the most promising treatment options for corneal ectasia. Currently, no evidence of endothelial cell damage has been found, but most of the studies to date are only preliminary, small in number, and are under strict research protocols.[77]

PHARMACOLOGIC TOXICITY

In addition to surgical injury, the corneal endothelium can also be influenced by pharmacologic toxicity.[7,78] Past studies that helped guide the development of intraocular irrigating solutions found that the best solutions were those that were most similar to aqueous humor in composition (Table 7.2). BSS Plus (Alcon Laboratories, Ft Worth, TX, USA) is currently the most physiologically compatible intraocular irrigants for intraocular surgery. BSS is probably the

Figure 7.12. *A,* Flat mount of an 8-mm diameter DSEK graft stained with 1% Alizarin red after trephination, viscoelastic placement on the endothelium with subsequent folding and insertion through a 5-mm wound using MacPherson forceps into an eye bank globe. Notice that 40% of endothelial cells were acutely damaged (lighter red) from this manipulation. In our experiments, the range of endothelial cell death was 30–70% using this identical DSEK insertion technique. *B,* Specular photomicrograph (×250) showing air bubble damage to the human corneal endothelium, which was mounted in an in vitro specular microscope and the endothelium was perfused with BSS Plus. The damaged area (dark area) from the air bubble shows a ring of endothelial damage. This bubble damage can occur within minutes.

Table 7.2 Composition of aqueous humor compared to various intraocular irrigating solutions

Ingredient	Human aqueous humor	BSS Plus	BSS
Sodium	162.9	160.0	155.7
Potassium	2.2–3.9	5.0	10.1
Calcium	1.8	1.0	3.3
Magnesium	1.1	1.0	1.5
Chloride	131.6	130.0	128.9
Bicarbonate	20.15	25.0	—
Phosphate	0.62	3.0	—
Lactate	2.5–4.5	—	—
Glucose	2.7–3.7	5.0	—
Ascorbate	1.06	—	—
Glutathione	0.002–0.010	0.3	—
Citrate	—	—	5.8
Acetate	—	—	28.6
pH	7.38	7.6	7.4
Osmolarity (mOsm)	304	305	298
Protein	0.135–0.237	—	—

[a] All concentrations are expressed in millimoles per liter or millequivalents per liter of solution.

Table 7.3 Causes of toxic anterior segment syndrome

1) Irrigating solutions or viscoelastic devices
   - Incomplete chemical composition
   - Incorrect pH (<6.7 or >8.1)
   - Incorrect osmolality (<270 mOsm or >350 mOsm)
   - Preservatives or additives (e.g. antibiotics, dilating medications)
2) Ophthalmic instrument contaminants
   - Detergent residues (ultrasonic, soaps, enzymatic cleaners)
   - Bacterial LPS or other endotoxin residues
   - Metal ion residues (copper and iron)
   - Denatured viscoelastics?
3) Ocular medications
   - Incorrect drug concentration
   - Incorrect pH (<6.7 or >8.1)
   - Incorrect osmolality (<270 mOsm or >350 mOsm)
   - Vehicle with wrong pH or osmolality
   - Preservatives in medication solution
4) Contaminated water sources
   - Water baths
   - Autoclave reservoirs
   - Non-sterile or non-pyrogen-free water
5) Intraocular lenses
   - Polishing compounds
   - Cleaning and sterilizing compounds

next best alternative. Overall, it became apparent that the main ingredients needed in intraocular solutions to be biologically compatible are essential ions, glucose as an energy source, bicarbonate as a buffer, and glutathione. It was also found during this time period of studying ophthalmic irrigants that intraocular tissues, particularly the corneal endothelium, had a relatively narrow physiologic range with which it stays healthy—a pH between 6.7 to 8.1 and an osmolality between 270 and 350 mOsm. Furthermore, any medications used intraocularly need to be at a nontoxic concentration and to contain no preservatives.

Pharmacologic toxicity to the anterior segment tissues of the eye, including the corneal endothelium, has recently become better understood through the discovery of a condition known as toxic anterior segment syndrome (TASS).[78] TASS is a sterile postoperative inflammatory reaction caused by a noninfectious substance that enters the anterior segment, resulting in toxic damage to intraocular tissues (i.e. cells and extracellular matrix). Most severe cases result in a 50% loss of central endothelial cell density or more. The process typically starts 12–48 h after cataract or anterior segment surgery, is limited to the anterior segment of the eye, is always Gram stain and culture negative, and usually improves with steroid treatment. The primary differential diagnosis is infectious endophthalmitis. Review of the literature indicates that possible causes of TASS include intraocular solutions with an inappropriate chemical composition, concentration, pH, or osmolality; preservatives; denatured ophthalmic viscosurgical devices; enzymatic detergents; bacterial endotoxin; oxidized metal deposits and residues; and factors related to intraocular lenses such as residues from polishing or sterilizing compounds (Table 7.3).[78] Therefore, as TASS is an environmental and toxic control issue, it has made anterior segment surgeons and surgical staff more aware that the health of the corneal endothelium requires a thorough understanding of all medications and fluids used during surgery. Additionally, it has helped all involved in intraocular surgery understand the importance of proper cleaning and sterilization of intraocular instruments since most cases of TASS appear to be directly caused by retained detergents or contaminated water sources.

In summary, although born with a substantial reserve of extra corneal endothelial cells for maintenance of normal corneal hydration and function, normal growth, development, and aging to an average lifespan of 75–80 years of age reduces one's endothelial cell numbers on average by 50%. Compounded to this normal decline are other exogenous stressors that could potentially damage the endothelial monolayer further so that it reaches another 80% reduction in cell numbers, which is the level (central cell density of 500 cells/mm^2) associated with the development of corneal edema and loss of transparency. Perhaps the most concerning of these stressors are trauma, infections, keratoplasty procedures, intraocular surgery when very young in age, and TASS.

8 The keratometer in the diagnosis of corneal disease

Peter C. Donshik, William Ehlers

The keratometer, or ophthalmometer, is not a new instrument. Since it was first developed by Herman von Helmholtz in 1854, significant improvements have been made. Today, several companies manufacture these machines, such as the Haag-Streit Ophthalmometer (Lagomarsino Medical, Inc, Ft Lauderdale, FL), the keratometer from Bausch & Lomb (Buffalo, NY), and the CLC Ophthalmometer by A 0 Reichert Scientific Instruments (Buffalo, NY). In addition, over the last few years the keratometer has been automated. The nomenclature associated with this instrument is confusing. Helmholtz used the term 'ophthalmometer', which is the generic name for this instrument. However, this term is not accurate because it implies a measurement of the entire eye, not just the cornea. Bausch & Lomb introduced the term 'keratometer' as its trade name for the instrument that was designed to measure the curvature of the central cornea, and it is the term most commonly used today.[1]

The keratometer measures the central 2–4 mm of the anterior curvature of the cornea, commonly referred to as the corneal cap. The measurements, known as K readings, are expressed in either diopters or millimeters of radius. From an optical perspective, the cornea is similar to a convex mirror. The mires of the keratometer form an image that is reflected from the anterior corneal surface. This image is virtual, small, and erect. Using equations based on the theory of reflection from a convex mirror, one can determine the radius of curvature of this anterior corneal surface. By aligning the mires of the keratometer, which are the targets that are reflected from the anterior corneal surface, one obtains the K readings in both the flat and steep meridians of the cornea.[2] This gives an objective measurement of the corneal astigmatism and power. The target image differs depending on which keratometer is used.

TYPES OF KERATOMETERS

With the Bausch & Lomb keratometer, the operator sees three reflected images, or mires, each consisting of a circle with a plus sign at the 3 o'clock and 9 o'clock positions, and a minus sign at the 12 o'clock and 6 o'clock positions (Fig. 8.1). The lower right-hand circle is the 'central' circle, which is the image of the reflected mires from the cornea. The image is reflected from approximately the central 3.2 mm of the cornea. However, this can range from 2.6 to 3.7 mm, depending on the steepness or flatness of corneal curvature.[1] This reading represents the distance between the two reflective points that the keratometer is measuring from the corneal surface. The assumption is that the curvature between these two points is spherical. This is not always the case and can lead to errors in measuring the corneal surface. However, the quality of the image that one obtains can also identify a steep or flat cornea. For example, a steep cornea gives a smaller image than a flat cornea. With the Haag-Streit keratometer, there are two images of different colors with a horizontal line through their centers (Fig. 8.2). Multiple steps are required to obtain the K readings. The operator aligns the two front surfaces of each image in first horizontal and then the vertical meridians to obtain the K readings of the corneal surface. Likewise, the operator can also obtain information about the corneal surface from the quality of the boxes and the mires. The boxes will be somewhat smaller in a very steep cornea and larger in a flat cornea. In the last 20 years, several intraoperative keratometers have been developed. The main rational for the development of these instruments was to help control surgically induced astigmatism during cataract and corneal transplant surgery. Although some are still available and may be helpful during corneal transplant surgery, the popularity of small incision cataract surgery, with minimal surgically induced astigmatism, has obviated the need for these devices.

USING THE KERATOMETER

The keratometer is very helpful in identifying and verifying corneal astigmatism. The difference between the measurements of the horizontal and vertical meridians indicates the amount of regular corneal astigmatism. In the presence of regular astigmatism, the plus and minus mires of the Bausch & Lomb, or the horizontal and vertical mires of the Haag-Streit, easily align themselves in the vertical and horizontal meridians. If the flattest meridian is within 30° of 180°, then the corneal astigmatism is considered to be with the rule, whereas if the flattest meridian is 30° of 90°, then the corneal astigmatism is against the rule. In the presence of irregular astigmatism, the operator, using the Bausch & Lomb keratometer, is unable to align the horizontal and vertical meridians

simultaneously. With the Haag-Streit keratometer, the alignment of the front surfaces of the two images is slightly ajar. As the irregular astigmatism increases, the operator sees distortion of the boxes and has greater difficulty in aligning the flat surfaces of each of the target boxes. This instrument is very sensitive and can detect the slightest presence of irregular astigmatism. The ability to detect minimal amounts of irregular astigmatism may be very important in the evaluation of the refractive surgical patient. In keratoconus, a lack of parallelism of the mires of the Haag-Streit keratometer with distortion of the size of the two box images is seen (Fig. 8.3). With the Bausch & Lomb keratometer, there is an inability to line up the plus and minus mires (Fig. 8.4). Also, the plus mires may jump from one side to the other when alignment is attempted (Fig. 8.5), and often the circles can be irregular or blurry.[3]

In patients with tear film deficiency, the practitioner can see abnormalities on the corneal surface.[4] The mires of the keratometer become distorted as dry spots occur on the corneal surface. Immediately after the blink, the mires are sharp, but as the tears begin to break up, the mires are distorted. In patients with dry eye who have rapid breakup of the tear film, one can easily visualize this irregularity during the course of obtaining the K readings of the cornea. The amount of mire distortion is a good measure of the severity of the corneal surface. The keratometer is invaluable in the fitting of contact lenses.[2] It helps the contact lens fitter to decide on the appropriate back and central optical radius of the contact lens, to monitor changes in the central cornea with contact lens wear, to evaluate the quality of the soft contact lens front surface, and to check the radii of curvature of the contact lens before dispensing it to the patient. In both soft and rigid contact lens fitting, the keratometer provides baseline information on the corneal curvature. The practitioner can then determine by repeated keratometry studies whether the contact lens, either soft or rigid, is affecting the corneal curvature or causing corneal molding.[5] With rigid contact lens fitting, the keratometry readings obtained provide a starting point for determining the base curve of the rigid lens that is applicable to that patient's cornea. In soft contact lens fitting, keratom-

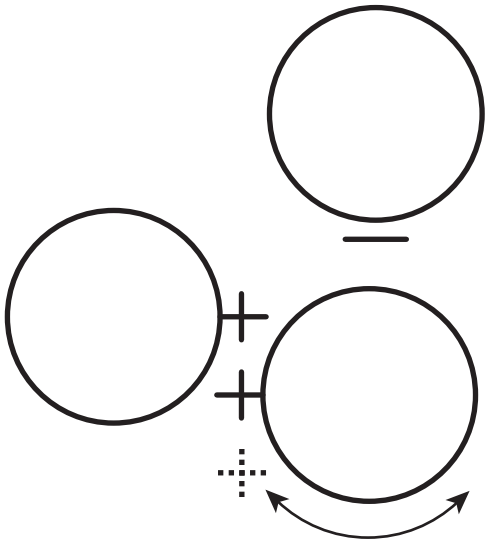

Figure 8.5. The plus mire jumping from each side as the operator tries to align the plus mires of each of the two circles. (From Leibowitz HM. Corneal Disorders: Clinical Diagnosis and Management. Philadelphia: WB Saunders; 1984. © Elsevier 1984.)

etry can demonstrate the corneal surface characteristics of the soft lens by the quality and stability of the mires.[5]

When observing patients with both soft and rigid contact lenses, comparisons of keratometry readings made on successive visits provide valuable means of detecting corneal changes secondary to the contact lens. If the contact lens is deforming the cornea, then the mire images will be distorted. This can vary from mild distortions, as in irregular astigmatism, to severe distortion, as in keratoconus. Keratometry taken on the front surface of a soft contact lens can reveal the quality of the contact lens surface. If the contact lens becomes coated, mire images will appear indistinct. In refractive surgery, the keratometry is helpful in the pre-evaluation in determining the presence of irregular astigmatism. The K readings are important in determining keratome selection and settings. Preoperative keratometric readings are often used to predict the expected corneal curvature following the refractive procedure. While the acceptable range of postoperative corneal curvature values will vary from surgeon to surgeon, most refractive surgeons feel comfortable with a postoperative corneal curvature between 38 and 50 D. Outside this range abnormalities in the cornea's optical performance can degrade visual results.

Studies have found that following refractive surgery the mean subjective refraction decreased more than the mean corneal dioptic power measured with either videokeratoscope or manual keratometry.[6] The central corneal power as measured by the keratometer as well as by video keratoscopes is thus erroneously higher than the actual central corneal power.[7,8] This can have an adverse effect on the determination of IOL power when cataract surgery is considered. Various formulas and methods have been developed to improve the accuracy of IOL power calculation in postrefractive patients.[8,9]

LIMITATIONS

There are limitations of the keratometer of which one must be aware. The keratometer only measures a small area of the cornea, approximately 2.6–3.7 mm, and thus does not give an accurate picture of the peripheral cornea. However, with certain adaptations, such as the topogrameter or by having the patient look up, down, or to the side, one can determine certain peripheral corneal values.[1] In addition, it is important to understand that the measurements obtained are taken along the visual axis, rather than the geometric axis. The visual axis is usually nasal compared with the geometric axis, and thus the curvature of the visual axis may be slightly flatter compared with the geometric axis. If, in taking the measurement, the eye rotates so that the mires do not have a perpendicular incident to the eye, abnormal readings of the corneal surface can be obtained. Highly myopic corneas and highly astigmatic corneas can yield incorrect values. However, in our experience, the amount of astigmatism in the axis obtained with the keratometer is very similar and consistent when compared with the computerized topography studies available.

CONCLUSIONS

In summary, the keratometer is a relatively inexpensive instrument that can easily be used by all eye care personnel. The operator can verify the amount of corneal astigmatism present, can determine whether the surface is regular or irregular, and can identify possible abnormalities, such as dry eye surface characteristics. In addition, it provides valuable information for contact lens fitting and follow-up care. It is helpful in determining the presence of regular or irregular astigmatism and the presence of corneal astigmatism and residual astigmatism.

In the presence of more sophisticated computerized corneal measuring instruments, the keratometer, even with its limitations, still remains an instrument that is important for all eye care practitioners.

9 Corneal structure and function: Placido-based corneal topography

Stephen D. Klyce, Tetsuro Oshika

Corneal topography analysis has become the standard of care for the anterior segment specialist. Accurate analysis of corneal shape has become particularly indispensable for refractive surgeons as a method for preoperative screening, surgical planning, assessment of surgical outcomes, detection and management of complications, and the development and refinement of surgical techniques. Other important applications are in the fields of contact lens fitting, evaluation of intraocular surgery such as cataract surgery, postoperative management of keratoplasty, and diagnosis as well as monitoring of keratoconus and other corneal ectatic noninflammatory diseases. This chapter reviews the basic concepts of Placido disk-based corneal topography.

PRINCIPLES OF THE PLACIDO DISK CORNEAL TOPOGRAPHER

Modern corneal topography was first developed using Placido disk technology,[1] and this approach has been recognized as the most widely accepted, used, and understood. The Placido target is a series of concentric illuminated rings (mires) that are reflected by the convex, mirror-like corneal surface and are imaged, along with the cornea, by a video camera (Fig. 9.1). The number of mires projected onto the cornea varies with the model; in general, closely spaced mires with a large area of coverage are desirable. Close spacing with a small diameter central mire will permit the highest spatial resolution; however, the more closely the mires are spaced, the sooner will large corneal irregularities merge adjacent mires and make analysis inaccurate. Since the detection of subtle surface distortions is paramount for the early detection and diagnosis of corneal pathology, the fine mire Placido disk may be optimal. Area of coverage becomes important for contact lens fitting as many contact lenses ride on the peripheral cornea. Good area coverage is also needed to detect keratoconus when it involves the peripheral, usually inferior, cornea. Variations in mire geometry are shown in Figure 9.1.

The two-dimensional digital image of the eye with the reflected mires is stored in computer memory and analyzed to reconstruct the three-dimensional corneal shape. The size and distortion of ring patterns are the basis for the calculation. The ring location relative to the center of the pattern determines radial distance, and the size of rings and the spacing between rings determine the local radius of curvature. Closely spaced rings indicate higher corneal powers, and widely spaced rings represent lower powers. Corneal powers are calculated for 6000–23 000 points with topography units. There are several algorithms used for reconstructing corneal shape from the mire positions; the arc-step method is generally agreed to be the most accurate.

The dioptric power of the cornea is derived from the local radii of curvature using one or more methods. Axial power is calculated using a fixed center of curvature on the corneal topographer axis for calculating the power at all points along semimeridians on the corneal surface:

$$P_{\text{axial}} = (n' - 1) / r_{\text{axial}} \quad (1)$$

where $n' = 1.3375$ (the keratometric index of refraction) and r_{axial} is the distance from the corneal surface to a point of intersection on the corneal topographer axis. The n' is not a true refractive index of the cornea, but an approximated index to yield the total corneal power as a single refracting surface by compensating for the negative power of the posterior surface.

Axial power tends to have a spherical bias because each curvature measured is referred to the optical axis. For aspherical surfaces, this bias gives an accuracy better than 0.25 D in the central cornea, but this can fall to 3 D in the periphery by comparison to 'instantaneous power.'[2]

The 'instantaneous power' is calculated based on a floating center of curvature by means of a standard mathematical method for determining the local radius of curvature:

$$P_{\text{inst}} = (n' - 1)/r_{\text{inst}} \quad (2)$$

where again, $n' = 1.3375$ and r_{inst} is the radius of curvature for any given point on the cornea. Calculations have less spherical bias because curvature is calculated without reference to the reference axis or the overall shape of the cornea. However, the method is more sensitive to small measurement error than the axial power calculation, which can introduce unwanted 'noise' artifact in the color-coded map.

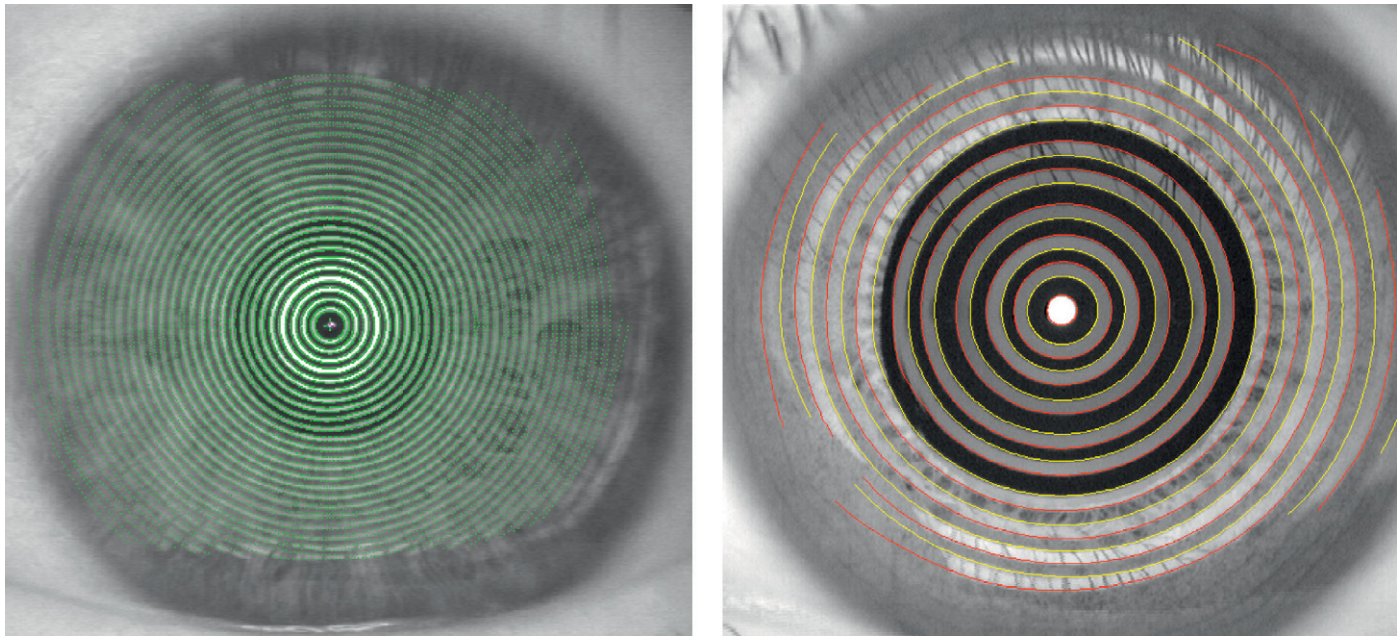

Figure 9.1. Placido mire patterns differ among corneal topographers. The pattern generated by the fine mire cone projector of the Nidek Magellan topographer is shown on the left, while the wide mire pattern made with the Nidek OPD-Scan is shown on the right.

For the central paraxial rays where the sagittal depth is approximately proportional to the curvature, paraxial power formulas can be used. Outside the central region, however, the assumptions used in Equations (1) and (2) are not necessarily valid.[3] The appropriate equation for the 'refractive power (secondary focal point power)' for the incoming parallel rays is given as:

$$P_{\text{ref}} = n/f \tag{3}$$

$$f = z + y/\tan(\theta_i - \theta_r) \tag{4}$$

where f is the distance from the vertex normal to the secondary focal point (where the refracted ray intersects the videokeratoscopic axis) located in the image space, z is the dimension along the videokeratoscopic axis from the vertex normal to the surface point, and θ_i and θ_r are the angles of incidence and refraction, respectively. It should be noted that in order to successfully calculate corneal power using the focal length method, the local shape or slope of the cornea must be known beforehand in order to calculate the angles of incidence and refraction.

No unanimous opinion has been reached regarding which of these three methods is the best for displaying corneal power (Fig. 9.2). The axial power formula produces inaccurate refractive power values for peripheral portions of the cornea as it does not encompass the effects of spherical aberration. However, the method does have the advantage of providing maps that are very simple to interpret for the clinician and values that are directly comparable to keratometry. The instantaneous power formula attempts to offer a more realistic representation of the peripheral corneal topography by determining corneal power from the local slope. This method produces significantly better estimates of the peripheral corneal power than the axial power formula. However, repeatability is less and noise is greater than the axial power measurement, since the instantaneous value is a conversion from the axial value based on a second derivative.[4,5] The refractive power (secondary focal length power) analysis is theoretically valid and provides realistic values for corneal power in the periphery, but the refractive power map is less familiar to clinicians and not easy to interpret. In addition, although the refractive power map shows the residual corneal spherical aberration in the periphery, it cannot show how much of this is further compensated by the shape and the radial refractive index gradients present in lens of the eye, since this information is not available on a per patient basis unless aberrometry is simultaneously employed.

DISPLAY FORMAT

COLOR-CODED MAP: SCALING

The color-coded contour map of corneal surface power has been adopted as a standard presentation scheme in corneal topography.[6] The color-coded contour map markedly facilitates the viewer's interpretation through the association of power with color and recognition of pathology with the patterns formed by the map contours. Warm colors—red and orange—are used to represent relatively higher powers (steeper curvatures), green and yellow are used for powers associated with normal corneas, and cool colors—hues of blue—are used to denote relatively lower powers (flatter curvatures). This concept, along with standard scales, provides an intuitive basis for the interpretation of corneal topography.

The use of a standardized and fixed color scale for routine clinical examinations is important for consistent and correct evaluation of corneal topography. Scales that adapt themselves to the range of powers on an individual cornea can lead to confusion (Fig. 9.3). A physiological asymmetry or astigmatism may be amplified by an adaptable scale and possibly lead to misdiagnosis as pathological. Alternatively, a cornea with substantial irregular astigmatism can be made to look less abnormal with an adaptable scale.

Initially, a standardized absolute scale was proposed,[6] ranging from 9.0 to 101.5 D with the central portion of the range in 1.5-D

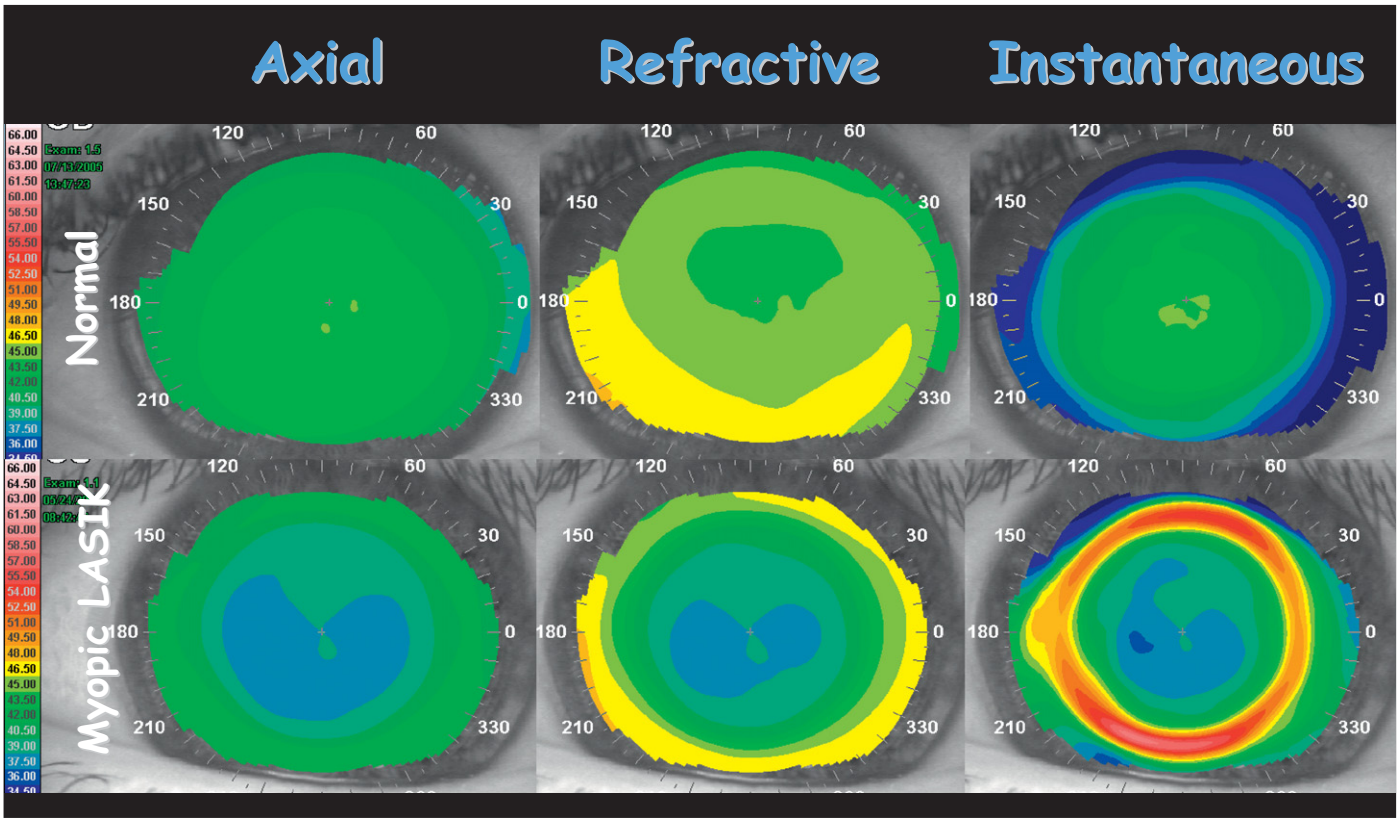

Figure 9.2. Corneal topography displayed with different power calculation methods. Upper row is a normal cornea. Lower row is a cornea following the LASIK procedure for the correction of myopia. Left-hand column uses the axial power method; central column uses the refractive power calculation; while the right-hand column uses the 'instantaneous power' (also called tangential) calculation (see text for details). Note that using the axial power method, both normal and LASIK cornea display the sense of corneal shape—the normal cornea is uniform in the center and flattens toward the limbus; the LASIK treated cornea has been flattened in the center. Note the 'red ring' illustrated with the instantaneous power method with the LASIK cornea. This is an example of the usefulness of that power method as the red ring (not seen with the axial method) is known to be responsible for night vision complaints in some patients.

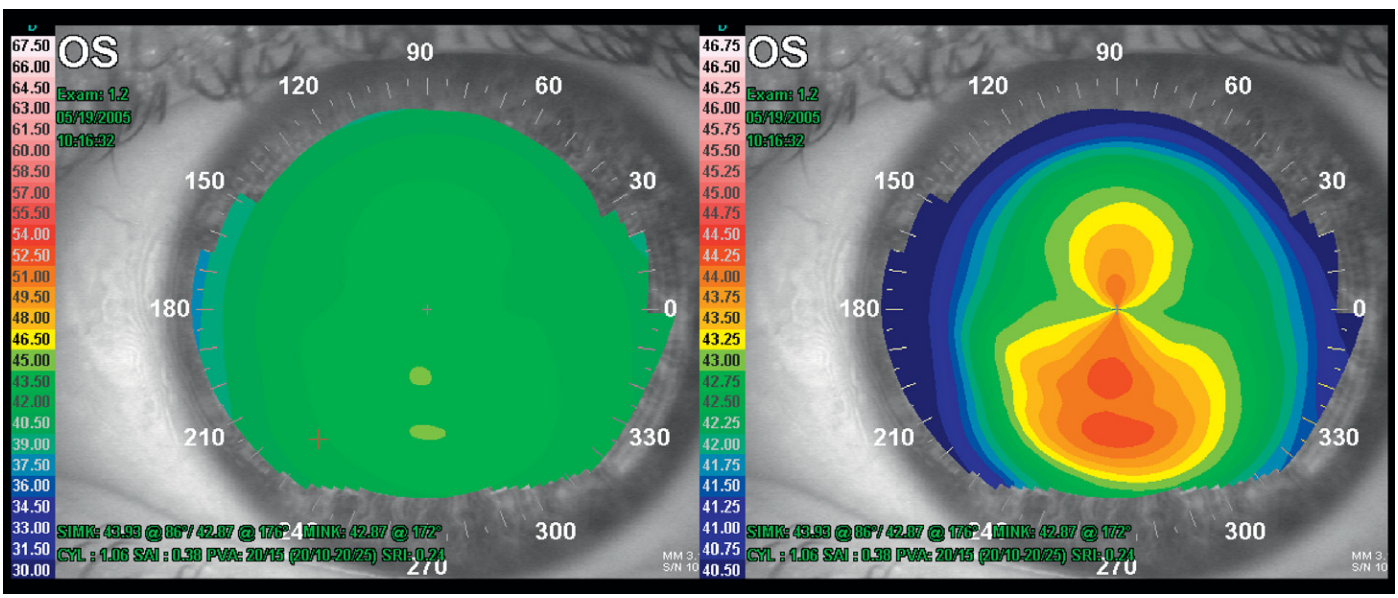

Figure 9.3. Corneal topography scales that are fixed and of a proper dioptric interval are important to establish consistent interpretation. The cornea illustrated above has a minor amount of asymmetry, but is otherwise normal. It has that appearance with the Smolek/Klyce scale used on the top left display, but the same cornea looks pathologic (keratoconus?) with a 0.25-D scale often used in corneal topography.

steps, and the extreme limits of the range in 5.0-D steps. While this range covered the entire corneal power spectrum seen in corneal practice, salient topographic features were occasionally lost within the 5-D intervals, particularly at the low end of the scale. Hence, this was modified to the so-called Klyce/Wilson scale,[7] which ranges from 28.0 to 65.5 D in equal 1.5-D intervals. It has been argued that the 1.5-D interval between contours is so wide that irregularities in corneal topography may be masked. However, it has been demonstrated that the 1.5-D scale could detect all the topographic characteristics sensed by a more sensitive 1.0-D scale in a consecutive series of patients that included contact lens wearing corneas, early to moderate and advanced keratoconus, penetrating keratoplasties, extracapsular cataract extraction, excimer laser photorefractive keratotomy, radial keratotomy, aphakic epikeratophakia, and myopic epikeratophakia.[7]

The corneal topographers currently on the market have their own standard color scales and the actual power values, intervals, and colors used differ from machine to machine. Presentation of data in varying or nonstandard formats inhibits easy interpretation and precludes comparison from one machine to another. One absolute color scale should be common to all devices as a standard feature, independent of technology. If all topography machines provided the same data using the same color scale, the resulting consistency would greatly facilitate interpretation.[8]

ELEVATION MAP

With the expanding application of the new forms of refractive surgery, especially LASIK and new forms of surface ablation, increasing attention is directed toward a topographic map which depicts the corneal shape in terms of height, as well as curvature and power. There is a claim that the elevation map is the true representation of corneal topography as opposed to a derivative form. The elevation map could be highly useful in contact lens fitting and keratoconus shape analysis. In Placido disk systems, the corneal height is calculated from the curvature, while in the non-Placido disk system height information is first obtained and then the curvature is derived.

Although the idea of comparing corneal height before and after refractive surgery appears interesting, there are several difficulties in doing so with sufficient reproducibility. Firstly, alignment of the two elevation data sets for comparison is challenging, in that a stable reference zone must be identified where the elevation has not been altered by the surgery. The corneal apex is inappropriate. Secondly, geometric elevation is relatively insensitive to optically significant surface features, and thus all systems that use the elevation actually must display a map of the relative change in elevation by subtracting a spherical component from the data. There are currently no standards for the best-fit sphere component to be subtracted. Thirdly, standardization of the color-code remains to be established. If color is standardized to the elevation relative to a mean sphere, the scale will not be consistent from map to map where the mean sphere varies from eye to eye. This is similar to the comparison difficulty that occurs with the adaptable scale for the dioptric map.

Another potential problem is the inherent discrepancy in the way the elevation and dioptric maps are interpreted. Since many of us are familiar with the Placido disk system and the dioptric map which has been in use for a decade, reading the newer elevation map requires a learning curve. The slope (or power) and elevation are rarely synonymous. The fact that cool colors indicate an area of lower power in the dioptric map vs. a depressed area in the elevation map may be somewhat incomprehensible. In astigmatic keratotomy, the incisions are always made in the steeper meridian. On a power map, the incision is placed in the axis of warm colors. On an elevation map, it would be placed in the axis of cool colors (the area of depression).

QUANTITATIVE INDEXES

The color-coded map is a qualitative display of the data, which is designed to allow rapid and easy pattern recognition. On the other hand, there have been several means to mathematically analyze the data so that the information is represented as quantitative indexes (Fig. 9.4). These indexes can be compared to a normal range, or grouped to summarize the topography of several patients, as in clinical studies.

Simulated keratometry (Sim K) is a relatively simple corneal index that is equivalent to the conventional keratometer readings, and is offered by all topography devices. The indexes first incorporated in TMS system include the surface asymmetry index (SAI), which measures the difference in corneal power at each ring and compares symmetry, and the surface regularity index (SRI), which represents local fluctuations in the central corneal power.[9,10] The potential visual acuity (PVA) is an estimation of predicted visual acuity based on SRI. The Holladay diagnostic summary display of EyeSys system also provides several numeric indexes, such as asphericity values (Q), regular astigmatism (Reg Astig), corneal uniformity index (CU), and vertical and horizontal pupil decentration data.[11]

The numerical approach has been also extended for the quantitative method of differential diagnosis. This was first done by Rabinowitz and McDonnell, who examined central corneal powers and inferior to superior midperipheral power differences obtained from corneal topography examinations in order to detect keratoconus.[12] In a system designed to detect and discriminate keratoconus from other clinical situations, eight topographic indexes were evaluated:[13] Sim K1 and K2, SAI, the differential sector index (DSI), opposite sector index (OSI), the center surround index (CSI), the irregular astigmatism index (IAI), and the analyzed area (AA). The analysis yielded the keratoconus prediction index (KPI), which could detect keratoconus with very high sensitivity and specificity among corneas of various entities, i.e. normals, keratoconus, regular astigmatism, keratoplasty, epikeratoplasty, photorefractive keratectomy, radial keratotomy, contact lens-induced warpage, astigmatic keratotomy, scarred corneas, postretinal detachment surgery, postcataract surgery, and keratomileusis.[13] This approach has been extended to use neural networks[14] and to simultaneously classify normal, astigmat, keratoconus suspect, keratoconus, pellucid marginal degeneration, penetrating keratoplasty, myopic refractive surgery, and hyperopic refractive surgery.[15] This automated classification of corneal topography (Fig. 9.5) is a very useful tool as a screening of refractive surgery candidates as well as a tool with which to explore the natural history of keratoconus and other corneal conditions.

Other applications of quantitative indexes of corneal topography are the assessment of refractive surgical results, including the quantitative analysis of irregular astigmatism, central islands following excimer laser photorefractive keratectomy, and decentration of refractive surgeries.[16,17] Other approaches, such as decomposition of topographic data using the Fourier series[18,19] or the Zernike polynomials,[20] are useful to investigate the optical quality of the cornea after ocular surgery or trauma (Fig. 9.6).

Figure 9.4. Statistics derived from corneal topography can be useful to differentiate specific shortcomings of individual corneas. In the illustration, the right column lists statistics developed from analysis of the topographies shown in the left column. On the top row is a normal topography while the bottom row is a decentered radial keratotomy procedure. Each of the statistics are color coded so that those within the range for a normal population are green, those two to three standard deviations from the mean of normals are colored yellow, while those more than three standard deviations from the normal are indicated in red. See text for further details.

LIMITATIONS

Corneal topography has become an integral part of refractive surgery and diagnosis of corneal diseases. As with many clinical tests, however, topography has limitations and can provide misinformation if intentionally or unintentionally abused. For example, topography devices, including the Placido disk system, can be sensitive to alignment and focusing errors.[21–23] Inadequately compensated focus and/or alignment has been found in the past to produce artifactual information. Tear film breakup can be a source of artifacts if a prolonged fixed gaze is requested by the operator; the effect is usually poor tracking with missing data and a map with the appearance of irregular astigmatism. In routine clinical settings, both keratometry and corneal topography are best done as the first procedure, before instillation of topical medication, intraocular pressure measurement, refraction, or external examination, to preserve the normal corneal tear film. It should be noted that precise and meaningful analyses are only possible when data acquisition is proper; correct operation of the topographer and patient cooperation are all important.

CONCLUSION

Corneal topography has established its unique role in ophthalmology as a noninvasive, qualitative, as well as quantitative measurement tool which processes huge amounts of data to be viewed and utilized in various forms. It is said that this technology is one of the most important diagnostic advances in recent years. The development and evolution of modern refractive surgery seem to have been the wind that fanned the rapid growth of corneal topography, and vice versa.

Corneal topography is a continuously evolving technology which has yet to achieve its final form. Several important issues remain to be further elucidated, and new technologies are on the horizon. The exciting fields in the future include real-time topographic analysis in the operating room, more robust and device-independent expert systems for classification of corneal topography, and further analyses of the correlations between optical quality of the cornea and corneal shape. The advancements in topographic technology will play ever-expanding roles in adding to our knowledge and understanding of the most powerful refractive surface in the eye, the cornea.

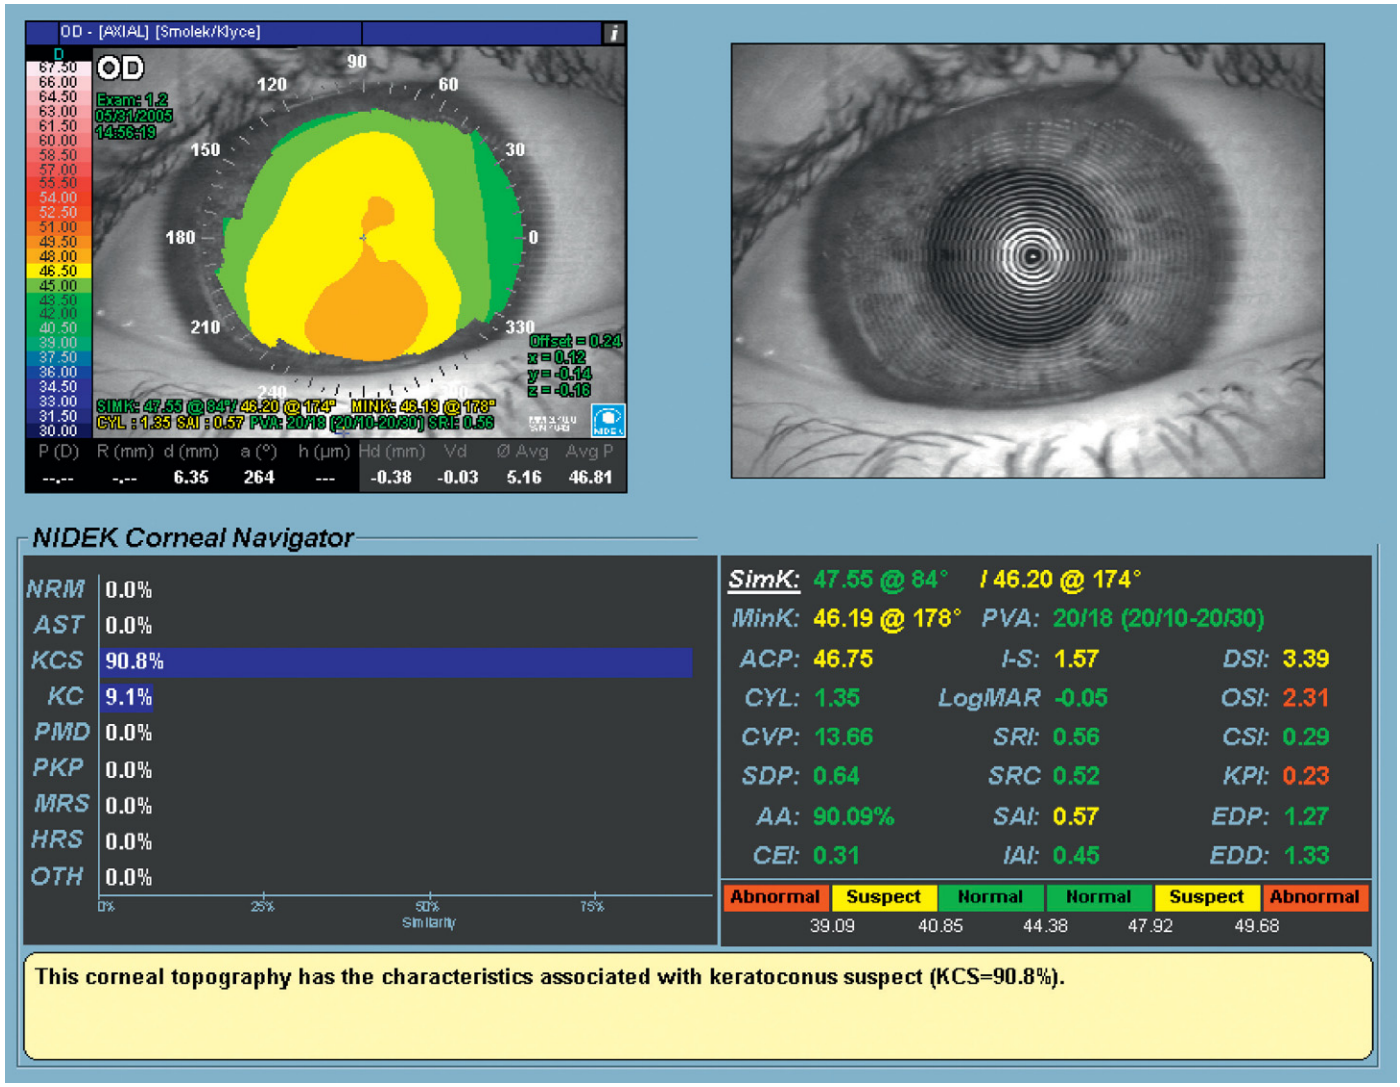

Figure 9.5. An example of the Nidek Magellan Navigator (corneal navigator) program, which classifies several categories of corneal topography. This cornea has the features consistent with a suspect keratoconus (KCS) cornea and is on the borderline for classification of clinical keratoconus (KC).

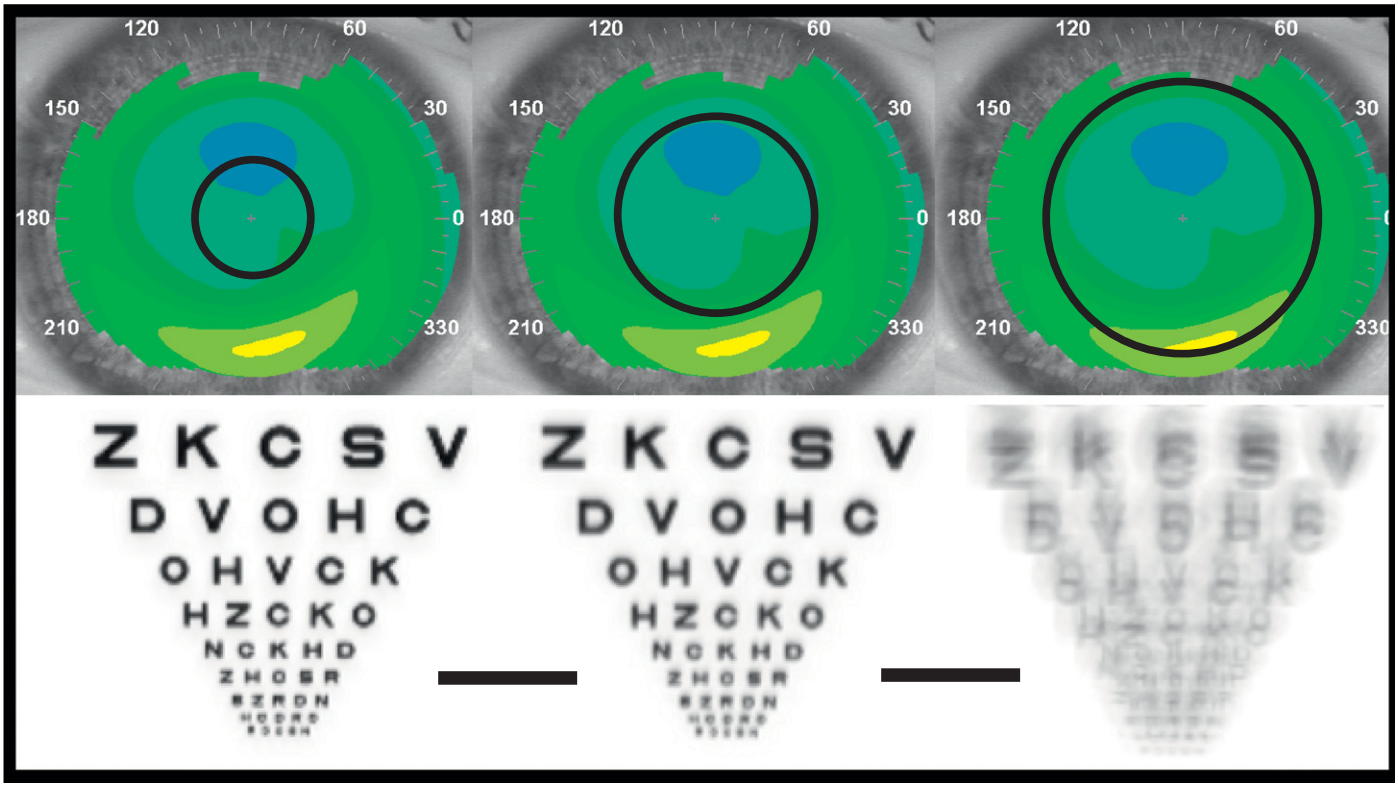

Figure 9.6. Using Zernike analysis to demonstrate corneal optical performance. The cornea received LASIK for myopia. Illustrated is a standard eye chart viewed with the aberrations contained within a 3-mm pupil (top left), 5-mm pupil (top center), and 7-mm pupil (top right). Note that the cornea has 20/20 potential for the 3-mm and 5-mm pupils, but when the pupil is expanded to 7 mm, vision falls to 20/60 (top row of letters on this chart). This demonstrates the need for large, well-centered treatment zones with refractive surgery which should avoid potential night vision complaints.

10 Corneal tomography and anterior chamber imaging

Catherine E. Wheeldon, Charles N.J. McGhee

INTRODUCTION

The word 'topography', derived from the Greek words *topos* meaning 'place' and *graphien* meaning 'to write', can be defined as the science of describing, or representing, the features of a particular place in detail. The similarly sounding, but differing, tomography is derived from the Greek *tomos* meaning 'a section' and herein lies the essential distinction between topography and tomography: the former is a two-dimensional representation of the anterior corneal surface, the latter a three-dimensional representation (or section) of the cornea and anterior segment. Thus, a contemporary computerized tomographer may also be a corneal topographer but the reverse is not necessarily true.

As detailed in earlier chapters, although Christopher Scheiner (1619) was the first to document attempts to measure the anterior corneal curvature, and Helmholtz introduced the concept of ophthalmometry (keratometry) in 1856, it was not until 1880 that Placido's disk of alternating white and black circles with a central perforation enabled qualitative assessment of more than four points of the central corneal surface. Surprisingly, despite the development of several techniques, the quantitative clinical potential of the Placido disk was not realizable until the development of the personal computer and video frame grabbers 100 years later—in the mid-1980s. Since the late 1980s the most widely established computerized video-keratography systems have been based on Placido disk technology. Through a set of complex algorithms, quantitative assessment and virtual reconstruction of the curvature of the corneal surface is possible. However, such Placido-based curvature topography does not directly measure true elevation topography nor provide a three-dimensional reconstruction of corneal thickness or the anterior chamber. The first widely commercially available corneal tomographer was the Orbtek Orbscan slit-scanning device launched in 1995, more recently (2002) the Oculus Pentacam tomography device has attracted considerable clinical interest.

The first system to use elevation topography to establish the true anterior corneal surface shape was the no longer available PAR Corneal Topography System (PAR Vision Systems Corp.) using the principle of triangulation. However, when the Orbscan (Orbtek, Inc.) was introduced into clinical practice in 1995 it provided a new paradigm for corneal analysis. Using eye tracking with scanning-slit or parallelepiped methodology, and the principle of measuring the dimensions of a slit-scanning beam projected onto the cornea, it can assess both the anterior and posterior surfaces of the cornea, as well as the anterior surfaces of the lens and iris.[1]

This chapter deals in some detail with the more widely available contemporary corneal/anterior segment tomography units—the slit-scanning Orbscan II and the rotational Scheimpflug-based Oculus Pentacam system. It will also outline the more established method of ultrasound pachymetry and specialized anterior segment tomographic applications of ultrasound biomicroscopy (UBM) and optical coherence tomography (OCT).

ORBSCAN II SLIT SCANNING TOPOGRAPHY

More than 100 scientific publications have documented the significant advantages and modest limitations of Orbscan tomography since its clinical launch a decade ago.[1] The original Orbscan was designed to acquire elevation information directly, but important curvature information can also be derived from this. However, the later development of the Orbscan II (Orbtek, Inc.) following the incorporation of the slit-scanning technique with a Placido disk attachment meant that curvature information could be derived directly (Fig. 10.1). The most recent model, the Orbscan IIz (Bausch & Lomb), is integrated with a Shack-Hartmann aberrometer in the Zyoptix workstation where information from both examinations can be transferred for direct treatment with the Bausch & Lomb Technolas excimer laser systems.

The Orbscan II and IIz devices incorporate both a Placido disk and a slit-scanning technique using white light, enabling both two-dimensional anterior corneal topography and three-dimensional corneal and anterior segment tomography (Fig. 10.2). During the data acquisition phase with the Orbscan IIz, the Placido disk is illuminated and the reflection of its mires from the anterior corneal surface is stored. Following this, 40 slits, 20 from left and 20 from right, 12.5-mm high and 0.3-mm wide, are projected onto the cornea at an angle 45° to the instrument axis. The appearance of the backscattered light from these slits is recorded as a two-

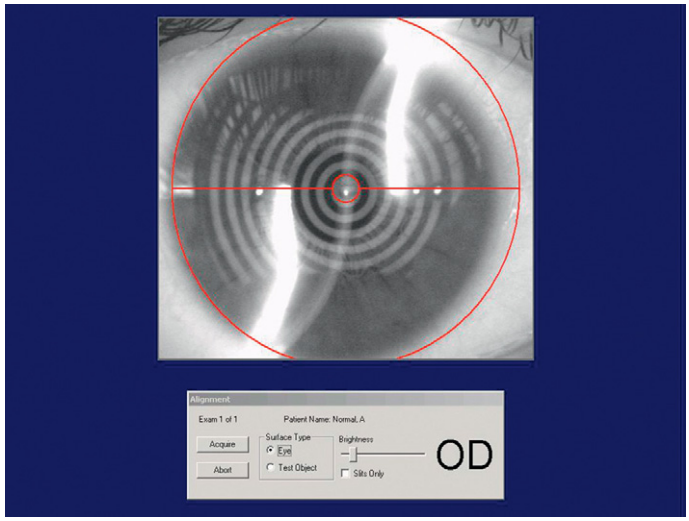

Figure 10.1. Screen image of Orbscan II showing the combination of Placido and scanning slit mires (overlapping centrally).

A

B

Figure 10.2. Orbscan II: Patient's view (*A*) and patient position (*B*) during scan. The data calculated on internal surfaces of the eye are not as precise as the anterior surface, as it is measured indirectly. These surfaces are calculated from the previously generated anterior topographic representations of elevation and curvature which will therefore exert an influence on the measurements.[2]

dimensional image by the digital video camera in the device. The acquisition is rejected if there is excessive movement or incomplete images, and the examiner is prompted to reacquire the data. By detecting the anterior edge of each slit and the edge of the reflected mires from the Placido disk, using the principles of triangulation, the system creates an elevation topographic representation and curvature reconstruction of the anterior surface of the cornea. Further processing of the collected data enables the system to then digitally recreate the posterior cornea, anterior iris, and lens.

This noncontact examination process takes a few seconds and relies on the subject placing their chin on the chin rest, and maintaining steady fixation on the center of the fixation target while not blinking. The processing phase, of up to 9000 data points from each assessment, takes approximately 30 s and following this a total of more than 30 anterior segment topo/tomographic maps can be created. The more practical display options tend to include axial and tangential keratometric curvatures, pachymetry, and anterior and posterior floating best-fit sphere (BFS) (Fig. 10.3).

The most established method of depicting the anterior corneal surface topography is the curvature or keratometric (dioptric) power map. Technically, since the relationship between power and radius of curvature is nonlinear, dioptre scales should be used only to describe the refractive power of the cornea and not its curvature. Axial topography is presented from the radius of curvature measurement by analyzing the reflection of the Placido disk to provide the normal to the surface, and then relating this to the instrument axis. If adjacent data are collated these will then reveal local curvature change or tangential topography. While derivations on axial curvature can describe how the cornea performs in a 'global' refractive sense, tangential curvature can better represent the 'local' shape of the anterior corneal surface (see Ch. 9 for further details).

In analyzing the anterior and posterior surface of the cornea, Orbscan can also provide total optical power (TOP) maps, a measure of the optical focusing capacity of the cornea. TOP maps have shown an encouraging correlation with manifest refraction when compared to anterior axial maps for detecting the refractive change postmyopic LASIK.[3]

True corneal elevation data are relatively insensitive to optically significant surface components; therefore, for the presentation of elevation topography the Orbscan uses a BFS technique, i.e. a sphere whose radius of curvature and position relative to the instrument axis can be altered to best fit the surface being measured. This allows small deviations in the surface shape to become more apparent (Fig. 10.4). The default floating BFS offers a useful means of analyzing the surface profile of the entire area measured. The BFS can be constrained in various means to highlight particular examination features. For example, limiting the radius of curvature of two separate anterior elevation maps to the same value might aid in the understanding of their topography, or fixing the virtual center of the BFS to the instrument axis to monitor for progression in keratoconus by preventing the floating BFS fitting off center, which could otherwise normalize the appearance of the maps.[4]

It is important to note that not all Orbscan acquisitions provide a complete map due to the effect of eyelids, reflections, etc. If peripheral, typically flatter, data are missing a BFS will have a decreased radius of curvature to best fit the steeper, more central

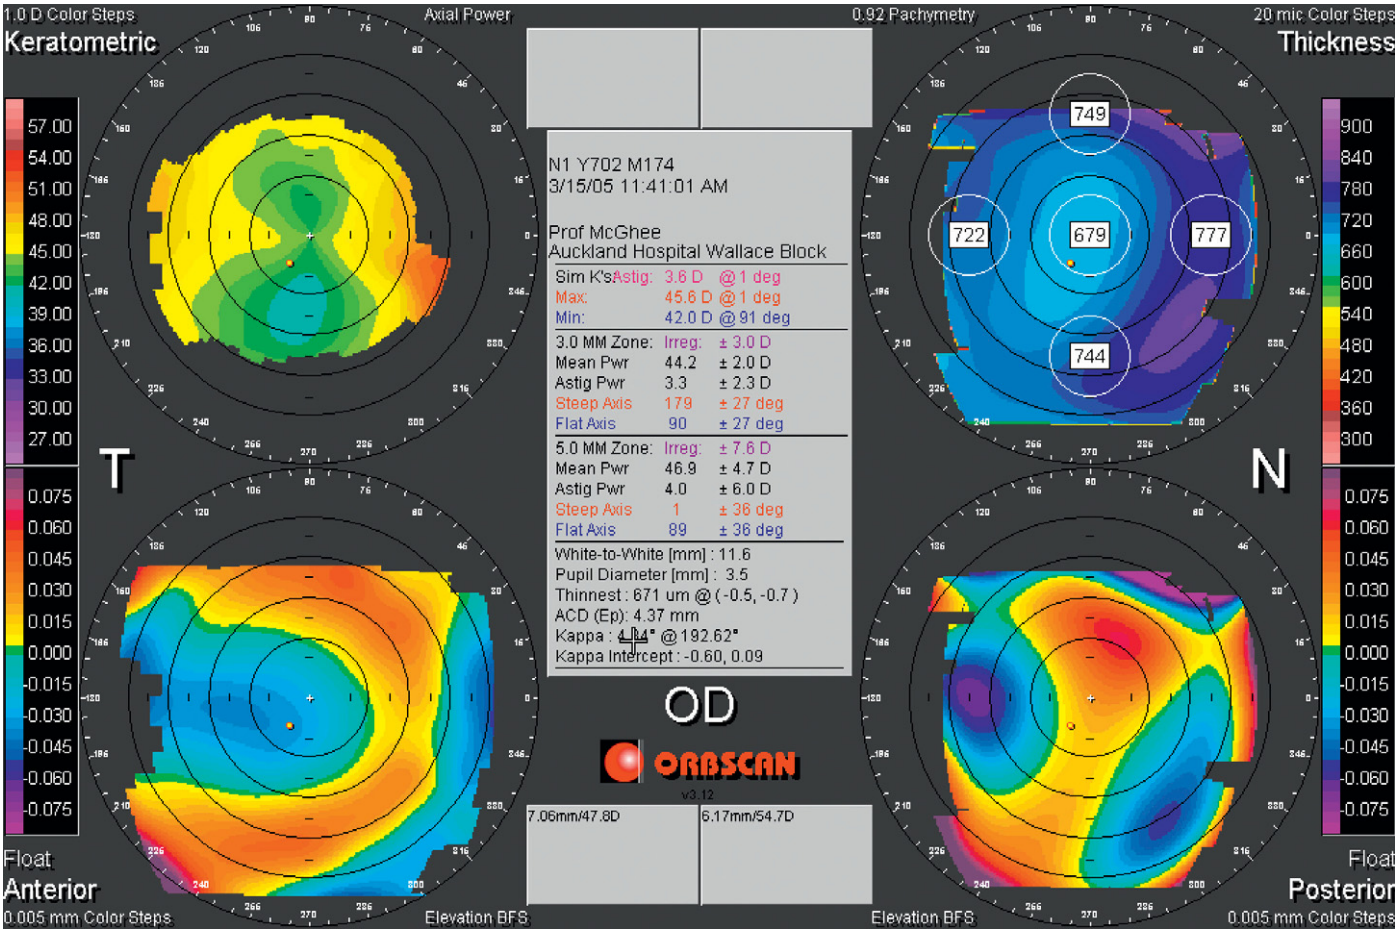

Figure 10.3. Orbscan II quad-map of a cornea with early Fuchs endothelial dystrophy. Clockwise from top left this display presents: *A,* a keratometric or power map in dioptres; *B,* a wide-field pachymetry map in micrometers (679 µm centrally); *C,* an anterior elevation map in microns relative to a BFS; *D,* a posterior elevation map in microns relative to a BFS.

region that will imply deceptive values and induce inconsistency. The development of any classification scheme must therefore be restricted to a specific zone of consistent complete data coverage between maps.

In an independent study, the Orbscan II demonstrated extreme accuracy in measuring the anterior surface using a variety of test surfaces, although the authors cautioned that no direct comparison can be made to the cornea in vivo.[5] The repeatability of Orbscan II slit-scanning topography for measuring anterior elevation in human corneas has been shown to be approximately 2 µm, decreasing towards the more peripheral cornea.[6,7] However, to date, no peer-reviewed publication has presented a reproducible technique to establish the accuracy of the Orbscan posterior surface elevation measurement and thereby the absolute accuracy of pachymetry maps.

The repeatability of early morning or peripheral measurements of pachymetry by Orbscan II is poorer than that of central measurements (±3.0 µm SD), which produce results generally comparable to ultrasound.[8,9] However, since the initial scientific publications it has become apparent that in normal corneas the Orbscan consistently produces pachymetry measurements thicker than ultrasound, by approximately 30 µm.[10–12] Possible explanations of this phenomenon include compression of the cornea or probe misalignment with ultrasound, or Orbscan measurement including the tear film and mucus layer. Owing to the concern that in LASIK patients the pachymetry may be measured thicker than with ultrasound, creating the impression that the maximum safe ablation depth for LASIK patients is greater than genuinely acceptable, the manufacturers introduced a correction factor to more closely align the results from Orbscan and ultrasound pachymetry. This correction factor is known as the 'acoustic factor' and reduces the entire Orbscan pachymetry map by 8%. Obviously, the use of a single correction factor across the entire cornea and different populations must be accepted with significant reservations when a constant linear relationship between ultrasound and Orbscan pachymetry has not been proven.[11] This disparity is compounded when considering corneal tomography that deviates from normal, such as post-LASIK. Studies that compare Orbscan and ultrasound pachymetry post-LASIK show, in contrast to the trend in normal corneas, that Orbscan has a general tendency to underestimate corneal thickness.[11,13,14] Moreover, the introduction of an acoustic correction factor of 8% induces further reduction in Orbscan pachymetry and therefore greater reduction when compared to ultrasound. Postoperative ultrasound pachymetry has been demonstrated to correlate well with preoperative predicted values, whereas Orbscan measures postoperatively have been reported to be approximately 40 µm less than predicted.[13] This would suggest that the inconsistency lies with the Orbscan measurement rather than with that of the ultrasound. Indeed, the presence of clinically significant haze is associated with an underestimation of corneal thickness,[15] and more recently the authors have demonstrated a

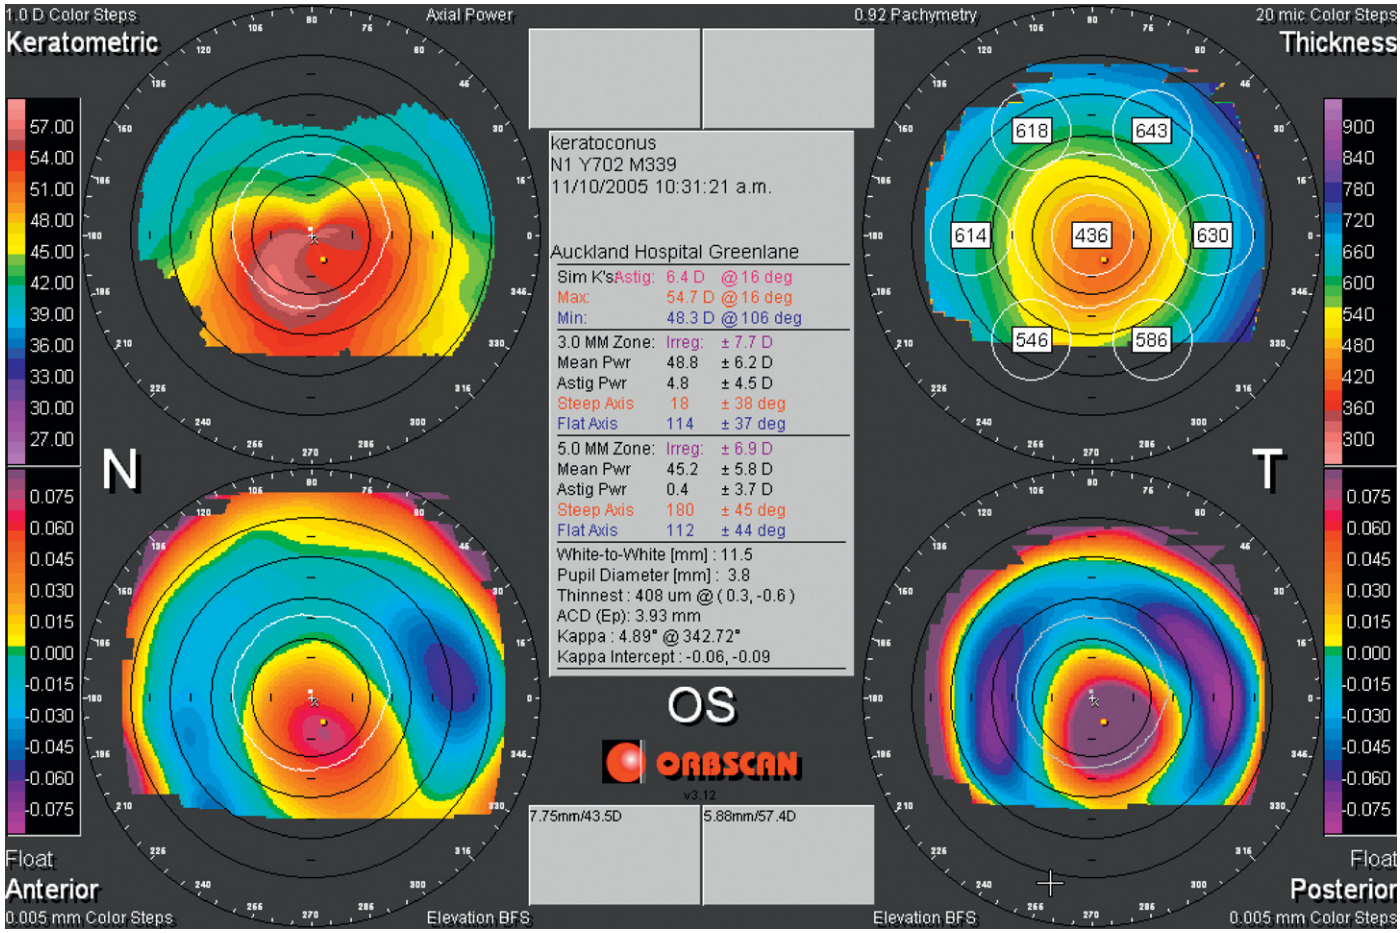

Figure 10.4. Orbscan II quad-map of cornea showing keratoconus. Clockwise from top left: *A,* the keratometric axial power map highlights a large inferior, oval cone with simulated K values of 54.7 and 48.3 D at 106°; *B,* the thickness map reveals significant central thinning with a value of 436 μm; *C,* the anterior elevation map highlights central elevation of greater than 60 μm relative to the BFS, of more than 75 μm; *D,* the posterior elevation map shows central protrusion, relative to the BFS, of more than 75 μm.

similar association with subclinical interface haze following LASIK (unpublished data).

When measuring anterior chamber depth (ACD) in phakic and pseudophakic eyes, the Orbscan appears to have good repeatability and the mean values correlate well with ultrasound A-scan.[16–18] Orbscan measurements also appear similar to those of the intraocular lens (IOL) master (Carl Zeiss Meditec) in the determination of ACD, but not as reliable as the IOL master in measurement of white-to-white corneal diameter.[19,20]

A significant observation highlighted by Orbscan tomography in eyes following laser keratorefractive surgery is the (apparent) anterior shift of the posterior corneal surface. Significant debate continues as to whether this is a genuine physical corneal ectasia or largely an optical phenomenon, although a number of large studies have generally suggested that this phenomenon does occur[21–23] even though the magnitude of the ectasia may be artifactually increased. It has been postulated that removal of tissue from the central cornea coupled with a superficial LASIK flap weakens the integral mechanical structure of the cornea and under the effect of intraocular pressure (IOP) causes a forward protrusion or true keratectasia. The mild regression seen in a significant number of eyes after LASIK could be partly explained by a genuine shift, or keratectasia of the cornea, which would effectively increase the axial length of the eye. However, many inconsistencies between studies prevent a resolute answer to this question, and it should be remembered that all evidence is based on the yet to be independently confirmed premise that Orbscan can accurately measure the posterior surface of the cornea after refractive surgery. Interestingly, the authors have recently reported a paradoxical reduction in ACD associated with apparent keratectasia following successful LASIK procedures, which tends to suggest this forward ectasia is at least partly artifact.[4]

OCULUS PENTACAM

The Oculus Pentacam (Oculus Inc., Germany) system is a multifunctional tool that images the cornea and anterior segment. Using a rotating Scheimpflug camera and a monochromatic light source (blue LED at 475 nm) that rotate together around the optical axis of the eye, multiple images are taken of the anterior segment from the anterior corneal surface to the posterior surface of the crystalline lens (Fig. 10.5). These measurements are subsequently used to generate three-dimensional images and animations from which data can be calculated and analyzed. This information can be used for a broad range of clinical applications. At the time of writing, the Pentacam has only been widely available in clinical practice for approximately 3 years and therefore the evidence base, in relation to the advantages and potential limitations of this system, is limited to a little over 20 peer-reviewed scientific publications.

In practice, the operator visualizes a real-time image of the patient's eye on a computer screen and can manually focus and align the image, with the machine identifying the corneal apex,

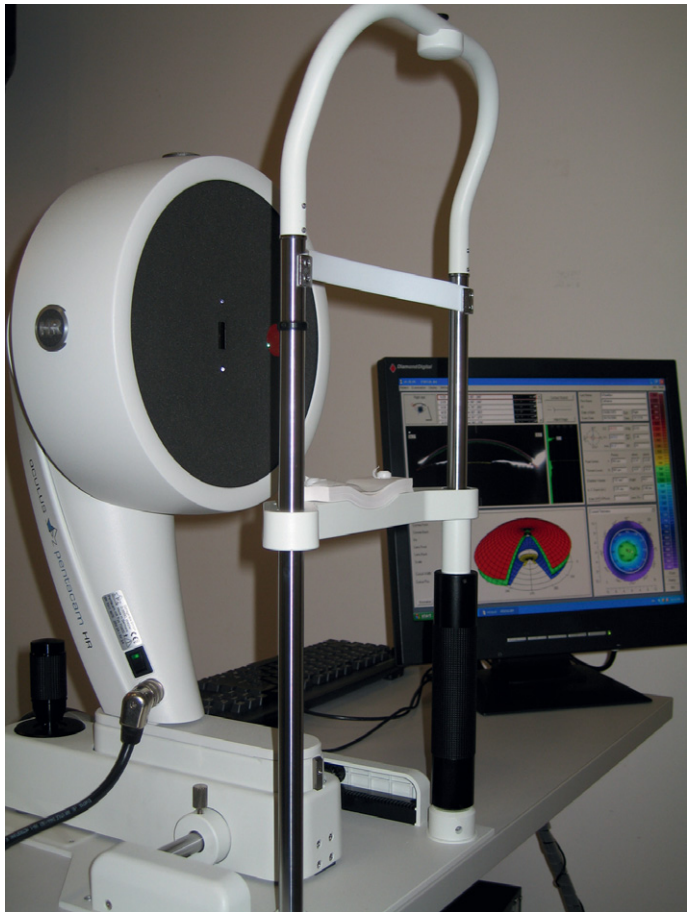

Figure 10.5. Oculus Pentacam Scheimpflug tomography device.

pupil edge and center in real time. Arrows that guide the operator's alignment in the horizontal, vertical, and antero-posterior axes are displayed on the screen. An automatic release mode can be used for the machine to automatically perform the scan on achieving the correct focus and alignment with the corneal apex. This noncontact measurement process takes less than 2 s to rotate 180°, and in this time performs up to 50 single captures depending on the function mode. Each capture consists of 500 true elevation points so a total of up to 25 000 height values are detected and processed into a three-dimensional mathematical model of the anterior segment. According to the manufacturer the condition of the tear film has no effect on measurements. Minute eye movements are captured by a second camera and automatically corrected simultaneously. The quality factor (QF) takes into account possible measurement confounders from blinking or extraneous light influences so users can easily determine whether an examination should be repeated. A QF > 95% indicates a reliable examination.

There are five evaluation modes: Scheimpflug tomography, pachymetry (including adjustment for IOP), three-dimensional anterior chamber analysis (chamber depth, angle and volume, including a manual measuring function for any location in the anterior chamber), densitometry of the lens, and corneal topography (including anterior and posterior corneal surface as well as keratometry) (Fig. 10.6). Comparison screens allow the user to obtain the optimal impression of any general changes, the difference between examinations shown as color maps, as well as numerical values. In axial terms, imaging is limited to the posterior capsule of the lens. Being optically based and imaging the eye from several angles, theoretically data can often be captured from behind a modest opacity or through corneal haze.

The Pentacam software generates a full-color-coded pachymetry map from limbus to limbus (potentially) and also highlights the thinnest part of the cornea (Fig. 10.7). Any point on the cornea can then be manually located onscreen to determine the precise corneal thickness at that point. This mode is particularly useful in refractive surgery, especially for evaluating patients seeking re-treatment, to determine if there is sufficient residual stromal tissue to allow a safe enhancement procedure. In glaucoma patients, the pachymetry-based IOP correction function allows the operator to enter the tonometrically measured eye pressure and, on selecting a formula for IOP correction, the Pentacam, like the Orbscan system, will calculate the patients 'corrected IOP' based on the measured corneal thickness.

A study comparing central corneal thickness (CCT) measured by the Pentacam and ultrasound pachymetry demonstrated that on average the Pentacam yielded slightly, but systematically, thinner values for CCT.[24] Similar results have been reported when comparing the Pentacam with both ultrasound pachymetry and Orbscan scanning-slit corneal topography.[25] In keratoconus it has been suggested that caution is needed when using data on corneal thickness interchangeably between the Pentacam, ultrasound pachymetry and noncontact specular microscope as significant differences between the measurements from these instruments have been shown.[26]

As an objective, noncontact measurement of CCT the Pentacam has been reported as yielding excellent intraoperator repeatability, and interoperator reproducibility, in the region of 0.84–1.1%, respectively.[27,28] The Pentacam might provide further insight into the presence of post-LASIK 'ectasia' that has been documented when assessing corneal thickness with the Orbscan, which as previously noted underestimates corneal thickness compared to ultrasound. Recent reports of change in the posterior corneal surface after refractive surgery suggest that contrary to previous studies, posterior 'ectatic' changes are not routinely identified after LASIK surgery.[29]

In addition to information about the central ACD, the Pentacam also measures depth at the periphery, an application which is useful for the suitable selection, surgical planning, and follow up of cases of phakic IOL implantation. Interestingly, in phakic eyes ACD measurements with the Pentacam, ultrasound A-scan, and Orbscan have been shown to be similar.[30,31]

The Pentacam can also evaluate safety distances between the posterior surface of a phakic IOL implant and the crystalline lens and from the anterior optic surface of an anterior chamber IOL to the corneal endothelium. The latter may be regarded as the most critical distance for determining endothelial safety.

In glaucoma patients, it is claimed that the Pentacam can be used to follow changes in anterior chamber angle, depth, and volume dimensions in response to surgical or pharmacological intervention. Additionally, users have claimed that the device can image the filtration bleb following glaucoma surgery and visualize the position of glaucoma drainage implants in the anterior chamber. However, anterior chamber dimensions measured by the Pentacam suggested that ACD and anterior chamber angle only correlate moderately and that ACD is only minimally correlated with the potential risk of developing angle-closure glaucoma.[32]

The use of Scheimpflug photography to quantify cataract has previously been well established using systems such as the Nidek EAS-1000 system,[33] and in addition to other functions the Pentacam lens densitometry function should enable quantification of lens density and the differentiation of various forms of cataract. The

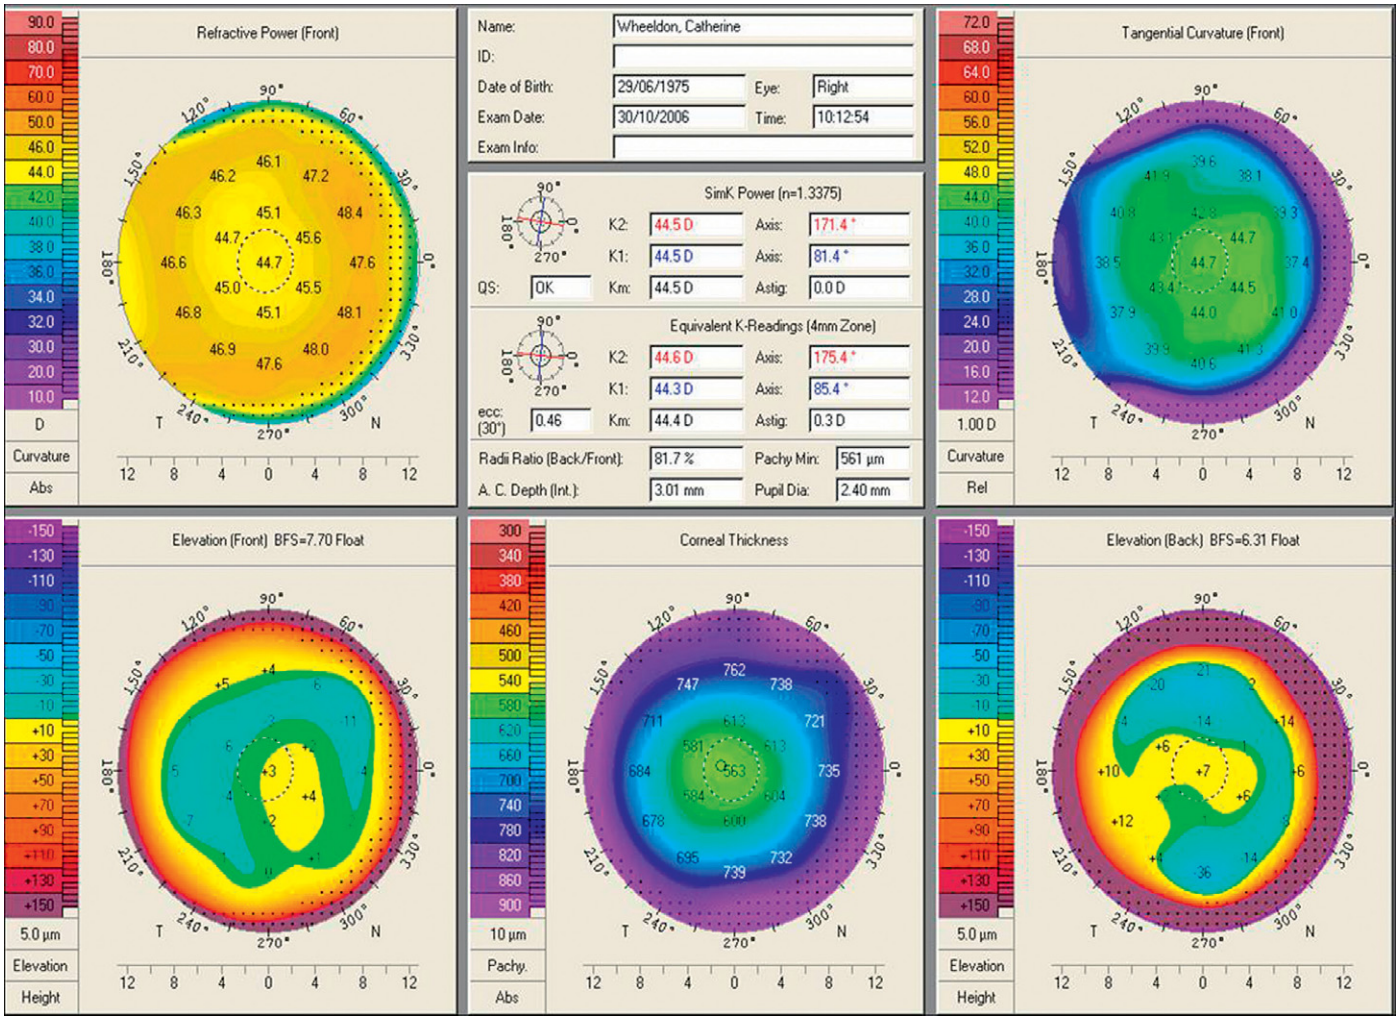

Figure 10.6. Oculus Pentacam maps of a normal cornea with SimK values 44.5 and 44.5 D at 81.4° and CCT of 563 µm. From left to right the six screens provide: top row: *A,* refractive power (front); *B,* patient bio-data and summary statistics; *C,* tangential curvature (front); bottom row: *D,* front elevation map; *E,* corneal thickness map; *F,* back elevation map (*D* and *F* are presented in respect to the BFS).

precise monitoring of cataract progression can be documented over time as well as the quantitative status of the crystalline lens following phakic IOL refractive surgery. The density of the lens is standardized from 0 to 100, where 0 shows no clouding and 100 represents a completely opaque lens. It is important to note that maximum pupil dilation is needed in order to fully visualize the posterior surface of the crystalline lens for thickness measurements, the edges of implanted IOLs, or the location and extent of opacification of the anterior and posterior capsule.

The Pentacam software enables a 'true net power' map, similar to the Orbscan TOP map, to be calculated and displayed. This takes into consideration the posterior surface of the cornea, potentially providing the basis of a more accurate calculation of refractive power of the cornea compared to Placido-based systems. The obvious potential for improving the predictability of pseudophakic IOL power calculation using the Pentacam's true net power map, in a growing population of cataract patients with a history of refractive surgery, is encouraging.

In the wider field of corneal disease, serial studies can be used to document and evaluate the progression of conditions such as keratoconus, pterygium, and Terrien's disease. The interfaces between corneal graft and host tissues and implanted intracorneal ring segments can be visualized. The 12.0-mm diameter topography map may be useful in guiding decisions about suture removal post-penetrating keratoplasty compared to the 9.0–10.0 mm zone of placido-based instruments.

ALTERNATIVE MEASUREMENT OF PACHYMETRY

Accurate corneal pachymetry plays an important role in several areas of ophthalmology. It can be regarded as an indirect correlation to the physiological condition of the corneal endothelium and may be useful in the diagnosis and management of conditions such as Fuchs corneal dystrophy and keratoconus.[34] Pachymetry is also vitally important in the avoidance of complications such as corneal ectasia in keratorefractive surgery. Recent evidence of the link between decreased IOP measurement readings and apparently decreased CCT have also highlighted its integral role in the early diagnosis and management of glaucoma.[35–37]

Ideally, a pachymeter should be safe to use, noninvasive, reliable, and provide accurate reproducible results. There are many different ways of measuring CCT thickness, including those techniques highlighted in the preceding sections, i.e. Orbscan and Pentacam tomography. However, pachymetry can also be usefully assessed by OCT, UBM, in vivo confocal microscopy, and ultrasound pachymetry—the

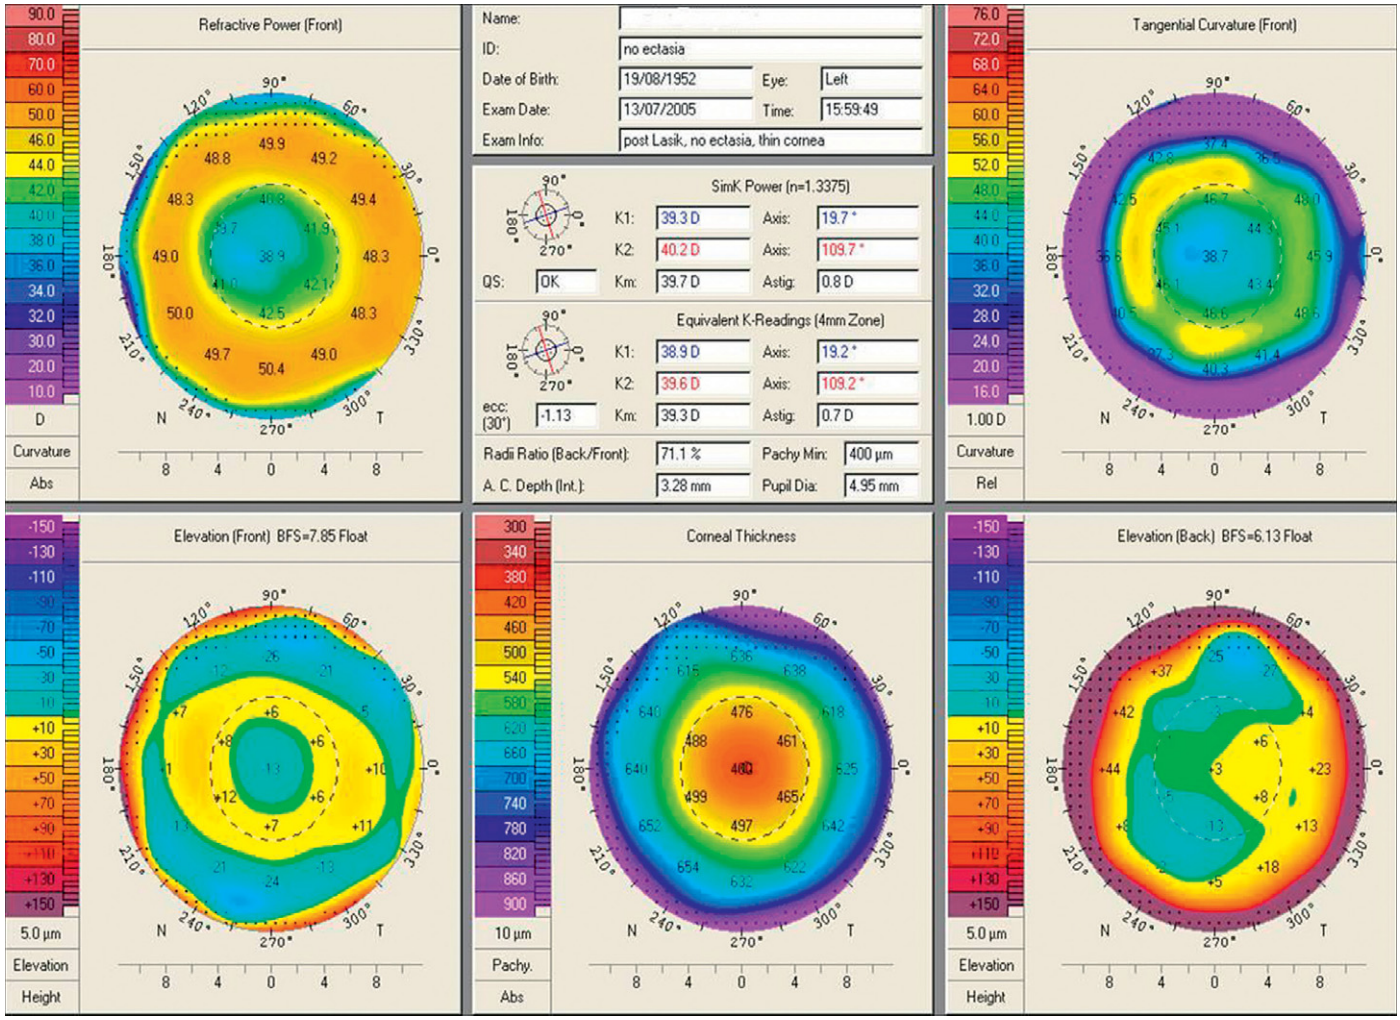

Figure 10.7. Oculus Pentacam maps of a post-LASIK cornea. Top row left to right: *A,* a central area of reduced refractive power; *B,* summary statistics highlighting SimK of 39.3 and 40.2 D at 109.7°; *C,* a more complex appearance of reduction in central and mid-peripheral tangential curvature. latter has historically been used most commonly and is often regarded as the gold standard.

ULTRASOUND PACHYMETRY

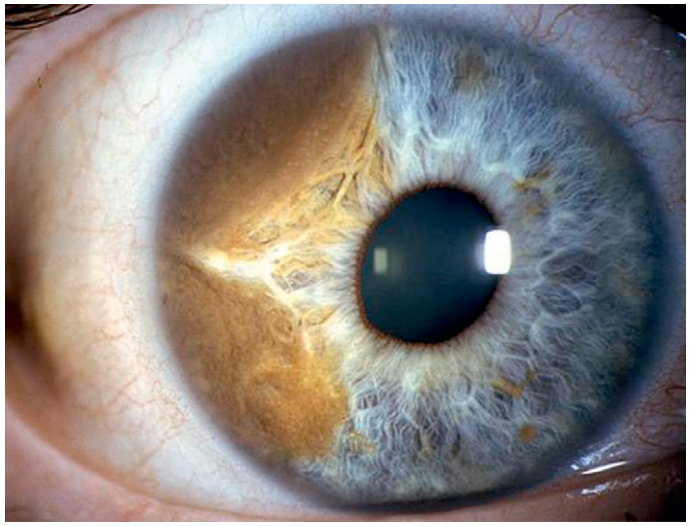
In use, the ultrasound probe is applied perpendicularly to the anesthetized cornea and an ultrasonic pulse is generated by the stimulation of a Piezoelectric crystal by an electromagnetic pulser. This ultrasonic pulse is reflected by Descemet's membrane back through the cornea and stimulates the crystal to generate an electronic pulse. From the time it takes for the ultrasonic pulse to travel through the cornea and back the corneal thickness can be calculated. The formula used to calculate this relies on a measurement of 1640 m/s for the speed of sound in the cornea:

corneal thickness = (total travel time × speed of sound in cornea)/2

The pachymeter usually analyzes a series of around 100 measurements at each site and can store multiple readings from different locations on the cornea. Hand-held ultrasound pachymeters offer the advantage of relative ease of use, portability, and low cost. In general, ultrasound pachymetry has been shown to have a reasonable degree of intraoperator, interoperator, and inter-instrument reproducibility.[9,38,39] However, limitations of this system include difficulties in alignment and centration with consequent off-center placement of the probe yielding thicker measurements, the lack of a fixation light for gaze control, and the variability of sound speed in wet and dry tissues. In addition, relying on corneal contact necessitates the administration of a topical anesthetic, risk of epithelial damage, possible transmission of infection, and may yield slightly thinner readings as a result of unavoidable tissue indentation.

ULTRASOUND BIOMICROSCOPY

Ultrasound biomicroscopy provides high resolution, in vivo contact imaging of the anterior segment. Structures in the posterior chamber hidden from clinical observation can be assessed, and the relationship between tissues and their architecture in disease can be studied. The technology is based on 50–100 MHz transducers incorporated into a B-mode clinical scanner.[40] The resolution and depth of penetration are moderated by transducer frequency. Lower frequency transducers provide greater depth of penetration with less resolution, whereas higher frequency devices provide better resolution of more superficial structures. Commercially available units operate at



A

Figure 10.9. The Visante OCT (Carl Zeiss, Meditec) in use.

up to 50 MHz, providing a penetration depth and tissue resolution of approximately 5.0 mm and 50 µm, respectively. Generating a 5.0 × 5.0 mm field of view, consisting of 256 A-scans, at a scan rate of 8 frames/s, the UBM provides a dynamic image of the anterior segment. When gathering quantitative information it is important to consider the effect that room illumination, fixation, and accommodation can have on anterior segment anatomy.

UBM is an effective tool in both the diagnosis and management of anterior segment tumors. Tumor size can be measured and extent of invasion determined (Fig. 10.8). However, in terms of corneal pachymetry per se, UBM is significantly more expensive but no more accurate than standard ultrasound pachymetry.[41]

ANTERIOR SEGMENT OPTICAL COHERENCE TOMOGRAPHY

The anterior segment OCT is a noncontact, high-resolution tomographic and biomicroscopic device aimed at in vivo imaging and measurement of anterior chamber structures such as the anterior chamber angle, depth, corneal diameter, and corneal and LASIK flap thickness (Fig. 10.9). Anterior segment OCT has only been available over the last 5–6 years and therefore the published evidence base is still relatively limited though growing quickly.

The OCT acquires and analyzes cross-sectional tomograms of the anterior segment using low coherence interferometry to obtain high-resolution images. Coherent light is sent along two optical paths, the sample path into the eye and the reference path of the interferometer. The typical light source is a 1310 nm, infrared, super-luminescent light-emitting diode that employs a wavelength that has limited penetration in the eye. Light returned from the sample and reference paths are combined at the photodetector. The strength of the combined returned signal is a measure of the reflectance of a small volume of tissue at that specific location. In a similar fashion to ultrasound A-scan, by changing the optical length of the reference path at each scanning spot the axial depth of the tissue reflectivity signal can be determined. By laterally moving the scanning spot across the eye, the OCT acquires multiple A-scans that can be aligned to construct two-dimensional images analogous to an ultrasound B-scan. The anterior segment OCT typically performs 4000 scans per second with a scan width of 1.0–16.0 mm, scan depth of 1.0–8.0 mm, and axial resolution of 15 µm.

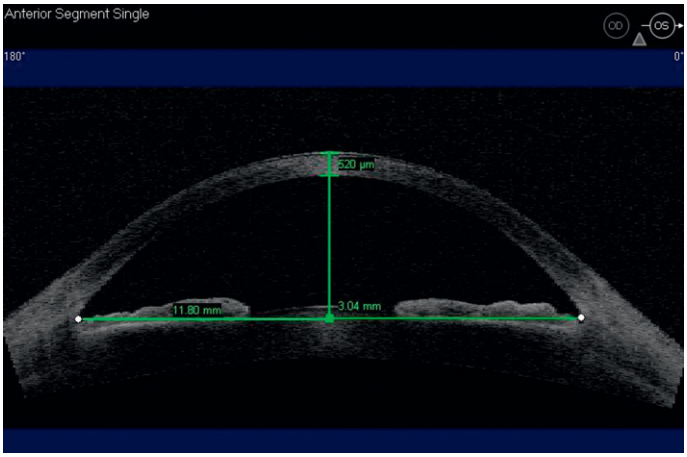

Figure 10.10. Anterior segment OCT of the cornea, iris, angle, and limbal region highlighting corneal pachymetry, angle to angle, and ACD measurements.

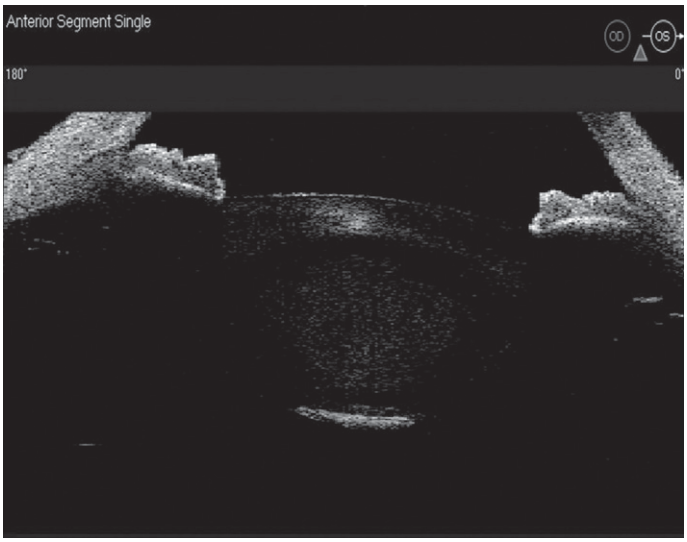

Figure 10.11. Anterior segment OCT image of an eye highlighting a dilated pupil and a posterior subcapsular cataract.

Potential applications of OCT in anterior chamber imaging include corneal pachymetry, LASIK flap thickness measurement, narrow angle glaucoma screening, internal angle-to-angle dimensions, and ACD (Fig. 10.10). As the infrared light beam is stopped by iris pigment a satisfactory view of structures behind the epithelial pigment layer of the iris is not usually possible, and usually only the central, anterior portion of the lens is seen (Fig. 10.11).

The in vivo analysis of the eye is a quick, noncontact procedure that provides data of high spatial resolution with no mechanical distortion of tissue, within a few seconds of alignment having been achieved. During the procedure the subject fixates on an optical target. The targets focus can be adjusted with positive and negative lenses to compensate for the subject's spherical ametropia and thus allow acquisition of images of the un-accommodated eye. It is also possible to defocus the target with negative lenses to induce physiological accommodation in the eye.

The OCT central and peripheral corneal pachymetry map consists of eight radial lines, 10 mm in length, each containing 128 axial scans. Measurements can be made of LASIK flap and bed thickness (Fig. 10.12). This allows comparison of predicted and achieved flap

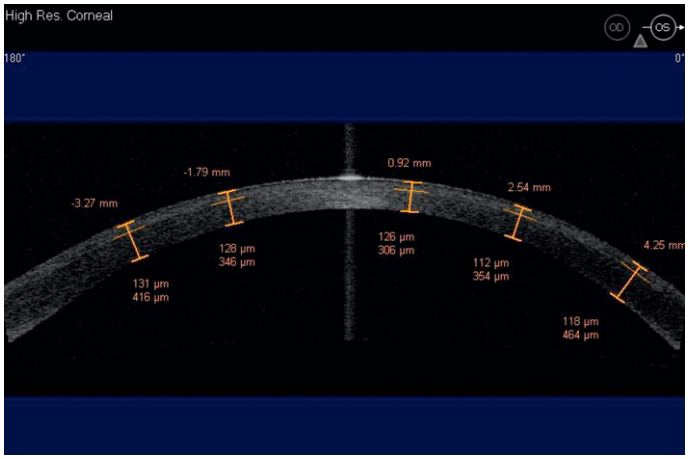

Figure 10.12. Anterior segment OCT image post-LASIK highlighting the LASIK flap dimensions.

thickness and ablation depths, and is therefore a useful guide to the feasibility of secondary procedures. Flap architecture can be viewed, and, being noncontact, assessment can be carried out immediately after corneal surgery. Difference maps can be used to monitor for the progression of corneal conditions such as Fuchs endothelial dystrophy. Measurements of CCT have been shown to have good repeatability with results equivalent to ultrasound pachymetry in eyes before and after LASIK.[42] In contrast, repeatability in measurements of corneal epithelial thickness has shown to be poor.[43]

In refractive surgery, eyes with high ametropia are often not suitable for corneal refractive laser ablation because of the combined risks of induced ectasia and optical aberrations. Clear lens extraction can be an alternative but this is associated with loss of accommodation and the risk of retinal detachment. In certain patients the use of phakic IOLs may be an option. The use of these IOLs relies on accurate sizing in order to avoid complications such as pupil ovalization, iritis, and iris atrophy that can occur if the IOL is too large, or endothelial damage and peripheral anterior synechiae if the IOL is too small and becomes mobile. Traditionally, external 'white-to-white' corneal diameter measurement has served as a guide to anterior chamber width; however, external measurements can be biased by anatomical variations, vascular pannus, and arcus senilis, and thus external landmarks may not correlate well with internal landmarks. The OCT is claimed to assess true anterior chamber dimensions including depth, angle size, and angle-to-angle measurements that can be used in the evaluation of suitability for phakic IOL surgery. Additionally, postoperatively the distances between implanted phakic IOLs and the corneal endothelium and anterior lens capsule can be measured and monitored. Reproducible OCT anterior chamber biometry has been demonstrated but with a high variation between users.[44] This could be partially addressed by the incorporation of automated software for biometric measurements within the OCT to eliminate human error.

Anterior segment imaging allows evaluation and assessment of corneal pathology such as keratoconus, and the outcome of penetrating and lamellar keratoplasty.

CONCLUSION

Corneal analysis has come a long way since the advent of the keratometer and Placido's disk. Largely due to computer processing we can now measure thousands of corneal data points and analyze

them in seconds rather than the hours, or even days, it would have taken only 25 years ago. As this brief overview highlights, true corneal tomography is now available in a number of systems with applications that can be tailored for the precise needs of the corneal and the refractive surgeon.

11 Confocal microscopy of the cornea

Matthew Giegengack, William D. Mathers

Confocal microscopy is a technique that continues to gain utility in both clinical and experimental ophthalmology. Increasing numbers of ophthalmology centers are employing this exciting technology. Confocal microscopy has many advantages over other modalities of examination. It has the distinct advantage over traditional laboratory light and electron microscopes of being usable with living tissue. Compared with other in vivo techniques (slit-lamp biomicroscopy, spectroscopy, etc.), it provides both higher resolution and, perhaps more importantly, the ability to produce optical sections of the tissue being examined.

As the confocal becomes more popular, the number of papers on its use continues to increase. The subject has become prohibitively broad for an all-encompassing review. This chapter provides an explanation of the theory behind confocal microscopy. Clinically proven applications of the confocal are detailed. A sampling of some of the research previously and currently underway is also included. Many clinical photos are included so that the reader gets a sense of the power of the technology in its present uses as well as to stimulate ideas for future investigations.

PRINCIPLE OF CONFOCAL MICROSCOPY

In 1955, Marvin Minsky[1] constructed the first microscope based on the confocal principle. In all types of light microscopy, the specimen to be examined is illuminated by a light source and the light from that specimen is then collected and magnified by an objective lens. The modification of this basic design, which defines confocal microscopy, is best understood with a diagram. Figure 11.1 is a depiction of a confocal microscope in its simplest form, similar to the microscope first designed by Minsky.[1]

A point source of light is created by shining a light through a pinhole P1. The light from this point source is then collected by a converging lens L1 and focused to a point X in the specimen. The light from the specimen is then collected by a second lens L2 and focused on the detector. L2 is placed in such a way that its focal point is at point X. In order to discriminate against light not originating at point X, a second pinhole P2 is placed in front of the detector. L1 and L2 (the light source and the objective lens) are therefore confocal, hence the name.[2]

This design allows for better transverse resolution than nonconfocal microscopy for a given wavelength of illumination. It also has enhanced axial resolution, as light from above and below point X do not reach the detector (note the blue rays in the diagram originating from a point deeper within the specimen than point X). The confocal described above would deliver excellent resolution of the specimen at point X at a set depth within the specimen as dictated by the focal lengths of the illumination and the objective lens. By moving the specimen in front of the microscope, multiple point Xs could be combined to provide an image of an optical section at that depth (as depicted in the diagram by the vertical line through the point X). Moving the specimen toward or away from the microscope would provide an image of an optical section at a different depth within the specimen. However, it is often difficult to move the specimen in a controlled manner (especially a living patient). Alternatively, the light source and objective can be scanned across (or moved closer to) the specimen.[2]

Different methods for scanning the light source across the specimen have been designed. The most common method employs a Nipkow disk. The Nipkow disk is a thin disk with multiple pinpoint holes (Fig. 11.2). Light from the source is directed through these holes to make multiple point sources; each of these point sources is focused to a point in the specimen. The reflected light from each focal point in the specimen is then refocused on the disk and either directed through the same hole that the illumination came from or through a corresponding hole on the other half of the disk. The disk is then rotated so that many points of the focal plain can be sampled quickly. Nipkow disk-based confocal microscopes have several variables that determine image quality. The size of the holes on the disk determines the resolution. The smaller the hole, the higher the resolution. This comes at a cost, the smaller the hole the less light transmitted, and consequently brighter illumination is required to obtain adequate contrast. Resolution is further affected by the power of the objective lens, higher power lenses having greater resolution. The rate at which the disk rotates determines the speed at which a complete image can be obtained. The faster the speed, the more forgiving the microscope is of patient movement. However, at faster speeds the alignment of the microscope parts is more difficult to maintain.[2]

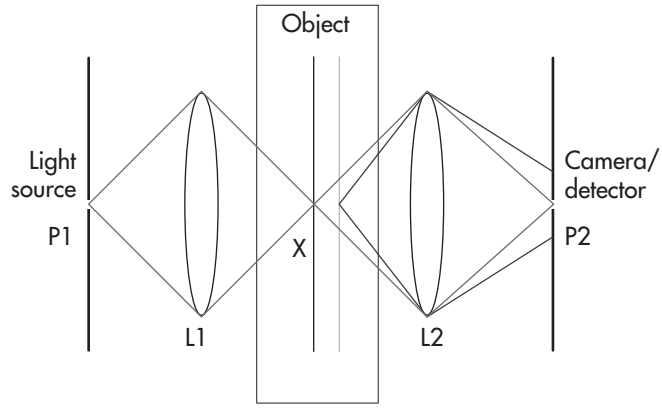

Figure 11.1. A depiction of a confocal microscope in its simplest form, similar to the microscope first designed by Minsky.

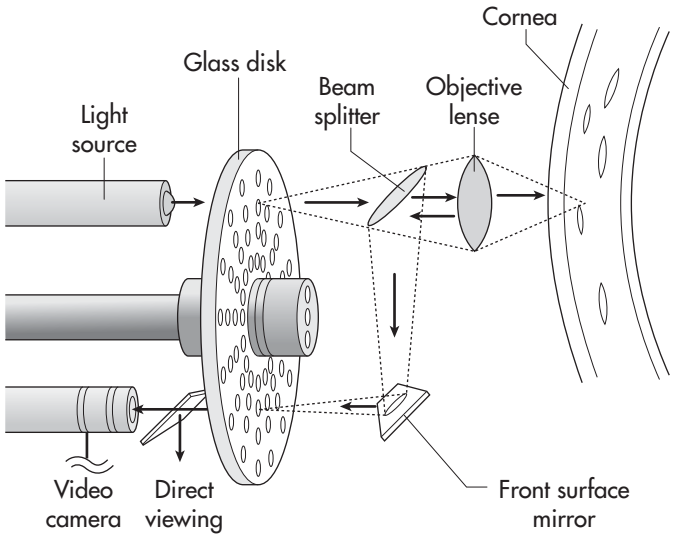

Figure 11.2. The Nipkow disk is a thin disk with multiple pinpoint holes.

A further modification of the confocal microscope has been developed by converting the scanning spot to a scanning slit.[3] Expansion of the field in one dimension decreases the confocal properties of the microscope but permits better transmittance and more rapid image capture.

One aspect of the confocal microscope not yet discussed is that of the detector or camera. Although confocal microscopy increases resolution, it does so at the expense of the brightness of the field. When images are stationary, the low light levels can be compensated for by longer exposure times with cooled CCD cameras, which can achieve startling resolution under very dim illumination. In vivo confocal microscopy is, however, significantly impaired by movement of the tissue being observed. Although normal eye motion does not appear to be significant when viewed without magnification, at a magnification of ×400, the surface of the eye moves considerably even when fixated on a small target. The eye is actually never stationary while awake. The rapidity of this motion must be compensated for by relatively short image acquisition times to avoid blur. Real-time video imaging requires 30 frames per second, limiting the amount of time available for any frame to 30 ms. This time is not sufficiently rapid to stop eye motion. The

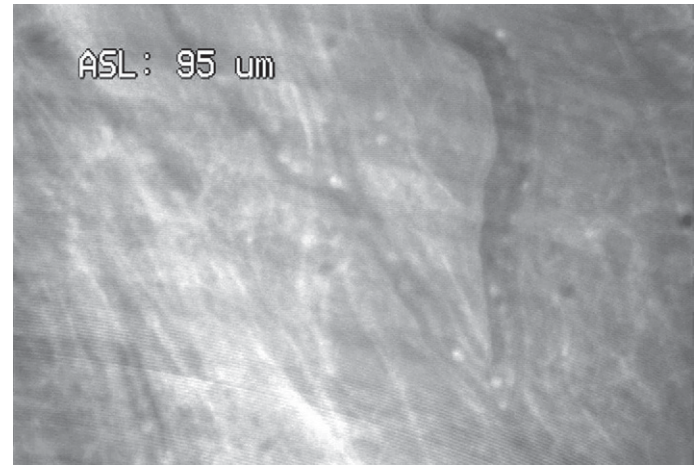

Figure 11.3. Vessels within the stroma of conjunctiva are also clearly visible.

low light level inherent with confocal microscopy imposes a severe limitation on exposure. One answer to this dilemma is pulsed light. The instrument devised by Koester[4] uses this solution effectively. Another method uses an intensified camera for image capture; however, the image intensification process induces some loss of resolution. Fortunately, camera technology continues to improve rapidly, and advances can be expected to aid image quality.

NORMAL MORPHOLOGY

Both the bulbar and the palpebral conjunctiva can be examined with the confocal. Bulbar conjunctival epithelial cells are slightly smaller than their palpebral counterparts. Goblet cells are present in greater numbers on the palpebral conjunctiva, and appear as larger cells amidst the epithelium. Vessels within the stroma of conjunctiva are also clearly visible (Fig. 11.3). It is further possible to image individual cells within the blood flow. The Palisades of Vogt are readily seen in the basal layer of the conjunctiva at the limbus. Conjunctiva-associated lymphatic tissue in the form of subepithelial follicles can also be imaged.[5]

The surface of tear film can be visualized with confocal microscopy using a standard ×5 or ×10 dry microscope objective.[6] Interference patterns from the lipid layer generate sharply demarcated interference patterns, which indicate lipid thickness (Fig. 11.4). White light illumination and color camera capture reveal the full spectrum of interference colors as seen by other systems for lipid interference imaging.[7,8]

The thickness of the tear film can be estimated with confocal microscopy, as demonstrated by Prydal and Dilly.[9] By correlating interference patterns with measurements taken on thin plastic films, they estimated the thickness of the water layer to be 45 μm in humans and several other animal species.[10] This measurement was thicker than the previous estimates, indicating a much greater tear volume than obtained with fluorophotometry.

Confocal microscopy of the epithelium represents one of the most important areas of investigation.[11] The surface of the epithelium can easily be seen and is especially vivid in patients following corneal transplantation for reasons that are not understood (Fig. 11.5). The dimensions of the epithelial cells and the size and position of the nucleus can be measured. Following desquamation, the smaller cells underneath are revealed. The depth encoder available for some confocal microscopes can measure the thickness of the epithelial

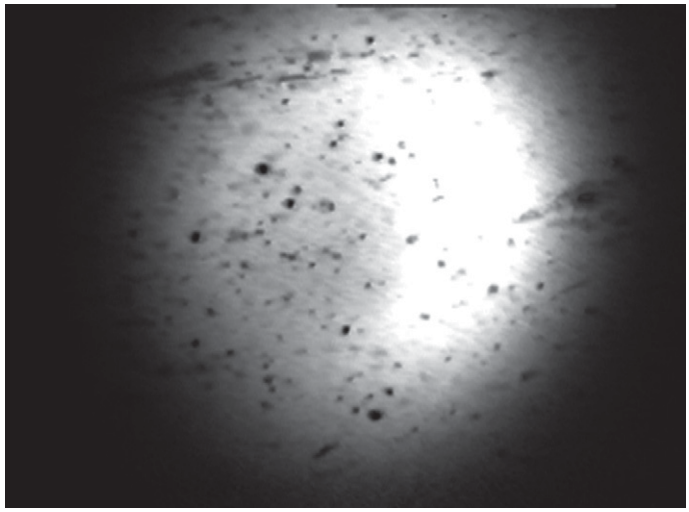

Figure 11.4. Interference patterns from the lipid layer generate sharply demarcated interference patterns, which indicate lipid thickness.

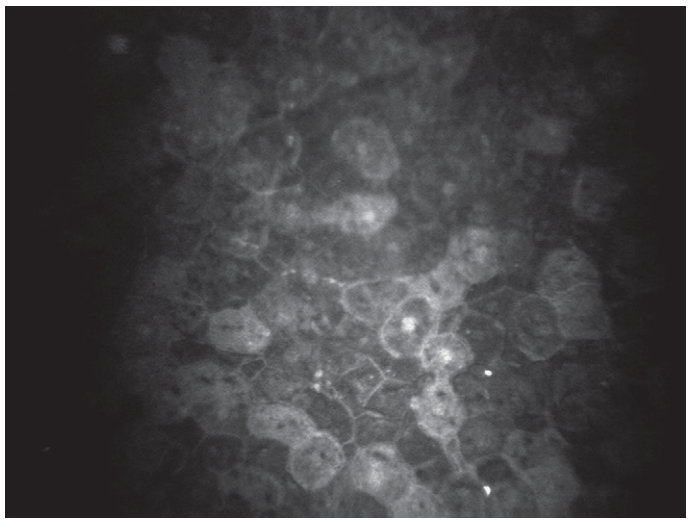

Figure 11.5. The surface of the epithelium can easily be seen and is especially vivid in patients following corneal transplantation for reasons that are not understood.

Figure 11.6. In inflamed conjunctiva, Langerhan's cells may sometimes be seen as dendritic reflective cells in the limbal and conjunctival epithelium.

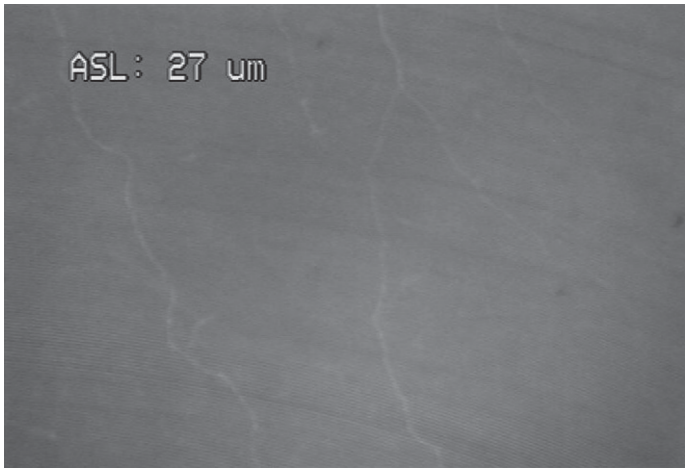

Figure 11.7. Corneal nerves underneath Bowman's layer are easily seen as long branching structures with a width of approximately 5 μm.

cells as well.[12] In inflamed conjunctiva, Langerhan's cells may sometimes be seen as dendritic reflective cells in the limbal and conjunctival epithelium (Fig. 11.6). They are also frequently seen in the cornea epithelium, near the limbus or diffusely following viral infection.

Bowman's layer can be visualized in some patients.[13] It is often seen as a wavy and irregular layer with crevices and folds. The details of Bowman's layer are often less easily visualized than other structures in the cornea.

Corneal nerves underneath Bowman's layer are easily seen as long branching structures with a width of approximately 5 μm (Fig. 11.7). The sites where these nerves pierce Bowman's layer and enter the epithelium appear to be stationary, enabling observation of the distal growth of corneal nerves in the epithelium. Corneal nerves in the epithelium itself are considerably smaller than the subepithelial nerve plexus and are much less easily seen.[14]

Corneal stroma consists of a relatively dense meshwork of keratocytes that have relatively long and thick processes in contact with many other keratocytes in the vicinity.[11] These thin processes are not seen with in vivo confocal microscopy but have been demonstrated with laser scanning confocal microscopy in vitro.[15,16] The relative density of keratocyte cell bodies can be estimated and demonstrated with three-dimensional reconstructions of stacked optical sections.[17]

The endothelium can be seen in detail over a relatively wide area using confocal microscopy even when the stroma is not completely clear (Fig. 11.8).[11] Details of the endothelial cells are similar to those seen in high-quality specular microscopy.

The normal trabecular meshwork has not been visualized with in vivo confocal microscopy. The confocal microscope can be used to focus through the trabecular meshwork area; however, Schlemm's canal is not identifiable. The vascular supply to the limbus is easily visualized, but individual trabecular meshwork cells cannot be identified.

CLINICAL APPLICATIONS

ACANTHAMOEBA KERATITIS

The most significant clinical application of confocal microscopy has been the identification of organisms causing keratitis, particularly

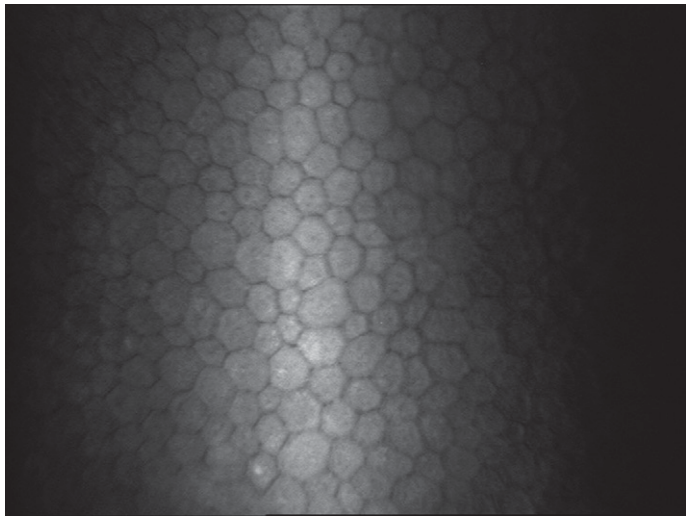

Figure 11.8. The endothelium can be seen in detail over a relatively wide area using confocal microscopy even when the stroma is not completely clear. (From Cavanagh HD, et al. Clinical and diagnostic use of in vivo confocal microscopy in patients with corneal disease. Ophthalmology 1993; 100: 1444. © Elsevier 1993.)

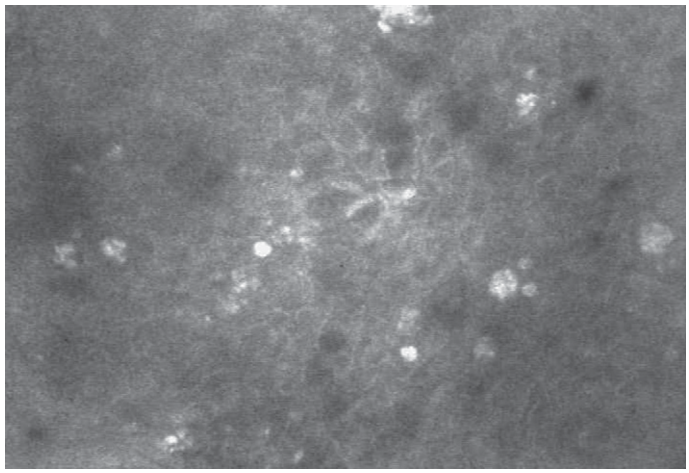

Figure 11.9. The most significant clinical application of confocal microscopy has been the identification of organisms causing keratitis, particularly Acanthamoeba.

Acanthamoeba (Fig. 11.9). Chew and co-workers[18] first reported in vitro identification of *Acanthamoeba keratitis* in a rabbit. In 1994, Auran and co-workers[19] reported the first case in a human using confocal microscopy. That single case report identified a 26-µm diameter organism in the anterior stroma subsequently confirmed histopathologically. Cavanagh and co-workers[11] reported a similar appearance in an animal model. Pfister and co-workers[20] reported a single case in a human.

Winchester and co-workers[21] reported eight cases of human Acanthamoeba keratitis identified with confocal microscopy; in each case, the highly reflective ovoid organisms were 10–25 µm in diameter located in the deep epithelium. Many other investigators have since demonstrated the utility of identifying Acanthamoeba in the corneas of patients with suspected Acanthamoeba keratitis and using the instrument to follow the course of the disease. A larger series demonstrated that the disease is more common than previously estimated.[22] Most cases do not have the previously reported association with contact lens use. Many cases are, however, associated with herpes simplex keratitis, and both infections may be present in the same person.[23] Acanthamoeba organisms have been demonstrated within an active dendrite (Fig. 11.10). Although internal details of Acanthamoeba organisms can be visualized with confocal microscopy, the instrument does not reveal sufficient detail to enable the diagnosis to be made with certainty based on confocal findings alone. Most physicians still use epithelial or stromal biopsy or culture to make a definitive diagnosis.

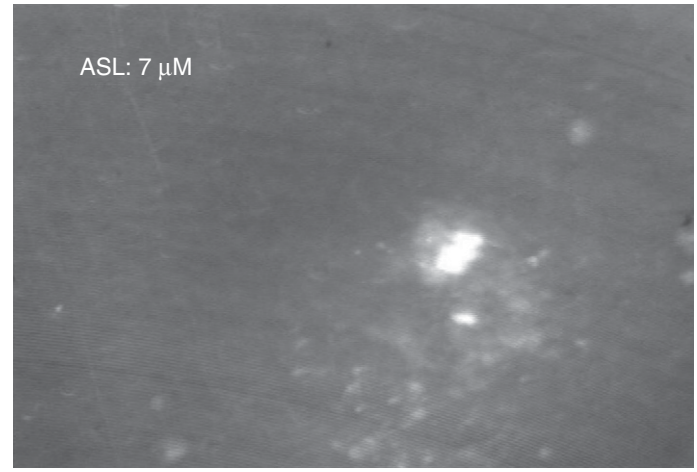

Figure 11.10. Acanthamoeba organisms have been demonstrated within an active dendrite.

Acanthamoeba keratitis often requires months of topical medication, and it can be difficult to evaluate when the organism has been eradicated.[24–26] Confocal microscopy has made a major contribution in the ability to identify when an organism has been eradicated since repeated examinations can easily be performed.

FUNGAL KERATITIS

The diagnosis of fungal keratitis is another problem that has been aided by confocal microscopy.[18,27] Branching hyphae in the deep epithelium and stroma are relatively easy to identify, which enables treatment to begin much sooner. Yeasts, such as Candida, which usually do not form branching filaments, are much more difficult to diagnose because they cannot reliably be discriminated from inflammatory cells. As with Acanthamoeba, the efficacy of treatment can be followed with repeated examinations.

BACTERIAL KERATITIS

Bacterial keratitis is much more difficult to identify with confocal microscopy. Although the theoretical limit of resolution for the instrument is actually better than standard white light microscopy of fixed specimens, the practical application with video capture using intensified CCD cameras, rapid motion of an in vivo subject, and low light conditions make the practical resolution approximately 1 to 2 µm. Because most bacteria are 0.5 µ in length or less, it is generally impossible to see individual bacteria in the cornea. Some organisms, however, are much larger, approaching the 2-µm range. These organisms probably can be identified with confocal microscopy, as reported by Kaufman and co-workers.[28] The inflammatory component, consisting of lymphocytes, macrophages, and polymorphonuclear leukocytes, is readily identified in the area of the keratitis. Dense infiltrates induce considerable light scattering and reduce the visibility of deeper structures.

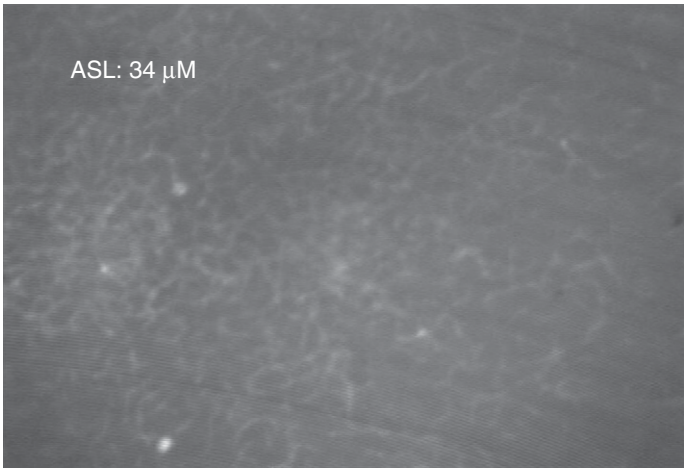

Figure 11.11. Dendritic cells are found to intertwine with the subepithelial nerve plexus to make a web-like pattern.

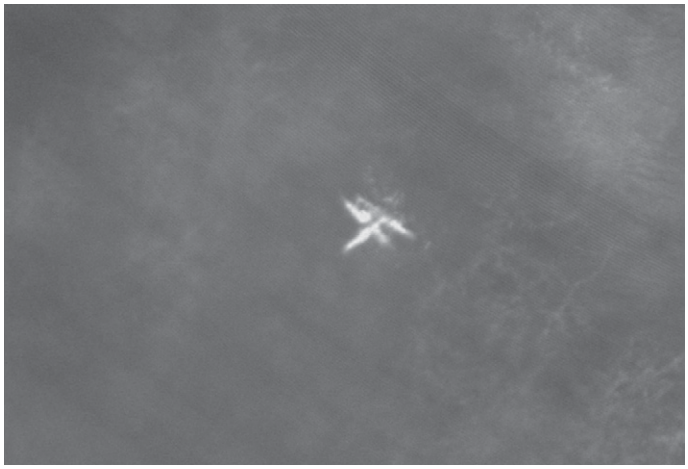

Figure 11.12. Bacteria can form crystalline-like patterns or amorphous shapes as they colonize the cornea, particularly following topical steroid use in corneal transplants. (From Wilhelmus KR, Robinson NM. Infectious crystalline keratopathy caused by *Candida albicans*. Am J Ophthalmol 1991; 112: 322. © Elsevier 1991.)

Microsporida may also be identified with confocal microscopy as a series of small cellular structures and spheroid clumps in the deep epithelium and anterior stroma. The appearance is quite characteristic and can be confirmed with biopsy.[29]

VIRAL KERATITIS

Viral keratitis (herpes keratitis and epidemic keratoconjunctivitis) has a characteristic appearance on confocal that can be used to aid in the diagnosis. Dendritic cells are found to intertwine with the subepithelial nerve plexus to make a web-like pattern (Fig. 11.11). As the infection runs its course, these dendritic cells decrease in density. This can be followed clinically as sign of recovery.[30]

CRYSTALLINE KERATOPATHY

Crystalline keratopathy is a bacterial phenomenon that is highly invisible with confocal examination.[31,32] Bacteria can form crystalline-like patterns or amorphous shapes as they colonize the cornea, particularly following topical steroid use in corneal transplants (Fig. 11.12).[33] The most common organism causing this phenomenon is *Streptococcus viridans*, although many others, including fungi, also produce this pattern. The crystals are very easily seen with confocal microscopy and often are quite dramatic.[32] They may, however, be confused with deposits of cholesterol or other substances. This discrimination is particularly important because often it is very difficult to obtain a sample of the organisms when they are located only in deeper structures. Often, there is no active infection or epithelial defect on the ocular surface. Prolonged application of an appropriate antibiotic therapy can result in complete eradication of the organism if the diagnosis is made early; otherwise, corneal retransplantation is often necessary.

DRY EYE SYNDROME/MEIBOMIAN GLAND DYSFUNCTION

The appearance of the lipid layer can be correlated with tear film function and disease states.[34] In seborrheic meibomian gland dysfunction with excess lipid production, large amounts of lipid are usually expressible from the meibomian gland orifices. Confocal microscopy of meibomian gland dysfunction shows large areas of linear interference layers and pools of lipid. When meibomian glands are expressed and the lipid viewed immediately after expression, this seborrheic pattern becomes more obvious as the lipid layer thickens.

Patients with dry eye often have increased amounts of debris in their tear film and relatively thin lipid layers. Sometimes they show a reticulated pattern of fine lines quite dissimilar from the appearance of seborrheic meibomian gland dysfunction. Normal eyes often have a very thin lipid layer (100 μm) despite low evaporation rates; thus it would appear that meibomian gland function can be normal with low evaporation without having a thick lipid layer. Patients with obstructive meibomian gland dysfunction and diminished amounts of lipid or those with very thick meibomian secretions display increased amounts of debris in the tear film and a very thin lipid layer.[34]

CORNEAL DEPOSITS

Confocal microscopy is not required to identify most foreign material, as the foreign material is large enough to be seen with slit-lamp microscopy. It may aid, however, in the identification of material such as ciprofloxacin deposits.[35] Their appearance as small, uniform crystals with confocal microscopy is characteristic, as is the appearance of amiodarone, in which many spheres 5–30 μm in diameter are dispersed through the deep epithelium without evidence of inflammation. Iron deposits are 8–10 μm, more densely packed, and uniform in size (Fig. 11.13).

CONTACT LENS WEAR

The confocal microscope has been used to identify corneal changes that occur in contact lens wearers. Eckard and co-workers used the confocal to quantify changes to the corneal epithelium. Cell bodies of superficial cells were smaller and consequently more dense. Corneal epithelial thickness was decreased in the periphery. Hollingsworth and Efron[35a] demonstrated an increase in microdot opacities (thought to be lipofuscin) in rigid gas permeable lens wearers relative to controls. Hamrah and co-workers[35b] found increased Langerhan cell density in both the central and peripheral cornea in contact lens wearers relative to controls. The clinical significance of these corneal changes is not known.[36]

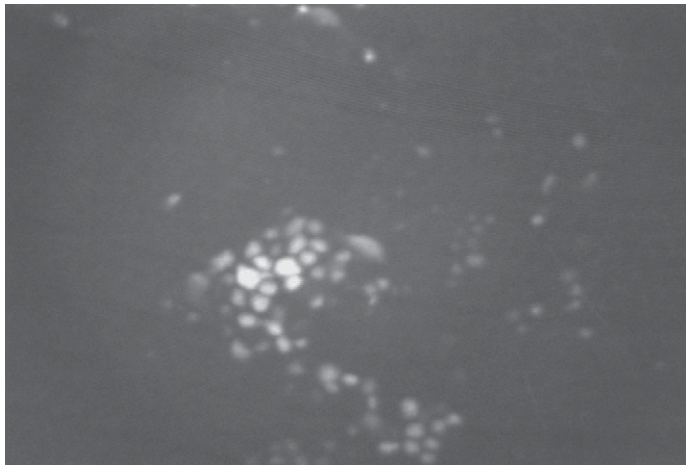

Figure 11.13. Iron deposits are 8 to 10 μ, more densely packed, and uniform in size. (From Wilhelmus KR, Robinson NM. Infectious crystalline keratopathy caused by *Candida albicans*. Am J Ophthalmol 1991; 112: 322. © Elsevier 1991.)

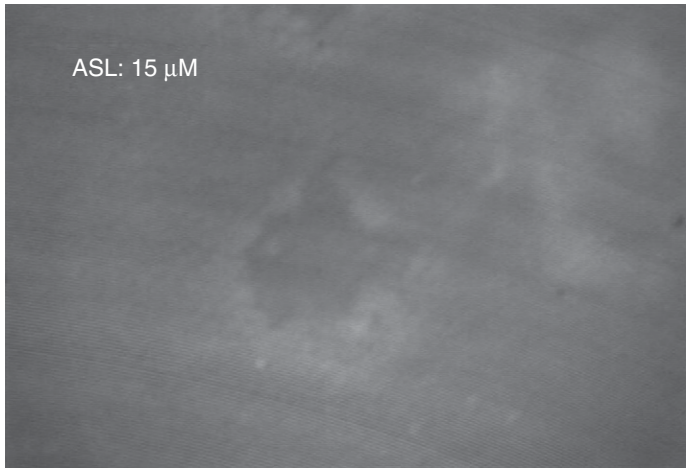

Figure 11.14. The redundant basement membrane is also identifiable with confocal microscopy as wavy semitransparent material without evidence of inflammation.

CORNEAL DYSTROPHIES

The normal basement membrane between the epithelium and Bowman's layer is not identifiable with confocal microscopy. Basement membrane dystrophy (also referred to as map, dot, fingerprint dystrophy, or recurrent erosion syndrome) has a thickened, irregular basement membrane and epithelial microcysts usually identifiable with slit-lamp microscopy. The redundant basement membrane is also identifiable with confocal microscopy as wavy semitransparent material without evidence of inflammation (Fig. 11.14). Additional basement membrane material may form large cysts within the epithelium, forming irregular patterns and whorls.

Meesman's epithelial dystrophy can appear as whitish, moderately reflective, spherical deposits 20 to 50 μ in diameter, interspersed with cysts in the midepithelium. The cysts can be as large as 200 μ in diameter and contain degraded basement membrane material. It is important to distinguish this from Acanthamoeba keratitis, in which the organisms are smaller, are more uniform in size, and show internal structure. With Meesman's dystrophy, there is also an absence of inflammatory cells and bilateral symmetry.

The deposits in lattice, granular, and Avellino dystrophies are less sharply demarcated than expected from slit-lamp microscopy.[11]

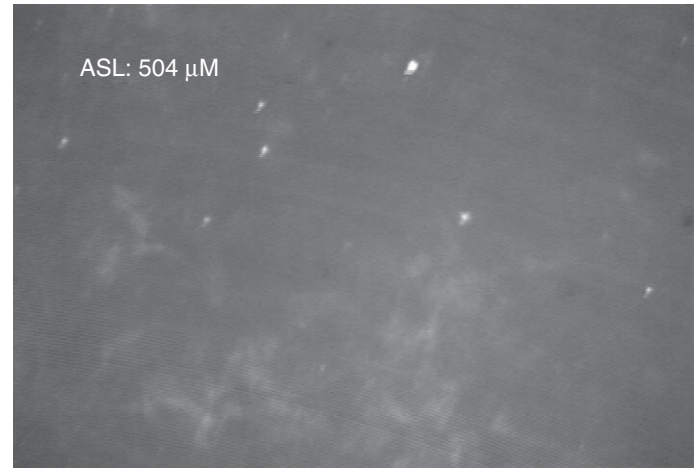

Figure 11.15. In posterior polymorphous dystrophy, normal epithelium is interspersed with nests of abnormal cells, forming irregular patterns.

Amorphous material without characteristic shape or reflective quality can be seen in the stroma. Macular dystrophy also shows deposition of reflective material in the anterior and midstroma.

In Fuchs' endothelial dystrophy, guttata can be identified in the endothelium and, when epithelial edema is present, hollow cysts in the basal epithelium 100 to 200 μ in diameter.[37] The stroma does not have a characteristic appearance.

In posterior polymorphous dystrophy, normal epithelium is interspersed with nests of abnormal cells, forming irregular patterns (Fig. 11.15). The demarcation between the dystrophic and normal cells is usually distinct.

Examination of Fleck dystrophy reveals small, discrete, amorphous shapes in the deep stroma. These shapes have the semblance of large keratocytes, suggesting that this may in fact be what they are. There is an absence of inflammation, and the other keratocytes otherwise appear normal.

CORNEAL GRAFT REJECTION

Confocal microscopy has been used to investigate corneal graft rejection.[38] In rabbits, corneal transplant rejection appears as inflammation in the graft and is especially pronounced around sutures. This application has not been useful to evaluate corneal graft rejection in humans as the response appears to be relatively nonspecific and can be easily evaluated with other modalities.

WOUND HEALING

Confocal microscopy is particularly useful to investigate wound healing.[39] The cell migration and general reparative process can be studied in vivo with repeated observations to assess the progress over time.[40,41] Keratocyte infiltration and wound gape have been measured following radial keratotomy type wounds.[42,43] Epithelial and endothelial migration following various types of injury have also been assessed.[44]

REFRACTIVE SURGERY

The effects of photoablative keratectomy have also been investigated and the resulting epithelial and stromal thickness changes measured.[45] Confocal microscopy is uniquely suited to measuring

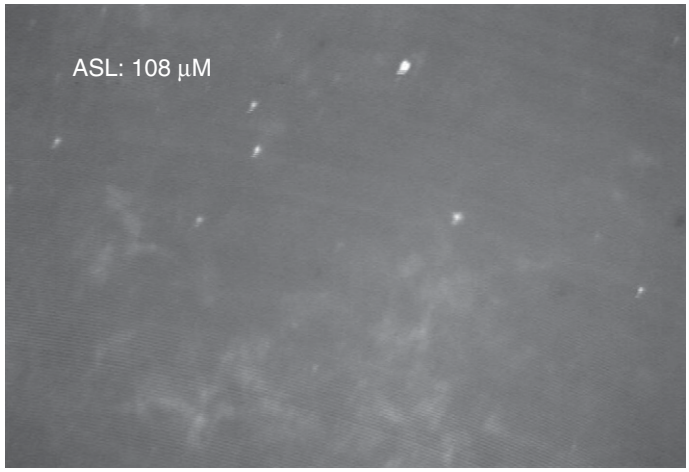

Figure 11.16. Confocal microscopy can also be used to accurately assess flap depth. Cuts made with the microkeratome leave behind microscopic metal fragments.

Figure 11.17. In cases of known scleritis an increased number of rolling leukocytes is seen along the vessel walls relative to controls and allergic patients. (From Lim L, Hoang L, Wong T, Mathers WD, Rosenbaum JT. Intravital microscopy of leukocyte-endothelial dynamics using the Heidelberg confocal laser microscope on patients with scleritis and allergic conjunctivitis. Mol Vis 2006 Oct 26; 12: 1302–1305.)

epithelial thickness following photorefractive keratectomy. Epithelial thickness has been shown to decrease following photoablation, and the effect appears to persist.[12] Following photorefractive keratectomy, keratocytes appear activated and fewer in number with increased haze in the area of ablation.[12,45] Over 6 months, they return to a more normal appearance and density. Preliminary studies have been done on the keratocyte density following in situ keratomileusis, but the technique has not been used to full advantage as yet.[46]

Confocal microscopy can also be used to accurately assess flap depth. Cuts made with the microkeratome leave behind microscopic

Figure 11.18. At least six different morphologies of keratic precipitates have been differentiated based on their confocal appearance. (From Wertheim MS, Mathers WD, Planck SJ, et al. In vivo confocal microscopy of keratic precipitates. Arch Ophthalmol 2004 Dec; 122(12): 1773–1781.)

metal fragments (Fig. 11.16). These fragments are easily detectable in the interface with the confocal. The flap thickness and residual stromal thickness can be determined, thereby aiding in surgical planning if retreatment is necessary. The interface created by the femtosecond laser is less easy to find.[12]

SCLERITIS/UVEITIS

Conjunctival and scleral vessels are easily examined with the confocal microscope. In cases of known scleritis, an increased number of rolling leukocytes is seen along the vessel walls relative to controls and allergic patients (Fig. 11.17).[47] Keratic precipitates are readily visible with confocal microscopy. At least six different morphologies of keratic precipitates have been differentiated based on their confocal appearance (Fig. 11.18).[48] It is promising that the keratic precipitate morphology may aid in diagnosing the etiology of the underlying inflammation.

FUTURE STUDIES

Confocal microscopy extends our vision beyond that achieved with current magnification. It is hardware and software dependent, and advances will rely on future improvements in camera technology and computer power. Limitations now imposed by low light levels and the need for rapid multiple image acquisition are the next obstacles to overcome. Current levels of computational power have improved to such an extent that high-resolution images can be captured in real-time, digitized, and stored without excessive expense. Problems with digital image storage will continue; however, continual improvements in disk storage should keep up with demand. As processing power continues to evolve, video resolution can be increased correspondingly. Eventually, very high-resolution video will be captured in real time without destructive compression.

Another technique of considerable future importance is the use of fluorescein markers for identification of pathogens and physiologic and biologic processes. Confocal microscopy can be modified to incorporate filters for fluorescent microscopy. This application has already been reported in preliminary animal studies. Current methods and low light conditions still limit this application; however, these difficulties can and should be overcome. Eventually, confocal microscopy may represent a method of diagnosing a wide variety of pathogens and biologic conditions in the cornea rapidly, safely, and with minimal expense.

12 Specular microscopy

Ronald A. Laing

A primary concern in evaluating corneal tissue before surgery or before its use as donor tissue in penetrating keratoplasty is the condition of the corneal endothelium, the region of the cornea that is primarily responsible for the maintenance of normal corneal thickness, turgor, and transparency. Through changes in cell morphologic characteristics, the corneal endothelium reflects stresses and strains that have been placed on the cornea. Thus, any morphologic changes seen in the endothelium are indicative of the current status of the endothelium and its functional reserve, the ability of the endothelium to respond favorably to unexpected stress.

Specular microscopy is a method of evaluation that allows, in either a clinical or eye bank setting, for the direct observation of the corneal endothelium. Other tissues that may be seen with the specular microscope include the corneal epithelium, the cells of the crystalline lens, various types of ocular debris, inflammatory cells, and optically reflecting structures. The optical principles of specular microscopy[1] and the evaluation of corneal endothelium using specular microscopy[2] have been described. Also, several reviews of the general field of ocular specular microscopy have been published.[3–5] In many respects, the information obtained in specular microscopy of the corneal endothelium is similar to that received from scanning electron microscopy, but specular microscopy has the distinct advantage of allowing the observation to occur in the living cornea without inflicting any damage to the cornea. If desired, serial observations may be made to observe morphologic changes over time in the same cornea. In addition, the specular microscope allows for the observation of reflecting structures within the cells that cannot be discerned with scanning electron microscopy.

The importance of determining the viability and functional reserve of the corneal endothelium before penetrating keratoplasty makes specular microscopy a valuable tool as a noninvasive, nondamaging method of endothelial cell evaluation.[6–9] Combining the specular microscope, either a clinical specular microscope or an eye bank specular microscope, with appropriate computer and software enables rapid quantitative and statistical analysis of the state of the corneal endothelium, instant photographs and reports, and the ability to send photographs, endothelial analysis data, and other data over the Internet to other physicians or to centralized analysis centers.

PRINCIPLES OF SPECULAR MICROSCOPY

The specular microscope is an optical reflection microscope that reflects a slit of light from the cornea and allows observation of this specularly reflected beam. In this context, the term 'specular reflection' refers to the situation where, as with a mirror, the angle the reflected beam of light makes with the reflecting surface is equal to the angle that the incident light beam makes with the reflecting surface.

Because of its design, the specular microscope does not allow nonspecular light rays to be observed, so that the image that is seen is attributable solely to the specularly reflected light rays.

Figure 12.1 shows a simplified optical design of the specular microscope. As is seen in Figure 12.1, a projected slit is focused onto the posterior endothelial surface by an objective lens. The light that is reflected from this surface is collected by the same objective lens and is focused onto a focus plane, generally either a film plane or sensor of a video camera, or it may be directly observed by the examiner. An image of the posterior surface is seen at the focus plane and is directly viewed, captured on photographic film, or displayed on a video monitor screen. By focusing the specular microscope at places other than the posterior corneal surface, one may observe various other reflective surfaces. For example, by focusing the instrument on a plane within the stroma, one may detect the presence of ghost vessels, typically seen as linear refractile structures, nerve fibers, and so forth.

In the normal endothelial image, one sees the cells as having dark cell borders and bright cell surfaces. The reason for this appearance is illustrated in Figure 12.2, which shows the nature of the specular reflection from various types of endothelial surfaces: smooth, rough, wavy, and with excrescences, respectively. In each case, the ray indicated as 1 reflects from a 'flat' portion of the surface and is specularly reflected directly into the objective lens, thus causing the surface to appear as a bright structure to the observer. The rays indicated as 2 are specularly reflected from a curved part of the

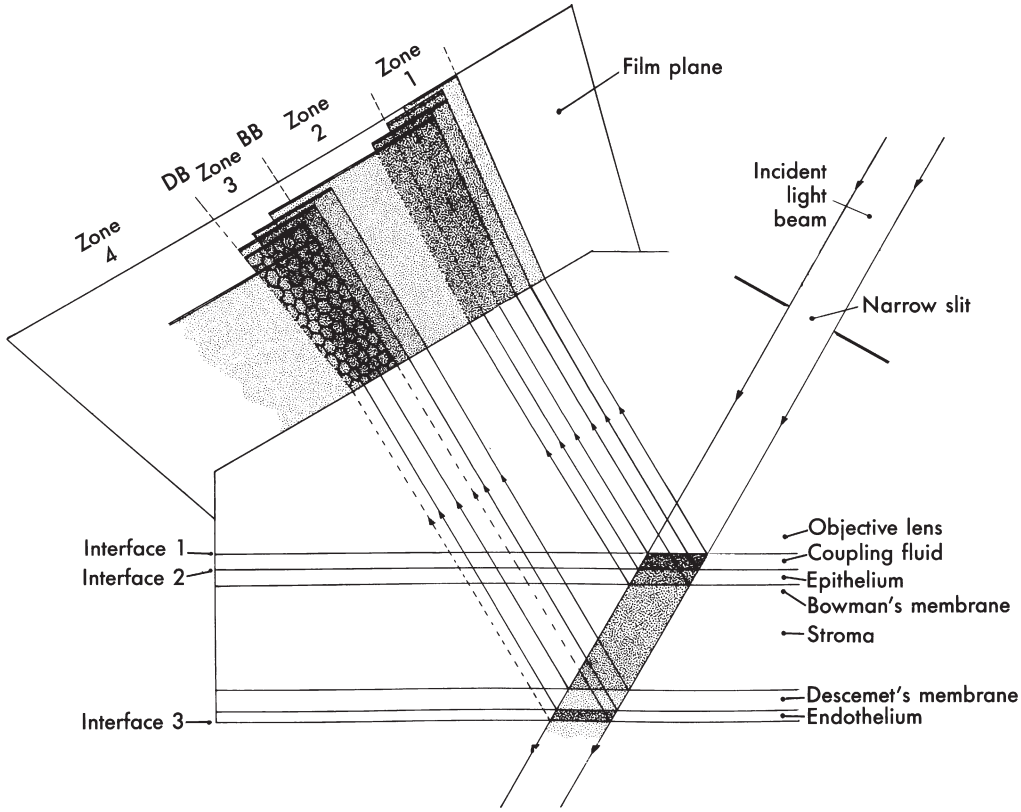

Figure 12.1. Optical principles of the eye bank specular microscope. A slit of light is focused onto the surface of interest (normally posterior endothelial surface). Specularly (mirror-like) reflected light rays are focused onto the film plane. In general, image at the film plane can be viewed with a viewing ocular lens or seen on a real-time video monitor.

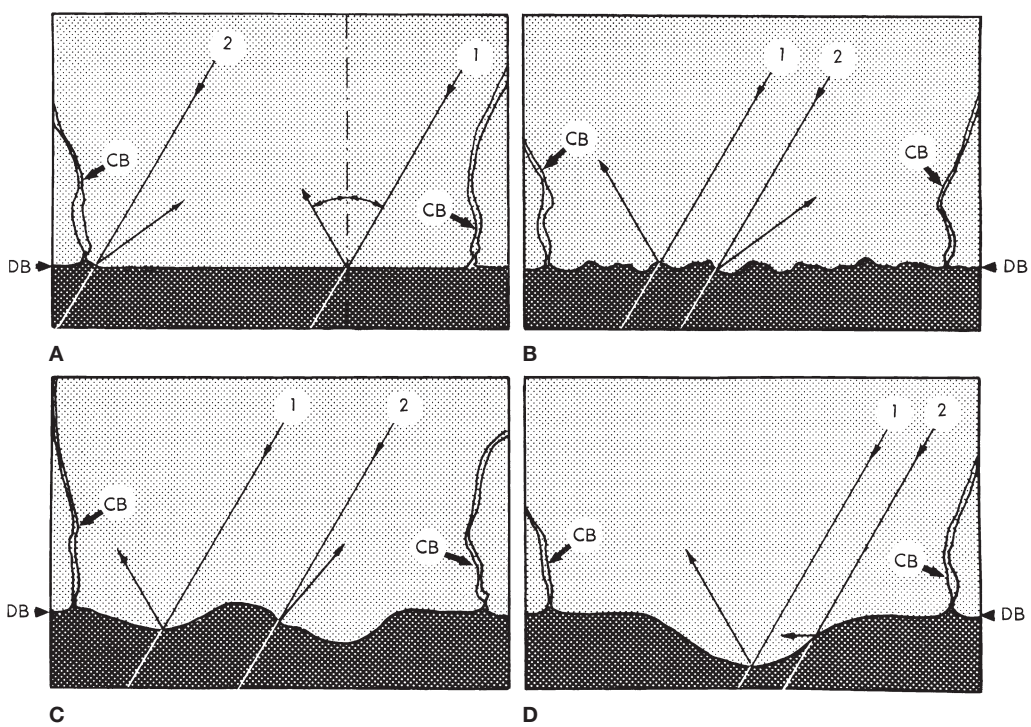

Figure 12.2. Nature of specular reflection from various types of posterior endothelial surfaces. Surfaces shown are: *A,* smooth; *B,* rough; *C,* wavy; and *D,* a posterior endothelial surface containing an excrescence. In each figure, cell boundary is denoted by CB; ray denoted as 1 is collected by objective lens of specular microscope and results in a bright area on film, whereas ray denoted as 2 is not collected by objective lens and result is a dark region on film plane. DB, dark boundary as seen on specular micrographs.

surface and as such are not collected by the objective lens. Therefore curved surfaces, such as the cell borders, the sides of rough areas, and the sides of an excrescence, appear dark to the observer. Thus in specular microscopy, the normal endothelial cell having a smooth surface appears as a bright circle surrounded by a dark border. If, instead of a smooth surface, the cell has a rough surface, the inside of the cell will have a granular appearance with the spacing between the granular dark regions being indicative of the degree of the roughness of the surface. As may be seen in the Figure 12.2, *D*, isolated corneal guttae appear as roundish dark structures with a central bright spot, which marks the apex of the excrescence.

CLINICAL AND EYE BANK SPECULAR MICROSCOPES

Depending on the objective lens used, the specular microscope may be either a contact microscope, in which the front of the objective lens touches the cornea, or a noncontact microscope, in which there is an air space between the front of the objective lens and the cornea. As is true of all optical microscopes, the resolution (sharpness) of the image and the optical sectioning ability depend on the numerical aperture (NA) of the objective lens. Contact specular microscopes generally have objective lenses with an NA that is higher than that of noncontact instruments such that the image quality obtained is somewhat better with contact instruments.

Clinical contact specular microscopes somewhat inhibit eye motion, thus reducing motion artifacts in the image. Contact instruments also enable stromal, epithelial, and lens epithelial cells to be observed and generally give a readout of the corneal thickness. In the past few years, several noncontact instruments have been developed that have the advantage of not having to touch the cornea. A typical clinical noncontact specular microscope that was recently developed is shown in Figure 12.3.

Eye bank contact specular microscopes can and have been used for observation of the corneal endothelium in the whole globe. However, most modern eye banks prefer to observe the cornea after it has been excised and placed in storage media. In such cases, contact objective lenses cannot be used because the cornea cannot physically be placed in contact with the objective lens. Again, the resolution and optical sectioning ability of the eye bank specular microscope depend on the NA of the noncontact objective lens, and these can often be improved for older instruments by changing the objective lens to one of the newer designs that are now available. Eye bank specular microscopes used for observing the cornea in eye bank storage chambers have been popular, and observation in chambers remains the most common method of endothelial observation. A typical eye bank specular microscope for observing the cornea in storage chambers is shown in Figure 12.4. This and similar instruments allow observation of the corneal endothelium, epithelium, and stroma either in whole globes (using a contact objective lens) or in excised corneas in storage chambers (using a noncontact objective lens). The instrument shown allows the cornea to be tilted about its center of curvature, allowing observation of the peripheral and the central endothelium. Because the optics head is mounted to a rigid column, a variety of cameras may be attached to the unit without concern for the weight of the camera. Often, both direct observations and documentation of the image on film or display of the image on a video monitor are used concomitantly. Recently there has been renewed interest in observing the cornea in the vials in which storage media is supplied.

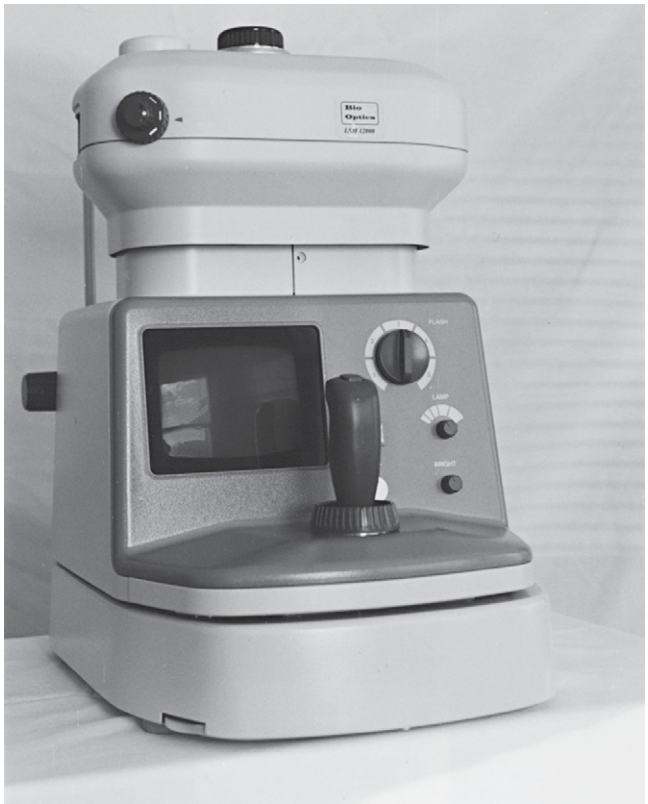

Figure 12.3. Typical modern clinical noncontact specular microscope. This instrument, the LSM-12000, allows both video and 35-mm film images of the corneal endothelium to be obtained. (Courtesy of Bio-Optics, Inc., Portland, OR.)

TECHNIQUES OF EYE BANK SPECULAR MICROSCOPY

Most eye banks store corneas at 4°C either in special plastic eye bank chambers or in glass vials. At this temperature, the endothelial fluid pump is relatively inactive, the cornea is somewhat edematous, and the endothelial surface has lost its normal smoothness. For most corneas, the endothelium is not easily seen at 4°C and must be warmed to 25°C for observation. Figure 12.5, *A* shows the appearance of the corneal endothelium at 4°C, and Figure 12.5, *B* shows the corneal endothelium after warming to room temperature. Note that there is a noticeable abnormality in the appearance of the endothelial cells of the cornea at 4°C, yet the cells appear normal after warming to room temperature. The warming time required to obtain a good endothelial image can be highly variable, ranging from 45 min to more than 2 h. The reasons for this variability are currently unknown. As the cornea warms to room temperature, the endothelial pump becomes reactivated, pumps fluid out of the swollen stroma, and restores the corneal endothelium to its normally smooth shape. In the absence of epithelial trauma resulting from the excision process, corneas having a shorter warming time may be expected to have a more active endothelial pump than those having a longer warming time and thus are 'better' corneas. However, the barrier function of the corneal epithelium is extremely sensitive to manipulation during excision so that there may be differences in the 'leakiness' to fluid of the epithelium of different donor corneas. The cycle of cooling, warming, and recooling of donor corneas has been shown to have no adverse effects on the

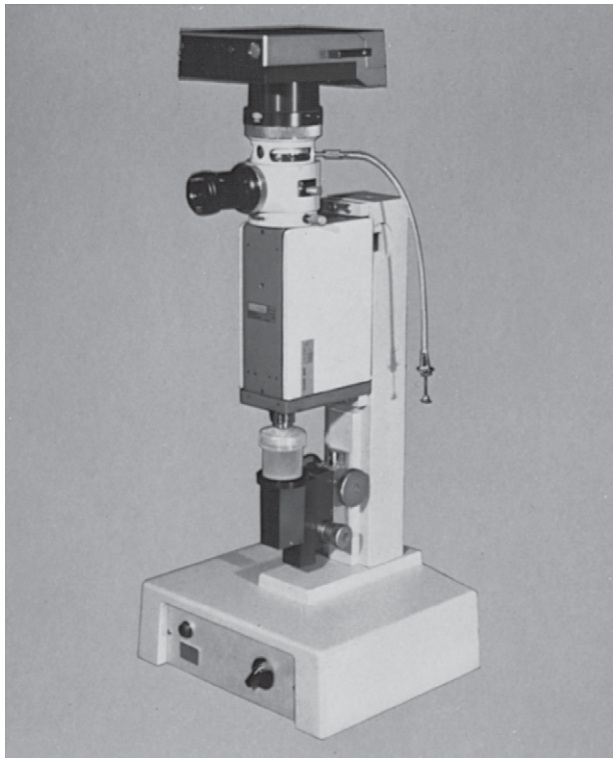

Figure 12.4. Eye bank specular microscope. Various magnifications and modes of operation are possible when objective or ocular lens are changed. As well as high-resolution direct observation, this instrument allows for real-time viewing on a video monitor, hard-copy documentation on 35-mm, Polaroid, or other film type, and recording of image obtained on videotape. This instrument also has capability of direct input of image into a computerized morphometric analysis system. (Courtesy of Bio-Optics, Inc., Portland, OR.)

metabolic or morphometric parameters of the cornea, even when warmed and cooled each day for 7 days.[10]

TECHNIQUES OF CLINICAL SPECULAR MICROSCOPY

In clinical specular microscopy, the technique used depends on the particular instrument that is used. In all cases, however, the basic technique is to align the instrument to the patient's eye so that the conditions for specular imaging are obtained.

NECESSARY CONDITIONS FOR NORMAL OBSERVATION OF THE CORNEAL ENDOTHELIUM

As with any microscope, the endothelium being observed must be at the correct distance from the objective lens (the working distance) so that its image is in focus on the focus plane of the specular microscope. In addition, to see sharp cell borders, the corneal endothelium must satisfy the conditions of specular imaging as described above. For eye bank specular microscopes and clinical contact specular microscopes, this essentially requires that the region of the endothelium being observed be perpendicular to the optic axis of the objective lens. For clinical noncontact instruments, this essentially requires that the region of the endothelium being observed be perpendicular to the line bisecting the optic axis of the illuminating objective and the optic axis of the light-collecting objective.

As one progressively focuses the specular microscope toward the endothelial surface and beyond it, there is light reflected back into the specular microscope that is minimal when the focus point is far from the endothelial–fluid interface and is maximal at this interface. The corneal endothelium is located at the point of maximum reflected light level. It is unlikely, however, that the image seen will resemble, at least to the inexperienced user, anything remotely similar to the appearance of the endothelial cells in the photographs in this book. At this point, the cell borders may not be visible because the conditions necessary to see the specular image have not yet been met. With practice, the nonspecular image is easy to recognize as an amorphous, low-contrast image that moves as the chamber or vial (for the eye bank specular microscope) or the microscope itself (for the clinical specular microscope) is moved laterally. To visualize the cell borders, the instrument must be aligned so as to observe the specular image as described in the previous paragraph. When this is completed, the cell borders become apparent, and the normal corneal endothelial image can be seen.

FACTORS AFFECTING IMAGE QUALITY

A variety of factors affect the quality of the image seen with the specular microscope including the NA of the objective lens. Advances in the design and manufacture of objective lenses in the past few years have made possible lenses that give considerably improved image quality as compared with lenses manufactured some years ago. In addition, it is very important that the front surface of the objective lens be clean. A slight oily film, possibly resulting from someone rubbing their finger across the lens to wipe off dust or from mascara, on the front of a clinical objective lens can degrade the image considerably. For eye bank specular microscopes, the condition of the plastic or glass between the corneal endothelium and the objective lens is very important. Optical distortions in these materials can adversely affect the image quality. Such distortions may arise in the manufacturing process or be the result of heat changes in the plastic top of eye bank chambers because of heat shrinking the protective seal onto the chamber. It is important to cover the specular microscope with a dust cover when it is not in use to minimize the possibility that the lenses become contaminated and dirty. A regular cleaning and alignment of the specular microscope by the factory every 2 to 3 years may be appropriate to ensure that the specular microscope is giving the best possible images.

IMAGE CAPTURE, STORAGE, AND ANALYSIS

In past years most corneal endothelial images were captured on photographic film and analysis was performed on enlargements from the photographic negatives. The film and the enlargements can be easily stored to provide documentation of the endothelial image should this subsequently be required for legal or other reasons. Although photographic film is still used in some clinics, most specular microscopes sold today capture video images that can be instantly seen on a video monitor screen; and with the availability of the personal computer and frame grabbers, computerized image capture, image enhancement, and image analysis systems have been developed.[7] One such system that has been available and in wide use for many years is the Bambi endothelial evaluation system (Bio-Optics, Inc., Portland, OR), which is now only a Windows-based systems, as shown in Figure 12.6. The latest system,

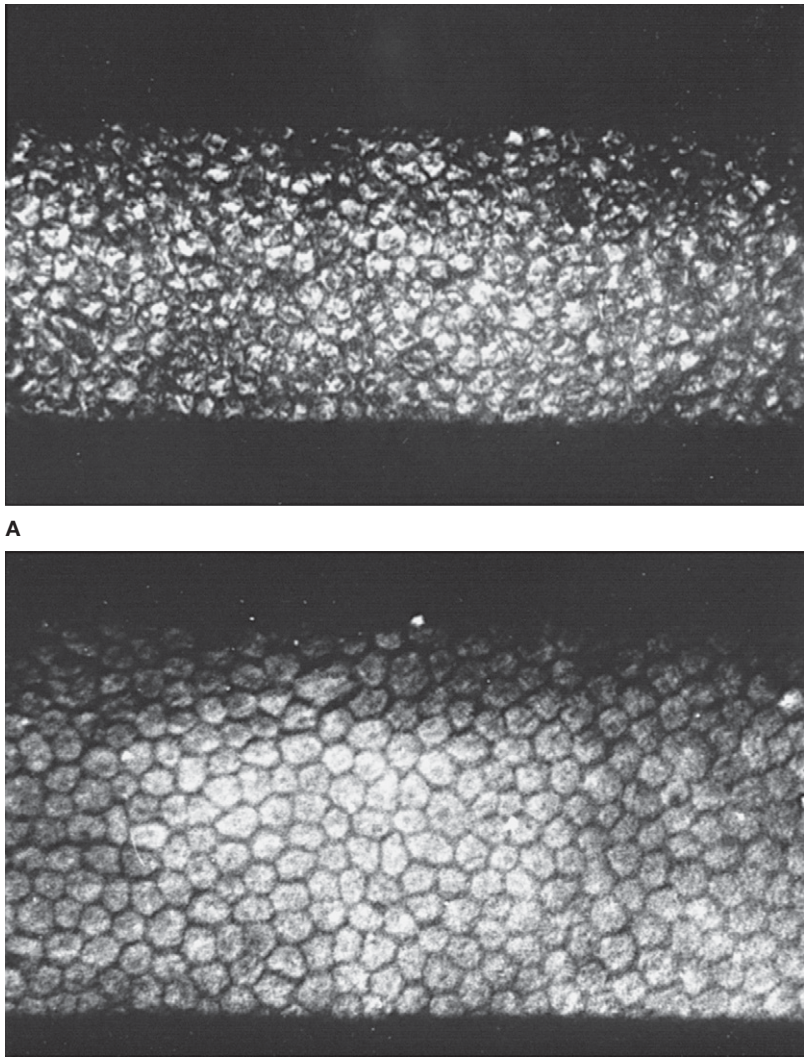

Figure 12.5. Appearance of corneal endothelium at different temperatures: *A,* 4°C; *B,* room temperature.

A

B

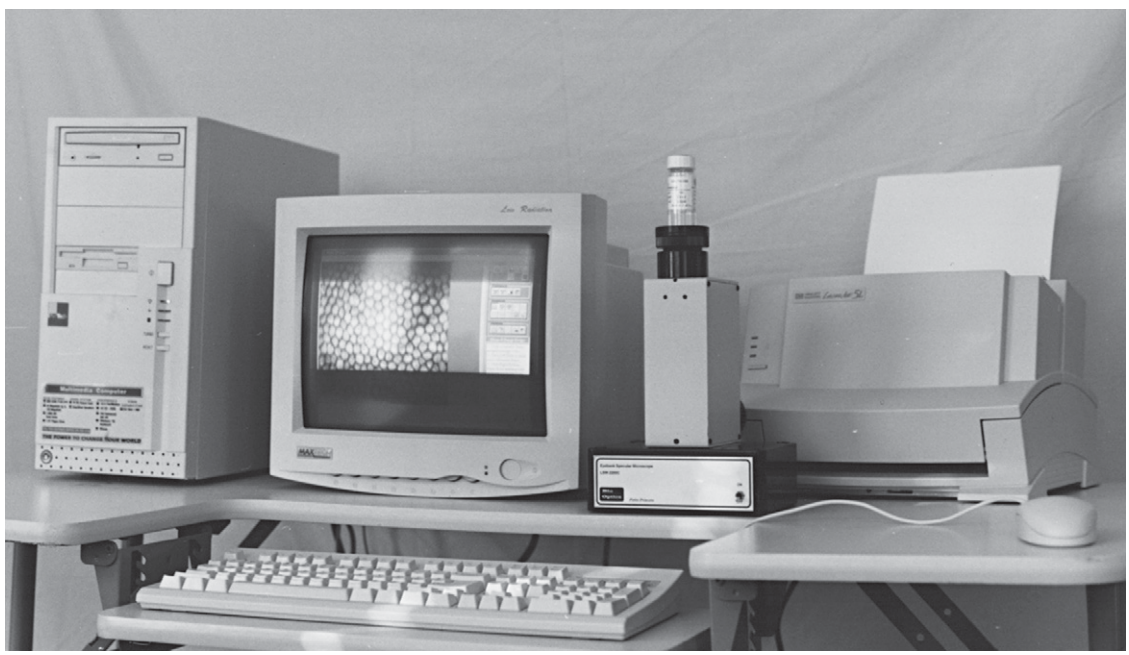

Figure 12.6. Bambi 97 computerized system for endothelial image documentation and analysis. This system captures and digitizes the endothelial image. The normally low-contrast image can then be contrast enhanced and analyzed to obtain the cell count and other morphometric parameters characterizing the corneal endothelium. The endothelial image can be printed out on a laser printer, stored on computer disk, and sent via the Internet to another location. A database is maintained of images and numerical and clinical (or eye bank) data. Letters and reports can be generated containing the image obtained. (Courtesy of Bio-Optics, Inc., Portland, OR.)

Bambi 2500, allows direct video input of the endothelial image from the video specular microscope or, alternatively, by scanning 35-mm negatives or enlargements. This system enables the user to enhance the normally low-contrast endothelial image rapidly, and to obtain the cell count and other morphometric data from the image. Determination of such evaluation parameters as cell density, degree of pleomorphism, and polymegathism is easy and fast. The image can be stored digitally on the local computer or sent to a server so that the endothelial image can be viewed in any other computer. Letters and reports that can include the endothelial image can also be generated with this system. The images and screen displays can be sent to other programs, such as Microsoft PowerPoint, for presentations. The data obtained are stored in a database that is expandable to allow the user to add additional data or to merge into an existing database. Such a computerized analysis system speeds up the entire process of specular microscopic endothelial evaluation and provides additional information not obtainable by manual methods of evaluation.

If the images are stored along with the morphometric data, then after a sufficiently large database is obtained, these data can be analyzed to obtain information concerning such things as possible risk factors and contraindications for procedures and to compare the relative efficacy and safety of new procedures.

QUALITATIVE EVALUATION OF THE CORNEAL ENDOTHELIUM

The specular microscopic image of a young, normal endothelium is shown in Figure 12.7. The cells are similar in size and shape, with no abnormally dark or bright structures being apparent and no evidence of inflammatory cells or adherent debris. The cell density is between 2000 and 3500 cells/mm^2 on the corneal surface. This is an ideal image of the endothelium of a donor cornea. In practice, the appearance of the endothelium of most donor corneas cannot be expected to be this good. In the older cornea and in corneas that have undergone various types of prior trauma or disease, the endothelium has a much different appearance. For the donor cornea, factors contributing to a change from normal include time from death to preservation, whether the eyelids were closed after death, whether any light ice packs were applied to the lids of the donor, trauma inflicted on the donor, trauma resulting from the excision procedure, and so forth. For the clinical cornea, factors contributing to changes from normal appearance include trauma, exposure to environmental pollutants, corneal dystrophies, and so forth.

Ideally one would prefer that a corneal endothelium, either from a donor cornea or a patient's cornea, has endothelial cells that are uniform in size, shape, and appearance. In practice, however, a variety of cell sizes (polymegathism) and shapes (pleomorphism) and abnormally bright or dark structures are encountered (Figs 12.8–12.10).

For corneas that are in the process of healing or recovering from certain types of stress, the processes of cellular coalescence[11–13] and cellular mitosis[14] can occur. In the first case, the coalescing endothelial cells appear as shown in Figure 12.11. In this process, a common cell border between two cells disappears, and the two cells fuse into a single cell. Although it is not presently known if this would contraindicate the use of the cornea in transplant, prudence dictates that, as long as other suitable tissue is available, corneas exhibiting such cells should not be considered for use in penetrating keratoplasty. It has been reported that corneas with considerable polymegathism or pleomorphism have an increased incidence of postoperative decompensation[15] and have a reduced functional reserve.[16] These studies indicate that donor corneas with such findings should not be used in transplant surgery. These findings in the clinical environment would indicate that one should be cautious with any ocular procedures performed on such a patient.

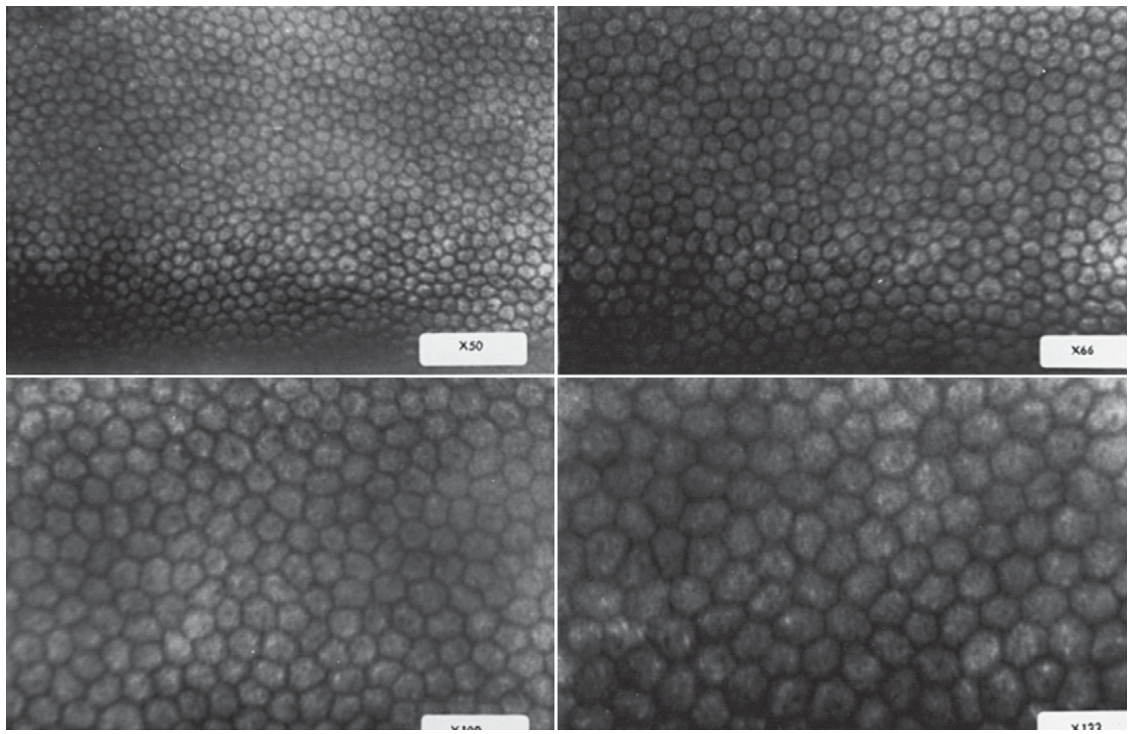

Figure 12.7. Appearance of young, normal endothelium at room temperature viewed at different magnifications. Cells are hexagonal and uniform in size and appearance.

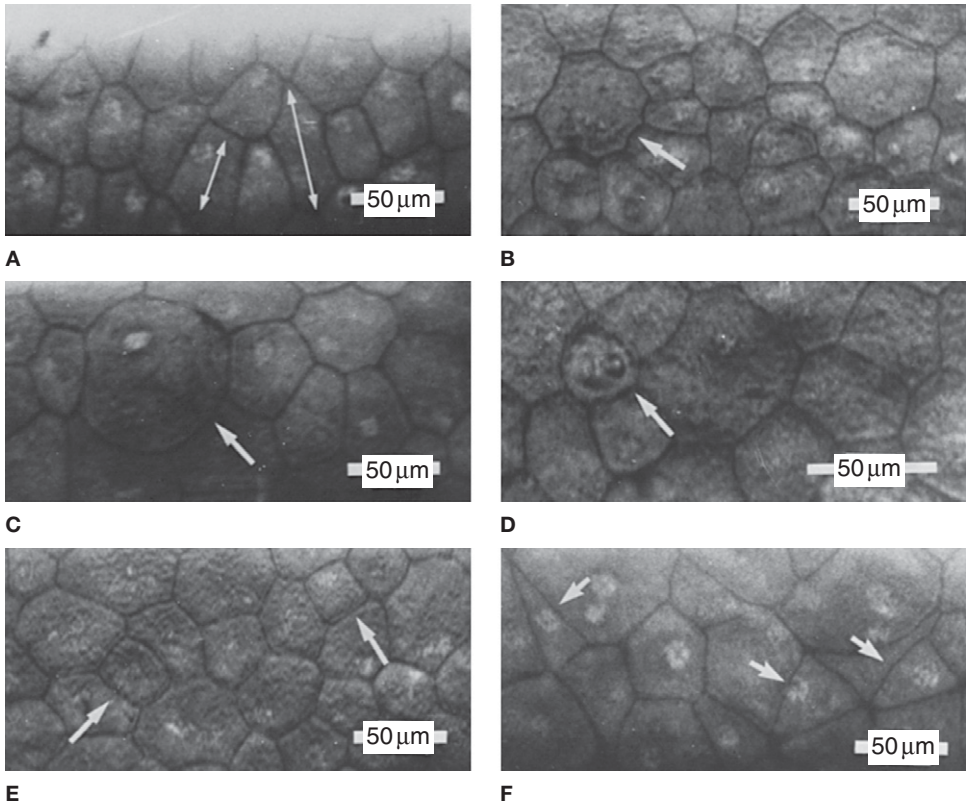

Figure 12.8. Various abnormal endothelial cell shapes, arrows: *A,* stretched; *B,* scalloped; *C,* large; rounded; *D,* small, rounded; *E,* square; *F,* triangular.

As shown in Figure 12.12, one may observe corneal guttata on examination with the specular microscope. Cornea guttata has been reported to reduce endothelial function or functional reserve,[17,18] and for this reason any cornea showing significant guttae should not be considered as acceptable for use in transplant surgery and should be treated gently during ocular surgery.

Bacteria and inflammatory cells are easily seen under the specular microscope. Bacteria are observed as small, bright twinkling objects whose shape and position rapidly change. Inflammatory cells have a similar appearance but are slower in their motions than bacteria. The presence of either bacteria or inflammatory cells (see Fig. 12.9, *H*) probably indicates contamination of either the storage media or the cornea, and as such would contraindicate the use of such a cornea for transplantation.

Other abnormal appearances are indicative of disease states (Figs 12.13 and 12.14) when seen under the specular microscope. Such corneas should not be considered for transplantation use.

QUANTITATIVE EVALUATION OF THE CORNEAL ENDOTHELIUM

A variety of methods have been developed to obtain quantitative information about the state of the corneal endothelium. In early studies, what became known as fixed frame cell counting was used. This method was subsequently modified to allow fixed frame cell counting to be done on a computer, generally with a mouse being used to draw the frame and to mark the cells. This method was shown to have very large and unpredictable errors unless the number of cells completely inside the frame was very large in comparison to the number of 'border cells', i.e. those cells that were cut by one of the borders of the frame.[19] Since this is seldom the case, fixed frame cell counting should seldom be used these days.

A method of eliminating the 'border errors', i.e. those errors due to not knowing how much of the area of the border cells were inside, or outside, the frame was solved by the variable frame cell counting method[19] in which a frame border is traced around a group of cells such that all cells inside the frame are whole cells—the frame does not cut any of the cells in the group. The number of cells inside the frame is divided by the area of the frame to determine the cell count. With the use of personal computers and endothelial images on monitor screens, this method became easy to implement since the frame could be drawn with a mouse and the cells inside the frame could be marked and counted by clicking the mouse when the cursor was inside the frame. The variable frame cell counting method remains the most accurate and reliable semiautomated method for obtaining a cell count. It does not, however, provide information about the distribution of cell sizes in the sample being studied and the method is tedious to perform if the number of cells in the sample is large. To reduce the time required and tedium of drawing a frame and marking the cells, as well as to be able to obtain statistical information about the cell sample, several methods for automated cell counting and analysis have been developed. As might be expected, some give more accurate and reliable results than others. Probably the most difficult aspect of developing an automated method is the complex nature of the endothelial image. When looked at casually, the cells all seem to have clean, dark, and unbroken borders. If looked at more closely, that is far from the case for most endothelial images. Some borders have 'missing border points' and/or places where a clear border between two apparently adjacent cells is unclear. This problem essentially eliminates the use of many of the standard automated image analysis methods that programmers are familiar with. In some cases, a 'medical' decision has to be made as to whether or not an elongated cell with a faint or partially missing interior border is one large and irregular cell, a coalescing cell,[11–13] or two individual cells. This

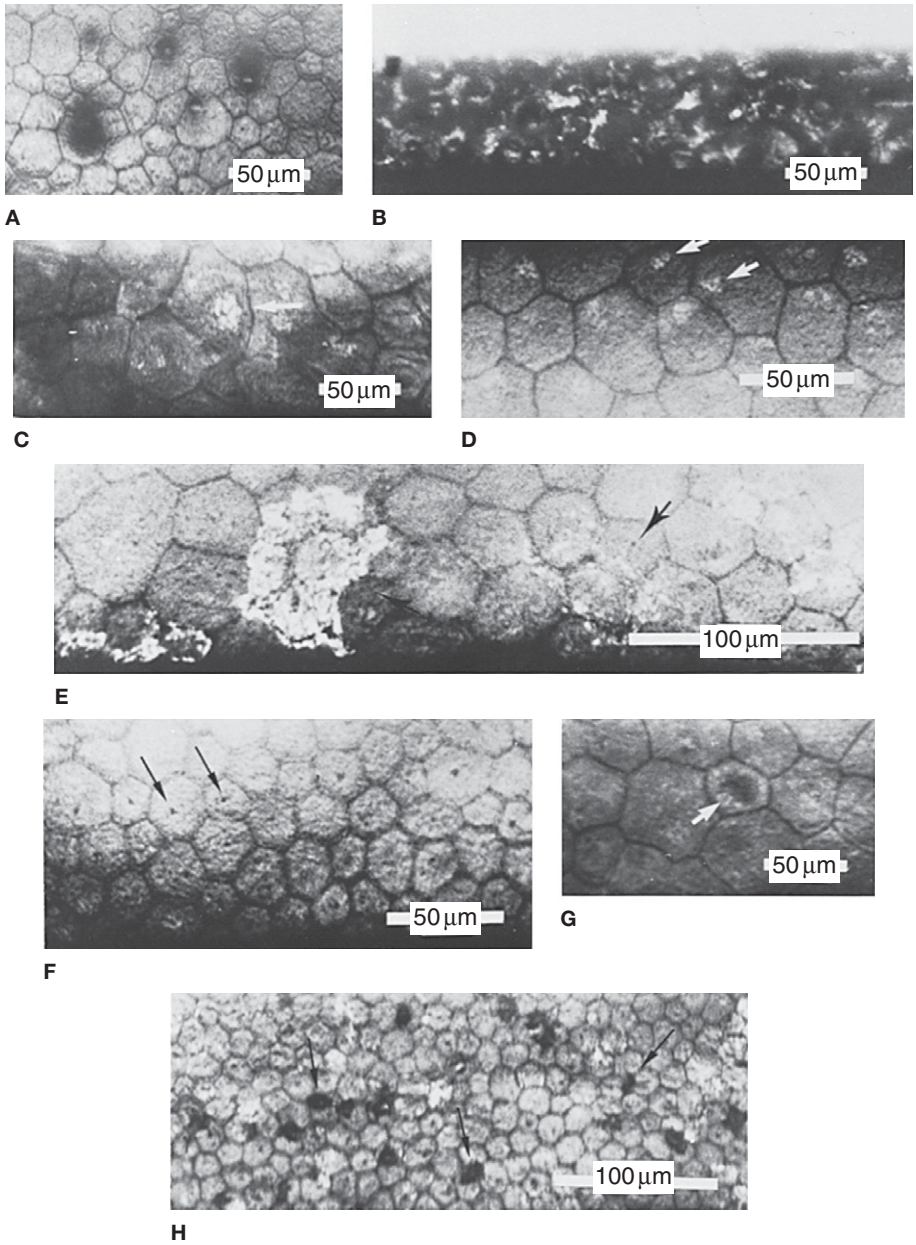

Figure 12.9. Various abnormal intracellular and intercellular structures: *A,* isolated smooth excrescences (cornea guttata); *B,* multiple coalesced guttae; *C,* pigment deposits and linear structures; *D,* bright structures (presumably nuclei); *E,* adherent pigment deposits; *F,* central cilia; *G,* large, dark structure; *H,* inflammatory cells.

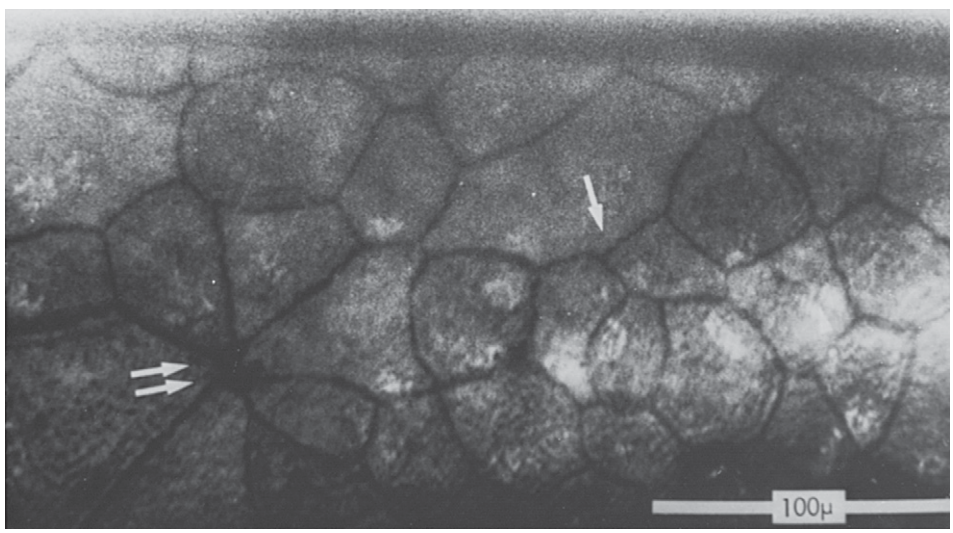

Figure 12.10. Abnormal corneal endothelium showing a 'reformation figure' (double arrow) believed to be indicative of endothelial repair by sloughing and cell sliding. Also seen is a cluster of 'smaller' cells (single arrow), probably resulting from mitosis. Large, multisided cells seen are believed to have resulted from coalescence of cells.

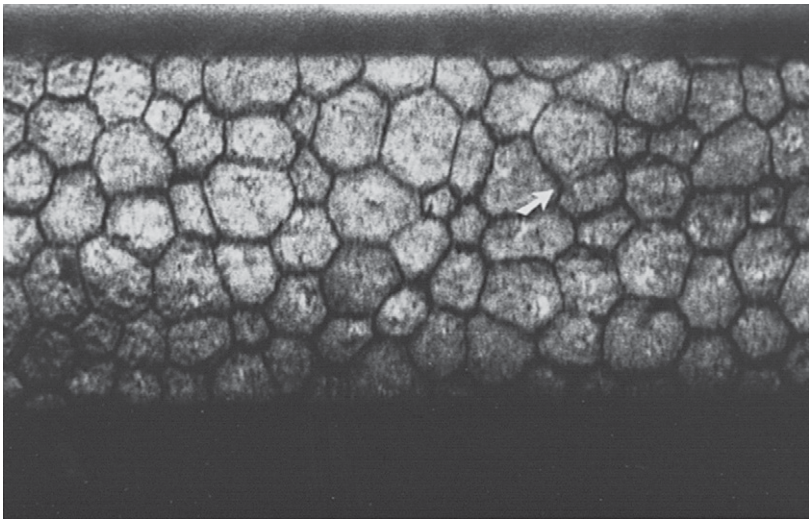

Figure 12.11. Abnormal corneal endothelium showing endothelial cells in the process of 'healing', or recovering from stress, by process of cell coalescence. The cell border (arrow) was seen to disappear over time. Endothelium exhibits pronounced polymegathism and pleomorphism.

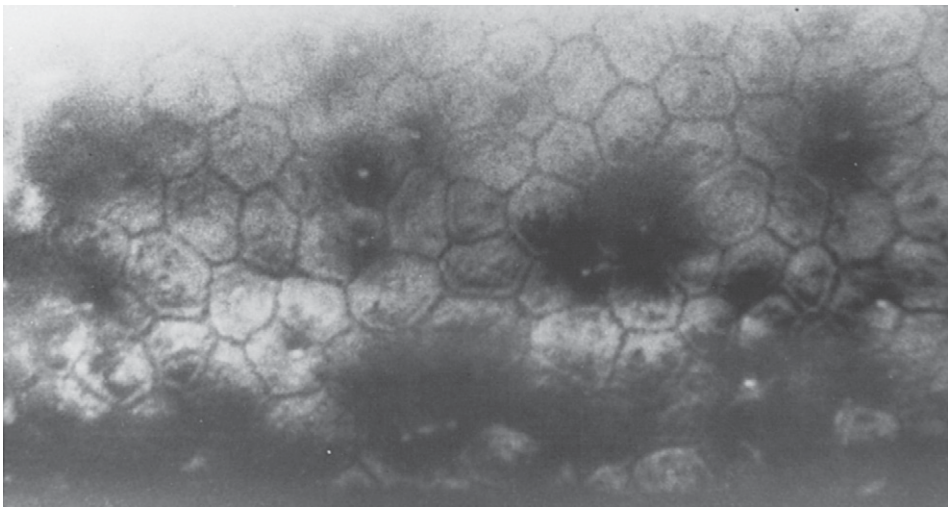

Figure 12.12. Abnormal appearance of corneal endothelium resultant from Fuchs' dystrophy. Notice guttae, seen as irregular, dark patches.

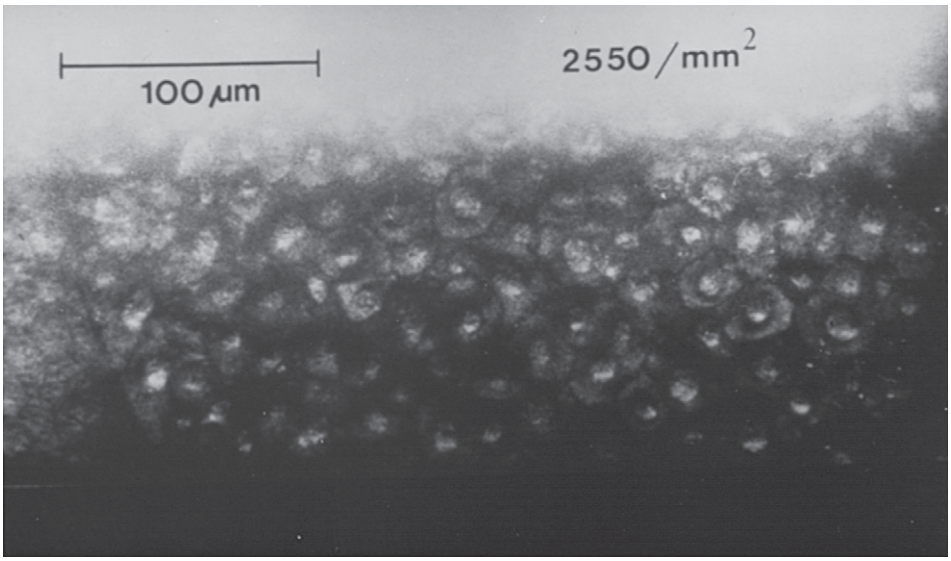

Figure 12.13. Abnormal appearance of corneal endothelium as seen in patients with posterior polymorphous dystrophy.

decision should be made by a trained medical professional and should not be determined a priori by a programmer who generally has minimal understanding of the complexity of the corneal endothelial image. One of the fully automated methods for endothelial cell analysis is the AutoCount program used in Bambi 2500. Figure 12.15 shows a screen shot of what is displayed for a typical endothelial image from the Bio-Optics LSM2100C Eye Bank Specular Microscope. A total of about 200 cells were marked, the red round marks denoting cells 'inside' the variable cell count frame, and the purple triangular marks denoting cells 'outside' the frame and thus not counted in the determination of cell count. The AutoCount program marked the 200 cells and drew the cell borders in less than 1 s. To mark 200 cells manually and then draw an external border around a group of 150 cells takes about 100 s, or more. In practice, the accuracy with which the cells are marked should always be checked, and corrected if necessary, to make sure that there is one, and only one, mark per cell. With AutoCount this might take an additional 3–5 s after which time an accurate cell count is calculated and displayed, again in less than 1 s.

If accurate statistical information is desired about the endothelial mosaic, then there must not only be one, and only one, mark per cell but the marks must be in the centers of the cells. This should always be checked. With AutoCount it is easy to eliminate a mark that is in the wrong place and add one that is correctly in the center of the cell. Again the time taken to do a recount is less than 1 s. A variety of statistical information and reports can also be obtained. Figure 12.16 shows a screen shot of a cell density histogram showing that the distribution is quasi-normal but with a rather long tail at the higher density levels. Figure 12.17 is a screen shot showing a 'colorized' view of the endothelial image with 'normal' cells being colored gray, cells 'larger' than normal being colored red, and cells 'smaller' than normal being colored blue. Such displays are useful in studying localized trauma of the corneal endothelium.

As instrumentation improves and images with larger numbers of cells are obtained, the automated cell counting and analysis programs become even more valuable. Figure 12.18 is a screen shot of an image obtained with the Bio-Optics LSM2200C/E2 Eye Bank Specular Microscope. AutoCount marked almost 700 cells, 491 of them being 'inside' cells, drew the cell borders, and calculated the statistical parameters of the image in less than 1 s. To mark this number of cells manually would take about 7 min and it is doubtful that anyone would want to do this more than a few times before

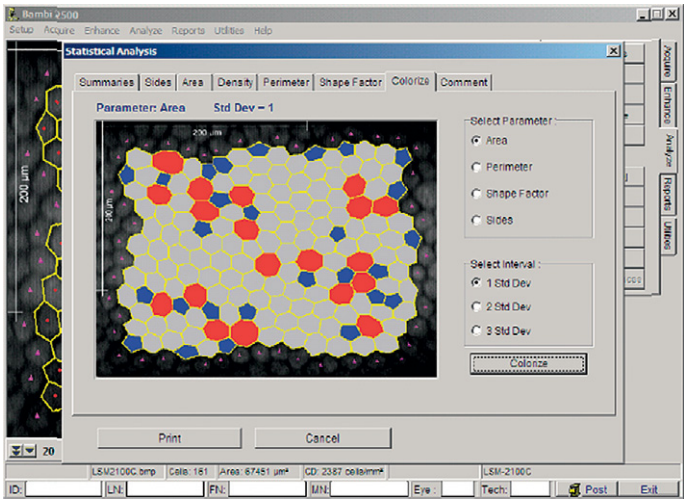

Figure 12.17. Screen shot showing a 'colorized' image from the image shown in the previous figure. (Courtesy of Bio-Optics, Inc., Portland, OR.)

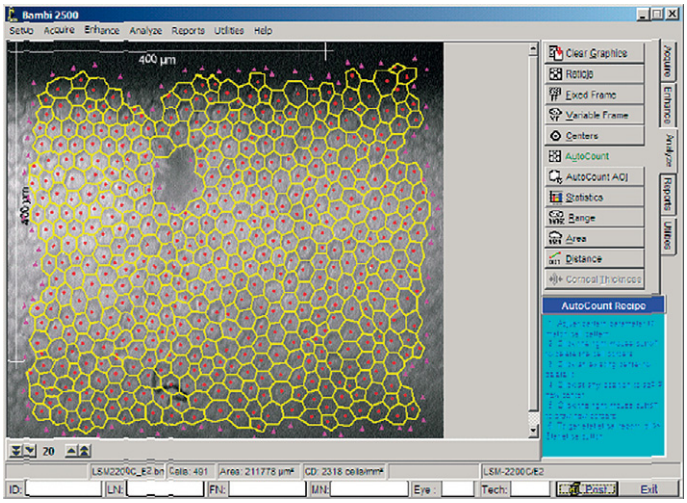

Figure 12.18. Screen shot showing the results of Bio-Optics AutoCount program in which a cell count of 2316 cells/mm^2 for a sample of 491 cells was obtained in less than 1 s. (Courtesy of Bio-Optics, Inc., Portland, OR.)

finding another line of work. This figure also shows two things that any automated, semiautomated, or manual method of cell counting must do if it is to give accurate and valid cell counts. In the upper left of the image is an area in which cell borders cannot be seen. In AutoCount this area is excluded from the frame area that is used. In the past, this has sometimes not been appreciated and has resulted in many invalid cell counts being calculated and used. Whatever method is used to obtain a cell count, any area in which cell borders cannot be seen must be excluded from the analysis used or else the cell count will be too small and invalid. The second thing shown in Figure 12.18 is the black object, probably due to a piece of lint on the image sensor. In this case this artifact did not interfere with the cell borders being seen and drawn automatically, and any automated cell counting system used should also have the feature of not giving invalid results due to lint, dust, or similar image artifacts.

Whatever automated cell counting and analysis system is used, it is important that the user has a way of checking to determine the accuracy of the analysis. Although computers can do numerical calculations very rapidly and accurately, all automated analysis programs, by necessity, make assumptions about the nature of the endothelial pattern being analyzed. If the assumptions made by the programmer are correct for the endothelium being analyzed then the cell count will be correct. If they are not, then the cell count will be incorrect and invalid. The user should always have a way of seeing the intermediate results from the computer and have a way of correcting them so as to get a valid count. Of concern in cell counting and analysis is the question as to whether enough cells have been counted to obtain a valid number. The conventional wisdom has long been that 100 cells are needed to reduce the errors of the counting method used to an acceptable value. As discussed above, the counting errors depend upon the method used, the fixed frame method having much larger counting errors than the variable frame, and AutoCount methods, for the same number of cells counted. Another issue is whether or not the number of cells in the image analyzed is sufficient to characterize that part of the endothelium that is of interest, i.e. the central endothelium, the superior endothelium, the entire endothelium, etc. The Bio-Optics MICS (Multiple Image Cell Statistics) program enables data from multiple images to be merged and analyzed as a whole and provides statistical parameters of the multi-image sample. A recent program, Cells Analyzer[20] also provides this ability and also calculates the statistical significance of the sample. Although for general clinical or eye bank use such programs may not be necessary, they are essential for research applications in which detailed endothelial changes with time and/or treatment are needed.

EVALUATION CRITERIA

The presence of an abnormal, or 'bad-looking', corneal endothelium most likely indicates that the cornea is functionally deficient and compromised. Such characteristics of an abnormal endothelium, as seen by specular microscopy, are:

1. An endothelial cell density less than 1500 cells/mm^2. (In general, corneas whose only flaw is a low cell density still present the risk of a continued cell loss,[21] which could ultimately lead to a density low enough for corneal decompensation.)
2. Severe polymegathism or pleomorphism of the endothelial cell pattern.
3. Presence of corneal guttata.
4. Presence of many abnormally shaped cells, such as those seen in coalescence.
5. Abnormal single-cell defects.
6. Extensive areas of severe edema.
7. Presence of inflammatory cells or bacteria on the endothelium.
8. Presence of ghost vessels in the stroma.

The age of the cornea appears to be of secondary importance in determining the health and functional reserve of the tissue. An older cornea having a high endothelial cell count, low degrees of polymegathism and of pleomorphism, and a normal overall appearance is most likely functionally superior to that of a younger cornea that has a lower cell density or exhibits an abnormal appearance. Specular microscopy, especially when used with computerized morphometric analysis, proves to be extremely useful in the evaluation of corneas from older patients because it allows for the determination of suitability of the tissue for ophthalmic procedures or for use

in transplantation, rather than an arbitrary decision based on age alone.

ANTICIPATED CHANGES

At the time of writing (December 2006), the current specular microscopes available generally use video cameras or Charge Coupled Device (CCD) sensors that output a standard video signal. The cell counting and analysis systems input this video signal via a cable that leads to a computer frame grabber. Standard video signals are constrained to have only 480 vertical lines (in the USA) and this standard limits the resolution of current endothelial images. Such images characteristically have a resolution of about 0.25 megapixels (MP). At the present time there is considerable activity in the development of high definition television, with 1080 vertical lines and in digital camera sensors with resolutions of up to 12 MP. It can be expected that such technology will be utilized by the major manufacturers of specular microscopes and cell counting and analysis systems in the near future. Another activity that can be expected to alter our field is the rapid expansion of WiFi and WiMax networks around the world. By the publication date of this book, it may well be that higher resolution images will be obtained on very high-resolution sensors and sent wirelessly to a server and/or notebook computer for cell counting and analysis and perhaps even to a counting and analysis center in a different part of the country. Although the instrumentation may be better, the underlying accuracy and validity of the obtained cell counts and analysis will still be limited by the complex nature of the corneal endothelial image, and the skill and knowledge of the user in understanding what is seen in those images and how to correct for possible incorrect assumptions made by the computer software.

SUMMARY

The specular microscope is a valuable tool for use in the evaluation of the corneal endothelium. In the eye bank, specular microscopy can be used to identify corneas that are functionally deficient or that have a marginal functional reserve so that such corneas are not used for human transplantation. Specular microscopy can thus help to improve the quality of the tissue used in penetrating keratoplasty and to reduce the number of grafts that fail. In the clinic, specular microscopy can be used to evaluate the function and functional reserve of the cornea, as a tool in diagnosing various corneal disease states, to demonstrate that no untoward trauma has resulted from an ocular procedure, and to observe and better understand the wound healing process after surgery.

13 Tonometry and biomechanical analysis

Mujtaba A. Qazi, Eric Y. Yoon, Jay S. Pepose

Supported in part by the Midwest Cornea Foundation, St Louis, MO

INTRODUCTION

Ophthalmologists have long appreciated that the inherent properties of the cornea—such as curvature, astigmatism, rigidity, and hydration—can affect the quality and accuracy of intraocular pressure (IOP) measurements using Goldmann applanation tonometry (GAT). Goldmann tonometry is a static measurement calculating IOP, using the Imbert Fick Principle, from the force applied during a steady-state applanation of the cornea.[1] Goldmann applanation assumes that the cornea has a standard thickness and behaves biomechanically as an infinitely thin and perfectly flexible membrane. In reality, Goldmann IOP measurements are filtered through the viscoelastic characteristics of the cornea, influenced by inter-individual corneal variations, and can be substantially affected by corneal surgery.

In 1975, Ehlers et al[2] showed that eyes with thinner corneas had lower Goldmann pressures compared to manometry, while thicker corneas had higher GAT IOP than manometric reading in the same eyes. Recently, the relationship between central corneal pachymetry (CCT) and GAT IOP measurement has been highlighted by the Ocular Hypertension Treatment Study,[3] which showed an inverse correlation between CCT and the risk for developing glaucomatous damage. Several investigators have suggested linear algorithms to 'correct' Goldmann IOP measurements based upon CCT.[4] However, the basis for linear correction of IOP is fraught with potential error, as there is only a weak correlation between GAT and CCT (R^2 = 0.06 to 0.17) in normal eyes.[4,5]

Corneal biomechanics reflects more than central pachymetry. For example, GAT generally decreases following a number of surgeries (i.e. radial keratotomy and hyperopic laser in situ keratomileusis (LASIK)) where there is little change in CCT but profound changes in corneal rigidity.[6–9] Attempts at linear 'correction' of Goldmann tonometry based on CCT can, in fact, be in the wrong direction in select cases.[10,11] More accurate measurement of IOP, in theory, requires instruments that perform dynamic, rather than static, applanation measurements and therefore assess and compensate for corneal biomechanics. This is particularly important in eyes with altered structure and biomechanical properties, such as those with corneal ectasias (keratoconus and pellucid marginal degeneration), Fuchs' dystrophy, or following incisional or ablative corneal surgery.[12] We review below the definitions of biomechanical metrics and their impact on tonometry—a subject that encompasses the effects of corneal hydration, regional pachymetry, viscoelasticity, and other inherent corneal characteristics that may not yet be fully defined.

GENERAL PRINCIPLES OF CORNEAL STRUCTURE

The structural characteristics of the cornea facilitate its essential functions, specifically to serve as both a transparent barrier and the predominant refractive element of the eye. Given the integral relationship between form and visual function, the biological and mechanical responses of the cornea to surgical interventions impact its optical performance.[13,14] While major advances have occurred in the refinement and standardization of corneal surgical techniques, our ability to compensate for individual biological responses to surgery remains limited and can influence the predictability and stability of visual outcomes after corneal surgery. Further understanding of these factors provides the basis for improving outcomes and reducing complications of corneal surgery, by identifying individual response outliers and developing strategies for regulating or compensating for these biomechanical features.[15]

The cornea is a complex composite (of collagen, proteoglycans, water, and salts) with nonlinear elastic and viscoelastic properties. It is characterized by important local variation in organization in central versus peripheral and anterior versus posterior architecture. Swelling studies have shown that the interlamellar adhesive strength of the central cornea depends upon proteoglycan bonding, whereas branching and interlacing of lamellae provides additional adhesive strength peripherally (Table 13.1).[16] Changes in the proteoglycan matrix may explain the increased pliability of the central cornea in keratoconus and may potentially impact the corneal response to keratorefractive surgery, contact lens wear, and tonometric testing.[17] The anterior-most stromal lamellae have oblique branching and interweaving fibers that insert into Bowman's layer.[18] Because of these features, the anterior stroma swells less and is about 25% stiffer than its posterior counterpart.[19] These findings suggest that

peripheral and/or posterior incisional surgery may have less of a profound impact on corneal biomechanics than anterior, central surgery. Mathematical modeling of such a complex system is therefore quite difficult, but begins with identification of intrinsic properties of corneal tissue, as described below (Table 13.2).

METRICS OF CORNEAL BIOMECHANICAL PROPERTIES

Elasticity (Young's modulus, E) is an indicator of material stiffness, with a higher modulus corresponding to a stiffer material. Elasticity can be calculated by determining the stress applied to a material (force per unit cross-sectional area) divided by the resultant strain (i.e. change in the material's length divided by the unit starting length). This ratio of stress to strain (i.e. elasticity), measured in Pascals, can be thought of as a measure of the material's resistance to a change in length. For example, a metallic rod would have a higher modulus than a wooden rod (Fig. 13.1). A perfectly elastic material returns to its original form when an external stress is withdrawn in a completely reversible and symmetric manner, i.e. along the same stress–strain pathway.[20] Elasticity is traditionally measured *ex vivo* with an extensiometer that records the force generation required during steady axial elongation of a tissue sample. The slope of stress (force per unit cross-sectional area, measured in Pascals) over strain (the change in length divided by the starting length) is calculated for a representative portion of the curve. A linear approximation can be obtained from the instantaneous slope of the stress–strain curve (tangent modulus) or as a chord between two points on the curve (secant modulus). Whereas *ex vivo* dissection of strips of human cornea and application of weights to cause elongation has allowed the estimation of regional strain characteristics, such *in vitro* modeling has been difficult to translate into *in vitro* correlates.[21–24] Other methods, such as electronic speckle pattern interferometry and dynamic corneal imaging following indentation,[12,25] may be better suited for *in vitro* studies of corneal biomechanics and elasticity. These will be discussed in detail in a later section.

Viscoelasticity extends the biomechanical response of biological tissues into complex mathematical descriptions of viscous fluids, where responses are time and rate dependant.[26] Viscoelastic materials return to their pre-stress shape via different stress–strain pathways that depend upon loading rates. Viscoelastic properties can be described through metrics of hysteresis, stress relaxation, and creep. Viscoelastic creep is a time-dependent elongation of tissue (or increasing strain) that occurs under a sustained or constant stress

Table 13.1 Local Variation in Corneal Lamellar Ultrastructure

Collagen Lamellae in the Peripheral Cornea:
Greater number
Greater branching and interlacing
Circumferential orientation
Greater resistance to swelling
Collagen Lamellae in the Anterior Cornea:
Anterior strands insert into Bowman's layer
Greater proteoglycan bonding centrally
Greater stiffness than posterior cornea

Table 13.2 Descriptors of Corneal Biomechanical Properties

Elasticity (also known as the Young's modulus, modulus of elasticity, or elastic modulus): A measure of the stiffness of a given material, defined as the ratio of the rate of change of stress with strain and can be measured as the instantaneous slope of a stress–strain curve.
Stress: Force per unit cross-sectional area, measured in Pascals.
Strain: The change in length of a material divided by its original length. Strain is positive if the material has gained length during the application of an external force or tension, but can be negative if it has reduced length (compression) during this process. Strain has no units of measure but can be expressed as a percentage.
Viscoelasticity: Property of a material that has the ability to store energy of deformation and in which the application of a stress gives rise to a strain that approaches its equilibrium value slowly.
Hysteresis: In general terms, hysteresis refers to the lag between making a change, such as increasing or decreasing power, and the response or effect of that change. Using the Ocular Response Analyzer ORA, corneal hysteresis is the difference between intraocular pressure measured during the two applanation events produced by compression of the cornea with a collimated air pulse (CH = P1 – P2).
ORA corneal resistance factor: An ocular response analyzer metric that is derived as a linear combination of P1 and P2 to maximally correlate to central pachymetry.
Creep: A situation where there is a slow change in the dimensions of a material from prolonged stress, such that application of a step constant stress causes increasing strain.
Stress relaxation: A situation in which strain is held constant while a slow, quantifiable time-dependant decrease in stress is observed.
Shear strength: The maximum stress which a material can withstand without rupture or splitting into two parts that slide past each other.
Ocular rigidity: A measure of the resistance which the eye exerts to distending forces, described by pressure–volume calculations that relate the change in intraocular pressure to the change in intraocular volume.
Ocular pulse amplitude: The difference in intraocular pressure between systole and diastole (IOP systolic – IOP diastolic) measured by the Pascal Dynamic Contour Tonometer. This may be a marker for ocular rigidity.

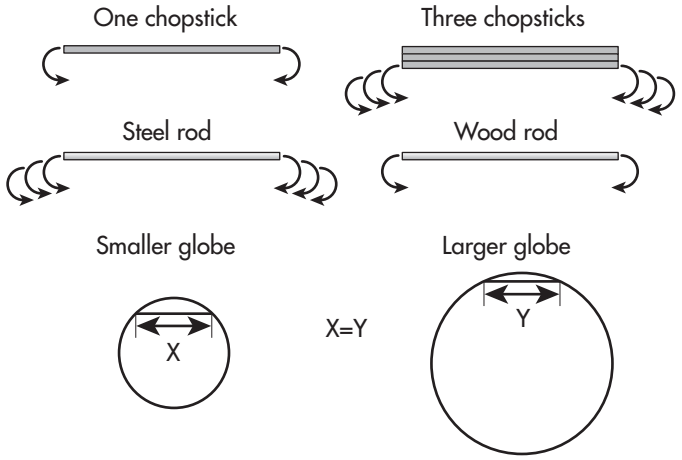

Figure 13.1. The influence of structural and material properties on the ability to deform the cornea. Bending a single chopstick is usually easy. However, bending three of the same type of chopsticks at once is much more difficult (top row). Hence, a larger deformation will be generated for thinner corneas given the same applied force. This partially explains the underestimation of IOP in eyes with thinner corneas. In contrast, it requires greater pressure to applanate or indent a thicker cornea, which contributes to overestimation of IOP in eyes with thicker corneas. Similarly, much more force is required to bend a steel rod than a wooden rod of the same dimensions (middle row). The difference in this case is the elastic properties of the material, specifically Young's modulus. Steel has a much higher Young's modulus (w200 000 MPa) than wood (w10 000 MPa); therefore, if all other parameters are the same, it is much harder to deform a steel structure than a wooden structure. Corneal curvature is another variable that can affect the accuracy of IOP measurement, possibly because of the difference in the volume of the displaced fluid after a given area is flattened (bottom row).[47]

(such as IOP).[26] The effect of creep is a reduction in effective tissue stiffness, which can lead to a decrease in resistance to stretch. Creep may be a precursor to ectasia, where stressed collagen fibrils undergo a pathologic weakening without an initial change in length. Once the collagen fibrils are weakened, a gradual stretching then occurs under constant stress or IOP. Viscoelastic stress relaxation refers to a situation where strain is increased then held constant (no more tissue elongation) while a slow but quantifiable time-dependent relaxation of the load is observed (Fig. 13.2).

Hysteresis, in general, is a property of physical and biological systems that do not instantly follow the forces applied to them but react slowly or do not return completely to their original state.[26] Hysteresis describes a lag between making a change, such as increasing or decreasing power, and the response or effect of that change. Whereas a rubber band can be described as elastic because it springs back to its original shape at the same rate as when it is stretched, a putty exhibiting viscoelastic behavior quickly assumes a new shape when pushed upon but will not immediately return to its original shape when the mechanical pressure is released. In broad terms, corneal hysteresis can be thought of as a metric of the ability of the cornea to absorb energy.

Volumetric distension experiments provide a measure of whole globe stiffness, or ocular rigidity. The slope of a pressure–volume curve can be recorded during such experiments. Ocular rigidity is nonlinearly dependent upon IOP and has been shown to increase with age.[27] The utility of metrics describing ocular rigidity may be limited with respect to their impact on the understanding of corneal surgery, given the contributory role of the scleral and uveal tissue to ocular rigidity.

New techniques for in vivo measurement of corneal biomechanical properties and intraocular pressure

While ex vivo diagnostic techniques, such as extensiometry, have provided valuable information on the biomechanical nature of normal and pathological corneas,[28] a new era is dawning in biomechanical research with the development of techniques to measure structural and biomechanical properties in vivo. Imaging of the cornea can now be performed by confocal microscopy, very high frequency ultrasound,[29] optical coherence technology, and holographic interferometry.[30,31] Dynamic corneal imaging uses stepwise central indentation of the cornea and computer analysis of videokeratography images during indentation to assess corneal elastic properties in vivo.[25]

Alternative techniques that dynamically derive IOP from corneal movement in response to a rapid air pulse stimulus simultaneously assess and compensate (to varying degrees) for the effect of the cornea's viscous and elastic qualities on IOP measurement. The Ocular Response Analyzer (ORA; Fig. 13.3, Reichert Ophthalmic Instruments, Depew, New York, USA)[12] utilizes a metered collimated air pulse to applanate the cornea and an infrared electro-optical system to record inward and outward applanation events. The air-pulse deforms the cornea through an initial applanation event (peak 1), then beyond into concavity and then gradually subsides, allowing the cornea to rebound through a second applanation (peak 2). Corneal hysteresis (CH; Fig. 13.4) is defined as the difference between the applanation pressure at peak 1 (P1) and peak 2 (P2), so that CH = P1 − P2. Whereas corneal hysteresis may reflect mostly corneal viscosity, corneal resistance factor (CRF, defined as a linear combination of P1 and P2, weighted for P1 and maximal correlated to CCT) may predominantly quantify corneal rigidity. The ORA provides an IOP-G (Goldmann-equivalent) IOP reading, based upon a linear regression formula compared to GAT, and an IOP-CC (corneal compensated) IOP, based upon a regression ($P2 - 0.43 \times P1$) of measurements from normal and postrefractive surgery patients.

Pascal Dynamic Contour Tonometry (PDCT; Swiss Microtechnology AG, Port, Switzerland) employs a concave tip (Fig. 13.5) to 'contour match', rather than applanate, a convex segment of the central cornea and thus may be relatively independent of the effects of CCT or surgical intervention on IOP assessment.[32–34] The instrument dynamically records over 100 IOP measurements per second, measuring IOP fluctuations throughout the cardiac cycle and digitally displaying the average diastolic IOP. Ocular pulse amplitude (OPA), the difference in IOP between systole and diastole (IOP systolic – IOP diastolic), is also reported and may be a marker for overall ocular rigidity,[27] although it is also affected by ocular blood flow.

Another dynamic or rebound tonometer (RBT; Tiolat Oy, Helsinki, Finland) comprises an assembly of two coils coaxial to a probe shaft that bounce a magnetized probe off the cornea and detect the deceleration of the probe caused by the eye. A change in voltage at the two ends of the coil generates a magnetic field, which is detected by the tonometer sensor. The inverse of the probe's deceleration speed seems to correlate with the IOP.[35] Clinical evaluation demonstrated that RBT gives higher IOP readings than GAT and is also dependent upon CCT.[36]

The Proview (Bausch & Lomb, Rochester, New York, USA) eye-pressure monitor is based on the principle that pressure applied to

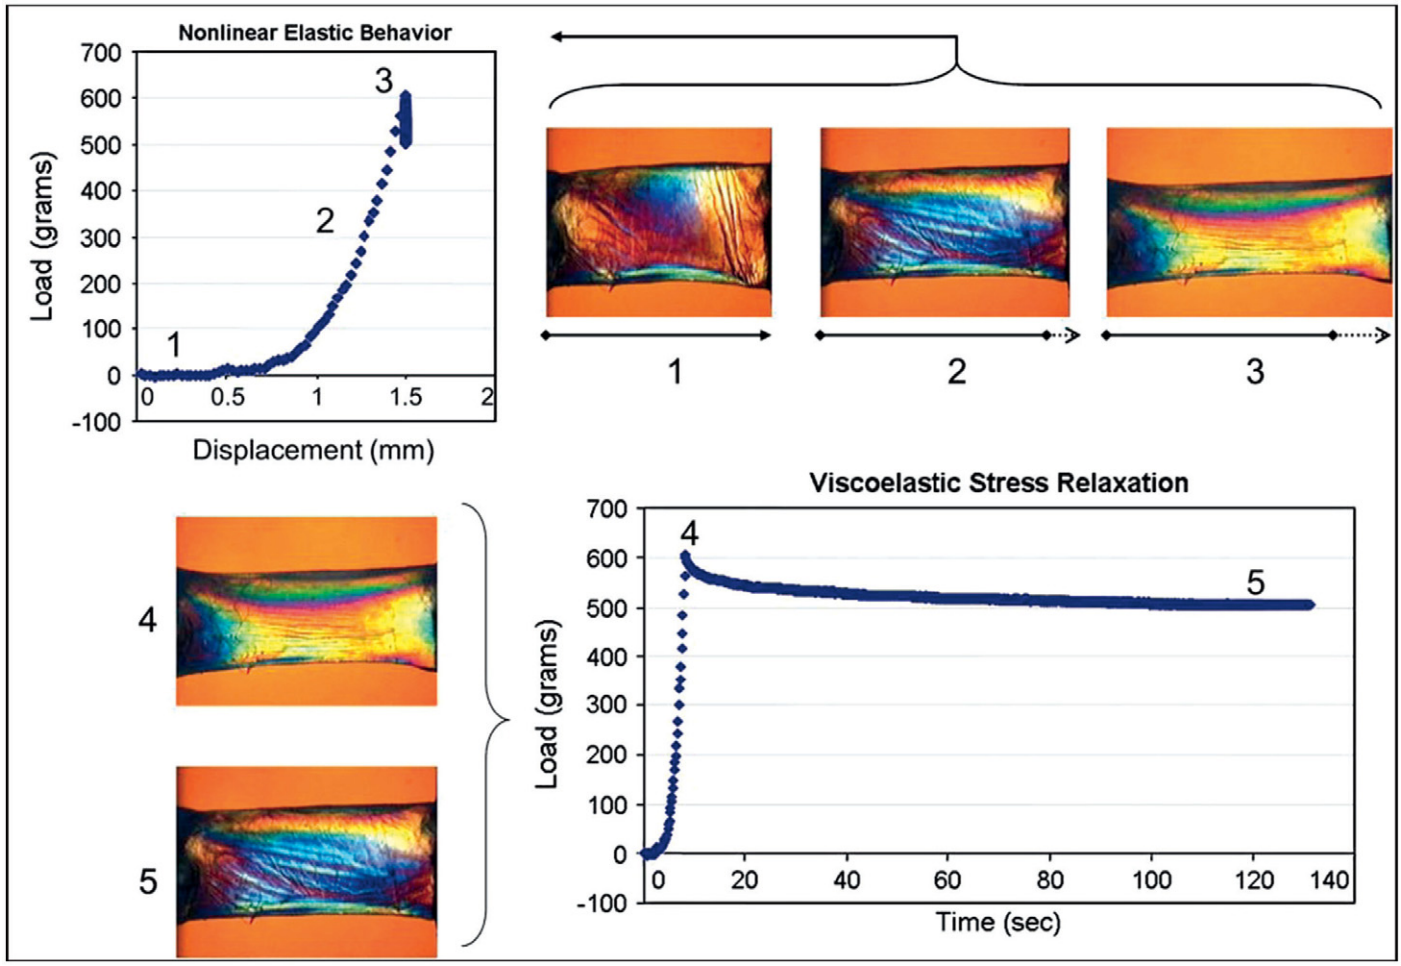

Figure 13.2. Experiments illustrating elastic and viscoelastic properties in a 7-mm, full-thickness horizontal corneal strip from a 63-year-old donor. Elliptical polarization allows visualization of nonhomogeneous internal stresses. Progressive stretching of the sample (1, 2, and 3) and measurement of the induced load (stress) allows calculation of the elastic (Young's) modulus from the slope of the stress–strain relationship. The relationship is nonlinear. A second experiment in which a constant displacement is imposed in the same sample demonstrates time-dependent stress relaxation, a viscoelastic property of biological soft tissues (4 and 5).[20]

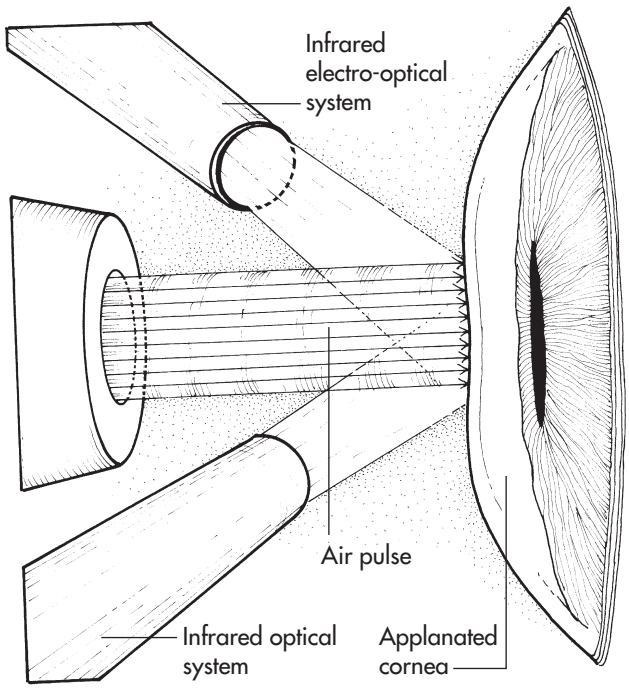

Figure 13.3. The Ocular Response Analyzer utilizes a collimated air pulse to applanate the cornea. Courtesy of D. Taylor, Reichert, Inc.

the sclera generates a self-perceptible visual phenomenon, known as a phosphene spot. The threshold pressure for creating a phosphene spot may be used to estimate IOP. The tip of the tonometer is pressed against the closed eyelid, and the pressure is recorded when the patient detects the phosphene. The Proview method may be useful for patients with corneal abnormalities that may interfere with accurate pressure measurements and may avoid artifact related to corneal thickness. The accuracy of the instrument in the clinical setting requires further investigation.[37–40]

BIOMECHANICS AND INTRAOCULAR PRESSURE

It appears that corneal shape is not determined on a random basis, but results from a steady-state balance between the biomechanical properties of the cornea and IOP.[41] The cornea assumes the shape for which its potential energy content is minimal (i.e. for which its stromal fibrils are in a relatively relaxed state) as a function of variables such as tissue elasticity, thickness, fibril length, and rate of change of IOP. Physiologic corneal stresses (such as from normal blinking or diurnal variation in IOP) and nonphysiologic corneal stresses (such as from forceful lid closure or rubbing) may potentially impact the corneal shape. However, normal corneas have been found to show low extensibility, measured by changes in anterior

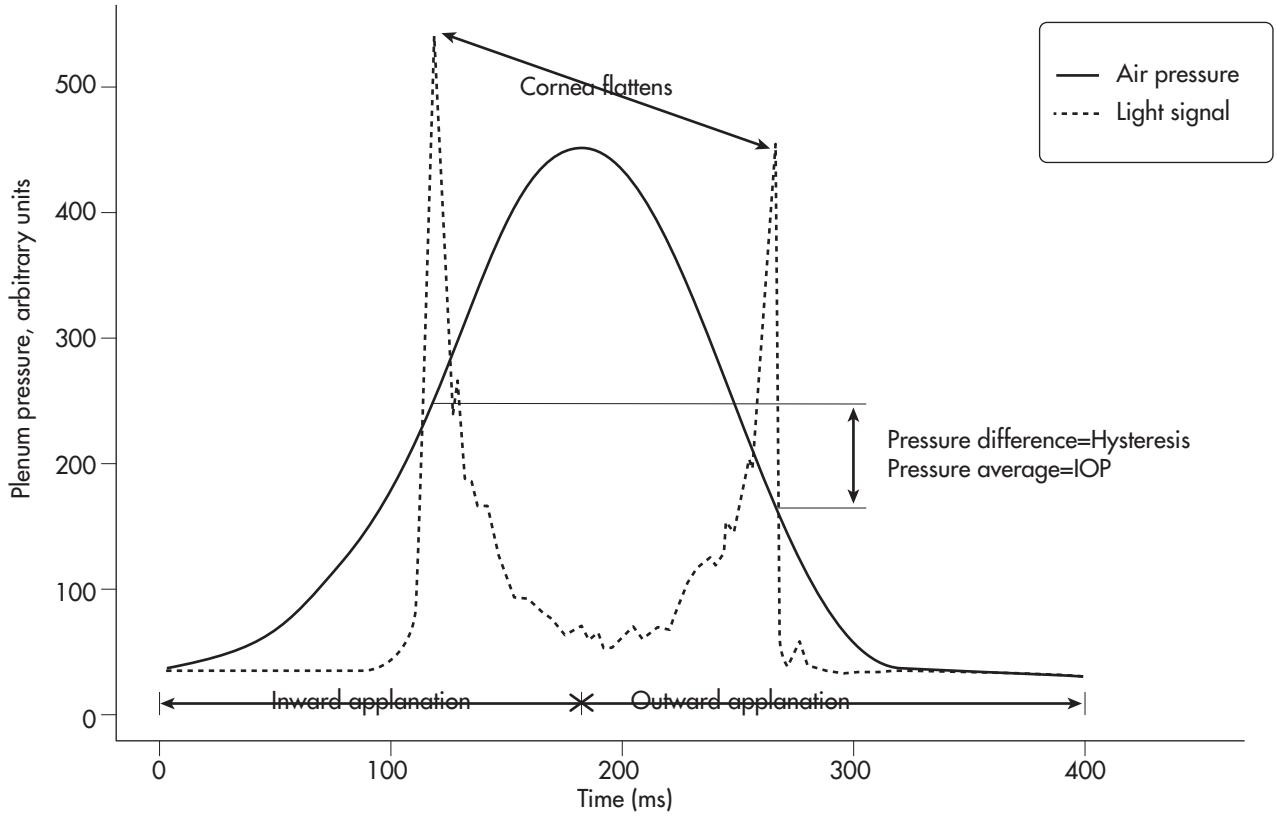

Figure 13.4. The waveform generated from the Ocular Response Analyzer identifies the pressure difference, or hysteresis, during inward (peak 1) and outward (peak 2) applanation events during noncontact tonometry.[49]

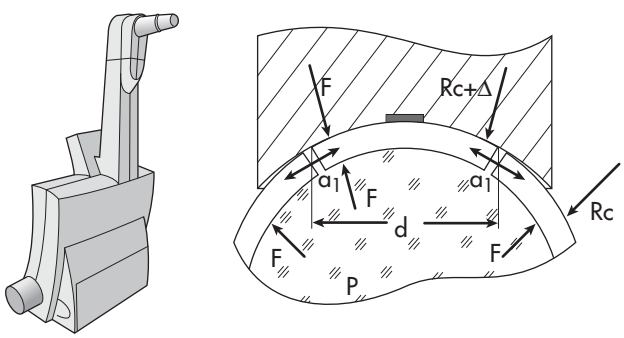

Figure 13.5. The Pascal Dynamic Tonometer utilizes 'contour-matching' to measure intraocular pressure via a microchip at the tonometer tip.

surface sagittal height, for a wide range of physiologic conditions in order to maintain refractive stability, even with marked elevations in IOP.[20] Conversely, when corneal biomechanical properties are altered via incisional surgery such as radial keratotomy, diurnal variation in IOP can lead to fluctuation in corneal refractive power by greater than 1 D.[20]

Increasing attention has focused on the impact of corneal parameters, particularly central corneal thickness, on the measurement of IOP.[4] IOP measurements have been demonstrated to vary with CCT using the Goldmann applanation,[42] pneumotonometry,[43] and noncontact tonometry.[44] The deformation of the cornea during applanation is determined by an interaction of the external applied force with the intrinsic properties of the cornea. With the same applied force, a larger deformation will be produced for less rigid corneas. This partially explains the underestimation of IOP in eyes with thinner corneas. In contrast, it requires greater force to applanate a more rigid cornea, partially explaining the overestimation of IOP in eyes with thicker corneas. The clinical implications of this observation are seen in the classification of patients as normals, ocular hypertensives, or with low-tension glaucoma. A number of studies have found a significant difference in the mean CCT of these three groups. After adjustment of GAT by regression algorithms for CCT, several studies have suggested that a third of low-tension glaucoma eyes can be reclassified as having primary open angle glaucoma. With similar adjustment factors, 30–65% of ocular hypertension eyes can be reclassified as normal.[45,46] It is possible that a larger percentage of misclassification errors may be found if biomechanical metrics other than CCT are also taken into account and properties are also taken into account when correcting GAT IOP measurements.

It is clear that tonometry is affected by biomechanical properties not fully measured by CCT. Liu and Roberts[47] attempted quantitatively to analyze the influence of corneal biomechanical properties on GAT IOP measurements through a mathematical model. The authors analyzed the separate influence of CCT, radius of curvature, and modulus of elasticity on IOP measurements obtained by applanation tonometry. They demonstrated a nonlinear relationship between CCT and IOP, and between corneal radius of curvature and IOP readings. Steeper curvature has a more significant impact on IOP accuracy than a flatter curvature. Theoretically, the steeper the corneal curvature, the more the cornea must be indented to produce the standard area of applanation. Therefore, more force must be applied, increasing the indicated value of IOP. This may have important implications in differences in the IOP measurement error after hyperopic photoablation than following myopic keratorefractive surgery. Furthermore, Liu and Roberts concluded, based upon their

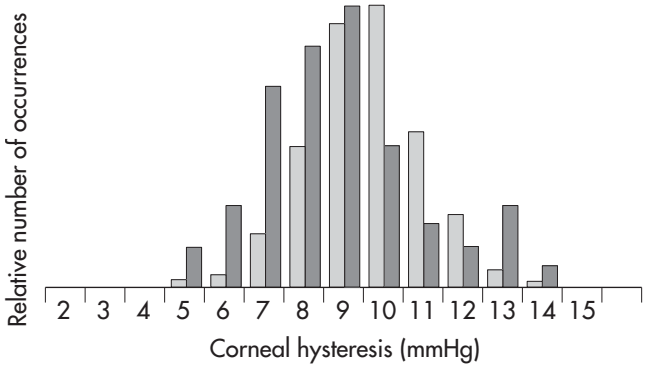

Figure 13.6. Distribution of hysteresis values in 339 normal (pale gray) and 60 keratoconic (dark gray) eyes. Mean hysteresis for normal and keratoconic eyes was 9.6 and 8.1 mmHg, respectively.[12]

mathematical model of tonometry, that variations of the elasticity of the cornea within a range predicted to occur in a normal population would result in an error of IOP measurement even higher than the one induced only by variations in corneal thickness.

Using the Ocular Response Analyzer, CH has been reported to range from 5.0 to 18.7 mmHg in normal eyes, with a mean hysteresis of 9.6 to 12.7 mmHg.[11,12,48] Hysteresis values did not show a statistical difference in a cohort of 21 normal patients between right and left eyes, with a mean difference of 0.4 mmHg ($p > 0.08$).[48] CH appears to be relatively insensitive to diurnal effects, although intrasubject variations have been observed. The correlations of CCT with CH and CRF were 0.59 and 0.62, respectively, in one study of normal eyes.[11] Lower hysteresis has been associated with visual field progression in a glaucomatous population.[49]

Martinez-de-la-Casa et al,[50] in a study of 48 eyes, showed that both IOP-G ($r = 0.460$, $p = 0.001$) and IOP-CC ($r = 0.442$, $p = 0.001$) correlated significantly with CCT, but not with corneal curvature or refraction. Pepose et al,[11] in a cohort of preoperative LASIK patients, confirmed a statistically significant correlation between IOP-G and CCT ($r = 0.322$, $p < 0.01$), although they suggested a nonlinear relationship. They did not find, however, a significant association between IOP-CC and CCT. Similarly, Medeiros and Weinreb,[51] in a univariable regression, did not find a significant correlation of IOP-CC to CCT ($p = 0.106$), corneal curvature ($p = 0.112$), or axial length ($p = 0.117$). IOP-CC measurements, in their cohort, were significantly associated with age ($p = 0.044$). Patients with thicker corneas tended to have higher GAT measurements compared with IOP-CC, whereas with thinner corneas had lower GAT readings than IOP-CC. In a multiple regression model, GAT, CCT, and corneal curvature each positively correlated with CRF.

Corneas with keratoconus (Fig. 13.6), Fuchs' dystrophy and postrefractive surgery demonstrate a general decrease in corneal hysteresis compared to corneas in normal eyes.[12] The low corneal hysteresis in the Fuchs' eyes is seen despite unusually thick, but edematous, corneas. However, the large 95% confidence interval of corneal hysteresis seen in normal controls has considerable overlap with diseased and postsurgical corneas, limiting its diagnostic value as a single metric in individual cases. What may turn out to allow better diagnostic differentiation are the significant changes seen in applanation waveform in diseased or postsurgical corneas. Keratoconic and post-LASIK corneas appear to have similar applanation signal morphology, indicating reduced or low corneal viscoelastic properties in both cases (Fig. 13.7). Investigations to quantify morphologic characteristics of the ORA waveform are now underway

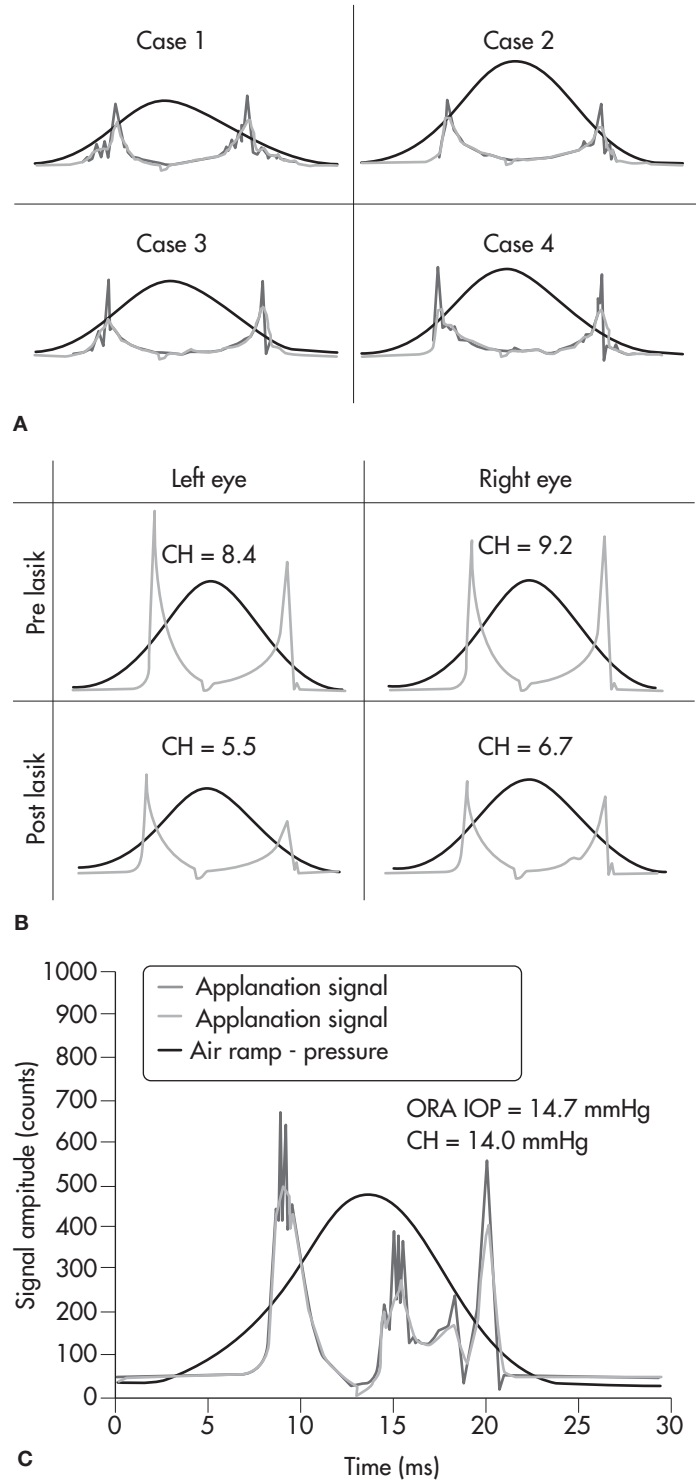

Figure 13.7. ORA applanation signal in keratoconic and post-LASIK eyes shows depressed applanation peak amplitudes and altered applanation peak widths: *A,* Case 1–4 are from keratoconic eyes; *B,* pre- and post-LASIK waveforms show a decrease in hysteresis postoperatively, along with reduced applanation peak amplitudes; *C,* waveform post penetrating keratoplasty shows marked alternation in the applanation signal, with increased noise during the applanation events.[12]

that attempt to extract additional corneal biomechanical information. Corneal hysteresis may be useful as a qualification factor for LASIK in corneas that have similar CCT but display significantly different waveform properties. Thus, the ORA waveform, along with the derived biomechanical metrics of corneal hysteresis and resistance factor, may provide a more complete characterization of corneal biomechanical properties than corneal thickness alone and is perhaps a better tool for assessing refractive surgery qualification and outcomes.

Corneal biomechanical properties appear to have only a limited effect on PDCT measurements. Several investigators have shown that PDCT IOP does not significantly correlate with CCT, including after keratorefractive laser surgery, and are higher than with GAT (as well as ORA).[11] A possible explanation for this is that the PDCT was calibrated against a manometrically controlled pressure standard. Manometric studies by Feltgen et al[52] indicate that the Goldmann IOP measurement averages 1.2 mmHg lower than manometry in human eyes in vivo. The OPA is a parameter affected by both ocular rigidity and ocular blood flow. Ocular rigidity has been reported to be reduced in enucleated pig eyes following corneal ablation (Pallikaris IG—ESCRS presentation, Lisbon, Portugal, 2005). In human patients, OPA was not significantly affected by LASIK, although it is unclear how potential changes in ocular rigidity or blood flow impact OPA measurements following photoablation *in vivo*.

CONCLUSION

A review of the biomechanical features of the cornea reveals complex interactions that influence the measurement of IOP. Dynamic tonometers may provide multiple metrics that may be combined with advanced structural and functional diagnostic imaging techniques to develop mathematical models of the viscoelastic features of the normal and postsurgical cornea during IOP measurement. As our understanding of these processes improves, so will our ability to offer rational interventions and strategies for further improving the predictability of keratorefractive surgery and may lead to a paradigm shift in the management of glaucoma.

14 Anesthesia for corneal surgery

Jerry G. Ford, John W. Reed

Prior to the 19th century, the only anesthetic available was a drink of brandy or a bullet to bite, making ocular surgery quite difficult. After the introduction of ether and nitrous oxide as general anesthetics in the mid-19th century, ocular surgery became much less stressful, but severe coughing and vomiting upon awakening caused many postoperative complications. A major breakthrough came in 1884 with the introduction of topical cocaine by Koller, and by the turn of the century ophthalmologists were primarily using repeated applications of topical cocaine as anesthesia for ocular surgery.[1] By the 1930s and 1940s in the USA, retrobulbar anesthesia was replacing topical anesthesia as the preferred method of anesthesia.[2] Recently, much has been written about returning to the use of topical anesthesia alone for many types of ocular surgery.

The decision to use general, local, or topical anesthesia is based upon many factors: the age, health, anxiety level, and cooperative ability of the patient; the technical difficulty and duration of the surgery to be performed; and the setting in which the procedure is to be performed. The surgeon's experience with one type of anesthesia or another also is a factor in the decision-making process. This chapter discusses the different types of anesthetic agents and modes of delivery for surgical procedures of the cornea.

GENERAL ANESTHESIA

General anesthesia has the benefit of complete immobility of the patient as well as complete anesthesia. This benefit allows for a more relaxed pace and eliminates stressful situations, such as when a patient suffers anxiety from being under sterile drapes, becomes restless with a lengthy procedure, or continues to blink with incomplete lid akinesia, thereby creating posterior pressure on the globe during 'open sky' procedures.

The disadvantages of general anesthesia include increased turnover time; increased labor and overall costs;[3] risk of intraoperative contamination of the operative field with nasal secretions;[4] increased incidence of postoperative nausea, sore throat,[5] and urinary retention;[3] slower recovery time; and, possibly, an increased physiologic stress to patients with systemic disease.[3]

General anesthesia is commonly achieved by a combination of different agents, such as inhalation anesthetics, narcotics, sedative-hypnotics, and muscle relaxants. Varying amounts of each agent can be individualized to fit the particular situation. The minimum alveolar concentration (the minimum concentration of anesthetic that allows complete anesthesia in 50% of patients) of some common inhalation anesthetics is listed in Table 14.1.

General anesthesia may result in greater physiologic stress to the patient. Studies have shown that patients undergoing ocular surgery under general anesthesia have higher plasma adrenalin, cortisol, and glucose levels than those being managed under local anesthesia.[6] The metabolic control of blood glucose of noninsulin-dependent diabetic patients undergoing cataract surgery has been shown to be better when local rather than general anesthesia is used.[7] One study of healthy, elderly patients undergoing cataract surgery who were randomly assigned to receive general or local anesthesia showed a greater incidence of transient hypoxia and more marked fluctuations of blood pressure and heart rate in the general anesthesia group, but there were no differences in significant adverse events or cognitive function 3 months later.[3] In addition, studies of patients with cardiovascular disease undergoing carotid endarterectomy or peripheral vascular bypass surgery randomly assigned to receive local or general anesthesia have shown no significant difference in (or even a reduced incidence of) adverse outcomes in patients in the general anesthesia groups.[8,9] In healthy patients, general anesthesia appears to have no greater risk than local anesthesia, but when systemic disease is present, the risk versus method of anesthesia choice is less clear.

LOCAL ANESTHESIA

Table 14.2 compares ester and amide injectable anesthetic agents, including onset and duration of action, dosages, and toxicity. The ester agents are of lower toxicity, but their short duration of action limits their use in ophthalmic surgical procedures. The amides (e.g. lidocaine and bupivacaine) have a longer duration of activity and are used very commonly in ophthalmic procedures, but they have greater toxicity. Central nervous system (CNS) toxicity, which is generally seen first, is manifested initially by CNS stimulation followed by CNS depression. However, with bupivacaine, CNS depression may occur without signs of excitation. Stimulation of the CNS

may be manifested by restlessness, apprehension, euphoria, tremors, twitching, and seizures. Hypotension, severe respiratory depression, and stupor may follow, representing depression of the CNS. Cardiovascular effects are seen with high systemic concentrations. Effects on the heart include a decrease in electrical excitability, conduction rate, and force of contraction. Early signs of cardiovascular involvement include hypertension, tachycardia, and arrhythmias. Later signs include bradycardia and hypotension.[2,10]

Hypersensitivity reactions to the local anesthetics are infrequent. Sensitivity to the amide-linked agents has been reported to be rare.[11] However, type IV hypersensitivity reactions to any of the local anesthetic agents can occur, ranging from contact dermatitis to an anaphylactic reaction with hives and angioneurotic edema. Cross-sensitivity does not exist between the amide and ester groups.[10]

MODES OF DELIVERY

Subconjunctival anesthesia is obtained using a syringe with a 26- or 30-gauge needle for injection of 2% lidocaine with or without epinephrine or 0.75% bupivacaine just beneath the conjunctiva (Fig. 14.1). This approach provides excellent anesthesia for procedures such as removal of conjunctival or corneal intraepithelial neoplasia as well as small pterygia, conjunctival biopsy, or other similar procedures. Globe penetration may occur with this route of delivery.

Intracone (retrobulbar) injection is a safe and effective method for excellent ocular anesthesia and akinesia. It was first described by Knapp[12] in 1884, but it did not gain widespread use until the 1930s and 1940s.[2] The technique described by Atkinson[13] in 1948, with a few modifications, has become the most commonly used technique for local anesthesia in ophthalmic surgery[2] (Fig. 14.2). The needle is introduced through the skin at the inferotemporal orbit with the globe positioned upward and inward, thereby moving the inferior oblique muscle out of the way; as described by

Table 14.1 Minimum Alveolar Concentrations of Inhalation Anesthetics

Anesthetic	Minimum Alveolar Concentration (%)
Halothane	0.75
Methoxyflurane	0.16
Enflurane	1.68
Nitrous oxide	105 ± 35
Fluroxene	3.4
Isoflurane	1.15

[a] With epinephrine.

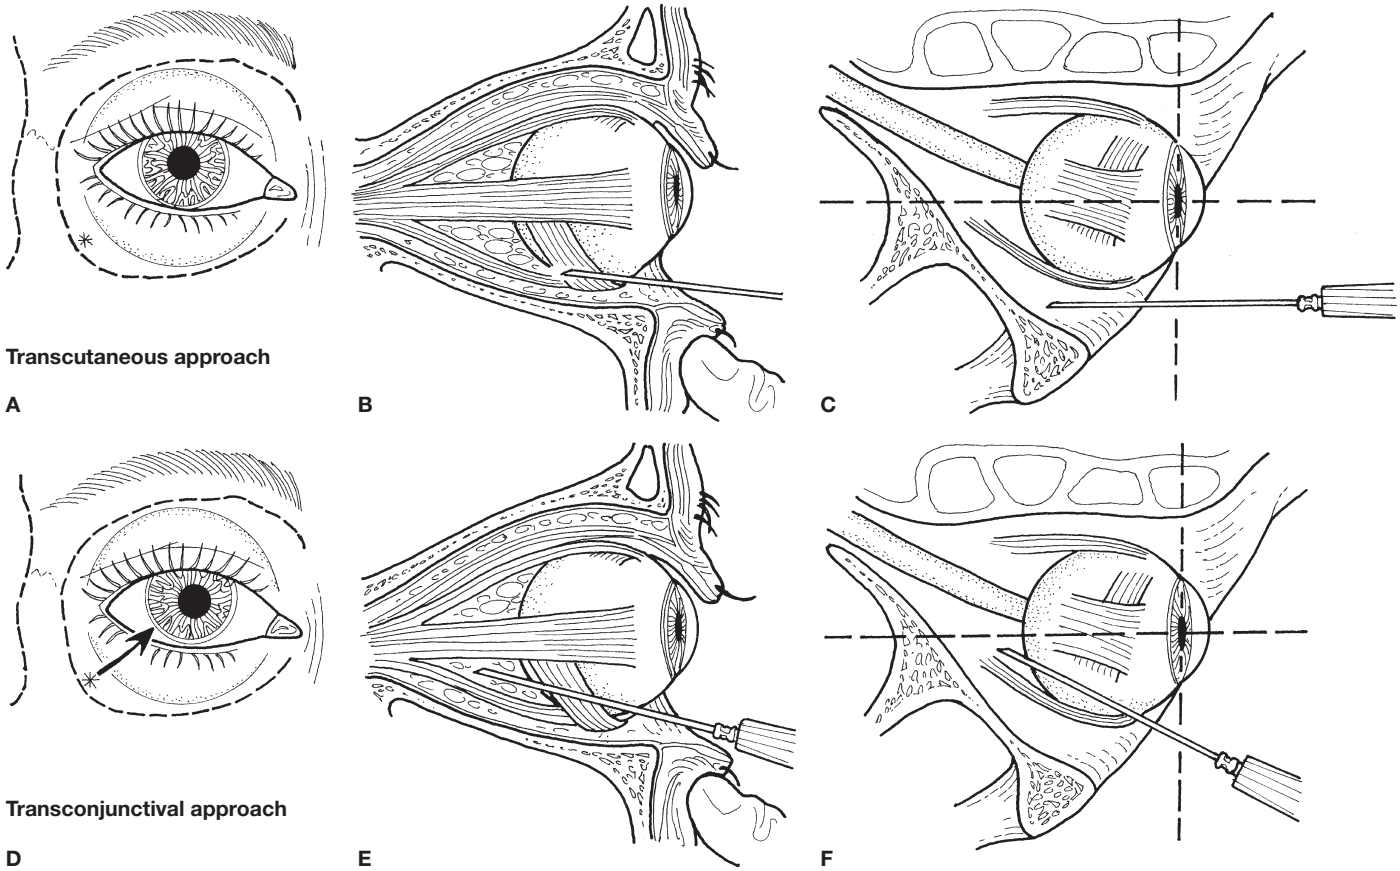

Figure 14.2. Inferotemporal intracone (retrobulbar) block. *A* and *D,* Views from front; *B* and *E,* views from lateral side; *C* and *F,* views from above (27-gauge, 31-mm sharp disposable needle). The asterisk (*) represents the injection site. The figure represents the transcutaneous (*A–C*) and transconjunctival (*D–F*) approaches. The approaches are similar except the lower lid is retracted in the transconjunctival method. The globe is in primary gaze. The needle tip enters at the lower temporal orbit rim, slightly up from the orbit floor *(A)* and very close to the bone. The needle track passes initially backwards in the sagittal plane *(C)* and parallel to the orbit floor; that is, with a 10° elevation from the transverse plane *(B)* until the midshaft of the needle has reached the plane of the iris and the needle tip has passed the globe equator *(B, C).* (If the needle were advanced further in the sagittal plane, contact with the lateral wall of the orbit would occur.) Following this step, the needle is directed with medial and slightly upward components *(D)* aiming for an imaginary point behind the globe on the axis formed by the pupil and the macula, so that the needle tip approaches but does not pass the midsagittal plane of the globe *(F)*. The needle enters the intracone space by passing through the intermuscular septum just inferior to the lower border of the lateral rectus muscle *(E).* The globe is observed continuously during needle placement to detect globe rotation that would indicate engagement of the sclera by the needle tip. During needle placement, continuing observation of the relationship between the needle/hub junction and the plane of the iris establishes an appropriate depth of orbit insertion *(E, F).* In a globe with normal axial length, as illustrated, when the needle/hub junction has reached the plane of the iris, the tip of the needle lies 5–7 mm beyond the hind surface of the globe *(E, F)*. After test aspiration, up to 4 mL of anesthetic solution is injected very slowly.

Atkinson, the needle is then directed to the orbital apex. Other authors fear that this technique puts the needle in close approximation to the optic nerve, posterior portion of the eye, and ophthalmic artery, and therefore recommend that the needle be directed to the inferior part of the superior orbital fissure.[14,15] To minimize complications, a blunt retrobulbar needle no longer than 35 mm has been recommended,[16,17] although many ophthalmologists use a sharp 25-gauge, 32-mm (1.25-inch) needle. The most common complication is retrobulbar hemorrhage, with an incidence of 0 to 1% with a blunt needle and as high as 5% with a sharp needle.[2,18] Other complications include perforation of the globe.[19] Various studies have shown an incidence of ocular penetration of less than 0.1% for eyes with an axial length of less than 26 mm and an incidence of less than 1% for eyes with an axial length of greater than 26 mm.[20] Optic nerve injury,[16] retinal vascular occlusion,[21,22] and strabismus[23] are other reported complications. Injection into the subdural space has been hypothesized as the mechanism causing contralateral amaurosis, brainstem anesthesia with apnea, and cranial nerve palsies[24–28] and has been demonstrated to occur following the injection of radio-opaque dye during positive-contrast orbitography.[29] Wittpenn and co-workers,[30] in a prospective study comparing 2 or 4% lidocaine with 0.75% bupivacaine in 3123 retrobulbar injections, found that 4% lidocaine had a significantly higher incidence of respiratory arrest (0.79% vs 0.09%). They hypothesized, as an alternative theory to direct injection into the optic nerve sheath, that the total amount of anesthetic agent placed in the retrobulbar space was an important risk factor for respiratory arrest. Systemic absorption via intrarterial injection is another theory proposed to explain these CNS and cardiovascular problems.[2]

Peribulbar injection was introduced as a method to achieve anesthesia and akinesia with less risk than that from retrobulbar injection.[31] The first stage of the technique, using 1% lidocaine with epinephrine, began as a 0.5-mL subcutaneous injection just above the inferior orbital rim and a finger-breadth distance from the

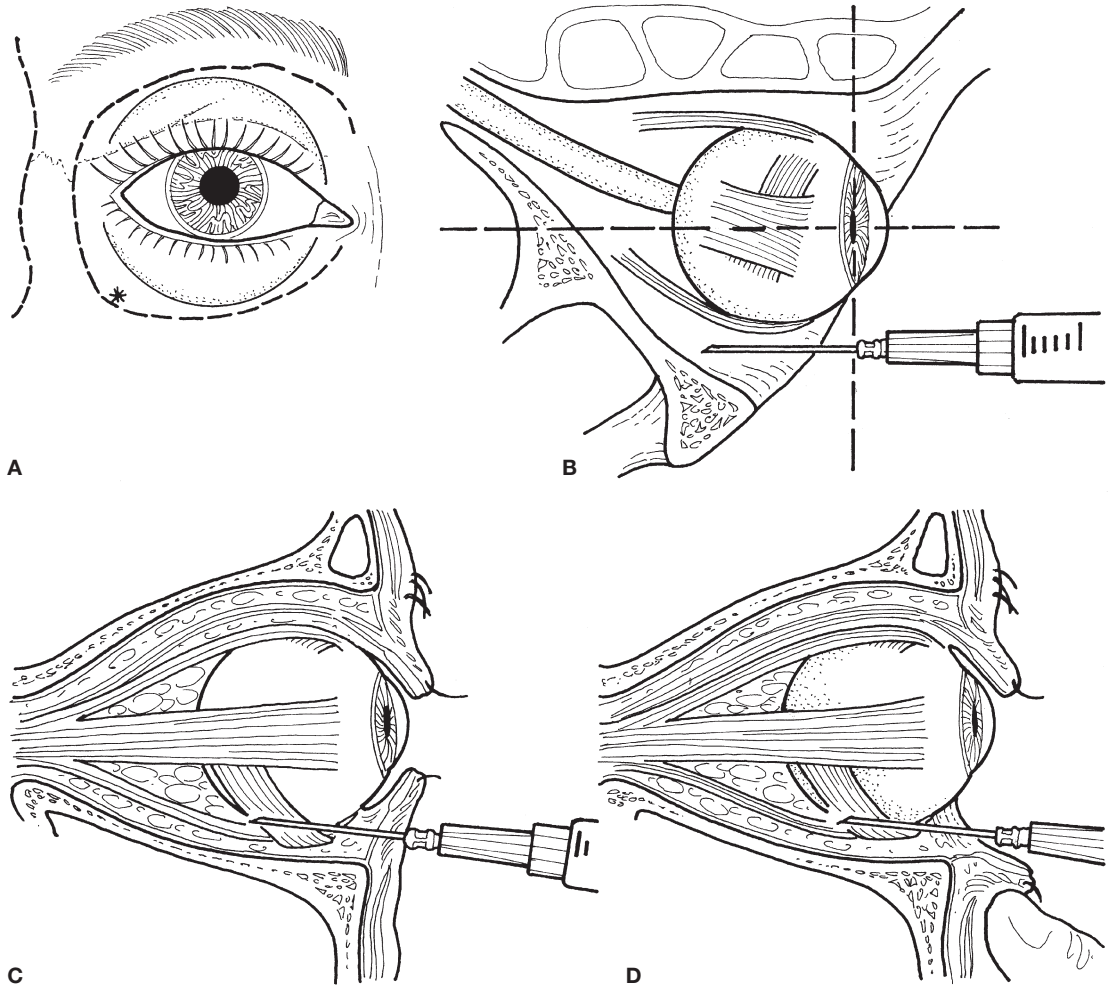

Figure 14.3. Inferotemporal pericone (peribulbar) injection. *A,* View from front; *B,* view from above; *C,* view from lateral side (transcutaneous injection); *D,* view from lateral side (transconjunctival injection). The globe is in primary gaze and the asterisk (*) is the injection site. A 27-gauge, 20–25-mm sharp disposable needle enters the orbit at the junction of its floor with the lateral wall *(A)* and very close to the bony rim. The needle passes backwards in a sagittal plane *(B)* and parallel to the orbit floor *(C, D),* passing the globe equator to a depth controlled by observing the needle/hub junction reach the plane of the iris *(B).* After test aspiration, up to 10 mL of anesthetic solution may be injected slowly (single needle technique) or up to 5 mL (if combined with complemental pericone block). The technique is equally applicable to the transcutaneous *(C)* or transconjunctival *(D)* route.

lateral canthus, followed by 0.5-mL injection into the orbicularis muscle and 1-mL injection into the anterior orbit. A similar injection was given just inferior to the supraorbital notch. The second stage included use of an Atkinson 23-gauge, 32-mm (1.25-inch) blunt retrobulbar needle to inject a 1-mL mixture of 0.75% bupivacaine and 1% lidocaine into the anterior orbit and an additional 1 to 2 mL at the equator of the globe as the needle was directed along the inferior orbit. Then, just below the supraorbital notch, the same amount was deposited into the anterior orbit and adjacent to the equator of the globe. Others have reported variations of this technique, including using a 25- or 26-gauge, 16-mm (0.5-inch) needle to deliver 5–7 mL of anesthetic in the inferotemporal orbit with sufficient pressure being placed on the syringe to place the needle at or behind the equator of the globe[32] (Fig. 14.3).

Peribulbar block appears to be as effective or better than retrobulbar block in achieving anesthesia and akinesia.[33,34] The complications of this technique are the same as retrobulbar block,[19,20,35] but because the needle is placed in a more anterior location, the complication rate may be lower.[31,36,37]

Sub-Tenon's infiltration, a mode of obtaining complete ocular anesthesia and akinesia without risk of globe perforation or other risks of retrobulbar injections, has been reintroduced (Fig. 14.4). This goal is achieved through a small conjunctival incision, by blunt dissection into one quadrant to obtain access below Tenon's layer for direct instillation of anesthetic agent as described by Turnbull[38] in 1884. Stevens[39] reported a variation of this technique that uses a blunt-tipped cannula to inject into sub-Tenon's space by way of a small conjunctival incision in the inferior nasal quadrant, thereby avoiding the inferior temporal vortex vein. Reported complications of the latter technique have included excessive chemosis or subconjunctival hemorrhage obscuring the operative site, and inefficient anesthesia if the anesthetic agent is not delivered far enough posteriorly.[39,40]

Retrobulbar and peribulbar blocks and sub-Tenon's infiltration allow for excellent anesthesia and akinesia with little risk. Under these conditions, procedures such as removing recurrent or large pterygia with or without conjunctival autograft; limbal cell harvesting or transplantation or other similar, extensive surface procedures; and lamellar keratoplasty can be performed. During 'open sky' procedures, such as corneal transplantation with or without cataract extraction or intraocular lens (IOL) exchange during local anesthesia, lid akinesia is desirable to prevent pressure from lid

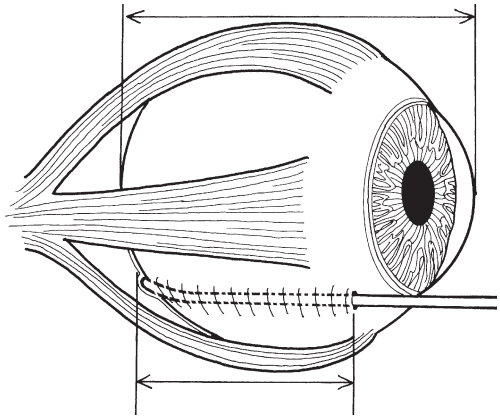

Figure 14.4. Schematic diagram of the path of the Southampton cannula, following the contour of the globe, to deliver anesthetic solution posterior to the equator.

blinks on the globe, which can create a risk of protrusion of intraocular contents. Reports have indicated that the peribulbar or retrobulbar block achieves effective lid akinesia by diffusion of anesthetic, especially with the use of hyaluronidase and orbital decompression devices.[41] However, some surgeons prefer to use an additional block to assure akinesia of the lids.

Several techniques have been described to achieve lid akinesia by way of anesthetizing the branches of the facial nerve at various locations. O'Brien[42] described a technique to block the temporofacial division of the facial nerve. In this block, the zygomatic arch is located with the index finger and followed along the underside of the arch backward to a point just in front of the tragus of the ear. At this location, the index finger is directly over the condyloid process of the mandible, which can be felt sliding back and forth as the patient opens and closes the mouth. A needle 1.5 cm in length is passed down to the anterior portion of the condyloid process, and 1–2 mL of local anesthetic is injected. The disadvantages of this type of block are the temporofacial branch of the facial nerve can be missed; the lower branches that supply the lips and face may be blocked, producing an undesirable and often prolonged facial paralysis; and the patient experiences a significant amount of discomfort if no sedation is used.[13] Other variations aimed at blocking the facial nerve at a more proximal location have been reported. The modified O'Brien block places the needle along the posterior portion of the mandible just below the condyle.[43] Wright[44] and, later, Nadbath and Rehman[45] described blocking the facial nerve as it emerged from the stylomastoid foramen. In addition to the undesirable effect of a total facial paresis that may last for several days, this type of block may also block the glossopharyngeal, vagus, and spinal accessory nerves where they exit the closely located jugular foramen, leading to significant respiratory and swallowing difficulties.[46–49]

van Lint[50] described a technique to block the more terminal branches of the facial nerve, thereby avoiding the total facial block encountered if the trunk of the nerve was blocked. In his description of the technique, a needle is introduced at the imaginary intersection of a horizontal line extending from the lowest part of the inferior margin of the orbit and a vertical line from the most temporal part of the lateral margin of the orbit. The needle is advanced as far as the bone and directed inward and slightly downward into the deep tissues just below the orbital margin. Anesthetic is injected while the needle is withdrawn until it reaches the entry site of the skin. Without being removed, the needle is then directed in a similar manner upward and inward near the orbital margin close to the bone.

Atkinson[13] described the disadvantages of this block: ballooning or edema of the lids may be produced; more of the anesthetic solution is required than for a proximal block, thereby increasing the risk of a toxic reaction to the anesthetic; and patient discomfort is great. He recommended inserting a 23-gauge, 3.5-cm long, blunt-tipped needle, at a location at the lower edge of the zygomatic bone about 1 cm posterior to the intersection of a vertical line drawn from the lateral margin of the orbit and a horizontal line drawn along the lower edge of the zygomatic bone. The injection is made along the lower edge of the zygomatic bone and upward across the zygomatic arch close to the bone.

One last technique involves injecting the anesthetic solution directly into the center of the lids beneath the orbicularis. One study measuring the force of lid closure and electromyographic activity of the orbicularis muscles compared these techniques and showed that the lid block and the O'Brien blocks were the most effective in producing akinesia of the lid.[41]

TOPICAL ANESTHESIA

As mentioned earlier in this chapter, the use of topical anesthesia appears to be increasing in frequency as the anesthesia method of choice for anterior segment surgery. Using it in combination with intravenous sedation creates a viable option to other anesthesia choices. The advantages include less cost, quicker turnover times, and a way to avoid the risks associated with local injections or general anesthestics.

Procedures that are commonly performed under topical anesthesia include: corneal scraping and biopsies, removal of conjunctival and corneal foreign bodies, epithelial debridement, superficial keratectomy, phototherapeutic keratectomy, corneal micropuncture, and corneal refractive surgeries (photorefractive keratectomy, laser assisted in-situ keratomileusis, and astigmatic keratotomy).

Some procedures, historically, have been done primarily under local block or general anesthesia. But, recently, for reasons mentioned above, surgeons are doing these procedures more frequently using topical anesthetics combined with intracameral lidocaine and intravenous sedation. These procedures include repair of corneal lacerations, exchange or reposition of an IOL, placement of a phakic IOL, placement of secondary IOL including iris-fixated IOLs, and endothelial keratoplasty procedures such as deep lamellar endothelial keratoplasty (DLEK), Descemet's-stripping endothelial keratoplasty (DSEK), and Descemet's-stripping automated endothelial keratoplasty (DSAEK).

Penetrating keratoplasty with or without other anterior segments procedures such as cataract extraction and IOL implantation most often are done under local anesthetic injection or under general anesthesia. However, under certain situations where these anesthesia options are not possible or less desirable, penetrating keratoplasty can be done under topical anesthesia.[51,52]

A complication of topical anesthesia is the lack of effective anesthesia with patient pain or the presence of patient anxiety (with or without adequate anesthesia). One can try to avoid the latter by appropriate patient selection and supplementing the topical anesthesia with intracameral preservative-free lidocaine when possible and intravenous sedation. In some cases, it may be necessary to switch to one of the other modalities of anesthesia described above in this chapter.

Table 14.3 Topical Anesthetics

Philadelphia: Lippincott-Raven; 1995 and Liu JC, Steinemann TL, McDonald MB, et al. Topical bupivacaine and proparacaine: a comparison of toxicity, onset of action, and duration of action. Cornea 1993; 12: 228.

Table 14.3 lists some commonly used topical anesthetics, times of onset, and durations of activity. These agents have a very quick onset of activity with excellent corneal anesthesia. However, the duration of activity is relatively brief.

These agents have toxic effects, especially locally on the corneal epithelium. A few drops of these agents can cause a significant epithelial disturbance and inhibition of epithelial healing.[53] One study comparing rabbit corneal epithelial toxicity of topical bupivacaine and proparacaine showed that with just a few drops, both caused epithelial toxicity, and proparacaine delayed epithelial healing in comparison to a saline control.[54] Data on tetracaine or cocaine were not included, but significant epithelial haze and irregularity can be seen shortly after application of these agents. Long-term abuse of these agents is known to cause severe surface disturbance with large epithelial defects, stromal infiltrates, and endothelial changes. Local allergic response of the lids and conjunctiva is possible, and systemic anaphylactic reactions occur, but they are less common.[53]

15 Corneal and conjunctival foreign bodies

Marc R. Criden, Steven E. Katz, Richard G. Lembach

Ocular surface foreign bodies are a common cause of patient visits to the emergency room and the ophthalmologist. The cornea is highly innervated by sensory branches of the fifth cranial nerve. A foreign body that lies embedded in the corneal stroma with disruption of the overlying epithelium will be aggravated with each blink response, thus prompting the patient to seek out medical care. Even if the foreign body is no longer present the foreign body sensation persists.

This chapter discusses protective mechanisms of the ocular adnexae, presentation of the corneal and conjunctival foreign bodies, their evaluation and management. A high degree of suspicion should always be maintained for the possibility of an eye wall rupture, intraocular and orbital foreign bodies associated with high velocity force.

PROTECTIVE MECHANISMS

The eyelids and ocular adnexae form a physical barrier for the ocular surface and contribute to a number of protective mechanisms against corneal and conjunctival foreign bodies, including blinking and tear film composition.

Spontaneous blinking (i.e. without an apparent external stimulus) occurs approximately 15 times per minute in adult humans.[1] Reflex blinking is initiated by corneal or conjunctival contact. The afferent arm of the blink reflex is the ophthalmic division of the fifth cranial nerve. First-order neurons synapse in the ipsilateral chief sensory nucleus in the pontine tegmentum. Second-order neurons then project to the nucleus of the facial motor nerve bilaterally. The seventh cranial nerve innervates the orbicularis oculi muscle to complete the reflex arc. Stimulation of either ocular surface thus leads to a bilateral blink response with increased lacrimal gland secretion and tear production.

Tear drainage is predominately driven by contraction of the orbicularis oculi muscle that occurs with blinking. The tear pump mechanism is described by Doane[2] as follows: positive pressure created within the nasolacrimal sac on blinking forces tears to drain into the nose, and negative pressure within the nasolacrimal sac as the lids open draws tears from the ocular surface into the lacrimal punctae. Rewetting of the ocular surface occurs with each blink. Surface foreign bodies caught in the precorneal tear film will lead to increased blink rate and reflex tearing, which will wash the foreign body out of the eye or into the inferior cul-de-sac.

Loss of these and other protective mechanisms predisposes to corneal and conjunctival foreign bodies and their sequelae. Proptosis and eyelid retraction, such as seen in thyroid-related orbitopathy, lead to increased exposure of the ocular surface. Lack of Bell's phenomenon may occur as an idiopathic phenomenon or may be due to inferior rectus muscle restriction in thyroid orbitopathy. Hypesthesia in the first division of the fifth cranial nerve due to herpes simplex keratitis, chronic contact lens wear, and dry eye syndromes may be associated with diminished tearing. Bell's palsy and eyelid malpositions such as entropion or ectropion decrease the tear pump function. Penetrating trauma may bypass all of the protective mechanisms.

HISTORY

Common conjunctival and corneal foreign bodies include loose eyelashes, wind-blown debris, or insects and organic foreign bodies frequently found in gardeners, farmers, and campers, and may be associated with fungal infection. Projectile foreign bodies may occur in relation to shattered glass (i.e. motor vehicle accident), use of tools (i.e. hammering, grinding metal on metal, sawing, or drilling) or explosion (Fig. 15.1). High-velocity metallic foreign bodies of this nature are often sterile due to high temperature at time of fragmentation.

In these cases, a detailed history of the materials involved may be important factors. For example, composition, shape, likelihood of single or multiple pieces, proximity of the point of impact to the globe, energy transferred to the projectile, and the angle of incidence are all relevant details of the history of injury. Foreign bodies may be inert (i.e. glass, gold, and silver) or may be associated with higher likelihood of toxicity (i.e. iron and copper) or infection (i.e. organic matter, eyelashes, and insects). It is important to note whether the incident was work related and whether alcohol was involved.[3] The presence of discomfort, including the time of onset, character, location, and exacerbating factors should be noted. For example, increased discomfort with blinking may indicate a

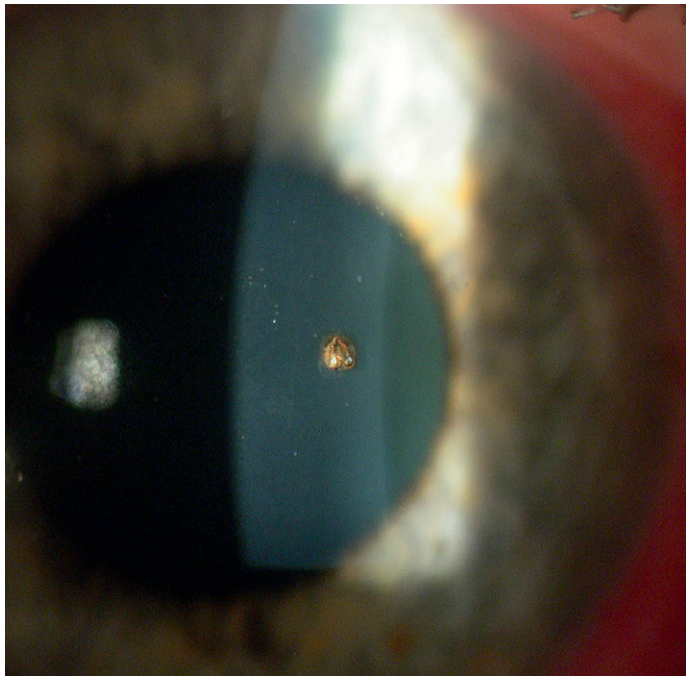

Figure 15.1 Central, superficial metallic foreign body (*photo courtesy of Ayad A. Farjo, M.D.*).

superior tarsal foreign body. Other complications may include redness, itching, tearing, photophobia, or decreased vision.

EXAMINATION

The importance of documenting initial visual acuity cannot be overstated. When the vision is significantly decreased out of proportion to the clinical findings suspicion is raised of occult corneoscleral or orbital penetrating injury. Slit-lamp exam using an angled beam is ideal for the evaluation and removal or corneal foreign bodies because of the ease in delineating depth of penetration. Surgical loupes, which provide ×2.5 to ×3.5 magnification, may be adequate when a slit lamp is not available. Confocal microscopy has also been utilized to detect small foreign bodies with or without infiltrates. This may be a useful tool to identify subtle inflammatory reactions and to monitor resolution.[4] The dimensions of the overlying epithelial defect noted with fluorescein stain should be measured for future evaluation of the rate of healing. Patients with delayed presentation may exhibit concomitant stromal infiltration, which may persist even after foreign body removal. Cells in the anterior chamber may occur as a traumatic iritis, in relation to a sterile or infectious corneal stromal infiltrate or in association with intraocular penetration, and may progress to form a frank hypopyon. A small gross or microscopic hyphema may indicate possible occult ocular perforation.

A high suspicion for intraocular or intraorbital foreign body should be maintained in the appropriate clinical setting, such as a high-velocity injury. A standardized classification system of ocular trauma terminology was published in 1996.[5] Common signs of globe perforation are broad and listed in Table 15.1.

Fluorescein dye 2% may be instilled to assess wound leakage under a blue light (positive Seidel's sign); however, small or shelved wound edges may be self-sealing, and the lack of aqueous leak and a formed anterior chamber does not guarantee against eye wall rupture. A self-sealing corneal laceration may be able to maintain normal or even elevated intraocular pressure (Fig. 15.2). The anterior chamber depth should also be compared to the fellow uninjured eye.

Once a ruptured globe is suspected, further evaluation and exploration should take place in the operating room after appropriate radiologic evaluation, if indicated. A metal shield is taped securely over the eye. Pain and nausea are controlled to avoid eyelid squeezing and emesis, which may cause extrusion of intraocular contents. Prophylactic antibiotic (cefazolin 1 g intravenously) should be given, and the tetanus prophylaxis status assessed and updated. The patient should be maintained without oral intake, and anesthesia should be consulted. Any preoperative studies (e.g. blood count,

electrolytes, EKG, and chest X-ray) should be ordered as soon as possible in preparation for surgery.

TREATMENT OF CONJUNCTIVAL FOREIGN BODIES AND LACERATIONS

Conjunctival foreign bodies may occur in a tarsal, forniceal, or bulbar location. Upper tarsal conjunctival foreign bodies may be associated with linear abrasions (i.e. vertical tracks best noted with fluoroscein staining) in the upper cornea and should be suspected in this setting. The upper eyelid should be everted after instillation of topical anesthetic, and the foreign body removed with a moist cotton-tipped applicator or jeweler's forceps. The upper lid should not be everted, however, if there is any suspicion of a globe rupture as this complication may increase intraocular pressure and cause extrusion of intraocular contents. Upper lid eversion may be achieved by pulling the lashes and lid margin superiorly over a cotton-tipped applicator placed centrally in the eyelid crease.

The superior and inferior fornices should be thoroughly examined with appropriate light and magnification. Contact lenses are commonly dislocated into the superior fornix and are generally retrieved without difficulty. They may become embedded into the conjunctiva and can be associated with chronic foreign body inflammation[6] and infection. Nicolitz and Flanagan[7] reported a 26-year-old woman with a hard contact lens embedded in the supratarsal space, who presented with a progressively enlarging anterior orbital mass lesion. Instillation of fluorescein dye will concentrate in a soft contact lens making visualization easier when a retained contact lens is suspected but not found. Elderly patients wearing aphakic contact lenses are vulnerable to this problem due to loss of orbital fat, deep-set globes, and lax lids.

Conjunctival lacerations may be obvious by direct visualization or detection of prolapsed Tenon's fascia, orbital fat, or exposed sclera. Bloody chemosis may obscure visualization of these details.

Signs of an orbital foreign body may include globe displacement, dysesthesia in the V1 or V2 distribution of the trigeminal nerve, abnormality of ocular ductions, or new onset of manifest deviation, ptosis, and conjunctival laceration. If the globe appears formed with no other evidence of ocular penetration, the conjunctiva can be explored under topical anesthesia in a cooperative patient. If there is any historical or clinical suspicion of an ocular or orbital foreign body, appropriate imaging studies should be obtained.

A computed tomography (CT) scan of the orbits with axial and coronal cuts of 3 mm or less is ideal in the setting of trauma. A CT scan is readily available, requires less scanning time per image than magnetic resonance imaging (MRI), provides a safer option when metallic foreign bodies are suspected, and offers better bony visualization. An MRI is contraindicated as the primary imaging modality in the setting of trauma until the presence of ferrous foreign bodies has been excluded. Posterior segment hemorrhage, vitreous space distortion, and lens disruption identified on a CT scan correlate with poor visual or anatomic outcomes. MRI may be superior in detecting nonmetallic foreign bodies, such as wood.[8] Although ultrasound has been successfully used in ocular[9] and orbital trauma, its routine use is not advocated in this setting. Pressure from the probe on the eye may be uncomfortable for the patient, and posterior pressure may lead to extrusion of intraocular contents if the globe is ruptured. The necessary ultrasound equipment is generally not available in the emergency room and an experienced ultrasonographer may not be readily available during the off hours when these patients frequently present.

In the absence of ocular or orbital penetration, most conjunctival lacerations do not require surgical repair. Larger conjunctival lacerations can be closed with 8-0 polyglycan sutures. With cooperative patients, this may be accomplished in a treatment room rather than an operating room by using topical viscous lidocaine anesthetic. When opposing the conjunctival edges, care should be taken to avoid incarcerating Tenon's fascia, which may lead to formation of Tenon's cysts. Tenon's fascia can be closed as a separate layer; however, it is generally much easier to partially excise this tissue when it has prolapsed anteriorly through the conjunctival wound. Topical antibiotic drops, such as a broad spectrum fluoroquinolone, or ointment with follow-up at 3 to 5 days is generally adequate in these circumstances.

TREATMENT OF SUPERFICIAL CORNEAL FOREIGN BODIES

Placement of a topical anesthetic reduces discomfort and blepharospasm and allows easier evaluation and treatment. Foreign bodies that lay on the epithelium or are loosely embedded may be gently removed with a moistened cotton-tipped applicator or a jeweler's forceps after applying topical anesthetic. When the foreign body is firmly embedded in the corneal stroma, an 18- or 21-gauge needle can be placed on a 1- or 3-mL syringe for stability. The beveled needle tip should face away from the surface of the cornea. The tip can be advanced beneath the anterior projection of the foreign body and gently teased from the stroma back through the entrance site. Once the foreign body has been dislodged it can be removed with a moistened cotton-tipped applicator. A wire speculum may be advantageous if the patient is not too blepharospastic or if an assistant is not available to hold open the upper lid.

It is often useful to give the patient a fixation target for the opposite eye, particularly when the foreign body is in the visual axis. The operating hand can be rested on the patient's zygoma for support. The upper eyelid is elevated to prevent blinking. The physician should inform the patient in advance of the steps to be taken and give reassurance that the needle will not enter the eye. However, it is a good practice to avoid showing the needle to the patient, if possible.

Most epithelial defects associated with foreign body removal will heal within 24 to 48 h. If the epithelial defect is small, topical antibiotic drops may be used and the patient re-evaluated the following day. Pressure patching is generally unnecessary and may be associated with increased discomfort and delayed epithelial healing. Larger (>50%) or poorly healing epithelial defects may benefit from a bandage contact lens with a topical antibiotic plus a nonsteroidal anti-inflammatory.[10] The presence of a stromal infiltrate will deter epithelial healing and should be treated aggressively with topical antibiotics to avoid progression to a nonhealing corneal ulcer.

Routine bacterial cultures of corneal foreign bodies without stromal infiltrate are unnecessary. DeBroff and co-workers[11] cultured 63 consecutive corneal foreign bodies and found that nine (14.3%) were positive for bacteria. In this study, the most common bacteria cultured was coagulase-negative *Staphylococcus*, which is commonly found as normal flora of the ocular adnexa. When a corneal ulcer is present, however, cultures for aerobes, anaerobes, and fungi should be considered especially if organic matter is involved.

Ferrous foreign bodies may be associated with a rust ring as soon as 3–4 h after the injury. Rust rings may be removed on the initial

visit with the use of a battery powered burr[12]; however, they are often more easily removed 24–48 h later when the surrounding corneal tissue has softened. They can gently be lifted off with a disposable needle. The burr often leaves a larger defect than necessary, and Liston and co-workers[13] found a trend toward deeper corneal stromal damage when using an electric burr drill versus a small gauge hypodermic needle in a rabbit model. Removal of most of the rust ring allows the epithelium to heal over; however, the importance of removing all of the rust has been overstated. A minimally noticeable scar by slit-lamp, which is usually off-axis, will generally have less visual significance than an overzealous attempt to remove the complete rust ring with a burr.

The use of topical anesthetics outside the office is contraindicated due to delayed healing, epithelial erosion, development of neurotrophic keratitis, and a secondary bacterial infection. Similarly, topical corticosteroid medications are contraindicated in the setting of an epithelial defect as they may predispose to a secondary infection. When an element of traumatic iritis is present, a short acting topical cycloplegic (i.e. cyclopentolate 1%) may be used and a topical corticosteroid added if necessary after the epithelial defect has healed. With an epithelial defect, steroids may be used judiciously in conjunction with a broad spectrum antibiotic only if there is no suspicion of fungus or infiltrate.

Patients should be advised that discomfort will return as the topical anesthetic wears off. Reassurance regarding the rate of healing is important for their peace of mind. Analgesia with extra-strength acetaminophen is generally adequate; however, the use of ketorolac, acetaminophen with codeine, oxycodone, or sleeping medications may be indicated on a short-term basis when large epithelial defects are present. Topical diclofenac has been reported to relieve pain associated with corneal rust rings in a prospective, double-blind, placebo controlled clinical trial.[14]

Fluoroquinolone antibiotics have been the mainstay of antimicrobial treatments for several years. Second-generation quinolones such as ciprofloxacin and ofloxacin are still frequently used and are effective agents. However, many organisms have developed resistance against these agents. The advent of fourth-generation fluoroquinolones (gatifloxacin and moxifloxacin) has expanded the spectrum of coverage against both gram-positive and gram-negative organisms and atypical bacteria.[15] These also demonstrate superior corneal penetration and should represent first-line agents for both prophylaxis and treatment of corneal ulcers and endophthalmitis.

Corneal wound healing and speed of re-epithelialization are essential to decreasing risk of infection and visual outcome. Rapid corneal healing also reduces the risk of stromal scarring, haze, or irregular astigmatism. Post-surgical management often includes steroids that may impair the healing process and their use should be monitored closely.

TREATMENT OF DEEP CORNEAL FOREIGN BODIES

Buried corneal stromal foreign bodies may be left in place if small and inert (i.e. without keratitis). Shattered glass often leaves multiple inert intrastromal fragments that are well tolerated by the cornea and may be observed. Attempted removal of deep fragments may result in unnecessary stromal scarring. Only an ophthalmologist in a controlled setting should remove foreign bodies that lie close to Descemet's membrane. Aggressive attempts at removal with inappropriate instrumentation or inadequate visualization may cause posterior migration of the foreign body, which may penetrate Descemet's membrane and convert a corneal foreign body into an intraocular foreign body.

Foreign bodies that are suspected to penetrate into the anterior chamber should be removed under the operating microscope in which corneal sutures may be placed to close an aqueous leak if necessary. Small leaks are often self-sealing or may be amenable to placement of a bandage contact lens with an adjunctive aqueous suppressant. Cyanoacrylate glue may also be used to close small corneal leaks. Meskin and co-workers recently described the feasibility and effectiveness of 2-octyl-cyanoacrylate glue as a temporary wound barrier following clear corneal cataract surgery.[16] This method was found easy to use, effective, and demonstrated a favorable side-effect profile. A hand-held magnet may also be useful in removing some intrastromal foreign bodies.

Inflammation in response to insect hairs is referred to as ophthalmia nodosa. The more common offenders are caterpillar and tarantula hairs that are blown into the eye or transferred by direct contact. These hairs frequently possess barbs that lodge into the corneal stroma. Repeated blinking, worsened by irritation, may force these hairs further into the cornea and, ultimately, into the anterior chamber.[17]

Within the stroma, these hairs may be surrounded by nummular infiltrates and there may be a profound anterior chamber reaction. A conjunctival nodule may also be present, although these hairs may be very difficult to visualize in this location. Attempts should be made to carefully remove visible, exposed hairs but this is often limited due to their fragility. The inflammatory response responds well to steroids and should be accompanied by a topical antibiotic. Steroids should be continued for several months and tapered slowly.[18]

Fiberglass particles are also a relatively common cause of corneal abrasion and source of corneal foreign body. These fine fibers easily penetrate the cornea and may be embedded within the corneal stroma or work themselves into the anterior chamber. They are often difficult to visualize and break easily when attempting to remove them. Fiberglass is relatively inert but may harbor a variety of bacteria. If the fiberglass particles cannot be removed then bacterial cultures should be obtained followed by broad spectrum antibiotic coverage and close monitoring for infectious keratitis or endophthalmitis.

16 Conjunctival and corneal cultures, resections, and biopsies

Sarah M. Nehls, Neal P. Barney

CORNEAL CULTURES

Infectious keratitis is a sight-threatening condition that requires urgent diagnosis and management. Identification of the organism responsible for infection by corneal scraping for culture and smears is important in guiding effective antimicrobial treatment and for tracking the epidemiology of infectious keratitis. Small, peripheral corneal ulcers are sometimes treated empirically, without culture, at the discretion of the treating physician. Larger, central, sight-threatening lesions and those with atypical features or a lack of response to empiric therapy should be cultured.

Most corneal cultures can be taken with the patient sitting at the slit-lamp microscope. For more extensive sample collections or to facilitate cooperation, the patient may also be positioned supine under a microscope. The eye should be anesthetized with topical proparacaine hydrochloride 0.5% drops and all necessary media and glass slides should be available for immediate plating or smears. A sterile Kimura platinum spatula, a 15-blade scalpel or a calcium alginate swab moistened with sterile broth can be used to scrape the cornea at the leading edge of the corneal ulcer.[1,2] Care should be taken to avoid contact with eyelid skin, lashes, or conjunctiva in order to avoid contamination of the sample. An increase in the size of the corneal epithelial defect is an expected outcome at the end of the procedure.

The samples are immediately inoculated onto agar plates and smeared on to glass microscope slides. Several samples may need to be collected to allow for the complete spectrum of culture plates and smears required for diagnosis. A platinum spatula can be flame sterilized by a Bunsen burner; alternatively a fresh spatula, blade, or swab can be used for each sample taken. All plates and slides should be carefully labeled with the patient's name, medical record number, date, and site of collection.

In some clinical settings it may be difficult to maintain appropriate culture media so the use of transport media such as Amies media without charcoal may be considered. The microbiology lab will plate the cultures upon receiving the sample. No difference in recovery rates for bacterial and fungal organisms was found for samples plated as long as 24 h after collection with Amies transport media.[3]

Cytology is often invaluable for rapid identification of the class of organism causing a corneal infection. Corneal samples smeared on to glass slides are transported to the laboratory where they are air dried, fixed, stained, and examined under the microscope. Gram stain is used to identify bacterial organisms. Giemsa stain or a 10% potassium hydroxide (KOH) wet mount is useful in diagnosing fungal pathogens. Atypical mycobacteriae can be seen with a Ziehl–Neelsen acid-fast stain. Giemsa, acridine orange, and calcofluor white stains are useful in detecting acanthamoebae (Table 16.1).[4,5] Herpes simplex virus (HSV) keratitis can be confirmed by finding multinucleated giant cells on Giemsa stain.[6] Smears can also be prepared for an immunofluorescence assay (IFA) to evaluate for the presence of HSV.

The identification of organisms causing bacterial keratitis is achieved by plating specimens on 5% sheep's blood, and chocolate agars. Most bacterial species will grow on blood agar; chocolate agar is needed for growth of *Haemophilus*, *Neisseria*, and nutritionally variant *Streptococcus* species. Fungal organisms can also grow on blood and chocolate agars or more specific fungal culture plates such as Sabouraud's agar can be used.[7] Atypical mycobacteria will grow on blood agar, Lowenstein–Jensen media, and Middlebrook 7H11 media.[8–10] Acanthamoeba should be plated on non-nutrient agar with an overlay of live *Escherichia coli*.[5] For the isolation of more unusual organisms such as fungi, atypical mycobacteriae and acanthamoebae, the microbiology lab should be contacted to establish the preferred culture media and means of plating.

Samples collected for analysis of HSV keratitis should be placed in viral transport media to be transported to the lab for cell culture (Table 16.1). Traditional cell culture has the disadvantage of a slow rate of detection. Faster detection rates can be achieved with a combination of an IFA and polymerase chain reaction (PCR) detection of HSV DNA.[6] Calcium alginate swabs should not be used for PCR specimen collection because of an inhibitory response; collection by a platinum spatula or Dacron swab is preferred.[11]

The overall yield of corneal cultures ranges from 38 to 67%.[3,7,12–15] If antimicrobial therapy is initiated prior to cultures, there does not appear to be a significant difference in rates of organism identification but a delay in pathogen recovery is more likely to occur.[13,16]

Table 16.1 Culture media and smears for identification of corneal pathogens

Organism	Culture Media	Smear
Bacteria	5% sheep's blood agar, chocolate agar	Gram stain
Fungi	5% sheep's blood agar, chocolate agar, Sabourand agar	Giemsa stain, 10% KOH wet mount
Atypical mycobacteria	5% sheep's blood agar, Lowenstein Jensen media, Middlebrook 7H11 media	Gram stain, Ziehl–Neelsen stain
Acanthamoeba	Non-nutrient agar with *E. coli* overlay	Giemsa stain, acridine orange stain, calcofluor white stain
Herpes simplex virus	Viral transport media for cell culture	Giemsa stain, immunofluorescence assay

The patient should be started on broad spectrum antibacterial therapy while awaiting culture results. Therapy can then be tailored as the specific infectious organism and panel of antimicrobial sensitivities are identified.

CONJUNCTIVAL CULTURES

Culture of the conjunctiva is an important procedure in the clinical setting of microbial conjunctivitis. Identification of causative pathogens, designing specific treatment plans, determination of the efficacy of treatment, or persistence of infection despite treatment is reason to perform conjunctival cultures. Because several classes of organisms may infect the conjunctiva, knowledge of modalities to identify these infecting agents requires review.

Bacterial conjunctivitis is most suspected when symptoms of gluey or sticky lids present with signs of purulent discharge.[17] Cultures to isolate bacteria are taken directly from the conjunctiva. The physician prepares the patient by describing the planned procedure. Topical proparacaine 1% may be instilled. The inferior lid is rolled away from or lowered from the globe and the sample is obtained by applying a premoistened swab into the fornix with both a sliding and rotating motion. The swab is then placed in transport media or may be plated directly to various media (reviewed in culture of cornea). The swab may be moistened with the sterile liquid transport media or both for culture. Care is taken to avoid swab contact with the lid margins to assure inoculation of organisms only from the conjunction. The swab may be that supplied with the transport media, a sterile cotton swab, or calcium alginate swab. Calcium alginate and cotton swabs have been demonstrated to inhibit recovery of different organisms.[18] It is believed that the glue used for the various swabs may be toxic to either the organisms directly or the cells in culture that are to be inoculated as in the case of *Chlamydia* culture. Transportation of the collected specimen should be directed to the laboratory immediately for processing.

Viral conjunctivitis more likely is bilateral, typically has a watery discharge or increased tearing, and may have associated sore throat and preauricular adenopathy. Cultures may be obtained in the same manner as for suspected bacterial conjunctivitis but transported in different media. Sodium chloride moistened cotton-tipped swabs gave better yield topical of virus detection than commercial viral transport media.[19] The use of topical anesthetic enhanced viral recovery rate. Cell culture for virus detection is viewed as the standard but may take 4–7 days to show the cytopathic effect. Quantitative polymerase chain reaction has been shown to be more sensitive in direct comparisons. Availability may be limited in some regions.

Chlamydia conjunctivitis is a chronic, follicular conjunctivitis in adults. Laboratory diagnosis relies on both microscopic slide evaluation and specimen submission for culture or molecular diagnostic evaluation. Collection of a specimen for microscopic evaluation differs slightly from other causes of conjunctivitis. When *Chlamydia* is suspected, the upper or lower tarsal conjunctiva should be scraped with a Kimura spatula or blunt end of a #15 blade. The slides may be air dry. Detection may be made with the use of Giemsa stain for basophilic cytoplasmic inclusions or with direct immunofluorescence. A swab for culture should be placed in appropriate *Chlamydia* transport media. Viral transport media may contain antibiotics that could reduce the likelihood of positive culture results. Positive growth of clinical specimen from adult inclusion conjunctivitis occurs in a lower percentage of patients than from neonates. Finally, serology may prove useful in identifying a patient with *Chlamydia* but would not be helpful unless clinical findings support the presence of active infection.

Neonatal conjunctivitis requires preparation of both slides and culture for suspected organisms most associated with this condition: *Chlamydia* and *Neisseria*. Ordinarily a scraping of the conjunctiva is appropriate to create slides for evaluation. Since cooperation of the infant is unlikely, one must minimize the risk to the patient. If necessary, use a swab of the conjunctiva to collect a specimen for slide preparation. As mentioned above, be sure to include a chocolate agar plate when *Neisseria* is suspected.

BIOPSY

Diagnostic conjunctival biopsy may be performed as an outpatient procedure. In general, the procedure poses such small risk to the patient that, with rare exception, a cooperative patient may undergo the procedure in the office minor operating room. Excisional conjunctival biopsy may be performed in the minor operating room or an outpatient surgical center depending on the extent of tissue removal and need for adjunctive procedures at the time of the biopsy. Indications for conjunctival biopsy include unknown lesions that are threatening vision or causing chronic irritation or lesions that may indicate systemic disease. Conjunctival biopsy may be used to determine the presence of a malignancy.

Anesthesia may be topical alone in a few patients, but some require subconjunctival injection of anesthetic. Depending on the nature of the procedure and expected duration of the procedure, retrobulbar anesthesia may be indicated. Topical anesthesia may be proparacaine 0.5%, tetracaine 0.5%, or lidocaine 2% gel. If concern is for effectiveness, a cotton-tipped applicator soaked in either anesthetic may be applied and held directly over the area of planned

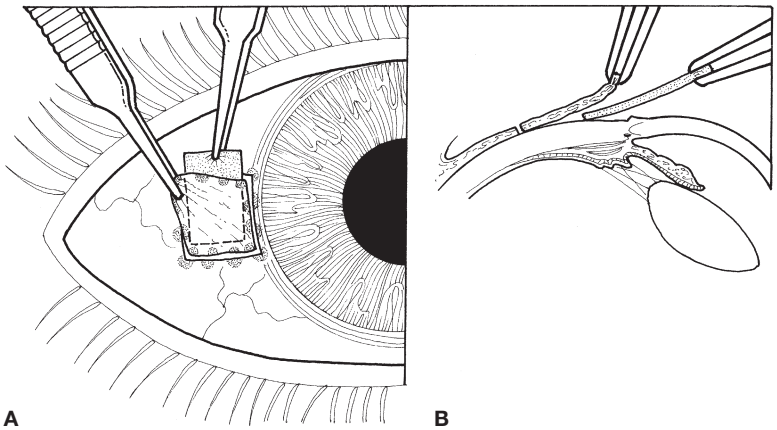

Figure 16.1. Conjunctival biopsy. *A,* The previously marked margins have been incised and the tissue to be removed has been undermined. Filter paper placement on the globe surface and gentle insertion beneath the specimen are performed as the tissue is drawn out to the filter paper. *B,* Cross-sectional view of the technique shows filter paper insertion beneath the excised tissue.

biopsy. If this approach is elected, care should be taken to avoid abrasion to the cornea and avoid abrasion or crushing injury to the area of pathology. Artifactual changes in the specimen may impact correct histologic diagnosis.

Subconjunctival anesthesia is useful in procedures requiring large biopsies or biopsies that require adjunctive treatment (e.g. cryotherapy). Retrobulbar anesthesia may be necessary for long procedures or procedures that require akinesia and traction sutures for appropriate eye positioning. Regardless of anesthesia type, topical phenylephrine 2.5% given as preoperative drops may reduce bleeding.

Appropriate movement of a specimen biopsy from the operating room to the pathology laboratory should first be planned with the pathologist. For most conjunctival specimens, immediate fixation in formalin is appropriate and easy. Specimen orientation may be assisted by immediately placing the biopsy on filter paper with the epithelial side facing up. The combined specimen and filter paper is then placed in formalin. A nonabsorbable suture may be placed in the specimen to assist the pathologist in orientation during the embedding process. If the differential diagnosis necessitates tissue collection for frozen sections or immunohistochemistry of nonfixed specimens, the following methods ensure adequate preservation of histologic architecture: In the operating room, the specimen is placed in a small (2-mL) freezing vial, sealed tightly, and immediately placed in liquid nitrogen to snap freeze the specimen. This frozen tissue should then be embedded in optimal cutting temperature compound and stored at −70°C until sectioned for staining. Discussion with the pathologist can also be helpful to insure the optimal method of tissue preservation and transportation for the suspected diagnosis.

Preparation of the site should include antiseptic cleansing of the skin and placement of a sterile drape. The operating microscope is preferred, but loupes may be used. If the area for excision needs to be demarcated, a hand-held disposable cautery or, preferably, a sterile marking pen can be used. Any lid speculum is acceptable. A nontoothed, serrated forceps is used to elevate normal conjunctiva within 1–3 mm of the lesion, and Westcott or Vannas scissors are used to incise the conjunctiva. It should be undermined without regrasping if possible. The predetermined margins are incised, and the specimen slid onto the precut filter paper with the epithelium remaining facing up (Fig. 16.1). Cautery of bleeding is at the discretion of the surgeon. It is usually not necessary to reapproximate the margins of the incised conjunctiva to cover the defect regardless of the size of the biopsy. Instillation of antibiotic ointment, such as erythromycin or bacitracin ophthalmic ointment, and placement of a pressure patch for 4–24 h are appropriate. Antibiotic ointment is applied three times daily for 1 week, during which the patient may experience blood-tinged tears. Control of pain may warrant the use of acetaminophen (325 mg)–codeine (15 mg) combination tablets every 4–6 h as needed.

TRAUMA

Conjunctival trauma may be blunt or sharp. It may be the result of a foreign body injury. The history surrounding the injury is most important in guiding the examination to determine the likelihood of deeper penetrating injury of the globe. Blunt injury may result in chemosis, subconjunctival hemorrhage, subconjunctival air, or a ruptured globe. Chemosis is a nonspecific reaction with swelling of the conjunctiva to irritating stimuli. It is usually self-limited, painless, and nonthreatening to vision. Regardless of the nature of the injury, focal hemorrhagic chemosis may be a sign of underlying scleral rupture. Treatment of uncomplicated chemosis is supportive alone (e.g. ice to the closed eye). If the chemosis is so large as to be exposed, antibiotic ointment should be applied three times daily until resolution. Subconjunctival hemorrhages also are self-limited. They require no treatment, and the patient should be reassured that they will resolve in 3 weeks.[20]

Conjunctival foreign bodies may be single or multiple, inert or reactive, and grossly evident or occult. The history of the exposure should alert the examiner to the likelihood of a foreign body. The examiner should determine the material, the speed of travel at impact, and the use of any protective eyewear during the incident. Examination should include double eversion of the upper lid, fluorescein staining, and direct observation of the conjunctiva. Superficial foreign bodies may be removed with forceps following use of topical proparacaine 0.5%. Subconjunctival foreign bodies may not generate much inflammatory reaction and remain present for many years without sequelae. Others may cause granuloma, cysts, or membrane formation, requiring removal.[21]

Lacerations of the conjunctiva are usually found on the bulbar conjunctiva and occur from a shearing force or sharp injury. Conjunctiva laceration combined with underlying scleral laceration would occur with penetrating injury. Maintaining a high index of suspicion for concurrent scleral laceration will help reduce oversight of this severe type of injury.[22]

Examination should include determination of best corrected visual acuity (pinhole is acceptable), motility tests, pupil examination, evaluation of muscle balance, slit-lamp examination, dilated funduscopic examination, and intraocular pressure measurement.

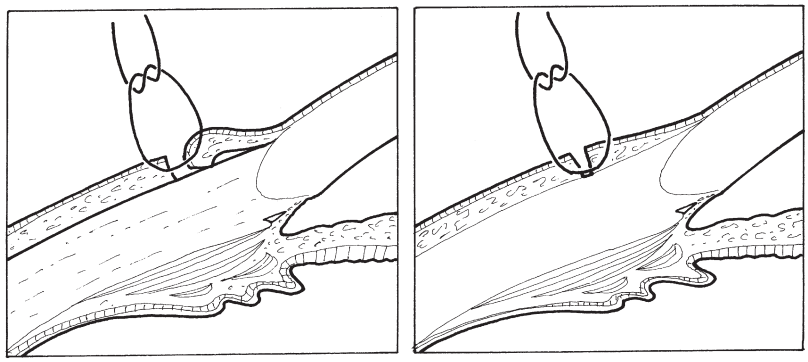

Figure 16.2. Conjunctival laceration repair using nonabsorbable suture. *A,* Care should be taken not to leave an inverted edge of conjunctiva as shown. *B,* Careful apposition of conjunctival edges and placement of a nonabsorbable suture are shown.

All portions of the examination requiring any diagnostic drop medications should be deferred until assessment of the presence or absence of scleral involvement is accomplished. The extent of any scleral injury may be greater than the conjunctival laceration.

If visual acuity is not compromised and the history does not suggest perforation, careful slit-lamp examination alone may verify if an intact globe is present. Injuries suspicious for concurrent scleral laceration but without slit-lamp evidence of hemorrhagic chemosis, pigmented tissue showing, or low intraocular pressure may be explored in the minor operating room. Exploration in the major operating room is indicated under general anesthesia if the likelihood of penetrating injury exists.

Minor operating room exploration would require topical anesthesia with tetracaine 0.5%, a lid speculum, nontoothed forceps, optional wound repair instruments, and the operating room microscope. The cut ends of the conjunctiva may be gently elevated off the globe to determine their fullest extent. The edges of the lacerated conjunctiva may be inverted. Careful observation for evidence of uveal or vitreous tissue beneath these elevated conjunctival edges should be performed.

All conjunctival lacerations with concurrent penetrating trauma should be closed at the time of surgery. The decision to close conjunctival lacerations with no concurrent penetrating injury depends on length of laceration, location, size of conjunctival defect, and involvement of Tenon's capsule. In general, lacerations smaller than 1 cm do not require repair. Epithelial closure will likely occur in 1–3 days, and even large epithelial defects (e.g. those in an avulsion) will re-epithelialize in 1 week. Lacerations in the fornix generally have good apposition and do not require sutures.

Anesthesia for laceration repair may need to be subconjunctival and not topical alone. Repair of the laceration should be in two layers if Tenon's capsule is involved. Incorporation of the injured Tenon's capsule in the conjunctiva laceration closure should be avoided as this approach may cause cyst formation, significant scarring, or contracture of the conjunctiva and reduce its mobility. Absorbable suture (e.g. 6-0 to 8-0 polyglactin 910) should be used to close Tenon's capsule. An absorbable or nonabsorbable suture may be used to close conjunctiva. If 6-0 to 8-0 polyglactin 910 is used, it should be placed so the knot is buried beneath the conjunctiva. The physician should be sure to evert the edge of the conjunctiva and pass the needle from the underside out and then from the outerside in on the opposite side of the wound. Based on the surgeon's preference, a running suture (in the same manner) or interrupted suture is then completed. Nonabsorbable suture is preferred by some but is limited by the need to remove it after healing has occurred. The knot should be placed so that it is exposed for easy removal (Fig. 16.2). Again, a running or interrupted suture is sufficient. Antibiotic ointment and a pressure patch, if necessary, are indicated for 24 h regardless if exploration is accomplished with or without repair. Antibiotic ointment should be used twice daily for 1 week following injury.

Complications include missed foreign body, missed scleral laceration, infection, inclusion cyst, pyogenic granuloma, and fibrosis. Infection in a wound of this highly vascularized tissue is very rare. A plain radiograph of the face can be used to rule out a metallic foreign body. Fibrosis may be severe with motility disturbance.

CONJUNCTIVAL RESECTION OR RECESSION

Conjunctival resections are performed usually to remove diseased tissue. Vision-threatening peripheral corneal disease is often associated with disease of the limbal conjunctiva. Corneal epithelial stem cells are located at the limbus.[23] The limbal conjunctiva contains Langerhan's cells, complement components, immunoglobulin, and mast cells and is considered to be an immune reactive site. The small vessel configuration of the limbal region makes the area predisposed to immune complex deposition.[24] Thus, cellular proliferation diseases (e.g. conjunctival intraepithelial neoplasia) and inflammatory diseases (e.g. peripheral ulcerative keratitis) are associated with changes in the limbal conjunctiva. Tabbara and co-workers[25] showed that conjunctival resection would reduce peripheral corneal infiltration of white blood cells in rabbits immunized by intravenous administration of antigen. Eiferman and coworkers[26] used conjunctiva resected from patients with rheumatoid arthritis and peripheral ulcerative keratitis to induce collagenolysis in vitro. With this background, it is not surprising that indications for conjunctival resections include reports of its use for Mooren's ulcer,[27] superior limbic keratoconjunctivitis,[28,29] peripheral ulcerative keratitis,[30–32] sebaceous adenocarcinoma,[33,34] Kaposi's sarcoma,[35] and conjunctival intraepithelial neoplasia.[36,37]

In the literature, conjunctival recessions are performed almost exclusively concurrent with or subsequent to strabismus surgery. However, a conjunctival recession may be used by some surgeons for any or all of the indications listed for conjunctival resection.

TECHNIQUE

Conjunctival resections may be performed in the minor operating room using local anesthesia as long as no scleral tissue inlay or tectonic grafting is planned. If these more involved procedures are planned, they are best performed in the major operating room with adequate intravenous sedation and a retrobulbar or peribulbar block. Local anesthesia should include subconjunctival injection of

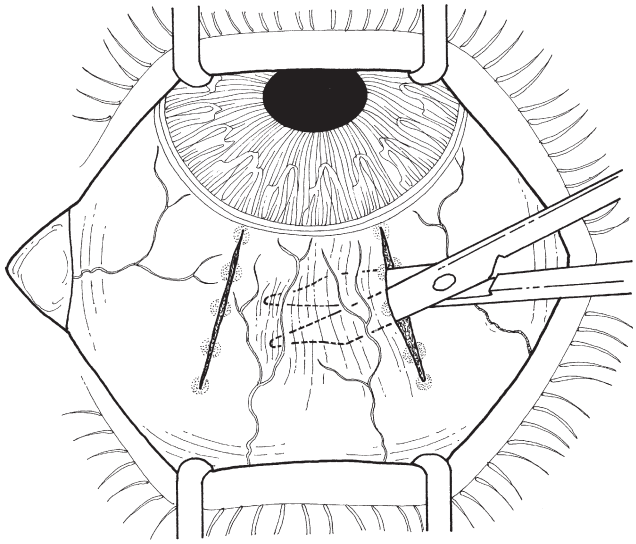

Figure 16.3. In conjunctival biopsy, the margins of the area to be excised are marked. Undermining of the entire area is accomplished before the limbal and posterior margins of resection are incised.

lidocaine 2% with or without epinephrine 1 : 100 000. The usually inflamed tissue, particularly if near the limbus will require more than topical anesthesia alone. If distinct margins of resection are to be adhered to, they should be marked with a sterile marking pen prior to subconjunctival anesthesia. An aseptic cleansing of the skin should be performed, and a sterile field established. An operating room microscope is required because resection of the conjunctiva is occasionally accompanied by lamellar dissection of underlying sclera. Anticipation of the specimen fixation and transport is the same as described for conjunctival biopsy.

Using blunt-tipped, serrated forceps, the physician elevates the conjunctival from the globe at a location posterior to the main pathology but at the anticipated margin of resection. After incising through conjunctiva and undermining the demarcated area, the physician should work toward the limbus and posteriorly until the area to be resected is free of underlying attachments (Fig. 16.3). Attempts to regrasp should be as infrequent as possible. The excision is completed by cutting along the previously designated margins. Bleeding may be controlled with wet field or thermal cautery. Attempts to reapproximate the cut edges of conjunctiva may be undertaken but are not necessary. Depending on the indication for surgical resection, adjunctive medications (e.g. mitomycin C) may be given or adjunctive treatment (e.g. freezing the cut edge of conjunctiva) may be performed.

Subconjunctival injection of gentamicin 20 mg or cefazolin 50 mg may be given at the end of the case. Antibiotic ointment application with a pressure patch for 4–24 h may be appropriate. Follow-up until complete conjunctival closure occurs is appropriate, as is antibiotic ointment three times daily.

17 Epithelial debridement and superficial keratectomy

Tina C. Lucas-Glass, Christopher J. Rapuano

Stripping or curettage of the corneal epithelium for treatment of map-dot-fingerprint dystrophy was noted to be therapeutically effective as early as 1965 in a report by Guerry[1] and by Wolter and Fralick[2] in 1966. Today, the terms 'epithelial debridement' and 'superficial keratectomy' can be used interchangeably with corneal stripping and curettage. However, epithelial debridement and superficial keratectomy are often incorrectly used interchangeably. Epithelial debridement is defined as surgical removal of just the corneal epithelium. Bowman's layer remains undisturbed with this procedure. Superficial keratectomy is a nonspecific term. Its more widely accepted definition is surgical removal of 'corneal epithelium plus subepithelial fibrous, fibrovascular, or otherwise dystrophic tissue',[3] typically with Bowman's layer and superficial stroma. The procedure is performed without tissue replacement. A new, but not necessarily superior, procedure that has similar indications to epithelial debridement and superficial keratectomy is excimer laser phototherapeutic keratectomy (PTK). PTK, also referred to as laser superficial keratectomy, involves the use of an excimer laser to ablate abnormal tissue in the anterior portion of the cornea.

INDICATIONS FOR EPITHELIAL DEBRIDEMENT

The most common indications for epithelial debridement are as follows:

1. For tissue diagnosis:
   Microbiology
   Histopathology
2. To speed resolution of a superficial corneal epithelial infection by debulking infected tissue (in combination with antimicrobial therapy):
   Herpes simplex virus epithelial keratitis
   Acanthamoeba keratitis[4,5]
   Fungal keratitis
3. For excision of dystrophic corneal epithelium and Bowman's membrane:
   Reis-Bücklers' dystrophy
   Map-dot-fingerprint dystrophy
   Post-traumatic and idiopathic recurrent erosion
4. For the removal of band keratopathy (in combination with a calcium chelating agent)
5. For treatment of epithelial ingrowth after laser in situ keratomileusis (LASIK)[6]
6. To remove epithelial edema for corneal clarity during vitrectomy and scleral buckling surgery
7. For debridement of vernal shield ulcers[7]

SURGICAL TECHNIQUE FOR EPITHELIAL DEBRIDEMENT

Prior to epithelial debridement, the patient should be informed that the procedure may need to be repeated in the future. Under topical anesthesia, an eyelid speculum is placed in the eye. Depending on the comfort of the surgeon and the cooperation of the patient, the procedure may be performed at the slit lamp or using an operating microscope. Epithelial debridement can be performed with a sterile cotton-tipped applicator, a dry cellulose sponge, a blunt spatula (e.g. Kimura), or a sharp rounded-end blade (e.g. #64 Beaver blade, Rudolph Beaver, Waltham, and Mass). Without exerting significant posterior pressure, the epithelium can be removed with gentle sweeps of the instrument of choice across the corneal surface (Fig. 17.1). If a sharp blade is used, great care must be taken to avoid cutting into superficial stroma. Fluorescein drops can be instilled on the surface to identify areas of persistent epithelium. When epithelial removal is complete, the denuded surface can be polished with a cellulose sponge. Patients can expect moderate to severe pain until the epithelial defect heals.

Often there are residual epithelial basement membrane complexes adherent to Bowman's layer, which may or may not be readily visible at the slit lamp or operating microscope. A diamond burr can be used to polish Bowman's membrane and remove these tenacious adhesions safely and effectively.[8] A large, round diamond burr (4–5 mm in diameter) is best (Fig. 17.2). A gentle circular motion is used to buff the de-epithelialized cornea for approximately 5–20 s, depending on the extent of the pathology. In an efficacy study by Sridhar and co-workers,[9] diamond burr treatment was shown to have advantages over PTK in the treatment of recurrent corneal erosions.

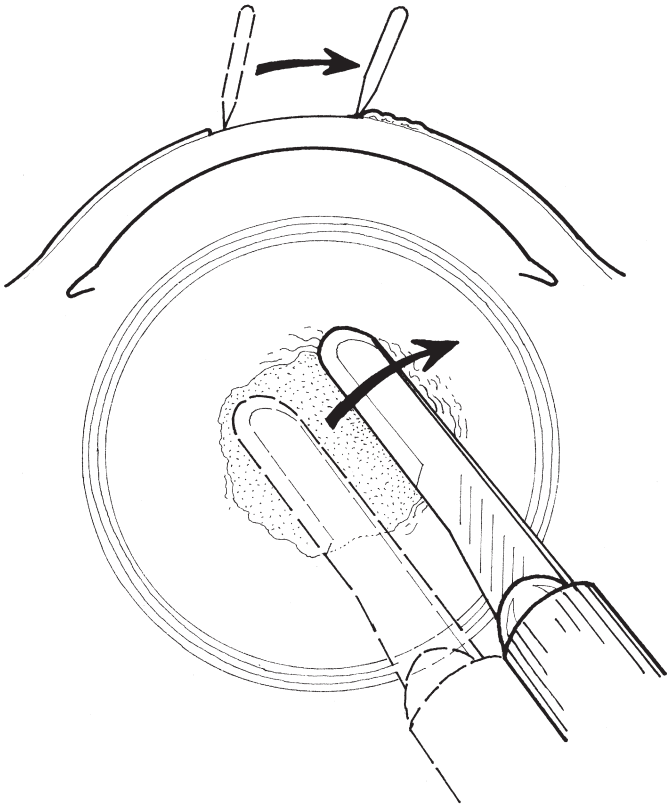

Figure 17.1. Epithelial debridement. A sharp rounded-end blade is used to sweep across the cornea, removing the epithelium without cutting into the stroma. The motion of the blade is sideways, perpendicular to the orientation of the blade.

INDICATIONS FOR SUPERFICIAL KERATECTOMY

Superficial keratectomy shares several indications with epithelial debridement.[3] The indications for a superficial keratectomy are as follows:

1. For tissue diagnosis:
   Microbiology
   Histopathology
2. For removal of hyperplastic, degenerative, necrotic, or scarred tissue:
   Salzmann's nodular degeneration
   Spheroidal degeneration
   Calcific band keratopathy (after or in conjunction with calcium chelation)
   Pterygium
   Corneal dermoid
   Keratoconus nodule
   Superficial corneal scar
   Peripheral hypertrophic subepithelial degeneration[10]
3. For excision of retained corneal foreign material
4. For removal of corneal haze after photorefractive keratectomy[11]
5. For excision of dystrophic tissue:
   Reis-Bücklers' dystrophy
   Map-dot-fingerprint dystrophy[12]
   Post-traumatic and idiopathic recurrent erosion
   Anterior stromal dystrophies (e.g. lattice and granular dystrophies)
6. For recurrent dystrophies in corneal grafts:
   Reis-Bücklers' dystrophy[13]
   Granular dystrophy[14]
   Lattice dystrophy

SURGICAL TECHNIQUE FOR SUPERFICIAL KERATECTOMY

As with epithelial debridement, the patient undergoing superficial keratectomy should be informed that this procedure may need to be repeated. The patient should know that until re-epithelialization occurs, there is often a significant amount of discomfort. Depending on the comfort of the surgeon and the cooperation of the patient, this procedure can be done under topical or peri- or retrobulbar anesthesia. The operating microscope is used, and an eyelid speculum is placed in the eye. Corneal epithelium over the involved area can be removed with a dry cellulose sponge. For blunt dissection of hyperplastic lesions, a plane is established between the fibrous membrane and normal Bowman's membrane with fine-toothed forceps and a cellulose sponge or a sharp rounded-end blade. The forceps are used to fixate tissue and stabilize the eye while the sponge or blade pushes (not cuts) between the lesion and Bowman's layer to create a plane (Fig. 17.3). Once a plane is established, blunt dissection can be completed with a cyclodialysis spatula, a cellulose sponge, or the blade in a noncutting fashion. With the forceps, epithelium, basement membrane, and fibrous membranes can often be peeled in one continuous sheet (Fig. 17.4). As the pathology is often diffuse and contiguous with the limbus, the abnormal tissue must be separated from the peripheral corneal and limbal tissue. The central sheet can often be torn away from the peripheral remnants in an epithelial-rhexis fashion using the toothed forceps and a circular pulling motion (Fig. 17.5). Occasionally, if the membrane resists tearing, it needs to be cut away from the limbus with a sharp blade or fine scissors.

When a smooth plane cannot be easily established, sharp dissection may be required. In this case, the goal is to create a lamellar plane with toothed forceps and a sharp rounded-end blade. It is critical to dissect in one plane to minimize corneal irregularity and scarring and to decrease the risk of perforation. A microkeratome has also been used to create a smooth plane. This technique involves applying a suction fixation ring to raise the intraocular pressure to over 65 mmHg and using a flat oscillating blade to shave off the

anterior cornea. A diamond burr can be used to treat areas of persistent corneal irregularity.

POSTOPERATIVE MANAGEMENT

Postoperative care after epithelial debridement and superficial keratectomy is similar. At the conclusion of surgery, a topical antibiotic and a cycloplegic agent should be instilled in the eye. A pressure patch or bandage soft contact lens may also be used. Otherwise frequent instillation of topical antibiotic ointment is preferred. The patient should be followed closely until re-epithelialization is complete. Topical nonsteroidal anti-inflammatory drugs may help to control pain. A topical corticosteroid–antibiotic drop may be beneficial after the procedure, especially if there is significant corneal inflammation. Depending on the size of the epithelial defect, re-epithelialization usually occurs within 2 to 7 days (Fig. 17.6). Close follow-up is required until re-epithelialization is complete, as these eyes are at risk for persistent defects and infection. Once re-epithelialized, the medications can be tapered and discontinued. For treatment of many conditions, and especially recurrent erosions, lubrication therapy with artificial tears, hypertonic solutions, or ointments should be instituted once re-epithelialization is complete.

RESULTS

Buxton and Fox[15] reported a series of 13 eyes with epithelial basement membrane dystrophy treated with epithelial debridement and soft bandage contact lenses. Of these patients, 84.7% were relieved of symptoms during a follow-up period ranging from 6 weeks to 48 months. One patient had two subsequent attacks of erosive symptoms which were managed with lubricants. Three corneas that had not received paralimbal diamond burr treatment developed peripheral erosions. All patients had a smooth corneal surface and tear film by 6 to 12 weeks postoperatively. Buxton and Constad[16,17] extended their initial series to 33 cases of symptomatic epithelial basement membrane dystrophy. In this report, the follow-up period ranged from 2 months to 7 years. Of these patients, 100% were relieved of preoperative symptoms after epithelial debridement. Only 3% showed evidence of recurrence of the epithelial basement membrane dystrophy.

Perhaps the biggest criticism of epithelial debridement and superficial keratectomy is the length of the postoperative recovery period. When compared to anterior stromal micropuncture, Rubinfeld and co-workers[18] thought that epithelial debridement was relatively safe and effective, was more technically difficult, resulted in more postoperative pain, and had a longer recovery time. Despite these drawbacks, epithelial debridement was thought to be the best treatment for diffuse map-dot-fingerprint dystrophy with spontaneous, bilateral, multiple erosions.

Diamond burr polishing of Bowman's membrane has been used as a supplement to simple epithelial debridement. Lance and co-workers[19] noted significantly more rapid healing in rabbit corneas when diamond polishing was combined with debridement.

Soong and co-workers[20] reported great success using diamond burr polishing of Bowman's membrane to treat recurrent erosion syndrome in 54 eyes of 47 patients with 3 to 53 months of follow-up.

In this era of laser treatments, diamond burr polishing still is a reliable, inexpensive procedure for recurrent erosions. Sridhar and co-workers[9] compared the efficacy of PTK to epithelial debridement and diamond burr polishing of Bowman's membrane in a total of 42 eyes of 39 patients. Their study compared these procedures in the treatment of recurrent corneal erosions associated with anterior basement membrane dystrophy. They found no statistically significant difference in haze and recurrence of erosions.

A statistically significant improvement in visual acuity after epithelial debridement and diamond burr polishing was noted in 13 eyes of 10 patients by Tzelikis and co-workers.[8] These patients were followed for an average of 21.8 months in this retrospective study.

SUMMARY

Epithelial debridement and superficial keratectomy, although different procedures, share similar indications and postoperative care. They are relatively safe and effective procedures for several epithelial and anterior corneal abnormalities.

18 Corneal micropuncture in recurrent erosion syndromes

Roy Scott Rubinfeld

Commonly encountered in ophthalmic practice, recurrent erosion syndrome is a painful, often frightening, and sometimes incapacitating condition for many patients worldwide. In this syndrome, as implied by its name, corneal epithelial cells erode, resulting in denuded areas on the corneal surface. These areas then re-epithelialize, and the process recurs when the epithelial cells slough again at a later time. Erosions are characteristically episodic in nature, with many patients free of symptoms other than perhaps a mild ocular foreign body sensation or vague 'awareness' of the affected eye between erosions. This sensation of awareness can be most noticeable in dry, cold, or windy environments. Most erosions occur during the evening or early morning hours and are described as an abrupt 'ripping' or 'tearing' sensation generally followed immediately by sharp pain, a marked foreign body sensation, epiphora, photophobia, visual disturbances, and often lid swelling.

These attacks may vary greatly in pattern and intensity. Some patients have mild symptoms every few months or years, and some experience severe, incapacitating, frequent erosions causing pain and other symptoms lasting for hours or days at a time. In some patients with recurrent erosion, the epithelial defects never fully close, and loose sheets of epithelium slide over the surface of the eye with each blink. These patients experience constant pain and can be some of the most distraught individuals encountered in clinical practice.

The unpredictable nature of recurrent erosions often heightens patient anxiety. For active people, the knowledge that, on any given day, they may suddenly experience acute pain and be unable to work or participate in normal activities for hours or days at a time can be extremely disturbing. It is not uncommon for patients with severe erosions to begin displaying signs of depression and anxiety disorders. Since most erosions occur during sleep or on awakening, some patients come to fear falling asleep and experience varying degrees of insomnia. The resulting disruption in normal sleep patterns may exacerbate the patient's psychologic stress as well as their experience of the symptoms. Anxiety may even make erosions more frequent by causing patients to open their eyes more quickly on awakening and by inducing more rapid eye movements as well as interfering with normal blinking and tear production.

PATHOPHYSIOLOGY

The pathophysiology of recurrent erosion syndrome is only partially understood. Normal adhesion of the corneal epithelium depends primarily on structures known as attachment complexes, which are composed of elements from the basal epithelial cell, basement membrane, Bowman's layer, and corneal stroma. Through electron microscopic and immunohistochemical staining methods, these elements are thought to include hemidesmosomes, basal lamina, lamina densa, lamina lucida, anchoring fibrils, laminin, fibronectin, and types IV and VII collagen.

Abnormalities of epithelial adhesion resulting in recurrent erosion can be associated with previous traumatic abrasions or with corneal dystrophies. In the case of erosions associated with previous trauma, superficial injury to the cornea may damage the basement membrane. Some corneas appear unable to re-form normal attachment complexes, resulting in recurrent erosions occurring up to many years after the original injury.

Many ophthalmic or systemic diseases are associated with an increased incidence of recurrent erosions. A partial list of these includes lattice, Reis-Bücklers', macular, granular, and Meesmann's dystrophies; diabetes mellitus; and bullous keratopathy. Anterior basement (Cogan's or map-dot) corneal dystrophy is the dystrophy most commonly responsible for recurrent corneal erosion. Basement membrane abnormalities, including reduplication of basement membrane within the epithelium (maps) and cystic degeneration of cells (microcysts), have been reported to be present in 6–42% of the general population.[1,2]

DIAGNOSIS

For clinicians familiar with the common features of recurrent erosion syndrome, a patient with a history of previous trauma to the involved eye, episodes of pain on awakening, and a ragged, grayish-staining area of epithelium (Fig. 18.1) constitutes little or no diagnostic challenge. The diagnosis of recurrent erosion syndrome in more subtle cases, however, can be quite difficult.

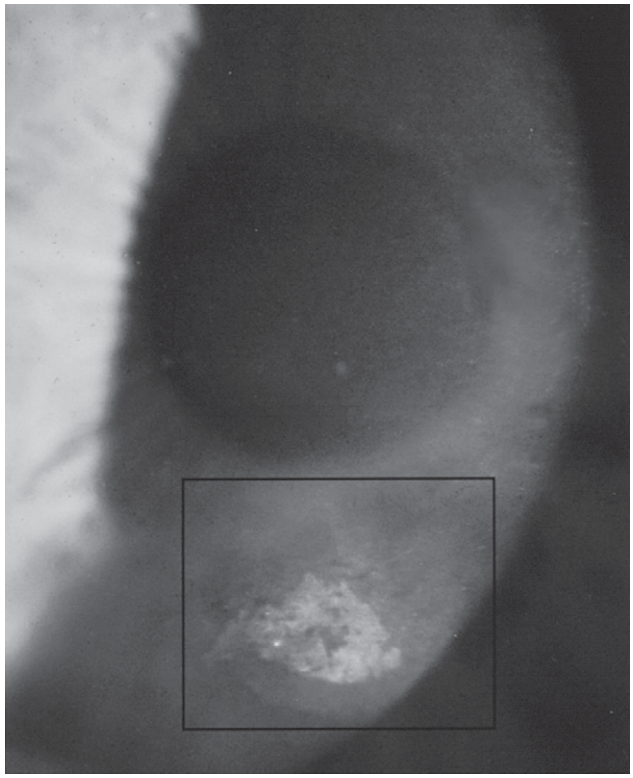

Figure 18.1. Slit-lamp appearance of active recurrent erosion showing ragged, edematous, disrupted gray epithelium (box). Note that the area of erosion is surrounded by apparently intact but also edematous grayish epithelium. (Courtesy of Peter R Laibson, MD; from Rubinfeld RS. Recurrent corneal erosion. In: Roy FH, ed. Master Techniques in Ophthalmic Surgery. Baltimore: Williams & Wilkins; 1995.)

Figure 18.2. Broad beam slit-lamp appearance of anterior basement membrane lines present in recurrent erosion patient. This pathology was much less obvious using standard narrow slit-beam illumination. (From Krachmer et al. Cornea, 2nd edn 2005, Elsevier, Chapter 91. © Elsevier 2005.)

The clinician should carefully inquire about trauma to the involved eye. Often the patient will describe previous milder episodes of erosion, which helps support the diagnosis. Keen slit-lamp examination is often required to find subtle signs of erosion. Several different examination techniques can be helpful in this situation. Broad, angled slit-beam examination of both eyes before and after instillation of fluorescein (Figs 18.2 and 18.3) should be performed as well as a retro-illumination examination of the cornea with dilation of the pupil to discern signs of basement membrane dystrophy or sites of previous erosion. This careful examination may not only confirm the diagnosis but may also indicate which areas will need to be treated. Gentle pressure applied to the cornea through the eyelid may demonstrate wrinkling of loosely adherent epithelium. A fine slit-beam examination may reveal subtle, residual brown granularity of the stroma (brawny edema), which persists briefly after restoration of epithelial integrity.

Sometimes even the best observer will discern no visible corneal abnormalities on slit-lamp examination because the epithelial defect has resolved in the time between the occurrence of the erosion and the examination of the patient. In this situation the clinician should be especially careful not to label the distraught patient with complaints of eye pain and no visible signs of disease as 'functional' or 'psychoneurotic.' Clinicians should remember that recurrent erosion patients often display signs of anxiety and depression, as previously described. In these situations when the diagnosis is in question, the patient should be instructed to return for examination immediately after the next episode of pain without allowing time for the epithelium to heal and cover the erosion. Usually this approach will not only confirm the diagnosis but will help in choosing the correct treatment as well as the areas to be treated.

MEDICAL TREATMENT

For decades, recurrent erosion syndrome remained one of the more frustrating ophthalmologic problems encountered in clinical practice because of its occasional resistance to available treatments and prolonged course. Today, new therapies and a rational stepwise approach to management of erosions provide opportunities to convert distraught individuals suffering from persistent recurrent erosion into some of the most grateful patients in a clinician's practice.

TOPICAL AGENTS

A mainstay of medical treatment that remains effective to this day for the vast majority of patients with corneal erosions involves the long-term nightly use of hyperosmotic lubricating ointments. The rationale for this treatment derives from the concept of nocturnal relative hypotonicity of the preocular tear film. At night, with the eyes closed, tear evaporation is reduced. The resultant lowered concentration of dissolved salts in the tears is postulated to shift the osmotic gradients, resulting in a relative increase in corneal epithelial edema and consequent reduction in epithelial adhesion. The vehicle (e.g. petrolatum) serves also to prevent erosions by keeping the eye lubricated during rapid eye movements or while opening the eyes in the morning. Hyperosmotic eyedrops during the daytime are sometimes added to this approach in an effort to minimize epithelial edema during waking hours as well, thus allowing re-formation of more normal attachment complexes. These agents must be used consistently for at least 6–12 months after the patient's last erosion, since it often takes this much time for re-

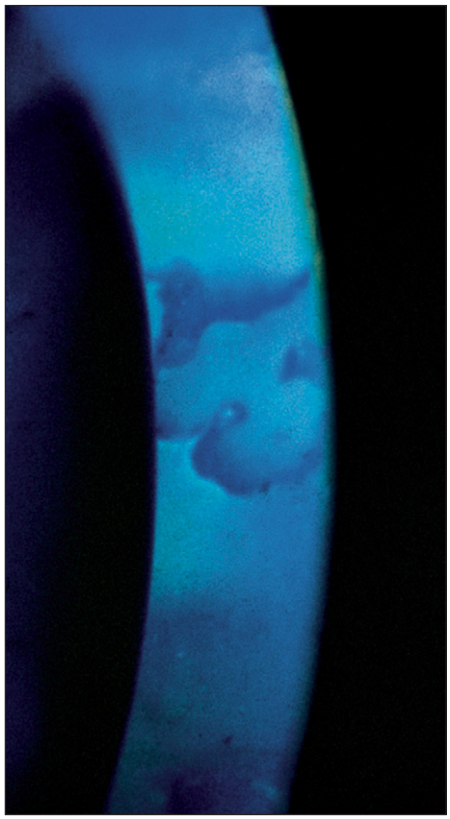

Figure 18.3. Slit-lamp appearance of the same patient's eye as in Figure 18.2 in which visualization of the basement membrane lines is enhanced with a tear film thickly stained with fluorescein. (From Krachmer et al. Cornea, 2nd edn 2005, Elsevier, Chapter 91. © Elsevier 2005.)

formation of normal attachment complexes. Unfortunately, patients frequently decide to stop the use of these topical agents soon after the erosions resolve, only to have a recurrence, which may prolong the time required for the attachment complexes to re-form. It is essential to query and educate patients in this regard. Some clinicians use only bland lubricants without a hyperosmotic component, but this approach may be less effective. Currently available hyperosmotic ointments include sodium chloride 5% (Muro-128, Bausch & Lomb) and sulfacetamide 10% (Bleph-10, AK-Sulf).

In addition to the hyperosmotic agents that are now available, other topical preparations may be of value in treating some patients with recurrent erosions. Some promising results have been reported in early studies using topical osmotic colloidal solutions[3] and clinical trials are now underway to further evaluate these preparations. Topical autologous serum eyedrops[4] as well as numerous investigational trophic growth factors may be demonstrated to be effective in treating some erosion patients, especially in patients with more severe types of epitheliopathy, such as those associated with long-term diabetes or neurotrophic keratitis.

Some investigators[5] have suggested that topical corticosteroids combined with oral doxycycline may help treat recurrent erosions by inhibition of matrix metalloproteinase-9. The use of topical steroids in the treatment of recurrent erosion must, however, be weighed against the potential risks of infection, cataract, and intraocular pressure elevation.

PATCHING AND BANDAGE LENSES

Patching during acute erosions in conjunction with lubricant/antibiotic agents is another effective treatment that helps to resolve the acute erosion in the vast majority of patients. Bandage contact lenses may be helpful in the case of acute erosions, but there may be an increased risk of microbial keratitis associated with their use.[6,7] In addition, they are often not effective in preventing further erosions except in cases where abnormalities in lid anatomy play a significant causative role in the erosions. Patching acute erosions and the consistent long-term nightly use of hyperosmotic ointments effectively resolve recurrent erosion syndrome for the vast majority of patients.

In addition to lid abnormalities or corneal inflammation, patients with recurrent erosions may be found, on careful examination, to have other concomitant ophthalmic diseases. Conditions such as dry eye syndrome or meibomian gland dysfunction blepharitis should be treated aggressively with frequent nonpreserved tear supplements or systemic tetracycline (such as doxycycline 50 or 100 mg orally each day), respectively.

SURGICAL TREATMENT

For patients in whom consistent, aggressive medical management fails to resolve the erosions, there exist several effective surgical options. The indication for surgical intervention is any situation in which aggressive medical management does not improve the symptoms and signs of erosions, and when the patient's continued pain and epithelial defects interfere with normal activities. The presence of recurring epithelial defects may result in infectious keratitis. This risk of infection, in conjunction with the prospect of continued patient disability and pain, generally overshadows the limited risks of appropriate surgical treatment of recalcitrant recurrent erosions. The choice of surgical approach is determined by the frequency and severity of erosions, the presence of concomitant dystrophies or other diseases, the etiology and location of the erosions, and the patient's needs and desires (Table 18.1).

DEBRIDEMENT AND SUPERFICIAL KERATECTOMY

Historically, debridement[8,9] and then superficial keratectomy[10] were the first surgical approaches to the treatment of resistant corneal erosions, and these procedures remain in use today. Debridement may be useful for removing a localized area of very loosely adherent 'floppy' sheet of epithelium in a limited number of erosion patients (Fig. 18.4). This technique requires only a cotton swab or blunt instrument and can be performed at the slit lamp with topical anesthesia. The suboptimal efficacy and limitations of this procedure derive from the fact that no significant modifications to enhance epithelial adhesion are made in Bowman's layer or other deeper corneal structures. A more aggressive approach, generally requiring the use of an operating microscope, is that of a large superficial epithelial keratectomy. This technique is much more likely to benefit recurrent erosion patients. The optimum candidate for this procedure has spontaneous multiple erosions in different areas of the cornea, no history of trauma, and severe basement membrane dystrophy, resulting in poor vision and large areas of loosely adherent irregular epithelium. After subconjunctival, peribulbar, or retrobulbar injections of a local anesthetic agent (or, in some highly cooperative patients, the use of topical anesthetic agents) a lid speculum is inserted to hold the eye open. A superficial plane of dissection using a blade or spatula is established in the perilimbal area. Leaving approximately 1 mm of intact perilimbal epithelium, the rest of the epithelium and its basement membrane, if possible, are lifted and dissected free. An attempt should be made

Table 18.1 Surgical therapies for recurrent erosion syndromes

Procedure	ASP (ER)	Epithelial Keratectomy	Debridement	Excimer PTK	YAG Procedures
Optimum candidate	Localized erosions with or without mild to moderate ABM dystrophy	Erosions in multiple areas, moderate to severe ABM, with decreased VA; loose sheet of floppy epithelium	Single area of erosion with localized loose sheets of epithelium	Erosions in multiple areas, moderate to severe ABM, with decreased VA, loose sheets of epithelium with refractive error	Unclear

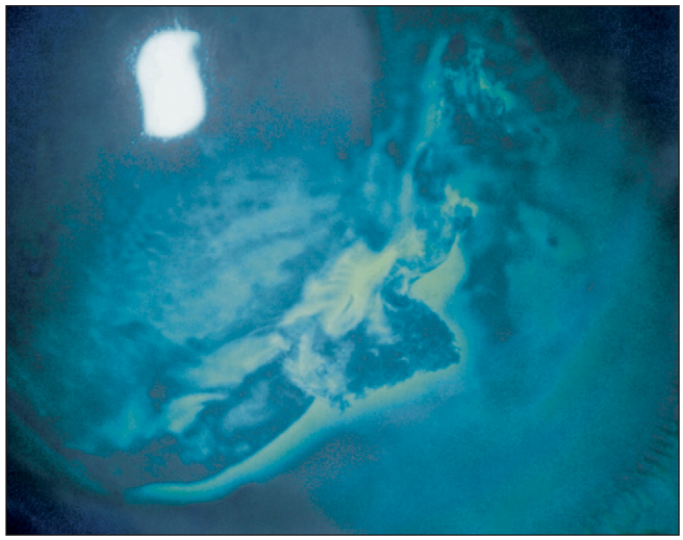

Figure 18.4. Slit-lamp appearance of loosely adherent sheet of floppy epithelium in a recurrent erosion patient. This sheet slid back and forth across the cornea with each blink. Note that fluorescein staining of the tear film helps make the loose epithelium more visible. (From Krachmer et al. Cornea, 2nd edn, 2005, Elsevier, Chapter 91. © Elsevier 2005.)

to peel and dissect away the epithelium in a continuous sheet. Persistent epithelial fragments may be visualized by instilling fluorescein. Bowman's layer should not be incised but should be scraped with a blade oriented perpendicular to the surface of the cornea, taking care not to produce linear scars in Bowman's layer. Alternatively, a diamond burr may be used to gently polish Bowman's layer to enhance epithelial adhesion as described by Forstot et al.[11] Preoperatively, the instillation of several drops of topical nonsteroidal anti-inflammatory agents such as bromfenac (Xibrom), ketorolac tromethamine (Acular), or diclofenac (Voltaren) generally helps greatly with pain management in patients undergoing debridement or superficial epithelial keratectomy procedures. Postoperatively the use of these drops, in conjunction with a well-fitted bandage contact lens for up to 3–5 days, usually improves patient comfort during the early postoperative period. More recently a technique known as alcohol delamination of the corneal epithelium[12] has been proposed to improve the efficacy of debridement in the treatment of recurrent erosions.

ANTERIOR STROMAL PUNCTURE (EPITHELIAL REINFORCEMENT, CORNEAL MICROPUNCTURE)

In 1986 McLean et al[13] described a significant innovation in the surgical management of resistant corneal erosions, which they termed 'anterior stromal puncture.' This highly effective office technique involved the use of a straight 20-gauge needle to make multiple shallow penetrations through the epithelium into anterior corneal stroma to improve epithelial adhesion, apparently by forming tiny scarring attachments similar to the metalworking technique of spot welding. Laibson[14] and co-workers expressed concerns about the possibility of corneal perforation with a straight needle, and several perforations have been reported using a 20-gauge needle.[15] Despite a high level of surgeon's skill, these perforations may occur because of the natural tendency for many patients undergoing stromal puncture to slowly back away from the slit lamp during the procedure and then jerk forward unpredictably once they realize their head position is wrong.

Concerns regarding this possibility of perforation, as well as questions regarding depth of penetration, the possibility of excessive scarring, and the reproducibility of results with stromal puncture, prompted the design of a disposable, inexpensive, specialized instrument for use in corneal micropuncture.[16] In histopathologic studies of cadavers and in clinical trials, this instrument has been

Figure 18.5. Hematoxylin and eosin-stained human cadaver eye after stromal puncture with conventional straight needle. The mean penetration depth with this technique was 208 μm (original magnification ×50). (From Krachmer et al. Cornea, 2nd edn, 2005, Elsevier, Chapter 91. © Elsevier 2005.)

Figure 18.6. Hematoxylin and eosin-stained histopathology slide of human cadaver eye after stromal puncture with a standardized specially designed needle. Mean penetration with this needle was 108 μm (Original magnification ×50). (From Rubinfeld RS, MacRae SM, Laibson PR, et al. Successful treatment of recurrent corneal erosion with Nd:YAG anterior stromal pressure. Am J Ophthalmol 1991; 111: 252–254. © Elsevier 1991.)

shown to produce consistent, shallow penetrations (Figs 18.5 and 18.6), minimal scarring (Figs 18.7 and 18.8), and virtually eliminated the possibility of perforation while retaining the high success rate of anterior stromal puncture with a straight needle.[15,16]

Anterior stromal puncture or micropuncture is an office procedure performed conveniently at the slit lamp under topical anesthetic. When discussing this procedure with patients, the term 'epithelial reinforcement' may be substituted for 'stromal puncture' to allay patient anxiety (Lindstrom, personal communication). In my experience, for most patients the use of the word 'puncture' is the most frightening aspect of this technique. Before the procedure (CPT Code 65600), the chart should be reviewed and drawings of previous erosions studied to determine the area to be treated. A careful preoperative slit-lamp examination should also include retro-illumination. Epithelial reinforcement may be performed either between erosive episodes or through loose, irregular epithelium during an active erosion without the need for debridement. Topical nonsteroidal drops such as ketorolac, diclofenac or bromfenac should be instilled every 10–15 min, starting 30 min to 1 h before the procedure to aid in postoperative pain management. In addition, several drops of a fluoroquinolone, or other broad-spectrum antibiotic, may be used preoperatively to reduce the likelihood of infection by decreasing the bacterial population of the external eye.

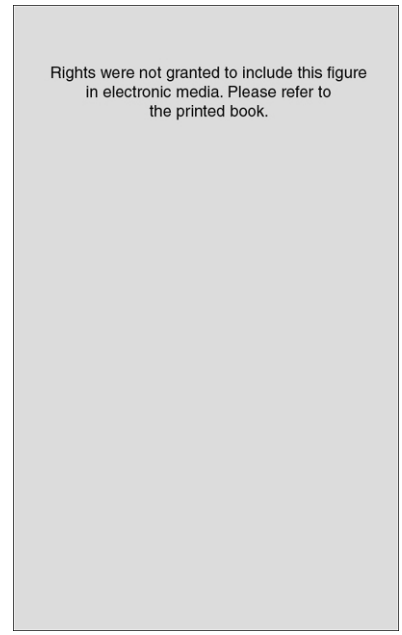

Figure 18.7. Slit-lamp photograph showing corneal scarring 3 months after anterior stromal puncture with a 25-gauge straight needle. This scarring faded slowly, becoming nearly invisible by 2 years after surgery. (From Rubinfeld RS, Laibson PR, Cohen EJ, et al. Anterior stromal puncture for recurrent erosion: further experience in new instrumentation. Ophthalmic Surg 1990; 21: 318–326.)

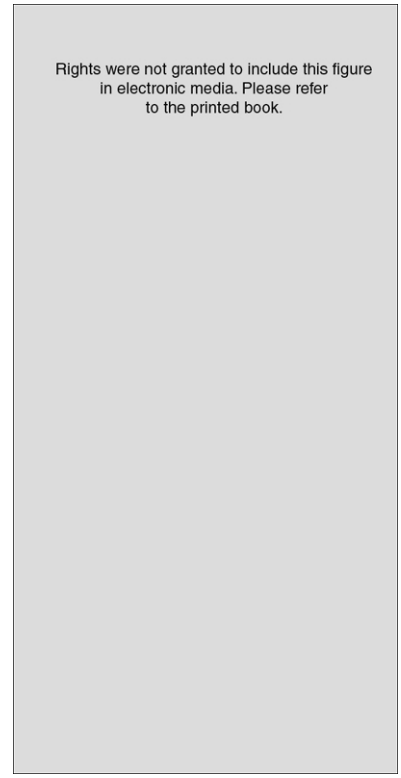

Figure 18.8. Slit-lamp photograph showing minimal corneal scarring only 2 weeks after anterior stromal puncture with a standardized, specially designed needle. This haze resolved completely by 2 months after surgery and was no longer visible by slit-lamp examination. (From Rubinfeld RS, Laibson PR, Cohen EJ, et al. Anterior stromal puncture for recurrent erosion: further experience in new instrumentation. Ophthalmic Surg 1990; 21: 318–326.)

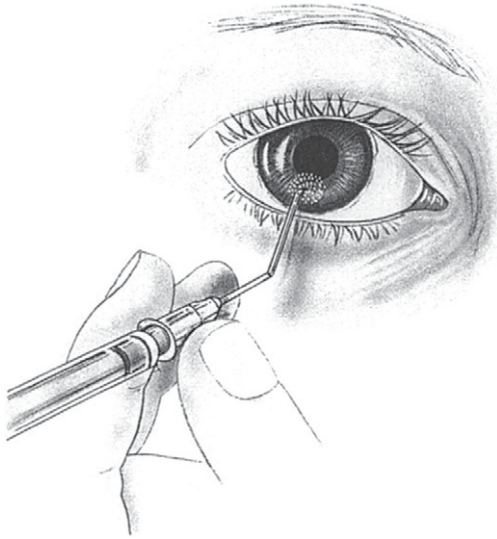

Figure 18.9. Epithelial reinforcement technique (stromal puncture). The two preset bends in the standardized needle prevent the patient from visualizing the needle tip and shaft, thereby reducing patient anxiety. (From Rubinfeld RS. Recurrent corneal erosion. In: Roy FH, ed. Master Techniques in Ophthalmic Surgery. Baltimore: Williams & Wilkins; 1995.)

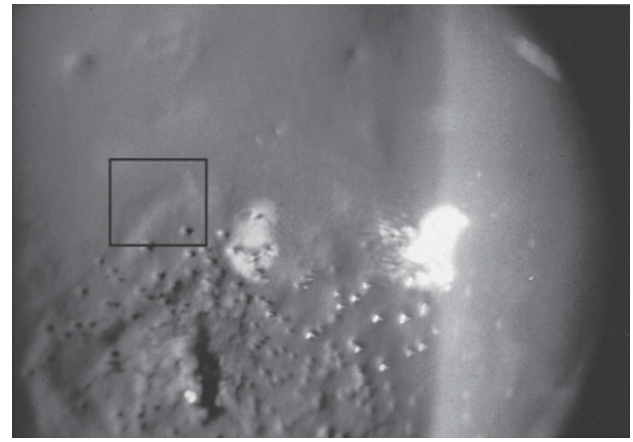

Figure 18.10. Retro-illumination slit-lamp photograph taken immediately after anterior stromal puncture. Note that the area of anterior basement membrane abnormality (box) extends beyond the limits of the treated fluorescein-stained erosive epithelium. (Reproduced from Rubinfeld RS, Laibson PR, Cohen EJ, et al. Anterior stromal puncture for recurrent erosion: further experience and new instrumentation. Ophthalmic Surg 1990; 21: 318–326, by kind permission of Slack Inc.)

Fortunately, however, infections after epithelial reinforcement (stromal puncture) are extremely rare.

Fluorescein, along with several drops of topical anesthetic, should be applied to help visualize the puncture marks. The patient is admonished not to move or blink without warning the surgeon and is assured that the procedure itself is completely painless because of the use of the topical anesthetic. A drop of anesthetic in the nonoperative eye may help to control the urge to blink during the procedure. The standardized disposable stromal puncture needle* is mounted on a tuberculin syringe. The angled tip of the needle is kept perpendicular to the surface of the cornea and a few punctures are made. It is helpful to pause at this point to confirm for the patient that the procedure is truly painless. Patient anxiety will thereby be lessened and cooperation enhanced. Generally, the design of the needle prohibits the patient from even visualizing the device during the procedure, which also helps allay patient anxiety (Fig. 18.9).

Closely placed, generally nonconfluent punctures should cover the entire erosive area and should also include 1–2 mm of apparently normal margins outside the visible limits of the erosive area. Treatment of these apparently normal margins is necessary because the loose epithelium usually extends beyond the visible limits of the erosion, as can sometimes be demonstrated by retro-illumination (Fig. 18.10). Treatment within the pupillary space should be minimized if possible, although in our experience subjective and objective glare testing has revealed no problems in patients who have been treated with the standardized needle in the pupillary space.[16] A topical antibiotic drop or ointment such as tobramycin ointment or fluoroquinolone drops, a cycloplegic agent such as scopolamine 0.25%, and more topical nonsteroidal drops are instilled postoperatively. A hydrophilic bandage lens can be applied and left in place for 1–2 days, but this may increase the risks of postoperative infection and, in the author's experience, this has not improved postoperative comfort significantly. Patients may use the topical nonsteroidal agent up to three times daily as needed for pain over the next 2–3 days. Alternatively, the eye may be patched without a bandage lens after the nonsteroidal and antibiotic drops or ointments are instilled. Oral oxycodone or codeine-acetaminophen tablets or a systemic nonsteroidal agent should be prescribed. Once re-epithelialization has occurred, hyperosmotic ointments are used three or four times daily to lubricate and protect the delicate healing epithelial tissue for several weeks postoperatively. Hyperosmotic ointments should then consistently be used at bedtime for 6–12 months (and occasionally longer) after stromal puncture while attachment complexes and other ultrastructural components are re-forming to achieve maximal epithelial adhesion.

Postoperatively, following micropuncture, it is not uncommon for patients to experience a foreign body sensation and occasionally some subtle discomfort on awakening in the morning or at other times when the eye is poorly lubricated. Also, patients often experience an 'awareness' of the eye for many months or more after their erosions resolve. As with most erosion patients, this is particularly noticeable on exposure to wind or dry air currents. In our experience with several years' follow-up, a single anterior stromal puncture (epithelial reinforcement) procedure is effective approximately 80% of the time in selected recurrent erosion patients (Laibson, personal communication).[17] Treatment failure generally tends to occur when the surgeon treats too small an area, and erosions then develop outside of the treated area (Fig. 18.11). A second, larger treatment can often resolve the erosions in patients in whom the initial epithelial reinforcement procedure was unsuccessful. The optimum candidate for anterior stromal puncture or epithelial reinforcement is the patient with a single persistent area of erosion associated with previous trauma or minimal anterior basement membrane dystrophy.

A technique dubbed 'pancorneal puncture' by MacRae, in which large areas of the cornea are treated in patients with moderate

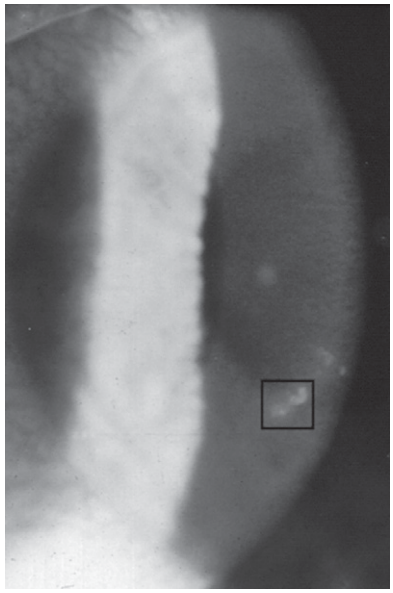

Figure 18.11. Slit-lamp photograph of small erosion (box) that occurred 4 days after stromal puncture in an untreated area adjacent to the original erosion. This is the same patient as shown in Figure 18.10. (Reproduced from Rubinfeld RS, Laibson PR, Cohen EJ, et al. Anterior stromal puncture for recurrent erosion: further experience and new instrumentation. Ophthalmic Surg 1990; 21: 318–326, by kind permission of Slack, Inc.)

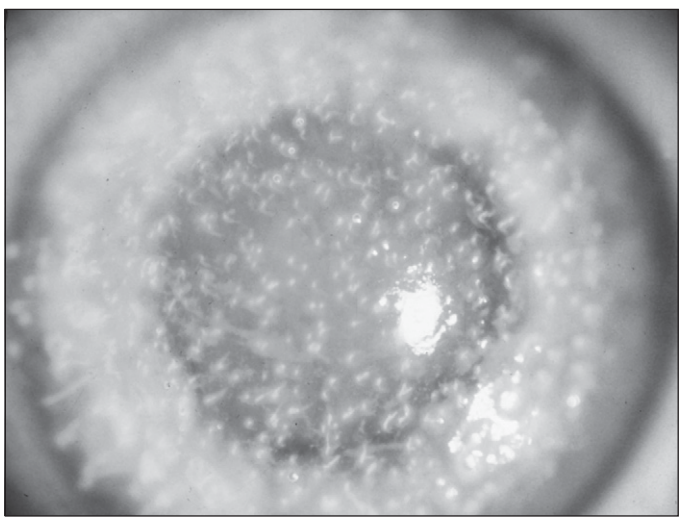

Figure 18.12. Slit-lamp photograph taken immediately after epithelial reinforcement in a patient with moderate degrees of diffuse basement membrane dystrophy and multiple recurrent corneal erosions. This technique has been dubbed 'pancorneal puncture.' (From Krachmer et al. Cornea, 2nd edn, 2005, Elsevier, Chapter 91. © Elsevier 2005.)

amounts of basement membrane dystrophy, can be quite effective (Figs 18.12 and 18.13). Patients with severe basement membrane dystrophy, however, with consequent loss of visual acuity and numerous spontaneous, multifocal erosions are better candidates for superficial keratectomy than anterior stromal puncture.

Although the efficacy of anterior stromal puncture has been established, the mechanism of action of this technique has not been fully elucidated. It has been postulated that multiple plugs of epithelium fill the puncture sites and function as a series of 'spot welds,' focally binding the loosened sheets of corneal epithelium to the underlying edematous stroma until more normal ultrastructural

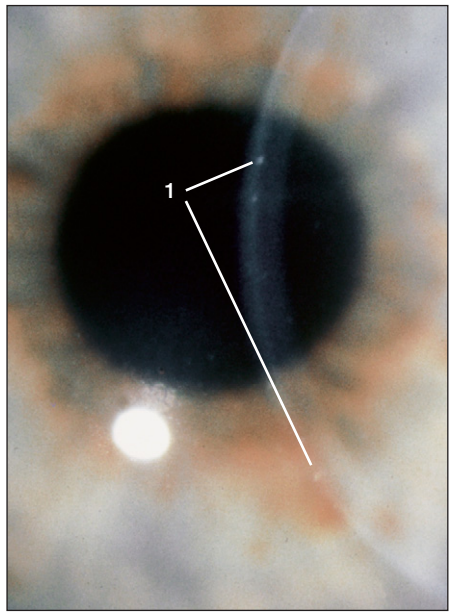

Figure 18.13. Slit-lamp photograph of the same patient as in Figure 18.12 taken 2 months after pancorneal puncture treatment. The patient is completely free of erosions at this point and remains so throughout 2 years of follow-up. Note that almost no scarring (1) is visible. (From Krachmer et al. Cornea, 2nd edn, 2005, Elsevier, Chapter 91. © Elsevier 2005.)

architecture and attachment complexes can form.[15,18] Katsev et al[19] describe a case of stromal puncture in which punctures of 0.1 mm depth caused a fibrotic reaction and new basement membrane formed as well. Hsu et al[20] performed electron microscopic and immunohistochemical studies of stromal puncture in human corneas with bullous keratopathy. Fibronectin, type IV collagen, and laminin were found within the puncture sites and in the reactive subepithelial pannus adjacent to the puncture site. They postulated that stimulation of production of these extracellular matrix proteins may be important in the attachment of epithelial cells to the underlying connective tissue. Epithelial–stromal reactions in the development of subepithelial fibrosis may also play a role in re-establishing epithelial attachment.

Encouraged by the success of anterior stromal puncture in recurrent erosion patients without corneal dystrophies and in those with basement membrane dystrophy, some surgeons have used this technique on patients whose corneal erosions are associated with bullous keratopathy. Although corneal stromal edema is generally well tolerated, rupture of epithelial bullae and the resulting corneal erosions in these patients can be very painful. For some of these bullous keratopathy patients with erosions, who are poor candidates for penetrating keratoplasty because of poor visual potential or medical contraindications, stromal puncture has been shown to be a useful treatment.[15,17,20,21] Epithelial reinforcement can also be used to control painful erosions in patients with bullous keratopathy, who are awaiting corneal transplantation. The optimum candidates for this type of treatment are those whose bullae are localized[20,21] and not diffusely distributed throughout the cornea (Figs 18.14 and 18.15).

YAG LASER PROCEDURES

Several investigators have suggested the use of YAG laser treatments for resistant corneal erosions. Geggel[22] initially proposed a technique in which epithelial debridement was performed and then

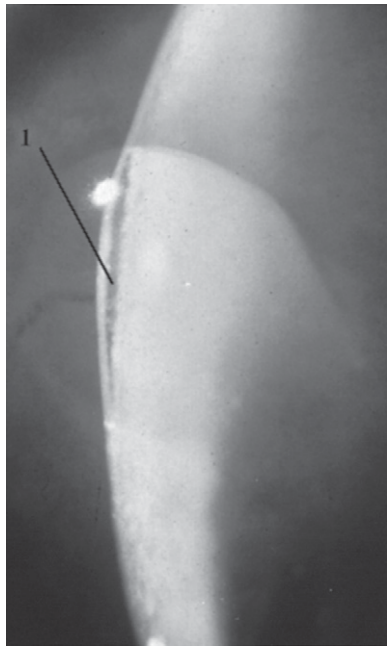

Figure 18.14. Slit-lamp photograph of patient with bullous keratopathy and secondary painful corneal erosions. Note bullous elevation of the corneal epithelium (1). (Reproduced from Hsu JK, Rubinfeld RS, Barry P, et al. Anterior stromal puncture. Immunohistochemical studies in human corneas. Arch Ophthalmol 1993; 111: 1057–1063. © 1993 American Medical Association.)

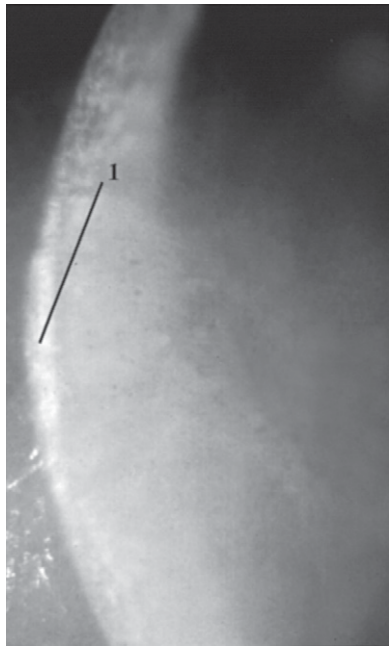

Figure 18.15. Slit-lamp photograph of the same patient as in Figure 18.14, 8 months after anterior stromal puncture treatment. This patient remained free of any further painful corneal erosions for over 4 years of follow-up. Note the resolution of the subepithelial bullae and the formation of subepithelial fibrosis/pannus (1). (Reproduced from Hsu JK, Rubinfeld RS, Barry P, et al. Anterior stromal puncture. Immunohistochemical studies in human corneas. Arch Ophthalmol 1993; 111: 1057–1063. © 1993 American Medical Association.)

photodisruption of the anterior corneal stroma was induced with the YAG laser. Katz et al[23] reported modifying the procedure so that debridement was not necessary. They renamed this technique Nd:YAG laser photo-induced adhesion. Extensive experience and long-term follow-up are not available with these techniques, and they involve more expensive technology than stromal puncture.[16] However, these approaches, especially the technique that eliminates the need for debridement, may have some role in the treatment of patients with resistant corneal erosions.

EXCIMER PHOTOTHERAPEUTIC KERATECTOMY

The ArFl excimer laser has been used to treat patients with recurrent corneal erosions.[24–26] This application of the excimer laser is covered more extensively in Chapters 19 and 20. However, a limited discussion of this approach is appropriate here. Phototherapeutic keratectomy (PTK) using the excimer laser involves treating Bowman's layer or anterior stroma, resulting in an ultramicroscopically modified, roughened surface to anchor the corneal epithelium (Stein, unpublished). This approach involves extremely expensive technology, and clinical experience and long-term follow-up data are limited. Also, surgical technique and success rates vary widely with individual surgeons, patient characteristics, and laser techniques. One group of investigators[29] has, in fact, reported that symptoms of recurrent erosion were more common and more pronounced in patients who had PRK than in patients who had LASIK for the correction of myopia.

The patient's epithelium is usually removed mechanically by scraping with a spatula or blade, since using the laser to ablate the epithelium in patients with severe basement membrane dystrophy can induce irregularities in the deeper corneal tissues. Development of better coupling or masking agents may eliminate this problem in the future. Once the epithelium is removed, the laser is used to treat or 'dust' Bowman's layer.

Excimer PTK usually results in a postoperative refractive shift toward hyperopia. In patients with myopia and corneal erosions associated with marked basement membrane dystrophy the excimer laser can be used to perform a combined PTK and photorefractive keratectomy (PRK) procedure. In this case, the PRK parameters and techniques are determined in part by the patient's preoperative refractive status. Combining PTK and PRK can reduce or eliminate ametropia, improve the best corrected vision by reducing the surface irregularity of the dystrophic epithelium, and resolve the recurrent corneal erosions. Postoperatively, bandage contact lenses along with topical nonsteroidal agents and antibiotics are generally used.

Despite questions regarding cost, refractive shift, long-term success rates, and wide variation in technique, excimer PTK may be an important treatment for recurrent erosions, especially in patients whose corneal erosions are associated with marked basement membrane dystrophy and ametropia. In addition, patients with corneal erosions caused by other corneal dystrophies, such as superficial variant of granular dystrophy, Reis-Bücklers' dystrophy, and other similar conditions involving the anterior cornea may be excellent candidates for excimer PTK.

19 Phototherapeutic keratectomy: indications, contraindications, and preoperative evaluation

Liane M. Clamen, Waleed Mahran, Dimitri T. Azar

In 1981, the US Air Force School of Aerospace Medicine first began researching the effects of the 193-nm argon fluoride (ArF) excimer laser on the eye.[1] Trokel and co-workers[2] in New York then found that the excimer laser could produce precise corneal ablations in bovine eyes; in 1983, they published the first article to describe the surgical potential of excimer photoablation. By 1985, Seiler performed the first excimer laser phototherapeutic keratectomy in a sighted eye.[3] In the spring of 1995, the US Food and Drug Administration issued premarket approval of the Summit (Waltham, MA) and VISX (Santa Clara, CA) lasers for phototherapeutic keratectomy.

The popularity of PTK for treatment of corneal opacities and irregularities stems from the fact that the 193-nm ArF excimer laser emits pulses of light that ablate the cornea with submicrometer precision and with minimal damage to adjacent tissue.[4] The high-energy ultraviolet light emitted by the laser allows for accurate control of the depth and shape of tissue removal. By removing precise amounts of superficial corneal stroma, PTK leaves an optically smooth surface with reformation of basement membrane complexes and minimal corneal scarring.[2,4–8] Phototherapeutic keratectomy has various advantages over manual keratectomy surgery. Manual keratectomy with diamond and steel blades produces more irregular and diffuse tissue damage when compared to a 193-nm ArF excimer laser. Although manual keratectomy cannot create a clear boundary between the treated and untreated area at the histologic level, PTK can produce an exact histologic border.[2] Patients who are successfully treated with PTK can postpone or avoid more invasive techniques, such as surgical keratoplasty.

INDICATIONS

Many cases of visual loss resulting from corneal pathologic conditions can be corrected with corneal keratoplasty. However, corneal transplantation carries the risk of rejection, graft failure, endophthalmitis, dramatic postgraft astigmatism, and expulsive choroidal hemorrhage. In addition, the initial corneal infection or dystrophy may recur in the graft. Of the more than 34 000 corneal transplants performed each year in the USA, as many as 10% produce poor results.[9–11] In some circumstances, PTK is a less expensive, easier, and more effective method than corneal keratoplasty. The efficacy of PTK varies widely, depending on both the underlying diagnosis and the preoperative condition of the cornea.

A multicenter trial that reviewed the results of PTK treatment in 232 eyes concluded that the best candidate eyes are those with superficial corneal opacities and without significant corneal thinning.[12] In eyes with a central corneal thickness of less than 400 µm or an opacity deeper than the anterior 100 µm of the corneal stroma, there is an increased likelihood that PTK will cause complications. In these eyes, PTK may create an exceptionally thin cornea, thereby causing regular and irregular astigmatism, postoperative haze, a hyperopic shift, or a combination thereof.[12] Similarly, Marshall and co-workers[13] noted endothelial cell loss after PTK when the remaining unablated stromal thickness is 40 µm or less. It is not known, however, if similar endothelial loss would occur with equally deep mechanical lamellar dissection. The results of reports on PTK for various indications are summarized in Table 19.1.

RECURRENT CORNEAL EROSIONS

For patients with recurrent corneal erosions recalcitrant to conventional treatments, surgical options include manual epithelial debridement, anterior stromal puncture, and phototherapeutic keratectomy. Because the treatment depth of excimer laser photoablation is relatively shallow (5–10 µm) and usually limited to Bowman's layer, corneal wound healing is faster and significant postoperative hyperopic shift is absent (Table 19.2).

One disadvantage of PTK is postoperative pain caused by epithelial removal. Ardjomand and co-workers introduced a modified technique to reduce the immediate pain from removal of the epithelium after PTK in the treatment of recurrent corneal erosion. PTK with an epithelial flap or epithelial reflap similar to laser-assisted subepithelial keratectomy (LASEK), in which the peeled epithelium is placed back on the stroma, may result in faster postoperative visual rehabilitation and reduction of ocular pain in the immediate postoperative period. The relatively weak adherence of the epithelium to the stroma makes ethanol treatment before epithelial peeling unnecessary.[14]

Kim and co-workers evaluated the use of multifocal PTK for the treatment of indolent and persistent epithelial defect (PED) in 15 eyes. Ablation was performed along the sites surrounding the epithelial defect until a smooth corneal ablative bed was achieved. The ablation depth was less than 45 μm at each site to prevent going beyond Bowman's membrane. Re-epithelialization occurred in 13 eyes within 7 days. It required 11 and 12 days in 2 eyes. One case developed an epithelial defect in a different site on the cornea 3 months after surgery and was subsequently retreated.[15] Successful retreatment with PTK has been employed for patients with persistent macroerosions who have failed primary phototherapeutic keratectomy.[16]

BULLOUS KERATOPATHY

Two studies have evaluated the role of PTK in bullous keratopathy (BK). Maini and co-workers[17] studied the efficacy of PTK for pain relief for patients with painful BK and poor visual potential. Lin and co-workers[18] evaluated the therapeutic effects of PTK combined with therapeutic contact lens for painful recurrent corneal erosions secondary to BK not suitable for penetrating keratoplasty. Both studies concluded that PTK can be a useful therapeutic measure in painful BK. Deep PTK appears to be more successful in pain management than superficial treatment.

CORNEAL DYSTROPHIES

Corneal dystrophies are a group of hereditary disorders that affect the central part of both corneas and are not associated with inflammation or systemic disease. Typically, the disorders show autosomal dominant inheritance with variable expressivity, early onset (present in the first few decades of life), and either stationary or slow progression. Corneal dystrophies may involve any of the five layers of the cornea. Phototherapeutic keratectomy is most effective for superficial corneal dystrophies that involve the epithelium, the epithelial basement membrane, and Bowman's layer. For these conditions, PTK may obviate the need for conventional invasive surgery such as lamellar and penetrating keratoplasty. Such traditional surgeries may be necessary in cases of deep stromal dystrophies, however, for which PTK is less effective.[19,20]

Dystrophies of the epithelium and basement membrane: Superficial corneal lesions of the epithelium and epithelial basement membrane include juvenile hereditary epithelial (Meesmann's) dystrophy and map-dot-fingerprint (Cogan's) dystrophy. Phototherapeutic keratectomy ablation to a depth of 3–4 μm has been shown to be an effective treatment for these conditions.[19] Although a high success rate for PTK has been reported in the management of superficial corneal dystrophies, PTK is usually unnecessary.[9–12,21] Most often, the decreased visual acuity accompanying these dystrophies is the result of an irregular epithelium over the pupil. Because corneal scraping should be sufficient to remove the irregular epithelium, PTK should be reserved for recalcitrant eyes.[12,19]

Reis–Bücklers' dystrophy of Bowman's layer: First defined by Reis in 1917,[22] Reis–Bücklers' dystrophy was later described in more detail by Bücklers.[23] Reis–Bücklers' dystrophy is a bilateral disorder with deposits limited to Bowman's layer, leading to episodes of ocular irritation, photophobia, and watering. After the third decade of life the attacks become less frequent, but visual acuity decreases as scar tissue replaces Bowman's layer. The decrease in visual acuity is secondary to both the diffuse, subepithelial opacification and the irregular corneal surface.[19,24]

Although advanced cases of Reis–Bücklers' dystrophy can be treated with lamellar or penetrating keratoplasty, the dystrophy often recurs in the grafts, requiring repeat grafting. However, nine

recently published studies have independently documented the high success rate for PTK in the treatment of Reis–Bücklers' dystrophy (Table 19.3). Typically, laser stromal treatment does not exceed 15–20 μm.[19]

Stromal dystrophies: Although phototherapeutic keratectomy is an excellent treatment for dystrophies of the superficial cornea, it has a lower success rate with the deeper, stromal dystrophies.

Granular dystrophy: Treatment options for late-stage granular dystrophy include lamellar keratectomy or PTK. One problem with transplantation is that recurrences often occur in the grafts, sometimes as early as 1 year after surgery.[25,26] The success rate of PTK for the treatment of granular dystrophy is variable (Table 19.4). Note that recurrent granular dystrophy in a graft is another indication for PTK, and that just as granular dystrophy may recur after a surgical keratectomy, it can also recur after PTK treatment.[27,28]

Macular dystrophy: Macular dystrophy is a bilateral, symmetric autosomal recessive disorder, presenting in the first decade, that results in opacities which can affect stroma, Descemet's membrane, and corneal endothelium. The distribution of opacities thus makes the efficacy of PTK questionable.

Hafner and co-workers investigated the functional and morphological long-term outcome of PTK in macular corneal dystrophy in 10 patients. They concluded that PTK may be a reasonable treatment option in a case of superficially accentuated plaque-like stromal deposits in the central cornea, increasing BSCVA moderately for a limited period of time. Despite possible complications, primary PK still appears to be the definitive therapeutic option for patients with macular corneal dystrophy.[29]

Lattice dystrophy: In the early stages, lattice dystrophy can present as dots and branching lattice lines in the anterior axial stroma or as a diffuse haze in the center of the cornea. Over time, the faint central haze becomes more dense and eventually leads to reduced visual acuity.[19] Recurrent erosions can become a prominent feature.

PTK is a very successful method of treating lattice dystrophy (Table 19.5). As with granular dystrophy, lattice dystrophy often

recurs after corneal transplantation. Fortunately, PTK can be particularly valuable in patients who have recurrent lattice dystrophy in the graft because these recurrences tend to be relatively superficial.

Schnyder's dystrophy: Central crystalline dystrophy of Schnyder is characterized by bilateral central corneal opacities that generally occur in early life, sometimes as early as 2 months of age. A slowly progressive autosomal dominant disease, Schnyder's dystrophy may often go unnoticed, but it may cause a moderate reduction of visual acuity. The yellow-white opacity of Schnyder's dystrophy primarily involves Bowman's layer and the anterior stroma; frequently, it extends into the deeper layers. The epithelium and intervening stroma are usually clear, but punctate white opacities may be scattered in the stroma.[19]

In cases of decreased visual acuity, PTK can be used to remove the central opacities only if they are superficial.[30] There have been very few reports of eyes with Schnyder's dystrophy that have been treated with PTK (see Table 19.1). In instances when PTK fails to improve the vision, penetrating or lamellar keratoplasty can be performed.

CORNEAL SCARS

Phototherapeutic keratectomy treatment of corneal scars that are limited to the superficial stroma produces significant improvement of visual function.[4,12] Visual improvement after phototherapeutic keratectomy of deeper corneal scars is less likely to occur for the following reasons: (1) the scar may ablate at a different rate than the adjacent normal stroma and (2) this irregular ablation, along with the presence of calcified or cartilaginous tissue, may result in postoperative irregular astigmatism.[21]

Post-traumatic scars: Although there has not been a large cohort of reported cases of post-traumatic scars that have been treated with PTK, some investigators have described the results of such treatment (Table 19.6). In general, PTK should be avoided if the scar is of full thickness, but may be attempted if the scar is superficial.

Postinfectious and postherpetic scars: Although most investigators agree that PTK should not be used in the treatment of active infectious keratitis (see later discussion), there is still some controversy over the success of PTK in treating postinfectious scars. Perhaps the controversy stems from the variable success rate in PTK treatment of postinfectious and postherpetic scars (Table 19.7). Migden and co-workers[31] reported significant visual improvement in none of the five postinfectious eyes at 3 months follow-up after treatment with PTK. Campos and co-workers[32] found significant improvement in two of six eyes with postinfectious scars.

Some investigators have attempted to use PTK to treat both postinfectious scars and postherpetic scars. Sher and co-workers[33] reported significant visual improvement in three of five eyes with postinfectious scars, but in only one of four eyes with scars resulting from herpes simplex virus (HSV) infection. Fagerholm and co-workers[34] reported a 73% success rate (22 of 30 eyes) with scars secondary to infection, and an 80% success rate (12 of 15 eyes) with scars secondary to HSV infection. Eyes with scars from HSV keratitis are at risk for recurrence of HSV keratitis after PTK.[35] It is still unknown, however, whether PTK increases the incidence of recurrences of HSV or whether patients would experience the same frequency of recurrences without PTK treatment.[34] Nonetheless, with the variable success rates for postherpetic scars, many investigators believe that the risk of recurrence in herpetic disease outweighs the potential benefits of treating herpetic scars with phototherapeutic keratectomy, unless the alternative is penetrating keratoplasty.[4,32,35,36]

Postpterygium scars: After pterygium surgery, superficial corneal scars may remain on the eye, occasionally causing irregular astigmatism and opacification. Because the postpterygium scars are usually superficial, PTK is often a successful treatment (Table 19.8). Using PTK during the primary surgical excision of the pterygium may be more complicated because of the presence of corneal swelling and intraoperative bleeding. Walkow and co-workers investigated the long-term functional results of the combination of PTK and local mitomycin C therapy after bare sclera technique pterygium excision. They found that this technique led to improvements in visual acuity, low recurrence rate, and minimal complications.[37]

CORNEAL IRREGULARITIES

Band keratopathy: Band keratopathy is a degenerative condition characterized by the gradual development of a gray-white opacity of the superficial cornea. Calcium is deposited in the basement membrane, Bowman's layer, and anterior stromal lamellae. When the pathologic condition extends over the visual axis, patients may complain of glare and decreased visual acuity. In addition, considerable ocular irritation and discomfort arises if the epithelial surface is breached.[38]

Treatment of primary band keratopathy typically involves removing the opaque calcium deposits by manual debridement combined

with a chelating agent such as ethylenediaminetetraacetic acid (EDTA).[4,32,33,36,39] Some investigators have attempted to treat band keratopathy with PTK (Table 19.9). O'Brart and co-workers[40] report a high success rate of 91% in treating band keratopathy (113 of 122 eyes improved after PTK). Others have had less positive results. Maloney and co-workers[12] performed PTK on 21 eyes with band keratopathy and recorded a mean improvement in vision of only 0.1 line. Stewart and co-worker[41] found that BCSVA was improved or unchanged in 18/33 eyes (55%), while there was loss of one or more lines of acuity in 15/33 (45%). They suggested that these poor results are the result of coexisting ocular disease, which often accompanies calcific band keratopathy. Sher and co-workers[33] and Campos and co-workers[32] also had little success with PTK for the treatment of band keratopathy. One possible reason for the poor results is that calcium does not ablate at the same rate as corneal stroma. Because of this difference, there is a high risk of obtaining a severely irregular corneal surface after treatment with PTK. Thus, it is best to remove the superficial calcium first with a calcium chelating agent such as EDTA and later, if necessary, PTK can be used to treat any residual corneal opacification.[36,42]

SALZMANN'S NODULAR DEGENERATION

Salzmann's nodular degeneration is characterized by degeneration of the superficial cornea. In Salzmann's degeneration, the combination of corneal nodules, corneal surface irregularities, and

Table 19.9 Band keratopathy

associated refractive error may lead to visual impairment. The preferred treatment is mechanical debridement. However, if this cannot be achieved or if there are remaining opacities or elevations after the superficial corneal debridement, then laser treatment can be useful. By filling in depressed areas so that nearby elevated areas can be treated further, masking agents are useful in creating a smooth corneal surface.[43]

When the pathologic condition secondary to Salzmann's nodular degeneration involves the anterior one-third of the cornea, PTK is generally effective in establishing a uniform, smooth surface and in removing opacities causing optical degradation, while minimizing any induced refractive change.[44] Elevated corneal opacities, such as Salzmann's nodular degeneration, often have good results after treatment with PTK (Table 19.10), but the condition may recur.[12]

Corneo-conjunctival carcinoma

Spadea and co-workers[45] evaluated the use of PTK in the treatment of recurrent intraepithelial corneo-conjunctival carcinoma. They found that PTK was very effective in destroying dysplastic superficial corneo-conjunctival cells, preventing a recurrence of the tumor and resulting in a clear cornea, normal corneal topography, and visual acuity of 20/20 with correction. The laser ablation was very superficial and the Bowman's layer only partially ablated. They concluded that PTK could be considered a minimally invasive, effective, and safe treatment for recurrent corneal in situ carcinoma.

CONTRAINDICATIONS

HYPEROPIA

Phototherapeutic keratectomy can create a significant hyperopic shift as a result of associated corneal flattening. Four potential mechanisms for the hyperopic shift include: (1) greater degrees of epithelial hyperplasia and tear film thickness at the edge of ablation; (2) greater ablation in the center of the area of the corneal pathologic condition thins progressively toward the visual axis; (3) increased shielding of the stroma toward the edge of the ablated zone by the ablation products (plume); and (4) the oblique angle of incident radiation falls on the more peripheral cornea, causing a decreased peripheral ablation.[21,46,47]

One may attempt to minimize undesired hyperopic shifts through careful planning before surgery and through periodic slit-lamp examination during the procedure.[38] In addition, the use of appropriate masking agents may minimize the hyperopic shift.[21] Other strategies for minimizing hyperopic shifts include Stark's modified taper technique[4] or Sher's method of using the laser system to cut a secondary hyperopic correction ('combined' ablation).[21,33] However, in patients who already have a considerable degree of hyperopia, it may be best to avoid PTK.

CORNEAL THICKNESS

As noted later, when PTK treatment leaves a thin cornea, laser-induced scarring may significantly limit visual improvement and corneal instability may ensue. One may choose to exclude eyes with central corneal thickness less than 400 µm or an opacity deeper than the anterior 100 µm of the corneal stroma.[12] Typically, eyes with a predicted postoperative corneal thickness less than 250 µm are less likely to have good results from PTK, and this may also be used as a criteria for exclusion from treatment.[39]

OTHER OCULAR AND SYSTEMIC CONTRAINDICATIONS

It has been suggested that scarring resulting from adenoviral epidemic keratoconjunctivitis should only be treated after the keratitis has been quiescent. At this time, the eye should be treated as gently and lightly as possible because continued corneal remodeling and possible antigen–antibody reaction reactivation may cause new scarring.[48] Uncontrolled uveitis, severe blepharitis, and lagophthalmos are also contraindications to PTK under many protocols. Systemic contraindications to phototherapeutic keratectomy include immunosuppression, collagen vascular disorders, and other problems that affect healing.

RELATIVE CONTRAINDICATIONS

INFECTIOUS KERATITIS

There are a variety of reasons why the treatment of active infectious keratitis has been discouraged. First, one must be concerned with the potential dissemination of microorganisms during or after PTK treatment. Second, stromal involvement in most corneal infections extends deeper than the clinically visible lesion; PTK would not be effective in treating mid- or deep stromal infiltrates because tissue penetration depth of 193-nm radiation is 1 µm at most.[43] Lin and co-workers,[49] however, showed different results. They evaluated the efficacy of using PTK in the treatment of superficial keratomycosis in nine patients and concluded that PTK can shorten treatment time, hasten re-epithelialization, and restore reasonably good vision. PTK can be a valuable therapeutic alternative for superficial keratomycosis, especially in instances where there is poor response to treatment by topical antifungal agents alone.

LONG-STANDING POST-TRAUMATIC AND DEEP STROMAL SCARS

Although the success rate of PTK treatment of post-traumatic scars averages approximately 60%, PTK has been less successful in the treatment of post-traumatic scars in the superficial stroma that are long standing. These scars may prove resistant to ablation.[50] The use of surface-modulating agents or the 'smoothing' technique may make it easier to ablate these scars. The smoothing technique involves gently rotating the head under the laser beam to blend the edges of the irregularities. In addition, further irregularities can be avoided by maintaining the corneal surface meticulously clear of debris and cellular remnants. Deep corneal scars should not be treated with PTK because of the untoward effects of corneal thinning that may result from such treatments.

BAND KERATOPATHY

As noted above, the standard treatment for the removal of band keratopathy is debridement with a chelating agent such as EDTA combined with manual debridement. Although some investigators have experienced success in treating band keratopathy with PTK alone, one should use caution. First, patients with band keratopathy often have coexisting ocular disease. Band keratopathy is often associated with juvenile rheumatoid arthritis, and it has been described in long-standing inflammatory conditions of the eye. Second, because calcium does not ablate at the same rate as corneal stroma, PTK can create an irregular corneal surface when used to treat band keratopathy. As previously discussed, if one uses PTK to treat band keratopathy, it is best to apply EDTA on the eye first to remove the superficial calcium.[27]

RECURRENT EROSIONS

As noted above, PTK has a success rate of 77% in the treatment of recurrent corneal erosions. One hypothesis for this high success rate is that by smoothing the subepithelial corneal surface, PTK creates a substrate conducive to epithelial migration and adhesion.[51] Although PTK is useful for recalcitrant recurrent epithelial erosions, conservative methods should continue to be the first line of treatment because most patients with recurrent corneal erosions experience relief of symptoms with such methods. Current treatments include manual epithelial debridement, anterior stromal puncture, and bandage contact lenses.

PREOPERATIVE EVALUATION

The preoperative evaluation should include a thorough history of systemic and ocular problems so that patients with contraindications to the procedure are identified. A complete preoperative exam should also include best spectacle-corrected and -uncorrected Snellen acuity. In addition, best spectacle-corrected acuity should be compared with the visual potential, which may be evaluated with a pinhole, hard contact lens, and potential acuity meter. One should

also perform intraocular pressure measurements, manifest refraction, keratometry, dilated fundus examination, a visual fields test, and a test of extraocular movements. A slit-lamp microscopy examination is necessary to determine the type, depth, and extent of the corneal pathologic condition. To devise the best treatment plan, it is important to determine the type of pathologic condition before surgery. For example, disorders such as Salzmann's nodular degeneration can usually be scraped mechanically off Bowman's layer before determining if excimer laser therapy is then necessary to remove residual nodules and smooth the surface. The depth of the corneal pathologic condition is important to determine in a preoperative evaluation because the best candidates for excimer laser PTK are those whose pathologic condition is limited to the anterior 20% of the cornea. Candidates with very deep corneal damage are less likely to benefit from PTK. Finally, optical pachymetry or ultrasonic biomicroscopy can be used to measure the depth of the intended treatment.

To ensure optimal performance, the excimer laser must be finely tuned and calibrated before each treatment. Because the excimer laser beam is not adjusted during surgery, its overall operation must be confirmed before surgery by ablating a standard treatment into a calibration plate test block made of a material such as polymethylmethacrylate (PMMA). Using nomograms, the exact corneal ablation rate is calculated and entered into the laser computer program. The plane of the corneal surface is measured before treatment by focusing the microscope at high magnification. This step is important because a suboptimal outcome may result from poor centration of laser treatment.

WOUND HEALING

THE HEALING RESPONSE

Wound healing after PTK is similar in type and rate to healing after surgical keratectomy. In a review of rabbit corneas that underwent either excimer laser photoablation or lamellar keratectomy, Tuft and co-workers[52] found no quantitative difference in the synthesis of new connective tissue over a wound made by the laser or the lamellar keratectomy. Like the type of healing, the rate of healing is similar for laser and surgical keratectomy. Microscopic observation of monkey corneas showed that re-epithelialization occurred within 24 to 48 h after PTK, or at approximately the same rate of healing recorded in monkeys that underwent surgical keratectomies.[7]

In a recent study of human eyes that underwent PTK, re-epithelialization occurred in 59% of eyes within 1 week, and in 93% of eyes within 2 weeks. The remaining two eyes re-epithelialized completely in 3 and 4 weeks, respectively, after receiving bandage contact lenses.[4] Some studies have noted that a pseudomembrane forms over the ablated zone almost immediately after surgery. This pseudomembrane seals the exposed surface and confers enough stability to serve as a template to help hyperplastic migrating epithelial cells fill in the wound and achieve an orderly and smooth re-epithelialization.[7,53,54]

Although re-epithelialization after PTK typically occurs within the first week, anchorage of the epithelium to the stroma is not achieved until 1 to 3 months later. It takes that amount of time for the adhesion structures of the new epithelium (hemidesmosomes, basal lamina, and anchoring fibrils) to be deposited adequately on the underlying stroma.[5,53] Interestingly, the synthesis of stromal connective tissue does not begin until epithelial cells have regrown over the wound. It is proposed that epithelial cells exert a stimulatory influence on keratocytes during stromal wound healing.[52]

To evaluate the effect of intraoperative mitomycin C (MMC) on corneal light scattering after PTK, Jain and co-workers performed PTK in 24 rabbit eyes followed by application of MMC in different ways and concentrations. Corneal light scattering was measured weekly from 1 to 6 weeks, at 10 weeks, and at 8 and 13 months using a scatterometer which measures back-scattered light from a defined region of the cornea under standardized illumination conditions. They found that controlled application of 0.5 mg/mL MMC in the corneal midperiphery transiently reduces corneal light scattering after excimer keratectomy.[55]

In a recent study, Ayres and co-workers,[56] performed to determine the safety and efficacy of the use of intraoperative MMC during PTK for anterior corneal disease, showed that MMC is safe for intraoperative use during PTK, does not appear to inhibit epithelial healing, and may help prevent recurrent anterior corneal disease.

THE EFFECT OF DEPTH OF ABLATION ON WOUND HEALING

In animal models, it appears that the depth of laser ablation plays a role in the healing process. It is important to know how deeply one can ablate the cornea and still achieve complete remodeling. Tuft and co-workers[52] found that although the processes of epithelial hyperplasia and stromal collagen synthesis work together to restore the original corneal surface contour of shallow wounds in rabbits (15 µm), remodeling of deeper wounds (50 and 75 µm) is incomplete, leaving a residual depression in the surface that persists 6 months after surgery. After performing laser refractive keratectomy on rabbit corneas, Goodman and co-workers[6] also concluded that for ablations less than 50 µm, no scarring, collagen regrowth, or epithelial hyperplasia was observed. Faktorovich and co-workers[57] reported that 100 µm PTK ablation resulted in significantly more corneal scarring than the 15 µm PTK ablation, even though there was no difference in the pattern of TGF and bFGF expression after deep and shallow ablations through immunohistochemical analysis.

In humans undergoing corneal ablations deeper than 50 µm, laser-induced scarring may significantly limit visual improvement. Wu and co-workers[8] report four cases of anterior stromal scarring after PTK ablation to a central depth of 50–113 µm. In these four cases, visual acuity was so poor that a keratoplasty was eventually necessary. The authors studied the changes in the corneas of these four patients at 6 to 15 months after excimer laser PTK ablation, but the cohort was small and a few similarities were found. They did note slightly more scarring in the more central aspect of the ablated areas, and they postulated that this might be the result of the delayed re-epithelialization of the central zones.

Although the US Food and Drug Administration-approved indications allow for ablations of up to 33% of the corneal thickness, deep ablations can cause severe corneal flattening or irregularity, or both. The best results from PTK occur when the pathologic condition is limited to the top 10 to 20% of the corneal stroma.[27]

After PTK, the cornea may develop subepithelial haze for 3 to 6 months after surgery.[52] Haze may be the result of light scattering by 'activated' keratocytes in the wound. Another cause of haze is the deposition of new, irregular collagen fibers.[13,52,54,58] Postoperative treatment with steroids can help decrease the thickness of the subepithelial layer of collagen and the density of subepithelial scarring.[52] How corticosteroids achieve these results is not fully understood. However, the postulated mechanisms of action include the following: steroids reduce DNA synthesis and collagen deposition in activated fibroblasts, and steroids prevent the recruitment

of lymphocytes and macrophages.[59] The benefits of continued steroid use may be outweighed by potential side effects, such as steroid responsiveness.[21]

CONCLUSIONS

Phototherapeutic keratectomy is often an effective alternative to penetrating keratoplasty. It is faster and less expensive than surgery, and it allows one to avoid the risks of surgical complications and of graft rejection. As PTK techniques improve and we advance our understanding of the subtleties of PTK methods and of wound healing, perhaps we will increase the efficacy of PTK and expand the applications of this technique. It is the authors' hope that, in the future, we will also decrease the number of post-PTK complications and diminish the number of cases that are contraindicated for phototherapeutic keratectomy.

20 Phototherapeutic keratectomy: operative techniques and complications

Timothy B. Cavanaugh

Treatment for anterior corneal pathologic conditions has progressed beyond the standard techniques of superficial keratectomy, lamellar keratoplasty, and penetrating keratoplasty. Mechanical superficial keratectomy usually involves removal of the epithelium and the area affected by the anterior corneal pathologic condition with a surgical microblade such as a no. 64 Beaver blade. Although the blade is a very effective tool for epithelial debridement, removal of subepithelial or anterior stromal lesions in this manner can result in a rough surface with irregular astigmatism that prevents optimal visual acuity. If the media is clear, alternative treatment has traditionally been hard contact lenses, but this is not possible in all patients, especially the elderly. For pathologic surfaces combined with media opacity, lamellar or penetrating keratoplasty have been the treatment of choice. It is well known, however, that keratoplasties can be plagued with both operative and postoperative complications, not to mention asymmetric or irregular astigmatism after keratoplasty, necessitating hard contact lenses.

Given the aforementioned problems with standard surgical techniques, a powerful new procedure to treat anterior corneal disease was developed that provides superior results with less cost, risk, and morbidity. Since the advent of excimer laser phototherapeutic keratectomy (PTK), the excimer laser has been shown not only to remove anterior corneal pathologic material in a precise, controlled fashion, but also to leave behind a remarkably smooth stromal surface. It is the smoothness of the stromal surface that enhances corneal clarity and promotes uniform re-epithelialization with reformation of basement membrane complexes, even in the absence of Bowman's layer.[1–3] The PTK-treated stromal surface not only can prevent corneal erosion, but also yields the quality refractive surface necessary for good visual acuity.[4–7] The excimer laser is the best corneal polishing tool that has been developed to date. The diamond burr is sometimes used to polish the corneal surface after blade mechanical keratectomy, but the smoothness of the resultant surface is clearly inferior to the surface achieved with excimer PTK.[8] Phototherapeutic keratectomy has a distinct advantage over mechanical superficial keratectomy in that topically applied masking agents may be used during broad-beam laser ablation in PTK to provide a smoothing effect in the pathologic area.[4,5]

BACKGROUND

In the USA in 1988, investigational clinical trials of PTK involving humans began under the close guidance of the US Food and Drug Administration (FDA) and two laser manufacturers, Summit Technology, Inc. (Waltham, MA) and VISX (Sunnyvale, CA). The author's research site was involved in the Summit study, which consisted of 13 centers across the country with a total of 249 eyes treated by PTK during the entire clinical trial. All patients were over 21 years of age and were categorized into one of the three treatment groups: corneal scars, irregular astigmatism, and recurrent corneal erosion. The VISX study consisted of 17 investigational sites, with a total of 271 patients treated. The VISX study included four categories of patients: corneal opacities, irregular corneal surface, superficial infectious keratitis resistant to medical therapy, and postsurgical refractive abnormalities. The clinical trial successfully proved the efficacy and safety of PTK with both machines; thus, the procedure gained FDA approval for the Summit laser in the spring of 1995 and for the VISX laser later the same year.

Phototherapeutic keratectomy has an uncanny ability to rid the anterior cornea of pathologic material in a relatively noninvasive manner with low attendant surgical risk to the patient. Many of the potential PTK candidates would have been forced to consider either lamellar or penetrating keratoplasty before the advent of this exciting new laser technology. There are nearly 32 000 corneal transplants performed in the USA each year, and converting a fraction of eligible patients to PTK achieves significant savings in cost to patients and payers, not to mention greatly reduced surgical risk and potential morbidity. Furthermore, failure of PTK to provide adequate visual recovery does not preclude the possibility of keratoplasty at a later date.

PATIENT SELECTION

Consistent success in PTK depends on careful patient selection (see Ch. 19 for indications and contraindications). Even state-of-the-art laser technology is prone to complications if the operation is performed incorrectly or on a poor surgical candidate. Candidates for

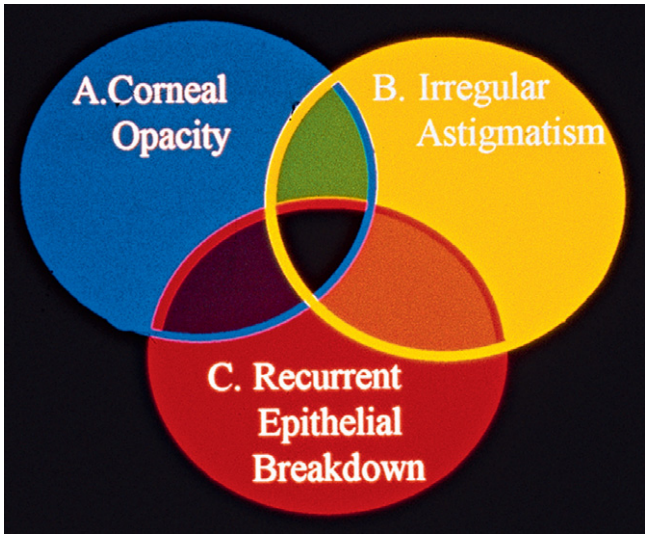

Figure 20.1. Diagram depicting overlap of indications for phototherapeutic keratectomy.

BOX 20.1 IDEAL PATIENT CRITERIA FOR PHOTOTHERAPEUTIC KERATECTOMY

- Significant visual compromise
- Pathologic condition in anterior third of cornea
- Elevated or flat opacity
- Myopic
- Under consideration for corneal transplant
- Realistic patient expectations for surgical outcome
- Quiet, uninflamed eye
- Recurrent erosion that has failed medical therapy

PTK fall into three general categories: corneal opacities, irregular astigmatism, and recurrent corneal erosion. Overlap between two or three categories in a single patient is not uncommon (Fig. 20.1). The ideal condition for PTK is an elevated anterior corneal opacity in proximity to the visual axis, which causes decreased visual acuity and irregular astigmatism in a myopic eye (Box 20.1).[4]

Special caution should be exercised when considering treatment of herpetic corneal scars with PTK[9] (Box 20.2). Often herpes simplex virus (HSV) scars are flat or depressed and associated with tissue loss that makes treatment difficult and can leave the patient with significant residual irregular astigmatism, large hyperopic shifts, or both. In addition, reactivation of HSV keratitis has been reported after PTK, and such patients must be well informed about the potential risks.[10,11] The author's recommendation is to pretreat HSV patients with oral antiviral agents (acyclovir 400–800 mg five times daily or famciclovir 500 mg thrice daily) for 2–4 weeks before surgery and for 4–12 weeks after surgery on a tapering dose. This regimen is similar to what the author uses in penetrating keratoplasties on HSV patients and to date no HSV recurrences with PTK have been seen using this methor.

INDICATIONS FOR PHOTOTHERAPEUTIC KERATECTOMY

Patients undergoing PTK typically fall into one of three categories. There are a wide variety of causes of corneal opacities and irregular surfaces that are amenable to treatment using PTK (Box 20.3). The list is self-explanatory, but one must remember to consider the patient selection criteria and various surgical techniques along with these indications to maximize positive results.[12–24] Although some of the listed dystrophies are stromal, PTK can fully treat the anterior varieties and partially treat those that extend deeper into the stroma by smoothing the corneal surface and lightening the amount of opacification.

Painful recurrent corneal erosion or nonhealing epithelial defects have traditionally been treatment challenges and a source of considerable distress to patients. Excimer PTK has a definite role in treating a variety of epithelial adherence problems (Box 20.4). Although the mechanism for the re-establishment of epithelial basement membrane complexes with PTK is poorly understood, its remarkable effectiveness in treating recurrent corneal erosion syndrome recalcitrant to medical and standard surgical therapies has been well documented.[1,2,25–30] Candidates with corneal erosion should try (and fail) medical therapy with lubricants, hyperosmotics, and bandage contact lenses, as well as surgical adjuncts such as epithelial debridement, before considering PTK. Some surgeons advocate the use of stromal micropuncture or diamond burr superficial keratectomy first, but it is the author's bias that PTK is superior to both.

BOX 20.2 RELATIVE CONTRAINDICATIONS FOR PHOTOTHERAPEUTIC KERATECTOMY

- Pathologic condition deeper than one-third of depth
- Tissue loss or depressed opacity
- Thin preoperative cornea
- Active ocular inflammation, i.e. uveitis
- Hyperopic refractive error
- Severe blepharitis
- Lagophthalmos or poorly controlled dry eye
- Collagen vascular diseases, i.e. rheumatoid arthritis
- Immunosuppression
- Unrealistic expectations for surgical outcome
- Herpes simplex keratitis

BOX 20.3 INDICATIONS FOR PHOTOTHERAPEUTIC KERATECTOMY: CORNEAL OPACITY AND IRREGULAR ASTIGMATISM GROUP

- Anterior corneal dystrophies[12]
- Anterior membrane dystrophy
- Reis-Bückler's dystrophy[13,14]
- Lattice dystrophy
- Granular dystrophy
- Macular dystrophy[15]
- Schnyder's crystalline dystrophy
- Meesmann's dystrophy
- Recurrent dystrophies after keratoplasty[16]
- Anterior corneal scars, postinfectious or post-traumatic[17,18]
- Salzmann's nodular degeneration[19]
- Band keratopathy
- Postpterygium scars
- Keratoconus apical scars[20,21]
- Shield ulcers and corneal plaques in vernal keratoconjunctivitis[22]
- Recurrent corneal intraepithelial dysplasia[23]
- Infectious crystalline keratopathy[24]

BOX 20.4 INDICATIONS FOR PHOTOTHERAPEUTIC KERATECTOMY: CORNEAL EROSION AND PERSISTENT EPITHELIAL DEFECT GROUP

- Recurrent erosion syndrome secondary to basement membrane dystrophy[25–28]
- Traumatic recurrent erosion syndrome
- Idiopathic recurrent erosion syndrome
- Bullous keratopathy-associated recurrent erosion[29,30]
- Neurotrophic keratopathy
- Nonhealing epithelial defects after keratoplasty

Little or no scarring results from PTK in contrast to micropuncture, the very mechanism of which depends on the inducement of stromal scars; micropuncture overlying the visual axis in same eyes may be problematic.

The success of PTK in the treatment of long-standing neurotrophic or similar epithelial defects is also a mystery. It is postulated that the laser smoothens the damaged Bowman's membrane or anterior stroma to provide better substrate for epithelial adherence. For these patients, the author strongly recommends the concurrent use of adjunctive therapy with bandage contact lenses or lateral tarsorraphies.

SURGICAL TECHNIQUE

BASIC CONCEPTS

Phototherapeutic keratectomy can be one of the most challenging surgical procedures to perform correctly. PTK has been described as one of the most 'artistic' surgical procedures, with each cornea representing a different 'canvas' on which the surgeon applies the masking agent ('paint') with the laser beam ('brush'). It involves a thorough understanding of each patient's disease process, topography, and refractive needs, as well as the nuances of the excimer beam parameters and techniques. Careful attention should be given to hand position, head movement, epithelial debridement, transepithelial ablation, use of masking agents, and polishing. The excimer computer-controlled software can lull the surgeon into a false sense of security, but, unlike its PRK counterpart, the PTK technique is very surgeon dependent and will vary with the type of corneal pathologic condition.

The initial lasers used in the USA for PTK were manufactured by Summit Technology, VISX, and Chiron Technolas. The techniques for the Summit and VISX lasers were essentially identical in that both used a stationary broad beam of variable diameter with patient head movement to provide the necessary polishing motion. The Technolas laser used a joystick to move the beam, which allowed for more precision when targeting the pathologic areas. The author's initial experience was on the Summit Omnimed, Apex, and Apex Plus excimer lasers, and the description of the surgical technique reflects the suggested technique for these machines. In addition, the procedure described is the author's bias, and it should be noted that technique can vary between surgeons and also between laser systems.

PREOPERATIVE EVALUATION

Preoperative evaluations should be performed no longer than 90 days before surgery. Visual acuity with and without correction, phoropter refraction, intraocular pressure, careful slit-lamp examination, and dilated fundus examination should all be performed. Irregular astigmatism and surface profile should be evaluated by keratometry, corneoscopy, computerized corneal topography, or a combination thereof. Standard keratometry is often suboptimal because of the limited surface area evaluated; placido disc-type evaluations are generally superior in finding distortion in the central two or three mires. Although corneal topography provides the greatest amount of detail, the color maps can sometimes be overinterpreted by the computer's smoothing software and can be potentially misleading to the surgeon. Because of this, the author always recommends comparison of the color map with the clinical appearance and the placido disc image for surgical planning. The degree of irregular astigmatism from corneal epithelial irregularity can be quite striking, with as high as 3 D measured by placido disc topography measurement. Slit-lamp photographs to document preoperative clinical appearance for comparison with postoperative photographs may be indicated.

The potential for improvement in visual acuity from elimination of the irregular astigmatism or paraaxial opacification is estimated by pinhole vision, potential acuity meter, and/or gas-permeable contact lens over-refraction. If the corneal opacity is axial, a gas-permeable contact lens over-refraction may still improve the visual acuity solely from its smoothing effect. Decreased visual acuity from a corneal stromal opacity is measured objectively in comparison with the patient's visual loss tolerance and lifestyle; from this data a risk-benefit assessment is made, as one may do in the case of cataract. Photophobia and glare in the setting of anterior stromal opacity are assessed subjectively by symptoms and objectively by the decreased visual acuity caused by the opacity. Brightness acuity testing can be a useful adjunct to quantify the degree of degradation of visual acuity. Preoperative corneal thickness is measured by ultrasonic pachymetry, and the depth of the pathologic condition can be measured by optical pachymetry (Fig. 20.2, *A* and *B*).[31] Full informed consent outlining potential risks and benefits is obtained. Careful discussion of potential refractive error shifts and the potential need for later corneal transplant is mandatory.

The recurrent erosion patient workup varies only slightly. The use of a cellulose Weck-cel microsurgical sponge at the slit lamp may be extremely helpful in determining the presence of loosely adherent epithelium (Fig. 20.3). The sponge is gently rubbed over areas of suspicion, causing the loosely adherent epithelium to detach and wrinkle into folds while tightly adherent epithelium remains undisturbed. Drawings documenting the exact location of abnormal epithelial adherence should be used as guides during surgery.

LASER PARAMETERS

After the excimer laser is appropriately calibrated, the surgeon should verify that the parameters of fluence, repetition rate, ablation rate, and ablation diameter are appropriate for the desired PTK treatment. The desired fluence and ablation and repetition rates are usually standardized according to the type of excimer laser used and not to the corneal diagnosis necessitating PTK. The ablation diameter may be set or varied throughout the session, according to type, size, depth, and location of the corneal pathologic area. For example, the surgeon may select an ablation diameter of 6 mm, which provides a wide treatment of the entire cornea, for a patient with anterior basement membrane dystrophy with recurrent erosion syndrome. Conversely, for an elevated isolated scar, the surgeon

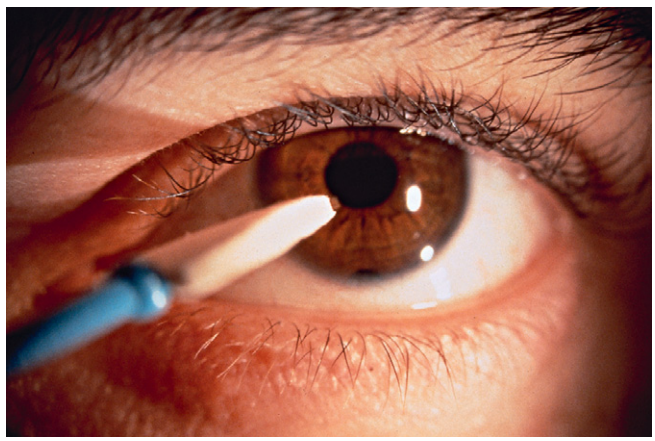

Figure 20.3. Cellulose sponge test used to assess adherence of corneal epithelium in patients with recurrent erosion.

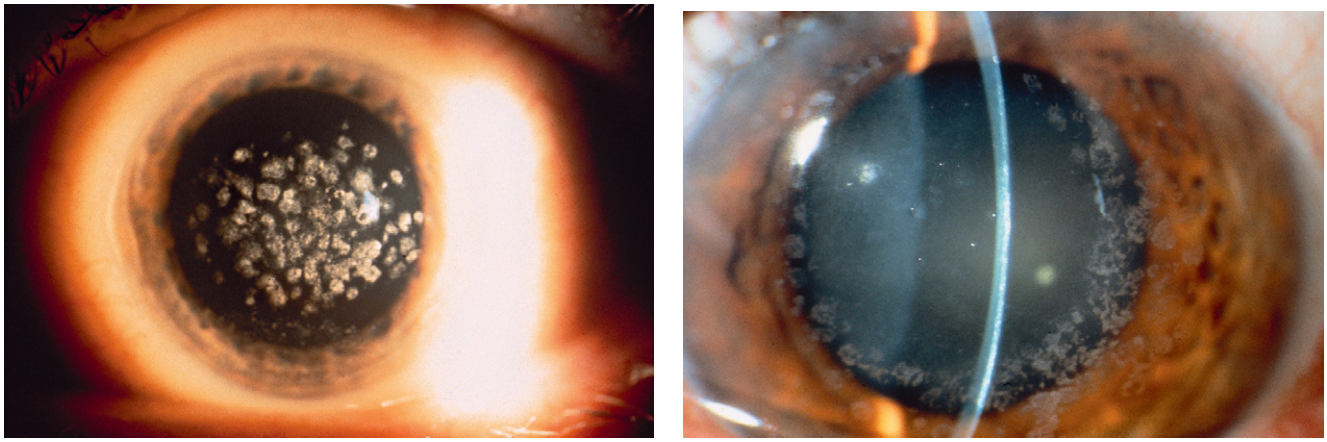
may use successively larger ablation diameters to flatten the elevated peak of the scar. Novice PTK surgeons can make the mistake of using ablation zones that are too small. This is usually performed with the intent of targeting localized pathologic areas but often results in a poor outcome because of rapid ablation and the creation of holes or divots in a cornea with irregular astigmatism. It is far better to use the largest-diameter beam possible to polish while isolating localized pathologic areas with masking agents.

PREOPERATIVE PREPARATION

With good patient education and expectations, preoperative sedation is usually unnecessary. Thirty minutes before surgery, the eye is anesthetized with topical tetracaine, repeated every 10 min. All patients should be examined at the slit lamp immediately before placement in the operative chair so the surgeon has a clear view of the pathologic areas and treatment plan. The patient is then reclined supine in the operative chair and a betadine preparation is applied, followed by a wire-lid speculum. An eye patch is placed over the nonoperative eye to encourage fixation only with the operative eye. The patient is then placed under the laser operating microscope and instructions are given. Visualization and familiarization with the



A B

fixation beam in the laser are achieved, and the patient is instructed to maintain this fixation throughout the procedure. The aiming beam is focused on the central cornea, and the pass-through beams are visualized on either side of the pupil. The snapping sound and smell of the laser are discussed, followed by a trial run of a few sample pulses of the laser. Encourage the patient to relax their shoulders and neck, and explain how you will be moving their head from side to side or around in small circles in a polishing fashion.

EPITHELIUM REMOVAL

Corneal epithelium removal is typically performed with a no. 64 or similar Beaver blade, but a blunt spatula, rotating brush, or alcohol may be used as well. In patients with recurrent erosion, all loose epithelia are first removed with a cellulose sponge. The Merocel sponge (Xomed Surgical Products, Inc., Jacksonville, FL) is preferred because it does not leave any fibers on the corneal surface. The epithelium may come off in incomplete sheets, so debridement should be complete, extending to the level of Bowman's layer. The no. 64 Beaver blade should be used (at an angle of 45° so that the blade scrapes but does not cut corneal tissue) to debride a wider margin, usually resulting in an approximately round corneal epithelial defect measuring about 7–9 mm. The Merocel sponge is then used to remove final epithelial remnants and dry the surface for visual inspection. In treatment of opacities, the edge of epithelial removal should *never* be in the visual axis to prevent a ridge in the line of vision; an additional margin of epithelium is often removed to prevent this.

In some cases, transepithelial ablation with the laser is preferable to mechanical removal. Subepithelial scar tissue should always be removed manually if possible, but in cases of significant surface irregularity caused by anterior stromal lesions, it may be best to ablate directly through corneal epithelium, taking advantage of the uncanny natural smoothing or masking ability of the laser. Determining an endpoint can be very challenging. Transepithelial ablation should be performed in a darkened room with a large-diameter ablation zone. Intact epithelium autofluoresces a light purple hue with laser beam interaction, but this hue changes to a dark purple/black when ablation begins to break through the epithelial layer. Ideally, the breakthrough spots should correspond to the elevated pathologic areas visualized before surgery at the slit lamp. Corneal epithelium and stroma ablate at slightly different rates, so one must be careful to pay special attention to the endpoint when epithelium and stroma are being ablated simultaneously.

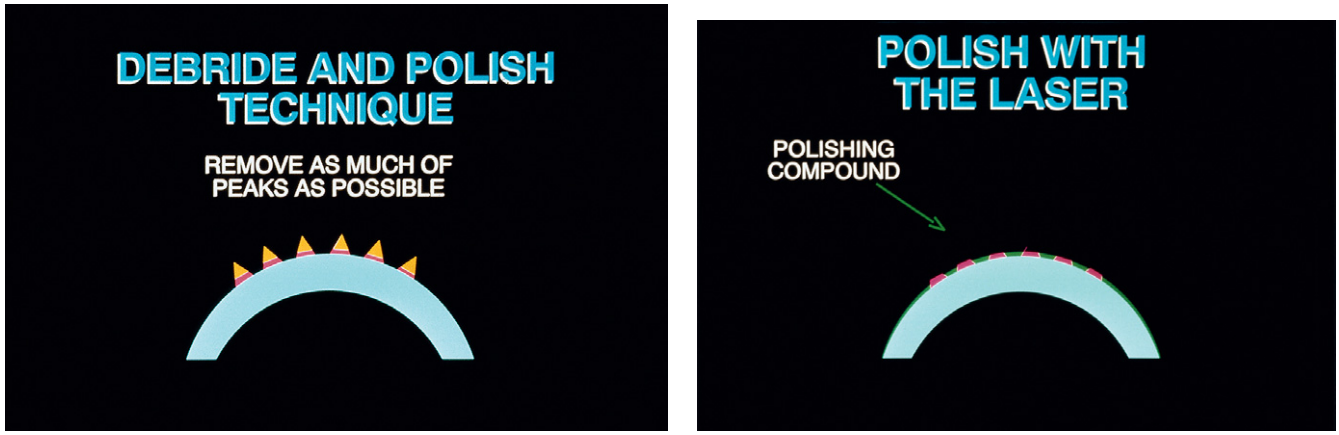
MECHANICAL REMOVAL OF PATHOLOGIC AREAS

One of the first mistakes made by early PTK surgeons in the clinical trials was to attempt removal of all pathologic areas with the excimer laser. Although the effect looked quite dramatic, the resultant surfaces were often not as smooth as desired, and excessive laser pulses resulted in thinner postoperative corneas and large hyperopic shifts. This PTK method has been termed the *point and shoot* method and has since been abandoned for more advanced techniques (Fig. 20.4).[5] The current recommended method is the *debride and polish* technique, which has proven quite effective (Fig. 20.5).[5] This technique uses mechanical keratectomy with the no. 64 Beaver blade to remove cleanly a corneal nodule or elevated corneal pathologic areas in which clear cleavage planes exist between it and the stromal lamellae. Surprisingly, dense and large pathologic areas can be removed manually, leaving a smoother underlying surface. Usually this tissue is subepithelial in nature, but occasionally anterior stromal lesions can be cleanly removed also. The excimer laser is then used as a final polishing tool to achieve as pristine a surface as possible (Fig. 20.6). Calcific band keratopathy should always be chelated with disodium ethylenediaminetetraacetic acid (EDTA) and scraped, leaving PTK to treat only the rough underlying exposed stroma. Finally, depressed corneal pathologic areas where there is absence of tissue are not improved with mechanical keratectomy and should be treated with laser only, with strong consideration given to using the transepithelial approach.

LASER ABLATION

Hand position

The surgeon's hands are positioned with the palms covering the patient's ears, the fingers relatively straight and in contact with the patient's cheeks, and the fingertips slightly bent around the angle of the mandible (Fig. 20.7). The surgeon may need to resist bending the fingers too much, as this may increase the patient's discomfort



A B

Figure 20.5. *A,* The debride portion of the 'debride and polish' technique involves removal of largely elevated pathologic areas manually with a blade. *B,* The final polish is performed with laser phototherapeutic keratectomy using a masking agent to aid in smoothing.

and cause the neck to stiffen. A relaxed grip will facilitate smooth movements of the patient's head.

Head movement

Appropriate movement of the patient's head will facilitate corneal polishing maneuvers with PTK. When head movement is desired, the surgeon should initiate head movement before depressing the foot pedal so that the desired degree of excursion is being attained *before* the photoablating begins. This familiarizes the patient with the concept of circular head movement while maintaining fixation on the green target light in the laser. Practice movement should always be conducted before initiating laser treatment.

Masking agents

In recurrent erosion cases, a masking agent is rarely used and the laser is applied directly to the affected Bowman's layer. For other

Figure 20.7. Photograph of proper surgeon hand placement for phototherapeutic keratectomy. Note thumbs on forehead and fingers lightly cupped on side of face and curved toward mandible.

cases, after mechanical removal of epithelium and any subepithelial scar tissue, the surgeon should assess the resulting corneal surface. If the surface is relatively smooth, the surgeon may then elect to proceed with PTK without a masking agent. In most cases, however, the resultant surface is sufficiently irregular to warrant further smoothing adjuncts such as masking agents. When an excimer laser beam encounters an irregular corneal surface profile, it will ablate and remove the corneal tissue, but the pattern of the irregularity is preserved and etched into deeper corneal layers (Fig. 20.8).[4] Masking agents are variable viscosity solutions of carboxymethylcellulose or similar substances that may be applied to an irregular corneal surface and act to regularize the 'peaks and valleys', so the excimer laser beam encounters a fairly smooth corneal surface. The masking agent will fill the corneal tissue valleys to the level of the tissue peaks. The excimer beam can then simultaneously ablate the corneal tissue peaks while the valleys are prevented from deepening.[4] The masking agents are typically used after corneal epithelial removal (Fig. 20.9).

Various masking agents tried over the years with varying degrees of success include Tears Natural II (Alcon Laboratories, Inc., Fort Worth, TX),[32] polyvinyl alcohol, 1% hydroxypropyl methylcellu-

lose,[33] Healon (AMO, Inc., Santa Ana, CA),[34] carboxymethycellulose, and Unisol.[32] The most common masking agent for PTK procedures is carboxymethylcellulose. A highly viscous agent does not cover uniformly and can become clumped during ablation. A low-viscosity solution tends to run off quickly or be knocked aside by the laser impact, thereby exposing both peaks and valleys.

The author prefers to use different viscosity solutions based on the task at hand. The surgical field has a triple-well container with three different concentrations of carboxymethylcellulose: 1.0% (Celluvisc), 2.0% (Goniosol), and balanced salt solution used to dilute the Celluvisc or Goniosol (Fig. 20.10).[4] A thicker masking agent is used initially to flatten highly elevated peaks. As the treatment continues and the surface becomes progressively smoother, the thinner agents are used. The carboxymethylcellulose 1% solution is the workhorse masking agent, because it is viscous enough to fill the corneal tissue valleys and remain, yet liquid enough to flow relatively easily. The masking agent is applied with a cellulose sponge dipped into the well like a paintbrush; the excess is removed with a dry sponge. As soon as the surgeon is satisfied with the smoothness of the confluent layer of masking agent, PTK commences. Short sessions of PTK ablation are interrupted by wiping the masking agent off and drying the corneal surface for close inspection. The entire process is repeated multiple times using decreasing viscosities until the surface is sufficiently smooth on final inspection. It is impossible to fill every valley and selectively ablate each and every corneal tissue peak, but with successive cycles of masking and photoablating, the opacity diminishes and the stromal tissue becomes more regular. With experience, the PTK surgeon acquires better judgment and 'touch'. For a typical single PTK treatment, the surgeon executes rapid, efficient sequences of masking agent application, cellulose sponge blotting, and excimer laser photoablation. Phototherapeutic keratectomy is an artistic procedure, and deciding how much to mask and which concentrations to use depends on the surgeon's judgment.

Laser treatment

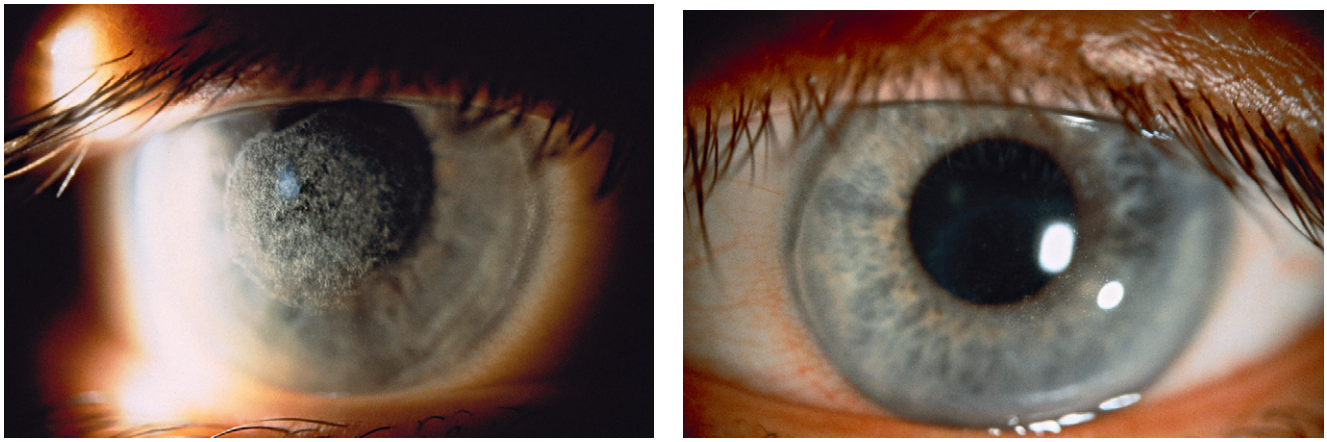
The laser aiming beams should be focused on the cornea before application of masking agents because the viscous fluid sometimes blurs the beam image. The aiming beam should then be focused more anteriorly to compensate for the thickness of the methylcellulose before commencing ablation. The laser is armed with from 25 to 100 pulses, and the optical zone diameter is selected, usually 5–6.5 mm.[4] With a masking agent in place, the author does not recommend applying more than 100 pulses before reassessing the confluency of the methylcellulose layer, the smoothness of the underlying corneal surface, and the need for an additional agent. The PTK pulses are applied while rotating the patient's head in a small circular motion to facilitate a polishing or 'spray painting' technique. The entire area of corneal epithelial debridement is treated with PTK, and the ablating area should overlap the undebrided epithelium by a small amount.

For the patient with corneal surface irregularity, the surgeon must rely on both visual and audible cues, termed the *sight and sound technique*, as PTK progresses.[4] Ablation on the masking agent will turn it blue/white as the excimer laser beam photoablates the carboxymethylcellulose, and this is accompanied by a rapid soft audible ticking sound. When the excimer beam contacts unprotected cornea, the fluorescence is a darker blue/purple and the sound changes to a louder snapping or popping sound. The corneal tissue appears as lakes of white-blue flashes interspersed with dark peaks of exposed corneal tissue. If the photoablation produces an entirely white-blue area without gaps, only the masking agent and no corneal tissue peaks are being photoablated. Ideally, the darker areas will correspond to the areas of elevation that were noted on the preoperative slit-lamp examination, signifying that these areas are successfully, selectively ablated. The force of the beam impact moves the masking agent and changes the sight and sound during ablation. If the patterns seen and heard deviate from what is expected based on the pathologic condition, the ablation should be stopped and the surface reassessed. The first set of pulses with masking agent produces the greatest masking agent flash, the quietest pop, and the least obvious smoothing effect because the corneal tissue peaks are narrow near the apex and the most viscous masking agent is used in the early stages of the operation. As the surface is polished, the less viscous agents applied in smaller amounts result in less flash, louder sound, and more rapid ablation of corneal tissue. Be careful not to induce an irregular corneal surface by ablating through clumped methylcellulose (this occurs if the masking agent is applied too thickly or if the surgeon fails to stop and reassess frequently).

The optical zone diameter can be incrementally increased or decreased by programming the desired value with each set of 25–100 pulses. The choice of optical zone diameter, when to increase it, the number of pulses within a set, and the total number of sets are determined by the surgeon with experience and are part of the art of PTK. Twenty-five to one hundred pulses per set before assessment of effect is a good, conservative benchmark for providing a demonstrable effect and forces frequent assessment of decreased opacification and increased smoothness, while minimizing the tendency to overtreat. After one or two short treatment sessions, the surgeon should consider taking the patient to the slit lamp for a more thorough assessment of the depth of treatment and of the remaining pathologic areas. Phototherapeutic keratectomy can be thought of as multiple small surgeries combined into one session. One should always be cognizant of the total number of pulses given and the depth achieved, because the laser ablates approximately 0.25 μm per pulse. The last set of pulses is usually performed at an optic zone diameter of 6 mm with wide rotational movement for a generalized polishing, nonrefractive effect.

Phototherapeutic keratectomy endpoint

The endpoint of the PTK session itself requires judgment. If the opacity is clear and the cornea is smooth, the session is finished. If the opacity is cleared and the cornea is slightly rough, a final polish with carboxymethylcellulose is often used. It may be impossible to



A B

Figure 20.11. *A,* Significant corneal opacification causing visual loss to 20/80 in this preoperative photograph of a patient with Schnyder crystalline dystrophy. *B,* Significant corneal clearing and improvement in vision to 20/25 in this 1-month postoperative phototherapeutic keratectomy photograph.

completely remove the opacity, but partial removal may be sufficient to improve the visual acuity markedly. Because the hydration state of the cornea is not as critical as with photorefractive keratectomy, the surgeon may move the patient between sessions of PTK to a slit lamp to judge the decrease in the opacity. The same principle applies with regard to titrating the final corneal smoothness; one should perform enough PTK until the best smoothing agent can provide the final uniformity restoration. The principal rule of PTK is that an undertreatment is better than overtreatment, an intuitively obvious concept that is easy to forget when one is actually treating the pathologic condition. An undertreated patient can return for additional treatment. With proper technique, the results can be rather dramatic, as demonstrated by the patient in Figure 20.11. Figure 20.12 demonstrates the smoothing ability of PTK in a patient with a visually significant pericentral corneal scar with severe irregular astigmatism. The application of mitomycin-C in concentrations of 0.02 or 0.002% for varying intervals from 10 to 120 s after the ablation may become a method to help minimize postoperative haze.

POSTOPERATIVE CARE

Simply stated, the postoperative care involves three phases:
1. Managing the epithelial defect and preventing infection;
2. Controlling wound healing to prevent scarring; and
3. Fine tuning refractive error.

The author's postoperative regimen after PTK includes immediate administration of a single drop of topical antibiotic (ofloxacin 0.3% or trimethoprim/polymyxin) and a topical nonsteroidal agent (diclofenac 0.5%). A disposable bandage soft contact lens is placed and the fit confirmed while the patient remains supine. Typically, a loose-fitting lens with a flat base curve (9.1 or 9.3) allows for tightening of the lens with hydration over the next few days. Oral pain medications such as meperidine 50 mg with promethazine 25 mg or Tylenol with codeine can be taken every 4–6 h as needed for pain, and the patient is cautioned to minimize activity.

The patient is seen on postoperative day 1 and every 2–3 days until the epithelial defect heals, at which time the bandage soft contact lens is removed. Recently, the author has removed the bandage lens at day 3 because lens tightening occurs and the relative hypoxia causes discomfort and delays re-epithelialization. Topical antibiotic is given four times daily along with the topical nonsteroidal agent until the epithelial defect heals. Patients are instructed to use diclofenac only as needed for pain because it has been shown to delay epithelialization. In the authors' experience, 70–80% of patients experience re-epithelialization by the third postoperative day, but this varies greatly depending on a host of factors, including the size of the original epithelial defect induced at the time of surgery. For patients with recurrent erosion whose PTK did not extend too deeply, no topical steroid is used because greater than trace reticular healing haze is rare. For patients with scars or deeper treatments, postoperative reticular haze is commonly seen and a course of topical fluorometholone 0.1% is prescribed, starting at four times daily and tapered according to need. Most patients experience complete epithelialization by 1 week after surgery, and the next follow-up should be at 1 month, with further visits at the surgeon's discretion. Final refractions are performed no earlier than the 1-month visit to allow for wound healing, stromal remodeling, changes in epithelial thickness, and astigmatism shifts, which all affect the final refractive result. If a patient has significant healing haze at the 1-month visit, final refraction should be delayed, because this is indicative of ongoing healing activity that will shift the refraction.

SIDE EFFECTS AND COMPLICATIONS

REFRACTIVE SHIFTS

The principal side effect of PTK appears to be a flattening of the central cornea with induced hyperopia of varying degrees.[35] Proper technique, an appropriate use of masking agents, and a conservative surgical mindset can minimize the amount of induced hyperopia. If the patients are well informed about the progression of hyperopia and accept the methods of treatment, such as contact lenses, then hyperopic patients can be good candidates as well. Conversely, excessive ablation of peripheral corneal pathologic areas can result in a myopic shift resulting from relative steepening of the central cornea induced by flattening of the periphery. If the surgeon realizes that undertreatment is better than overtreatment and that the cornea need not be completely clear or smooth on completion of PTK, this complication is alleviated to a large degree.

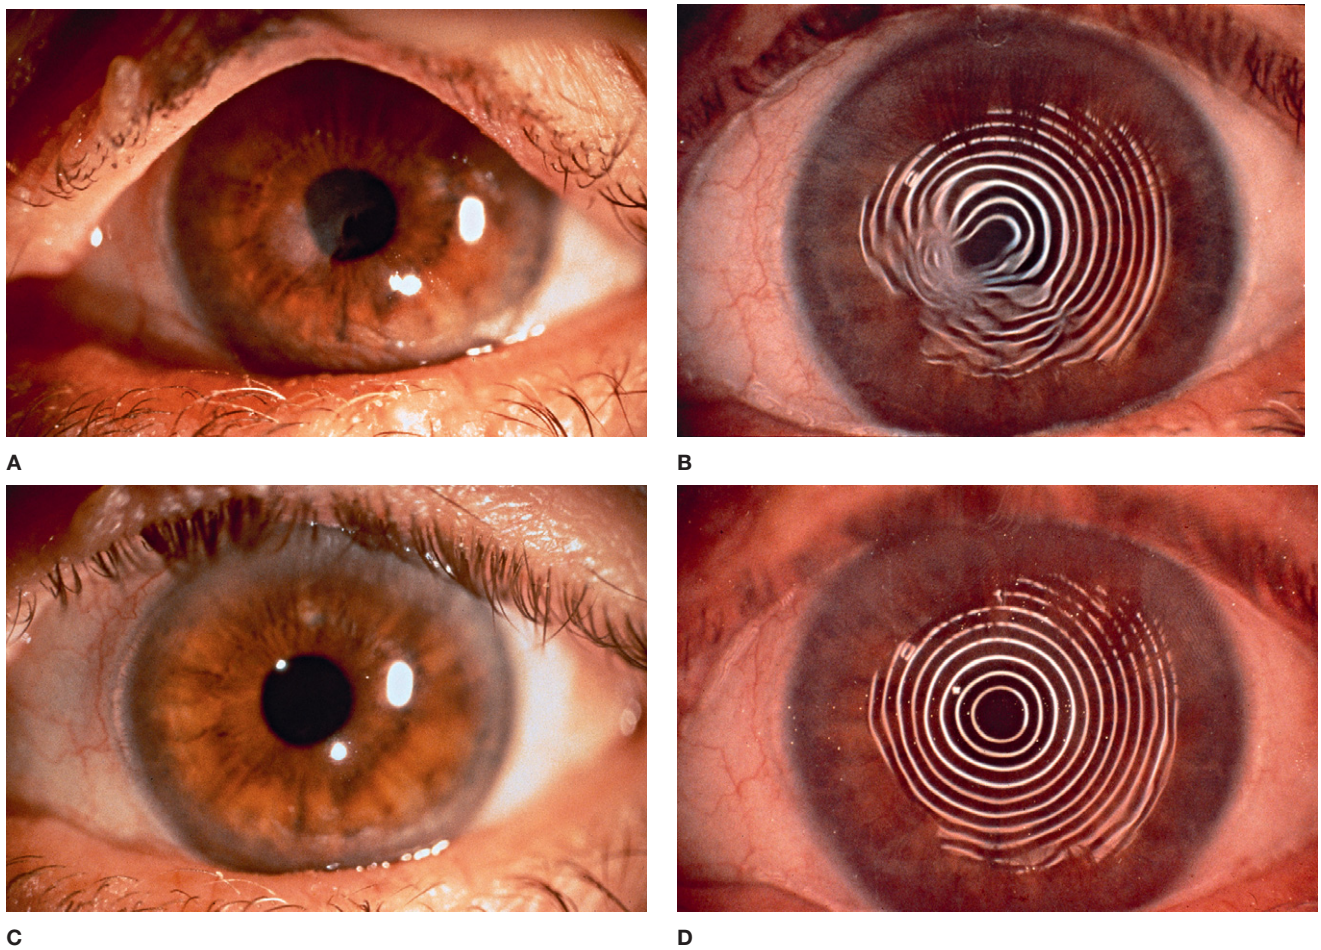


Figure 20.12. *A,* Photograph showing preoperative view of a visually significant pericentral anterior stromal corneal scar with best corrected acuity of 20/200. *B,* Preoperative corneascope shows impressive distortion of the surface profile. After phototherapeutic keratectomy there is dramatic clearing of the opacity *(C)* and improvement in the smoothness of the corneal surface *(D)* with enhanced best corrected vision to 20/30.

PAIN

Postoperative pain may be severe during the first 24–48 h but dissipates rapidly when the epithelium heals. During the clinical trials, only patching and oral pain medications were allowed after surgery; needless to say, postoperative pain was significant. Since PTK approval, good pain control has been achieved with the use of postoperative bandage soft contact lenses, diclofenac 0.5%, and oral meperidine 50 mg with promethazine 25 mg every 4–6 h. Most patients experience only burning and irritation rather than frank pain. Cycloplegics are of questionable value for patients with severe pain after PTK.

DELAYED EPITHELIALIZATION

Although most PTK patients experience complete re-epithelialization between days 3 and 7, delayed wound healing can occur. Chamon and coworkers[36] reported delayed epithelialization requiring 3–4 weeks for complete healing in two patients with morbidity factors such as Salzmann's nodular degeneration and significant alcohol intake. The patients who most commonly experience prolonged re-epithelialization are those with band keratopathy (PTK with mechanical superficial keratectomy and calcium EDTA chelation), severe dry eyes, and Salzmann's nodular degeneration. The routine use of bandage contact lenses has aided epithelialization in most cases, but lens hydration and tightening can occur in the first few postoperative days, which delays healing because of corneal hypoxia. Adjunctive therapy such as a temporary lateral tarsorraphy with or without inferior punctal occlusion (silicone plug or cautery) has been extremely beneficial in recalcitrant cases.

INFECTION

Postoperative infection is rare and occurs with the same frequency as in any eye with a large corneal abrasion. The author managed one pericentral staphylococcal ulcer at his center that responded to topical ofloxacin without adverse outcome. Infections can be prevented by treating adenexal infections such as blepharitis before surgery, using sterile operative technique, using postoperative antibiotics, and closely monitoring until complete re-epithelialization occurs. Although not a primary infection, reactivation of herpes simplex keratitis has been reported after PTK and steps to prevent recurrence should be undertaken.[37,38] Herpes simplex virus scars are a *relative* contraindication for PTK because the scars are flat or depressed and associated with tissue loss, which makes treatment difficult and can leave the patient with significant residual irregular astigmatism, large hyperopic shifts, or both. In addition, reactivation of HSV keratitis has been reported after PTK.[39,40] There has been

some success in treatment of herpetic corneal scars with PTK, but these patients must be well informed.[41] The author's recommendation is to pretreat HSV patients with oral antiviral agents (acyclovir 400–800 mg five times daily or famciclovir 500 mg thrice daily) for 2–4 weeks before surgery and for 4–12 weeks after surgery on a tapering dose. This regimen is similar to what the author uses in penetrating keratoplasties on HSV patients and to date has not seen any HSV recurrences with PTK.

STROMAL HAZE AND SCARRING

After PTK, most corneas are either clear or have trace to 1+ reticular haze that is not visually significant and clears within 3–6 months. Prompt treatment with topical steroids can minimize the severity and course of haze. Visually significant scarring as a result of PTK is rare. Significant residual scarring is more common when scars are too deep to ablate fully. Treatment depth should not exceed 160–170 µm, assuming an average central corneal thickness of 500 µm. A good rule of thumb in thinner corneas is to always leave *at least* 250 µm of corneal thickness after PTK; treatment deeper than that can result in significant scarring, instability, and possible ectasia over time. Patients with suboptimal visual function resulting from residual scarring or irregular astigmatism 3–6 months after full healing may benefit from either lamellar or penetrating keratoplasty.

CORNEAL GRAFT REJECTION

In some cases, patients who have had previous penetrating keratoplasty are candidates for PTK. This is most commonly seen when dystrophies recur after grafts. Caution is advised in this group because corneal graft rejection after PTK has been reported by both Hersh and coworkers[42] and Epstein and Robin.[43] As with any rejection episode, prompt aggressive immunosuppressive therapy can lead to successful reversal. Pretreatment with topical steroids may be prudent, but they should be discontinued after surgery until complete re-epithelialization occurs to avoid infection, delayed epithelial healing, or corneal melting. Corticosteroids should be restarted as soon as possible after re-epithelialization to prevent rejection. In addition, graft patients typically have more postoperative haze requiring steroid therapy for rapid resolution.

TREATMENT FAILURE AND NEED FOR SUBSEQUENT PENETRATING KERATOPLASTY

Phototherapeutic keratectomy was originally intended to obviate the need for keratoplasty in a certain number of patients, but it is not always successful. It is reasonable to attempt PTK in lieu of transplant if there is a reasonable chance for PTK success. Patients with corneal scars should be well informed before surgery of the possible need for subsequent keratoplasty, and this should not necessarily be viewed as a complication.

OUTCOMES

The author's site was one of the clinical investigative centers for Summit Technology's Food and Drug Administration clinical PTK trial involving 249 patients with variable pathologic conditions (Table 20.1). Good improvements in best corrected visual acuities (BCVAs) were achieved (Table 20.2 and Fig. 20.13). Most patients in the corneal opacity and irregular surface groups had substantial

Table 20.1 Corneal diseases treated with phototherapeutic keratectomy in the Summit technology clinical trial

Condition	Number of Procedures
Anterior basement membrane disease	13
Band keratopathy	24

[a] Improved or decreased represents at least one line of vision.

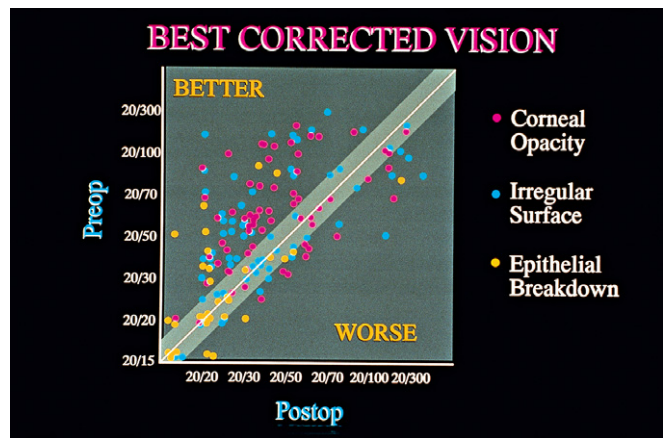

Figure 20.13. Scatter plot of patients gaining or losing vision as a result of phototherapeutic keratectomy in the Summit clinical trial.

improvement in acuity; unfortunately, there was also a loss of at least one line of vision in 18–22% of these patients. As anticipated, most patients in the recurrent erosion group (42%) had no change in vision, because the goal of surgery was to relieve pain rather than to improve vision. Corneal cylinder reductions are shown in Table 20.3.

The success of PTK is largely measured by improvement in BCVA. Maloney and coworkers[44] reported that 45% of their patients had an improvement in best corrected spectacle acuity at 12 and 24 months, whereas 9 and 8% of treated eyes lost two or more lines of vision at 12 months and 24 months, respectively. Sher and coworkers[45] reported similar results, with 48% of patients improving

Table 20.3 Comparison of preoperative and postoperative levels of astigmatism with phototherapeutic keratectomy for all three treatment groups in the summit clinical trial

Condition	Preoperative Average (D)	Postoperative Average (D)
Corneal opacity	–1.84	–1.69
Irregular surface	–2.33	–1.63
Epithelial breakdown	–0.98	–0.97

two or more lines of vision after PTK and 15% worsening two or more lines. Azar and coworkers[46] reported the average improvement in BCVA to be 1.8 lines; 10% of patients lost two or more lines of BCVA and 45% gained two or more lines. These results were confirmed in other studies as well.[36,38]

The outcome of PTK is also dependent on the underlying corneal pathologic condition. Maloney and coworkers[44] showed that treatment was most effective in eyes with hereditary corneal dystrophies, Salzmann's nodular degeneration and corneal scars. Eyes with calcific band keratopathy appeared to improve the least. This study confirmed the results of both Chamon and coworkers[36] and Campos and coworkers.[38] Reis-Bücklers' dystrophy has also been successfully treated with PTK.[47,48] Fagerholm and coworkers[49] successfully treated 37 of 37 patients with recurrent corneal erosions with no further recurrences reported at 1 year, and 28 of 30 patients with a history of a postinfectious corneal scar also had successful treatment outcomes.[19] Goldstein and coworkers[50] successfully treated two of three patients with corneal scarring from trachoma. Other studies, however, have not reported as much success with regard to treatment of corneal scars.[38] Dausch and coworkers[51] reported a 74% success rate in the treatment of recurrent corneal erosion with PTK. Cameron and coworkers[52] successfully treated three eyes with shield ulcers and corneal plaques secondary to vernal keratoconjunctivitis. In general, patients with more superficial corneal pathologic conditions (anterior 100 μm), regardless of the underlying cause, tend to have better outcomes after PTK. Those patients with deeper stromal involvement or calcific band keratopathy tend to have poorer visual outcomes.[36,38,44,45]

Changes in refractive error are common after PTK. Postoperative-induced hyperopia is directly related to the number of stromal pulses.[36,49] Maloney and coworkers[44] reported 41 and 48% of patients with a hyperopic shift of 1 D or more at 12 and 24 months, respectively. Previous studies have reported hyperopic shifts in 50–81% of treated eyes.[36,38,45] This finding is not surprising because removal of central corneal tissue during PTK lessens the corneal curvature. Treatment of deeper stromal lesions can be expected to produce more postoperative hyperopia. Astigmatism may change after PTK, with 30–50% of treated eyes developing an increase in astigmatism of 1 D or more.[38,44] Stability of both the mean refraction and the mean best spectacle corrected visual acuity has been shown to occur at the third postoperative month.[44]

FUTURE ADVANCES

The technique and understanding of the procedural nuances of PTK have come a long way since the inception of the clinical trials. Second- and third-generation lasers are equipped with devices such as joysticks and tracking systems that may improve technique and results, and future technologic advances may exponentially improve outcomes in the years to come.

Improvements in masking agents and techniques will be a key to better success in patients with corneal scars and irregular astigmatism. Work has already begun in at least three clinical centers on different variations of collagen-based masking agents.[53–55] A collagen polymer gel can be applied to a rough corneal surface, and a hard contact lens of a predetermined curvature can be placed on the gel. When the gel polymerizes to its more solid state, the contact lens is removed and the smooth curvature of the lens is transferred to the corneal surface. Because the gel is made of collagen similar to corneal collagen, theoretically it will ablate at the same rate as cornea, thereby leaving a perfectly smooth corneal surface of the same curvature as the lens. With this technique, there is potential to tailor the postoperative refractive effect based on the curve of the lens selected and the resulting keratometric profile.

21 Pterygium

Christopher Y. Chow, Steven P. Dunn, David G. Heidemann

INTRODUCTION

Pterygia are common fibrovascular lesions of the bulbar conjunctiva and cornea. Their triangular shape, reminding some of a bird wing, accounts for the name, which originates from the Greek word *pterygos*, meaning wing. Ancient medical texts dating back over 3000 years discuss the clinical presentation and treatment of pterygia. The passage of time has improved our understanding of their pathogenesis and treatment, but has not diminished their importance or, by best estimates, their frequency. They continue to be a source of local irritation, cosmetic aggravation, or visual loss from a patient perspective and, frequently, a source of frustration for the physician due to their proclivity to recur after removal.

CLINICAL APPEARANCE AND ANATOMY

Pterygia typically develop in the interpalpebral space, with a significantly greater number occurring medially than temporally. Those developing inferiorly and superiorly may be reactive in nature, overgrowing a previous area of limbal irritation or inflammation. Many are bilateral, although their rate of growth and central extent are often quite asymmetric. The degree of elevation varies considerably depending on the amount of fibrovascular proliferation. Cystic spaces are not uncommon and may occasionally account for relatively rapid enlargement of these lesions (Fig. 21.1).

Anatomically, the pterygium can be divided into different parts. The *body* extends from the limbus over the bulbar surface and often incorporates the semilunar fold and caruncle proximally when medially situated. The *neck* is the narrowed portion of tissue overlying the limbus and extending onto the peripheral cornea. The most central extension of fibrovascular tissue is the *head*. A white-gray avascular subepithelial 'cap' (Ilots of Fuch's, Fuch's Islands) is frequently present with a subtle red-brown iron line (Stocker line) occasionally being present along its central edge (Fig. 21.2). *Double pterygium* describes a situation in which there are two pterygia present in one eye, one nasally and one temporally (Fig. 21.3).

A *recurrent pterygium* is one that develops after removal of a true pterygium. It is often more adherent to the underlying limbus and anterior stroma (Fig. 21.4). The majority of recurrences develop within 6 months of the primary surgery and are more common in young patients, individuals who have had a high level of sunlight or ultraviolet exposure, and those who have had an aggressive, inflammatory growth pattern.[1,2]

Pseudopterygia are differentiated from true pterygia (as described above) by the former's lack of adherence to the limbus. Pseudopterygia bridge this area, allowing a muscle hook or similar instrument to be easily passed beneath it. Many of these result from limbal or corneal inflammation secondary to trauma or chemical insult (Fig. 21.5). Thinning beneath a pseudopterygium can present problems at surgery if not recognized or anticipated preoperatively.

PRESENTATION

The vast majority of pterygia develop gradually and quietly over an extended period of time. As a result, they do not attract much attention. The age of earliest development has not been studied; however, pterygia typically become clinically evident between the ages of 20 and 50 years. Pterygia are uncommon in children. While the majority of cases are sporadic, there have been a number of pedigrees reported in which the frequency suggests a hereditary factor.[3–5]

Most patients first notice their pterygia when looking in the mirror, although some are brought to their attention by friends or family. Occasionally, localized drying or surface irregularity may result in a foreign body sensation or focal injection. A small percentage of patients will present with complaints of blurred vision, which may be related to either overgrowth of the visual axis by the pterygium (advanced) or, more commonly, the development of secondary astigmatism. Since the astigmatism develops insidiously, it is usually attributed initially to normal refractive changes rather than to the progressing pterygium. The amount of astigmatism is related to the length, width, and elevation of the pterygium, with reports reaching as high as 9 D (Fig. 21.6).[6,7] Given the fact that most pterygia occur in the horizontal meridian, contraction of the fibrovascular tissue more commonly results in flattening between 3 and 9 o'clock and with-the-rule astigmatism. One study found that 61% of patients demonstrated with-the-rule

astigmatism, 31% against-the-rule astigmatism, and 8% no astigmatism.[8] The amount of astigmatism may be dynamic, varying with the field of gaze.[9] Surgical excision of the pterygium characteristically results in a dramatic reduction in secondary astigmatism when it is significant. Decreased contrast sensitivity and increased glare sensitivity may also be seen in pterygia patients.[10] Diplopia can occasionally develop with large or recurrent pterygia and may vary with eye position.

DIFFERENTIAL DIAGNOSIS

The characteristic appearance and presentation of most pterygia make this lesion reasonably easy to diagnose clinically. Pinguecula, Terrien's marginal degeneration, leukoplakia, papillomas, and conjunctival/corneal intraepithelial neoplasia may masquerade or accompany pterygia. Punctate staining with lissamine green or rose bengal, as well as the presence of a scalloped or fimbriated central edge, brings into question the true nature of any lesion. When there is doubt as to the diagnosis, an excisional biopsy is the wisest course.

PREVALENCE AND PATHOGENESIS

An extensive review of the world's literature shows considerable variation in published prevalence rates. Factors that influence these figures relate in large part to the characteristics of the particular population being evaluated, i.e. rural vs. urban, tropical vs. temperate climate, public vs. private hospital, or clinic-based vs. a general population sampling. Age-, lifestyle-, and gender-associated occupational roles in different cultures also influence these figures.

A significant relationship between cumulative sun exposure (an indirect measure of UV exposure) and age was noted in a study from rural Indonesia, which showed an overall prevalence rate of 10.0%, with the age group of 21–29 years having a prevalence of 2.9% as compared with 17.3% in the group of 50 years or older.[11] The Australian Blue Mountain Eye Study found an overall prevalence of 7.3%; 11% of men and 4.5% of women had pterygia. A population-based study in rural southern China showed a prevalence of 33.01% in individuals aged 50 years or older. In this cohort, there was a significantly higher prevalence in females (35.70%) than in males (29.70%).[12] A population-based study of residents of the Australian state of Victoria looked at clusters of patients from three settings: urban, nursing home, and rural. Pterygium was present in 1.2% of patients from the urban setting, 1.7% of the nursing home residents, and 6.7% of the rural residents.[13] The Barbados Eye Study looked at prevalence rates in a random sampling of 4700 patients aged 40–84 years. They found a prevalence rate of 23.4% in the island's black population, a prevalence of 23.7% in the mixed population, and 10.2% in the white population.[14] A West Malaysia study also found racial differences, with a greater prevalence in individuals of Chinese descent as compared to those of Malaysian and Indian descent.[15]

Despite the varying prevalence rates reported, a number of risk factors keep reoccurring in studies where multivariant analysis has been preformed.[11,12] These include occupation, particularly when involving extended periods of work outdoors and progressive age (cumulative sun exposure). Ultraviolet exposure seems to be a critical factor in these situations, with the prevalence of pterygia clearly being higher in regions that straddle the equator.[16,17] The question has been raised as to whether excessive sun exposure during certain periods of life (i.e. early childhood) has a disproportionate influence on the risk of subsequent pterygium development.[18] Risk factors that are less well substantiated

are the influence of race, dust/grit exposure, gender, smoking, and ethanol intake.

HISTOPATHOLOGY

Histopathologically, a primary pterygium involves the conjunctival and corneal epithelium, and their associated subepithelial layers. The epithelium undergoes changes characterized by acanthosis, parakeratosis, and hyperkeratosis.[19] The basal epithelium has a distorted orientation, and immunohistochemical staining has demonstrated alterations within the limbal basal stem cells.[20,21] Austin et al described the subepithelial changes as (1) hyalinization of the subepithelial connective tissue of the substantia propria, (2) diffuse or lobular collections of eosinophilic granular material with an associated increase in the number of fibroblasts and other cells, (3) an increased number of thickened and tortuous fibers that stain strongly with elastin stains immediately adjacent to and beneath the hyalinized region ('elastotic material'), and (4) concretions within the hyalinized and granular areas that may show either eosinophilia or basophilia.[22] A fibrovascular layer develops beneath the epithelium and is separated from the sclera and prevented from adhering to it by the presence of the episclera. Activated fibroblasts, mast cells, and lymphocytes are found within this layer in quantities significantly greater than in the normal conjunctival substantia propria. Extension of activated fibroblasts onto the cornea leads to fragmentation and destruction of Bowman's layer. In some cases, the superficial stroma immediately beneath the pterygium may also become involved.[23,24]

The term 'elastotic degeneration' is frequently used in association with pterygia. It was originally applied because fibrillary material within the specimens stained with Weigert's and Verhoff's elastic tissue stain. One unexplained finding was the observation that this material showed no evidence of elastolysis when incubated with the enzyme elastase.[25] Subsequent studies have indicated that this material is composed of newly synthesized elastic fiber precursors and immature or aberrant elastic fibers that are not cleaved by elastase.[21] Elastase only works on mature elastic fibers.[26] The origin of this material is still unclear; however, radiation-activated fibroblasts are known to produce elastic fiber precursors in the skin and may do the same in pterygium.[21]

The molecular composition of pterygium tissue and the immunologic significance of various findings have attracted increasing attention. The findings, however, have yet to be fully understood. Raman spectral analysis as well as immunohistochemistry have demonstrated the presence of increased elastoid fibers, lymphocytes, contractile myofibroblasts, and mast cells as compared with normal bulbar conjunctiva.[27] The detection of T-lymphocyte infiltration and ICAM-1 and HLA-DR expression in pterygium epithelium (typically absent in normal conjunctiva) strongly supports the suggestion that cellular immunity plays a role in pterygium formation. The level of HLA-DR expression appears related to the density of T4 cells, especially CD4 lymphocytes.[28,29]

Activated fibroblasts within the pterygium produce elevated MMP-1, MMP-2, and MMP-9 expression, which probably are the agents responsible for the dissolution of Bowman's layer. Overexpression of MMP-1 and MMP-3 in dermal fibroblasts has been linked with UV exposure and may play a similar role in pterygium.[30] The increased expression of insulin-like growth factor-binding protein mRNA and protein in pterygium fibroblasts is strong evidence to support the transformed phenotype of these cells and helps explain why there is increased growth of fibrovascular tissue.[31] Increased levels of VEGF in pterygium tissue, together with the abundance of von-Willebrand factor-stained new vessels, indicate activation of angiogenesis.[32] Understanding the role these molecules play may lead to novel therapies (i.e. MMP blocking agents and VEGF inhibitors) aimed at reducing the progressive nature of pterygia.

MANAGEMENT—MEDICAL

Treatment of a pterygium is determined by the amount of irritation or inflammation it induces, its effect on vision, its cosmetic appearance, and the actual or perceived threat of extension into the central cornea. Patient and physician factors influence how aggressively medical treatment is pursued and at what point surgery is advocated.

Irritation and inflammation, when not self-limiting, can often be treated with ocular lubricants or intermittent topical NSAIDs, cyclosporin, or steroids. The judicious use of topical vasoconstrictors may be helpful for patients who are bothered by occasional segmental hyperemia. Some patients experience recurrent episodes due to repeated exposure to environmental or work-associated stimuli. Reducing exposure by the use of a brimmed hat, UV-blocking sunglasses, or wrap-around moisture chamber glasses (i.e. 7 Eye®, Wiley X®, and Bugz®) may be helpful in some of these cases.

Glasses can be used to correct mild to moderate amounts of astigmatism. Rigid gas-permeable contact lenses are not very useful in the management of astigmatism in patients with pterygia because of lens decentration and edge-related mechanical irritation. Scleral lenses are a theoretical option, but one rarely pursued because of availability, cost, and handling difficulties.

MANAGEMENT—SURGICAL

INDICATIONS FOR SURGERY

Surgical intervention for pterygium is indicated in a number of circumstances. These include obstruction of vision secondary to encroachment of the pterygium into the visual axis, loss of vision secondary to induced irregular astigmatism, the threat of vision loss due to progressive growth of the pterygium toward the central cornea, restriction of ocular motility with secondary binocular diplopia, and atypical appearance of a pterygium suggestive of possible malignancy. Removal of the pterygium may also be warranted in cases of significant irritation, discomfort, and burning refractory to medical treatment if the symptoms are clearly thought to be related to the pterygium and not to other coincidental conditions such as blepharitis, dry eye, or allergic conjunctivitis. A pterygium that interferes with contact lens wear, cataract surgery, or corneal refractive surgery may also benefit from or require removal. Finally, patients often desire removal of pterygia for cosmetic reasons. This may be an acceptable indication for surgery following a careful discussion of benefits and risks, including the possibilities of postoperative redness, scarring, and recurrence of the pterygium.

SURGICAL MANAGEMENT OF PTERYGIUM

A number of techniques are available for surgical management of pterygia. All methods generally begin with excision and removal of the pterygium from the globe. These techniques then vary in their

handling of the conjunctival defect and in the adjunctive measures taken in an attempt to achieve a safe, cosmetically acceptable, and recurrence-free procedure. Unfortunately, even with the large number of treatment options developed over the centuries, none have completely satisfied that criteria. Even in the modern medical literature, attempts to ascertain the procedures most likely to result in an optimal outcome are hampered by a number of factors including limitations in study design, a range of geographic locations with differing levels of ultraviolet exposure, poorly described and dissimilar patient populations, variations in management technique, small patient numbers, limited durations of follow-up, and inconsistent definitions of recurrences.

Excision of pterygium

Historically, some surgical efforts attempted to redirect the head of the pterygium away from the cornea and into the adjacent inferior fornix, into the adjacent upper fornix, or into both fornices after splitting of the pterygium head.[33,34] These procedures resulted in poor cosmetic outcomes and high recurrence rates. As a result, the vast majority of modern surgical techniques involve excision of the pterygium head and body, rather than redirection. A description of the basic surgical approach for pterygium excision follows.

Topical and subconjunctival anesthesia may be adequate for excision of small pterygia with either the 'bare sclera' technique, where the conjunctival and corneal defects are left to re-epithelialize postoperatively without surgical closure, or a very simple closure. However, for the majority of procedures with extended conjunctival dissection, creation of conjunctival flaps, conjunctival autografting, or transplantation of an amniotic membrane, peri- or retrobulbar anesthesia will allow for more careful dissection, better control of globe positioning, better hemostasis, more precise suturing and closure, etc.

Once adequate anesthesia is obtained, a lid speculum is utilized for optimal exposure of the globe. Traction sutures are placed superiorly and inferiorly either in the peripheral cornea or in the anterior sclera to facilitate positioning of the globe. Several drops of 1:1000 epinephrine or 2.5% phenylephrine may be topically applied to the pterygium to aid in hemostasis. The conjunctival aspect of the pterygium may be marked with gentian violet to guide excision. Most surgeons remove the head of the pterygium first, usually beginning at the apex. This may be performed by lifting the head of the pterygium with fine forceps and then dissecting the pterygium off the underlying corneal stroma with a sharp, rounded blade. Alternatively, techniques have been described in which the pterygium head is avulsed from the cornea by passing a suture, a pair of forceps, or a scissor underneath and through the neck of the pterygium to then shear the pterygium head off the cornea.[35,36] With any method, it is important to excise the soft tissue of the pterygium only and to avoid dissection into the corneal stroma as much as possible.

After excision of the pterygium head, the body of the pterygium can be excised with Wescott scissors following the previously placed gentian violet marks. Some surgeons advocate a subconjunctival injection of balanced salt solution to balloon the conjunctiva for easier excision. Anteriorly, underlying Tenon's capsule and episclera are dissected and removed down to bare sclera. With certain pterygia, these tissues may be quite thick and vascular. More posteriorly, care must be taken to avoid injury to the underlying rectus muscle which may be difficult to identify, particularly if there is significant fibrovascular scarring as is often the case with recurrent pterygia. Bleeding may be profuse, and hemostasis is obtained with wet-field cautery as necessary. The cornea, limbus, and exposed sclera are then smoothed by scraping with the edge of a blade or by polishing with a diamond-dusted burr. Again, care should be taken during this step to avoid excessive removal of corneal stroma or scleral tissue.

Bare sclera technique

The simplest method for managing the bulbar conjunctival/scleral defect after excision of a pterygium is to let the surrounding conjunctiva migrate over the area of exposed sclera on its own, hence the name 'bare sclera' technique. This is the quickest option for completing the surgery, the one most amenable to in-office surgery with topical or subconjunctival anesthesia and a method that can be completed without an operating microscope. For a period of time, this was a popular technique for pterygium surgery. However, a number of studies have shown high recurrence rates with the bare sclera technique, with one study that combined bare sclera excision with excimer laser smoothing of the corneal surface having a recurrence rate of 91%.[37,38] Meta-analysis found that the odds of recurrence with the bare sclera technique are six times higher than that for conjunctival autografting and 25 times higher than that for adjunctive mitomycin C, both of which are discussed below.[39] Many recurrences with the bare sclera technique are rapidly progressive and significantly inflamed and can result in a larger pterygium than the primary one. Consequently, it is preferable to attempt to reduce the risk of recurrence by performing some type of closure over the bared sclera or including an adjunct such as mitomycin C or beta irradiation. A number of investigators have utilized combinations of more than one type of closure or adjunct.

Simple conjunctival closure

This technique involves suturing the superior and inferior cut conjunctival edges together to close the scleral defect following pterygium excision. Undermining of the bulbar conjunctiva adjacent to the defect is required to facilitate closure. While this may be an acceptable procedure for smaller primary pterygia, caution must be exercised in attempting simple conjunctival closure with larger pterygia. If the pterygium body is entirely excised resulting in a large initial conjunctival defect, attempted closure may result in forniceal foreshortening or increased likelihood of wound dehiscence due to the tension required to bring the cut conjunctival edges together. Alternatively, to allow for closure of the conjunctival defect from a large pterygium, a portion of its body may have to be left behind. In either case, the chances of increased postoperative inflammation, scarring, granuloma formation, and recurrence of the pterygium would be higher. There are few published reports discussing simple conjunctival closure after pterygium excision. The published results of this technique in these few studies have been variable, with recurrence rates ranging from 2 to 88%.[40,41]

Conjunctival flaps

Conjunctival flaps have been employed to close the pterygium site for decades. These have most commonly been sliding, rotational, or pedicle-type flaps. The use of a conjunctival 'z-plasty,' where normal conjunctiva is rotated into a limbal position while the pterygium body is rotated toward the bulbar conjunctiva, has been described.[42] The reported recurrence rates following various conjunctival flap procedures have ranged from 1 to 5%.[37] Two relatively large series utilized a sliding conjunctival flap with recurrence rates of 3.2% in 258 eyes[43] and 1.6% in 913 patients.[44]

Conjunctival grafts

The technique of conjunctival autografting involves closure of the conjunctival defect following pterygium excision with a free conjunctival graft harvested from another area of the globe. This technique has been popular due to a relatively low recurrence rate and general lack of sight-threatening complications. Conjunctival autografting also has the advantages of a more normal anatomic and physiologic reconstruction of the surgical area and potentially a better cosmetic result than other surgical methods (Fig. 21.7). Disadvantages of this technique include greater disruption to the ocular surface, prolonged surgical time, and increased patient discomfort.

The basic procedure for conjunctival autograft transplantation was introduced by Kenyon et al in 1985.[45] With this technique, the head and body of the pterygium are excised as described previously. The posterior cut conjunctival edges may be partially closed. The residual conjunctival defect is then measured with calipers. The traction sutures are used to rotate the globe downward to expose the superotemporal bulbar conjunctiva. Gentian violet is used to outline the conjunctiva to be harvested according to the previous measurements and general shape of the surgical defect. The limbal edge of the graft should be denoted with specific marks so that this edge can be subsequently easily identified. The conjunctival autograft is then harvested by undermining and careful dissection with blunt Wescott scissors. Better results are achieved by removing only a thin layer of tissue and leaving Tenon's capsule behind. This step may be aided by ballooning of the conjunctiva with a subconjunctival injection of balanced salt saline. The eye is then rotated with the traction sutures to expose the area of the pterygium excision. The free conjunctival autograft is then positioned over the area of bare sclera, being careful to maintain the limbus-to-limbus and epithelial-side-up orientations. The autograft is then sutured to the underlying sclera at the limbus and to the cut conjunctival edges with 10-0 nylon and/or 8-0 or 9-0 Vicryl sutures. In general, the graft harvest site does not require closure and will re-epithelialize on its own. Postoperatively, topical steroids and antibiotics are employed, initially at a rate of 4–8 times a day, and tapering over 4–8 weeks depending on the degree of inflammation and postoperative course.

Recently, fibrin tissue adhesive has been utilized as an alternative to sutures to secure the conjunctival graft. The use of fibrin glue has been reported to result in reduced surgical time and better postoperative patient comfort with comparable recurrence rates to sutured conjunctival autografts (Fig. 21.8).[46,47]

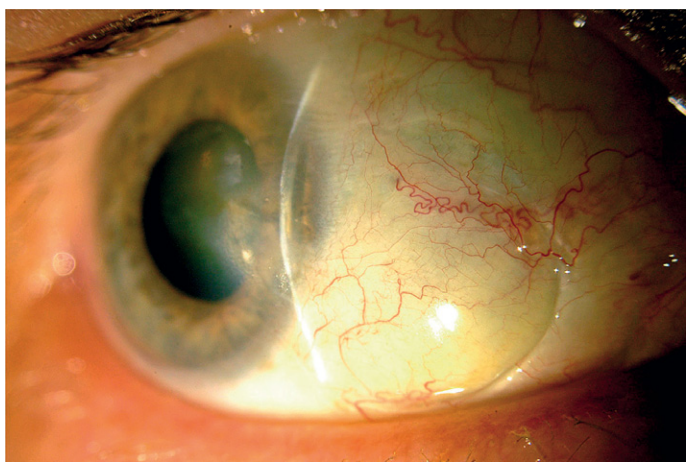

Figure 21.7. Appearance of well-healed conjunctival autograft.

Kenyon et al reported a recurrence rate of 5.3% after 57 conjunctival autograft procedures in their original publication.[45] While the majority of subsequent papers have found recurrence rates of under 10%,[48,49] several reported higher rates, even for primary lesions.[50,51]

Some investigators have emphasized the importance of including limbal tissue in the conjunctival autograft. It has been postulated that a pterygium represents a local stem cell deficiency and that the transplantation of healthy limbal tissue with corneal epithelial stem cells could act as a barrier, preventing recurrence. The technique of transplanting a limbal-conjunctival autograft is similar to that for the conjunctival autograft, except that the graft includes limbal epithelium with or without 0.5 mm of peripheral lamellar superficial cornea. Limbal-conjunctival autografts have had low, but variable, recurrence rates for primary and recurrent pterygia ranging up to 14.6%.[52–54] One report found that this technique may be superior to conjunctival autografting without limbal tissue in cases of recurrent pterygia.[52] Limbal allografts, as opposed to autografts without inclusion of limbal tissue, have also been successfully utilized for treatment of recurrent pterygia.[55] This method, however, requires donor tissue and introduces the potential complication of graft rejection.

Other variations on conjunctival autografts have included harvesting of the autograft from the inferior bulbar conjunctiva[56] and rotational autografts.[57]

Amniotic membrane transplantation

The amniotic membrane is the thin, innermost layer of the placenta. It is comprised of an avascular stroma and a basement membrane. Amniotic membrane components have been demonstrated to have anti-inflammatory and antifibroblastic activity, properties that make it a suitable, and perhaps excellent, tissue for use in pterygium surgery. In addition, it contains growth factors, has antimicrobial properties, is nonimmunogenic, and is readily available. Amniotic membrane is available commercially as both frozen and dehydrated lyophilized tissue.

Amniotic membrane may be used in a manner similar to that of a conjunctival graft. It is generally placed on the ocular surface with the stromal side down and the basement membrane side up. The stromal surface can be identified by a 'sticky' interaction when contacted by a surgical sponge. The amniotic membrane transplant can be cut and shaped as needed and then sutured to the sclera, conjunctiva, and cornea with 10-0 nylon or with 8-0 or 9-0 Vicryl sutures. Amniotic membrane transplantation may be especially useful when it would be difficult to harvest enough conjunctival autograft tissue to close the scleral defect such as in cases of very large or double pterygia. Amniotic membrane can also be utilized to spare the superior bulbar conjunctiva for possible future trabeculectomy or implant surgery in glaucoma patients.

In the modern era of pterygium surgery, Prabhasawat et al first reported on the use of human amniotic membrane grafts.[48] They found a recurrence rate of 10.9% with amniotic membrane transplantation following surgery for primary pterygia. Other studies have found recurrence rates of 3.8–15.4% for primary growths.[49,58] Prabhasawat et al found a much higher recurrence rate of 37.5% for amniotic membrane transplantation when utilized for recurrent pterygia, more than four times their recurrence rate for conjunctival autografts of 9.1%. For recurrent pterygia, others have combined amniotic membrane transplantation with a limbal autograft[59] and

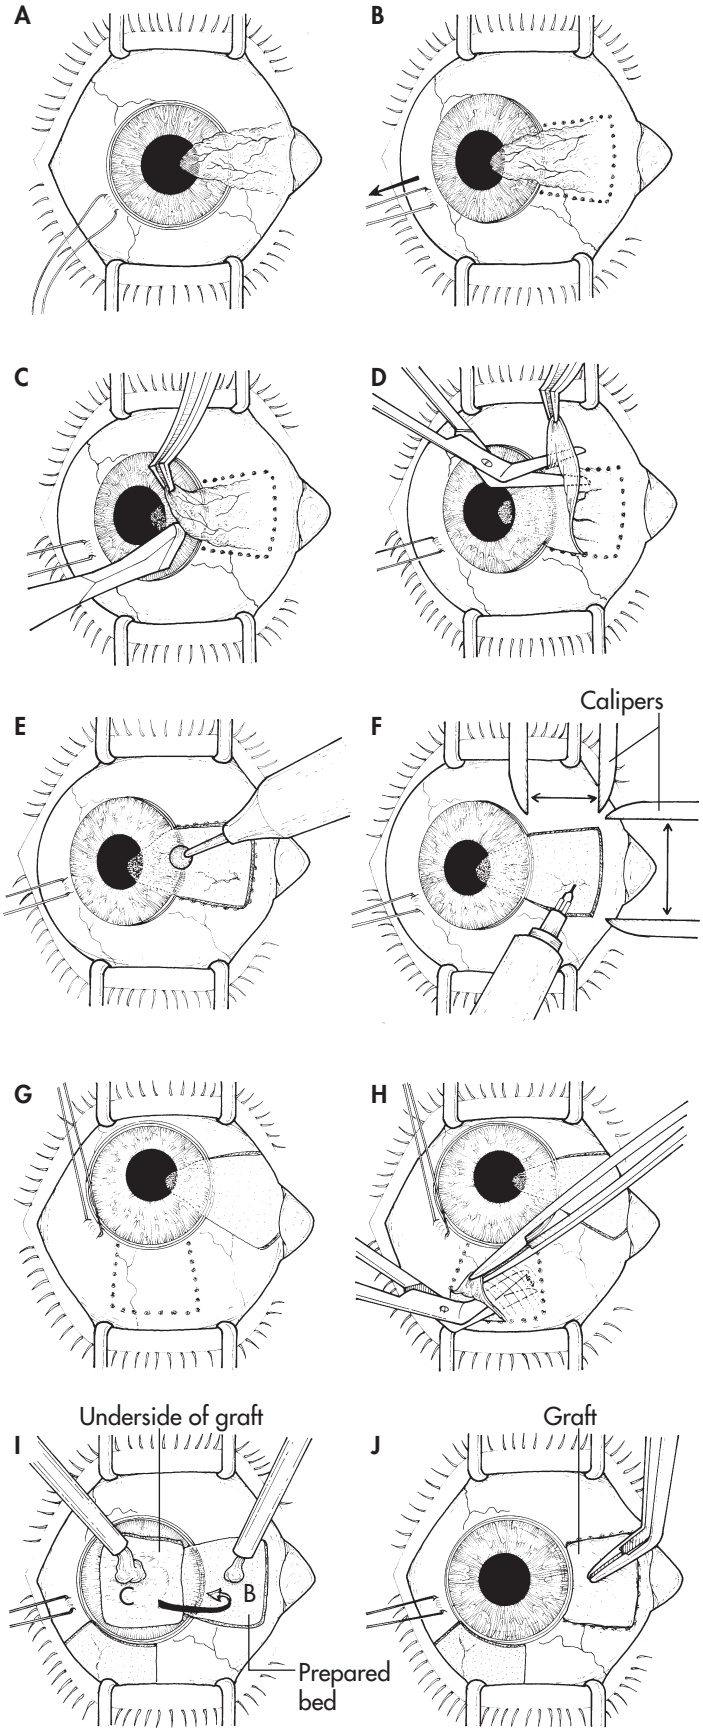

Figure 21.8. Pterygium surgery—basic technique. (*A*) A traction suture is placed at 2 o'clock and the eye is rotated temporally (*B*). The margins of the pterygium are marked off. (*C*) A superficial keratectomy using a 57 Beaver blade or similar is performed starting central to the 'cap' and working peripherally to the limbal region. (*D*) The body of the pterygium is undermined with scissors and the pterygium is excised along the previously placed marks (*B*). (*E*) A diamond burr or rounded microblade is used to smooth the corneal and limbal area if rough or irregular. (*F*) Excess episcleral tissue is removed from along the cut edge of the conjunctiva. Cautery is used to establish hemostasis. The conjunctival defect is measured. (*G*) The eye is rotated downward using the traction suture and the measurements transferred onto the superior bulbar surface. (*H*) The autograft is harvested by careful removal of the conjunctival epithelium. Injecting saline with epinephrine beneath the epithelium can be helpful. (*I*) Flip the autograft over onto the cornea: apply one part (usually the thicker, fibrin component) to the inner surface of the autograft and the second part (usually the thinner component) to the exposed sclera medially. (*J*) Mate the two surfaces, smooth out the conjunctival layer, and allow the two to set.

also with both a limbal allograft and an intraoperative mitomycin C[55] with no recurrences in those series.

Ang and colleagues recently reported on the use of ex vivo cultured autologous conjunctival epithelial sheets grown on amniotic membrane for transplantation following pterygium excision.[60] This technique resulted in faster epithelialization and more rapid healing and resolution of inflammation compared to transplantation of amniotic membrane alone. However, this procedure requires a conjunctival biopsy several weeks prior to surgery and also calls for tissue culture facilities and techniques that are probably not readily available to the vast majority of ophthalmic surgeons.

In addition to conjunctiva and amniotic membrane, investigators have reported on the utilization of mucous membranes, split thickness skin, and processed pericardium to close scleral defects following pterygium excision.[61–63]

Lamellar keratoplasty

Recurrent pterygia with significant underlying corneal thinning from previous surgery may necessitate lamellar keratoplasty to improve and restore the structural integrity of the cornea and globe. Some have also suggested that lamellar keratoplasty itself may aid in prevention of pterygium recurrence.[64] The results with various lamellar keratoplasty techniques have varied widely, with recurrence rates ranging from 0 to 100%.[65–67] Disadvantages of lamellar keratoplasty include increased difficulty of surgery, prolonged surgical time, and the requirement for donor tissue. It is now generally employed only in cases where augmentation or restoration of corneal or globe integrity is essential.

Surgical complications

Complications during or following pterygium surgery are not common and are generally not sight or globe threatening. Intraoperative complications include perforation of the cornea or sclera with the traction sutures, excessive removal of corneal stromal tissue, perforation when removing recurrent pterygia if there is marked or unrecognized underlying thinning, improper orientation of a transplanted conjunctival graft or amniotic membrane, excessive bleeding, and injury to an underlying rectus muscle. In general, these complications can be prevented with careful preparation and meticulous surgical technique.

When discussing postoperative complications of pterygium surgery, one must always begin with recurrence of the pterygium, a frequent source of frustration for both the patient and the surgeon. The majority of recurrences will be relatively small and quiet. However, at times the recurrence can be far more aggressive and rapidly progressive, resulting in a recurrent pterygium which may be more inflamed, larger, and thicker than the primary one. Surgery for recurrent pterygia may be difficult, potentially complicated by profuse bleeding, corneal thinning, scarring, fornix loss and symblepharon formation, and injury to the rectus muscles. The majority of recurrences appear in the first year following surgery.[68,69] Risk factors for recurrences may include younger patients[41] and pterygium morphology which includes loss of transparency and fleshiness.[70] The level of surgeon experience and skill also has an impact on recurrence rates.[69]

Other postoperative complications include wound dehiscences, graft chemosis, dellen formation, persistent epithelial defects, formation of conjunctival granulomas or epithelial inclusion cysts, astigmatism, forniceal foreshortening and symblepharon formation, ptosis, poor cosmesis and scarring and subconjunctival fibrosis involving a rectus muscle that restricts eye movement. Scleral necrosis has been reported following all types of pterygium surgery, with rates being higher following use of certain adjuncts as discussed in the following sections.[71]

Adjunctive therapy

A number of adjuncts have been developed for pterygium surgery in an effort to reduce the incidence of recurrences. The most commonly used adjunctive therapies have included radiation and various chemotherapies. These may have a role, particularly in cases of recurrent pterygia where significant inflammation and increased risk of yet another recurrence may be anticipated.

Radiation therapy

Numerous investigators have looked at the use of beta irradiation after bare sclera removal of a pterygium. The most common agent used is strontium-90. Beta irradiation works to reduce recurrence rates by inhibition of mitosis in rapidly dividing cells such as fibroblasts and vascular endothelial cells. Use of this type of radiation is advantageous because the energy is delivered in a depth-dose pattern, as the delivered dose drops to 19% at 2 mm tissue depth and 1% at 5 mm tissue depth.[72] This is important in limiting radiation delivered to deeper structures, such as the crystalline lens.

There is currently no consensus as to the total dosage required and the need for fractionation. Most recent protocols involve a dose between 1000 and 3000 rad, which have been given either as a single intraoperative dose or in fractionated doses over several weeks. If radiation therapy is to become a commonly used adjunct, it would seem that delivery at the time of surgery would permit the best control of treatment and the least inconvenience for the patient.

Recurrence rates following pterygium excision with adjunctive beta irradiation have varied widely. Studies involving radiotherapy have been many, more than 50 since the mid-1900s, and have been difficult to compare due to differences in dosage and delivery regimens, as well as variations in study populations and duration of follow-up. The recurrence rate is most commonly in the 5–13% range for primary pterygia, and there have been reports that demonstrate reduced recurrence rates in irradiated patients compared to nonirradiated controls.[73–76]

While the recurrence rates with the use of radiation therapy are low, there remains significant concern over potential complications. It is well known that radiation therapy leads to cataract formation in a dose-dependent manner. Other complications include keratoconjunctivitis sicca, corneal ulceration, symblepharon formation, ptosis, episcleritis, and iritis. Of greatest concern is the incidence of corneal and scleral necrosis (Fig. 21.9), which may become secondarily infected and lead to frank endophthalmitis. This incidence is not trivial as, in one study involving 63 eyes which had received a radiation dose of 750–5200 rads (mean 3475 rads), 51 (81%) developed scleral ulceration and 4 (6.4%) developed *Pseudomonas endophthalmitis*.[77] Because many of the complications developing following radiation therapy have a delayed onset, averaging 14.45 years in one study,[78] any report looking at this procedure would ideally include 15 or 20 years of follow-up. A report with less than this duration of follow-up could under-report the true complication rate. With the published rates of potential late, serious complications, this procedure, as we know it now, may be difficult to justify for a disease such as a pterygium.

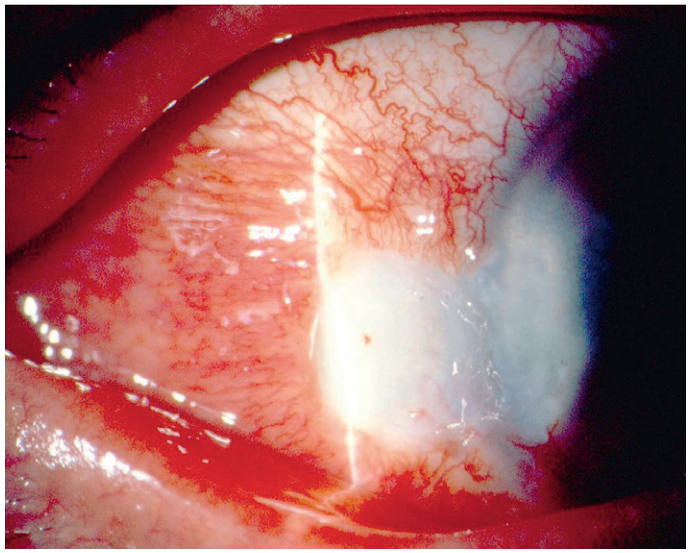

Figure 21.9. Scleral melt following pterygium surgery.

Chemotherapy

Thiotepa

Thiotepa is an alkylating agent that interferes with mitosis in rapidly proliferating tissues. It is believed to reduce pterygium recurrence by inhibiting vascular endothelial proliferation. Its first use in pterygium surgery was reported in 1962 by Meacham.[79] This agent is most commonly used at a dilution of 1:2000 or 1:5000, which the patient administers topically every 3 h for 6–8 weeks following bare scleral excision of a pterygium. The recurrence rates reported in a number of studies, primarily from the 1960s and 1970s, were quite good, ranging from 0 to 16%.[80] Several studies demonstrated significant reductions in the rate of recurrence in thiotepa-treated patients when compared to that in a control group.[81,82] Use of this agent, however, has been limited by side effects, primarily poliosis and permanent periorbital skin depigmentation, especially in darkly pigmented patients.[83] Other complications have included allergic reactions, conjunctival pigment deposition, chronic conjunctivitis, and scleral ulceration.

Mitomycin C

Mitomycin C is an antibiotic that has antineoplastic and antimetabolite properties. Mitomycin C inhibits DNA replication, having the greatest antiproliferative effect on cells with the highest rate of mitosis. In pterygium surgery, as in glaucoma-filtering surgery, it is thought to aid in the procedure by inhibiting episcleral fibroblast proliferation, reducing fibrovascular regrowth and scarring. It was first described as an adjunct for pterygium surgery in 1963 by Kunimoto and Mori in Japan.[84] Since that time, and especially in the last several decades, there has been great interest in the use of this agent. While there have been reports of injection of mitomycin C into the pterygium 1 month before surgical excision,[85,86] the majority of studies have utilized this agent postoperatively or intraoperatively.

Postoperative use of mitomycin C has been reported for both primary and recurrent pterygium. Typically, a dose of 0.4 or 0.2 mg/mL is applied topically two to four times a day for 4 days to 2 weeks after surgery. The majority of studies have demonstrated the effectiveness of mitomycin C in the reduction of the recurrence rate. Singh et al treated patients with 1.0 mg/mL mitomycin C eyedrops, 0.4 mg/mL mitomycin C eyedrops, and placebo four times daily for 2 weeks following excisional surgery. The recurrence rate after 5 months was 2.3% in the 44 patients in the mitomycin groups and 89% in the placebo group.[87] Another study utilized 0.2 mg/mL mitomycin C drops bid for 5 days postoperatively and found a recurrence rate of 9.4% compared to 25.9% in a group that had undergone conjunctival autografting.[88] These rates have been thought to be somewhat better than those with radiation therapy and comparable to conjunctival autografting.[89]

Although postoperative use of mitomycin C has been described as a safe adjunct,[90] other reports have been published that raise concerns as to the potential risks of this therapy. Complications reported include wound dehiscence, secondary glaucoma, corneal edema, corneal ulceration and perforation, scleral ulceration, necrotizing scleritis, iritis, sudden-onset mature cataract, scleral calcification, photophobia, and pain. Rubinfeld found a high incidence of serious complications in patients who had associated ocular surface disease and suggested that topical mitomycin is contraindicated in patients with dry eyes, blepharitis, atopic keratoconjunctivitis, and herpes keratitis.[91] Hayasaka et al reported four cases of scleral ulceration with calcific plaque formation, which occurred between 18 and 25 years after the use of topical mitomycin drops following simple pterygium excision.[92] Those patients required scleral patch grafting. One additional concern with mitomycin C utilized in a topical postoperative fashion is the potential for prolonged use or misuse by patients, which may lead to a greater incidence of complications. As was the case with radiation therapy, additional long-term studies are needed to determine the true complication rate and safety profile with the use of adjunctive mitomycin C.

Mitomycin C has also been utilized as an intraoperative application during pterygium surgery. This method of use has been employed as an attempt to decrease ocular morbidity and to eliminate the potential for patient noncompliance. Many surgeons are comfortable with this technique, as mitomycin C is now routinely used intraoperatively during glaucoma-filtering surgery. Although the published reports utilize a wide range of treatment protocols, intraoperative application of mitomycin C appears to be an effective adjunct for pterygium surgery. The majority of studies have utilized concentrations of 0.2 or 0.4 mg/mL applied directly to the exposed bare sclera for 2–5 min following pterygium excision. Recurrence rates using intraoperative mitomycin have been comparable to those using postoperative mitomycin drops, generally under 10% for primary pterygia and under 20% for recurrent pterygia.[93,94] One study did compare three groups, conjunctival autografting, postoperative mitomycin C (0.2 mg/mL q.i.d. for 1 week), and intraoperative mitomycin C (0.4 mg/mL for 3 min), and found recurrence rates of 22.2, 21.1, and 10.5%, respectively.[95] Recurrence rates may be somewhat lower for recurrent pterygia with intraoperative mitomycin than with limbal-conjunctival autografts.[53] Another study compared the use of intraoperative mitomycin C plus a conjunctival autograft with the bare sclera technique alone, with adjunctive mitomycin C alone, and with a conjunctival autograft alone. This report found the combined technique to be the best in preventing recurrence with no recurrences in 30 patients compared to 14 out of 30 (46.6%) for the bare sclera group, 2 out of 30 (6.6%) in the mitomycin C alone group, and 4 out of 30 (13.3%) in the conjunctival autograft alone group.[96]

Reported complications following intraoperative use of topical mitomycin C include scleral melting, corneal thinning and perfora-

tion, punctate keratitis, and subjective complaints of pain and photophobia. Three patients with scleral or limbal melting following pterygium surgery with intraoperative mitomycin C 0.02% for 3 min, each ultimately requiring tectonic corneal or conjunctival grafting, have been reported.[97] Lower concentrations of mitomycin C may reduce the rate of complications. Others have looked at mitomycin C application times as short as 30 s.[94] Finally, most surgeons now routinely close the scleral defect with conjunctiva following application of mitomycin C to reduce the rate of complications.[98–100] Certainly, additional long-term studies are necessary to establish the complication rate and safety of intraoperative mitomycin C. Patients undergoing adjunctive mitomycin C for their pterygium surgery should be carefully screened and monitored long term.

5-Fluorouracil

A few investigators have also utilized 5-fluorouracil (5-FU), another antifibrotic agent that inhibits DNA synthesis, as a surgical adjunct. One initial study found it to be ineffective when applied intraoperatively at 10 mg/mL for 5 min with a bare sclera technique.[101] The recurrence rate in that series was 60%. A pilot study looked at utilizing 5-FU injections directly into the head of early pterygium recurrences and found that the recurrence process was arrested in five out of six patients.[102] A subsequent study included 39 patients who received intralesional injections of 5-FU for impending recurrent pterygia (fibrovascular tissue in the area of recent pterygium surgery without corneal involvement) and found that this intervention reduced the rate of actual recurrence to 7.7% compared to 31.4% in the control group.[103] 5-Fluorouracil has also been employed as a 3-min intraoperative application with pterygium surgery in 28 patients with a 25% recurrence rate.[104] The results in these few studies suggest that further investigation of the role of 5-FU in pterygium patients may be warranted.

CONCLUSION

Pterygia are common lesions that can be a source of patient complaints, and ocular and visual morbidity. Our understanding of their etiology and pathogenesis has improved in the last few decades. An array of options exists for the management of pterygia. Despite this, the ideal and perfect method, one that is easy to perform, results in a good cosmetic outcome, and is risk free and recurrence free, has yet to be established. Our present options are good and consist primarily of surgical excision with conjunctival flap or autograft closure of the surgical defect. Amniotic membrane grafts or adjunctive mitomycin C may be utilized in certain carefully selected cases. As our understanding of the etiology and pathophysiology of pterygia and their recurrence process advances, refinements to present techniques and novel techniques will emerge to further our ability to manage these lesions successfully.

22 Tissue adhesives

Erich H.P. Braun

INTRODUCTION

The use of tissue adhesives in ocular surgery was first reported in 1963 by Refojo et al and Webster et al for the management of corneal perforations.[1,2] Since then cyanoacrylate-based adhesives have become a standard adjunctive therapy for anterior segment surgery and treatment. Over the last several years, human fibrin-based tissue adhesives have also proved to be advantageous in many areas of ocular surgery. Currently, all adhesives used in ophthalmology are considered 'off-label' applications.

Tissue adhesives may be used as structural fillers or tissue scaffolding in place of or in addition to sutures and donor transplant materials. They are readily available, quickly and easily applied, and relatively inexpensive. They have been used primarily to seal small corneal perforations or progressive thinning as well as adjuncts for pterygium surgery.[3] Tissue adhesives also have the advantage of reducing operating time, temporizing a corneal perforation to permit more optimal planned surgery, reducing pain and surgical risks for the patient, reducing the need for donor tissue, improving visual prognosis, and allowing more flexibility for surgeons without immediate access to operating rooms. The cyanoacrylate adhesives have especially been shown to have bacteriostatic properties, reducing the risk of corneal melting, and the need for penetrating keratoplasty or conjunctival flap procedures.[4–8]

CYANOACRYLATE ADHESIVES

Cyanoacrylate tissue adhesives (CTAs) are rapidly polymerizing synthetic monomer compounds, which achieve very high tensile strength after setting. They polymerize on contact with basic fluids such as water or blood, forming a solid adherent plaque within seconds. Bonding to biological materials occurs during polymerization in the presence of minimal fluid. They may form a barrier to both bacteria as well as collagenase-secreting inflammatory cells from the tear film and stroma.[9] CTAs resist biodegradation but they may cause local foreign body inflammation with neovascularization and tissue necrosis.

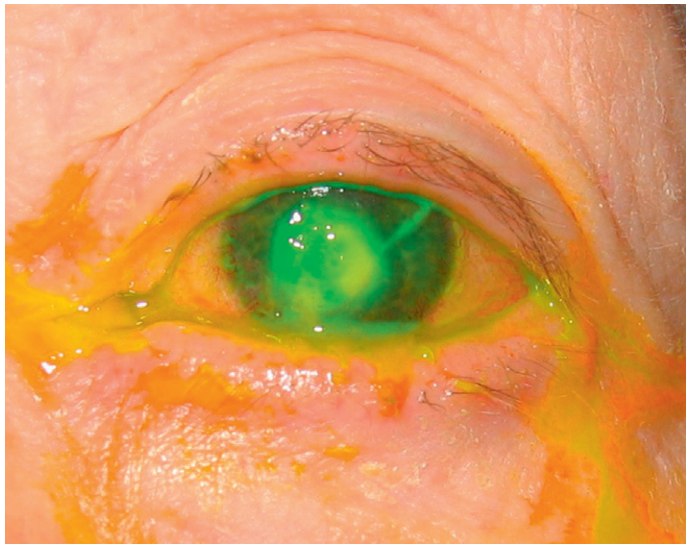
HISTORY AND MECHANISM OF CTAs

The family of cyanoacrylate glues include methyl 2-cyanoacrylate, the first commercially available CTA, followed by *n*-butyl (Isodent™, Indermil™), *n*-heptyl (Histoacryl™), and octyl derivatives (Dermabond™). While approved for dental and dermatologic applications, no cyanoacrylate glue has yet been approved for ophthalmic applications. The various cyanoacrylates bond rapidly in an exothermic reaction via polymerization of liquid monomers in the presence of anions thereby forming a solid polymer. Polymerization entails two steps: first, isocyanate reacts with water and forms a carbamic acid component that rapidly decomposes to carbon dioxide and the corresponding amine, then the amine reacts with residual isocyanate groups, cross-linking the adhesive through substituted urea groups.

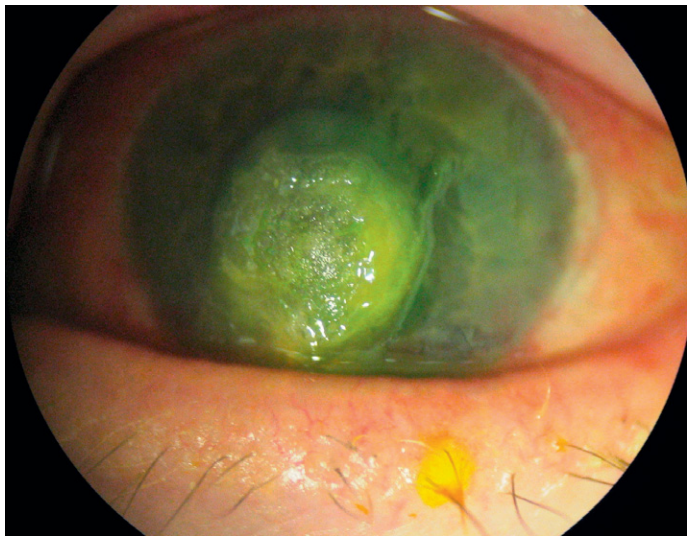
INDICATIONS FOR CTAs

Use of CTAs in treatment of corneal perforations and progressive corneal thinning has been well documented. Therapeutic success has been demonstrated in thinning secondary to bacterial keratitis, sterile ulcerative keratitis, neurotrophic ulcers, stromal melts, fungal keratitis, keratitis sicca, herpes keratitis, and other surface diseases.[10–12] Early treatment of corneal thinning may prevent progression to perforation by creating a barrier between the cornea and inflammatory cells and collagenase-secreting cells in the tear film.[6,7,9] Cases of peripheral corneal ulceration or perforation demonstrated resolution with good visual outcome solely with the application of CTA. CTAs also have a role as a temporizing measure until a definitive procedure such as penetrating keratoplasty or conjunctival flap can be performed (Fig. 22.1). Use of CTAs for corneal perforations or progressive thinning may decrease the rate of penetrating keratoplasty, conjunctival flap surgery, and enucleation.[5,6,13]

CTAs leave a hard, non-absorbable, impermeable foreign body, which limits its applications in ophthalmic surgery. They have been used successfully for leaking glaucoma blebs,[14,15] scleral reinforcement,[16] temporary tarsorraphies,[17,18] and blepharoplasty.[19,20]



A



B

Figure 22.1. *A*, Seidel-positive corneal perforation due to pseudomonas ulcer with flat anterior chamber and lenticular-corneal touch. *B*, Following cyanoacrylate adhesive application, the perforation is sealed and the anterior chamber has reformed.

Applications in glaucoma, strabismus, retinal detachment surgery and punctual occlusion have also been published.[21,22]

APPLICATION METHOD FOR CTAS

Corneal application of CTAs for thinning or perforation is complicated by the rapid polymerization and low viscosity of the glue and the need for a clean and dry substrate on which to adhere. CTAs can be applied successfully using one of two methods: the 'drop' method involves direct application with a dropper or small syringe while the 'disk' method uses a plastic disk to apply the glue. Corneal thinning and small perforations may be treated at the slit lamp but larger perforations are easier to treat with the patient supine. Perforations larger than 2–3 mm or with significant surrounding necrotic tissue may not be amenable to adhesive repair.

A lid speculum is required to keep the area dry and avoid an inadvertent tarsorraphy. It is critical to prepare the surface well by debriding necrotic tissue and surrounding epithelium and then drying the area well. After the glue has set and before application of a bandage contact lens, it is important to gently retract the glue to ensure that appropriate adhesion has been achieved. If the adhesion is inadequate, removal of the glue and re-application is recommended. If the iris or lens is plugging a corneal perforation, we recommend taking the patient to the operating room. Introduction of air and or a small amount of viscoelastic agent can be used to push the iris or lens away from the perforation before gluing to avoid incorporation in the wound.[5,23,24] A free tissue patch or loose supporting reticulum of 10-0 nylon suture may also facilitate closure of larger defects.[13,25]

After application, the patient is placed on prophylactic antibiotic drops, with or without additional topical steroid. Topical aqueous suppressants may also be indicated to encourage retention of the adhesive. The patient is followed on a regular basis to ensure adequate repair and to monitor the adhesive status, intraocular pressure, anterior chamber depth, and chance of secondary infection. The risk of subsequent infections, estimated to be 9%, is likely due to the severity of the disease in the eye as well as the extended use of a therapeutic contact lens.[6,26] The duration of the glue for corneal perforations may vary from one day to over 2 years (mean 45–72 days).[6,27,28] The glue will typically be displaced as the epithelium and stroma grow under the glue.[1,29]

For the 'drop' method of application, use a tuberculin syringe with a short 30-gauge needle, draw up a small amount of CTA. Dry the surface immediately before applying the glue and apply only the smallest drop of glue possible. Application of multiple thin layers of glue may be necessary to cover the defect. Avoid using a single large drop as this will not adhere as well, takes longer to cure, may detach earlier, and will be more uncomfortable for the patient. Apply a soft bandage contact lens and re-examine to ensure the integrity of the repair and the fit of the contact lens (Fig. 22.2).

The 'disk' method of application uses small trephine, cut a 2–3 mm disk of sterile plastic drape. Apply a small amount of ophthalmic ointment or gel on the stick-end of a sterile cotton applicator and seat the disk on the gel. Place a small drop of CTA on top of the disk. Dry the surface and immediately cover the defect with the glue-disk. Once the glue has cured, apply a soft bandage contact lens directly over the plastic disk and re-examine to ensure the integrity of the repair and the fit of the contact lens (Fig. 22.3).[1,29]

HUMAN FIBRIN ADHESIVES

Human fibrin adhesives (HFAs) have become increasingly popular adjuncts to various ophthalmic surgeries. They may be used in place of CTAs in the treatment of progressive corneal thinning and small perforations, potentially resulting in less corneal and conjunctival inflammatory reaction. They are biodegradable into nontoxic metabolites and may be used underneath biologic surfaces such as conjunctival autografts, which may promote faster re-epithelialization. However, they have less tensile strength and require more complex preparation and longer cure times. HFAs also have the potential to transmit infection from the donor-derived thrombin and fibrinogen. Additional uses of fibrin glues in ophthalmic surgery include minimizing sutures in recurrent pterygium surgery, forniceal reconstruction, conjunctival and amniotic membrane transplantation, and lamellar corneal grafting.[30–35]

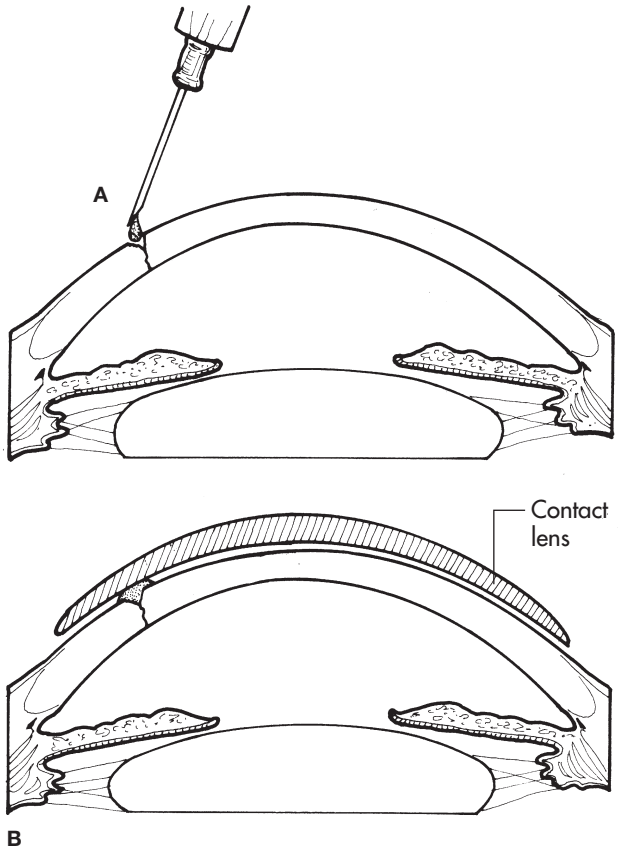


Figure 22.2. Technique for direct application of cyanoacrylate cornea glue. *A*, Once the area is prepared, a micropipette or 3 mL TB (tuberculin) syringe with a 30-G needle is partially filled with glue. After drying the area carefully, a tiny drop of cyanoacrylate glue is placed directly on the cornea (Pearl: Warmth from fingers on the syringe will expand air in the syringe to elicit the smallest drop of glue). *B*, Allow to dry then repeat to cover the wound and place a contact lens over the glue.

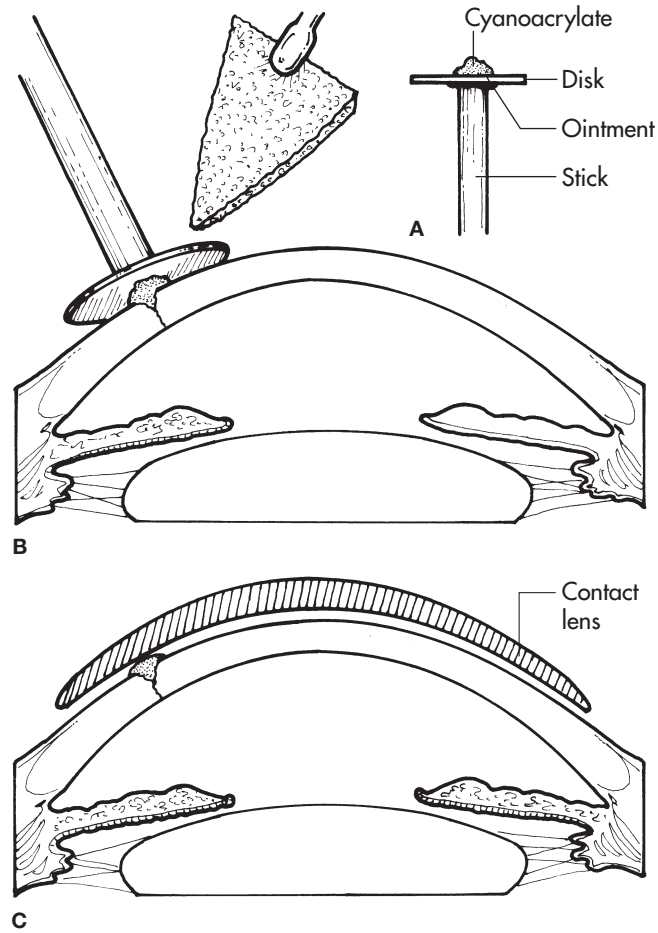

Figure 22.3. Technique for cyanoacrylate cornea glue with a plastic disk. *A*, Prepare the area carefully debriding the wound and drying with an absorbent spear. A trace of antibiotic ointment is placed on the stick-end of a cotton swab and a sterile plastic disk is applied. A small drop of cyanoacrylate glue is then placed on the disk. *B*, After drying the site carefully, the glue and disk are then applied to the corneal perforation. *C*, A contact lens is applied over the glue/disk.

HISTORY AND MECHANISM

Fibrin-based adhesives were first introduced in the 1970s in Europe for use in hemostasis. Introduced as bovine-derived products, they evolved with the use of human-derived thrombin to improve allergic tolerance and aprotinin to retard lysis of the fibrin clot, gaining acceptance especially in the general and vascular surgery fields.[36] One commercial preparation, Tisseel VH Fibrin Sealant (Baxter AG, Vienna, Austria) was approved by the US Food and Drug Administration only for hemostasis in some general and cardiovascular surgery procedures. Application in ophthalmic procedures represents an off-label use.

While single donor and autologous fibrin glue preparations are available, they still require the use of exogenous thrombin.[37] These preparations require significant additional preparation time and result in a lower concentration of fibrin, reducing the tensile strength of the fibrin clot.[36,38]

The Tisseel VH preparation forms a firm, clear, gelatinous fibrin clot when pooled human fibrinogen, plasminogen, fibronectin, and factor XIII in a bovine aprotinin solution is combined with human thrombin initiating the final stage of the coagulation cascade. Once mixed, thrombin cleaves fibrinogen into fibrin, then factor XIII crosslinks the fibrin to form a fibrin clot. Both fibrin and fibronectin are able to crosslink with tissue collagen to adhere the clot to surfaces such as corneal stroma. The bovine aprotinin acts as a fibrinolysis inhibitor to resist degradation of the clot.[39]

APPLICATION METHOD FOR HFAs

A typical HFA system requires a fibrin solution to mix with an activating solution such as thrombin immediately prior to application. The Tisseel kit has duel syringes with linked plungers and a common mixing hub (Duploject) that mixes and ejects equal volumes of the two solutions. For multiple applications, the two syringes may be separated to allow mixing on the field and to avoid clogging of the applicator tip. Alternatively, each solution may be applied to opposite sides of the tissue to be glued to better control glue distribution and to postpone activation until the two sides are apposed.[8,40]

HFAs may be used much like the CTAs with several modifications. HFAs require additional time to prepare as they must be reconstituted, warmed, and transferred to a delivery device. The HFAs do

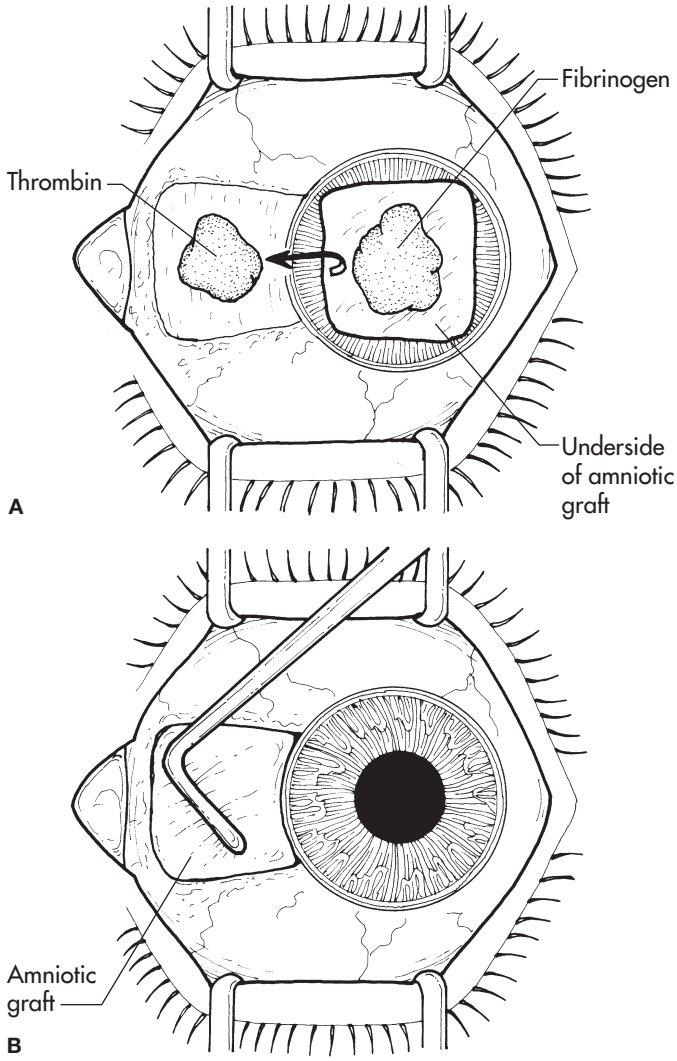

Figure 22.4. Technique for application of fibrin-based adhesive. *A*, Reconstitute the adhesive early in the surgery. After removing the pterygium and preparing the surface, the conjunctival or amniotic graft is placed base-up on the cornea. Thrombin is spread over the bare sclera and fibrinogen is placed on the base of the graft. *B*, The graft is then placed base-down on the site, smoothed with a muscle hook, and allowed to set. The graft may be trimmed with scissors if any tags remain.

not harden as quickly as CTAs, allowing for some manipulation after application. The speed of HFA congealing can be manipulated by diluting the thrombin component prior to mixing. Typical setting times allow HFAs to be manipulated, smoothed, or wiped off in the first 30–60 s to achieve a better seal.

For conjunctival or corneal repairs, the HFA and any adjunctive materials such as donor lamellar grafts, conjunctival flaps, or amniotic membrane should be prepared prior to application of the glue. Non-corneal grafts may be trimmed after bonding. After drying the two surfaces, apply a thin layer of adhesive and appose the surfaces with minimal tension or manipulation. The surface may be gently stroked with a smooth instrument or wet cellulose sponge to remove excess glue and adjust the overlying tissue (Fig. 22.4).[41] Allow several minutes for the HFA to form a firm adhesive clot. For corneal applications, a bandage contact lens may be necessary to protect the repair from mechanical disruption.[42]

Autologous HFAs have been prepared and used with success though they lack the strength and durability of the commercial HFA due to their lower fibrinogen content.[43] The duration of HFA on eyes in vivo is typically less than 2 weeks.[30,43,44] Postoperative application of aprotinin drops may be used to slow lysis of the clot.[42]

IMMUNOLOGIC RISKS OF HFA

Current commercial sources of HFA use human thrombin and fibrinogen and still use bovine aprotinin thereby carrying a risk of antigenic response or transmissible infectious agents such as viruses or prions.[36,45,46] In particular, parvovirus B19 (HPV B19) is difficult to remove or inactivate. Human infection has been reported after the use of fibrin glue in cardiothoracic surgery.[47,48] However, the risks are thought to be low and no reports of HFA-related viral infections have yet been reported following ocular surgery applications.

INDICATIONS FOR HFAs

HFAs have been used for corneal perforations and thinning with or without amniotic membrane.[29,31,32] Of note, in a prospective randomized study, Sharma et al compared HFA to CTA in treating corneal perforations. While both adhesives performed well in closing the perforations, HFA-treated patients developed less giant papillary conjunctivitis and deep stromal vascularization compared to CTA-treated patients.[30] HFAs have become increasingly popular for pterygium surgery with conjunctival or amniotic membrane graft. The surgery is faster with improved hemostasis and the graft can be secured with few or no sutures (Figs 22.5 and 22.6).

Postoperative discomfort and inflammation is also diminished and the risk of pterygium recurrence may be lower than with sutures.[40,49–51]

HFAs have also been used for other conjunctival closures,[52–54] limbal stem cell transplants,[55] lamellar keratoplasty and amniotic membrane patch,[35] prevention of recurrent epithelial ingrowth after LASIK surgery,[56] glaucoma surgery and bleb repair,[57–59] scleral ulcers,[60] blepharoplasty,[61] and anterior segment reconstructive surgery.[33]

THE FUTURE OF OCULAR ADHESIVES

While CTAs and HFAs have become increasingly popular surgical adjuncts, some of their surgical characteristics and potential infectious issues limit broader use. Modifications of current HFAs include use of recombinant protein components, antibiotic-, growth factor-, or stem cell-infused preparations, and platelet gels. Novel adhesives under investigation include a photo-polymerized hyaluronic acid compound,[62] a poly-ethylene glycol hydrogel,[63] a porous poly (L-lactic-*co*-glycolic acid) scaffold with a laser-activated serum albumin solder[64] and a riboflavin-fibrinogen compound,[65] chondroitin sulfate aldehyde,[66] and biodendrimer compounds.[67] These new compounds offer additional desirable qualities in a tissue adhesive—flexibility, absorbability, biocompatibility, durability, adhesion strength, ease of application, and a lower risk of infection and inflammation.

Tissue adhesives play an essential and expanding role in state-of-the-art anterior segment surgery and ophthalmic care.

23 Conjunctival flaps and amniotic membrane transplantation

Christopher I. Zoumalan, Glenn C. Cockerham, C. Stephen Foster

The beneficial effects of covering a diseased or damaged cornea with vascularized autologous conjunctiva were noted in the latter half of the 19th century. Schoeler in Berlin described a conjunctival flap in 1877, but Kuhnt popularized the concept in 1884.[1] Byers[1] listed uses for flaps in cataract surgery, eviscerations, and corneoscleral lacerations in 1912. In the same year, Van Lint proposed placement of conjunctiva over cataract incisions to retard infection and expedite healing.[2] In 1927, Green[3] advocated surgical duplication of 'nature's third process of repair,' or wound healing by conjunctival in-growth, as beneficial for various corneal ulcerations, including herpetic and Mooren's ulcers, and for perforations. In 1954, Haik[4] described his wartime experience with fornix conjunctival flaps in severely injured eyes, noting that such flaps, although temporary, were expeditious. In 1958, Gundersen[5] published a technique for fashioning a thin flap by dissecting conjunctiva from underlying Tenon's fascia, thereby describing the operation, which, because of its success, remains in use today. Prior to that publication, conjunctival flaps were purse-string flaps drawn over to a corneal sector after complete peritomy or advancement flaps (hood flaps) of conjunctiva and Tenon's capsule. Purse-string flaps retracted in a few days, whereas hood flaps could last a few months.[5] Gundersen's technique of removing Tenon's fascia reduced flap contractility, allowing permanent coverage of diseased corneas.

Tissue adhesives, bandage contact lenses, amniotic membranes, and improved antibiotic, antifungal, and antiviral therapy offer alternatives for management of corneal injury and disease not available to previous generations of surgeons. Such new alternatives in ocular surface disease management have decreased the indications for Gundersen conjunctival flaps; however, flaps remain appropriate and reliable therapy in selected cases.[6] Unfortunately, fewer ophthalmologists are performing and learning the procedure, and conjunctival flaps may not be performed, even when appropriate, because of surgeon inexperience. Gundersen flaps may be a temporizing measure, followed by penetrating keratoplasty at a later date, or they may be definitive therapy for chronic conditions. In addition to the total conjunctival or hood flap, described by Gundersen to cover the entire cornea, partial flaps are designed to cover a specific sector. Partial advancement flaps are created by undermining perilimbal conjunctiva to cover an adjacent peripheral corneal abnormality. They offer the advantage, unlike a Gundersen flap, of better visualization of the anterior chamber, accurate intraocular pressure (IOP) measurements, and suitability in patients with short fornices.[7] Racquet flaps are produced by rotating, or swinging, a flap of limbal conjunctiva onto the cornea.[8] Bucket handle flaps can be used to provide a richly vascularized bed to central corneal areas without the extensive dissection necessary for total flaps.[9]

Thick flaps, with the inclusion of Tenon's capsule, are commonly used in treating corneal disorders with stromal loss. Gundersen modified his own procedure by using thick conjunctival flaps in the treatment of bullous keratopathy. More recently, Khodadoust and Quinter have successfully used thick partial conjunctival flaps with Tenon's capsule in treating deeper corneal ulcers and perforations.[7] In instances of severe loss of stromal tissue, as seen in peripheral mycotic corneal abscesses, Sanitato et al have advocated the use of thick conjunctival flaps with a keratectomy.[10] Geria and associates have been successful in using thick conjunctival flaps with the use of deep, localized keratectomy in four patients with infected corneal grafts.[11]

The exact mechanism for the success of conjunctival flaps remains unclear. In general, prompt relief of ocular pain is achieved after flap placement.[12–14] Refractory ulcerations and necrotic areas heal with scar formation, and inflammation subsides. Earlier, surgeons speculated on the restorative capacity of full-thickness flaps and ascribed it to the introduction of blood vessels and a protective layer to corneal tissue.[1] Gundersen,[5] in his original article, hypothesized that a thin flap provides protection from tears and irritants and places a highly vascular membrane supplying blood factors in contact with damaged or infected cornea. Later authors have suggested that a vascular conjunctival flap expedites processing of bacterial antigens, allows neutralization of proteases, and provides a source of viable fibroblasts for wound repair.[15] A conjunctival flap provides some degree of tectonic support in thin corneas, although a flap as sole management is contraindicated in actual corneal perforation.[6,16]

Disadvantages of total conjunctival flaps include impairment of vision and a diminished view of the anterior chamber and intraocular contents. In general, conjunctival flaps are performed in poorly sighted eyes for which no visual rehabilitation is planned.

Intraocular pressure measurement by applanation tonometry will be affected.[17]

INDICATIONS

Indications for conjunctival flaps are listed in Table 23.1.

INFECTIOUS ULCERATIVE DISORDERS

Herpetic keratitis

Progressive or necrotizing herpetic stromal keratitis remains a difficult management dilemma. Surgeons used conjunctival flaps as a reliable way to arrest inflammation and to provide relief from pain in the era before topical and systemic antiviral therapy. In a series of patients reported by Wiedman and Gundersen[2] in 1968, 60 of 177 conjunctival flaps were performed for chronic herpetic keratitis. Flaps remain useful in cases of herpetic ulcerative stromal disease refractory to intensive medical management. Herpes simplex and herpes zoster accounted for 11 of 33 cases requiring conjunctival flap in a published review by Insler and Pechous.[18] In a series of 122 consecutive partial and complete conjunctival flaps performed over 8 years, Paton and Milauskas[19] reported 36 involved eyes with herpetic keratitis. Only four eyes had postoperative persistence of keratitis, two of which had incomplete coverage caused by buttonholes. In a series of 14 conjunctival flaps published by Brown and associates,[20] 9 were indicated for herpetic keratouveitis (7 with herpes simplex and 2 with herpes zoster). All patients had persistent epithelial defects (PEDs) with significant ocular inflammation. Various modalities had been used, including multiple medications, bandage contact lenses, and tissue adhesives. All eyes were comfortable by 1 week after flap placement. No patient had recurrence or deeper inflammation with a follow-up of 1–6 years. Additionally, there was a significant reduction in office visits and use of medications after the procedure.[20]

Most recently, Alino and associates performed a significant percentage of conjunctival flaps (26%) on patients with herpetic corneal disease in their study group of 61 eyes in 1998.[21] None had recurrence, and flap retraction was the only reported postoperative complication, which ranged from an average of 8% in full conjunctival flaps to an average of 23% in the partial conjunctival flap group. These percentages should be similar in theory, but gravity and mechanical effects on the horizontal partial flaps may have predisposed them to more retraction than expected.[21]

Tectonic support

Fungal keratitis

In cases of peripheral fungal keratitis unresponsive to medication, debridement of necrotic material and lamellar keratoplasty in conjunction with a partial inlay conjunctival flap have been suggested to halt progression. Sanitato et al reported resolution in three cases of keratomycosis managed in this manner.[10] The authors suggested that saprophytic fungi do not survive in a well-vascularized cornea. Additionally, Townsend[22] proposed that conjunctival flaps permit access of the cell-mediated immune system to intracorneal fungal elements. The timing of the procedure is important. Intensive medical management should be attempted for 1 week. Progression or lack of response is an indication for surgery in order to avoid the formation of a corneal or anterior chamber abscess.[22] Penetrating keratoplasty is the treatment of choice for central, progressive fungal ulcers.[10,22]

Bacterial keratitis

Pseudomonas species may produce rapid dissolution of corneal tissue, leading to descemetocele formation or perforation. Intensive topical and subconjunctival antibiotics are first-line management. In cases of progressive pseudomonal ulceration refractory to medical management, conjunctival flaps have demonstrated utility (Fig. 23.1). Buxton and Fox[15] reported resolution in three of four cases of culture-proven *Pseudomonas* managed in this manner; failure in one case was attributed to scleral involvement at the time of surgery. Indications for surgical intervention were extension of the abscess to three-quarters corneal depth or three-quarters of the total corneal area.

Parasitic keratitis

Early identification and treatment of *Acanthamoeba* keratitis are the keys to successful medical management. However, it often presents clinically similarly to bacterial and herpetic keratitis, thus delaying diagnosis. The use of conjunctival flap with combined lamellar keratoplasty has been shown to arrest inflammation in cases where medical therapy provided little benefit.[23]

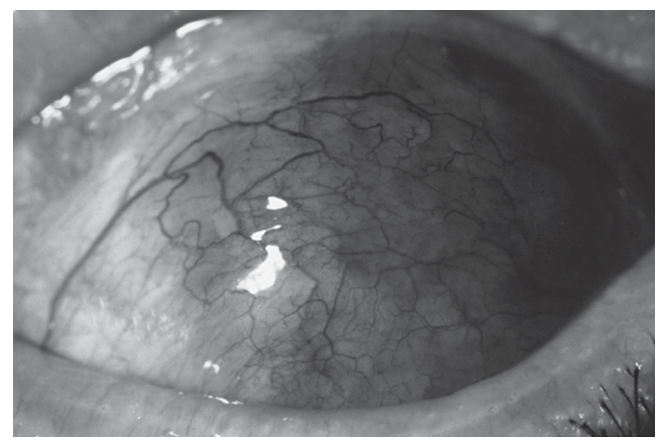

Figure 23.1. A Gundersen flap. This 79-year-old man had recurrent culture-proven *Pseudomonas* corneal ulcers with hand motion vision. Within several weeks of surgery, the eye was quiet and comfortable.

OCULAR SURFACE DISORDERS

Persistent epithelial defects or painful recurrent erosions from a variety of causes that are unresponsive to lubrication, bandage contact lenses, and tarsorrhaphy may require a conjunctival flap. Specific molecules, including topical fibronectin, autologous serum factors, nerve growth factor, and substance P, may accelerate epithelial healing.[24–31] In corneas unresponsive to other measures, replacement of damaged corneal epithelium by conjunctiva may stabilize the surface, prevent further erosions, and arrest stromal melting. Lugo and Arentsen[32] performed a total conjunctival flap in seven patients with neurotrophic ulcerations resistant to lubricants, patching, and contact lenses. Corneal anesthesia was secondary to herpes zoster ophthalmicus in six patients and trigeminal nerve injury in one patient. The neurotrophic ulcer resolved in all patients after flap placement, with thinning and clearing of the flap within 3 months.

Epithelial breakdown despite aggressive medical management may occur in dry eye syndromes from a variety of causes. Exposure keratopathy was listed as the diagnosis in 16% of the conjunctival grafts from 1974 to 1980 reported by Hirst et al.[33] Conjunctival flaps may be the only useful alternative if lubricants, punctal occlusion, therapeutic contact lenses, and tarsorrhaphy are not effective in preventing stromal loss.[13] Portnoy et al[34] prevented further corneal thinning in two children with lagophthalmos and exposure keratopathy by placement of partial inferior conjunctival flaps.

Bullous keratopathy of varied etiology has been successfully treated with conjunctival flaps, with relief of pain and cessation of recurrent erosion.[35] Gundersen reported success using thick conjunctival flaps (including Tenon's capsule) with a lamellar keratectomy to treat bullous keratopathy.[36] However, recent authors have also found success in using a thin conjunctival flap alone.[19,21]

STROMAL THINNING DISORDERS

Since the advent of tissue adhesives, conjunctival flaps have assumed a lesser role in the management of stromal thinning disorders. From 1960 to 1974, conjunctival flaps were used in 37% of cases of corneal thinning or perforation in a series reported by Hirst et al[33] but only in 10% of such cases from 1974 to 1980 after tissue adhesives were introduced.[37] Similarly, conjunctival flaps were used and in 8.6% of 58 eyes treated between 1978 and 1982 by Arentsen et al.[6]

Flaps have been successfully used as adjunctive care in cases of rheumatoid arthritis, systemic lupus erythematosus, and Mooren's ulcer.[18] Filipec[13] recommended flaps for progressive marginal ulcerations threatening global integrity. Conjunctival flaps may be used as adjuncts to lamellar or full-thickness grafts in melting disorders to stabilize the surface and prevent lytic destruction of the grafts.[16] Despite their reinforcing ability, conjunctival flaps should not be considered sole management for corneal perforations. A flap will help the anterior chamber to reform, but leakage of aqueous is common.[22] The perforated eye may develop endophthalmitis or secondary angle closure.[38]

MISCELLANEOUS

Conjunctival flaps may be an alternative to enucleation in the blind and painful eye. In phthisical eyes, a conjunctival flap provides a strong bed for a cosmetic shell.[22] It allows for good retention of the globe with acceptable cosmesis. The flap can also provide a suitable surface for the placement of a cosmetic scleral shell or painted contact lens.

SURGICAL TECHNIQUE

TOTAL ADVANCEMENT FLAP (AFTER GUNDERSEN)

The technique of fashioning a thin flap was first described by Gundersen[5] in 1958. Since then, numerous modifications have been proposed.[19,39–41] The basic procedure is as follows:

1. Local anesthesia is achieved with lid block and retrobulbar or peribulbar injection.
2. A lid speculum is placed.
3. All of the corneal epithelium is removed with a blade. This technique allows flap adherence and prevents epithelial cyst formation. Any necrotic tissue is also removed. A superficial keratectomy is unnecessary.
4. A complete 360° peritomy is made. Hemostasis is obtained as needed by cautery.
5. A traction suture of 6-0 silk is placed through the superior cornea at the limbus, and the eye is rotated downward. Alternatively, a traction suture may be placed through the superior rectus to infraduct the eye (Fig. 23.2).
6. The area to be dissected may be marked with a surgical marking pen. Enough conjunctiva must be mobilized to cover the cornea without tension or traction on the flap. The vertical height of the flap should be 16–18 mm above the superior limbus, allowing 1.5 mm of conjunctiva for each millimeter of cornea to be covered. Superior tarsal conjunctiva may be used if necessary, although this increases the possibility of postoperative ptosis. The horizontal extent of the flap should be 15–20 mm.
7. Conjunctiva is separated from Tenon's capsule by a subconjunctival injection of balanced salt solution, 2% lidocaine with 1 : 100 000 epinephrine, or air. The needle is inserted outside of the intended dissection area to avoid a perforation in the flap.
8. The superior edge of the flap is incised horizontally. An assistant provides exposure by elevating the flap with smooth forceps. Fascial tags and connections are removed from the

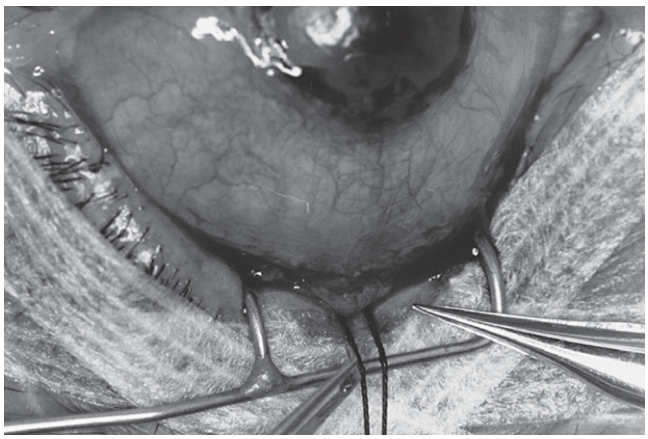

Figure 23.2. Creation of a Gundersen flap: surgeon's view. The superior bulbar conjunctiva is exposed. A 4-0 silk traction suture has been placed through the superior rectus, and the eye is infraducted. (Photograph courtesy of Jonathan H Talamo, MD.)

underside of conjunctiva by blunt dissection with a moist cotton-tip applicator, or by spreading and cutting with blunt scissors, until the superior half of the limbus is reached. The flap should be kept moist with saline irrigation (Fig. 23.3).

9. The conjunctival flap is then pulled down to cover the entire corneal surface. Sufficient tissue must be available to cover without stretch or tension (Fig. 23.4).
10. The inferior edge of the flap is secured to the inferior limbus incision using 10-0 nylon sutures (mattress or interrupted), incorporating episclera into the bite. Episcleral anchoring is important to prevent retraction of the suture line over the cornea. Care must be taken to approximate the cut conjunctival edges, to avoid epithelium implantation into the wound. The superior flap margin is secured with 10-0 nylon sutures to episclera. The superior defect is left bare to re-epithelialize (Fig. 23.5).
11. If a buttonhole occurs, it should be repaired with 10-0 nylon on a tapered vascular needle. If one occurs near the medial or lateral edge of the flap, it may be possible to undermine enough additional conjunctiva to place the defect in an area away from the corneal surface.
12. It is preferable to have an intact corneal covering. There is generally not enough inferior bulbar conjunctiva to perform a total flap. However, if a superior flap cannot be mobilized sufficiently to completely cover, then the inferior edge of the flap may be sutured into the cornea. Alternatively, inferior bulbar conjunctiva may be mobilized and sutured to the superior flap along the cornea.
13. Antibiotic ointment and a pressure patch are applied. The sutures may be removed in 1 month.

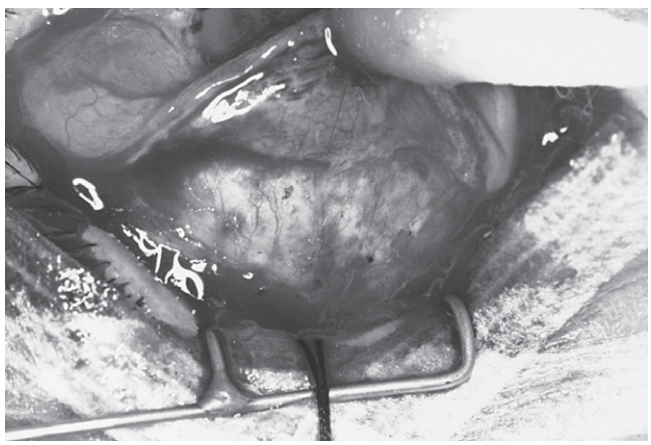

Figure 23.3. The conjunctival flap has been dissected free of fascial attachments down to the superior limbus. A moist cotton-tipped applicator is used for retraction. (Photograph courtesy of Jonathan H Talamo, MD.)

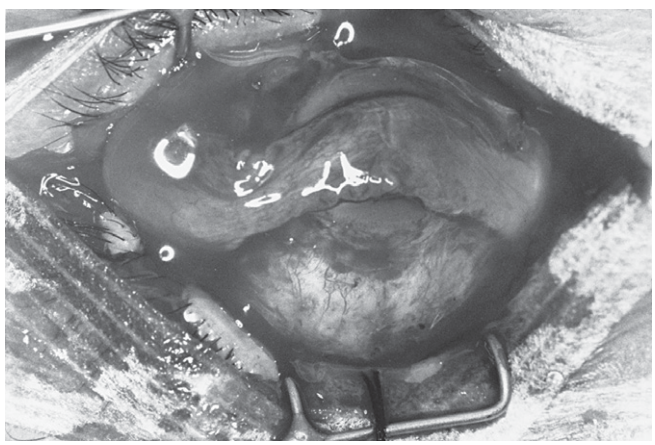

Figure 23.4. Dissection of a flap and 360° peritomy are completed. Sufficient conjunctiva is available to cover the cornea without tension. All corneal epithelium has been removed mechanically. (Photograph courtesy of Jonathan H Talamo, MD.)

PARTIAL ADVANCEMENT FLAP[10,41]

1. A lid block with retrobulbar or peribulbar anesthesia is obtained, with supplementation with topical anesthetics as needed.
2. A lid speculum is placed.
3. Corneal epithelium in the area to be treated is removed with a surgical blade (Fig. 23.6, *A*).
4. If necrotic tissue is present, a lamellar keratectomy is performed to remove as much of this tissue as possible. This dissection should be extended to the limbus.
5. In noninfectious cases of peripheral thinning with threatened perforation, a conjunctival flap may be used in conjunction with a scleral or corneal patch graft.
6. A limbal peritomy is made, extending one clock hour to either side of the area to be covered. A fornix-based conjunctival flap is created by sharp and blunt dissection, undermining conjunctiva and releasing Tenon's capsule with blunt scissors (Fig. 23.6, *B*). Enough conjunctiva is mobilized to completely cover the area of concern without tension.
7. The flap is secured to the corneal bed with interrupted 10-0 nylon sutures. Care should be taken to avoid the visual axis with central sutures (Fig. 23.6, *C*).
8. An antibiotic ointment and pressure patch are placed on the eye. Sutures may be removed in several weeks.
9. A partial 'bridge' flap may be constructed inferiorly for exposure or neurotrophic ulceration using the technique described above. An inferior relaxing incision in the mid-peripheral bulbar conjunctiva allows greater mobility of the bridge. Viability must be maintained by wide vascularized horizontal margins (Fig. 23.6, *D* and *E*).

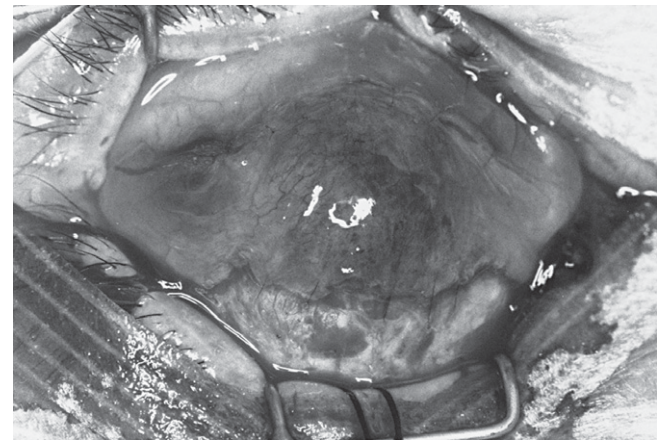

Figure 23.5. Suturing of a flap is completed. 10-0 nylon sutures are used to secure the inferior flap edge to episclera, then to the apposing conjunctival edge. The superior flap edge is also secured to episclera. The superior bulbar area is left bare to re-epithelialize. (Photograph courtesy of Jonathan H Talamo, MD.)

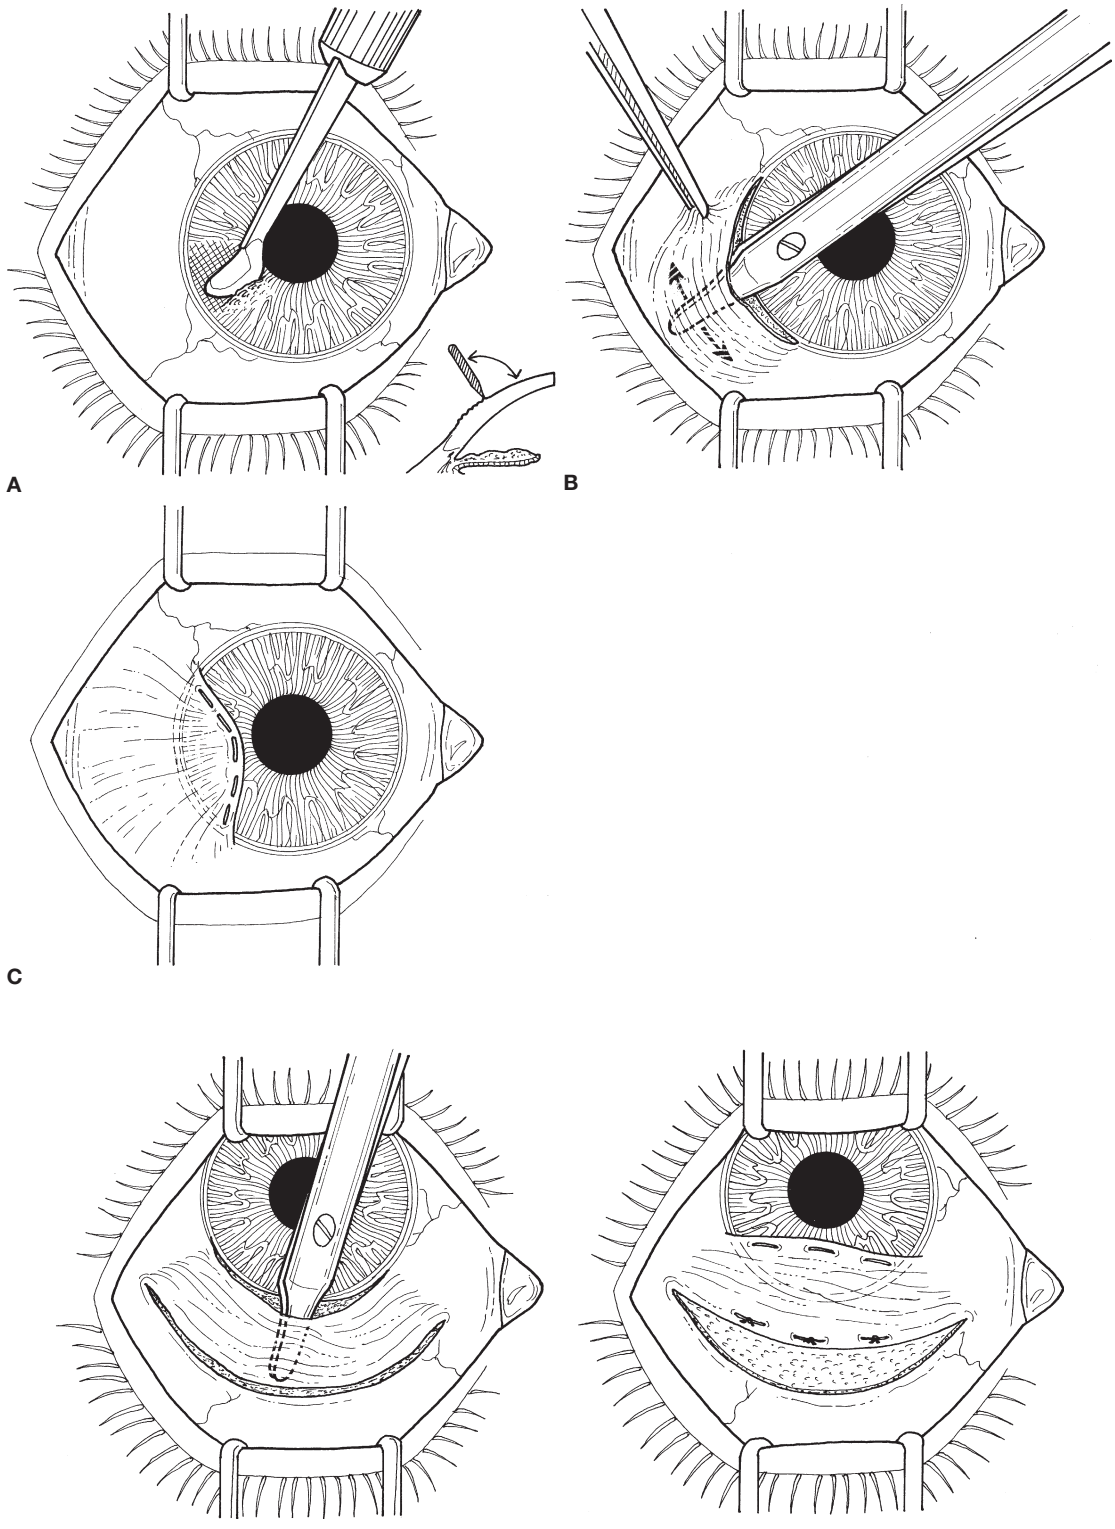

Figure 23.6. A partial conjunctival flap: surgeon's view. *A*, A surgical blade is used to remove epithelium and necrotic tissue. If necessary, a lamellar keratectomy and patch graft are performed. *B*, A fornix-based conjunctival flap is created beginning with a peritomy and bluntly dissected deep and wide enough to cover the abnormal area. Smooth forceps are used to elevate the flap. *C*, The partial flap is advanced over the area without tension and secured, avoiding suture placement in the visual axis. *D* and *E*, A partial 'bridge' flap may be constructed inferiorly for exposure or neurotrophic ulceration using the technique described in *A* through *C*. A relaxing incision in the mid-peripheral bulbar conjunctiva allows greater mobility of the bridge. Viability is maintained by wide horizontal margins.

Table 23.2 Complications of conjunctival flap

Buttonhole
Flap retraction
Epithelial cyst formation
Ptosis
Recurrence, with or without erosion

COMPLICATIONS

Potential postoperative complications are listed in Table 23.2. A fenestration of the conjunctival flap, or buttonhole, will almost certainly enlarge, and this complication will defeat the purpose of the flap. Repair of the tear with 10-0 nylon on a tapered vascular needle should be attempted. It may be possible to position a buttonhole away from the corneal surface by undermining additional conjunctiva laterally or nasally.

Retraction of a flap results from tension placed on the inferior anastomosis and subsequent tearing away of the suture line. This complication usually occurs within 2 months of surgery.[19] Alino and associates identified retraction in 11.4% of 61 eyes, all of which occurred by 1 month after surgery.[21] Retraction can be avoided by securely attaching the flap to the underlying episclera without tension. In most instances, retraction can be managed by observation if enough flap coverage is sufficient to suppress the inflammatory process. Adequate mobilization and dissection of the flap, with secure anchoring of sutures to episclera, are preventative. Reoperation may not be necessary, as several weeks of flap coverage may suffice to quiet an inflammatory process.

Cyst formation may occur from inadequate removal of corneal epithelium, or from inclusion of conjunctival epithelium in the wound. Cysts are usually located at the limbus.[19] They may be multiple and as large as one-third of the corneal circumference.[36] If cysts are problematic, they may be excised. Needle decompression of a cyst is a temporary solution.

Postoperative ptosis of 1–3 mm has been noted.[19] This complication is the result of downward traction on the superior fornix and may be an unavoidable consequence of mobilizing enough conjunctiva to cover the cornea. An additional small amount of ptosis is generally well tolerated in patients with long-standing ptosis from chronically inflamed, painful eyes.[19] Müeller's muscle should be avoided in dissections high in the superior fornix.

Recurrence of culture-proven herpes simplex type 1 in a conjunctival flap has been reported 2 years postoperatively.[42] Corneal recurrences with involvement of the overlying flap have been reported in two cases; one resolved with topical antivirals and corticosteroids, and the other required penetrating keratoplasty for perforation.[43] Erosion of conjunctival flaps has been reported in cases of chronic herpetic keratitis and Mooren's ulcer.[19]

AMNIOTIC MEMBRANE TRANSPLANTATION

Amniotic membrane is a fetal tissue derived from placenta that is beneficial in the corneal and conjunctival reconstruction of various ocular surface disorders. Davis first described the use of amniotic membrane in skin transplantation in 1910.[44] Since then it has been used in tissue regeneration for a variety of cutaneous and mucosal lesions. De Rotth in 1940 and Sorsby and Symons in 1946 were the first to use amniotic membranes in ocular surface reconstruction.[45,46] Difficulties in tissue processing and preservation limited its availability. Kim and Tseng introduced amniotic membrane to ophthalmology in 1995 with better tissue techniques.[47] Amniotic membrane dissolves slowly and produces local anti-inflammatory, antiangiogenic, and antifibrotic effects. It promotes epithelial regeneration through growth factors and prevention of apoptosis. Anatomically, amniotic membrane is the innermost layer of the fetal membrane, consisting of a single layer of epithelial cells attached to a thick basement membrane maintained structurally by an underlying avascular stromal matrix.[48–50]

Table 23.3 Current uses of amniotic membrane transplantation in ocular surface disorders

Symblepharon
Limbal stem cell deficiency
Scleromalacia
Corneal reconstruction
Corneal ulcers
Nontraumatic perforations
Bullous keratopathy
Persistent epithelial defects

INDICATIONS

Amniotic membrane can be used as a graft (with basement membrane side facing up) or as a protective patch (with basement membrane down). Grafts are generally used to cover nonhealing ulcerations or postsurgical tissue defects. Several layers of amniotic membrane tissue, up to three or four, may be used at a time to cover the bed of an ulcer. The goal is to maintain appropriate wound coverage while stimulating epithelial growth over the amniotic membrane. Amniotic membrane patches are effective in persistent corneal epithelial defects, where it protects the cornea from the mechanical forces of blinking and exposure, thus allowing epithelial growth and adhesion. Table 23.3 effectively summarizes the current uses of amniotic membrane transplantation in ocular surface disorders.

Amniotic membrane has traditionally been sutured into place, but recent research has shown promise in placing sutureless amniotic membrane onto the ocular surface. Fibrin adhesives produce adequate adhesion of amniotic membrane onto the corneal surface in rabbit models.[51] It has also shown excellent results in adherence onto bare sclera and healing in a patient who underwent an excision of an atypical conjunctival melanosis.[52]

CONJUNCTIVAL GRAFTS

Amniotic membrane has been shown to be a suitable alternative to conjunctival autografts in extensive resections of conjunctival

Figure 23.7. Amniotic membrane graft sutured over a nasal pterygium excision site of a right eye. Fluorescein staining highlights the corneal epithelial defect. Photograph was taken on postoperative day 1. (Photograph courtesy of Christopher N Ta, MD.)

lesions such as pterygia, tumors, intraepithelial lesions, symblepharon, and scleromalacia.[48,53–57] It may be employed when insufficient or inadequate host conjunctiva is available for autografting, as occurs in scarring from prior surgeries, injury, pemphigoid, or autoimmune disease.

PTERYGIUM

The use of amniotic membrane in primary pterygium excision has repeatedly shown similar results to conjunctival autografts, ranging from 3.0 to 15% recurrence rates. Equivalent recurrence rates with the two techniques have been reported for recurrent pterygia (38–95%).[53,54,58–61] Amniotic grafts can provide a bed for epithelial regeneration in cases of large pterygium excision (Fig. 23.7). Amniotic membrane transplantation does not require the use of adjunctive therapies, as often seen with conjunctival autografts, such as beta radiation and mitomycin C, thus avoiding the risk of scleral necrosis and perforation.

TUMORS AND INTRAEPITHELIAL LESIONS

Amniotic membrane transplantation has been used successfully in the treatment of ocular surface neoplasias including conjunctival intraepithelial neoplasia, primary acquired melanosis, and malignant melanoma. It has a significant advantage by allowing regeneration of healthy epithelium within large areas without the use of adjunctive cryotherapy. A recent study by Espana and associates showed complete epithelial healing in all 16 patients who underwent single-layer amniotic membrane grafts for large neoplastic lesions up to 20 mm in diameter.[62]

CICATRICIAL OCULAR SURFACE DISEASES

Cicatricial disease can result from chemical/thermal burns, Stevens–Johnson's syndrome, and ocular cicatricial pemphigoid. Amniotic membrane serves an important role in restoring healthier ocular surface in cicatricial surface diseases. It has properties to repopulate the diseased ocular surface and permit healing to occur.[55,63] Amniotic membrane has been successfully used in patients with conjunctival and corneal stem cell dysfunction and deficiency in conjunction with limbal stem transplantation. However, amniotic membrane alone will not restore normal corneal epithelial phenotype in limbal stem cell deficiency. Amniotic membrane grafts have been shown to be helpful in patients with severe cicatricial ocular surface diseases, including chemical/thermal burns, Stevens–Johnson's syndrome, and ocular cicatricial pemphigoid. Early surgical intervention may arrest progression of ocular surface inflammation.[64,65] Amniotic membrane has shown good results in restoring a deep fornix after symblepharon lysis in 12 of 17 eyes.[53] However, inadequate lubrication is a significant risk factor for surgical failure in such populations. Patients with severe dry eyes (Schirmer's value less than 5 mm in 15 min) have shown to respond poorly to amniotic membrane grafts.[66,67] Early surgical intervention with adequate lubrication or sufficient tear film production will ultimately provide suitable factors for healing.

CORNEAL GRAFTS

Corneal ulcers and perforations

Amniotic membrane grafts are a suitable alternative in treating nontraumatic corneal perforations. Usually one or more layers have been used for the treatment of corneal ulcers and subsequent perforations. Solomon and associates reported a successful outcome in 28 of 34 patient eyes (82.3%) with deep ulcers and descemetoceles.[68] Similarly, Rodriguez-Ares and associates reported successful long-term outcomes in corneal perforations (less than 1.5 mm in diameter) in 11 of 15 eyes (73%).[69] Fibrin glue with multilayer amniotic membrane has been proposed as an alternative to treating larger corneal perforations. Hick and associates reported an overall success in 13 of 14 eyes (92.9%) with perforations up to 3 mm in diameter, with the combined use of fibrin glue and amniotic membrane.[70]

Bullous keratopathy

Amniotic membrane provides symptomatic relief in patients with bullous keratopathy, especially in cases of intractable pain, poor visual potential, and/or when penetrating keratoplasty is not indicated. Loose epithelium within the affected area is first completely debrided and an amniotic membrane graft subsequently placed. Gris and associates reported complete epithelialization in all five patient eyes with bullous keratopathy within the first 16 days after the transplantation.[71] Espana and associates also showed long-term success in 17 of 18 eyes and significant immediate pain relief in over 88% of the patients.[72]

Persistent epithelial defects

Persistent epithelial defect may occur in neurotrophic keratopathy, exposure keratopathy, and scarring disorders such as chemical or thermal burns, Stevens–Johnson's syndrome, and ocular cicatricial pemphigoid. Currently accepted treatments include topical lubricants, topical and systemic anti-inflammatory medications, punctal plugs, bandage contact lens, conjunctival flap, amniotic membrane transplantation, and tarsorrhaphy.[47–50,58] Amniotic membrane is a relatively simple option after medical therapy has failed. Long-term healing of PED after amniotic membrane placement was reported in 82% of patients in a study by Prabhasawat and associates; the study included corneas with and without stromal thinning and perforation.[58] The mean healing time was 2.1 weeks, with significantly shorter times in eyes that underwent multilayer amniotic membrane versus single-layer transplantation.

AMNIOTIC MEMBRANE TRANSPLANTATION SURGICAL PROCEDURE

1. Local anesthesia is achieved with lid block and retrobulbar or peribulbar injection.
2. A lid speculum is placed.
3. Conjunctiva is incised horizontally along the diseased surface area. If Tenon's fascia is disease free, the conjunctiva is undermined from Tenon's fascia to allow the tissue to retract to its normal anatomical position. The adjacent extraocular muscles are identified and hooked. If there is diseased conjunctiva near the muscle insertions, carefully blunt dissect the abnormal tissue around the muscle sheaths. Use cautery for hemostasis of the exposed sclera.
4. If cornea is involved, the affected corneal epithelium is removed with a blade. This technique allows better graft adherence.
5. An amniotic graft is prepared from the preserved membranes, by measuring it to be approximately 20% larger than the corresponding area of conjunctival and/or corneal defect. Care must be taken to provide sufficient tissue to cover the area without stretch or tension.
6. If the amniotic membrane's function is to serve as a graft, it should be placed basement membrane side up on the scleral and/or corneal surface and secured to the conjunctival edge with 8-0 vicryl sutures, incorporating episclera into the suture bite. If the amniotic membrane's function is to serve as a patch, it should be placed basement membrane side down (stromal matrix side up) on the scleral and/or corneal surface and secured to the conjunctival edge with 8-0 vicryl sutures, incorporating episclera into the suture bite. Episcleral anchoring is important to help prevent any graft or patch retraction.
7. Antibiotic ointment and a pressure patch are applied overnight. The sutures can be removed in several weeks.

SUMMARY

Surgeons have used autologous conjunctival tissue to stabilize inflamed, infected, or thinned corneas for over a century. Early full-thickness flaps were temporary, retracting in days to weeks. Gundersen described a permanent flap, using thin conjunctiva from which underlying Tenon's fascia had been removed. Therapeutic Gundersen-style conjunctival flaps have been supplanted in many instances by bandage contact lenses, tissue adhesives, and improved topical antibiotic and antiviral therapy. Although less commonly used today, conjunctival flaps have demonstrated utility in selected conditions. Conjunctival flaps may arrest progressive inflammatory and ulcerative conditions and control chronic ocular pain; thus they remain an important procedure in the anterior segment surgeon's armamentarium.

Amniotic membrane is a useful adjunct in ocular surface reconstruction. Although temporary, its antiangiogenic and anti-inflammatory environment promote regeneration of epithelium. It is advantageous in covering surface defects too large for conjunctival flaps. Advancements in understanding the biology of corneal thinning and wound repair will hopefully lead to additional refinements in the medical and surgical management of these potentially blinding conditions.

24 Central corneal thinning and perforation

Stephen P. Ginsberg, Frederick S. Brightbill, Tracy L. Aigner

Many ocular conditions predispose the cornea to thinning and possible perforation. These conditions range from chronic, indolent circumstances associated often with long-standing ocular or systemic problems to more acute and rapidly progressing processes. Common to them all are persistent corneal epithelial defects,[1–4] stromal dehydration with associated thinning, and often Descemet's membrane rupture and global collapse. Although the rapidity of the process varies from one condition to the next and the speed of the therapeutic response may often vary as well, the ultimate result of inadequately treated corneal thinning and perforation is devastating to the eye. The persistent loss of the integrity of the anterior chamber in an eye that is leaking aqueous through a corneal perforation can—and probably will—result in anterior synechiae and secondary glaucoma, cataract formation, and possible endophthalmitis. Prompt measures to seal the perforation, even if only temporarily in preparation for a more definitive treatment, must be instituted as quickly as possible.

FACTORS LEADING TO LOSS OF CORNEAL EPITHELIAL INTEGRITY

The factors that can lead to the loss of corneal epithelial integrity and subsequent potential for corneal perforation have been summarized by Doughman.[2]

INFECTION

Although some bacterial organisms can invade the intact corneal epithelium, such as *Neisseria gonorrhoeae,* Koch–Weeks bacillus, and *Corynebacterium diphtheriae,* most other bacteria, fungi, and viruses require a defect in the surface for entry.[6–17] Once established in the corneal stroma, these organisms create a necrotic process that can ultimately lead to loss of stromal mass with perforation. In addition to the destructive nature of the organism itself, the surrounding regenerating epithelial cells and the polymorphonuclear leukocytes called forth by the severe inflammatory reaction then liberate proteolytic enzymes, which further damage the collagen matrix and hasten the corneal dissolution. Herpes simplex corneal infections, because of the often severe inflammation and the high frequency of recurrences, seem to be ideally suited for the creation of the string of events that may culminate in corneal perforation (Fig. 24.1).[6,8,18,19]

In herpes zoster ophthalmia, the corneal hypesthesia often seen may lead to a persistent epithelial defect and a subsequent corneal perforation from the trophic (sterile) process, the active viral necrosis,[6] or both. Secondary keratoconus with a Fleischer ring pattern has been reported following trachomatous infections as well.[20]

XEROSIS

Many systemic and local ocular conditions result in corneal desiccation caused by inadequate mucus and water components in the tear film. Diseases such as rheumatoid arthritis, erythema multiforme, epidermolysis bullosa, vitamin A and B complex deficiencies, and others are often associated with chronic epithelial abnormalities and persistent healing defects.[5,14,21–30] Inadequate corneal fibroplasia and vascularization are also characteristic and retard corneal stromal healing. When combined with persistent epithelial defects, conditions are ripe for corneal perforation in these patients.

Localized specific ocular diseases (e.g. Mooren's corneal ulceration,[31–33] Terrien's marginal dystrophy, and severe cases of keratitis sicca[34,35]) can, for reasons still unknown, lead to severe corneal stromal melting and perforation, often in the corneal periphery. These mainly peripheral corneal conditions are discussed in Chapter 25.

The topical use of corticosteroids for treating corneal disease, particularly when there is an epithelial defect, has led to melting of the corneal stroma and subsequent perforation.[18,36] The mechanism by which this effect occurs is not fully understood, but corticosteroids probably act by perpetuating the lytic action of the proteolytic enzyme collagenase, which is produced in various corneal conditions rather than by a direct alteration of the collagen molecule.[37] Conditions in which production may occur include corneal infections, such as *Pseudomonas aeruginosa* or herpes simplex neuroparalytic keratopathy, the ulcers of alkali-burned corneas, the ulcers of patients with rheumatoid arthritis or Stevens–Johnson syndrome, and the corneal graft wounds of patients with collagen diseases, alkali burns, Stevens–Johnson syndrome, or ocular pemphigoid.

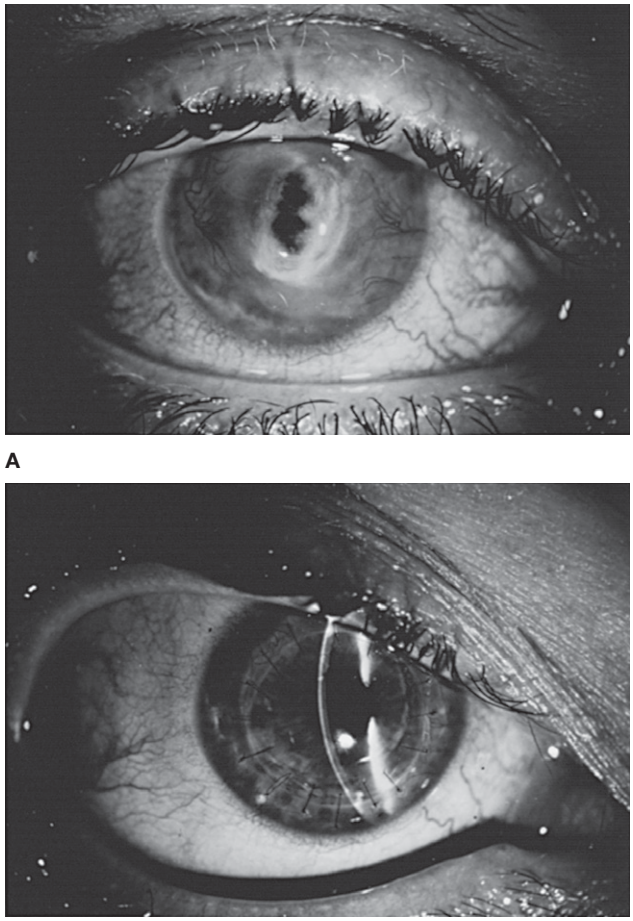

Figure 24.1. *A*, Corneal perforation caused by stromal herpes simplex keratitis in a 28-year-old woman. *B*, The same eye 6 months postoperatively. Eleven years later, the graft remained crystal clear and vision was corrected to 20/20.

Corneal ulcers seen in rheumatoid arthritis are often central as well.[38–40] The systemic use of the antigout medicine colchicine has been shown to possibly delay epithelial healing of wounds in the cornea. Cessation of this systemic medication should therefore be considered if its use is associated with a nonhealing corneal ulcer.[41]

TRAUMA

Incidental corneal trauma, such as an abrasion or, more seriously, penetrating or perforating corneal laceration, can result in situations similar to the cases discussed. Incidental trauma requires the same vigorous therapeutic intervention.[3,4,42–45]

Superficial corneal abrasions, especially linear types such as a corneal scratch from the edge of a piece of paper or a baby's fingernail, can cause destruction of the hemidesmosome bonding of the basal epithelium to the underlying basement membrane.[3,4,46] This event can lead to recurrent, nonhealing, epithelial defects with ultimate stromal melting. The failure of prompt hemidesmosome reformation may be attributable to localized basement membrane injury, or it can be associated with systemic conditions such as diabetes mellitus, severe malnutrition, and other metabolic derangements.

Corneal ulcerations can also occur after cataract and intraocular lens surgery, especially if there is an associated dry eye condition.[47]

CHEMICAL INJURY

The classic chemical injury that frequently leads to persistent epithelial defects with associated stromal melting, defective fibroplasia, and vascularization is the alkali-burned cornea. The result of increased collagenase activity, severe ischemia from the destructive effect of the burn on the limbal vessels, and the alteration in the fibroplastic response of these corneas often leads to corneal melting and perforation with perhaps the worst prognosis for treatment of all corneal perforations.[1,37,48–58]

SPONTANEOUS PERFORATION

Rarely, spontaneous corneal perforation can be seen. In immunologically incompetent individuals (e.g. patients with acquired immunodeficiency syndrome), spontaneous corneal perforation has been reported with molluscum contagiosum infections of the eyelid and conjunctiva.[59] Advanced degenerative corneal conditions, such as keratoconus, posterior keratoconus, Ehlers–Danlos syndrome,[60] and that following refractive procedures (e.g. repeated radial keratotomy operations)[5] and posterior polymorphic corneal dysgenesis[17,61] have all resulted in extreme thinning and occasional corneal perforation. Premature infants may spontaneously undergo corneal perforation following epithelial defects and infiltration.[62] Advanced climatic keratopathy may go on to spontaneous perforation after corneal dissolution and secondary infection.[16] Finally, one case was reported of spontaneous corneal perforation after extracapsular cataract surgery in a patient with rheumatoid arthritis.[47]

DIAGNOSIS

In the initial examination of the cornea, the surgeon must decide (1) whether or not an epithelial defect is present, (2) the extent of stromal thinning, and (3) whether or not corneal perforation has occurred. When fluorescein pools over the thinned area rather than staining Bowman's membrane and when the eye is not inflamed, the likely diagnosis is dellen (saucer-shaped excavation of dehydrated corneal stroma) rather than a more worrisome form of corneal thinning. Often the limbal area near the thinned portion is elevated, causing problems with corneal wetting. The thinning may respond only to hydration and removal of the contiguous elevated area.[2]

If a true epithelial defect is seen with associated stromal thinning and loss of tissue, the surgeon needs to observe for white blood cell infiltration beneath the ulcer. When the involved tissue and surrounding area appear whitish grey or creamy yellow, the surgeon should assume that the tissue is infected, as well as edematous. Appropriate corneal scrapings should be obtained directly over and adjacent to the stromal infiltrate for Gram's, periodic acid-Schiff, or other fungal stains and smears plated for bacterial (aerobic and anaerobic), viral, and fungal cultures.

When frank perforation is observed, the surgeon must determine the size of the opening. If the perforation site is large (over 2 mm), the treatment may be different from what it would be if it were small (less than 2 mm). Pre-existing conditions, such as viral infections, corneal trauma with vegetable matter, prior topical use of corticosteroid medication, generalized predisposing local or systemic problems, corneal exposure, or dry eye conditions, may indicate the source of the presenting problem.

The examination is completed when the visual acuity and intraocular pressure measurements are recorded. A careful examination

is then made for evidence of anterior synechiae formation or central iris adherence (leukoma), hypopyon or hyphema, cataract formation, or signs of an intraocular foreign body. Trauma associated with corneal perforation indicates the possibility of a penetrating foreign body, and orbital X-ray examination, ocular computed tomography scans, and B-scan ultrasonography are then appropriate.

TREATMENT

The specific treatment of epithelial defects (ulcers) is dependent on the presence or absence of perforation, concomitant infection, size of the perforation, and possible association with an autoimmune disease process (Table 24.1).

A. *The following recommendations are for epithelial defects with stromal thinning only:*

1. Topical antibiotics even if there is no infiltrate present.[2]
2. With infiltration, specific antibacterial, antiviral, or antifungal treatment combined with frequent debridement, after initial scrapings for stains and cultures.
3. Corneal lubrication (artificial tears, bland ointment, punctal occlusion, or all) in cases of dehydration (dellen) or associated corneal drying.
4. Avoidance of topical corticosteroids to prevent stromal melting.
5. With or without collagenase inhibitors (acetyl-cysteine drops 10–20%).
6. Lid closure with tape, eye pad, or possible temporary tarsorrhaphy surgically or with glue[63,64] if exposure, corneal drying, or both are present and nonresponsive to local lubrication measures, including drops and ointments. No patching has also been recommended[65] in cases of small noninfected corneal abrasions.
7. Extended-wear therapeutic standard soft lens fitting if it is preferable to lid closure (8.0–8.7-mm lenses are adequate for most cases).
8. Anterior stromal puncture (needle or laser) or epithelial debridement for resistant recurrent erosion syndrome epithelial defects.
9. Conjunctival flap placement for unresponsive ulcers.
10. Glued-on hard contact lens, if severe healing problems (i.e. alkali burn).[66]
11. Amniotic membrane transplantation for persistent epithelial defects with sterile ulceration possibly helpful.[67,68]

B. *The following recommendations are for noninfected epithelial defect with corneal perforation:*

1. Antibiotic coverage with topical solutions.
2. Orally or topically given carbonic anhydrase inhibitors optional because decreased aqueous flow may help in sealing.

Table 24.1 Treatment options for corneal thinning and perforation

Epithelial Defect (Stromal Thinning Only)	Noninfected Epithelial Defect (With Corneal Perforation)	Infected Epithelial Defect (With ≤2 mm Corneal Perforation)	Infected Epithelial Defect (With ≥3 mm Corneal Perforation)
Topical antibiotics associated with debridement as needed	Topical antibiotics	Debridement	Debridement
Corneal lubrication if evidence of dehydration	Oral or topical carbonic anhydrase inhibitors	Topical or subconjunctival antibiotics	Topical or subconjunctival antibiotics
No corticosteroids	Collagenase inhibitors (optional)	Oral or topical carbonic anhydrase inhibitors	Collagenase inhibitors (optional)
Collagenase inhibitors (optional)	Short trial pressure patch with or without soft contact lens	Collagenase inhibitors (optional)	No pressure dressing, soft contact lens, and conjunctival flap
Possible lid closure and/or punctal occlusion	Tissue adhesive glue or fibrin sealant	After 24–48 h of antibiotics, soft contact lens (with or without a patch over eye)	Tissue adhesive or fibrin sealant (with or without patch graft or soft contact lens)
Extended-wear contact lens	Partial conjunctival flap	Tissue adhesive glue or fibrin sealant	'Blow-out' patch graft
Conjunctival flap or glued-on hard contact lens (temporary)	'Blow-out' corneal patch graft	Conjunctival flap (partial after glue removed)	Delay of penetrating keratoplasty
Amniotic membrane transplantation	If associated with autoimmune disease (i.e. rheumatoid arthritis and Sjögren's disease) consider topical corticosteroids, short-term cytotoxic agents, or autogenous periosteal or split-thickness dermal graft	'Blow-out' patch graft	

3. Topical collagenase inhibitors optional.
4. Short trial (6–8 h) with pressure dressings if opening 1 mm or less in an attempt to reform anterior chamber and prevent anterior synechiae formation until more definitive treatment is instituted.
5. Soft contact lens with pressure dressing if defect is 1 mm or less.
6. Tissue-adhesive glue or fibrin sealant[69–72] with or without soft contact lens.
7. Partial conjunctival flap for small opening if glue not successful or unavailable with the anterior chamber depth always being left observable.
8. 'Blow-out' corneal patch graft if no reformation by other methods by 24 h.

C. *If corneal perforation is associated with autoimmune disease, the surgeon should consider:*

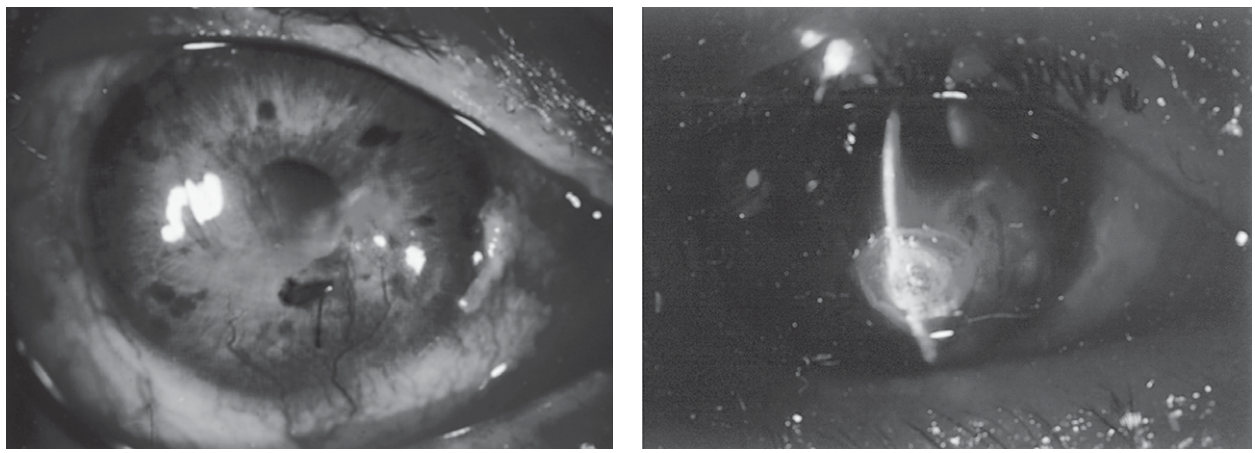
1. topical corticosteroids for 1–3 days depending on response;
2. cytotoxic agents (cyclophosphamide or azathioprine 50–100 mg/day, with dose adjustment depending on local and systemic effect);
3. autogenous periosteal graft or split-thickness dermal graft in face of significant thinning and failure of above methods to heal area.[32,73]

D. *The following recommendations are for an infected epithelial defect with 2 mm or less corneal perforation:*

1. Debridement of necrotic material.
2. Apply appropriate topical anti-infective agent or agents.
3. Subconjunctival antibiotics every other day, optional.
4. Carbonic anhydrase inhibitor, optional.
5. Topical collagenase inhibitors or thiol-based peptides,[52,53,74] optional.
6. Avoid patching an infected eye.
7. After 24–48 h of anti-infective therapy, a soft contact lens with or without a pressure dressing may be tried (allows observation and continued topical medication).
8. Tissue-adhesive glue or fibrin sealant with or without corneal patch and soft contact lens (Fig. 24.2).
9. Partial conjunctival flap after careful removal of all previously placed glue.
10. 'Blow-out' corneal patch graft if no chamber reformation is effected by other methods within 24 h (Fig. 24.3).

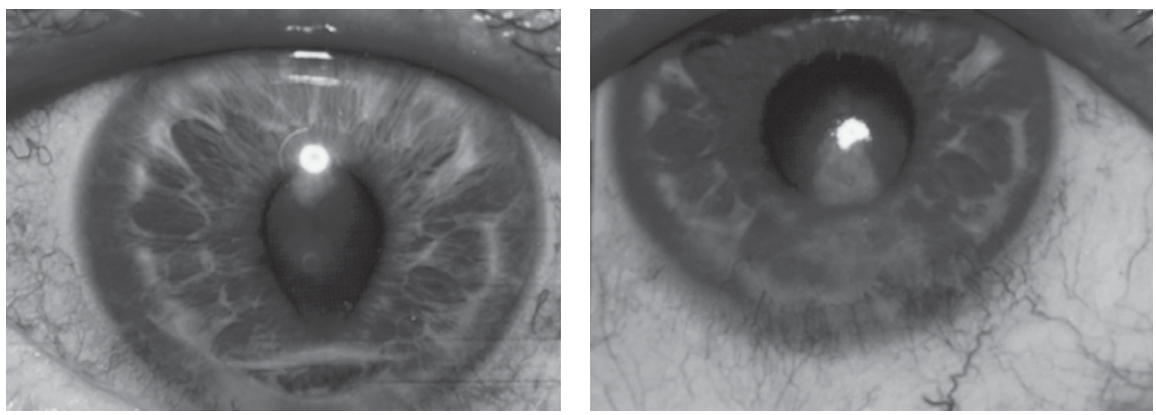
E. *The following recommendations are for an infected epithelial defect with 3 mm or more corneal perforation:*

1. Debride necrotic material.
2. Apply appropriate topical anti-infective agent or agents; subconjunctival antibiotics optional.



A B

Figure 24.2. *A*, Corneal perforation (beneath pigment) associated with herpes simplex keratitis. *B*, Corneal perforation in the same eye 24 h after sealing with cyanoacrylate tissue adhesive.



A B

Figure 24.3. *A*, Rheumatoid corneal melt with iris prolapse. Notice the quiet, noninflamed nature of eye. *B*, Healed corneal patch graft in the same patient.

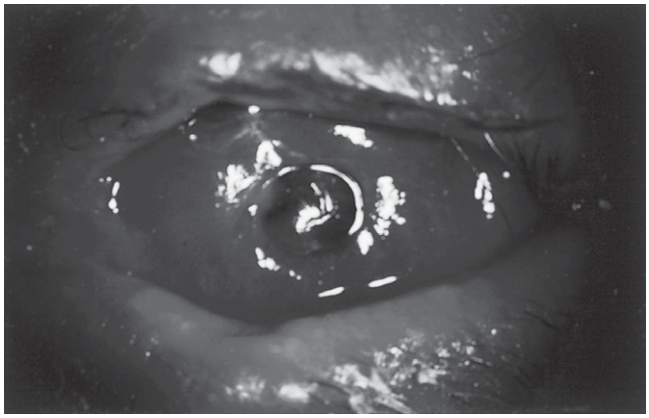


Figure 24.4. Herpes simplex perforation through center of the conjunctival flap. Total flap placement must be avoided in large corneal perforations (over 1–2 mm).

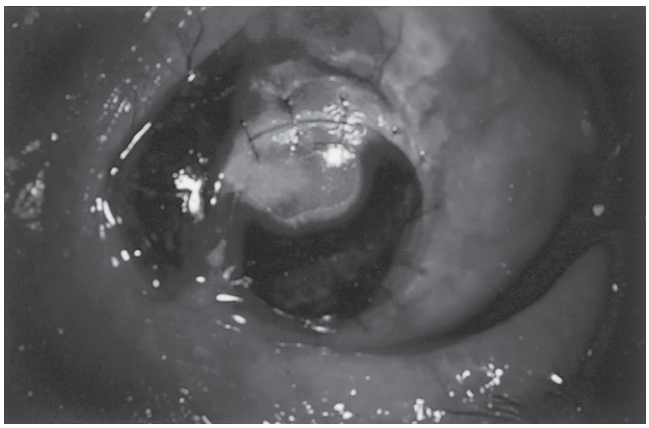

Figure 24.5. Recurrence of epithelial herpes simplex infection in penetrating corneal graft. Many corneal grafts fail if performed on inflamed or infected corneal ulcerations.

3. Collagenase inhibitors optional.
4. Avoid pressure bandage, soft contact lens, or conjunctival flap (Fig. 24.4).
5. Tissue-adhesive glue or fibrin sealant with or without corneal or scleral patch and with or without soft contact lens.
6. 'Blow-out' patch graft if anterior chamber is not easily reformed after glue. Carefully remove all glue placed previously before positioning patch graft because glue-degradation products cause necrosis of overlying patch graft.
7. Avoid penetrating corneal graft in an inflamed, infected eye as initial therapy (Fig. 24.5). Spread of infection to donor graft along with failure is common. Use only as the last resort.[75]

SPECIFIC THERAPEUTIC MEASURES

The treatment of recurrent corneal erosion by anterior stromal puncture and the technique for performing a conjunctival flap are reviewed elsewhere in this text.

GLUING TECHNIQUE FOR CORNEAL PERFORATION

Tissue-adhesive glue

In the past almost 30 years since Refojo and coworkers[76] reported the initial use of cyanoacrylate glue on a human eye, many other articles have followed, finding uses for glue involving every area of the eye from the treatment of corneal perforations to leaking filtering blebs, lid abnormalities, and even choroidal perforations. In the past, the most popular tissue adhesives used in ophthalmic care have included the *N*-heptyl octyl and isobutyl cyanoacrylate monomers. Bucrylate, the brand name of isobutyl cyanoacrylate, has been, in the past, available from Ethicon (Somerville, NJ). Isobutyl (Histacryl) and *N*-butyl (Histacryl-*N*-blue) has come from Germany via Tri Hawk International (Montreal, Canada). The *N*-butyl cyanoacrylate glue (Nexacryl) is now being manufactured by Closure Medical Corporation (Raleigh, NC). Patients who require the glue application can be referred to a center that has a tissue-adhesive investigational device status or can be treated with glue not yet approved by the Food and Drug Administration (FDA), possibly obtained from a local veterinary clinic or from the Veterinary Products Laboratories (Phoenix, AZ) (phone 888 241–9545). Because no tissue glue has been approved by the FDA, there are none currently available to the human ophthalmic community directly. Nexacryl has received an orphan device status to treat 'corneal melting' as there are no FDA-approved products presently available.

Reports have appeared in the literature extolling the virtues of cyanoacrylate tissue adhesive (CATA) as the first-line treatment to close leaking corneal wounds and to thereby restore temporarily or even permanently the integrity of the anterior chamber.[19,29,30,76–82] As a simple office procedure, the gluing of corneal wound leaks can quickly restore a deep anterior chamber with normal intraocular pressure until a more definitive corneal procedure can be done.

By rapid polymerization of carbon molecules, the adhesive readily sets up on contact with dry non-necrotic tissue and bonds firmly with the cornea until the natural scarring process of the cornea can take over in a few days to 1 or more weeks. Later, the degradation of the polymer will occur with cleavage of its carbon-to-carbon backbone and release of formaldehyde and other products.[79,83] These toxic by-products have led to stringent criteria for the use of this product and the reluctance of the FDA to approve it for general use. In truth, however, there has not been good evidence showing any deleterious ocular effects from these toxic by-products, and the inflammation observed with their use is probably more related to a foreign body reaction.[80]

The degree of reaction to the glue may be related to the amount used and to the specific monomer used, with perhaps less reaction being observed with higher monomers.[80,84]

The actual technique for applying the glue varies among corneal surgeons,[29,76,80,81,85] but certain basic principles apply. A common method is illustrated in Figure 24.6, *A*. Alternately, after topical anesthesia, the wet area of application can be blotted to remove any excess fluid, and necrotic tissue is debrided prior to glue application. The adhesive can then be directly applied to the perforation site in a drop-wise fashion using a sterile, tuberculin syringe and a 25–27-gauge needle so as to lightly coat and not entirely fill the defect (Fig. 24.6, *B*).[86,87] Another method for glue application involves the aerosolization of the glue and its application by a fine mist spray. This approach has only been attempted in cadaver eyes, and the initial results appear promising.[85] Although techniques for applying glue (see Fig. 24.6, *A* and *B*) vary, the following general principles apply:

1. Topical anesthesia is used, with a lid speculum being optional but also useful.
2. All necrotic tissue and epithelium are removed around the perforation site for at least 2 mm.

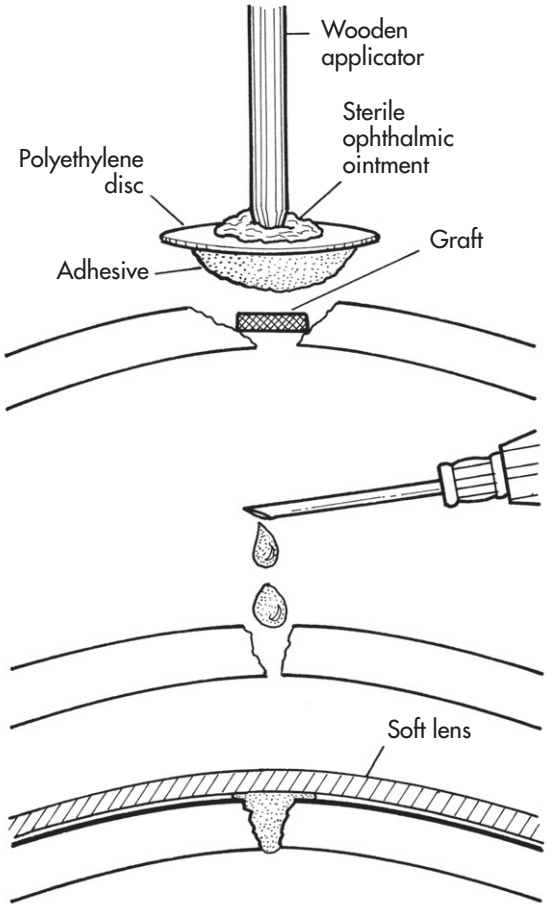

Figure 24.6. *A*, Method for sealing corneal perforation using a lamellar donor graft and cyanoacrylate tissue glue. *B*, Alternative method for glue application using tuberculin syringe and a 25- to 27-gauge needle to fill the defect.

3. The area is thoroughly dried with cellulose sponges because the polymerization of the glue occurs more efficiently without moisture.
4. Often optional, a lamellar piece of fresh or glycerin-preserved cornea or sclera is created and free-hand cut to fill the defect.
5. A small polyethylene disc having a 3–4 mm diameter is cut and affixed to the blunt end of a wooden applicator stick with a small amount of sterile ophthalmic ointment.
6. A tiny drop of the cyanoacrylate glue is placed on the face of the disc, and the disc–glue combination is pressed onto the once again dried perforation site and held in place for 1–2 min while polymerization occurs.
7. Often optional, a soft contact lens is fitted over the corneal glue site with a small air bubble maintained to demonstrate vaulting. This contact lens acts to separate the lids from the often heaped-up and hardened glue that can appear around the edges of the disc, which is otherwise quite irritating to the eyelid.
8. If the chamber does not deepen, the area is not sealed and the procedure can be repeated immediately.
9. If the gluing procedure is not successful and a lamellar patch graft with or without a partial conjunctival flap is contemplated, all the previously placed glue must be carefully removed just before placement of the patch graft. If this removal is not done, the underlying glue may cause considerable inflammation and necrosis of the overlying tissue with continued leaking of the site (Fig. 24.7).

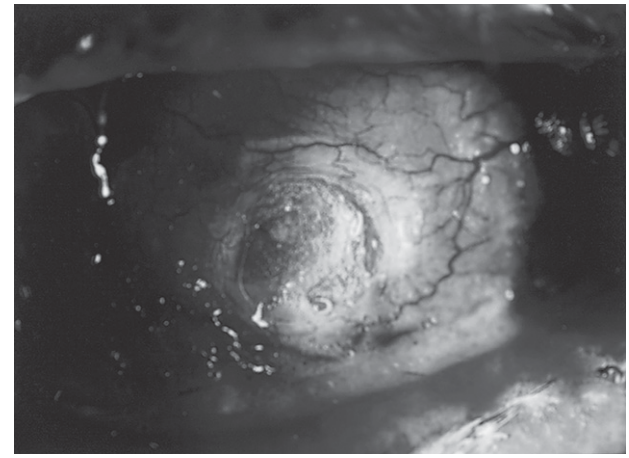

Figure 24.7. Necrosis of conjunctival flap 3 weeks after placement over tissue adhesive used to seal perforation. Toxic breakdown products of glue cause severe necrosis of overlying tissue (conjunctival flap or corneal patch graft). All glue should be meticulously removed before placement of tissue over the perforation site.

Fibrin tissue glue

Fibrin tissue glue has these components: human fibrinogen concentrate, bovine fibrinolysis inhibitor, human freeze-dried thrombin, and calcium chloride solution.[64] By mimicking the body's own response to injury, fibrin creates a clot that allows tissues to stick together. Within 3–5 min of delivery a coagulum forms, with 70% of its ultimate strength derived in the first 10 min and full strength developed by 2 h.[88] Fibrinogen converts to fibrin strands, which bind collagen together into a clot-like structure. In order to minimize the risk of pathogen transmission, the fibrinogen is vapor heated and freeze dried in its commercial preparation.[72]

METHOD OF APPLICATION OF FIBRIN GLUE

Prior to mixing, the components are placed for 10 min in a 37°C water bath. To avoid premature coagulation, the fibrinogen and thrombin are separately placed into each side of a double-barreled syringe, allowing their mixing only when the two components come together in a common cannula on injection at the surgical site. The glue rapidly solidifies at the treatment area and forms an opalescent gel solid, which fades with time. The fibrin complex acts to provide a smooth surface for epithelial overgrowth and stable matrix for later scar formation. The incorporation of the fibrin plug under the epithelium and into the corneal stroma provides an additional tectonic benefit for the weakened cornea.[64] Individual techniques notwithstanding, the following is a general method for fibrin glue placement:

1. Prepare the fibrin glue according to kit instructions.
2. After applying topical anesthesia, remove the epithelium around the involved area to better demarcate the level of the stroma involved.
3. Remove loose debris and dry the area to be treated thoroughly with cellulose sponges.
4. Apply fibrin glue with the fine cannula provided, which both mixes and delivers material to the treatment site.

5. Place the drop solution only to the anterior-most level of the stroma, which will thereby underfill the ulcer and allow transverse horizontal re-epithelialization.
6. The immediate post-treatment placement of a soft bandage lens to be used for the next 2–3 weeks aids in both supporting the plug and allowing the epithelial regrowth to proceed more easily.[64]

Fibrin glues are currently available commercially from these sources: Beriplast Fibrin Sealant (Nycomed, Roskilde, Denmark), Hemaseel Fibrin Sealant (Haemacure Corporation, Sarasota, FL, USA), and Tiseel VH Fibrin Sealant (Baxter, Deerfield, IL, USA).[72]

ADVANTAGES OF FIBRIN GLUE AS A TISSUE SEALANT

Fibrin glue in the operating room is more quickly applied than multiple suture placement[88] and may permit more rapid healing than CATA. There is less corneal vascularization than with CATA.[89] Its placement is quite easy and can be performed by most ophthalmologists in a simple setting.[64] The fibrin material does not foam up, thereby allowing better judgment on application height; it lies flat once applied and is better biologically incorporated, thus promoting more rapid re-epithelialization.[64] Finally, because it is biodegradable and flexible, it can be placed more easily beneath tissues with less inflammatory response and less discomfort to the patient both during and after treatment.[72]

DISADVANTAGES OF FIBRIN TISSUE GLUE AS A SEALANT

Fibrin requires a significantly longer time for adhesive plug formation than CATA.[89] CATA may be better for perforations that are smaller than 2 mm, as it adheres more strongly to stromal elements than fibrin.[64] Fibrin's low inflammation-inducing property may be a disadvantage if vascularization is desired in order to hasten wound healing.[72] Autologous fibrin glue must be used to limit the potential transmission of diseases such as those caused by prions and viral particles.[72] Other disadvantages of fibrin glue are its relatively short life of less than 2 weeks, which may require repeated applications, and its being a somewhat more expensive treatment if it is required to be used repeatedly.[72,88]

TECHNIQUE FOR LAMELLAR 'BLOW-OUT' PATCH GRAFTING

If a corneal perforation of greater than 2–3 mm is present, the site should be repaired with a small lamellar or full-thickness graft (Fig. 24.8). An alternative method of converting the circular defect to an elliptical one, which is then sutured and glued, has also been reported.[90] Penetrating keratoplasty is to be avoided because these grafts do poorly in inflamed, often infected, and hypotonous eyes.[75] The technique itself varies, but general principles apply.[2]

Preparation of recipient perforation:

1. Local anesthesia is preferred, but care must be taken to minimize ocular squeezing during the placement of the lid and retrobulbar block.
2. A lid speculum is placed.
3. The epithelium and necrotic tissue are carefully removed for 2–3 mm outside the perforation site, and an application of cyanoacrylate glue can be made in the usual manner to seal the perforation (see Fig. 24.8, *A*).
4. After the glue has been placed, a paracentesis can be made, and balanced saline solution, hyaluronate, or both are injected into the anterior chamber to restore normal depth and pressure.
5. Small 'sizing' corneal trephines are gently placed over the perforation site so as to leave a small cuff of normal tissue about the central inflamed core (Fig. 24.8, *B*). Usually a 3- or 4-mm trephine will suffice.
6. A mark is made with a trephine, and the resulting circle is deepened with a razor blade or diamond knife to one-half to two-thirds the corneal depth (Fig. 24.8, *B*). The usual spinning trephination is more difficult because of the ocular hypotony.
7. The area of clear cornea inside the ring is dissected off to about one-half the corneal depth with a #6600 Beaver lamellar or comparable blade (Fig. 24.8, *C*). Air can be injected into the recipient stroma around a descemetocele to temporarily thicken the stromal bed and to facilitate the deep lamellar dissection without perforation.[91]

Preparation of donor:

1. A donor whole eye—fresh, frozen, or glycerin preserved—is inflated to normal or just above normal intraocular pressure and is placed in a donor eye holder.

TECHNIQUE FOR CREATING A LAMELLAR DONOR BUTTON

1. The epithelium of the donor is removed and a one-half corneal-depth trephination (0.3–0.4 mm) is made with a 6–8-mm corneal trephine (Fig. 24.8, *D*).
2. Using a lamellar dissector, a two-thirds corneal-depth incision is created over 80% of the button, with care being taken to allow a small area of nonseparated cornea to remain at the distal edge of the dissection so that the button created remains hinged along this remaining area (Fig. 24.8, *E*). The proximal edge of the button is sutured back to the edge of the adjoining corneal surface with one to three interrupted 10-0 nylon sutures (Fig. 24.8, *F*). The hinge on one side and the interrupted sutures on the opposite result in a firm seating of the lamellar button once again on its bed. This approach prevents graft rotation on subsequent trephination of the button to be used in creating the patch graft.
3. The appropriately sized trephine, determined on prior inspection of the recipient eye, is then used to create the exact-sized button for the patch graft (Fig. 24.8, *F*).
4. The donor button thus created is placed over the recipient site and affixed with multiple interrupted sutures, a short running 10-0 nylon suture, or Figure 24.8 mattress sutures with buried knots (Figs 24.8, *G* and 24.9, *A*).
5. Often optional, a soft contact lens may be used to promote re-epithelialization, and appropriate antibiotics and cycloplegic drops are administered.
6. Corneal sutures are removed 1–3 months after surgery (Fig. 24.9, *B*).
7. Some surgeons prefer a full-thickness corneal button to use as the donor. In this case, it is appropriate simply to create a 3–4-mm full-thickness button with a corneal punch as described above.

8. The use of donor, preserved keratoconus corneas has been recently described as useful in therapeutic corneal patching in fungal ulcers with perforation.[92]

AMNIOTIC MEMBRANE TRANSPLANATION

Amniotic membrane is the innermost layer of fetal membranes. It is comprised of stromal matrix, a thick collagen layer, and an overlying basement membrane with a single layer of epithelium. It has a combination of antiadhesive effects, bacteriostatic properties, and wound-protective abilities, and its surgical use allows both the reduction of pain and the enhancement of tissue epithelialization. It has a lack of immunogenicity and has been used as a surgical material for several decades.[93]

MECHANISM OF ACTION OF THE AMNIOTIC MEMBRANE GRAFT

The presence of normal corneal substrate is critical to normal epithelial differentiation and proliferation. The corneal basement membrane acts to facilitate the migration of epithelial cells and reinforce the adhesions of basal epithelial cells, and helps to promote epithelial differentiation while preventing epithelial apoptosis. The amniotic membrane also acts as a transplanted basement membrane, which serves as a healthy substrate 'scaffolding' allowing proper re-epithelialization. In addition, the membrane provides various growth factors such as basic fibroblastic growth factor, hepatocyte growth factor, and transforming growth factor β, which can stimulate epithelialization. The tissue can act as a 'bandage lens' promoting healing while simultaneously acting to inhibit protease activity. Through its antifibrotic effect it induces a downregulation of the transforming growth factor β's signaling and thereby reduces the fibroblastic activation seen in wound healing. Finally, amniotic membrane material can serve as a barrier that separates two potentially sticky surfaces, and its relatively avascular nature is believed to inhibit the incursion of new blood vessel growth.[94]

CONDITIONS WHICH MAY BENEFIT FROM AMNIOTIC MEMBRANE GRAFTS

Amniotic membrane grafts have been found to be useful in a variety of anterior segment conditions including: Mooren's ulcers;[95] severe

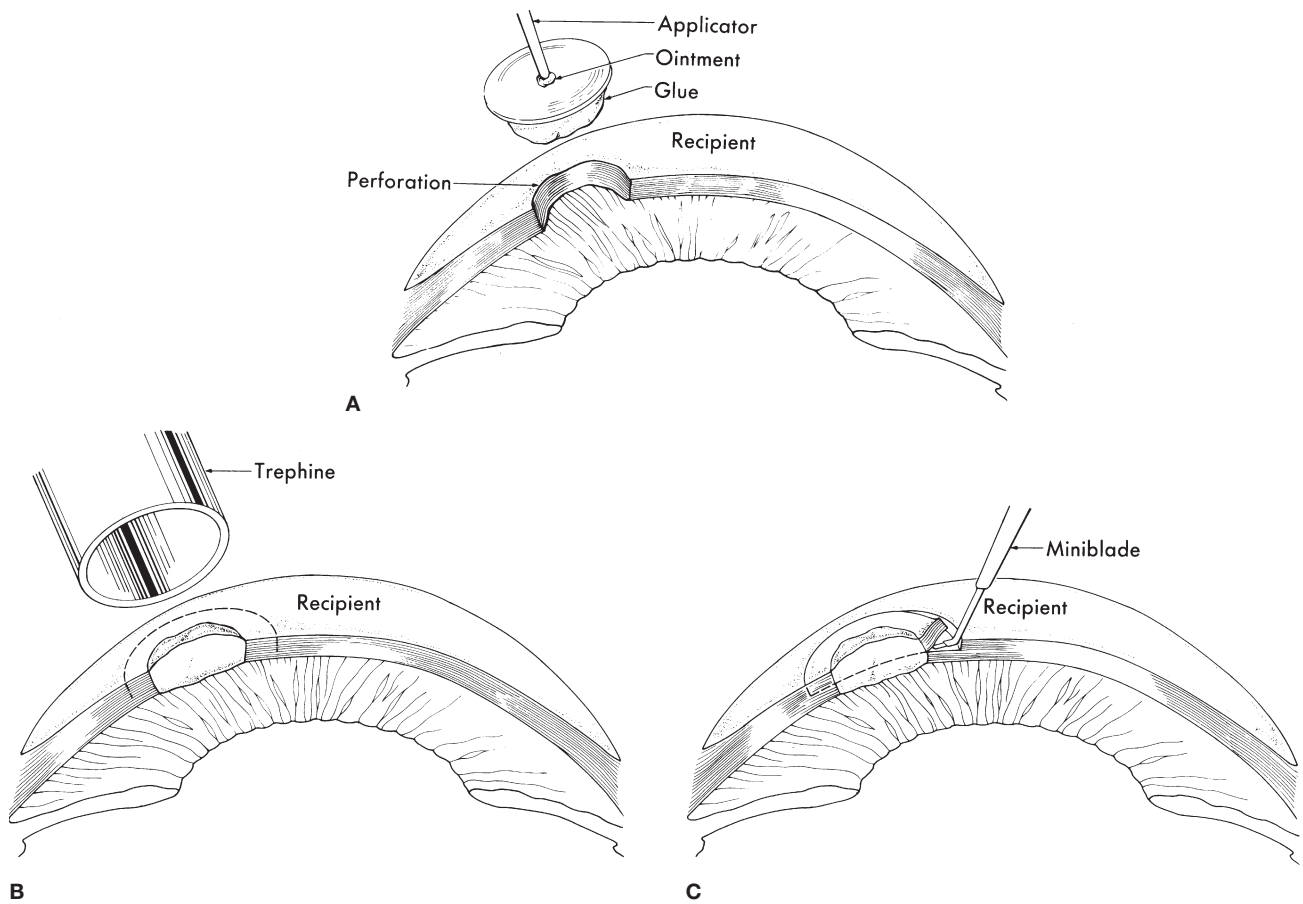

Figure 24.8. Lamellar keratoplasty principles used in creating a 'blow-out' patch graft for sealing a corneal perforation. *A*, Cyanoacrylate adhesive on a rounded plastic drape before application over the perforation site. Sodium hyaluronate can be used to push back adherent iris if necessary. *B*, Recipient perforation 'plugged' with glue. Sizing trephine outlines a one-half to two-thirds depth incision in normal cornea surrounding the perforation. *C*, No. 6600 lamellar blade dissection inside the trephine mark creates a bed for the 'patch' graft. Notice the perpendicular wall, which facilitates suturing of the button into the recipient bed. *D*, Trephination of donor cornea in the same general area as the recipient hole, outlining an incision of 0.3–0.4-mm depth. In some cases, full-thickness donor buttons trephined from the anterior corneal surface are satisfactory and will ultimately thin down and conform to recipient bed thickness. *E*, One method for dissecting donor lamellar graft in deep stromal plane. *F*, After reanchoring of dissected lamellar button with suture, a properly sized trephine creates the exact button desired. *G*, Donor cornea is sutured into the perforation with 10-0 interrupted nylon. Knots should be trimmed short or buried.

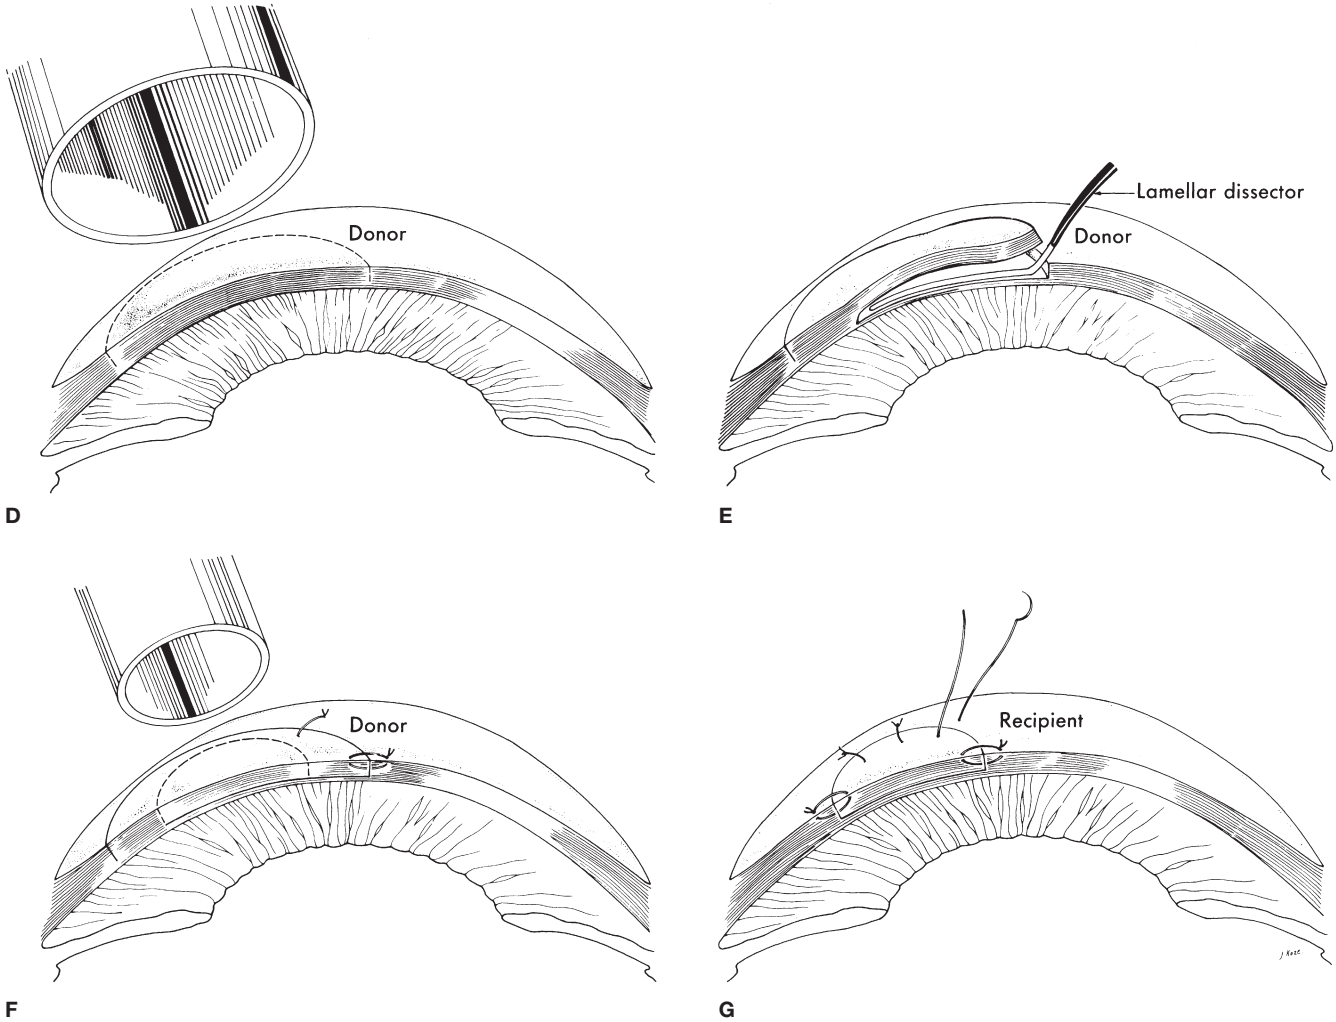

Figure 24.8. Continued

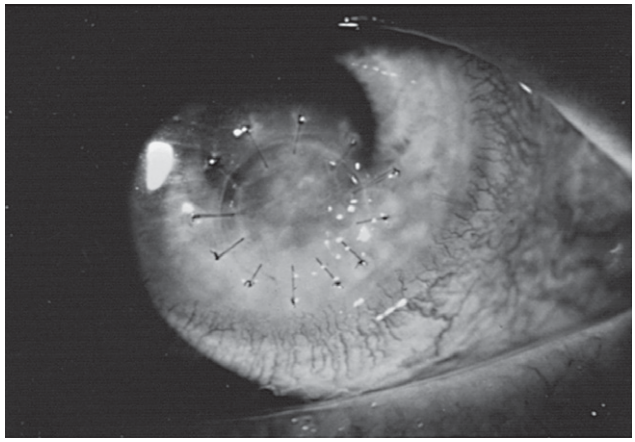
neurotrophic corneal ulcers;[96] persistent corneal epithelial defects;[68] as an adjunct in corneal and conjunctival surface reconstruction procedures;[96] as an alternative to conjunctival flaps, botulinum toxin injection or tarsorrhaphy;[94] as a substitute for transconjunctival grafting in pterygium surgery;[94] in combination with limbal stem cell transplantation in diffuse limbal stem cell deficiency states such as with Stevens-Johnson syndrome, advanced ocular pemphigoid, or chemical and thermal burns;[94,97,98] symblepharon;[93] nonhealing corneal ulcers;[99] nontraumatic corneal perforations and descemetoceles;[100] perforations of the cornea in hypovitamin A states;[101] severe and nonresponding corneoscleral and/or corneal ulcers;[102] corneal surface disorders in patients with Grave's disease;[103] and in acute ulcerative and necrotizing herpetic keratitis.[104]

PREPARATION OF PRESERVED HUMAN AMNIOTIC MEMBRANE FOR GRAFTING

The membrane is screened for HIV infectivity, both types 1 and 2, human T-lymphoma virus type 1, hepatitis B and C viruses, and syphilis both at the time of caesarean delivery and at 6 months postpartum.[96] The harvested amniotic membrane is next flattened onto nitrocellulose paper, with the epithelium/basement membrane oriented surface up. It is stored in a sterile plastic vial at −80°C. When needed for use, it is defrosted by warming the container at room temperature for 10 min. The tissue is then rinsed three times in plain saline and then once in saline containing 100 mg dibekacin sulfate.[94] Celgene Cellular Therapeutics offers a packaged dehydrated human amniotic membrane allograft called Acelagraft. While this is a simple alternative to the preparation of the membrane, the major disadvantages are poor availability and high cost.

TECHNIQUE FOR PERFORMING AN AMNIOTIC MEMBRANE GRAFT FOR A PERSISTENT CORNEAL EPITHELIAL DEFECT OR ULCERATION

Debride the base of the ulcer or defect and the loose epithelium around the edge of the ulcer. Separate, with blunt forceps, the underlying chorion from the amniotic membrane or purchase prepared dehydrated or frozen amniotic membrane. Spread the membrane on the eye surface and cut it slightly larger than the area needed to be covered. The membrane is always placed with the epithelial side up and the mesenchymal surface in contact with the eye to facilitate adherence of the membrane to the ocular surface. Use 10-0 sutures to attach the membrane to corneal tissue and 9-0 Vicryl sutures to attach the membrane to the episcleral/conjunctival surface. After membrane suturing is complete, place a bandage contact lens, and apply antibiotic and steroid drops. Sutures can be removed approximately 3 weeks post-op.[94]



A

Figure 24.9. *A*, Lamellar patch graft anchored with 10-0 interrupted nylon sutures for rheumatoid patient with corneal melt (early in postoperative course). *B*, The same eye after healing and suture removal.

ADVANTAGES OF USING AMNIOTIC MEMBRANE GRAFTS

Amniotic membrane material contains both biological growth factors and anti-inflammatory factors.[64] The membrane is easily obtained and plentiful;[94] and can be preserved at –80°C for several months.[94] It does not express HLA-A, B, or DR antigens and is therefore not host rejected.[94] It may contain antimicrobial properties with a reduced risk of post-op infections.[94] Its antifibroblastic and cell migration/growth activities are helpful in complication-free healing.[94] Since the membrane heals rapidly and becomes transparent in a few weeks, vision recovery is sooner. The graft's relative avascularity also achieves greater cosmesis in comparison to conjunctival graft's more opaque appearance.[68]

DISADVANTAGES OF AMNIOTIC MEMBRANE GRAFTS

Amniotic membrane materials are not always available at all treatment centers worldwide. Cryopreservation technology and tissue banking facilities are required. Sutures are needed to hold tissue in place; as the grafted material can become unstable, tear and be dislodged, or can disintegrate before epithelialization has taken place. Experience is required for proper orientation of both the smooth epithelial and the sticky mesenchymal sides against the ocular surface.[64,94]

25 Peripheral corneal disease with thinning

Yuri S. Oleynikov, Tania M. Onclinx, Ella G. Faktorovich, Bartly J. Mondino

Peripheral corneal ulcers and thinning disorders are unusual diseases that may be difficult to treat but rarely require surgical intervention. The mainstay of therapy for Mooren's ulcer is medical, with surgical intervention treatment only in the event of perforation or threatened perforation. Terrien's marginal degeneration and pellucid marginal degeneration may require surgical therapy to improve visual acuity or reinforce the cornea in the presence of severe thinning.

MOOREN'S ULCER

Mooren's ulcer is a chronic, painful, and devastating peripheral keratitis, rare in the USA but more common in developing countries. It was first described by Mooren in 1867.[1] The lesion begins with a steep, undermined, and occasionally infiltrated leading border and characteristically is confined to the periphery of the cornea in the early stages, but it relentlessly progresses, circumferentially and centripetally, to involve the whole cornea and occasionally the adjacent sclera.[2] With progression, the entire cornea may become thin, vascularized, and opaque. It is bilateral in 25% of cases but does not necessarily develop simultaneously. An interval of several years may lapse between the involvement of the first and the second eyes.[3,4]

CLINICAL DESCRIPTION OF PERIPHERAL CORNEAL DISEASE WITH THINNING

Patients with Mooren's ulcer usually complain of tearing, photophobia, and redness of the eye, but severe pain is typically the main symptom. Visual acuity can be decreased because of irregular astigmatism from peripheral corneal thinning or extension of the ulcer into the pupillary area. On examination, the disease may begin as one or two patches of grey infiltrate near the margin of the cornea, which slowly spread, coalesce, and eventually break down to form a shallow furrow. It may also begin as a narrow grey infiltrate near the limbus, which in a few weeks breaks down to form a marginal ulcer. The ulcer spreads around the periphery, toward the center of the cornea and occasionally into the sclera. The ulcer spreads slowly, undermining the corneal epithelium and the superficial lamellae so that a grey, infiltrated, overhanging edge is formed. This edge is characteristic of Mooren's ulcer.[5]

Wood and Kaufman[2] divided Mooren's ulcer into two groups. The first is a limited type that is unilateral, occurs in older male patients, does not have a racial predilection, and responds to conservative measures.[6] The second is a progressive type, most commonly occurring bilaterally in young black patients between 20 and 30 years of age and frequently involving the sclera as well as the peripheral cornea.[7] It is associated with severe pain and has a poor prognosis because it does not respond well to therapy, and one-third eventually develop corneal perforations.

HISTOPATHOLOGY

Histopathologic examination of the conjunctiva adjacent to the lesion shows numerous plasma cells, lymphocytes, and mast cells in various stages of degranulation. The corneal stroma, as well as the conjunctiva, is infiltrated with inflammatory cells, such as lymphocytes and neutrophils, that appear to be actively releasing their granules and forming phagocytic vacuoles.[8] The leading edge of the ulcer is infiltrated with leukocytes. The epithelium and Bowman's membrane overlying the lesion are destroyed, and in some cases all that is eventually left is Descemet's membrane. When the cornea is healed, conjunctival epithelium and vessels cover the most posterior corneal lamellae.

ETIOLOGY

The disease can be divided into two groups: primary and secondary. The most common of these groups is primary or idiopathic. The ulcer usually occurs without any precipitating cause and can manifest itself in either a limited or a relentless form. The secondary form, or Mooren's-like ulcers, occurs after various insults to the cornea, including cataract surgery,[9–11] penetrating keratoplasty,[12,13] corneal injuries such as foreign bodies or alkali burns,[2] and herpes zoster ophthalmicus.[10–14] Most secondary cases are unilateral and clinically behave like a limited form and generally respond well to therapy.

An association with Mooren's ulcer and chronic hepatitis C virus (HCV) has been described.[15–17] In these cases, the corneal disease

improved after treatment of the systemic disease. However, when a study in India compared 21 patients with Mooren's ulcer to 44 controls, none of the patients were hepatitis C positive, while one of the controls was. There was also no statistically significant difference in seropositivity rates for rheumatoid factor, ANCA, and antinuclear antibodies, but history of trauma, surgery, or infection was reported 3.4 times more frequently in patients with Mooren's ulcer.[18] Another study at Nehru Hospital examined 50 patients with chronic HCV infection and found that none of them had any evidence of Mooren's ulcer, suggesting that screening of HCV patients for Mooren's ulcer is unnecessary.[19] This agrees with the low estimated frequency of Mooren's ulcer in HCV patients—1 : 10 000 by Wilson et al.[17] The same team is investigating the possibility that HCV-associated flaviviruses are involved in Mooren's ulcer pathogenesis.[20]

In the past, Mooren's ulcer has been related to metabolic disorder and malnutrition, trophic disturbances involving the trigeminal nerve, deficiency of vitamin B1, and ancylostomiasis.[21] An Association with hookworm infection in patients from Sierra Leone was proposed in 1963[22] but could not be confirmed due to high rate of this parasitic infestation in the study population. Both patients and controls had the parasite and antibodies to it, although Mooren's ulcer patients had significantly higher titers.[23]

The etiology of Mooren's ulcer is unknown, but evidence suggests an autoimmune basis. Supporting evidence includes the presence of plasma cells and lymphocytes in the conjunctiva adjacent to the ulcer;[24] circulating antibodies to conjunctival and corneal epithelium in the serum of patients with Mooren's ulcer;[25–27] an elevation of serum levels of immunoglobulin (Ig)A, IgG, IgM, and C3;[25,26,28] lymphocytes sensitized to saline-soluble cornea antigen;[8] increased antibody levels to a cornea-specific stromal protein antigen;[29] increased helper T cell to suppressor T cell ratio;[28,30] and favorable response to immunosuppressive agents in some patients.[6,28] A unique cornea-associated protein that is present in the cornea and is the target of autoantibodies from patients with Mooren's ulcer was isolated and sequenced.[29,31] This Ca-binding protein, termed calgranulin C, is identical to a neutrophil protein found on the surface of filarial nematodes.[32] Calgranulins are a family of Zn- and Ca-binding proteins secreted by neutrophils, monocytes, and other immune cells. Calgranulin C absorbs on the surface of a parasite and has filaricidal and filaristatic activities.[33] Recognition of this complex on a filarial nematode is suspected to lead to autoimmunity to the cornea in patients with persistent parasitic infection resulting in Mooren's ulcer.

Mooren's ulcer may represent a final common pathway to a variety of insults to the cornea in susceptible patients. Trauma or infection may alter normal corneal antigens, which may lead to an autoimmune response. The cornea is further damaged, liberating more altered corneal antigens that aggravate and perpetuate the process until the corneal stroma is completely destroyed.[34]

DIFFERENTIAL DIAGNOSIS

Mooren's ulcer is a rare disease.[35] The differential diagnosis includes other inflammatory or noninflammatory causes of peripheral thinning, such as catarrhal ulcer, collagen vascular disease, and Terrien's degeneration. Terrien's degeneration[36] is a noninflammatory peripheral corneal thinning disorder that is usually superior, bilateral, and not associated with significant pain or inflammation unless there is an associated episcleritis or superficial scleritis. The corneal epithelium remains intact, and the disease progresses slowly circumferentially but does not involve the central cornea. Peripheral marginal keratitis (catarrhal ulcer), seen in association with staphylococcal blepharitis, can also demonstrate peripheral infiltrates. In these patients, the infiltrate is usually unilateral and separated from the limbus by a lucid interval, the pain is not severe, and the course is benign and self-limited.

Collagen vascular diseases, such as rheumatoid arthritis, polyarteritis nodosa, Wegener's granulomatosis, and systemic lupus erythematosus,[37] may also be associated with peripheral-corneal infiltrates and ulcers with features that resemble Mooren's ulcer, and an associated scleritis may be present.[38–43]

Scleritis is a well-recognized complication of rheumatoid arthritis.[40,42] The scleritis can spread into and involve the adjacent cornea as a sclerokeratitis, which may be associated with marginal thinning. However, a characteristic marginal corneal ulcer has been described in patients having rheumatoid arthritis with or without scleritis. The characteristic marginal furrows of rheumatoid arthritis were observed in patients who had the disease for at least 5 years. The marginal furrows were located approximately 1 mm within the limbus and usually in the inferior cornea, usually bilateral. It could be superficial and nonprogressive, or it could progress to epithelial breakdown, marked stromal thinning with descemetocele formation, and finally perforation. Usually, there was minimal inflammation and vascularization unless the lesion perforated. The marginal furrows may encircle the cornea, and bilateral involvement may be found. Occasionally, the entire superficial part of the remaining central island of corneal stroma may slough away.

To make the distinction between all these diseases, history and serologic testing may be indicated. Foster[30] recommends that all Mooren's ulcer patients need to undergo a general history, a medical examination, and laboratory studies that should include complete and differential blood cell counts, platelet counts, erythrocyte sedimentation rate, rheumatoid factor, antinuclear antibody, antineutrophil cytoplasmic antibodies, chest X-ray examination, liver enzymes, Venereal Disease Research Laboratory, fluorescent treponemal antibody absorption test, blood urea nitrogen, serum protein electrophoresis, and urinalysis.

THERAPY

Currently, a stepladder approach to therapy is recommended.[6] The objective of the therapy is to stop the progression of the ulcerative process and promote the re-epithelialization of the ulcerated area. Symptoms of pain and photophobia and inflammatory signs of conjunctiva hyperemia and edema generally disappear shortly after healing is complete. Brown and Mondino[6] suggest a stepladder approach that includes topical corticosteroids, conjunctival resection, and systemic immunosuppressives. Table 25.1 summarizes results using this approach in 44 eyes of 28 patients. Most of the cases (31 of 44 eyes) healed with this regimen. Other surgical treatments are possible, but their indications are rare and specific.

Topical corticosteroids

Initially, patients with Mooren's ulcer are treated with topical corticosteroids, usually prednisolone acetate 1% every hour, as long as there is no sign or danger of imminent perforation. If the ulcer heals completely, the frequency of topical drops can be slowly tapered. Aggressive therapy with topical corticosteroids may be effective in unilateral and bilateral nonsimultaneous cases but not in bilateral simultaneous cases. Patients with Mooren's ulcer are treated with topical antibiotics to prevent secondary bacterial infection. Cycloplegics can be administered to control the pain from spasm of the

Table 25.1 Treatment results for mooren's ulcer

	Topical Corticosteroid[a]	Conjunctival Excision[a]	Immunosuppression[a]	Total[a]
Unilateral	8/12	3/4	0/1	11/12
Bilateral nonsimultaneous	3/6	3/3	—	6/6
Bilateral simultaneous	4/22	2/15	8/16	14/26
Total	15/40	8/22	8/17	31/44

[a] Number of eyes healed/number of eyes treated with each treatment.

ciliary body. Topical corticosteroids must be used with extreme caution in patients having rheumatoid arthritis associated with corneal ulcers.

A novel experimental therapy of noninfectious corneal ulcers utilizing lecithinated superoxide dismutase in a form of topical drops has been described in a study on 19 eyes with corneal ulcers, 6 of them being Mooren's ulcer.[44] Superoxide dismutase reduces reactive oxygen metabolites produced by polymorphonuclear leukocytes to hydrogen peroxide, thus limiting tissue destruction by these toxic mediators of polymorphonuclear neutrophilic leukocyte (PMN) function. Dismutase therapy has been also successfully used in limiting hypoxic damage of muscle and lung tissue. In this study, Mooren's patients who failed topical corticosteroid therapy had an average 71.5% reduction of epithelial defect in 2 weeks of dismutase application, and some healed completely after 5 weeks of therapy.

Conjunctival resection

If there is an incomplete or absent response to topical corticosteroids, conjunctival excision may be performed adjacent to the ulcer.[45,46] After the topical application of proparacaine hydrochloride 0.5% for anesthesia (sometimes patients may require subconjunctival or retrobulbar anesthesia) and phenylephrine hydrochloride 2.5% for vasoconstriction, the conjunctiva is incised approximately 3 mm from the corneoscleral limbus and adjacent to the ulcer. The conjunctiva is dissected to the corneoscleral limbus and excised. The epithelium in the bed of the ulcer and less than 0.2 mm of corneal epithelium central to the ulcer are removed by simple debridement. Postoperatively, topical corticosteroids and antibiotics are continued. The procedure can be repeated if necessary. Conjunctival resection may be beneficial to patients with peripheral corneal ulcers associated with collagen vascular disease. Pathological examination of tissue excised in six bilateral Mooren's ulcer cases showed intact epithelium and basal membrane but edematous stroma with mixed cellular infiltration primarily of plasma cells and lymphocytes, with few neutrophils, mast cells, and eosinophils.[47] Hyperemia and hemorrhagic infiltration were present, but vessels showed no signs of necrotizing vasculitis. Aviel[48] describes a surgical technique with cryotherapy and peritomy in patients with Mooren's ulcer, and his results may have a similar effect to conjunctival excision.

Systemic immunosuppressives

Sometimes, patients with bilateral and progressive disease are very difficult to treat, and conjunctival excision does not result in total healing of the ulcer. In these cases, immunosuppressive therapy is considered and the supervision of an internist or oncologist is needed.

The most common immunosuppressive drugs used are cyclosphosphamide (2 mg/kg/day) and azathioprine (2 mg/kg/day) with or without prednisone (1 mg/kg/day). Alternatively, other medications could be used, such as methotrexate (7.5–15 mg/week). Some authors treat Mooren's ulcer with systemic and topical cyclosporin A (0.5%) and report favorable results.[49–51] The efficacy of topical cyclosporin is attributed to local depression of the ocular immunopathologic reaction.[51]

If healing does not occur after 1 or 2 months, immunosuppressive therapy is slowly decreased and then discontinued. On the other hand, if some healing is observed, the medication is continued until complete healing and then for an additional month after which the dosages are slowly decreased. During treatment, dosages of the medication are titrated to maintain a hemoglobin level of 10 g/100 mL or more, a white blood cell count of more than 3000 cells/mm with at least 1500 neutrophils/mm, and a platelet count of more than 100 000 platelets/mm. A complete blood cell count, including platelet count, is obtained for each patient taking cyclosphosphamide or azathioprine weekly for the first month of therapy, twice each month for 2 months, and once each month thereafter if hematologic findings are stable.

The peripheral corneal ulcers associated with collagen vascular diseases may also respond to systemic immunosuppressives.[41] Therapy for corneal ulceration and scleritis in patients with collagen vascular diseases should focus initially on the management of the systemic disease. Medical and rheumatologic consultation is important because of the increased mortality in patients without proper treatment. Systemic immunosuppressive agents, including corticosteroids, have been proven effective in the treatment of scleritis and ulcerative keratitis. Moreover, cytotoxic agents may improve long-term survival.

Interferon-α2b

Recently, an association has been reported between Mooren's ulcer and hepatitis C infection.[15–17] In some cases, a bilateral ulcer that did not respond to any form of conventional therapy demonstrated a marked improvement after treatment with systemic interferon-α2b for the chronic active hepatitis. In another example, the corneal disease improved after 6 weeks of interferon-α2b treatment, abruptly worsened when interferon was discontinued, and improved again when the medication was reinstituted.

Surgical procedures

An overall schematic plan for the surgical treatment of peripheral corneal perforations is presented in Figure 25.1.

Tissue adhesive

Some patients progress to corneal perforation. If the perforation is less than 1 mm in size, the best treatment is the tissue adhesive, isobutyl-cyanoacrylate (see Fig. 25.1, *A*). The adhesion is formed by polymerization of d-alkyl-2-cyanoacrylate monomers. This

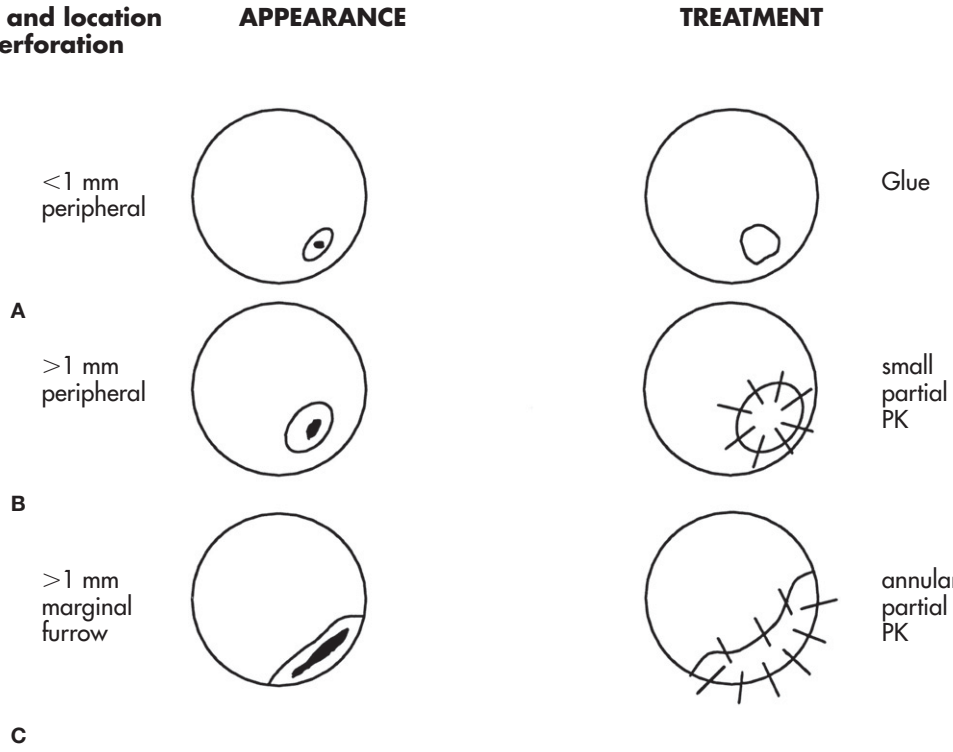

Figure 25.1. Diagrammatic approach to the treatment of peripheral corneal perforations. The area in the figures represents the ulcer bed, and the black area within represents the perforation. *A*, For peripheral perforations 1 mm and less, tissue adhesive is the first line of treatment. *B*, If tissue adhesive fails or the perforation is greater than 1 mm, a small partial peripheral penetrating keratoplasty may be performed. *C*, In cases of marginal ulcerations and perforations, an annular peripheral penetrating keratoplasty is often necessary.

monomer is an electronegative liquid that, in the presence of anions, polymerizes and becomes a solid adhesive. Animal and human studies show that if the application is done at an early stage, before perforation, prompt arrest of the ulceration may occur by preventing the migration of polymorphonuclear leukocytes into the ulcerated area.[52,53]

Several methods of application have been described; because the adhesive rapidly polymerizes on contact with water, it must be applied carefully on a dry surface to minimize formation of a large, elevated, rough mass. One technique that maximizes the chances of obtaining a smooth surface is to apply the adhesive using a small polyurethane disc, which may even be cut from surgical drape material. Then a small drop of adhesive is placed on the other side of the disc and held upright. The area of perforation or ulceration is de-epithelialized and dried. The adhesive and disc are then applied to the area. The eye is irrigated with balanced salt solution to completely polymerize the adhesive. The disc overlying the adhesive minimizes the chances for a rough surface.

Keratoplasty

When a perforation is too large for tissue adhesive to seal the leak, some type of patch graft may be necessary (see Fig. 25.1, *B, C*). This patch may range from a tapered plug of corneal tissue to a peripheral penetrating keratoplasty.[54] A small piece of corneal tissue is fashioned into a tapering plug to fill the defect. The anterior chamber can be filled with sodium hyaluronate or similar viscous substance to protect and cushion the corneal endothelium. The margins of the perforation site should be cleaned of any necrotic material and epithelial tissue. The plug is placed in the perforation site and sutured into place with interrupted 10-0 nylon suture. When suturing to the thin peripheral cornea, the bite should be through and through and extend into adjacent sclera.

In cases of larger peripheral perforations, a partial penetrating keratoplasty may be performed (Fig. 25.2, *A–C*). This procedure is performed by marking the area around the perforation with a trephine of appropriate size. Next, the perforation site is entered with one blade of the corneal scissors. The cornea is incised and then excised along the trephine mark. A button of larger size is then sutured into place using interrupted 10-0 nylon suture. Penetrating keratoplasty has also been described in patients with healed Mooren's ulcers, but the results are generally poor. Penetrating keratoplasty may be complicated by the recurrence and extension of the disease process into the donor tissue with resultant necrosis and sloughing. In Mooren's ulcer, penetrating keratoplasty may restore some vision in a healed and quiet eye with an opaque or scarred cornea (Fig. 25.3, *A* and *E*). When the cornea is not perforated, a crescentic annular lamellar graft is rarely used in cases of peripheral corneal thinning. In these cases, the area of the recipient cornea to be repaired is marked using trephines. The edge of the marked cornea is lifted, and a lamellar dissection is then performed. The donor cornea is then trephined and placed into the recipient bed and sutured in place with interrupted 10-0 nylon (Fig. 25.4, *B*).

AMNIOTIC MEMBRANE TRANSPLANTATION

An alternative treatment for reconstruction of ocular surface and corneal stroma damaged by an immunologic process involves the use of amniotic membrane (AM). Although exact mechanisms of its function are not clear, AM has been shown to possess anti-inflammatory and anti-immunogenic qualities and may be a substrate for stromal reconstruction due to abundance of collagen IV and fibroblasts in this tissue.[55] A few authors attempted to limit Mooren's ulcer progression as well as reconstruct damaged cornea with single- and multilayer AM transplantation. The former method involves placing an AM stromal side down onto the ulcerated defect and securing it with sutures.[56–58] Multilayer AM fragments can be

placed into a stromal ulcer defect to facilitate fibroblast migration and proliferation, as well as to provide a matrix for healing. This is then covered with a single-layer AM suture stromal side down. In summary, AM transplantation may be a promising anti-inflammatory treatment for Mooren's ulcer, but currently clinical data are limited and require further investigation.

OTHER SURGICAL PROCEDURES

Mooren's ulcer has been treated with keratoepithelioplasty.[59] In this procedure, donor corneal lenticules are sutured into the scleral bed after conjunctival excision. Corticosteroids are administrated postoperatively for more than 6 months. The use of an autogenous periosteal graft has been reported for the treatment of scleral thinning after lamellar keratectomy.[60]

When all fails, and the ulcerative process has progressed to the extent that only a central island of residual stroma remains, Brown and Mondino[6] recommend excision of the island to prevent central ulceration, accelerate epithelial healing, and resolve pain. The corneal stroma is probably the target of the destruction in Mooren's ulcer because once the stroma is totally destroyed or removed by excision, ulceration and associated inflammation stop and central transparency remains to allow some vision.

CONJUNCTIVAL FLAP

There are still occasions when medical and surgical therapy fail and the patient experiences pain from recurrent epithelial breakdown with stromal ulceration. A conjunctival flap will often provide comfort, reduce the ocular inflammation, and promote healing in these patients. It is especially useful for elderly, debilitated patients for whom prolonged hospitalization and medical therapy may not be warranted.

CATARACT SURGERY

After complete control of inflammation has been established, patients with Mooren's ulcer can undergo cataract extraction. Two small studies indicate that visual outcomes are usually good and ulceration is not exacerbated.[61,62]

TERRIEN'S MARGINAL DEGENERATION

Terrien's marginal degeneration is a chronic progressive thinning of the peripheral cornea associated with vascularization and lipid deposition. Two-thirds of the patients are males and are 40 years or older. The age at onset, however, ranges from 10 to 70 years. The disease is usually bilateral but may initially present in one eye.[63] As the disease progresses, marked astigmatism and severe peripheral corneal thinning often develop. The risk of spontaneous or traumatic corneal rupture is high.[64] Surgical intervention is required to correct visually disabling astigmatism, prevent impending perforation, and treat frank perforation.

CLINICAL FINDINGS

Terrien's marginal degeneration usually begins superonasally with peripheral, fine, yellow-white punctuate stromal opacities. A lucid zone separates the opacities from the limbus. With time, the opacities coalesce into a line similar to arcus senilis, superficial vessels advance into the line from the limbus, and the intervening stroma gradually thins (see Fig. 25.4, *A*).[63] The thinning slowly spreads circumferentially and in rare cases centrally.[65] In the advanced stages, localized areas of ectasia develop along the course of corneal thinning. Circumferential ectasia is rare.[64] Epithelium remains intact throughout the course of the disease.

The disease process is extremely slow, often taking 30 years. Vision gradually deteriorates because of increasing against-the-rule astigmatism. Perforation occurs in 15% of the reported cases and can be either spontaneous or following minor trauma.[64] Spontaneous breaks in Descemet's membrane have been reported as well. The overlying Bowman's layer remained intact, resulting in corneal intralamellar dissection and corneal cysts.[66,67] Occasionally, intracorneal aqueous pockets become continuous with subconjunctival space and result in filtering blebs with hypotony.[67] In two of the five reported cases, intracorneal cysts resolved spontaneously. The remaining three required surgical intervention.

Pseudopterygia occur in 20% of patients with Terrien's marginal degeneration. The pseudopterygia characteristically occur in positions other than 9 o'clock and 3 o'clock and grow onto the cornea at an oblique angle. They may occur in the early stages of the disease when thinning is subtle.[65]

Most patients with Terrien's lack significant inflammatory signs and symptoms. Austin and Brown,[64] however, reported six patients with recurrent, disabling ocular pain associated with episcleritis or superficial scleritis. Most of the patients were young females. None demonstrated progression of the corneal changes during the 6 years of follow-up.

HISTOPATHOLOGY

Histopathologic reports of corneal specimens from patients with Terrien's marginal degeneration reveal the following findings. The epithelium, except for the basal layer, is intact. Basal epithelial cells are degenerated. Bowman's layer and anterior stromal lamella are lost and replaced by vascularized loose connective tissue. The vessels originate at the limbus, advance centrally within the superficial connective tissue, loop at the central margin of the furrow, and migrate back to the limbus passing just anterior to Descemet's membrane.[68]

The remaining stromal lamella is compressed, and lipid deposition is evident. Lipid deposition is most prominent anterior to the vascular arcades. Histiocytes line the blood vessels and are laden with the phagocytosed lipid, corneal collagen, and ground substance. There is evidence of high lysosomal activity within the histiocytes, consistent with an ongoing degradation of corneal tissue.[68] Tear fluid in patients with Terrien's degeneration has a three-fold higher level of lysosomal enzymes than the tear fluid collected from age-matched controls.[69]

Descemet's membrane is usually intact but is either thickened or thinned. Several reports describe the presence of healed ruptures of Descemet's membrane. The endothelium is intact and is either normal or attenuated.[68,70]

PATHOGENESIS

The cause of Terrien's marginal thinning remains unknown. Its bilaterality, extremely slow progression, lack of significant clinical and histologic inflammation, and lipid deposition suggest a degenerative process in most cases. Association of Terrien's with posterior polymorphous dystrophy,[71] keratoconus,[72] and erythema elevatum diutinum[73] has been described in isolated cases.

Recurrent bouts of episcleritis and scleritis associated with Terrien's in the six patients described by Austin and Brown[64] suggest an inflammatory mechanism in a subset of patients. Iwamoto et al[74] distinguished two forms of Terrien's degeneration based on histopathology: quiescent and inflammatory. The inflammatory form was characterized by perivascular lymphocytic and neutrophilic infiltration, vascular occlusion, and fibrinoid necrosis. Austin and Brown,[64] however, disputed the existence of the inflammatory form of the disease, stating that the authors' clinical photographs and their description of central progression with epithelial breakdown were more consistent with Mooren's ulcer than with Terrien's degeneration.

DIFFERENTIAL DIAGNOSIS

Several conditions may clinically mimic some of the features of Terrien's disease. Arcus senilis may mimic the peripheral opacification associated with early stages of Terrien's disease. Arcus senilis, however, is characterized by both superior and inferior peripheral corneal opacification, absence of vascularization, and lack of corneal thinning. Peripheral corneal thinning is seen in collagen vascular diseases, gutter or furrow degeneration, pellucid marginal degeneration, and Mooren's ulcer. The symptomatology, morphology, and associated systemic findings should distinguish these conditions from Terrien's marginal degeneration.

Corneal thinning seen in collagen vascular diseases, such as rheumatoid arthritis, Wegener's granulomatosis, polyarteritis nodosa, and relapsing polychondritis, is usually associated with systemic findings of arthritis, renal and sinus abnormalities, or vasculitis. Rheumatoid factor, or antineutrophil cytoplasmic antibody, or antinuclear antibody levels are usually elevated. Gutter or furrow degeneration lacks vascularization. Peripheral corneal thinning associated with pellucid marginal degeneration is inferior and lacks lipid deposition and vascularization. The most common disease that can mimic Terrien's disease is a healed Mooren's ulcer. Both lack systemic findings. Mooren's ulcer may be either bilateral or unilateral, whereas Terrien's is usually bilateral. An

active Mooren's ulcer is usually associated with pain and conjunctival inflammation, whereas Terrien's is usually painless and uninflamed.

An epithelial defect is usually present at the central edge of an active Mooren's ulcer, whereas the epithelium is intact in Terrien's marginal degeneration. Mooren's ulcer has an overhanging central edge, and inflammatory infiltrate may be present. Lipid is absent. Terrien's has a gradually sloping central edge with lipid deposition. Peripheral cornea may be vascularized in both conditions. Mooren's ulcer usually spreads rapidly, both circumferentially and centrally. Terrien's degeneration progresses slowly and circumferentially. Pathogenesis of Terrien's is unknown, but it is probably a degenerative process. Mooren's ulcer is probably an autoimmune process.

TREATMENT

Spectacles and contact lenses are used to correct astigmatism in mild cases of Terrien's marginal degeneration. When astigmatism becomes so extreme that optical means fail to correct the reduced vision or when thinning becomes so severe that corneal perforation occurs or is threatened, a reconstructive keratoplasty is performed (Fig. 25.4, *A–C*).

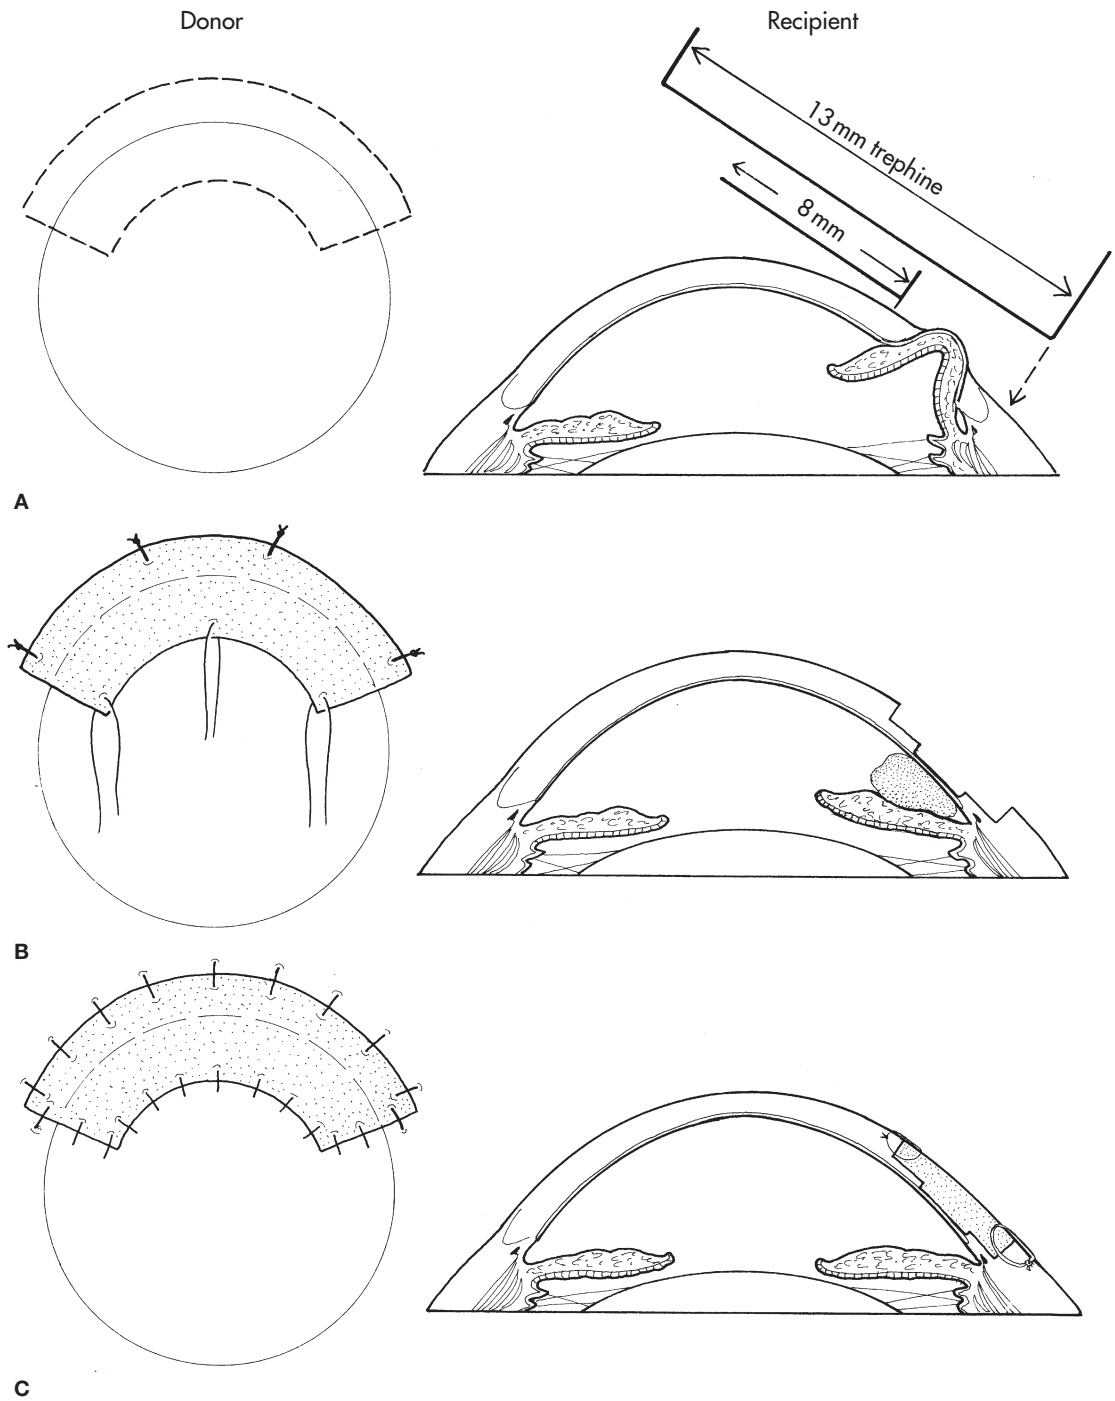

Figure 25.5. *A*, Smaller and larger trephines used to make initial incisions surrounding perforated area. *B*, Note perpendicular margins in the recipient bed from trephine and knife dissection. The iris was repositioned by viscoelastic. *C*, A crescentic piece is anchored using multiple interrupted sutures.

The most common technique for corneal reconstruction in Terrien's marginal thinning is crescentic lamellar or full-thickness keratoplasty. Lamellar keratoplasty is performed as follows. The center of the cornea is marked. A trephine is then used to outline the curvature of the inner edge of corneal thinning (Fig. 25.5, *A*). A blade is then used to deepen the trephine groove and to shelve the outer edge of the thinned cornea toward the limbus. Lamellar dissection of the cornea posterior to the trephine groove is performed, and the shelved outer edge of the thinned area is excised, leaving a crescent-shaped recipient bed (see Fig. 25.5, *B*).[75] The width of the bed is measured. A corneal crescent corresponding to the recipient bed is excised from the donor cornea either free-hand or using two trephines (Fig. 25.6). A large trephine can be used to separate the corneal donor button from the scleral rim. A smaller trephine is then used to excise a central button, leaving a corneal rim corresponding in width to the width of the recipient bed. Descemet's membrane is stripped, and the donor crescent is sutured to the recipient bed (see Fig. 25.5, *C*). A variation on this technique, called by the authors 'compressive C-shaped lamellar keratoplasty', utilizes a donor crescent that is 0.25–0.5 mm narrower than the recipient bed.[76] In combination with tight 9.0 sutures, this produces less progressive ectasia and against-the-rule astigmatism in the postoperative period, according to the authors.

Full-thickness crescentic keratoplasty can be performed as above, except that the thinned cornea is removed entirely and the Descemet's membrane of the donor is retained.[77] Caldwell and coworkers[78] described an alternative technique for restoring cornea in patients with Terrien's marginal thinning. An incision is made into the stroma down to Descemet's membrane along the anterior edge of the thinned cornea using a diamond knife set to a depth determined by preoperative pachymetry. A lamellar blunt dissection is performed to the level of Descemet's membrane toward the limbus. Corneal crescent superficial to Descemet's is then excised, and the wound edges approximated with sutures. This technique can be coupled with simultaneous cataract extraction. Corneal incision is made at the degeneration furrow, cataract extraction is performed, and the incision reapproximated to the limbus under keratoscopic control to reduce corneal torricity.[79]

PELLUCID MARGINAL DEGENERATION

Pellucid marginal degeneration is a bilateral, inferior corneal thinning disorder characterized by a narrow band of thinning (1–2 mm) of the inferior cornea running parallel to the limbus (Fig. 25.7). The thinned cornea is clear, and the cornea above and below the thinned cornea is of normal thickness. The cornea protrudes above the area of thinning, resulting in high regular and irregular astigmatism. Spontaneous perforation and hydrops have been described.[80,81]

Pellucid marginal degeneration is usually detected between the second and fifth decades of life. There is no sex predilection, and there is no evidence for hereditary transmission, although moderate or high astigmatism has been found in family members.[82]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of pellucid marginal degeneration includes other corneal thinning disorders, such as Terrien's degeneration, keratoconus, and Mooren's ulcer. Unlike pellucid degeneration, Terrien's degeneration affects both the superior and the inferior cornea and has vascularization and lipid deposition. In active Mooren's ulcer and other peripheral ulcerative disorders, the epithelium overlying the area of thinning is usually not intact. Healed peripheral ulcers are vascularized and scarred. The thinned cornea in pellucid marginal degeneration remains clear with epithelium intact. In contrast to keratoconus, patients with pellucid marginal degeneration have no iron ring, no Vogt striae, and no central corneal thinning or scarring of the protruding cornea. The corneal protrusion is located above rather than in the area of thinning.

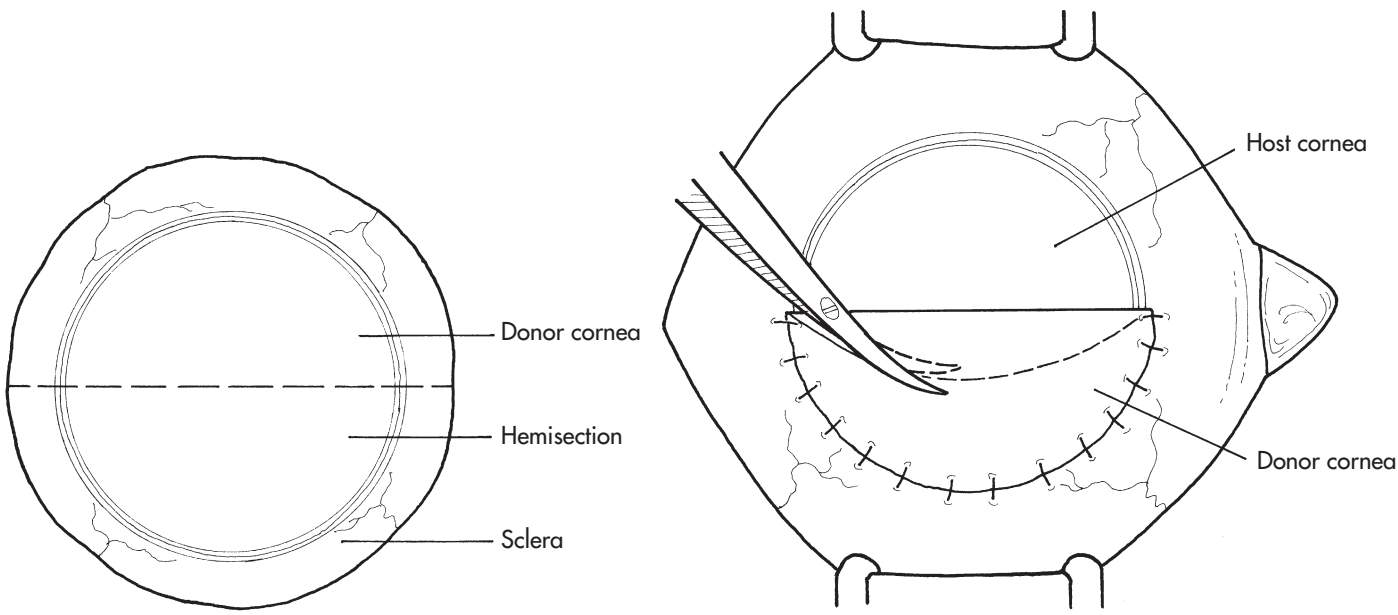

Figure 25.6. A demonstration of free-hand scissors dissection of a donor corneal crescentic piece matching the trephined recipient bed (trephines can be used to accomplish the same shape).

TREATMENT

Spectacle correction of pellucid marginal degeneration is usually inadequate because of the high astigmatism. Contact lenses initially offer good optical correction but are difficult to fit as the disease progresses. The cornea is flat centrally and steep peripherally, so the lenses are difficult to center and tend to lift off.

Surgical correction of pellucid marginal degeneration includes diathermy, thermokeratoplasty, crescentic wedge resection, lamellar keratoplasty, and penetrating keratoplasty (Fig. 25.8). If the area of thinning is less than 2 mm, wedge resection (Fig. 25.9) or crescentic lamellar or penetrating keratoplasty can be performed.[83,84] MacLean et al. report that full excision of thinned tissue is often possible with mean residual astigmatism of 1.4 D, but long-term astigmatic drift increases it to 2.1 D over 55–138 months.[83] If the area of thinning is large (i.e. >2–3 mm), large, eccentric keratoplasty can be performed. However, the risk of rejection and graft vascularization is higher because of the close proximity of the graft to the limbus. A better alternative may be a total lamellar keratoplasty followed by a smaller, central penetrating keratoplasty. Duran et al[85] have also described a technique for crescentic resection of the thin peripheral area to treat pellucid marginal degeneration. A combination technique described by Rasheed and Rabinowitz[86] for advanced pellucid degeneration includes a simultaneous inferior lamellar keratoplasty with a central full-thickness penetrating keratoplasty (PKP). Inferior ectatic cornea is initially reinforced by a lamellar graft, which is then trephined and a 7.5-mm graft is sutured centrally. Simultaneous technique allows for relatively rapid visual rehabilitation, and reinforcement of the inferior cornea helps minimize astigmatism.

A more conservative tissue-saving approach to early and moderate pellucid marginal degeneration involves reinforcement of ectatic corneal stroma with intrastromal rings and segments, such as Intacs and Ferrara rings. Initially developed for mild myopia and demonstrated to be effective in keratoconus,[87] these inserts can be used to minimize regular and irregular astigmatism by supporting weakened collagen fibrils. The segments are usually implanted through a temporal incision, one inferiorly and the second superiorly.[88–90] The inferior 0.25 or 0.45 mm segment is inserted through the thinnest part of the cornea or just above it providing reinforcement and a barrier minimizing irregular astigmatism induced by the ectatic band just below it. Dissecting the channels for the inserts through such thin tissue is prone to error, and femtosecond laser has been successfully used to precisely place the channels.[91] Overall, this reversible procedure may provide a safe approach to stabilize progressively degenerating corneas.

26 Epithelial transplantation for the management of severe ocular surface disease

Ali R. Djalilian, Hormuz P. Wadia, Siamak Balali, Nariman Nassiri, Edward Holland

Severe ocular surface disease is a clinical term for conditions that result from injury or disease of the limbal stem cells, the source for normal corneal epithelium, or the conjunctiva, with its mucin-secreting goblet cells, which are vital for normal tear film physiology. Patients with severe ocular surface disease are some of the most challenging to manage in ophthalmology. Conventional management techniques, including superficial keratectomy, penetrating or lamellar keratoplasty, and tarsorrhaphy, are generally unsuccessful because they fail to correct the underlying deficiency of normal conjunctival or corneal cells. Epithelial transplantation procedures have significantly improved the success rate of the management of these patients.

OCULAR SURFACE ANATOMY

The ocular surface is comprised of the tear film and the epithelium of the cornea and conjunctiva. Stratified, nonkeratinized epithelium covers the entire cornea, as well as the bulbar and palpebral conjunctiva. The corneal epithelium is constantly being sloughed and renewed. The proliferating cells responsible for the renewal of the corneal epithelium are stem cells and transient amplifying cells, located in the basal epithelial layers at the limbus.[1–7] Stem cells are long lived and demonstrate a capability to divide in an asymmetric manner.[3,5,6] This asymmetric cell division allows one of the daughter cells to remain a stem cell while the other differentiates to become a transient amplifying cell. The transient amplifying cell then differentiates into postmitotic cells and finally into terminally differentiated cells. Both the postmitotic cells and the terminally differentiated cells are incapable of cell division.[5] Schermer et al[2] proposed the cell proliferation scheme for the cornea as follows (Fig. 26.1): limbal basal epithelium (stem cells) to basal corneal epithelium (transient amplifying cells) and to suprabasal corneal epithelium (terminally differentiated cells), which is mature corneal epithelium. The normal conjunctival epithelium contains goblet cells. These cells are unicellular, mucin-secreting glands that account for approximately 5–10% of the total number of basal cells. The function of the mucin secreted by the goblet cells is to coat the surface of the epithelium. Mucin, which is extremely hydrophilic, allows the otherwise hydrophobic epithelium to be wettable. Mucin also maintains the stability of the tear film. The location of stem cells for conjunctival goblet and nongoblet epithelial cells is not known, although it is postulated that the forniceal zone is the most likely location for this stem cell population.[8]

ETIOLOGIES OF STEM CELL DEFICIENCY

Profound morbidity can result from conditions that severely compromise the ocular surface caused by damage or injury of the limbal stem cells or conjunctiva. Corneal disease can include development of chronic abnormal epithelium, neovascularization, scarring, ulceration, and possible perforation. Conjunctival sequelae include inflammation, scarring, and aqueous tear, as well as mucin deficiency. Pain and loss of vision are common complications in severe cases.

A stable ocular surface depends upon the proper functioning of the limbal stem cells. A limited number of disorders have been described that lead to ocular surface instability from abnormal stem cell function (Table 26.1). Aniridia is a primary stem cell disorder that appears to result from a deficiency in the development or maintenance of limbal stem cells.[9–11] Secondary disorders of limbal stem cells are more common. In chemical and thermal burns, there is direct injury to the limbal stem cells as well as to the corneal and conjunctival epithelium, including the goblet cells. Most damage and loss of stem cells occurs at the time of the initial injury, with further gradual attrition resulting from the chronic anterior segment inflammation, which often follows. Stevens–Johnson syndrome (SJS) and ocular cicatricial pemphigoid (OCP) are diseases primarily of the conjunctiva. They may result in severe inflammation, with conjunctival scarring, goblet cell depletion, aqueous tear deficiency, and the eventual loss of limbal stem cells.[12] Multiple surgical procedures or chronic use of toxic topical medications can also result in limbal stem cell deficiency. The authors proposed the term 'iatrogenic limbal stem cell deficiency' as a descriptor for patients with ocular surface disease from this mechanism.[13] Corneal intraepithelial neoplasia is a less common cause of limbal stem cell deficiency.[14] Corneal intraepithelial neoplasia almost always originates at the limbus and probably causes stem cell deficiency because of replacement of healthy stem cells with neoplastic cells. Severe

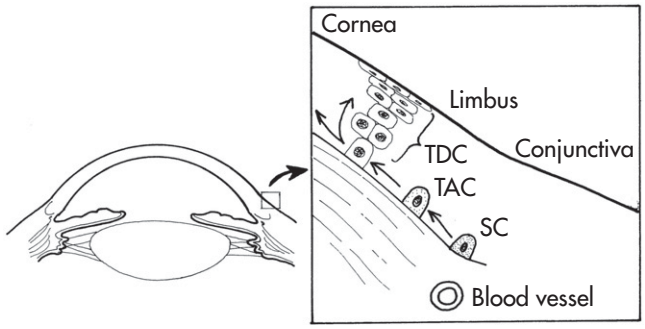

Figure 26.1. Schematic representation of limbal stem cells (SC). These cells are located at the basal epithelium of the limbus and give rise to transient amplifying cells (TAC) of the basal corneal epithelium and to terminally differentiated cells (TDC), which compose the suprabasal corneal epithelium.

contact lens-induced keratopathy is another category of stem cell-related ocular surface disease. The stem cells are injured as the result of chronic trauma to the limbus from the contact lens;[15] chronic hypoxia probably also plays a role.

CLASSIFICATION OF EPITHELIAL TRANSPLANTATION PROCEDURES FOR SEVERE OCULAR SURFACE DISEASE

A previous article reviewed in detail the history of epithelial transplantation procedures in the management of severe ocular surface disease.[16] Confusion arises when reviewing reports of these procedures because the use of terminology has been inconsistent; multiple terms have been used by different authors to describe the same technique, while the same term has been used for more than one technique. Therefore, a standardization of the classification of epithelial transplantation procedures for ocular surface disease has been proposed[17] (Table 26.2). All of the procedures share the common goal of transplantation of a new source of epithelium for a diseased ocular surface. Although the different techniques have similar goals, they vary based on the source of the donor tissue and whether the procedure is primarily a conjunctival or a limbal transplantation. Limbal transplantation procedures also vary depending on the carrier tissue used for the transfer of the limbal stem cells. Carrier tissue is needed in limbal transplantation because it is not technically possible to transfer limbal stem cells alone.

The source of donor tissue for epithelial transplantation can be the fellow eye (autograft), cadaveric whole globe (allograft), cadaveric corneoscleral rim (allograft), or a living relative (allograft). Conjunctival transplants transfer only conjunctiva. Limbal transplants, on the other hand, use either conjunctiva or cornea as a carrier tissue for the fragile limbal stem cells. Based on the source of donor tissue, the carrier tissue used, and whether the procedure is a conjunctival transplant or a limbal transplant, the following classification of surgical procedures for epithelial transplantation for ocular surface disease was devised. A conjunctival autograft (CAU) uses tissue from the fellow eye. A conjunctival allograft can use donor tissue from a cadaver or living relative and be designated as a cadaveric conjunctival allograft or living related conjunctival allograft. Limbal transplantation procedures can be subdivided based on the donor and the carrier tissues. A conjunctival limbal autograft (CLAU) uses tissue from the fellow eye, and conjunctiva is the carrier. A cadaveric conjunctival limbal allograft

Table 26.1 Ocular surface disease with limbal stem cell deficiency

Category	Disease	Pathogenesis of Limbal Deficiency
Congenital	Aniridia Ectodermal dysplasia	Abnormal development or maintenance of limbal stem cells
Trauma/toxic	Chemical and thermal burns Contact lens wear	Direct injury to limbal stem cells. hypoxia, mechanical trauma, and chemical toxicity
Inflammatory	Stevens–Johnson syndrome Ocular cicatricial pemphigoid Atopic keratoconjunctivitis	Inflammatory destruction of limbal stem cells
Iatrogenic limbal stem cell deficiency	Surgery Antimetabolites/ antifibrotics (e.g. mitomycin-C)	Excision or mechanical destruction of limbal stem cells and/or chronic exposure to toxic medications with damage to stem cells
Neoplasia	Squamous cell carcinoma	Replacement of normal limbal stem cells with neoplastic cells

Table 26.2 Classification for epithelial transplantation procedures for ocular surface disease

Procedure	Donor Source	Transplanted Tissue
CLAU	Fellow eye	Limbus and conjunctiva
lr-CLAL	Living donor or cadaver	Limbus and conjunctiva
KLAL	Cadaver	Limbus and cornea
Ex vivo cultured epithelium	Autologous, living donor, or cadaver	Limbus, conjunctiva, or oral mucosa

CLAU, conjunctival limbal autograft; lr-CLAL, living-related conjunctival limbal allograft; KLAL, keratolimbal allograft.

(CLAL) uses a cadaveric donor for conjunctiva and limbus. A living-related conjunctival limbal allograft (Lr-CLAL) is a procedure in which a living relative donates conjunctiva and limbal tissue. Finally, a keratolimbal allograft (KLAL) uses a cadaveric donor, transferring the limbal stem cells via peripheral cornea and sclera (i.e. limbus).

RECOMMENDATIONS FOR EPITHELIAL TRANSPLANTATION PROCEDURES

Indications for epithelial transplantation include cicatrizing conjunctival disease and limbal deficiency. Patients with limbal deficiency may benefit from epithelial transplantation to manage a persistent epithelial defect of the cornea, to improve decreased vision caused by an irregular epithelial surface, or to stabilize the ocular surface prior to keratoplasty.

The first consideration is whether the condition is unilateral or bilateral (Fig. 26.2). If unilateral, the autograft procedures hold the best prognosis because they eliminate the issue of immune rejection. If the condition results from a unilateral limbal deficiency, then the procedure of choice is a CLAU. However, the patients with the greatest need are usually those with bilateral disease. These patients require an allograft to manage ocular surface disease caused by limbal stem cell and/or conjunctival deficiency. The clinician may choose from three procedures to restore the ocular surface: CLAL, KLAL, or a combination of both.

CLAL allograft tissue may be obtained from either a cadaver or a living relative. The cadaveric CLAL procedure has only two published cases and appears to have significant disadvantages when compared to Lr-CLAL and KLAL: (1) cadaveric conjunctival tissue is difficult to handle and often is not available on donor globes, (2) the survival of cadaveric conjunctiva on whole globes in storage media has not been documented, and (3) the survival of this tissue post-transplantation has not been studied. Therefore, at this time, the only tissue sources for bilateral ocular surface disease are the Lr-CLAL and cadaveric KLAL.

To determine which epithelial transplantation procedure to perform for the patient with bilateral severe ocular surface disease, an assessment must be made of whether the cause is primarily limbal stem cell deficiency or combined limbal stem cell and conjunctival deficiency. For patients with conjunctival and limbal deficiency, if a living-related donor is willing and available, Lr-CLAL should be the first procedure considered. This recommendation is based on published studies. Human leukocyte antigen (HLA) matching and ABO typing may be useful in determining the best living-related donor match. The results of allograft procedures that include conjunctiva (living-related conjunctival allograft and Lr-CLAL) appear to have better outcomes than the results of published KLAL studies in the subgroup of patients with combined limbal and conjunctival deficiency.

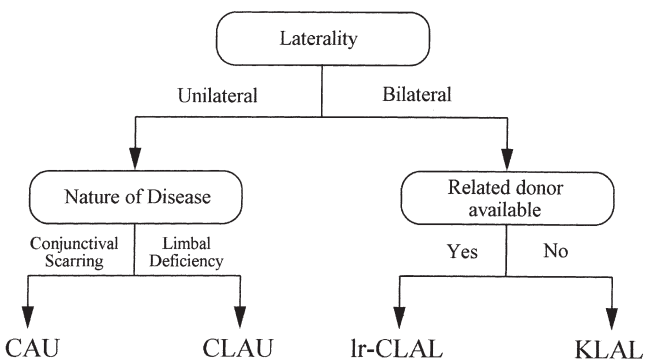

Figure 26.2. Recommendation for epithelial transplantation procedures. CAU, conjunctival autograft; CLAU, conjunctival limbal autograft; Lr-CLAL, living-related conjunctival limbal allograft; KLAL, keratolimbal allograft.

However, in cases of limbal stem cell deficiency without conjunctival deficiency (e.g. aniridia), Lr-CLAL does not appear to have a better success rate when compared with KLAL. In fact, patients with aniridia keratopathy benefit dramatically from KLAL. This technique offers one clear distinct advantage over other limbal stem cell techniques: three separate 180° segments of limbal tissue are used, thereby offering 150% more limbal stem cells.[18] Other advantages of KLAL include the ready availability of tissue for all recipients, elimination of surgery on a healthy living relative, and the fact that it is an avascular transplant, which may reduce the risk of rejection.

In patients with severe ocular surface disease with concomitant conjunctival and limbal stem cell deficiency, a living-related conjunctival allograft may not always provide adequate number of stem cells, and therefore the patient may be at risk of developing conjunctival in-growth in the large 'gap' areas nasally and temporally. Therefore, these patients may benefit from a combined KLAL and CLAL.

PREOPERATIVE CONSIDERATIONS

Ocular adnexa and anterior segment structures of patients with severe ocular surface disease must be carefully examined. Abnormal globe-to-eyelid anatomy can lead to chronic exposure, chronic inflammation, and direct corneal trauma. Significant abnormalities such as entropion or ectropion, trichiasis or distichiasis, and palpebral conjunctival keratinization should be corrected prior to epithelial transplantation. Patients with aqueous tear deficiency usually require permanent punctal occlusion. If lagophthalmos or poor lid closure exists, lateral tarsorrhaphy at the time of surgery should be considered. In patients with severe conjunctival deficiency and obliteration of the fornices, an autologous graft from the oral or nasal mucosa may be necessary to reconstruct the fornix prior to considering limbal transplantation.

It is also crucial to inquire about any past history of glaucoma and to look for evidence during the physical examination. Glaucoma should be managed aggressively because chronic glaucoma is a major risk factor for long-term poor visual functioning in patients who otherwise undergo successful limbal stem cell grafting.

SURGICAL TECHNIQUES

CONJUNCTIVAL-LIMBAL AUTOGRAFTS

Donor tissue selection

In considering a CLAL for unilateral ocular surface disease, the vital criterion for tissue selection is that the donor eye be free from any condition that may predispose it to later development of limbal stem cell deficiency, such as long-term contact lens use, multiple prior surgeries, or glaucoma (in which conjunctival surgery could jeopardize the success of later filtering surgery if needed). If any contraindications exist, then a Lr-CLAL is advised if a related donor is available, or a KLAL if no related donor is available.

Anesthesia

The procedure involves both eyes. If the patient is healthy and can safely tolerate general anesthesia, this method is usually preferred because it eliminates time constraints of local anesthesia and reduces patient anxiety over a bilateral procedure. When necessary, local anesthesia can be used with a peri- or retrobulbar block with or without a cranial nerve VII block (O'Brien) for the recipient eye and a topical or subconjunctival anesthesia for the donor eye.

Preparation of the recipient eye

Any speculum providing adequate exposure is used. A lateral canthotomy is sometimes necessary to increase exposure. If symblepharon formation has occurred and limits exposure of the ocular surface, conjunctival adhesions can be released at the limbus. A 360° limbal peritomy is performed, and conjunctiva is resected posteriorly 2–3 mm with Wescott scissors. It is important to remove this tissue from the limbus because the new source of epithelium must repopulate the ocular surface prior to reinvasion by the fibrovascular tissue of the conjunctiva. Extensive bleeding can occur because of neovascularization of the injured eye's surface. If bleeding interferes with visualization, one quadrant at a time can be operated on to control bleeding. Topical epinephrine (1 : 10 000 dilution) and thrombin applied with surgical spears are useful adjuncts to wet-field cautery. Once the limbal conjunctival tissue is excised, the recipient CLAUs are prepared (Fig. 26.3, *A*). The grafts will be centered at the 12 and 6 o'clock meridians and will measure approximately 8 mm horizontally by 5 mm vertically (no more than three clock hours each).

Next, abnormal corneal epithelium and fibrovascular pannus are removed by superficial dissection (Fig. 26.3, *B*). Various approaches can be useful. Blunt dissection with a cellulose sponge may work. If a dissection plane is established, forceps can sometimes be used to peel the abnormal tissue off in a sheet. However, sharp dissection is often needed in areas to find an adequate tissue plane to create a smooth ocular surface. A No. 64 Beaver blade can be used for this maneuver. Care is given to avoid cutting deep into stroma because of the risk of corneal perforation and postoperative optical distortion from surface irregularity. Bleeding is often encountered with the removal of corneal surface pannus, and topical epinephrine and thrombin can be used on this tissue as well. When hemostasis is achieved, the surface is moistened, the speculum removed, and the eyelids are closed while the autografts are being harvested from the other eye.

Harvesting the donor tissue

The speculum is placed in the fellow eye. The two CLAUs are taken from the corresponding 12 and 6 o'clock positions. A gentian violet surgical marking pen is used to mark the conjunctival portions of the grafts with the same 5 mm vertical by 8 mm horizontal dimensions. The conjunctiva can be elevated with a subconjunctival

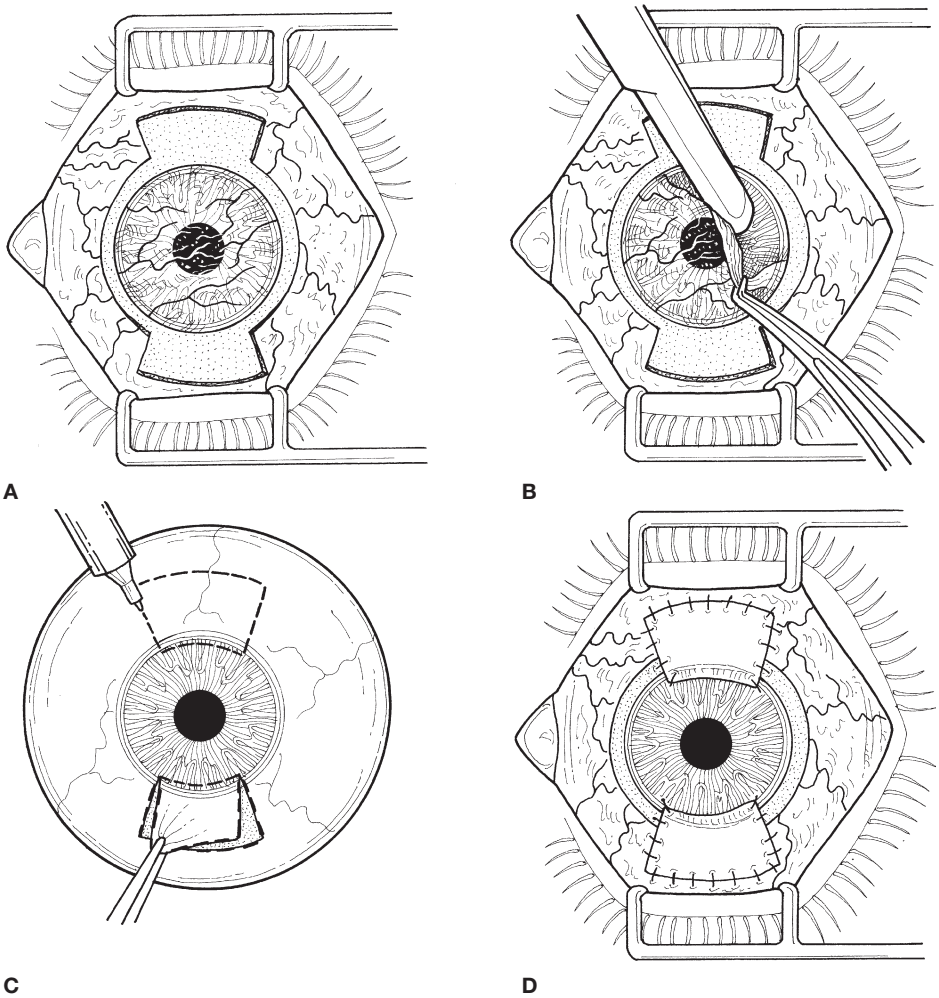

Figure 26.3. Technique for conjunctival limbal autograft or allograft transplantation. *A*, Recipient eye preparation. A 360° limbal peritomy is performed with removal of 2–3 mm of bulbar conjunctiva. *B*, Abnormal corneal epithelium and fibrovascular pannus are removed by superficial dissection using necessary techniques (peeling, blunt dissection, and sharp dissection). *C*, Donor tissue harvesting. Conjunctival dimensions of the grafts are marked with a gentian violet marking pen. The corneal epithelial extent of the graft is also marked 1 mm beyond the peripheral corneal vascular arcades with a blade. Harvesting begins with the bulbar conjunctival portion and proceeds anteriorly. *D*, The conjunctival limbal grafts are transferred to their corresponding anatomic positions on the recipient eye and secured with multiple interrupted 10-0 nylon sutures.

injection of balanced salt solution. Wescott scissors are used to begin the dissection by incising along the lateral borders, with complete undermining between the lateral edges if possible before cutting along the posterior edge (Fig. 26.3, *C*). This sequence helps keep the tissue on-stretch. The gentian violet markings should be included in the graft to help delineate the epithelial surface from the undersurface. Nontoothed forceps are recommended to help avoid button holes and tears through the conjunctiva.

Once the lateral and posterior edges are free, the conjunctiva is reflected anteriorly over the cornea, and blunt dissection is continued anteriorly. When the point of conjunctival insertion at the limbus is reached, further blunt dissection should be performed with a dull scarifier (e.g. Tooke blade) into the peripheral cornea approximately 1 mm beyond the peripheral corneal vascular arcades. The desired corneal epithelial extent of the dissection should be lightly marked with any type of blade from the corneal side. This maneuver is essentially a superficial epithelial keratectomy of peripheral limbus and cornea and not a lamellar dissection into stroma or sclera. It is also extremely important to carry the dissection onto the peripheral cornea and to avoid prematurely excising the piece of tissue without the stem cells. Once the tissue is free, it is transferred epithelial side upward to a Petri dish and covered with corneal storage media (or balanced salt solution if the former is unavailable). The donor sites are left open to heal.

Placement of the donor tissue

Each autograft is sutured into its anatomically correct position (limbus to limbus) with multiple interrupted 10-0 nylon sutures (Fig. 26.3, *D*). Some surgeons prefer nylon over polyglactin because it causes less postoperative inflammation. The corners are secured first, and then sufficient additional sutures are placed in between to prevent postoperative dehiscence. The sutures are placed first through the conjunctival graft, then through the recipient episcleral tissue, and finally through the recipient conjunctiva. The sutures are tied and cut on the knot, but the knots are not buried because the bites are short and attempts to bury them often result in the sutures being pulled out accidentally. The sutures can be left for many months. Some loosen and fall out on their own; others that loosen or cause irritation can be removed at the slit lamp, preferably after 2 weeks. During the suturing, the autograft epithelium should be protected from desiccation and trauma with balanced salt solution and a viscoelastic material. At the conclusion of the operation, an antibiotic-corticosteroid ointment is placed in the inferior cul-de-sac of the recipient eye and a drop of antibiotic-corticosteroid solution is placed in the donor eye. A patch and protective shield is placed over the recipient eye until the patient is seen the next day.

Postoperative care

The donor eye is treated with the antibiotic-corticosteroid drops three to four times daily until re-epithelialization is complete and inflammation has subsided. The donor eye should be followed until the donor sites are completely epithelialized (usually 1–2 weeks). A rare complication of this technique is the occurrence of a pyogenic granuloma at an autograft harvest site. The recipient eye is treated with a low-toxicity antibiotic once or twice daily as prophylaxis during re-epithelialization. Topical corticosteroids are used three or four times daily for inflammation. It is important to avoid overtreatment with topical corticosteroids because they can inhibit mitosis and retard epithelialization. If significant inflammation occurs in the immediate postoperative period, oral corticosteroids should be considered. In addition to controlling postoperative inflammation and preventing rejection of the allograft tissue, management of the ocular surface is the other key factor. All patients are instructed to use nonpreserved artificial tears every 1–2 h. Punctal occlusion, tarsorrhaphy, and use of a bandage soft contact lens are other interventions commonly used as needed.

Results

Several reports document the benefits of CLAU. In a series pterygium, or conjunctival intraepithelial neoplasia of 21 eyes, comprised mostly of unilateral chemical burns, 20 eyes achieved a stable corneal epithelium and 17 had significantly improved visual acuity.[6] Similarly, Dua and Azuara-Blanco attained successful epithelialization in six eyes with persistent epithelial defects from stem cell failure resulting from several causes including chemical injury, pterygium, or conjunctival intraepithelial neoplasia.[19]

CLAU has been used in combination with deep lamellar keratoplasty in a reported series of 39 patients with unilateral advanced chemical injuries.[20] In addition to conjunctival limbal tissue, conjunctival autografts were also harvested from the healthy fellow eyes to allow encircling of the recipient limbus. All of the eyes achieved a stable ocular surface.

A modification of CLAU involving the harvesting and repositioning of stem cells from a single eye sectoral stem cell deficiency has been reported with good results.[21] Attractive features of this procedure are the elimination of the need to perform surgery on a patient's unaffected eye and the ability to treat patients with only one eye. A major concern regarding this procedure is the risk of inducing further stem cell dysfunction in the diseased eye. In the future, ex vivo stem cell expansion may allow for further utilization of this procedure.

LIVING-RELATED CONJUNCTIVAL LIMBAL ALLOGRAFTS

Donor tissue selection

The related donor should be screened for potential blood-borne diseases including human immunodeficiency virus-1 and -2 and hepatitis B and C. These tests are the standard serologic screening required by the Eye Bank Association of America for tissue used for keratoplasty (including KLAL). Human leukocyte antigen typing is performed to find the best match if there are multiple siblings, but it is not necessary if a parent acts as the donor. The authors consider a three antigen match to be acceptable and this should be the case with donated tissue from either biological parent.

Anesthesia

In most cases, the authors use a peri- or retrobulbar injection for harvesting from the donor relative. A combination of topical and subconjunctival anesthesia is an alternative under selected circumstances. The recipient patient's eye is anesthetized with a peri- or retrobulbar injection, or occasionally general anesthesia is used if necessary.

Harvesting the donor tissue from the relative

Most surgeons will not have the luxury of running two operating rooms simultaneously. Therefore, the authors recommend harvesting from the donor first and transplanting to the recipient afterward. The procedure is identical to that of the CLAU section and is as follows:

1. Mark the donor conjunctival sites with a surgical marking pen, each three clock hours wide, centered at the 12 and 6

o'clock limbal positions and extending 5 mm posteriorly (Fig. 26.3, *C*).
2. Elevate the first site with a subconjunctival injection of balanced salt solution.
3. Begin the excision along the lateral edges, undermining the graft completely if possible with blunt dissection before cutting the posterior edge.
4. Reflect the tissue anteriorly over the cornea and continue the dissection into the peripheral cornea 1 mm past the peripheral vascular arcade with a blunt scarifier. This maneuver is a superficial epithelial keratectomy of peripheral cornea and limbus and not a lamellar dissection into stroma or sclera.
5. Place the tissue into a sterile Petri dish containing either corneal storage media or balanced salt solution and cover.
6. Repeat for the second site.
7. Antibiotic–corticosteroid ointment is placed in the inferior cul-de-sac, and the eye is patched until the patient is seen the next day.

Preparation of the recipient eye and placement of the donor tissue

These steps are described in detail in the discussion of CLAU and are summarized as follows:

1. Perform a lateral canthotomy if needed for exposure.
2. Perform a 360° limbal peritomy and remove 2–3 mm of conjunctiva (Fig. 26.3, *A*).
3. Achieve hemostasis with cautery. Use of topical epinephrine (1 : 10 000 dilution) and thrombin may be helpful.
4. Prepare the recipient graft sites to match the dimensions of the harvested tissue.
5. Carefully remove abnormal corneal epithelium and fibrovascular pannus with blunt and sharp dissection (Fig. 26.3, *B*).
6. Orient the first CLAU in its anatomic position and secure with interrupted 10-0 nylon sutures. Protect the graft from trauma and desiccation with viscoelastic and balanced salt solution while suturing. Cut the sutures on the knot and do not rotate to avoid accidental removal (Fig. 26.3, *D*). Repeat with the second graft.
7. Antibiotic–corticosteroid ointment is placed in the inferior cul-de-sac, and a patch and shield is placed over the eye until the patient is seen the following day.

Postoperative care

Topical medications for both the donor and the recipient are discussed in the CLAU section. Systemic immunosuppression consisting of oral prednisone, cyclosporin A (CsA) or tacrolimus, and azathioprine or mycophenolate mofetil is started on the day of surgery for allograft patients if no contraindication exists. Table 26.3 summarizes the dosing regimen. A thorough discussion of the postoperative monitoring for the various immunosuppressive medications can be found in Chapter 62 on immunosuppression after high-risk keratoplasty.

Results

Daya and Ilari performed lr-CLAL on 10 eyes with SJS, ectodermal dysplasia, chemical injury, OCP, and atopic keratoconjunctivitis.[22] HLA typing was done and systemic cyclosporin was given. Eight eyes achieved a stable corneal epithelium (80%), with a mean follow-up of 26 months. Both primary failures were in patients with SJS. Similarly, Kwitko et al reported on 12 eyes with SJS, toxic epidermal necrolysis (Lyell's syndrome), and chemical and thermal burns who underwent lr-CLAL. At 17 months, 11 of those eyes had a stable ocular surface and improved vision (92%).[23] Interestingly, in these patients systemic cyclosporin was not given and HLA typing was performed retrospectively. Samson and coworkers reported that only half (50%) of 10 eyes with SJS were successfully re-epithelialized after lr-CLAL with a follow-up of at least 2 years.[24] No systemic immunosuppression was utilized postoperatively, however. Similarly, Rao et al reported that all nine eyes with chemical burns and SJS that underwent lr-CLAL without postoperative systemic immunosuppression obtained initial successful restoration of corneal epithelium but subsequently developed corneal vascularization.[25] The authors concluded that lack of immunosuppression, incomplete encircling of the limbus, and HLA mismatch were potential explanations for failure. We believe that systemic and topical immunosuppression are essential for long-term graft survival.

KERATOLIMBAL ALLOGRAFTS

Donor tissue selection

To obtain appropriate tissue for performing a KLAL, the surgeon needs to communicate with the eye banks of potential supply to inform and educate them of the special requirements of this procedure, which is not commonly performed. If the eye bank is unaware of preferred differences in the age of the donor and preparation techniques, it will be impossible to obtain optimal tissue prepared in the desired fashion.

For routine penetrating keratoplasty, most surgeons avoid using tissue from infant donors (usually less than 4 years of age) because of the difficulty of working with the tissue. Its flaccid nature and its tendency to stretch postoperatively lead to unpredictable results. Eye banks are aware of this problem and thus do not routinely pursue such tissue. In performing a KLAL, the pliability of the tissue has not been an issue. More importantly, tissue from young children results in rapid re-epithelialization (5–7 days) of the recipient's cornea. It is intuitive that the limbal stem cells of infants and children would be the most active and vital. Thus, the authors prefer to use the youngest tissue possible, including neonatal. As an upper age limit, the authors have avoided using tissue from donors greater than 50 years of age. The authors inform their local eye bank when they have a patient on the waiting list for a KLAL so that they will accept infant tissue that they otherwise would decline. Additionally, both eyes of the donor should be obtained to provide sufficient tissue for the procedure.

When the eye bank is aware of the availability of appropriate tissue for a KLAL, contact is made with the potential recipient to confirm the pending procedure. Once tissue is obtained, the KLAL should be performed as soon as possible in an effort to maximize the viability of the limbal stem cells, preferably within 72 h of the donor's death. Thus, the patient is often asked to complete a preoperative evaluation even before final clearance of the donor tissue. If patients are coming from any considerable distance away, they need to be appropriately advised in advance on how to manage the logistics of such a short notice for their surgery.

Donor tissue preparation

As with the donor criteria, there are several variations from standard tissue harvesting techniques of which a prospective eye bank supplier needs to be informed. (1) Normally the emphasis during tissue harvesting is to avoid damaging the corneal endothelium and stroma, with less regard for the epithelium; in these cases,

the limbal tissue and epithelium need to be carefully protected from both trauma and desiccation. The authors want the entire corneal epithelium to appear as normal as possible to serve as an indirect sign that the limbal stem cells have hopefully undergone minimal harm. (2) Whereas most of the conjunctiva is normally removed during the harvesting procedure, the authors ask for a peripheral skirt of 3–4 mm to be left if possible. This step helps minimize damage to the limbal area, and it allows for some goblet cells to be included in the transplantation. (3) A 4–5-mm scleral rim should be included in the resection from the globe. (4) Finally, both donor eyes are needed to provide sufficient tissue for the procedure.

Anesthesia

Either peri- or retrobulbar anesthetic with a cranial nerve VII (O'Brien) block or general anesthesia is administered.

Preparation of the recipient eye

Exposure is often difficult in these patients because of superior and inferior symblepharon. A speculum is inserted, and a lateral canthotomy is performed if necessary. The initial incision is a limbal peritomy for 360°. In most patients with severe ocular surface disease, significant bleeding is encountered during the peritomy, which may necessitate resecting one quadrant at a time. Hemostasis is maintained with topical epinephrine (1 : 10 000 dilution), thrombin, and wet-field cautery. In areas of symblepharon, conjunctival tissue is first recessed at the limbus and then undermined to allow the conjunctival tissue to fall back, not only to create a new fornix but to supply tissue for a new palpebral surface as well. If the initial dissection was made at the fornix and the symblepharon simply excised, there would be a broad area of epithelial defect on the palpebral conjunctival side, leading to further symblepharon formation. Therefore, the symblepharon are actually used to help reconstruct the fornix and provide the epithelium of the palpebral surface. Care is taken to avoid damaging the superior or inferior rectus muscles in areas of broad symblepharon.

The conjunctiva is resected 4–5 mm from the limbus to expose an adequately sized bed of denuded sclera on which to position the KLAL tissue. Abnormal fibrovascular pannus and epithelium, which are typically present, are next removed from the surface of the cornea. Blunt dissection with a cellulose sponge is used initially, although often semisharp dissection with a rounded steel blade is needed to create a smooth surface. Care is taken to ensure that the dissection continue in a lamellar fashion, remaining anterior, and that the deep layers of the corneal stroma are not disturbed. The purpose of this dissection is removal of the abnormal fibrovascular conjunctivalized surface that has replaced normal corneal epithelium. Topical epinephrine and thrombin can be used to control bleeding during this step as needed.

Harvesting of the limbal tissue

The purpose of performing a KLAL is to provide healthy limbal stem cells to the recipient limbus. Because the stem cells lie in a narrow, fragile portion of the limbus, they must be delivered attached to a more robust carrier tissue. Using peripheral corneoscleral tissue allows for safe transfer and secure attachment of the stem cells to the recipient limbus. A recent corneoscleral crescent technique is a modification of the procedure first described by Tsubota and coworkers in 1995.[26] Unlike a lenticule technique,[27] in which a whole globe is needed, this technique uses a corneoscleral rim preserved in corneal storage media at 4°C (Fig. 26.4, *A*). The central cornea of the corneoscleral rim is excised with a 7.5-mm trephine. The authors use two donor corneas (for three available keratolimbal halves) with an Iowa cutting press and place the tissue epithelial-side down in the standard fashion used for cutting a corneal button for routine keratoplasty. This approach does not cause any apparent

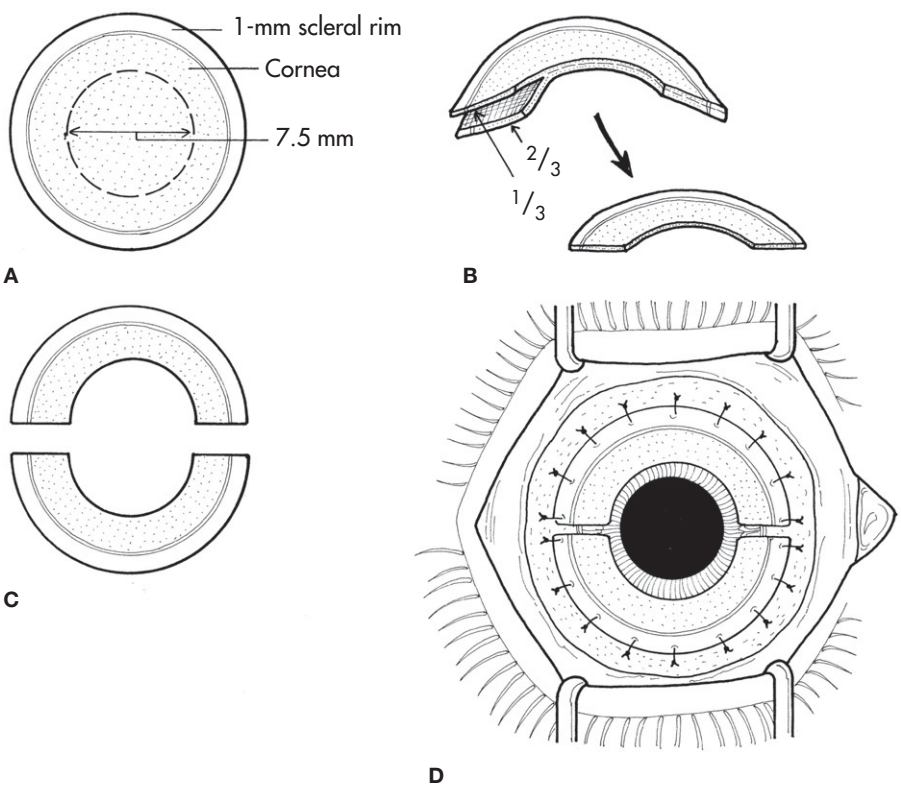

Figure 26.4. Technique for KLAL transplantation. *A*, Donor corneoscleral rim with central 7.5 mm of cornea removed using a trephine. *B*, Remaining corneoscleral rim is cut into equal halves, forming two crescents (total of four crescents from two donor eyes). *C*, Each corneoscleral crescent undergoes lamellar dissection to remove between half and two-thirds the posterior tissue. *D*, Three KLAL crescents are sutured to the recipient eye with the anterior corneal edges overlying the recipient limbus.

harm to the limbal stem cells. The corneal buttons are placed back into storage media for potential later use (e.g. if a combined penetrating keratoplasty and KLAL are planned). The remaining corneoscleral rims are sectioned into equal halves (Fig. 26.4, *B*). Scissors are used to dissect the excess peripheral scleral tissue, leaving approximately 1 mm of sclera peripheral to the limbus. The posterior half to two-thirds of each hemisection is removed by lamellar dissection using a super-sharp rounded steel crescent blade (Fig. 26.4, *C*). This step usually requires an assistant to help stabilize the tissue with forceps under the operating microscope. Aldave and Wong have reported a technique where the donor tissue is glued to a disposable acrylic sphere using cyanoacrylate.[28] Other techniques using an artificial anterior chamber to facilitate donor harvesting have been reported.[29,30] The dissection removes the posterior sclera and posterior stroma, including Descemet's membrane and endothelium. If the graft is too thick, there is greater likelihood that, once transplanted, the friction of the eyelids closing over the surface will impede re-epithelialization. The posterior tissue is discarded, and the second corneoscleral donor rim is prepared in the same fashion. The four pieces are then placed epithelial-side up in storage media solution while awaiting placement.

Two eyes are required to have sufficient tissue to place around the recipient limbus without gaps. Previously, tissue from only one eye was used, with resultant small gaps at the 3 and 9 o'clock limbal positions; conjunctivalization frequently occurred across the gaps, even if filled with lamellar sections from the remaining corneal button. These gaps are largest when using tissue from an infant eye because of the smaller limbal circumference. To eliminate gaps, corneoscleral rims from a pair of eyes are always needed. Using our current technique, a total of three crescents are used for each eye. Many surgeons, especially in areas where donor tissue is more scarce, use just one complete corneal scleral rim.[31]

Placement of the donor tissue

The crescents are next placed on the recipient eye with the anterior corneal edges overlying the recipient limbus (Fig. 26.4, *D*). The two anterior corners of a crescent are secured first at the limbus with interrupted 10-0 nylon sutures. The corneal edge of the KLAL should lie flush on the recipient cornea. Then the two posterior corners are sutured. An additional suture or two can be placed along the posterior edge if needed for security. Additional crescents are placed end-to-end in the same fashion until the entire circumference of recipient limbus is covered by healthy donor stem cell tissue. During suturing the authors place viscoelastic material on the KLAL tissue to protect the epithelium, and a balanced salt solution prevents desiccation. If there is a functioning bleb from a prior glaucoma filtering surgery, a gap can be left to preserve the bleb. In situations in which a seton drainage device has been placed, or is anticipated, the limbus can be covered with the new graft tissue without interfering with the success of these glaucoma procedures. It is not necessary to suture the free edges of the recessed recipient conjunctiva to the posterior edges of the segments. The patient's conjunctiva usually retracts minimally and adheres to the edges on its own accord. Recently, we have had success with using fibrin tissue adhesives (Tisseel) to adhere the corneoscleral rims to the host scleral surface. Sutures are still used on the corneal side to close the gaps. This has reduced the operating time and has reduced ocular discomfort postoperatively. At the conclusion of the procedure, an antibiotic-corticosteroid ointment is placed in the inferior cul-de-sac and the eye is patched until the patient is seen the next day.

Postoperative care

The postoperative regimen is essentially the same for Lr-CLAL recipients (Table 26.3). Patients use a topical antibiotic until the corneal and conjunctival epithelial defects are healed. Complete epithelialization usually occurs over 1–3 weeks. Topical corticosteroids are used three or four times daily for inflammation with overtreatment avoided to minimize retarding epithelialization. Patients are maintained on a tapering dose of topical corticosteroids indefinitely. Most patients receive oral prednisone 1 mg/kg/day, with a slow taper generally over 3–6 months. Systemic immunosuppression with CsA (Neoral) or tacrolimus (Prograf) and azathioprine (Imuran) or mycophenolate mofetil (Cellcept) are also begun postoperatively. In addition, topical CsA 0.05% (Restasis) is used four times a day indefinitely. All patients are instructed to use nonpreserved artificial tears on a frequent basis. Punctal occlusion and lateral tarsorrhaphy are additional steps to maximize surface lubrication. A therapeutic contact lens can be placed if a patient experiences significant discomfort or cessation of epithelial healing.

Table 26.3 Immunosuppressive regimen after keratolimbal allograft transplantation

Agent	Dosage and Duration	Monitoring
Corticosteroids		
Topical	q.i.d.–q.d., indefinitely	IOP, epithelial healing
Oral	1 mg/kg/day, taper over 6 months	BP, serum glucose, weight, gastritis, bone density, and lipids
Cyclosporin A		
Topical	0.05% q.i.d., indefinitely	Epithelial toxicity
Oral[a]	3 mg/kg/day, 12–18 months	Serum level 100–150 ng/dL, creatinine, BP, lipids, LFTs minerals, urinalysis, and CBC
OR		
Tacrolimus[a]	1–4 mg b.i.d., 12–18 months	Serum level 8–10 ng/mL for 3 months, then 5–8 ng/mL, creatinine, BP, lipids, LFTs minerals, urinalysis, and CBC
OR		
Azathioprine[a]	100 mg/day, 12–18 months	CBC and LFTs
Mycophenolate[a]	500 mg b.i.d., 12–18 months	CBC, chemistries, and LFTs

[a] Only one of these two agents is used.

IOP, intraocular pressure; BP, blood pressure; LFT, liver function test; CBC, complete blood count.

Results

In a recent review of our KLAL results in 31 eyes with aniridia, a stable ocular surface was achieved in 74% of cases and 7 out of 10 subsequent penetrating keratoplasties were successful.[18] Systemic immunosuppression appeared to be a crucial determinant of success in that series. We previously reported a similar ocular surface restoration rate of 72% in a series of patients with SJS.[16] Tsubota and coworkers published a series of 43 eyes with SJS or OCP that underwent KLAL.[32] They achieved a successful epithelialization in 51% of eyes transplanting entire circular corneoscleral rims and using oral cyclosporin for immunosuppression. Dua and Azuara-Blanco performed KLAL with only one donor cornea on six eyes using tacrolimus for systemic immunosuppression.[19] Five of those eyes had a successful outcome. The corneoscleral rim was obtained by lamellar dissection on a whole globe. In order to cover 360° of limbus in that series both the cadaveric corneal tissue and the CLAL from the recipient's fellow eye (a KLAL–CLAU hybrid) were performed. Not all studies, however, have demonstrated the same long-term success. Solomon and coworkers reported on 39 eyes that underwent KLAL for several diagnoses including chemical injuries (16 eyes) and SJS (9 eyes).[33] Twenty-four of these eyes underwent a penetrating keratoplasty, at the same time or at a later procedure. In their report, 77% of patients had a stable ocular surface at 1 year, but this fell to 24% at 5 years. Long-term survival of donor tissue in the recipient eye has been demonstrated conclusively after KLAL when adequate systemic immunosuppression is used.[34]

COMBINED LIVING-RELATED CLALs AND KLALs

In a select group of patients who have concomitant conjunctival and limbal stem cell deficiency, a combined lr-CLAL and KLAL may provide a better alternative for reconstructing the ocular surface. Specifically, patients with SJS and OCP who have a living relative donor may benefit the most from the added conjunctival tissue while having the maximum number of limbal stem cells transplanted. Specifically in these patients, the conjunctival loss contributes significantly to the ocular surface pathology. Severe symblepharon, forniceal loss, and trichiasis present mechanical barriers to successful stem cell transplantation. Additionally, the associated loss of goblet cells results in disruption of the mucin layer of the tear film.

The preoperative considerations previously discussed for KLAL and lr-CLAL apply to these patients. Typically, patients requiring the combined procedure have the most extensive ocular surface disease. Reconstruction of the ocular surface in these patients often requires restoration of the conjunctival fornices and lid procedures that are best performed with the assistance of an oculoplastic surgeon. In the most severe cases, mucous membrane grafting is appropriate, which may require the services of an otolaryngologist to harvest nasal mucosa from the inferior turbinate. Thorough evaluation by each subspecialist is required before proceeding with the surgery.

Surgical technique

The living-related tissue is harvested as described for lr-CLAL and stored in storage medium. A single corneoscleral rim is processed as previously described for the KLAL procedure and placed in storage medium. The second corneoscleral rim is not required because the superior and inferior aspects of the recipient limbus will receive the lr-CLAL tissue. Attention is then turned to the recipient eye, and all symblepharon and surface scarring are lysed to create space for new fornices. An encircling limbal peritomy is performed in areas where conjunctiva is present. Conjunctival preservation is essential whenever possible. A superficial keratectomy is performed to remove abnormal epithelium and fibrovascular pannus. Meticulous hemostasis is maintained with gentle cautery. When needed, the palpebral surfaces of the lids are resurfaced with mucous membranes. The CLALs are then positioned and secured at the 12 and 6 o'clock positions (Fig. 26.5). Interrupted 10-0 nylon sutures are used to secure the lateral and posterior aspects of the grafts. The cadaveric tissue is then positioned at the temporal and nasal limbus. The arrangement of the tissue must be planned to avoid gap areas between the allografts. The keratolimbal tissue is secured with 10-0 nylon sutures as previously described. Occasionally, a symblepharon ring is used to maintain the fornices while the ocular surface re-epithelializes. The results of our preliminary experience with combined CLAL–KLAL have been encouraging.[31] We have seen better results with this procedure in patients with severe conjunctival and limbal deficiency than with KLAL alone.

EX VIVO STEM CELL EXPANSION

A primary limitation of stem cell transplantation has been rejection. CLAU avoids rejection but is limited to a small percentage of patients in need of stem cell replacement. The ability to reliably harvest small numbers of stem cells from patients with bilateral stem cell failure, culture these cells in vitro, and transplant them back to the patient will revolutionize stem cell transplantation. While cost and technical difficulties currently limit the availability of this procedure, several researchers have demonstrated the feasibility of ex vivo stem cell expansion.

In 1996, Torfi et al reported on transplantation of ex vivo cultivated corneal epithelium, with a successful outcome in three of four

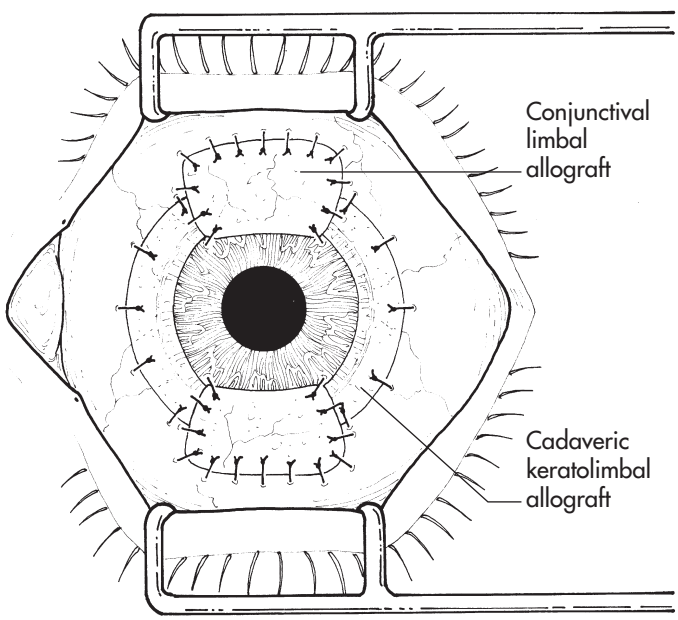

Figure 26.5. Technique for combined keratolimbal allograft (KLAL) and conjunctival limbal allograft (CLAL) transplantation. The CLAL are harvested as before (Fig. 26.3), and the KLALs are prepared from cadaveric tissue as shown in Figure 26.4. The CLAL tissues are placed in the superior and inferior quadrants, while the KLAL grafts are secured to the nasal and temporal limbus.

cases.[35] Similarly, Pellegrini and coworkers reported long-term stabilization of two eyes with unilateral alkali burns following transplantation of autologous corneal epithelium that was grown in vitro from a 1 mm biopsy from the healthy fellow eye.[36] Tsai and coworkers have demonstrated the benefits of amniotic membrane as a substrate on which to cultivate and transplant limbal epithelium. In their report, success was attained in six of six stem cell-deficient eyes that received expanded tissue from the fellow eyes.[37] Expanded stem cell allografts have also been described. Schwab and coworkers published studies on a series of 14 eyes, 10 of which received autologous expanded tissue harvested from the fellow eye and 4 of which received allogeneic tissue, with success in 10 of the eyes.[38] Koizumi and coworkers transplanted allogeneic corneal epithelial material, which had been expanded on an amniotic membrane substrate, cocultured with a layer of fibroblasts and subjected to air lifting, which is believed to promote formation of tight junctions.[39,40] All patients received systemic immunosuppression and all eyes had a stable ocular surface 1 year after surgery, except for three eyes that experienced rejection. Repeating the same procedure yielded a satisfactory outcome in those three eyes. In a final series of 13 eyes reported on by Shimazaki et al, limbal epithelium of cadaveric ($n = 7$) or living-related origin was cultivated on amniotic membrane and transplanted. Corneal epithelialization was achieved in only six of those eyes.[41] Recently, several groups have reported the successful use of cultured oral mucosal epithelial cells for reconstruction of the corneal surface.[42] This could be a very useful technique for patients with bilateral total limbal stem cell deficiency. In particular, by using autologous cells, the need for immunosuppression is negated. Further studies are needed to demonstrate the long-term results of this procedure.

PENETRATING KERATOPLASTY POSTEPITHELIAL TRANSPLANTATION SURGERY

In rare circumstances, namely significant corneal thinning with risk of perforation, penetrating keratoplasty is performed concomitantly with one of the above epithelial transplantation procedures. Otherwise, the authors prefer to wait at least 3 months for the ocular surface to appear stable before proceeding with additional surgeries, particularly penetrating keratoplasty. A relatively fresh donor cornea with near-perfect epithelium should be selected. Care is taken during the surgery to minimize trauma and desiccation of the limbal grafts already in place. Specifically, viscoelastic is used to cover the limbal grafts at all times. It is best to trephine the host immediately anterior to the limbal grafts and prevent any gap areas between the limbal graft and the penetrating corneal graft.

SUMMARY

Improvement in epithelial transplantation continues to progress. The role of systemic immunosuppression has been firmly established with the importance of triple therapy including steroids, a calcineurin inhibitor (cyclosporin or tacrolimus), and an antimetabolite (azathioprine or mycophenolate). The techniques discussed in this chapter represent significant advancement in the management of these very difficult groups of patients with severe ocular surface disease caused by limbal stem cell or conjunctival deficiency (Fig. 26.6).

27 Autologous conjunctival and scleral grafts

David W. Vastine

The use of autologous conjunctival grafting for reconstruction of the ocular surface was first introduced by Thoft.[1,2] Subsequent to his report, the use of autologous conjunctival grafting for the reconstruction of the periocular mucous membrane for multiple disorders including pterygium was reported by Vastine et al.[3] Autologous conjunctival grafts have been most frequently used for surface reconstruction following excision of primary or recurrent pterygium.[3,4] Similar surgical techniques can be used for surface mucous membrane grafting for symblepharon and ankyloblepharon from various causes.[3,5] Contralateral or ipsilateral donor sites have been recommended in surface mucous membrane reconstruction following scarring from traumatic injury, chemical burns, or severe cicatricial mucous membrane infections or disorders. The use of contralateral donor sites is essential in unilateral disease in which the recipient eye has had severe injury with no residual conjunctiva or the conjunctival stem cells have been obliterated, as in mitomycin toxicity or severe chemical injury. The theory and use of stem cell grafts are discussed elsewhere in this text.

INDICATIONS

Autologous grafting has been used for reconstruction after resection of tumors, cicatricial entropion, thermal and chemical injuries, and postsurgical cicatricial strabismus and in complex plastic reconstruction of the lids and conjunctiva. In severe bilateral injuries, donor heterologous conjunctiva has been shown to be effective in monkeys[6] but has not been used widely in humans because the prompt procurement and preservation of cadaver tissue is difficult. Alternatives such as donor corneal peripheral epithelioplasty for stem cells, amniotic mucous membrane, buccal mucous membrane, and hard palate mucosa have been used with varying degrees of success. None of these techniques has proven as satisfactory as conjunctiva in restoring the most natural cosmetic or functional result. As in any procedure, exacting technique and attention to detail in the reconstructive process are essential for good function and cosmesis after the surgery.

THEORETICAL CONSIDERATIONS

The theory of the procedure is based on the use of normal undisturbed conjunctival mucous membrane with its intact superficial vascular network and healthy surface cells to provide a source of normal goblet, columnar surface, and stem cells for resurfacing an injured membrane. Through careful observation after grafting, the surgeon can watch the migration of the normal cells as they spread over the abnormal surface and displace the cells that have filled the defect by transformation from the epithelial cells of the lid margins. The migration patterns can be outlined with fluorescein, and the abnormal cells frequently pick up rose bengal stain. The most dramatic effect of the conjunctival grafts is their minimalization of graft shrinkage, which is frequently seen after buccal mucous membrane grafts or after allowing the natural reparative processes to close a surface wound by secondary intention (e.g. after the bare scleral procedures for excision of pterygium or large tumors of the conjunctiva). The resultant pseudopterygium can be very dramatic in its appearance and alteration of function, leading to diplopia and restrictive strabismus (Fig. 27.1). Thin conjunctival patch grafts rapidly revascularize, thus limiting the stimulus for subepithelial fibrosis and shrinkage of the graft and surrounding tissues. The normal surface cells spread into areas lacking normal surface cells, thus reducing the stimulus for inflammation and scarring (Figs 27.2 and 27.3).

RESULTS

Most importantly, since previously reported in 1982,[3] this technique has been used for reconstruction of patients with symblepharon, ankyloblepharon, chemical burns, mitomycin toxicity, post-traumatic and postsurgical scarring and fibrosis, resection of primary and secondary pterygium, and tumor resection with plastic reconstruction. There have been no complications with this procedure over the past 17 years. As with many procedures, the confidence and familiarity with the procedure is a big factor in its use and success. The success rates have been well established with repair after primary or secondary pterygium.[3,4,7–10] The main controversy remains between the use of excision with primary closure by flap rotation or autologous conjunctival grafts and simple bare scleral excision with adjunctive therapy such as β-radiation or mitomycin-C.[11,12] The best cosmetic results with the lowest recurrence rates are achieved with the grafting techniques. Unlike β-radiation or mitomycin application, there are no short-term complications of scleral necrosis or long-term complications due to late infectious scleritis

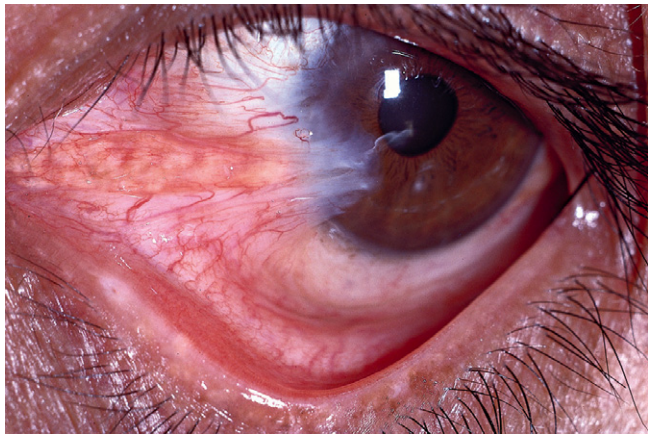

Figure 27.1. Medial symblepharon after pterygium excision with restriction and diplopia prior to reconstruction with an autologous conjunctival graft.

Figure 27.2. Multiple sutured small patch grafts are seen resurfacing the entire inferior bulbar conjunctiva in a patient with severe ocular shrinkage secondary to chronic atopic disease. The pseudopterygium is extensive with a mattress suture over the bolster and through the lid to redirect the scar tissue immediately postoperatively.

or cataract.[13,14] Severe surface disease with scleral necrosis has occurred with the use of mitomycin-C, which is an unnecessary risk to take with a readily available nontoxic surgical alternative.[15]

SURGICAL CONSIDERATIONS

No attempt at surgical repair should be initiated until the acute process or trauma has been controlled and is quiet for at least 6 months. The surgical approach to reconstruction can use simple conventional techniques in mild cases. Conjunctival Z-plasty and other simple conjunctival procedures may be helpful in the less severe cases. Advanced scarring and tissue destruction will require extensive reconstruction with free autologous conjunctival mucous membrane grafts. Surgical intervention should not be attempted until any acute inflammatory process has been controlled. Procedures done in the presence of aggressive inflammation and necrosis may result in failure of the graft or unsatisfactory results. However, in some cases, such as chemical injury in which lack of adequate stem cells results in progressive disease, it is necessary to intervene to prevent further damage. This case also occurs in mitomycin toxicity, in which progressive scleral necrosis and ischemic scleritis will not be controlled without intervention.

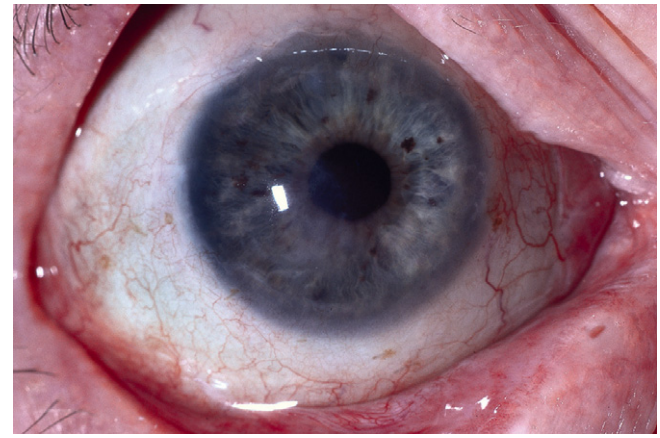

Figure 27.3. Seven months postoperatively, the grafts cannot be distinguished with a normal inferior fornix. A quiet eye is maintained with fluorometholone drops once a day and sodium cromolyn to control chronic atopic disease.

TECHNIQUES OF AUTOLOGOUS CONJUNCTIVAL TRANSPLANTATION

The procedure for successful grafting begins with a careful and full dissection and excision of the diseased portion of the eye. It is important to remove all the subepithelial fibrosis and recess as much of the remaining normal conjunctiva as possible to create a deep and healthy fornix. In most cases, there is sufficient virgin bulbar conjunctiva under the upper lid in the same or contralateral eye for proper reconstruction. In desperate cases, patches of conjunctiva can be sutured in the most critical areas around the corneal limbus, and the transplanted cells will migrate over the areas of bare sclera to fill in defects and create an intact mucous membrane layer with minimal resultant foreshortening of the fornix. It is important to save and reposition as much of the normal conjunctival membrane around the areas of pathology as possible without compromising the adequate resection of the diseased tissue. The first step is to prepare the recipient site to receive the graft. The excessive scar tissue must be excised, and any bleeding in the recipient bed must be controlled by bipolar cautery. Part of this process may require separation of the lids (ankyloblepharon) (Fig. 27.4, *A*). The recipient site is measured to establish the size of the donor graft required. The use of the binocular operating microscope is recommended for all of these procedures to achieve precise control and evaluation of the normal and abnormal anatomy. Anterior limbal 7-0 black silk sutures are placed to move the eye in all directions to assure lysis or remove any restrictive adhesions, to provide adequate surgical exposure, to allow resection of all submucosal scar, and to assure full mobility of the globe (Fig. 27.4, *B* and 27.5). Subepithelial resection of the excessive thickened Tenon's fascia is important to help debulk the recipient site and allow enhanced acceptance and adherence of the donor graft (Fig. 27.5). This approach also improves the final cosmetic and functional result. In advanced cases of foreshortening of the fornix, the remaining bulbar conjunctiva may be used to provide a palpebral conjunctival surface and create a new fornix with a through-the-lid mattress bolster suture. The bulbar conjunctiva is provided with the donor autologous conjunctival graft (Fig. 27.6; see also Fig. 27.2).

The preparation of the donor conjunctival graft from the ipsilateral or contralateral donor site is also done under microscopic control. The procedure includes the placement of a 7-0 black silk

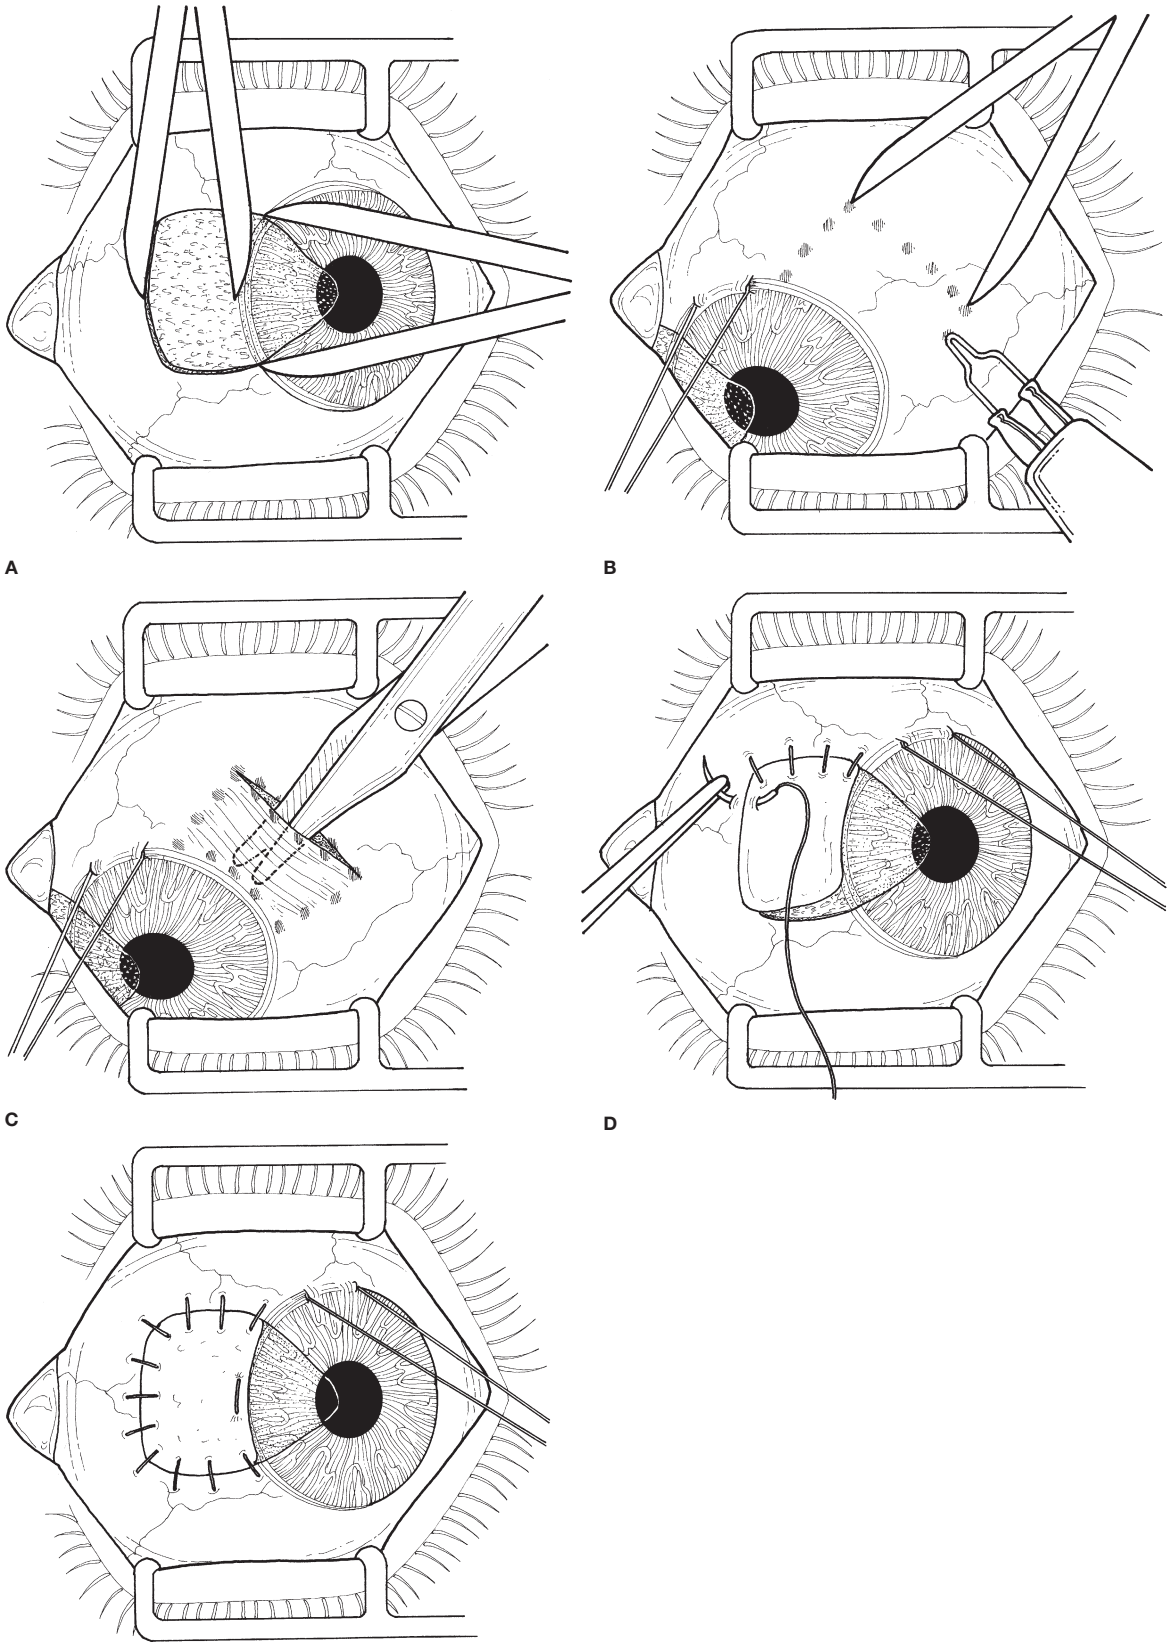

Figure 27.4. Autologous conjunctival grafting. *A*, After resection of the pterygium or symblepharon, the defect is measured with calipers to establish an exact match from the donor site. *B*, A 7-0 black silk suture is placed at the superior limbus to manipulate the globe and expose the superior bulbar conjunctiva, which is marked with a cautery to assure proper size and configuration of the donor graft. *C*, Fine-tipped Wescott or Vannas scissors are used to gently separate the conjunctiva and the underlying connective tissue, making the graft as thin as possible. *D* and *E*, The donor graft is slid into place and oriented properly to fill the defect. If a small defect remains, the adjacent conjunctiva may be undermined and slid in to fill the defect with primary closure.

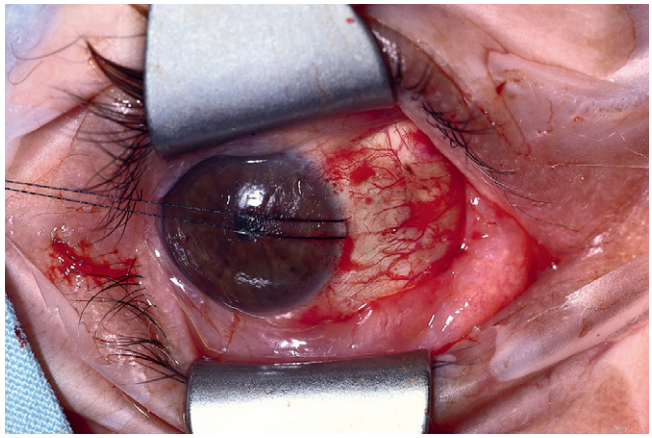

Figure 27.5. An intraoperative photograph shows the placement of a limbal-based black silk suture used for manipulation and control of the eye during surgery. Note the extensive resection of scarred conjunctival tissue required to get free mobility of the globe.

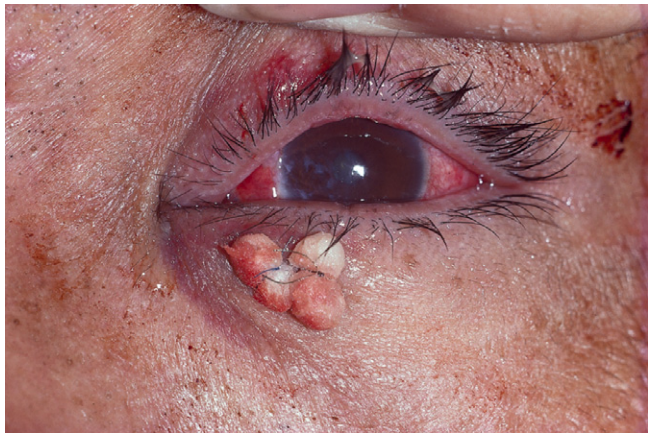

Figure 27.6. The appearance of a patient on the first postoperative day after his fifth surgery for recurrent pterygium and his first conjunctival graft. Because of obliteration of the inferior fornix, the pterygium was transposed and used to create a new inferior fornix held in position with a through-the-lid bolster.

suture at the superior temporal limbus, and the eye is displaced inferiorly and nasally, exposing the superior bulbar conjunctiva. The dimensions of the patch graft are marked with gentle bipolar cautery (see Fig. 27.4, *B* and *C*). A subconjunctival injection of 1% lidocaine with 1/100 000 epinephrine is given with a 30-gauge needle just under the mucosal surface. This injection is used to separate the surface mucous membrane from underlying Tenon's fascia. Careful dissection of the donor patches are done with Vannas or sharp, pointed Westcott scissors. Care is taken to avoid button-holing the patch or leaving too much underlying connective tissue (see Fig. 27.4, *C*). The graft may or may not include the limbal stem cells, depending on the needs of the recipient eye. The donor site is left bare and is not closed. Experience has shown that the donor site will re-epithelialize without significant shrinkage and can be used again for additional grafts in special circumstances. There have been no reported complications noted at the donor site.

The graft is transferred to the recipient site with care to prevent eversion. The most useful technique is to place it on a segment of plastic drape, sliding it on and off to maintain proper orientation. The donor patch is transferred to the recipient site and sutured into

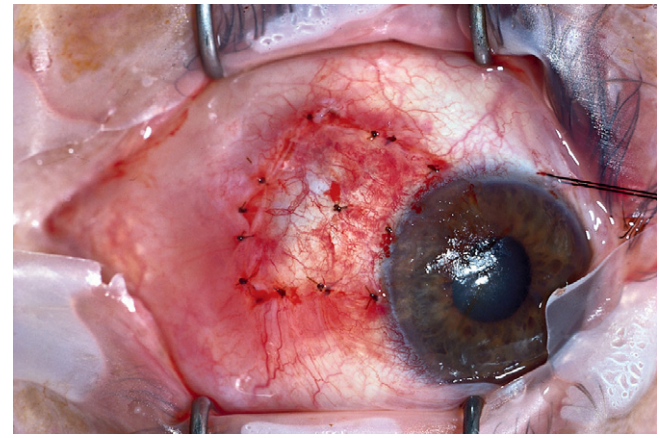

Figure 27.7. The intraoperative appearance of a small thin graft secured with multiple interrupted sutures.

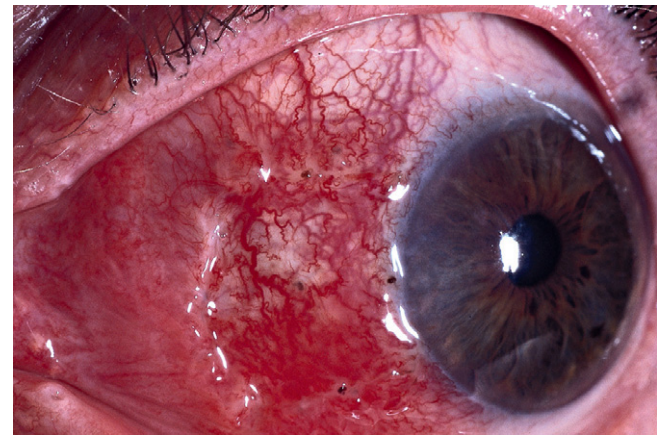

Figure 27.8. Typical postoperative chemosis and hyperemia are noted immediately after grafting.

place with multiple interrupted sutures. If some of the tissue at the recipient site has been rotated into the fornix, it can be secured with a through-the-lid double-armed mattress suture with a bolster. The donor patch is sutured to the underlying connective tissue and episclera with a 10-0 nylon (see Fig. 27.4, *D* and *E*). The suture of choice was 8-0 chromic collagen, which is no longer available. Monofilament nylon is superior to the current 8-0 or 9-0 monofilament polyglactin 910 suture, which may also be used (Fig. 27.7). The mechanical irritation and perisuture necrosis caused by the polyglactin 910 is not ideal and may cause excessive inflammation and graft reaction. The grafts that are well secured have remained stable during the revascularization process.

Postoperatively, the grafts appear edematous and avascular with no flow in the vessels for the first 3–5 days. The grafts will begin to revascularize and will become edematous and hemorrhagic in appearance for about 2 weeks (Fig. 27.8). Over 7–10 days, the patches become well adhered. Within the next 2–3 months, the patches assume a normal appearance (Fig. 27.9). During the post-operative period, topical antibiotic and corticosteroid drops are used initially from four to eight times daily and gradually tapered, depending on the degree of postoperative reaction.

ALTERNATIVE PROCEDURES

Alternative tissues have been used in cases in which no normal conjunctival cells exist (e.g. bilateral chemical burns). Prior to the

Figure 27.9. The same patient as in Figure 27.8, 1 year after surgery, with a quiet normal appearance at the recipient site.

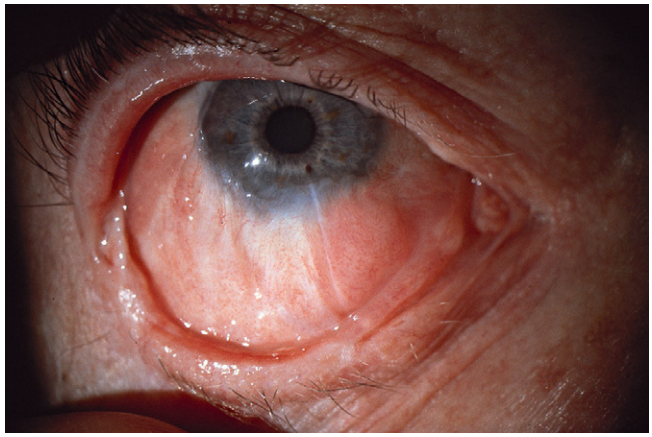

Figure 27.10. A buccal mucous membrane graft with thickened appearance and abnormal vascular pattern gives unsatisfactory cosmetic and functional results.

use of autologous conjunctival grafting, mucous membrane of the mouth has been the most commonly used source. The lack of a vascular tree and the need to revascularize result in shrinkage of these grafts, with an unsightly cosmetic appearance. In some cases, complete shrinkage and replacement of the graft can occur. The surgical procurement of buccal or labial mucous membrane is much more cumbersome, requires a dermatome, and does not supply a source of conjunctival stem cells for cellular transformation. The subsequent physiology of the tear film is not satisfactory in these patients. After complete healing, a partial-thickness buccal mucous membrane graft is more likely to shrink and may be cosmetically and functionally less satisfactory than autologous conjunctiva (Fig. 27.10). These grafts will frequently shrink despite the use of conformers, symblepharon rings, and stents to limit shrinkage and destruction of the grafts.[16]

Prior to using autologous conjunctiva for recurrent pterygium, lamellar keratoplasty[17] was advocated to prevent aggressive recurrence after multiple attempts at resection but is rarely used today. The author has not used either heterologous conjunctival grafts or amniotic membrane grafts. There are clear indications for these grafts, but the need for these extreme techniques is fortunately rare. The use of autologous conjunctival grafting has shown little evidence of postgraft shrinkage and resistance to fibrosis due in part to the supportive vascular network transplanted into the defect.

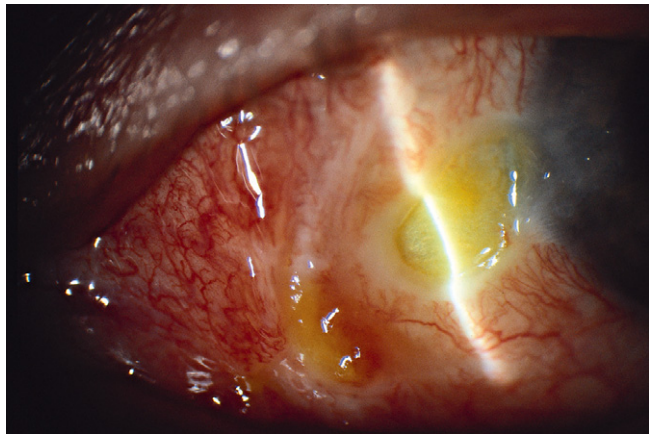

Figure 27.11. Localized scleral thinning, melt, and ischemia with surrounding conjunctival hyperemia and chemosis following simple excision of a pterygium with the application of β-radiation.

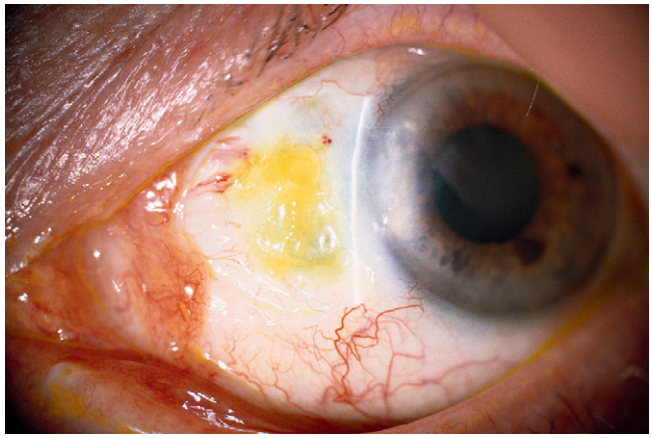

Figure 27.12. Scleral necrosis using mitomycin-C topical treatment after bare scleral excision of a recurrent pterygium. There is also mild corneal thinning. In some patients, there is extensive corneal surface abnormality due to lack of normal stem cells.

RESULTS

The results of several published studies[3,4,7,10] have shown conjunctival grafting to be the safest and the most effective technique for surface restoration after excision of recurrent pterygium. The recurrence rate with the autografting technique ranges from as low as 2% to as high as 16–25% in primary and recurrent pterygia. It appears as if the prospective studies show the best results, and the recurrence rate depends on a varying definition of recurrence. The results are compatible with those of studies showing a less than 6% recurrence for primary and recurrent pterygium combined. Meticulous surgical technique plays a vital role in the outcome of the procedure. The complications of scleral necrosis and ischemic scleritis have not been reported.

AUTOLOGOUS SCLERAL GRAFTS FOR RECONSTRUCTION

The complications of noninfectious and infectious scleritis after the use of β-radiation[13,14] and mitomycin[15] present challenges in restoring the ocular surface. Mitomycin toxicity offers the additional challenge of destruction of the surface stem cells and lack

Figure 27.13. Autologous scleral grafting in combination with contralateral autologous conjunctival graft to repair scleral necrosis. *A* and *B*, The diseased and ischemic conjunctiva is removed to a healthy recipient bed, and the underlying necrotic sclera is removed with a #69 Beaver blade. *C*, The eye is displaced inferiorly, and the conjunctiva is reflected with sharp dissection leaving the superior bulbar sclera exposed. The scleral patch is outlined with a caliper and a cautery, but the episcleral vessels are not treated with cautery. *D*, The sclera is incised with a diamond knife to approximately one-half thickness, and the scleral flap is dissected with a spatula knife and removed and transferred to the donor site. *E*, The donor site is closed carefully with adjacent Tenon's fascia sutured to the donor site with 7-0 polyglactin 910, and the conjunctiva is closed carefully with 10-0 nylon as it has poor healing secondary to mitomycin-C toxicity. The scleral graft is transferred and positioned to fill the defect and sutured into place with interrupted 10-0 nylon. *F*, The contralateral autologous conjunctival graft is sutured into place with primary anastomosis to healthy recipient conjunctiva surrounding the original area of resection. 10-0 nylon suture is also used to close the conjunctival graft.

of the ability of the surface to restore the persistent defect and stop the progression of ischemic necrosis of the sclera. These patients have consistent pain and discomfort with no response to topical noncorticosteroidal anti-inflammatory drops as well as topical corticosteroids.

THEORETICAL CONSIDERATION

Previous reports had documented the failure of ipsilateral conjunctival grafts in repair of this complication.[15] This finding was the result of failure of the stem cells to repopulate the normal cell structure. In addition, transplantation of healthy mucous membrane over a large ischemic area results in lack of revascularization of the graft and eventual graft failure.

In response to this challenge in 1993, reports were published about the successful use of autologous scleral patch grafting with contralateral autologous conjunctival grafting to restore ocular integrity in these complicated patients.[18] The rationale for the procedure relates to the effects of the use of mitomycin, which is strictly surface toxic in the areas of intact conjunctiva. The ischemic necrosis caused in the area of pterygium resection from β-radiation or mitomycin continues to break down, causing severe pain and chronic discomfort (Figs 27.11 and 27.12). Donor scleral grafts or periosteal grafts have been successfully used in scleral necrosis in patients with rheumatoid arthritis. The advantages of fresh autologous sclera with an intact episcleral vascular network are ease of procurement, ready availability, and low risk of infection. Periosteum is difficult to harvest from the patients' pretibium and is difficult to work with in comparison with autologous sclera.

TECHNIQUE OF AUTOLOGOUS SCLERA GRAFTING

The repair begins with debridement of the area of necrosis and removal of dead tissue from the defect (Fig. 27.13, *A* and *B*). The defect is measured, and the shape of the defect is outlined. Attention is drawn to the superior and temporal quadrant. 7-0 black silk limbal suture is placed in the superior corneal limbus. A limbal incision is made, and a fornix-based conjunctival flap is elevated from the sclera. Minimal cautery is used to preserve the intact episcleral vessels. A caliper is used to outline the pattern of the scleral defect with a light bipolar cautery (Fig. 27.13, *C*). An incision is made with a diamond knife to approximately one-half thickness of the sclera. Using a spatulated angulated blade, the scleral graft is elevated similar to the technique of creating a trabeculectomy sclera flap and undermined throughout the area of the donor graft. (Fig. 27.13, *D*). A Vannas scissors is used to remove the scleral patch. The graft is transferred to the recipient site and sutured into place with multiple interrupted 10-0 nylon sutures. The donor site is closed by drawing Tenon's fascia into the defect and suturing it in place with interrupted 10-0 nylon sutures. The conjunctival flap is closed over the scleral defect with nonadsorbable sutures (Fig. 27.13, *E*). The recipient site is covered with a contralateral, healthy, free autologous conjunctival graft. Care is taken to attach the graft to areas of undisturbed conjunctiva with relatively normal vasculature (Fig. 27.13, *F*). The technique used is as described previously.

OUTCOME

The combined technique has been used in four patients with mitomycin scleral necrosis with successful results on long-term follow-up in all cases[19] (Figs 27.14 and 27.15). The scleral grafts have remained stable, and the superficial scleral vasculature recanalizes and provides a stable patch. The contralateral conjunctival patch graft protects and supports the donor scleral graft and supplies healthy stem cells for stabilizing the conjunctival surface. In these cases, it is essential to harvest the limbal cells from the donor conjunctiva. Healthy corneal epithelial cells are imported as well and will correct the chronic epitheliopathy seen in severe toxicity after mitomycin application. There have been no complications noted at the donor site in any of the patients (Fig. 27.16).

CONCLUSION

The use of natural tissues with no additive chemical or radiation for reconstruction is a safe, effective, and nontoxic technique for preservation and reconstruction of the ocular surface mucous membrane in multiple conditions without significant complications.

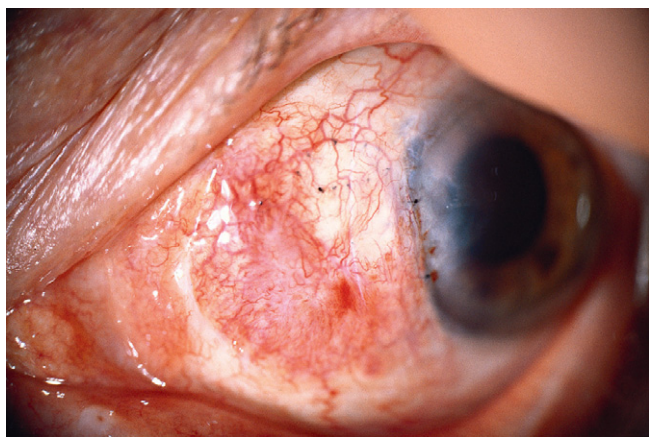

Figure 27.14. The postoperative appearance of the patient in Figure 27.12, 6 weeks after the combined grafts, shows vascularization of the conjunctival and scleral graft.

28 Surgery of limbal dermoids

David B. Glasser

Epibulbar limbal dermoids are choristomas: benign congenital growths of abnormally located tissue. To be histopathologically classified as a dermoid, a choristoma must contain epithelial elements in the form of hair follicles and sebaceous glands (pilosebaceous apparati). Dermoids are usually covered by keratinized stratified squamous epithelium and may contain other elements of ectodermal and mesodermal origin. These elements can include nerve, brain, lacrimal, adipose, and fibrous connective tissue, sweat glands, cartilage, bone; teeth, and blood vessels.

Choristomas comprise 22–33% of all surgically excised epibulbar tumors in children, with 48–58% of these lesions being classified as dermoids. Other epibulbar choristomas, which differ from dermoids by lacking pilosebaceous apparati, include dermolipomas (24–30%), ectopic lacrimal gland (18%), complex choristomas (6%), dermis-like choristomas (6%), osseous choristomas (2%), and simple choristomas (2%). The incidence of epibulbar choristomas is between 1/10 000 and 3/10 000.[1–3]

The pathogenesis of choristoma formation is uncertain, with theories dating back to the 19th century. Sequestration of dermal tissue in underlying layers during embryogenesis has been previously thought to account for choristoma formation. Duke-Elder[4] theorizes that the extent of a choristoma depends on the time during embryogenesis at which the malformation occurs. If it occurs prior to development of the lens, corneal tissue is replaced by fibrofatty growth, and the anterior chamber, iris, and lens are absent. If the malformation occurs during lens formation, the entire cornea is involved, but an ill-formed lens and rudimentary anterior chamber and iris structures are present.[4] Choristomas are thought to arise from metaplastic transformation of mesoblasts between the rim of the optic nerve and surface ectoderm during early development of the embryo. Most choristomas occur sporadically and are not inherited, although there have been reports of familial cases.[3] A rare syndrome of autosomal dominantly inherited bilateral dermoids forming a ring around the limbus with corneal and conjunctival extension has been described,[5] as has an X-linked form of bilateral corneal dermis-like choristomas.[6]

Epibulbar choristomas can be seen in association with Goldenhar syndrome (oculoauriculovertebral dysplasia) and the linear epidermal nevus syndrome. The classic findings in Goldenhar syndrome include preauricular fistulae, preauricular appendages, and epibulbar dermoids. Approximately 30% of patients with Goldenhar syndrome have epibulbar dermoids. Other reported ocular findings in Goldenhar syndrome include orbital or lid choristomas, lid, brow, or uveal colobomas, optic nerve hypoplasia, pseudopapilledema, peripapillary hypopigmentation, aniridia, iris heterochromia, microphthalmos and partial cryptophthalmos, lacrimal drainage abnormalities, Duane syndrome, neuropathies involving the third, fifth, or seventh cranial nerves, cataract, and retinal vascular tortuosity.[3] The epidermal nevus syndrome is manifested by dermatologic, skeletal, neurologic, and vascular disorders. The skin lesions that lend the disorder its name are linear epidermal nevi, which are congenital linear papules with increased pigmentation and variable hyperkeratosis. They usually do not cross the midline and have a predilection for the head and face. Lesions containing many sebaceous glands are called *sebaceous nevi* and, unlike linear epidermal nevi, are known to undergo malignant transformation. Epibulbar choristomas associated with the linear epidermal nevus syndrome are typically complex choristomas and are frequently bilateral and extensive. Other ocular findings may include choristomas of the lid or choroids, colobomas of the lid, optic nerve, or choroids, epidermal nevus of the lid, micro- or macrophthalmia, nystagmus, ophthalmoplegia, cortical blindness, and cataract.[3]

CLINICAL APPEARANCE

Typical epibulbar dermoids are solid round or oval raised dome-like lesions fixed to underlying tissue. They are usually well defined, are yellow, white, or pink, and may be hard, rubbery, or soft (Fig. 28.1). Fine hairs may be present on the surface. Multiple or bilateral lesions may be seen but are not typical. Epibulbar dermoids are located most commonly at the limbus (63–67%) or the conjunctiva (20–33%) or on the cornea (17%). Limbal dermoids are located temporally in 84–94% of patients, most often inferotemporally.[1,2] A ring of lipid is usually present in the cornea, separated from the anterior edge of the dermoid by a clear zone. In several series, 43–76% of patients with a single limbal dermoid demonstrated corneal astigmatism greater than 1 D in the affected eye, with central corneal flattening in the axis of the lesion.[7–12] In one small series,

Figure 28.1. A 7-year-old female with classical limbal dermoid. The patient desired cosmetic improvement. (Photo courtesy of FS Brightbill, Madison, WI.)

4 out of 10 patients demonstrated over 6 D of astigmatism.[11] The astigmatic error may induce amblyopia.

Limbal dermoids may vary in size from a few millimeters to a large mass filling the epibulbar area.[1,2,13] Growth can occur but is uncommon except at puberty, when the lesions are more likely to increase in size and develop more hairs. Mann[3] classified limbal dermoids into three grades based on anatomic involvement. Grade I lesions are epibulbar limbal dermoids with superficial corneal involvement and are the most common. Grade II dermoids affect the full thickness of the cornea, although Descemet's membrane and the endothelium may be uninvolved. The entire cornea and all anterior chamber structures are replaced in grade III lesions, which are rare.

SURGICAL MANAGEMENT

The most common primary indication for surgical removal of a limbal dermoid is reconstructive. The distinction is made between reconstructive and cosmetic surgery to emphasize that surgery is being performed to correct an abnormal growth, not an essentially normal tissue. There are additional medical indications. High degrees of astigmatism may lead to amblyopia, the lipid ring or the lesion itself may encroach on the visual axis, a large or elevated tumor may produce irritation from mass effect, drying and superficial keratitis or dellen formation may occur secondary to interference with tear flow, blinking, or lid closure, the hairs may produce irritation or keratitis, and a thinned area may perforate. Amblyopia therapy may be considered prior to surgical intervention if the visual axis is clear.

Simple excision (shaving or shelling out) and excision with peripheral lamellar keratoplasty are the two most commonly used techniques for removal of grade I limbal dermoids. The surgeon should carefully consider the possible need for donor tissue based on the preoperative examination. Small limbal dermoids can occasionally extend full thickness. The extent or depth of a lesion may be difficult to determine preoperatively, particularly if the dermoid covers a large portion of the central cornea. Careful examination through clear areas of cornea with the globe rotated may reveal intraocular involvement. Preoperative gonioscopy is helpful in determining whether a full-thickness procedure will be necessary. Ultrasound biomicroscopy prior to surgery may be able to reveal the extent of these lesions.[14,15]

SIMPLE EXCISION

General anesthesia is usually necessary in this pediatric age group, although retro- or peribulbar anesthesia may be used if the patient can cooperate. Scissors are used to perform a conjunctival peritomy around the dermoid. The lesion may then be shaved off or shelled out with a straight or angled blade. Sharp dissection is begun on the scleral border of the dermoid and carried forward into the cornea in one plane. A lamellar blade (Martinez, Troutman) and a pushing rather than a cutting motion make it easier to maintain a single plane of dissection within the cornea. The cornea is kept dry, and gentle traction is used to pull upward on the free edge of the tumor. A two-thirds depth excision is usually sufficient to completely remove the dermoid. Hemostasis is achieved with cautery. If the conjunctival defect is large, surrounding tissue is mobilized with blunt dissection and the defect is closed with absorbable sutures or fibrin glue. The eye is patched with antibiotic and corticosteroid ointment.

Follow-up is performed on the first postoperative day and frequently until the corneal and conjunctival epithelium have healed. Topical antibiotics are continued until epithelial healing is achieved. Topical corticosteroids are continued until inflammation has subsided. In one small series of 10 cases, epithelial healing was complete in 1–39 days (mean, 16.2 days). An epithelial defect persisted for 2 weeks or more in 4 out of 10 patients. Cosmetic appearance was improved, and the visual axis remained clear in all 10 patients. However, peripheral corneal vascularization and scarring were noted in seven cases.[8] Simple excision usually has little or no effect on the astigmatic error that accompanies a dermoid.[8,9] Therefore, amblyopia therapy may be necessary after surgery.

EXCISION WITH PERIPHERAL LAMELLAR KERATOPLASTY

Excision with lamellar keratoplasty is more complex and lengthier than simple excision. In addition, it necessitates suture removal, usually under anesthesia, 1–3 months after surgery. However, some corneal surgeons believe that lamellar keratoplasty is preferable to simple excision. The presence of a graft may produce a more satisfactory cosmetic result, with less scarring and vascularization than simple excision. Tight suturing of a lamellar graft can also steepen the cornea, thereby reducing the central corneal flattening and astigmatism in the axis of the dermoid. Published reports on astigmatism reduction after dermoid excision with lamellar keratoplasty have demonstrated variable results. Some indicate a significant reduction in astigmatism, particularly for those patients with greater than 6 D of astigmatism prior to surgery.[7,11] Others report no significant change[10] or a variable response with increased, decreased, and unchanged astigmatism in subgroups of those treated.[12]

General, retrobulbar, or peribulbar anesthesia is used, depending on the age and cooperation of the patient. Because the extent and depth of the lesion are not always known with certainty, the dermoid should be excised and the host bed prepared prior to preparation of the donor. A conjunctival peritomy surrounding the conjunctival side of the lesion is performed with scissors (Fig. 28.2, *A*). The smallest trephine that will completely surround the lesion is chosen and used to make a partial-thickness cut (Fig. 28.2, *B*). A razor or diamond knife is used to carry the dissection deeper, if necessary, until clear corneal stroma is reached. The vertical edges of the dissection should be kept perpendicular to facilitate donor tissue placement. A lamellar dissection is then performed beneath

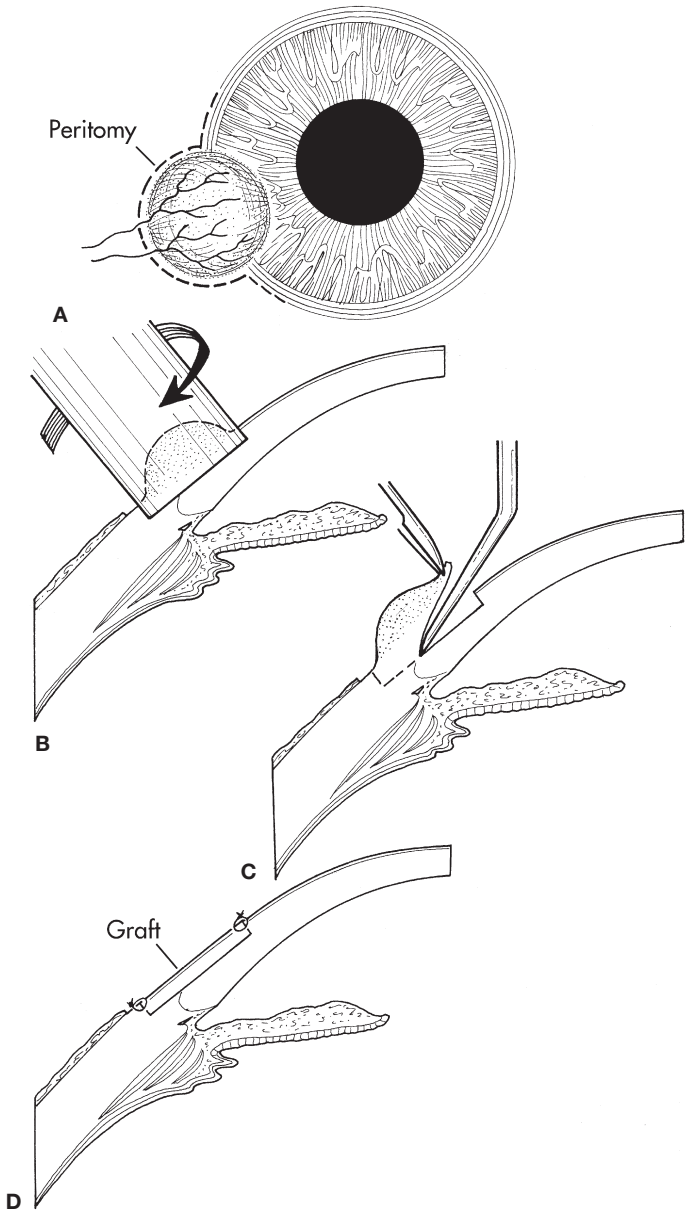

Figure 28.2. *A*, A conjunctival limbal peritomy is used to expose dermoid. *B*, The smallest trephine that will completely surround the lesion is used to make a partial-thickness cut. *C*, Lamellar dissection is performed for dermoids with deeper stromal opacification. Note that the perpendicular margins of the bed offer the best suture placement. *D*, A partial-thickness donor button cut slightly larger than recipient defect is anchored with interrupted sutures.

the dermoid, beginning on the corneal side of the lesion and carried across the limbus into the sclera (Fig. 28.2, *C*). A lamellar dissection spatula (Martinez, Troutman) and a pushing rather than a cutting motion make it easier to maintain a single plane of dissection within the cornea. The field is kept dry, and gentle traction is used to pull upward on the free edge of the tumor during the dissection. The dissection can be carried slightly beyond the edge of the bed to allow for easier placement of a swollen donor and reconstruction of a perpendicular wound if the edges become distorted during dissection. If deeper opacities remain, a deeper plane is created with the trephine, and the dissection is repeated. The dermoid should be completely removed at its peripheral boundaries because the abnormal tissue is too soft to hold sutures. Hemostasis is achieved with cautery. The donor is then sewn into the recipient bed with interrupted or running 10-0 nylon sutures (Figs 28.2, *D* and 28.3, *A* and *B*). If the graft is large, a paracentesis may be necessary to allow good wound apposition. The eye is patched with antibiotic and corticosteroid ointment.

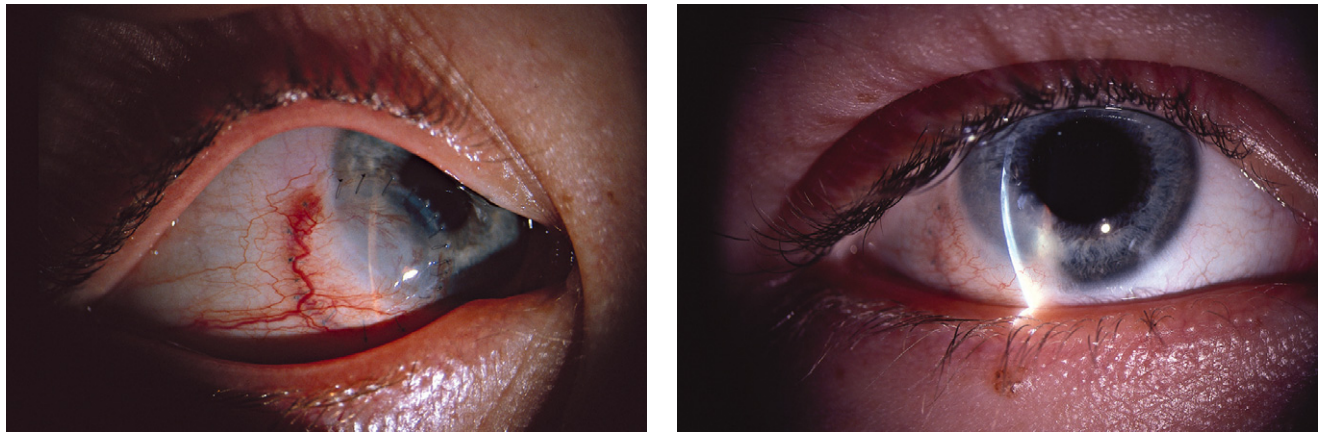
Preparation of the donor tissue is accomplished most easily if a whole globe is available. The donor eye is tightly wrapped in gauze. Intraocular pressure is elevated by manually compressing the globe or by placing a hemostat on the gauze. A razor or diamond knife is used to make a small incision at the limbus to the necessary depth. The donor should be slightly thicker than the depth of the recipient bed, as the initial swelling of the donor will disappear. If the donor is thinner than the recipient bed, the area will be depressed postoperatively. A Martinez lamellar dissection spatula is introduced into the incision so that it is parallel to the surface of the cornea. The end of the instrument should be directed slightly upward, as it is used to create a lamellar dissection of the entire donor cornea. A back-and-forth pushing and rotating motion is used. Care is taken to maintain a constant plane without pushing posteriorly. A trephine is then used to cut through the donor cornea. Unlike punching a donor button from the endothelial to the epithelial surface, which produces a graft that is approximately 0.2 mm smaller than the size of the trephine, this technique produces a donor button equal in diameter to the size of the trephine blade used. For small lesions, the same size trephine should be used for the recipient and the donor. When the recipient bed is 6 mm or greater, the donor should be oversized by 0.20–0.25 mm. If the donor is harvested from the limbus, the curvature of the donor will more closely match that of the host. Proper anatomic alignment using limbal tissue may produce a better cosmetic result,[16] but most patients achieve good cosmesis even when central corneal tissue is used for grafting.[10,11] Inclusion of sclera in the donor requires lamellar dissection of the donor beyond the limbus prior to trephination of the donor button.

Preparation of donor material from a corneoscleral rim can be accomplished with slightly greater difficulty. An orbital implant is tightly wrapped with gauze, and a hemostat used to maintain tight application of the gauze to the sphere. The corneoscleral rim is then anchored to the gauze with interrupted 5-0 sutures. The limbus is incised to the necessary depth, and the lamellar dissection is carried out as described above. If a microkeratome and artificial anterior chamber are available, and the donor rim is of sufficient diameter for mounting on the artificial anterior chamber, it is fairly simple to obtain a lamellar graft from a corneoscleral rim.

Postoperative care includes topical antibiotics until epithelial healing is achieved and topical corticosteroids until inflammation has resolved. The patch is removed on the first postoperative day, and frequent follow-up is maintained until epithelial healing is complete. Healing may be delayed in patients with Goldenhar's syndrome who have decreased corneal sensation or dry eye. Amblyopia therapy is instituted where appropriate if significant astigmatism is present. Sutures are removed in 1–3 months, or sooner if they become loose, collect mucus, or develop suture abscesses. If the patient is cooperative, suture removal can be accomplished at the slit lamp with topical anesthesia. Otherwise, general anesthesia is necessary.

PENETRATING KERATOPLASTY

Grades II and III dermoids involving the full thickness of the cornea or anterior segment and perforations that occur during dissection



A B

Figure 28.3. *A*, A 2-month postlamellar corneal graft is placed over the corneal limbus in the same eye as in Figure 28.1. Note the buried nylon sutures are 360°. *B*, The same eye 9 months postoperatively with some residual deep corneal opacity. (Photos courtesy of FS Brightbill, Madison, WI.)

of the recipient bed require penetrating keratoplasty or anterior segment reconstruction. Penetrating keratoplasties in children have a guarded prognosis because of accompanying amblyopia and the high incidence of graft rejection. A second full-thickness procedure is often necessary because the initial graft, whether lamellar or full thickness, commonly opacifies. If a grade II or III dermoid requires greater than a 7-mm graft, a planned two-stage procedure may be preferred. First, the external bulk of the tumor is excised and a large lamellar keratoplasty is placed in the bed. A freehand dissection may be necessary if the dermoid is too large for a trephine to encompass it. Several months later, when the lamellar graft has healed, a smaller central penetrating graft with excision of residual internal tumor can be done to establish a clear visual axis. This two-stage technique reduces the risk of anterior synechiae, vascularization, and rejection associated with large penetrating grafts.[17] The details of penetrating keratoplasty are covered in greater depth elsewhere in this text.

29 Tarsorrhaphy and lacrimal occlusion

Alon Kahana, Mark J. Lucarelli

Corneal desiccation can be vision and eye threatening. The etiology may be inadequate hydration, inadequate coverage, or both. Inadequate hydration is often referred to as 'dry eyes' and its symptoms often, but not always, manifest as foreign body sensation, ocular irritation, and decreased vision. Since other ocular diseases share these symptoms, a careful ocular examination is essential for proper diagnosis and treatment. For example, blepharitis, keratoconjunctivitis, pterygia, and ocular foreign bodies comprise a portion of the differential diagnosis for 'dry eyes'. Valuable portions of the examination include fluorescein and/or rose bengal staining, Schirmer basal tear production test, tear breakup time, and tear meniscus height, as these tests can be extremely helpful for diagnosis and follow-up assessments.

Corneal desiccation can also result from inadequate coverage by the eyelids, leading to corneal exposure and accelerated evaporation of the protective tear film. Inadequate coverage can result from eyelid malposition (e.g. ectropion or entropion), as well as lagophthalmos or poor blink. Hence, inadequate coverage may be related to cicatricial eyelid changes and facial nerve injury, as well as to central nervous system injuries and postoperative changes.

The medical treatment of corneal desiccation includes artificial tears as well as lubricating gels and ointments. For certain etiologies and patients, topical cyclosporin 0.05% (Restasis, Allergan, Inc.) may be helpful. It is important to keep in mind that the goals of therapy are to not only improve discomfort and blurred vision but also prevent ocular surface infections, scarring, and permanent loss of vision.

The neurotrophic cornea can present a particular challenge because lack of corneal sensation can also interfere with the tear secretion pathway, as well as diminish the protective blink reflexes. Hence, an aggressive and comprehensive treatment approach is often necessary to avoid vision-threatening complications.[1]

When medical therapy measures prove to be inadequate, more invasive interventions are often required. These may include temporary measures, such as punctal occlusion or temporary eyelid closure (through a temporary tarsorrhaphy), or permanent measures, such as punctal ablation or permanent transposition tarsorrhaphy. The most useful 'permanent' techniques are often reversible, providing the treating surgeons with maximum flexibility in the care of their patients.

LACRIMAL OUTFLOW: PUNCTAL AND CANALICULAR OCCLUSION

Corneal hydration and protection can be achieved through increased lubrication or decreased evaporation. Hence, an important therapeutic strategy to corneal desiccation involves occlusion of the lacrimal drainage system in order to decrease tear outflow and provide additional ocular surface hydration. Three general approaches can be used: temporary, reversible, or permanent occlusion of the lacrimal drainage system. Often, the treatment approach follows the same progression: temporary occlusion is tested using absorbable punctal plugs. If symptomatic relief and objective improvement are achieved, reversible long-term occlusion is attempted with a nonabsorbable device. In situations where lacrimal outflow occlusion achieves symptomatic resolution but requires frequent replacement or causes ocular irritation, permanent surgical occlusion using a puncto- or canaliculodestructive procedure may be cautiously considered.[2]

PUNCTAL AND CANALICULAR PLUGS

Occlusion of lacrimal outflow is a hallmark of treatment for moderate to severe corneal desiccation. Since the first description of punctal plugs by Freeman,[3] punctal and canalicular plugs have been shown to be effective in treating moderate to severe dry eye conditions.[4–11] Unfortunately, punctal plug placement has often been treated as even less than the minor procedure that it is.[12] Since lacrimal occlusion may be associated with complications, some of which may be quite significant, educating the patient about the risks, benefits, and alternatives to treatment would be appropriate.[13–23] Informed consent should be obtained prior to undertaking the occlusive measures. A careful ophthalmic examination with quantifiable measures (e.g. Schirmer test, corneal staining, tear lake height, fluorescein dye disappearance test, etc.) will facilitate determination of efficacy in follow-up visits.

A perfect occluder of the lacrimal drainage system would be easy to fit, simple to insert, and nonirritating, provide complete occlusion, last as long as needed, and be straightforward to remove. Alas, such a plug has not yet been devised. However, the modern clinician currently has a multitude of options from which to choose, each with its own advantages and disadvantages.

Temporary punctal plugs are made of a variety of absorbable materials, such as collagen, hydroxypropyl cellulose, gelatin, and catgut, and, after placement in the punctum, can last for approximately a week. These plugs are often used to test the efficacy and tolerability of punctal occlusion in the treatment of the patient's symptoms. A more durable but absorbable punctal occlusion can be achieved with plugs made of synthetic absorbable material (polycaprolactone or PCL), which can last 2–6 months (e.g. DuraPlug, Eagle Vision).

GRADED PUNCTOCANALICULAR OCCLUSION

On many occasions, a stepwise lacrimal occlusion is undertaken, and occlusion of only one canaliculus may produce sufficient relief. One functional punctocanalicular system appears to be sufficient for draining basal tearing but may not be sufficient for draining reflex tearing.[24,25] Many ophthalmologists, when choosing to occlude only one punctocanalicular system, preferentially choose to occlude the inferior one because of its accessibility.[7] However, several experimental studies suggest that the upper and lower canaliculi drain fairly equivalent volumes of tears.[25–29]

The choice of which punctum to occlude should take into account the ease of performing the occlusion procedure and the relative risk of failure. With punctal plugs, one common cause of failure is plug extrusion. Several studies have shown that an upper punctal plug is more likely to extrude than a lower punctal plug.[4,6] This may be related to the challenge of properly fitting the superior punctum or to an increase in ocular irritation associated with a punctal plug that moves across the ocular surface thousands of times per day. Another possible explanation is simply that the upper lid punctum moves much more than the lower lid punctum.

It has also been argued that after plug extrusion, a second plug may be even more likely to extrude.[4,6] One possible explanation is that by evaluating patients who have already experienced punctal extrusions, the authors may have selected for puncta that are larger, more flexible, and harder to fit. These individuals may also experience plug-related discomfort, leading to eyelid rubbing, which can result in recurrent plug extrusion. Another possibility is that overdilation of the punctum at the time of plug insertion caused trauma to the punctal annulus, which would result in a poor punctal plug fit on subsequent insertions.

The need for long-term but reversible punctal or canalicular occlusion led to the development of a variety of nonabsorbable plugs that fit snugly into the ampula or canaliculus. These fall into two general categories: punctal plugs and intracanalicular plugs. Punctal plugs are made of synthetic materials (e.g. silicone or polyethylene) and fit on the punctum (Fig. 29.1). The advantages of the punctal plug are simple placement, easy monitoring, and usually straightforward reversibility. The disadvantages include a high extrusion rate and occasional ocular irritation and epiphora.[4,6] Extrusion often results from a poorly fitting plug, although patients can also dislodge a well-fitting plug by rubbing.

INTRACANALICULAR OCCLUSION

The use of intracanalicular plugs is controversial. The Herrick plug (Lacrimedics, Inc.) is made of silicone and is designed for permanent placement inside the horizontal section of the canaliculus (Fig. 29.2, *A*). It is simple to place and can provide effective lacrimal occlusion,[5] but can be difficult to monitor and can cause complications such as granuloma formation, infection, scarring, and nasolacrimal duct obstruction with dacryocystitis[13,30,31] (Fig. 29.2, *B*). In theory, the Herrick plug was designed to be easily irrigated out of the canaliculus. However, several published studies have noted the unpredictability of Herrick plug removal. A recently introduced modified Herrick plug, the opaque Herrick plug (Lacrimedics, Inc.), may make it easier to monitor plug placement but does not address the other issues associated with the original Herrick intracanalicular plug. A dissolvable version of the opaque Herrick plug, made of polydioxanone, is now available and is designed to last approximately 6 months. At the time of writing, no comparative studies have been published regarding long-term efficacy and safety. It is interesting to note that an article was published by Dr Herrick describing his preferred techniques for canalicular reconstruction after canalicular scarring related to a Herrick plug.[32]

The SmartPlug (Medennium, Inc.) is a thermosensitive acrylic plug that changes its shape at body temperature to fit into and completely occlude the ampula and canaliculus. Specifically, it expands when warm and contracts when cold. The SmartPlug is simple to insert, but also difficult to monitor. It was designed to be a 'one-size-fits-all' plug that would not need to be fitted and would be easier to remove by irrigating the canaliculus with cold water. It can be useful in patients for whom Freeman-style punctal plugs are not a good option.[8] However, over the short time period of SmartPlug availability, a similar series of untoward side effects that have been reported with the Herrick plug are beginning to be reported to occur with the SmartPlug. As with the Herrick plug, the location of the SmartPlug can be more difficult to confirm (especially when the canaliculus is only partially occluded), and the plug

can either migrate when it should not or fail to get flushed out of the canaliculus when a reversal of the procedure is desired.[14,33] When the need for reversal arises, failure may lead to infections, surgery for canalicular reconstruction, and dacryocystorhinostomy (DCR).[14] Nevertheless, the SmartPlug may be the only good option in patients with stenotic puncta (under 0.3 mm) who require lacrimal outflow occlusion.

Given the difficulty of monitoring lacrimal occlusion with an intracanalicular plug, along with the somewhat higher rate of complications with such plugs, our bias is for using well-fitting Freeman-style silicone punctal plugs such as the Eagle plugs (Eagle Vision, Memphis, TN). While these plugs are not complication free, they are simple to fit and insert, easy to remove, and straightforward to monitor, and rarely migrate deep into the canaliculus. The exceptions are patients who report significant ocular irritation with Freeman-type plugs or patients whose stenotic puncta are too small for any commercially available punctal plugs. For these patients, other measures should be considered.

PUNCTAL PLUG INSERTION

Insertion of a synthetic plug into the ampula is done at the slit lamp (Fig. 29.3). First, the ocular surface is anesthetized with a topical anesthetic such as proparacaine. It is often useful to also treat the punctum directly with a topical anesthetic by applying proparacaine to a cotton-tipped swab, placing it between the upper and lower puncta next to the caruncle, and asking patients to close their eyes for 1–2 min. This can achieve excellent short-term anesthesia and comfort.[34] Next, the correct plug size is chosen using a punctal gauging instrument. The end point should be a snug fit that requires some gentle pressure for insertion and removal, causing slight expansion of the punctal tissues. When a perfect fit cannot be obtained, a slightly larger plug may be preferable to one that is too small.[4,6,21] Care must be taken not to overly stretch the punctal annulus, since such trauma may dramatically increase the risk of punctal migration or extrusion. The punctum should then be dilated very slightly using a punctal dilator. Dilation allows the correct size plug to be inserted, with the punctal tissues closing around the plug to form a good seal. We favor a reusable and autoclavable stainless steel dilator (such as the Wilder or the Hosford from Storz, Inc.) over the relatively blunt, plastic disposable dilator often provided with Freeman-type plugs. The plug is then inserted with the provided applicator or a generic applicator.

The end point should be a fit that is flush with the lid margin surface (Fig. 29.3, *C*). If the plug is too small, it could easily migrate and lodge in the ampula or fall out of the punctum, whereas if the plug is too large, it will distort the punctal anatomy and cause discomfort and possible annulus damage and punctal stretching. Removal is usually easy, using toothed or non-toothed forceps to grasp the flange of the plug and remove it.

The disadvantages of Freeman-style plugs include a high extrusion rate and occasional ocular irritation. Extrusion often results from a poorly fitting plug, although patients can also dislodge a well-fitting plug by rubbing. Techniques have been published for suture anchoring of punctal plugs,[35] but with a good fit and control of rubbing, punctal plugs should remain effective for a significant duration without additional surgical steps.

PERMANENT PUNCTAL/ CANALICULAR OCCLUSION

A variety of surgical techniques have been devised for permanently blocking tear drainage through the lacrimal drainage system. These include punctal ablation with cautery or Argon laser,[36,37] canalicular ligature,[38] canalicular excision,[39] punctal tarsorrhaphy, and punctal patch (for a review, see ref. 2). All the techniques share as a basic principle the introduction into the lacrimal drainage apparatus of a discontinuity that would block outflow. The most common techniques are punctal ablation with thermal cautery, electrocautery (diathermy), or argon laser. In recalcitrant cases, where punctal continuity is re-established, a combination of punctal ablation and canalicular ligature may offer the simplest and most efficacious outcome (Charleux 1978, as described in ref. 2).

Punctal ablation can be most easily performed with a battery-operated thermal cautery unit according to previously published methods.[40] A local anesthetic should first be injected so that discomfort will not limit the appropriate treatment needed for punctal ablation. Pressure anesthesia may also be effective.[34] The ocular surface is anesthetized with proparacaine and a lubricated corneal protective shield may be placed. The looped tip should be inserted deep into the punctum to the full depth of the ampula and vertical canaliculus before the cautery unit is activated (Fig. 29.4). The tip should be rocked and rotated inside the punctum so that the entire circumference of the punctum and vertical canaliculus are treated.

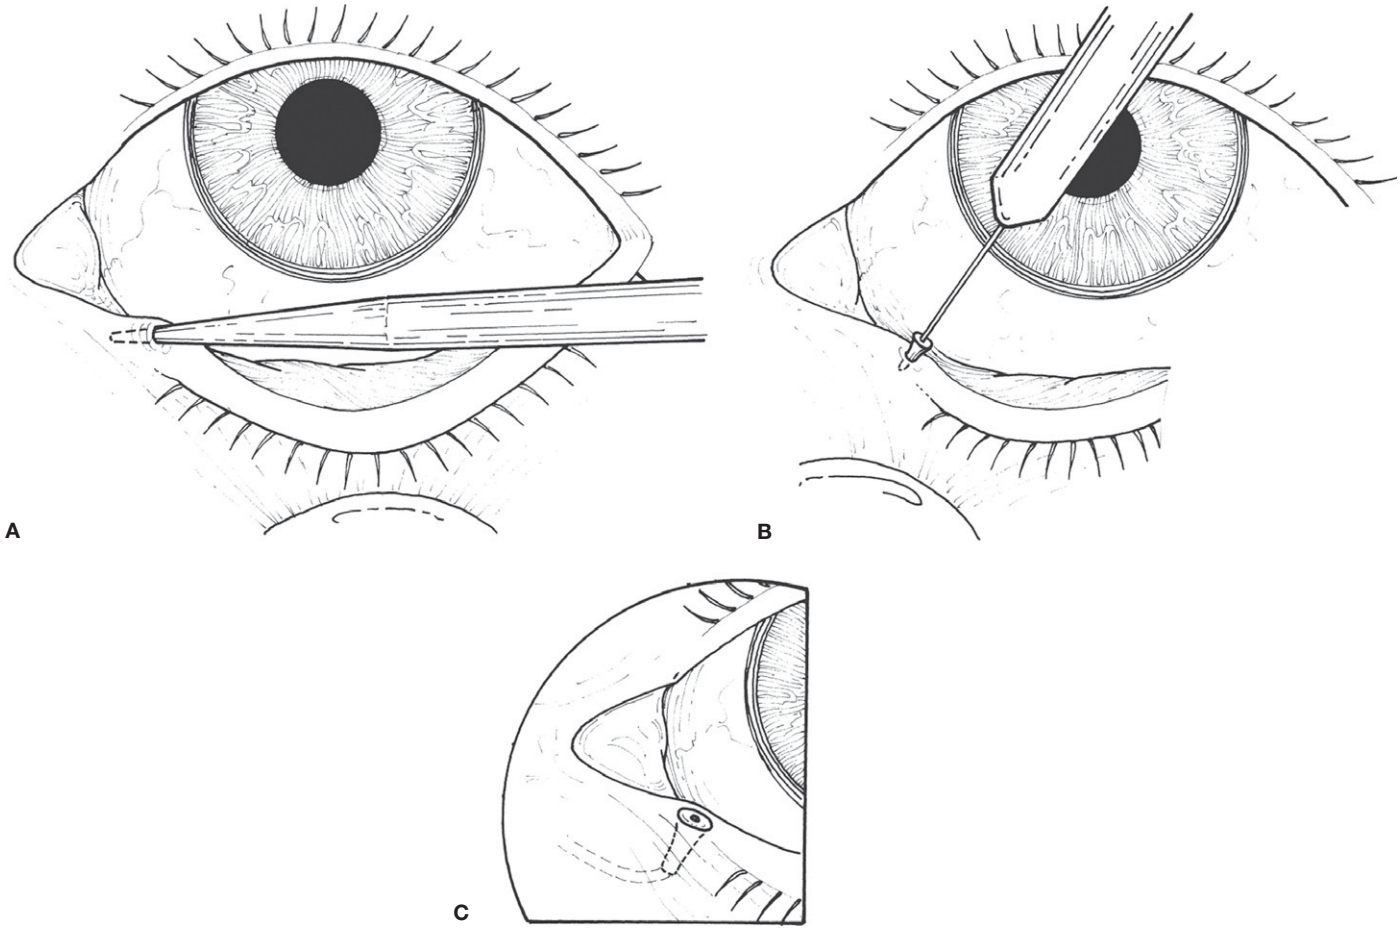

Figure 29.3. Punctal plug insertion. After punctal sizing, the punctum is gently dilated (*A*), and the plug is inserted (*B*). Following insertion, the plug should be flush with the lid margin (*C*).

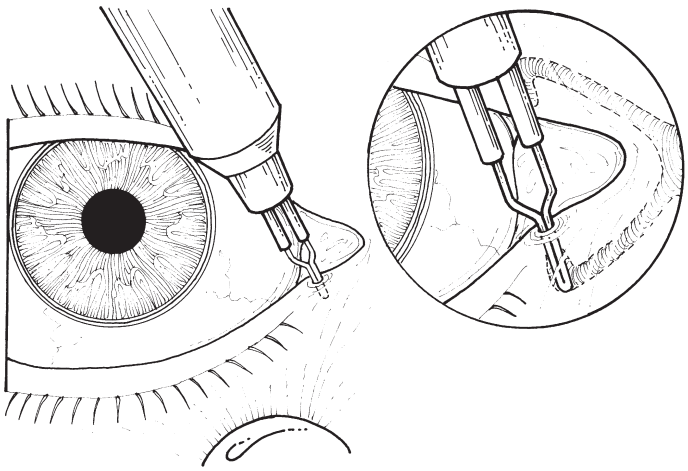

Figure 29.4. Thermal cautery of the punctum. The cold tip is placed deep into the punctum. After activation, blanching of the surrounding tissues indicates sufficient treatment. The tip should be turned around in the punctum and removed while still hot.

The tip should be removed while still hot so that adherent epithelium will be removed. Permanent adhesion and scarring require the removal of the epithelium; otherwise, the canalicular mucosa can heal and recannulate the punctum. Tissue swelling is typically sufficient to oppose the raw surfaces to create scarring and punctal closure. On occasion, placement of a simple interrupted absorbable suture through the cauterized punctum helps to achieve the required apposition.

Care should be taken throughout the procedure to avoid injury to the globe and adjacent tissues, especially during insertion, removal, and movement of the hot tip (a protective shield is particularly helpful in this regard). Punctal ablation with electrocautery can employ a partially insulated tip that will properly treat the deep vertical canaliculus and ampula while leaving the punctal opening intact.[2] Argon laser-assisted punctal ablation techniques vary, but a general guideline is to use 100–200 μm spots and start at 200 mW over 0.1–1.0 s. When the patient is lightly pigmented, dying the punctal epithelium with a marking pen[41] or a drop of blood from the anesthetic injection site[42] will facilitate absorption of the laser power. The power should then be titrated to effect, typically to significantly higher power settings. Initial spots should surround the punctum to contract and delineate it. Further surrounding of the punctum with laser burns will leave the punctal tissues elevated and isolated. Finally, laser burns should be applied directly to the punctum. Charring must be removed with forceps or cotton-tipped swabs before continuing. Sufficient laser burns should be applied to cause contracture and closure of the punctum. Variations on this technique have been described.[2]

Finally, canalicular excision and punctal ligature are two surgical techniques that obtain punctocanalicular destruction under direct visualization. Methods for each have been described,[38,39] but the underlying principle remains the introduction of permanent and complete scarring into the lacrimal drainage system.

TARSORRHAPHY

Tarsorrhaphy, or surgical closure of the eyelids, is an extremely powerful surgical tool for the protection of the cornea and ocular surface.[43] It has very few contraindications and can generally be reversed. Suture tarsorrhaphies can be performed at the bedside with local anesthesia under most circumstances. The indications include paralytic lagophthalmos from facial cranial nerve (VII) damage,[44–46] cicatricial lagophthalmos,[47–51] postsurgical lagophthalmos and exposure,[52,53] poor blink reflexes and incomplete blink, dry eyes (including keratoconjunctivitis sicca and filamentary keratitis), neurotrophic and congenital neurogenic keratopathies,[54–56] and nonhealing sterile keratopathies with thinning.[57,58] Lateral tarsorrhaphies have even been employed for the treatment of floppy eyelid syndrome.[59] Tarsorrhaphy can be performed for short-term efficacy, lasting days to several weeks, or as a permanent (but still reversible) protective measure that uses epithelialization and scar formation to maintain lid margin adhesion.

An assessment of the indication for a tarsorrhaphy must include an eye examination, with a careful evaluation of the cornea. The presence of an active ocular infection is generally a contraindication for a complete tarsorrhaphy. In the infrequent instance in which a complete tarsorrhaphy may be necessary, a comprehensive eye examination would be indicated prior to placement of the tarsorrhaphy.

The choice of temporary vs. permanent tarsorrhaphy is not always clear cut. The so-called 'permanent' tarsorrhaphy can still be divided with relative ease, although it would require a local anesthetic and careful technique to avoid untoward sequelae. Conversely, temporary suture tarsorrhaphies can often be effective for as long as 3 months, providing an easily reversible lid closure technique that can be a useful alternative to the more invasive 'permanent' transposition tarsorrhaphy. At the time of surgical planning, the predicted period needed for lid closure must be assessed. When in doubt, a temporary suture tarsorrhaphy can be placed, using an easily reversible technique that would allow for periodic opening of the lids for ocular examination, followed by reclosure of the lids if needed.

To enhance effective duration, 4-0 polypropylene suture is employed, and the lid is divided into medial, central, and lateral thirds, each supported by a dedicated tarsorrhaphy suture and two bolsters (see description below). Some surgeons prefer silk, but in our experience, silk causes more local inflammation and irritation and hence cannot be kept in place as long as nonreactive synthetic sutures such as polypropylene or nylon.

Occasionally, a tarsorrhaphy is required for a child of amblyogenic age. In such children, amblyopia may develop rapidly, and comanagement with an experienced pediatric ophthalmologist is essential.

SIMPLE TEMPORARY SUTURE TARSORRHAPHY TECHNIQUE

The simple suture tarsorrhaphy involves approximation of the eyelids with a permanent suture over a bolster, to protect the eyelid margin tissues. A double-armed 5-0 polypropylene suture is often used, unless the tarsorrhaphy is needed for over 4 weeks, in which case a 4-0 double-armed polypropylene suture is used. The polypropylene suture is very well tolerated and maintains tensile strength, allowing the suture tarsorrhaphy to remain in place for up to several months. Another commonly used suture is 4-0 silk, although local tissue reaction may limit the tolerated duration and require earlier removal.

Many different materials can be used for bolsters. However, for simplicity, sterility, and availability, the silicone tubing from a butterfly phlebotomy needle kit is a superior choice (such kits are available with differing needle gauges, but the tubing is typically the same). After the tubing is cut into small segments that are 2–3 mm long (Fig. 29.5, *A*), a needle is threaded through a tubing segment. Both needles are then passed through skin and tarsus and out through the gray line of the lower lid (Fig. 29.5, *B*), and then through the gray line of the upper lid and then out through skin 3 mm above the lashes (Fig. 29.5, *C*). Care must be taken to avoid injury to the globe during needle passage. Everting the lid margin with Adson forceps while the needle is passed can be helpful in this regard. One needle is then threaded through a second 3-mm silicone bolster, and the suture is tied tightly (Fig. 29.5, *D*). Tying the suture over the upper lid may prevent suture-related irritation caused by tissue crowding in the lower lid area. As many as three such sutures can easily be placed to achieve anywhere from a localized lid closure to a complete closure. Additional sutures also allow the tarsorrhaphy to remain effective for significantly more time.

ABSORBABLE TEMPORARY SUTURE TARSORRHAPHY TECHNIQUE

Occasionally, a temporary tarsorrhaphy is indicated where a patient may find it difficult to present for tarsorrhaphy removal.[60,61] In such a situation, a 4-0 chromic gut suture can be used to approximate the lateral eyelid margins without a bolster. Care must be taken not to overtighten the suture. An ophthalmic ointment is prescribed to help with the timely absorption of the suture. When placing central eyelid tarsorrhaphies, this technique should be avoided, since the suture may irritate the cornea during the absorption process as the eyelid margins separate.

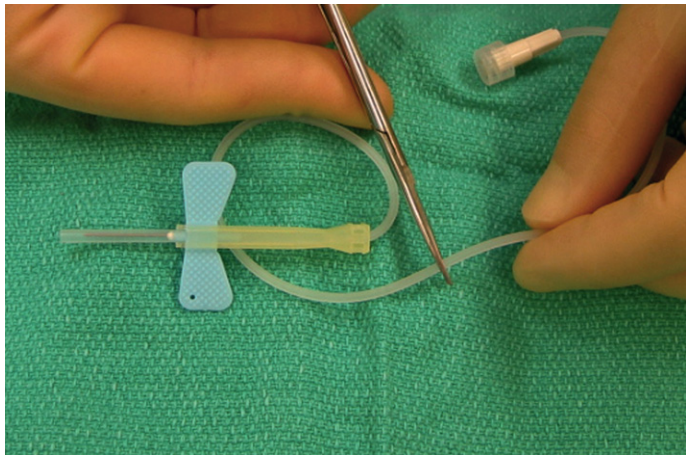
An alternative technique for short-term tarsorrhaphy is the use of cyanoacrylate glue (e.g. Dermabond, Ethicon, Inc.).[62–68] However, the duration of action may be less predictable, and glue may come in contact with the ocular surface, resulting in irritation. Nevertheless, this can be a useful technique in selected cases.

REVERSIBLE KNOT TEMPORARY SUTURE TARSORRHAPHY TECHNIQUE

When a tarsorrhaphy is required along with frequent ocular examinations, as is often the case with corneal thinning, a simple technical variation can be performed.[69,70] Each bolster can be sutured to the eyelid with partial-thickness tarsal bites, using 5-0 polypropylene or nylon suture. Protective corneal shields may be used when making the partial thickness tarsal passes. A 4-0 nylon, polypropylene, or silk suture can then be threaded through the bolsters, pulled, and tied to approximate the lids. This suture can then be cut in subsequent office visits, the lids separated for a complete ocular examination, and then a new suture threaded through the bolsters for reclosure of the lids.

SURGICAL APPOSITION AND TRANSPOSITION TARSORRHAPHY TECHNIQUES

The indications for a permanent tarsorrhaphy are varied but have the following in common: chronic exposure keratopathy that cannot be effectively treated with enhancement of lubrication (in



A

C

D

Figure 29.5. The temporary suture tarsorrhaphy using double-armed 4-0 polypropylene suture and tubing from a butterfly needle kit. *A*, The tubing is cut into small segments for bolsters. One needle is threaded through a bolster. *B*, Each needle is then passed in a partial thickness fashion through skin and tarsus, exiting at the gray line. *C*, Needle passage through upper lid margin and threading of the second silicone bolster. *D*, The sutures are tied to provide good lid margin apposition.

the form of lubricating preparation or punctal occlusion) or with the placement of a gold weight for paralytic lagophthalmos. The cosmetic and psychological aspects of a permanent tarsorrhaphy must be addressed preoperatively. At times, placement of a temporary tarsorrhaphy allows the patient to properly evaluate the effectiveness of the procedure before committing to a permanent tarsorrhaphy.

The technique, in its standard form, has been well described in numerous publications. Briefly, the anterior and posterior lamellae are split with a #11 Bard-Parker blade. The segments of the lid margins where adhesion is desired are de-epithelialized to expose raw edges on both the upper and the lower lids. The lash line and lateral commissure are spared. For apposition tarsorrhaphy, the anterior and posterior lamellae are then sutured using 4-0 chromic gut or 6-0 polyglactic acid (Vicryl) sutures, keeping the knots away from the ocular surface.

The 'tongue-in-groove' transposition technique provides a stronger adhesion but may be more challenging to reverse. Following splitting of the anterior and posterior lamellae and removal of the posterior lamellar epithelium, a short segment of inferior tarsus is removed, and the upper lid tarsus is fashioned for transposition into the newly created tarsal notch (Fig. 29.6). The epithelium of the anterior lamella is left undisturbed. A double-armed 4-0 chromic gut suture or 6-0 polyglactic acid suture can be used to attach the tarsal edges, using partial-thickness tarsal passes to reduce ocular irritation during the healing process.

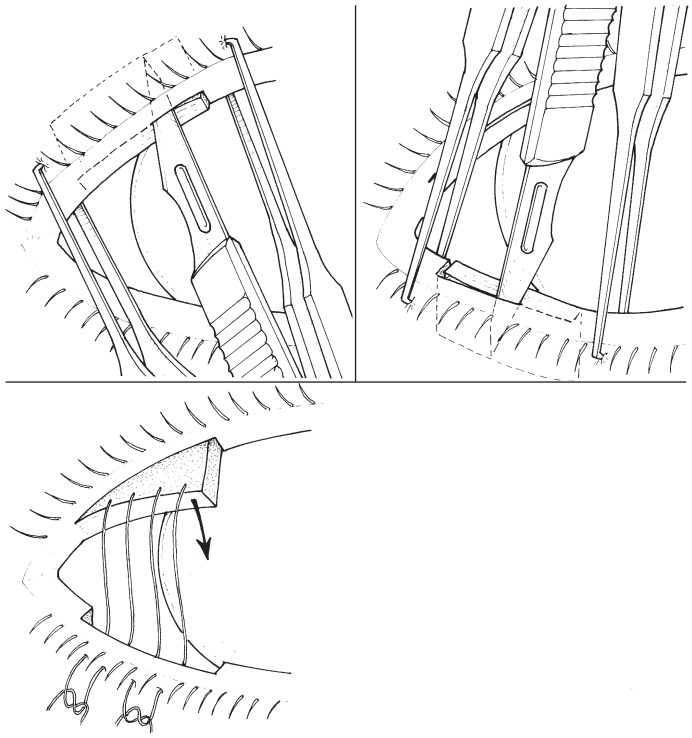

Figure 29.6. Tarsal transposition tarsorrhaphy. After splitting the lid margins and removing the margin epithelia, a back-cut helps create an upper lid tarsal tongue. A small amount of superior tarsus is removed from the lower lid to create the groove. The upper-lid tarsal tongue is sutured to the lower-lid tarsal groove employing either simple interrupted technique using 6-0 polyglactic acid sutures (Vicryl) or horizontal mattress technique using 4-0 chromic gut sutures. Partial thickness tarsal bites are employed to avoid ocular surface irritation. Comment: The depiction of the horizontal mattress sutures in the drawing is only meant to provide a general idea for the location of the sutures, and not a definitive illustration.

Reversal of a 'permanent' tarsorrhaphy can be performed in the office or the operating room. First, a local anesthetic is injected into both sides of the opposed lid margins, taking great care to avoid injury to the eye. A topical anesthetic drop is placed at the medial commissure and allowed to seep onto the ocular surface. A narrow malleable retractor can be placed over the ocular surface and under the opposed eyelid margins to provide protection to the ocular surface. A straight iris scissors or a #15 Bard-Parker blade is used to divide the tarsorrhaphy between the upper and lower lash lines. An ocular protective shield is then placed over the corneal surface, and minimal pinpoint cautery is used for hemostasis. No char should be left on the lid margin surface in order to avoid ocular irritation. Cautery-induced tissue contracture should be minimized. Gentle pressure for a few minutes with gauze over the closed eyelids will stop most bleeding. The possibility of lid margin abnormalities should be discussed prior to division of the tarsorrhaphy, and preferably even before the tarsorrhaphy procedure is performed.

SUMMARY

Corneal desiccation can be vision and eye threatening. Judicious use of lubrication and temporary or permanent lacrimal occlusion can be of great benefit to ocular surface health. Partial or complete closure of the lids with a temporary or permanent tarsorrhaphy can provide a powerful protective measure, although these procedures will often interfere with vision. Overall, these are important tools in the armamentarium of the ophthalmologist.

30 Aphakic and pseudophakic eyes

Alan Sugar

Pseudophakic bullous keratopathy (PBK) and aphakic bullous keratopathy (ABK) were the leading indications for penetrating keratoplasty for the last two decades of the 20th century.[1,2] Recently, these indications have declined slightly.[3] PBK, often in eyes with concurrent Fuchs' dystrophy, still accounts for a significant proportion of penetrating corneal grafts for endothelial disease. Newer posterior lamellar techniques of endothelial keratoplasty (EK) are increasing rapidly in frequency and are done primarily in pseudophakic eyes.[4,5] When aphakic and pseudophakic eyes are considered for keratoplasty, the noncorneal pathology is often greater than in most phakic eyes, requiring that other sequelae of the previous cataract surgery be evaluated. Thorough preoperative evaluation of these eyes can help to prevent intra- and postoperative problems. The resulting refinement of surgical planning and technique can decrease the risk of disappointment for both the patient and the surgeon.

HISTORY

Taking a careful history is a mandatory component of any preoperative evaluation. Such problems as amblyopia, previous retinal disease, and glaucoma or optic neuropathy may be known to the patient but may not be apparent on clinical examination of eyes with edematous or opaque corneas. A probing history of the course of the loss of vision is often helpful in determining whether the visual loss is related solely to the corneal disease. Knowledge of changes in vision throughout the day is often helpful in the evaluation of patients with corneal edema, especially when a patient who is being examined late in the day has good vision, despite a claim of poor vision much of the time. Information on past contact lens experience may be helpful in planning for possible future lens use. Increasingly, past refractive surgery is relevant. Past laser refractive surgery may not affect penetrating keratoplasty outcomes but will affect the refractive outcome of EK. Details of past trauma and its sequelae should also be sought. It is often useful to know about past and present use of corticosteroids and other anti-inflammatory agents, both to assess their need and avoid flare of inflammation with discontinuance, and to anticipate corticosteroid-induced ocular hypertension.

Any evaluation of history should also include an assessment of the patient's activities, employment, and avocations, and the effect of the visual loss on these. Without this information, the relation of current visual loss to visual needs, which provides the critical input into equations for deciding the indications for surgery, cannot be assessed. Formal methods of measuring vision-related 'quality of life,' such as the VF-14 test, have been used to appraise outcomes after keratoplasty and are likely to find a greater role in routine patient evaluation in the future.[6,7]

Detailed information on the best visual acuity that was obtained after the previous cataract surgery is often crucial. A history of visual loss from macular degeneration or cystoid macular edema (CME) may not contraindicate keratoplasty, but it is helpful in the prognostication of visual outcomes.

Perhaps the most crucial historical factor involves detailed information on the previous cataract surgery, including techniques used in cataract removal, status of the posterior capsule and zonules, and intra- and postoperative complications. If possible, the previous operative notes should be reviewed.[8] The type, power, configuration, and placement of the intraocular lens should be obtained from the records or from the intraocular lens (IOL) registration card given to most patients.

As in all ocular surgery, a history of general medical problems is helpful in planning for pre- and postoperative care and anesthesia. Management of systemic medications is imperative in the elderly aphakic and pseudophakic population that is generally undergoing keratoplasty.

VISUAL FUNCTION ASSESSMENT

Assessment of best-corrected visual acuity and potential visual acuity may be critical in decision-making for keratoplasty. Keratometry often makes accurate refraction easier, especially if corneal opacity limits retinoscopy, which it usually does in eyes being considered for corneal grafting. All experienced corneal surgeons have had the experience of greatly improving the vision of a patient who was referred for keratoplasty by using careful refraction rather than surgery. Although it is often less helpful for

refraction, computerized videokeratography may confirm irregularity of the cornea that is not readily apparent on slit-lamp examination or with the use of keratometry. In many cases, a rigid contact lens gives unexpectedly good vision and, even if not practical for use in a given patient, may help in determining the potential postoperative acuity.[9] A pinhole likewise may be helpful in estimating visual potential in eyes with milder opacity.

Glare testing has been used widely in the evaluation of cataract patients to demonstrate that visual function may be severely limited in some lighting situations, even though visual acuity using high-contrast letters in a dimly lit examining room may be quite good.[10] Likewise, contrast sensitivity testing may document symptomatic decreased visual function that is not well judged using standard visual acuity testing. Contrast sensitivity is decreased in the presence of CME, even when visual acuity is good.[11] Contrast sensitivity testing in patients with corneal disease has been limited.[12] The combination of glare and contrast testing approaches evaluation of 'real-world' visual function.[10] When patients already have documented poor visual acuity, these tests may have negligible added value.

When opacity of the cornea does not permit direct measurement of potential acuity, possible visual function must be inferred by indirect means. A relative afferent pupillary defect may be detected by the swinging flashlight test if the pupil can be seen, or by the reverse test in the opposite eye. Such a defect may indicate asymmetric glaucoma, other optic nerve disease, or retinal disease and is a certain sign that the corneal problem does not account fully for the visual defect.

TESTS OF RETINAL FUNCTION

Various entoptic phenomena have been used to assess retinal function behind opacities in the ocular media.[13] Light perception and projection should be tested routinely in eyes with very poor acuity. Occasionally, the bright light of the indirect ophthalmoscope must be used to obtain a response, in which case the prognosis is obviously very poor; keratoplasty may be precluded unless possibly when both eyes are similarly involved. Accurate light projection is not a guarantee of good retinal status, and poor projection may occur despite a normal retina and optic nerve, when corneal opacity is severe. Two-point light differentiation and color perception are likewise of limited predictive value.

Entoptic images, visual images originating within the eye, may be of some use in the estimation of gross visual potential. A light moving over the closed lid will cast retinal vascular shadows that are detectable by most patients with normal retinas. When this pattern is discerned, there is likely to be at least perifoveal function. Detection of the normal avascular zone indicates that the fovea may be functioning. The blue-field entoptic phenomenon allows assessment of the ability of the patient, while looking into a bright blue light, to detect white blood cells passing through perifoveal capillaries. This is a moderately good predictor of macular function in patients with anterior segment opacities, although it is not widely used.[14]

Laser interferometric visual acuity testing was developed to evaluate potential acuity in patients with cataract and other media opacities. It has been shown to be of value in patients with corneal opacity, but less so than in cataract patients.[15,16] This technique requires an adequate pathway for two laser beams to enter the pupil and is therefore limited in eyes with severe corneal opacity. Laser interferometry has a tendency to overestimate acuity in eyes with amblyopia, macular degeneration, or CME. White-light interferometers, such as the Lotmar Visometer (Haag-Streit, Waldwick, NJ) and the IRAS Visometer (Randwal, Southbridge, MA), use similar principles and are moderately accurate at predicting postoperative vision in patients with lens opacities, although the utility of the findings in cataract patients is limited because of the high success rate and the validity in corneal disease has not been evaluated.[17] These methods are all limited in eyes with severe opacities. False-negative responses (poor test results with good postoperative vision) are frequent, but a positive response is usually significant.

The potential acuity meter (PAM) of Guyton and Minkowski projects a visual acuity chart through a very small aerial aperature.[18] Like the interferometers, it requires at least a pinhole-sized clear pathway to allow the beam to focus on the retina. It is of less value in predicting outcomes before keratoplasty than before cataract surgery.[18] The accuracy of PAM can be increased significantly in patients with keratopathy if a hard contact lens is placed on the cornea during testing.[19] In cataract cases, the PAM tends to underpredict potential visual acuity.[20] Unfortunately, this method may give falsely optimistic readings in eyes with CME, a frequent comorbidity in eyes with bullous keratopathy.[18]

Electrophysiologic testing to predict potential visual acuity is rarely useful. Electroretinography occasionally may be helpful to rule out gross retinal damage in children, or when the tests discussed above are not helpful. The bright-flash electroretinogram (ERG) gives a response despite most dense media opacities and can be performed trans-sclerally to bypass the media.[21] The visually evoked response (VER) can be used to measure central retinal function but does poorly in eyes without clear media.[22]

Visual field testing is important in the evaluation of visual function, especially when there is a history of glaucoma or optic nerve disease and the fundus cannot be well seen. Although formal testing often is not feasible, a hand-held light can be used to estimate grossly the fields of eyes with vision of only hand motions or light perception. This penlight field can usually detect hemianopsia or a temporal island of advanced glaucoma. Diffuse preoperative field constriction, however, is not a reliable predictor of postoperative field restriction.

RETINAL STRUCTURE EVALUATION

Preoperative detection of retinal detachment is of particular concern in aphakic and pseudophakic eyes with opaque corneas, particularly when the original procedure was complicated by vitreous loss or nucleus dislocation. The presence of a long-standing detachment may contraindicate keratoplasty, but a more recent detachment may be an indication for a temporary keratoprosthesis (TKP) for combined keratoplasty and pars plana vitrectomy.[23] The visual function tests discussed earlier may suggest the presence of retinal detachment or macular disease. Indirect ophthalmoscopy should be performed, to the extent possible, on all prekeratoplasty eyes. Contact B-scan ultrasonography can be performed easily and rapidly as a screening procedure for retinal detachment, vitreous hemorrhage, and intraocular tumor. When a detachment or vitreous hemorrhage is found, a combined retinal–corneal procedure may be planned. A TKP, such as that of Landers or Eckardt[23] is inserted after corneal trephination, allowing a full range of posterior segment procedures followed by TKP removal and corneal donor grafting.

SCREENING FOR CYSTOID MACULAR EDEMA

Cystoid macular edema is a major problem, both pre- and postoperatively, in eyes with aphakic and PBK.[24] Cystoid macular edema was a great problem with several of the iris-supported and closed-loop anterior chamber IOLs used in the 1970s and 1980s, which are no longer implanted. Even with current cataract and IOL techniques, complicated cases, including capsule rupture, vitreous loss, and nucleus loss into the vitreous, are associated with CME.[25] In many such eyes developing late bullous keratopathy, there is associated late-onset CME. Together, this has been called the corneal–retinal syndrome.

Careful slit-lamp examination for vitreous in the anterior segment helps to determine the need for anterior vitrectomy, itself a risk for CME, at keratoplasty. Fluorescein angiography usually cannot be performed in eyes with significant corneal edema, but fluorescein angioscopy with the indirect ophthalmoscope and a blue filter often allows visualization of late cystoid macular pooling of dye. The presence of CME is the most frequent vision-threatening complication of pseudophakic keratoplasty, occurring in about one-third of eyes and accounting for up to two-thirds of those with poor vision.[24] CME in this setting can clear gradually over a period of 2 or more years.[26] Preoperative knowledge of CME can help to prevent disappointment and limit the tendency to blame poor vision related to earlier procedures on the keratoplasty.

CORNEAL EXAMINATION

Obviously, slit-lamp examination is the essential feature of the diagnostic evaluation. Careful attention should be paid to the status of the lids, conjunctiva, tear film, and cornea, as in any preoperative eye. Good lid apposition is necessary to avoid epithelial healing problems from exposure, entropion, or trichiasis. Blepharitis should be treated preoperatively. Conjunctival scarring increases the risk of graft surface problems, especially when it is a sign of mucus membrane pemphigoid.

Most aphakic and pseudophakic grafts are for bullous keratopathy. Because the severity of corneal edema may vary with humidity and time of day, the edema noted on examination late in the day may not appear to be adequate to warrant keratoplasty. Repeat examination early in the day, when edema is more likely to be maximal, may be helpful in explaining patient symptoms. Serial pachymetry may be of some use in documenting progression. Specular microscopy is not usually necessary but may be useful in predicting endothelial failure. An endothelial density of <500 cells/mm^2 suggests imminent decompensation.

Documentation of the slit-lamp examination should include variations in corneal thickness, extent and depth of vascularization, and location of opacities and edema. The colored-pencil drawing system described by Waring and Laibson is useful.[27] Anterior chamber depth, peripheral anterior synechiae, posterior synechiae, and the position, type, and stability of the intraocular lens, vitreous, and capsule are important to observe preoperatively.

Routine considerations for all corneal grafts should not be neglected. One of the most important of these is intraocular pressure. There is a high prevalence of glaucoma in eyes with PBK; about one-third are using glaucoma medications at the time of grafting.[24] Intraocular pressure should be controlled before keratoplasty, if possible, or a combined trabeculectomy or drainage device insertion should be considered.[28] The presence of uncontrolled glaucoma or a drainage tube is considered to be a strong risk factor for graft failure.[29,30]

EVALUATION OF THE INTRAOCULAR LENS

In the pseudophakic eye about to undergo keratoplasty, special attention should be paid to the IOL itself and to its relationship with surrounding structures. The presence, extent, and clarity of the capsule should be noted, as should the status of the iris. Gonioscopy should be performed when possible. New imaging modalities including ultrasound biomicroscopy, very-high-frequency ultrasound (Artemis), and anterior-segment optical coherence tomography (OCT, Zeiss) should be considered.[31–33]

The type of IOL present is still very important, although the population of patients with undesirable past IOL types is disappearing gradually. The approach to management of the original IOL was influenced by poor long-term results in eyes with iris-supported and closed-loop anterior chamber lenses. Clinical outcomes support the replacement of essentially all lenses other than stable posterior chamber lenses or well-positioned, semiflexible, one-piece Kelman-style anterior chamber lenses. Phakic intraocular lenses may be associated with endothelial damage in some cases and may require removal, usually before frank corneal decompensation.[34]

In aphakic eyes, it is usually reasonable to insert a secondary IOL. Scleral sutured or iris suture posterior chamber lenses, Artisan iris-claw lenses, and open-looped Kelman-style anterior chamber lenses are all reasonable options. Preoperative planning for IOL power includes axial length measurement and estimation of postoperative corneal curvature.[35]

CONCLUSIONS

The evaluation and preparation of the aphakic or pseudophakic eye and patient for keratoplasty include all of the considerations given to phakic eyes, with the addition of detailed assessment of the effects of the previous surgery. Corneal surgeons must be concerned about posterior segment complications that may affect postoperative visual function and anterior segment alterations that may affect the surgical approach. Often the most critical special consideration is the plan for an original IOL or its replacement. Improvements in cataract surgery and IOLs have made this a less critical issue in most eyes, but individualization and patient involvement in planning remain important for successful keratoplasty and visual outcomes.

31 Herpetic eye disease: ocular herpes simplex and herpes zoster

Jeffrey Day Lanier

Herpes simplex keratitis became the leading infectious cause of loss of vision in the USA within 6 years after the introduction of topical steroids in 1950, as was reported by Thygeson et al.[1] A simple clinical classification and description of ocular herpes simplex disease follows.

OCULAR HERPES SIMPLEX DISEASE

PRIMARY OCULAR HERPES SIMPLEX

Primary ocular herpes simplex infection occurs as the first encounter with the herpes simplex virus. It differs from recurrent ocular herpes simplex infections in that primary ocular herpes simplex infection may be unilateral or bilateral; it may or may not be associated with skin lesions; a tender, palpable preauricular node; a follicular conjunctival response; a membranous conjunctival response; or a transient mild epithelial keratitis. Primary ocular herpes simplex may be difficult to differentiate clinically from adenoviral keratoconjunctivitis, if there are no skin lesions. The duration of the infection is usually 1–4 weeks; it rarely has any significant sequelae such as visual loss due to corneal scarring. Exceptions to this natural course usually are seen in immunologically compromised patients.

RECURRENT OCULAR HERPES SIMPLEX

Epithelial herpes simplex keratitis

Epithelial herpes simplex keratitis is the most common form of recurrent ocular herpes simplex. It is usually mild and presents with few symptoms, and it rarely leaves any significant sequelae. The usual healing time for the epithelial lesion is 1–4 weeks; however, this healing time may vary within the same person from one recurrence to another. Topical antiviral medication may or may not shorten the healing time. Various combinations of antiviral agents and physicochemical techniques have been evaluated over many years.[2] Even though there are several clinical appearances of epithelial herpes simplex keratitis, the classical forms in order of development and severity include *punctate*, *dendritic*, and *geographic*. A granular subepithelial opacity may accompany the epithelial keratitis and usually fades with time.

Stromal herpes simplex keratitis

Stromal herpes simplex keratitis is the potential blinding stage of ocular herpes simplex disease when residual corneal opacities occur. There are many clinical appearances of stromal herpes simplex keratitis, but most fall into three basic categories of *disciform*, *infiltrative*, and *infiltrative necrotizing*. Marginal herpes simplex keratitis[3] is epithelial, stromal, or both. It is given a special recognition and description because of the danger of misdiagnosing this form as staphylococcal hypersensitivity marginal infiltrates (catarrhal ulcers).

Disciform herpes simplex keratitis

Disciform stromal herpes simplex keratitis presents as a localized annular stromal edema with minimal white blood cell (WBC) infiltration. There may or may not be keratitic precipitates (KP) on the endothelium (endotheliitis), but there are very few, if any, WBCs in the anterior chamber (AC). The natural healing course for disciform stromal herpes simplex keratitis is 2–6 months. Before 1950, disciform stromal herpes simplex keratitis rarely left significant corneal opacities.[4] However, the natural course of healing and residual sequelae are difficult to assess today because most patients with disciform stromal herpes simplex keratitis are treated with topical steroids.

Infiltrative herpes simplex keratitis

Infiltrative stromal herpes simplex keratitis presents with WBC stromal infiltration, with or without stromal edema. Again, there may or may not be KP on the endothelium (endotheliitis), but there are very few, if any, WBCs in the AC. The conjunctival hyperemia usually is localized as a ciliary injection. There is rarely a severe generalized conjunctival hyperemia as is seen commonly in bacterial and fungal keratitis. Corneal stromal WBC infiltrates vary in intensity, but they usually display a granular pattern that is seen best by retroillumination. This granular pattern is rarely seen in bacterial and fungal keratitis. Only in the severe forms of infiltrative stromal herpes simplex keratitis do the WBCs coalesce to form a

dense stromal infiltrate, which resembles the typical bacterial and fungal keratitis. The natural healing course for infiltrative stromal herpes simplex keratitis is 2–6 months. Before 1950, this form of stromal herpes simplex keratitis was rarely, if ever, seen.[4] Today, it is the most common form of herpes simplex keratitis that leads to corneal opacities and reduced vision.

INFILTRATIVE NECROTIZING HERPES SIMPLEX KERATITIS

Infiltrative necrotizing stromal herpes simplex keratitis presents as a severe WBC infiltrative keratitis with stromal tissue loss that may progress to a descemetocele or a perforation. This stage of stromal herpes simplex keratitis is likely to have a significant AC cellular response; therefore, it may be difficult to differentiate clinically between a bacterial and a fungal infection, and a corneal smear and culture are indicated. The natural course of healing for infiltrative necrotizing herpes simplex keratitis is at least 2–6 months. This is the stage of stromal herpes simplex keratitis for which a conjunctival flap may be indicated most strongly. Amniotic membrane transplantation has been shown to be helpful in herpes simplex necrotizing keratitis in mice.[5] Residual visual compromise is the usual result of infiltrative necrotizing herpes simplex keratitis.

HERPES SIMPLEX KERATOUVEITIS

Herpes simplex keratouveitis presents as a uveitis with varying degrees of keratitis, ranging from very mild to very severe. A significant AC cellular reaction is necessary to meet the criteria for herpes simplex keratouveitis. The Herpes Eye Disease Study (HEDS)[6] defined herpes simplex keratouveitis as having '11 or more AC cells in a slit-lamp beam that is 1 mm high and 0.5 mm wide, with the illuminating arm of the slit lamp at an angle of 45° to the viewing arm.' Herpes simplex keratouveitis is relatively rare, as is indicated by the fact that only 50 out of 104 patients needed for statistical purposes could be recruited from eight clinical centers over 4 years.[6] The fact that herpes simplex keratitis usually has a minimal AC cell reaction (fewer than 10 cells in a 1-mm beam), except in the keratouveitis and infiltrative necrotizing forms, is a very important clinical observation. Disciform and infiltrative stromal herpes simplex keratitis may have KPs on the endothelium (endotheliitis) but rarely do they demonstrate an AC cell reaction of greater than 10 cells in a 1-mm beam. Bacterial keratitis and fungal keratitis with the same degree of corneal involvement routinely have a more significant AC cell reaction. The natural healing course for herpes simplex keratouveitis is at least 2–6 months, and the visual sequelae vary with the severity and duration of the inflammation.

PREOPERATIVE CONSIDERATIONS

Cessation of inflammation

A common denominator that prevails in reported cases of keratoplasty for herpetic disease is that of increased success when the eye is free of inflammation for an extended period of time.[7–10] This may be the single most important variable in the determination of success or failure. The eye should be free of inflammation without the use of steroids for a period of at least 6 months.[10] It may be very difficult to reduce and stop the use of topical steroids if they have been used in stromal herpes simplex keratitis. The most common regimen is to taper steroid usage slowly by decreasing the frequency first, and then decreasing the concentration and frequency. As the frequency and concentration are decreased, ocular inflammation usually increases. Seldom does an eye remain noninflamed with steroid reduction. It is important that patients understand this fact when they are tapering steroids. Allowing the eye to retain some inflammation may be necessary to eventually obtain a noninflamed eye, without the use of topical steroids.

Vascularization

Stromal invasion of vessels is common in infiltrative and necrotizing stromal herpes simplex keratitis. It may be that the natural immunologic inflammatory response is necessary if the stromal herpes simplex keratitis is to be healed (Figs 31.1 and 31.2). The corneal vessels usually become attenuated or they become ghost vessels (Fig. 31.3) after healing takes place, which generally takes 2–6 months without topical steroids. Control of corneal vascularization before penetrating keratoplasty is performed has been attempted by various means over the years, but the benefit has never been shown. Most corneal surgeons simply control bleeding at the time of surgery using light cautery or irrigation. Further attenuation of vessels in the peripheral recipient corneal continues to occur post keratoplasty (Fig. 31.4). Preoperative recipient bed vascularization is generally thought to be a significant risk factor for homograft

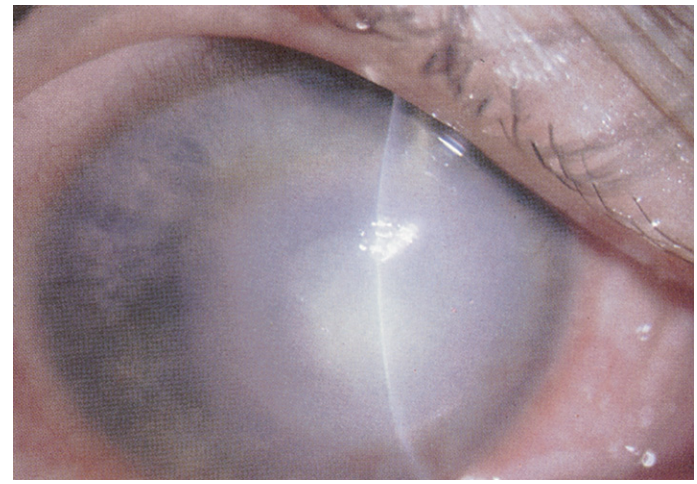

Figure 31.1. Infiltrative stromal herpes simplex keratitis.

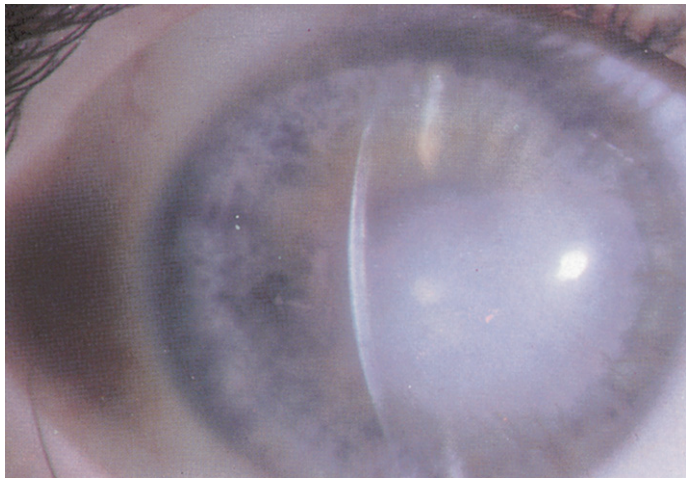

Figure 31.3. Same eye 6 months after discontinuation of topical steroids. Healing has occurred, the eye is quiet, and the vessels have become attenuated.

Figure 31.5. Stromal infiltrative necrotizing herpes simplex keratitis with descemetocele.

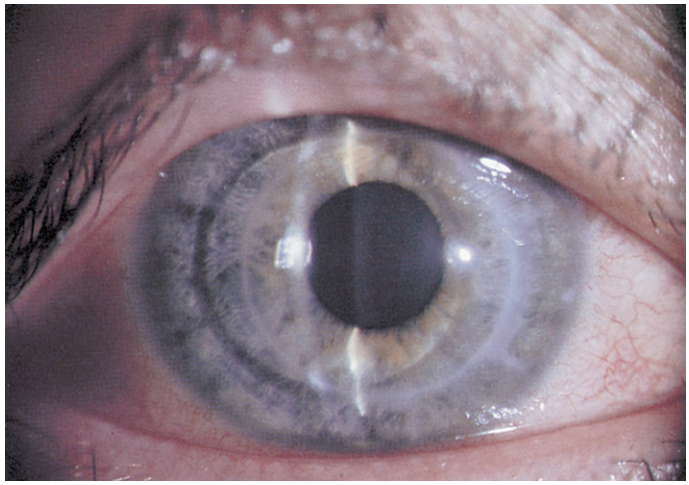

Figure 31.4. Same eye 15 years after keratoplasty with further attenuation of peripheral recipient vessels.

reaction in both herpetic[7,9,11] and nonherpetic[12–14] corneal transplantation. Others did not find vascularization to be statistically significant for increased homograft reaction in herpes simplex keratitis,[15] herpes zoster keratitis,[16] or corneal transplantation in general.[17]

Corneal sensation

Corneal sensation commonly is diminished by chronic stromal herpes simplex keratitis. This decreased sensation can range from minimal to totally absent, and the duration can be short to permanent. If sensation is diminished severely, neurotrophic keratitis may occur, resulting in poor healing of the overlying corneal epithelium.[9,18] A preoperative return of corneal sensation is not a prerequisite for keratoplasty. The return of corneal sensation may take years to occur, if it returns at all.

Topical antiviral drugs

The only stage of ocular herpes simplex keratitis for which topical antivirals have been shown to be of help is active epithelial herpes simplex keratitis. Topical antiviral drugs frequently are used in conjunction with topical steroids. This concept stems primarily from two early studies: one using 5-iodo-2 deoxyuridine (IDU)[19] and the other using trifluridine (Viroptic®).[20] No recent well-designed, well-controlled studies have been done to concur with this concept. The *Physicians' Desk Reference* states: 'Viroptic® has not been shown to be effective in the prophylaxis of herpes simplex virus keratoconjunctivitis and epithelial keratitis by well-controlled clinical trials. . . . Continuous administration of Viroptic® for periods exceeding 21 days should be avoided because of potential toxicity.'[21]

Systemic antiviral drugs

No antiviral, either topical or systemic, has been shown to be effective in the treatment of active stromal herpes simplex keratitis. The Herpetic Eye Disease Study showed no statistically or clinically significant beneficial effect of oral acyclovir.[6] Oral acyclovir also showed no benefit in preventing stromal herpes simplex keratitis or iritis when used in patients with epithelial herpes simplex keratitis.[22]

Conjunctival flap

Stromal infiltrative necrotizing herpes simplex keratitis can result in severe stromal tissue loss and perforation. Topical steroids may have little, no, or an adverse effect on the necrotizing process. A conjunctival flap should be considered *before* perforation occurs (Figs 31.5 and 31.6). Gundersen[23] described the surgical technique that is most commonly used today. This modality of surgical treatment should always be considered in the treatment of stromal infiltrative necrotizing herpes simplex keratitis, as well as with other types of refractory herpes simplex keratitis. The conjunctival flap can be used as a temporary measure (8–12 months); it may be removed before or at the time of keratoplasty. The conjunctival flap can also remain in place permanently. Amniotic membrane transplantation has been shown to be helpful in herpes simplex necrotizing keratitis in mice.[5]

Corneal perforation

Corneal surgery should be avoided when active inflammation is present with herpes simplex keratitis.[7,9,10,15,18,24] Unfortunately, infiltrative necrotizing stromal herpes simplex keratitis may lead to corneal perforation that requires some type of intervention. The integrity of the AC must be re-established. A conjunctival flap or

Figure 31.6. Two weeks post Gundersen conjunctival flap. The active inflammation has subsided and the necrotic process ceased. The eye is quiet and comfortable.

amniotic membrane will not do this. When the diameter of perforation is less than 2 mm, a therapeutic soft contact lens with pupil dilation, with or without tissue adhesive, may allow the AC to reform, with eventual healing of the corneal perforation. If this is not accomplished, or if the perforation is greater than 2 mm, surgical intervention must be undertaken. Both penetrating[10] and lamellar[9] keratoplasties have been advocated. Severe inflammation and perforation result in a much more difficult surgical procedure and adverse outcome.

OPERATIVE CONSIDERATIONS

Most corneal surgeons do not alter their surgical technique specifically for corneal scarring caused by previous herpetic keratitis. An exception is the use of interrupted stitches in vascularized and edematous corneas,[8,25] where rapid healing and loosening permit selective suture removal. Rapid loosening of stitches will occur routinely, regardless of stitch technique, if they are placed in fibrovascular or edematous recipient tissue. To minimize this loosening of stitches, longer bites that are tied with increased tension should be made. All stitches that become loose should be removed.

A basic principle in corneal transplant surgery is to sew into the healthiest recipient tissue possible. This principle is important when one is determining graft size and centration. When extremely thin or necrotic recipient tissue is present, large-diameter or eccentric grafts may be necessary.

POSTOPERATIVE CONSIDERATIONS

The postoperative course of keratoplasty for herpetic keratitis can be extremely variable.

TOPICAL STEROIDS

Titrating topical steroids that are given to control postoperative inflammation is necessary. The inflammation may be minimal or extensive. Some have reported an increase in the incidence of recurrent herpes simplex keratitis with the use of high-dosage steroids,[7] whereas others have reported no such increase.[15]

TOPICAL NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nonsteroidal anti-inflammatory drugs (NSAIDs) have undergone few clinical or investigative studies concerning herpes simplex keratitis, with or without keratoplasty. No well-designed study has proved their efficacy.

TOPICAL ANTIVIRAL DRUGS

The same concepts that were discussed in the section on preoperative considerations, regarding the concomitant use of antiviral medications with topical steroids, apply postoperatively. The literature does not support the theoretical postulation that the use of topical antiviral medications reduces the incidence of recurrent herpes simplex in postoperative keratoplasty;[11,15,18] it also provides no support for the theory that the use of high doses of topical steroids increases the incidence of recurrent herpes simplex in postoperative keratoplasty.[7,15] Topical antiviral drugs may delay wound healing,[18,26] and their use may lead to epithelial toxicity and persistent epithelial defects.[9,26]

SYSTEMIC ANTIVIRAL DRUGS

A herpetic eye disease study showed no statistically or clinically significant beneficial effect of oral acyclovir in active stromal herpes simplex keratitis.[6] Another herpetic eye disease study also showed no benefit of oral acyclovir in the prevention of herpes simplex stromal keratitis or keratouveitis in patients with epithelial herpes simplex keratitis.[22]

The frequency of genital herpes simplex type 2 recurrences has been shown to be decreased as long as the patient is taking acyclovir.[27,28] Once the oral acyclovir was discontinued, recurrences returned to the pretreatment frequency, and some patients reported unusually severe symptoms with the first post-treatment recurrence.[27] Similar findings in ocular herpes simplex keratitis were reported in a retrospective, uncontrolled study of 27 patients in which (1) disease recurrence seems to be reduced while the patients are maintained on a long-term prophylactic dose of oral acyclovir and (2) severe recurrences occurred in three patients when oral acyclovir was reduced or stopped.[29] Acyclovir-resistant herpes simplex strains emerge during treatment and are associated with prolonged infections in immunosuppressed patients.[30] Resistant strains are isolated from healthy patients who experience recurrences while they are taking oral acyclovir for long-term suppression.[31] Acyclovir-resistant herpes simplex keratouveitis that occurs after penetrating keratoplasty has also been reported.[32]

Later studies have indicated that oral acyclovir may be beneficial in the prophylaxis of recurrent herpes simplex infection in patients with and without grafts.[33–35] A follow-up herpetic eye disease study demonstrated that a 12-month suppressive oral acyclovir therapy reduced the rate of epithelial and stromal herpes simplex keratitis.[36] This study was designed with immunocompetent patients who had not undergone penetrating keratoplasty. Oral acyclovir's benefit was greatest for patients who had experienced prior stromal herpes simplex keratitis.[36] A recent study suggests that oral acyclovir effectively prevents herpes-related recurrences after penetrating keratoplasty in herpetic eye disease.[37] Others have indicated that a double-drug regimen with mycophenolate mofetil and acyclovir helps prevent both allograft rejection and herpes simplex recurrence following corneal transplantation.[38,39]

GRAFT REACTION VERSUS RECURRENCE OF HERPES SIMPLEX KERATITIS

The major complications of keratoplasty in eyes with scars caused by herpes simplex are (1) recurrent herpes simplex keratitis and (2) endothelial graft reaction. Graft failure is more likely to be caused by endothelial graft reaction than by recurrent herpes simplex keratitis.[8,40,41] Corneal graft reaction has been reported to be as high as 71%[9] and 79%,[7] whereas others have reported a much lower incidence of 20.6%.[15] The postoperative recurrence rate of herpes simplex keratitis varies with the duration of follow-up time and the criteria for diagnosis. The range of reported recurrence is from 6 to 47%, and it can occur immediately postoperatively or years later.[7,9,11,18] A recurrence of herpes simplex keratitis within a graft does not necessarily result in an opaque graft. Central scars or completely opaque grafts have been reported to occur in only 23.8% of herpetic recurrences.[18]

Differentiating the two problems diagnostically can be very difficult, but careful observation of clinical signs may be helpful. Recurrent herpes simplex keratitis can occur after a graft reaction, or a graft reaction may develop after the patient experiences recurrent herpes simplex keratitis, within a few days of initial onset of either.

The most specific clinical sign of recurrent herpes simplex keratitis is a classical herpetic epithelial dendrite, which can be appreciated best by staining with fluorescein or rose bengal. However, any epithelial defect can heal in a dendritic shape and mimic a herpetic dendrite. Cultures usually are positive in active epithelial herpes simplex keratitis. The first recurrence within a graft has been reported to be epithelial in 74.7% of patients, and it occurs at the line of union between the graft and the recipient in 61.5% of cases.[18] With both geographic and chronic epithelial defects, it is difficult clinically to assess the cause. Herpetic cultures should be considered to differentiate from poor epithelial healing in that the cornea is in a neurotrophic state. Topical antivirals are toxic and should be avoided unless there is an active epithelial herpes simplex keratitis. Most active cases of epithelial herpes simplex keratitis heal within 1–4 weeks. Topical antivirals should be used no longer than 21 days in the treatment of epithelial herpes simplex keratitis so that epithelial toxicity is avoided.[21] Topical steroids should be avoided in the presence of active epithelial herpes simplex keratitis, even if topical antivirals are used concomitantly.

Recurrent stromal herpes simplex keratitis is a much more serious postoperative complication than is graft reaction. The recurrence can occur at any location in the graft; it usually presents as an infiltrative stromal herpes simplex keratitis, with or without KP on the endothelium (endotheliitis). Herpetic cultures are usually negative in active stromal herpes simplex keratitis. The stromal infiltrates of WBCs can appear in the more common focal, irregular, coalescing granular pattern that is seen best by retroillumination, or they may occur as the less common dense stromal WBC infiltrates that mimic bacterial or fungal stromal keratitis. The natural healing course of stromal herpes simplex keratitis within a corneal graft is 2–6 months. If there is no favorable healing response within 1–2 weeks, and if there is no associated active epithelial herpetic keratitis, topical steroids commonly are used to suppress the natural inflammatory response. Titrating and tapering the frequency and concentration of topical steroids requires careful observation for months to years, with possible rebound inflammation as the topical steroids are reduced.

Compared with recurrent herpes simplex keratitis, graft reaction usually is associated with a more evenly distributed stromal edema with no significant WBC stromal infiltrates. The inferior cornea is the most common site of initial involvement, but the graft reaction may advance superiorly with time. A Khodadoust keratic precipitate line is pathognomonic of an endothelial graft reaction, but evenly distributed KP may also be found.

Even though corneal scarring caused by herpes keratitis is not the most favorable indication for successful keratoplasty, when surgery is performed in inflammation-free eyes and postoperative complications are anticipated and treated quickly, clear grafts with good visual rehabilitation can be obtained in 75[18] to 80%[15] of patients.

OCULAR HERPES ZOSTER DISEASE

There are many differences between ocular herpes simplex and ocular herpes zoster disease, but one of the most important is that herpes zoster does not recur within the same dermatome once the inflammatory response is allowed to clear totally without the suppression of topical steroids, which usually requires 2–6 months. Recurrent herpes zoster within the same dermatome has yet to be documented.[42] Recurrent herpes zoster in different dermatomes, bilateral herpes zoster, and disseminated herpes zoster are extremely rare and occur in immunocompromised hosts.[43,44] Herpes simplex can mimic herpes zoster, which is referred to as pseudozoster. Misdiagnosis of pseudozoster (herpes simplex) for herpes zoster can result in the false impression of recurrent herpes zoster.[42] Rebound inflammation, which may occur as topical steroids are decreased or discontinued, has also been interpreted as recurrent herpes zoster. Among patients in whom herpes zoster keratitis was determined to be completely free of inflammation and topical steroids had been stopped for at least 6 months, recurrence has never been documented by laboratory confirmation.[42] The clinical signs and symptoms listed in Table 31.1 help to differentiate herpes zoster from pseudozoster (herpes simplex), but laboratory confirmation is necessary for definitive diagnosis of the specific infectious agent.

Table 31.1 Differentiating features of herpes simplex (pseudozoster) and herpes zoster disease

Herpes Simplex (Pseudozoster)	Herpes Zoster
1. Incomplete dermatomal distribution	1. More complete dermatomal distribution
2. Less pain	2. More pain
3. Rarely scars the skin	3. Frequently scars the skin
4. Postherpetic neuralgia rare	4. Postherpetic neuralgia common over age 50 years
5. Iris atrophy very rare, except in keratouveitis	5. Iris atrophy more common, and usually in a sectoral pattern
6. Rarely bilateral	6. Very rarely bilateral
7. Often recurs	7. Recurrence has yet to be documented
8. Corneal hypesthesia	8. Corneal hypesthesia

The fact that herpes zoster does not recur within the same dermatome is a great advantage in keratoplasty. Recurrence of herpes simplex within the graft is a major complication that is eliminated in the treatment of herpes zoster if the eye is allowed to become inflammation free for at least 6 months while the patient is off topical steroids.

A more severe loss of corneal sensation is more likely to occur in herpes zoster keratitis. This loss of corneal sensation may result in poor epithelial healing more frequently in keratoplasty for herpes zoster than for herpes simplex.

Keratoplasty that is undertaken to treat herpes zoster ophthalmicus corneal scarring is relatively rare.[45,46] Two recent reports have shown good results, with clear grafts in 7 of 9 patients (78%)[16] and in 10 of 12 patients (83%).[47]

32 Preoperative tests and evaluations

Robert E. Brass, Frederick S. Brightbill

PREOPERATIVE EVALUATION FOR KERATOPLASTY

The success of any surgery, especially keratoplasty, depends on a thorough preoperative evaluation. A complete ocular and systemic history will help the surgeon to anticipate and avoid problems during and after the procedure. The ocular history often indicates the level of visual acuity that can be expected after keratoplasty and the likelihood of graft survival. This not only helps the surgeon in preoperative planning but also helps to give the patient realistic expectations. For example, a patient with a failed graft secondary to uncontrolled glaucoma has a different prognosis than a patient who is undergoing a primary keratoplasty for Fuchs' endothelial dystrophy. Systemic history is important in determining the overall health of the patient. This helps guide the physician in determining the type of anesthesia to be used, as well as the overall feasibility of performing the proposed procedure. The slit-lamp examination, combined with other forms of ocular diagnosis, provides the cornerstone of diagnosis and management. Proper patient selection, preparation, and evaluation maximize the potential for a favorable outcome.

COMPONENTS OF PREOPERATIVE EVALUATION

Medical history

When obtaining the patient's history and review of systems, the first goal is to determine whether the patient has the ability to undergo the proposed operative procedure. In considering local anesthesia, for example, a patient must be able to lie flat for the duration of the procedure, and comfortable being semiconscious for the surgery. This ability could be compromised by pulmonary, musculoskeletal, or cardiac abnormalities. General anesthesia may be warranted if severe arthritis makes it impossible for the patient to remain comfortably in one position for an extended period of time. The surgeon must ultimately decide whether the patient's surgery can be performed under local monitored anesthesia or general endotracheal intubation anesthesia. Pre-existing medical problems such as hypertension and diabetes should be stabilized in concert with the patient's primary-care physician before the keratoplasty is undertaken. Because preoperative anxiety is common, patients should be advised to take their normal dose of antihypertensive medication on the morning of surgery. Insulin-dependent diabetic patients should undergo surgery early in the day if possible, and one-half their normal dose should be administered before surgery, with the other half given postoperatively along with breakfast. Allergies to such medications as antibiotics, systemic medications, and anesthetics should be questioned directly, noted in the chart, and reviewed so that subsequent complications may be avoided. The presence of cardiopulmonary disease should be noted, in that it may limit the postoperative use of β-blockers. Patients may be allergic to the preservative in topical medications rather than to the drug itself. In such cases, skin testing can identify allergies to preservatives, before an entire class of medications is excluded.

Patients taking aspirin, nonsteroidal anti-inflammatory drugs, and other medications that interfere with blood coagulability deserve special preoperative consideration. It has been traditional practice to discontinue aspirin and nonsteroidal drugs 15 days before surgery, and discontinue Plavix® or Coumadin® 5 days before surgery. This is always done in consultation with the prescribing physician. Relative safety has been demonstrated in patients undergoing intraocular procedures who have continued to take medications that affect their coagulation. McCormack and coworkers[1] demonstrated that procedures such as extracapsular cataract extraction with intraocular lens implantation, vitreoretinal procedures, and trabeculectomy surgery all could be performed safely without changing the anticoagulation status of the patient. Gainey and coworkers[2] concluded, 'If anticoagulants are necessary for a patient's well-being, they should not be discontinued for cataract surgery.' When prothrombin times are in reasonably good range, the authors have had good success with simply discontinuing anticoagulation 48 h before keratoplasty and resuming treatment on the first postoperative day. If temporary cessation of anticoagulation is deemed inadvisable, patients on Coumadin® (warfarin) may require heparinization 24–48 h postoperatively.

Another goal for the clinician in obtaining a patient's medical history should be to understand the patient's social and family support systems. The outcome of the operative procedure will rely

in large part on the patient's compliance with postoperative medication and follow-up appointments. The patient's compliance with preoperative appointments and testing is a fair indication of postoperative compliance. Even compliant patients may be physically unable to self-administer topical eye medications. In such cases, family and local medical support (e.g. a visiting nurse) should be arranged before surgery is performed. History of substance abuse or abrupt changes in family conditions should be identified because they may interfere with patient follow-up and could be a relative contraindication to surgery, at least until conditions stabilize.

Ocular history

Understanding the pathophysiology of a patient's current status is essential when one is contemplating keratoplasty. The nature of the patient's ocular complaints can guide the physician during the ocular examination and can help lead to an accurate prognosis. For example, confirmation of good visual acuity in the affected eye before development of the current condition carries a better prognosis (i.e. good acuity post cataract surgery in eyes later developing pseudophakic bullous keratopathy) than does the presence of a corneal scar since childhood that has resulted in amblyopia. However, a patient with a failed corneal graft secondary to uncontrolled glaucoma may have a poor prognosis, even though good visual acuity was once present. Patients should be questioned about the onset of the visual disturbance—whether it was preceded by a previous intraocular procedure or infection, or whether it simply deteriorated over time. The presence of pain should be noted and its occurrence and severity should be quantified. Changes in quality of vision as the day progresses should also be ascertained. For example, in Fuchs' dystrophy, vision is often worse immediately upon awakening, with gradual improvement noted as the day progresses.

When they are available, old records are invaluable; they can alert the physician to potential operative problems and can confirm important information such as previous best-corrected visual acuity, past intraocular pressure control, and previous intraocular lens powers. Patients often carry intraocular lens identification cards that are useful in computing the replacement intraocular lens power. A history should be ascertained of previous ophthalmic surgical procedures such as cataract extraction, filtering procedures, or neodymium: yttrium-aluminum-garnet (Nd:YAG) laser for posterior capsular opacification. Knowledge of complications that developed during the preceding procedure helps to prevent potential surprises during keratoplasty.

OPERATIVE EVALUATION FOR KERATOPLASTY

Numerous factors affect the optimal timing of keratoplasty. The patient's subjective complaints and ability to perform daily activities are very important in the evaluation of a candidate for surgery and the relative urgency for the procedure. An active 55-year-old woman with painful bullae and decreased vision secondary to Fuchs' endothelial dystrophy and a 24-year-old keratoconus patient with an enlarging cone, diplopia, contact lens intolerance, and difficulty with night vision both may be in greater need of intervention than an 80-year-old patient with painless pseudophakic bullous keratopathy who is functioning well in her home environment with 20/100 visual acuity. The rheumatoid patient with acute corneal melting and impending perforation may require emergency patch grafting. At times, the status of the other eye must also be considered. A patient with pseudophakic bullous keratopathy in one eye and poor visual acuity and the same closed-loop anterior chamber lens in the other eye is in greater need of keratoplasty than is the keratoconus patient with asymmetric involvement and good contact lens tolerance.

The presence of glaucoma must be evaluated carefully, and the condition must be controlled before keratoplasty is performed. Elevated postoperative pressure can have deleterious effects on graft survival[3] and will ultimately lead to graft failure. Investigators have demonstrated that elevated intraocular pressure leads to thinning of the corneal endothelium, morphologic signs of damage, and decreased endothelial cell count.[4,5]

A corneal leukoma in the visual axis has important implications that are worthy of consideration. Was it the result of bacterial keratitis in a soft contact lens wearer, or was it of viral origin (e.g. herpes simplex, with increased potential for graft rejection), perhaps requiring a topical antiviral agent or oral acyclovir[6–8] post keratoplasty? Obviously, the prognosis for a successful outcome is linked inexorably to a thorough knowledge of the patient's preoperative history.

PHYSICAL EXAMINATION OF PATIENT DURING KERATOPLASTY EVALUATION

COMPONENTS OF PHYSICAL EXAMINATION

Visual acuity assessment

Good history taking should confirm when a patient's past visual acuity was better and what the best-corrected visual acuity is. Amblyopia secondary to anisometropia, strabismus, or corneal scarring during childhood should be ruled out, and visual acuity should be tested using standard Snellen testing. If the patient cannot read the chart at a distance of 20 ft (6 m), additional acuity task results such as counting fingers and detecting hand motions must be documented, along with data indicating the presence or absence of light perception. One of the most important acuity factors involves carefully testing the eye for light projection. In eyes with corneal opacity and light perception vision, the patient's ability to discern the direction from which a light is projected is an important indicator of retinal and optic nerve function. A patient with good retinal function should be able to appreciate in all quadrants the light emitted from a standard muscle lamp (Fig. 32.1). In some eyes with severe central visual loss, use of light emitted from the indirect ophthalmoscope may be required before the patient can determine its direction. Testing visual acuity in a darkened room to compensate for light scattering and glare may also be beneficial. Careful examination for afferent papillary defect as well as color discrimination can be helpful in identifying optic nerve pathology.

The importance of a good refraction cannot be overemphasized. In keratoconus, for example, in which retinoscopy is impossible because of scissoring light reflexes, one must consider checking keratometry and manifesting the patient by dialing in the high astigmatic components (i.e. +3.00 first at 90°, then 180°, and refining), then progressively changing the sphere. It is also helpful to test for visual acuity with a rigid, gas-permeable lens on the eye after topical anesthetic has been instilled. Even if a contact lens is not practical for long-term management, it often can eliminate irregular corneal astigmatism and provide an indication of better-corrected visual acuity and visual potential. Pinhole visual acuity, potential acuity meter, and glare testing in our experience have

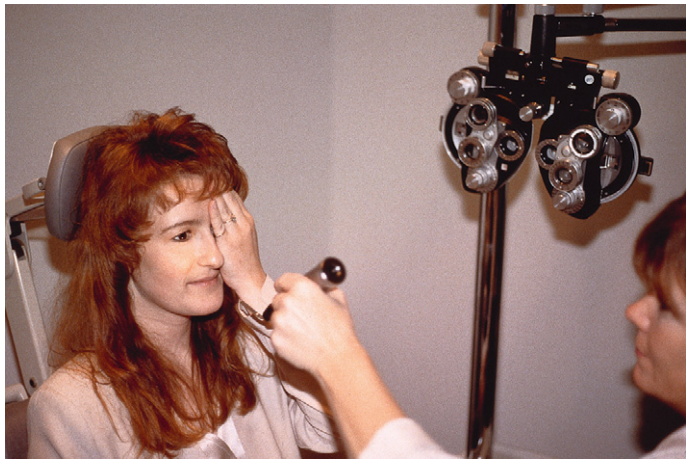

Figure 32.1. Evaluation of light projection. Note the patient looking straight ahead with the other eye completely covered.

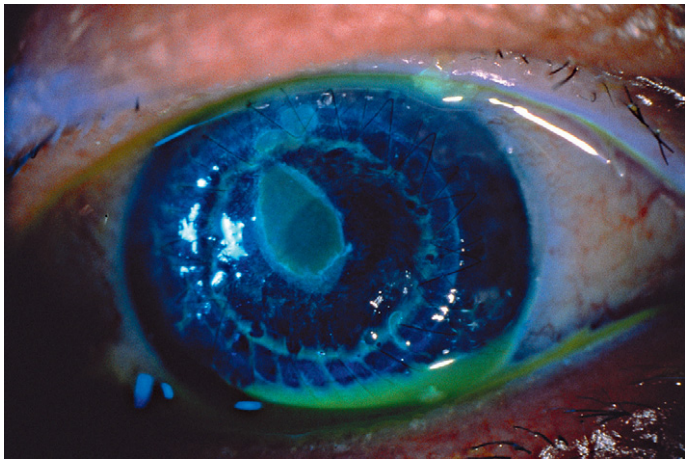

Figure 32.2. Nonhealing epithelial defect in corneal graft of a patient with dry eye.

limited value in predicting best visual acuity, probably because of severe light scattering that results from corneal pathology. One study suggests that it is beneficial to place a hard contact lens over the cornea before performing potential acuity meter testing.[9]

In eyes with corneal edema in which improvement in visual acuity post keratoplasty is questionable, it is worthwhile to attempt to improve acuity and to facilitate retinal viewing by using a topical glycerin that is instilled after topical anesthesia is administered; then, wait 20–30 min for corneal clearing. Epithelial debridement and intravenous fluorescein study may also be used preoperatively for evaluating pre-existing cystoid macular edema.[10]

External examination

The bony structures of the orbit and the prominence of the brow should be evaluated, especially if the patient has deep-set eyes or abnormally thin palpebral fissures, so that the patient's head position during surgery can be planned and an appropriate lid speculum can be chosen. If the patient has active acne rosacea with staphylococcal blepharitis, appropriate treatment should be instituted before the procedure is performed. Herpes zoster, trauma, or radiation may account for lid scarring or neurotrophic keratitis, and ultimate graft failure.

Slit-lamp examination

Lids, lashes, and lacrimal gland

Lid diseases such as blepharitis or meibomitis should be identified and controlled before keratoplasty is performed. If the patient has an ectropion, an entropion, or trichiasis, all of which can lead to epithelial scarring, permanent correction, usually surgical, is advised before keratoplasty is undertaken. Mild spastic entropion is frequently subclinical until the time of surgery; it should be treated rapidly when it is noted postoperatively.

Normal tear production is crucial to graft re-epithelialization; therefore, tear film abnormalities and dryness must be noted during the preoperative examination. Fluorescein and/or rose bengal and Schirmer testing indicate the extent of dryness and epitheliopathy. When there is significant evidence of dryness, consideration should be given to partial or complete punctal occlusion preoperatively, or at the time of keratoplasty, sometimes in combination with partial medial or lateral tarsorrhaphy (particularly when exposure keratitis is suspected).

Conjunctiva and limbus

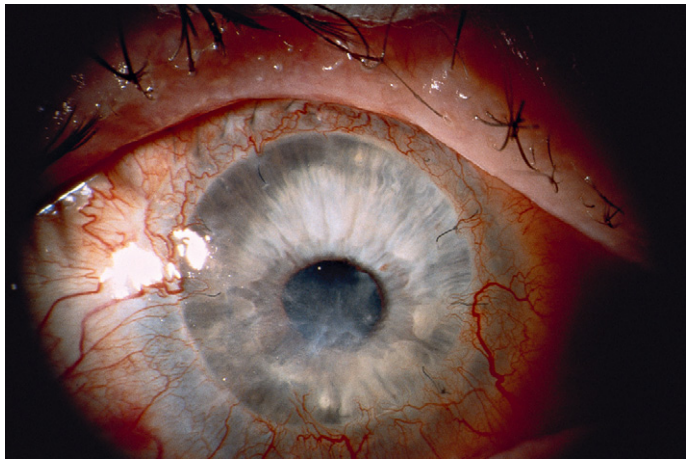
Patients with a history of Stevens–Johnson syndrome, ocular cicatricial pemphigoid, or chemical burn should be examined for scarring and symblepharon; these patients are at significant risk of dry eyes, nonhealing epithelial defects (Fig. 32.2), and postoperative infection because the normal external immune defense mechanisms of immunoglobin A and lysozyme are compromised. Procedures such as punctal occlusion, conjunctival transplant, and limbal stem cell transplantation,[11–13] when performed before keratoplasty, may increase the prognosis for graft survival in these high-risk patients (Fig. 32.3, *A* and *B*). On the day of surgery, the patient should be evaluated for blepharitis and conjunctivitis. If these are detected, the surgery should be canceled and then undertaken only after treatment is provided and complete resolution is attained.

Cornea

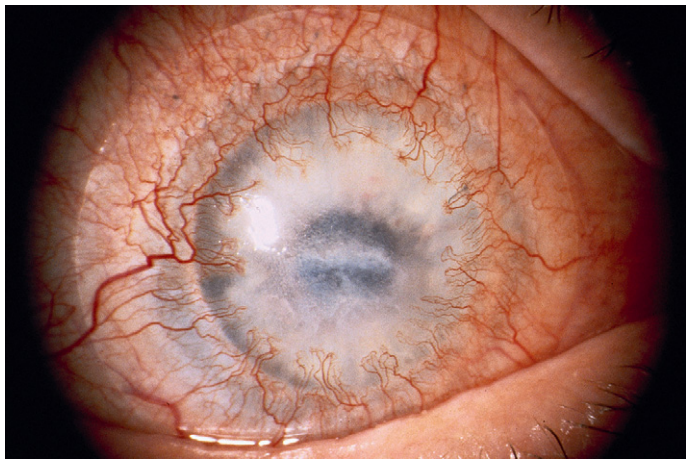
The causes of corneal opacification that require transplant can be divided broadly into ectatic and stromal dystrophies (keratoconus, lattice, granular, or macular dystrophy), postinfectious corneal scarring with or without corneal vascularization (bacterial or viral ulcers), endothelial dysfunction with secondary stromal and/or epithelial edema (Fuchs' dystrophy), and endothelial degeneration (pseudophakic bullous keratopathy). Table 32.1 provides a general outline of these causes and their prognosis for graft survival.

The diameter of the graft is determined in part by the diameter of the corneal irregularity and its proximity to the central visual axis. If possible, the diameter of the cone in keratoconus should be surrounded completely by the trephine so as to avoid thick-to-thin-edge suturing and progressive postoperative recipient bed thinning. Cone diameter is determined best using direct ophthalmoscopic viewing at +6.00 D following maximum mydriasis, or by viewing the Fleischer ring intraoperatively. The Fleischer ring can be seen well at the slit lamp using the cobalt blue light. Preoperative sketching is also of value. Leukomas do not necessarily need to be totally surrounded, except in scars caused by herpes simplex virus in which removal of latent virus would seem desirable.

The Oculus Pentacam® is an anterior segment and corneal imaging device that uses a rotating Scheimpflug camera, which provides Scheimpflug imaging of the cornea, topography, pachymetry, tomography, and keratometric power deviation. This new technology is useful in diagnosing and following progression of



A



B

Figure 32.3. *A*, Corneal graft in patient with severely dry eyes secondary to sulfuric acid burns. Photograph shows early vascularization and clouding 15 months after corneal transplantation. *B*, Photograph of the same eye 2.5 years later. The patient had numerous bouts with persistent epithelial defects. This patient may have benefited from limbal transplantation before penetrating keratoplasty.

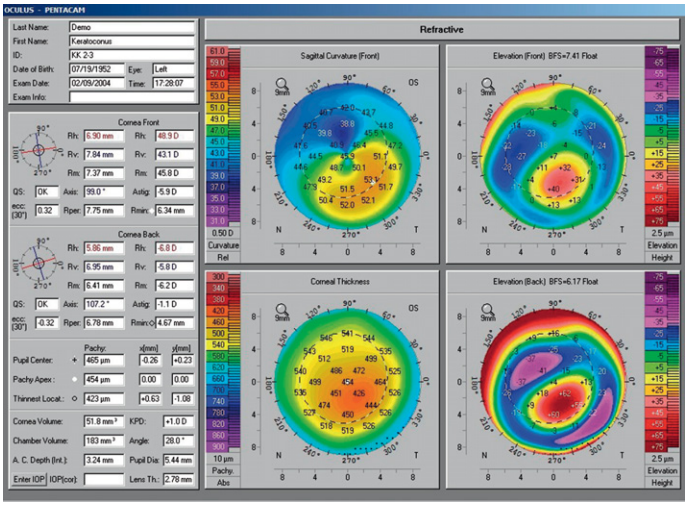
leukomas, Fuchs' dystrophy, keratoconus, and other corneal pathology that commonly leads to keratoplasty. This technology is also beneficial in postoperative care (Fig. 32.4, *A* and *B*). Optical coherence tomography is also available for corneal and anterior segment imaging. It can help to characterize corneal opacities, measure LASIK flap thicknesses, and give accurate anterior chamber angle measurements.

The condition of the host graft bed, its corneal thickness, and peripheral thinning must be assessed. Ultrasonic pachymetry should be performed to quantify thinning or thickening of the cornea. The presence of corneal vascularity dictates the graft sizing and suturing technique that best minimize the propensity toward vascularization of the graft and possible rejection. In eyes with a postinfectious leukoma without vascularization, or in corneal edema secondary to either Fuchs' or bullous keratopathy, the central visual axis should be the center of the donor button, with average diameters ranging from 7.5 to 8.5 mm. A diameter of 8 mm is usually a good average size for trephination, but, when overall corneal diameter is large, the surgeon should consider larger graft sizes. In most of the authors' patients, the donor cornea is oversized by 0.25 mm. In the keratoconus patient, to avoid inducing increased myopia, some

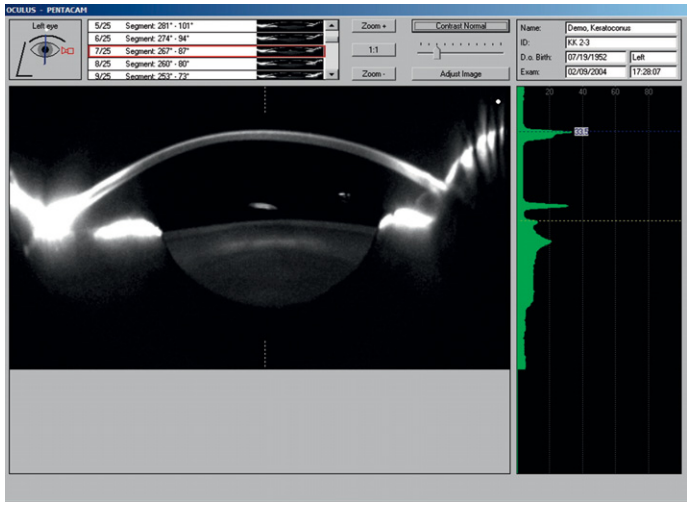
Table 32.1 Causes of corneal opacification and their prognoses for graft survival

Excellent Prognosis	*Diagnosis*
90% or more	Keratoconus
	Central Fuchs' dystrophy (early)
	Granular dystrophy
	Central or paracentral inactive scars
	Rotating grafts or autografts
Very Good Prognosis	*Diagnosis*
80 to 90%	Advanced Fuchs' dystrophy
	Pseudophakic bullous keratopathy
	Aphakic bullous keratopathy
	Inactive herpes simplex keratitis
	Macular dystrophy
	Interstitial keratitis
	Iridocorneal endothelial syndromes
Fair Prognosis	*Diagnosis*
50 to 80%	Active bacterial keratitis
	Active herpes simplex keratitis
	Congenital hereditary endothelial dystrophy and breaks in Descemet's membrane associated with birth trauma
	Active fungal keratitis
	Mild chemical burns
	Moderate keratitis sicca
	Lattice dystrophy
	Congenital glaucoma
Poor Prognosis	*Diagnosis*
0 to 50%	Severe chemical burns
	Radiation burns
	Ocular pemphigoid
	Stevens-Johnson syndrome
	Neuroparalytic disease
	Epithelial downgrowth
	Anterior chamber cleavage syndromes
	Multiple graft failures

This table is meant only as a guideline. The prognosis for each group is worsened by the presence of elevated intraocular pressure, intraocular inflammation, lid and conjunctival defects, and other ocular surface disorders. Failed grafts generally are considered to possess the prognosis for the group of their primary diagnosis, or slightly less. (From Brightbill FS, Corneal Surgery: Theory, Technique, and Tissue, ed 2, St Louis, 1993, Mosby.)



A



B

Figure 32.4. *A*, Pentacam® images showing topography, anterior elevation, corneal thickness, and posterior elevation. Note the decentered apex and the positive corneal elevation in the area of corneal thinning on both anterior and posterior elevation maps. *B*, Scheimpflug image showing the irregular contour of the keratoconic eye in the accompanying figure. Note the thinning of the cornea, and the irregular curvature.

surgeons will not oversize the donor button, and they even may use a smaller donor cornea.[14,15] In patients with postinfectious scarring with thinning and vascularization, or displaced corneal ectasia as in pellucid marginal degeneration, sizing and placement of the graft may be less straightforward, and some decentering may be required. The surgeon must decide the optimal sizing of the graft while avoiding areas of vascularization and peripheral thinning. Interrupted sutures may be indicated to allow for selective suture removal if the areas of vascularization become aggravated by the sutures (Fig. 32.5, *A* and *B*). In cases of corneal edema, an increased depth of trephination and deep suturing into the host bed to allow Descemet's membrane-to-Descemet's membrane graft–host approximation are important.

Anterior segment/iris

An anterior chamber lens must be identified as either an open- or a closed-loop lens. Iris-supported and closed-loop anterior chamber lenses should be replaced as should any open-loop anterior chamber lens when movement is suspected (Fig. 32.6, *A* and *B*).[16,17] Gonioscopy should be used to examine iridocorneal adhesions and peripheral iridectomies and to locate the positions of lens haptics if an anterior chamber lens is present. Ultrasound biomicroscopy reportedly aids in the evaluation of iris, lens, iridocorneal adhesions, and peripheral anterior synechiae in the cornea, with dense corneal scarring precluding direct visualization.[18] If the anterior chamber lens must be replaced, the patient's anterior chamber anatomy (i.e. the locations of posterior and anterior synechiae and of the residual lens capsule) will play a role in deciding the appropriate lens replacement type.

A thorough evaluation of the iris is important. The presence of rubeosis, fibrovascular membranes obscuring the pupil, and the locations of peripheral iridectomies must be noted. If the pupil can be visualized well, as mentioned previously, the presence or absence of a relative afferent pupillary defect should be documented. The presence of color visual perception also helps to rule out optic nerve damage.

During the ocular examination, it is perhaps most important to rule out active inflammation. In cases of elective transplantation, a

quiet, noninflamed eye offers the best chance for a favorable outcome. Ciliary flush, keratitic or intraocular lens precipitates, anterior synechiae, and iridocorneal adhesions all are signs of past or present inflammation, and they should be noted.

Lens

Before keratoplasty is performed, the patient's lens should be examined using the slit-lamp microscope. The lens may have weakened zonules, and it may exhibit phacodonesis. In many elderly patients, especially those with Fuchs' dystrophy, the lens may exhibit early cataractous changes that may signal the need for a combined keratoplasty and cataract extraction. It is the authors' belief that keratoplasty, perhaps aided by high-dose postoperative corticosteroids, is frequently a cataractogenic procedure. Triple procedures were routinely performed when even minimal lens opacities were present, to obviate the need for future cataract extraction, which may damage the endothelium and threaten the integrity of the graft. In a recent study, patients with Fuchs' corneal dystrophy with corneal pachymetry measurements less than 640 µm maintained useful vision after cataract surgery and were able to avoid keratoplasty.[19] With modern, less endothelial toxic cataract extraction techniques, the keratoplasty surgeon may be able to avoid the need for a triple procedure in Fuchs' dystrophy patients, depending on the preoperative lens opacity and corneal thickness. New techniques for endothelial transplantation without the need for penetrating keratoplasty will also affect the decision regarding the performance of triple procedures in the future.[20,21] Patients with chronic luetic inactive interstitial keratitis and scarring frequently do not present to the corneal surgeon until progressive cataract occurs, which necessitates a combined procedure.

In the treatment of eyes that have undergone previous cataract extraction, knowledge of intraocular lens design (anterior chamber, iris supported, or posterior chamber) or aphakia is critical to effective operative planning. The type of lens that was implanted will dictate whether it should be replaced. Important questions to answer include: is there a clear, intact posterior capsule, and has Nd:YAG capsulotomy been performed?

Intraocular pressure

The presence of borderline controlled or uncontrolled glaucoma is a contraindication to keratoplasty. Accurate applanation pressures in corneas with epithelial edema are difficult to obtain, and attempts may generate falsely low readings; the use of a Tono-Pen (Mentor Ophthalmics, Santa Barbara, CA), a pneumotonometer, or a MacKay-Marg tonometer is more accurate.[22,23] Intraocular pressure should be no higher than the low 20s with no more than two topical medications; otherwise, primary filtering or combined filtering and penetrating keratoplasty should be considered. Because all keratoplasty patients receive intraoperative viscoelastics to coat donor endothelium, to aid in the control of bleeding, and to help prevent synechiae,[24] eyes with pre-existent glaucoma usually require immediate postoperative oral ocular hypotensives and topical aqueous inhibitors to control intraocular pressure. The use of a lower-viscosity viscoelastic such as Healon® and its removal or dilution with balanced salt solution in the anterior chamber before final button placement and suturing are recommended. The long-term use of topical corticosteroids to prevent rejection may lead to steroid-induced glaucoma and requires careful intraocular pressure monitoring for the entire postoperative period. In our experience, long-standing chronic glaucoma with intraocular pressures in the low to mid-20s is a common cause of slow graft failure.

Retina/vitreous

Evaluations of both retinal function and the vitreous are required to ensure that decreased vision is secondary to problems with the cornea alone. Macular degeneration, cystoid macular edema, macular holes, and an opaque or hazy vitreous among other maladies are all conditions that do not improve after the keratoplasty procedure. Knowledge of such conditions before keratoplasty helps in prognostication; such information can often be obtained in examination of old records and discussions with the referring ophthalmologist. In cases in which there is a question, potential acuity meter testing, laser inferometry, or electrophysiologic testing may be tried, but these have limited sensitivity. If the retina and vitreous cannot be visualized using direct or indirect ophthalmoscopy, ultrasonography should be undertaken to rule out a retinal detachment, a retinal mass, or vitreous hemorrhage.

COMMUNICATION BETWEEN PHYSICIAN AND PATIENT WHEN EVALUATION IS COMPLETE

The keratoplasty patient is entering into a lifelong doctor–patient relationship—sound preoperative planning and open communication will help to make this relationship a fruitful one. The risks of

the procedure, the long healing time, the need for antiglaucoma treatment, and rejection rates should be addressed. The patient should be given realistic expectations for potential visual acuity and the time it may take to reach that acuity. The possible use of a contact lens, relaxing incisions, or wedge resection to reach best visual acuity should be understood by the patient before the procedure to ensure patient satisfaction in the postoperative period.

The procedure should be explained clearly using handouts, models, and/or videotapes as indicated. The authors' videotape, 'Patient Eye View,' is available through the Eyebank of Wisconsin, Inc.; it offers previous recipients' evaluations of their surgery, pre- and postoperative instructions, and education on drop instillation, eye care, and signs of rejection.

33 Gross and slit-lamp examination of the donor eye

William J. Reinhart

The majority of corneal transplant surgeons are no longer intimately involved with all aspects of eye banking. The surgeon places a request for tissue with an eye bank expecting that high-quality corneal transplant tissue will be procured, processed, and delivered to the operating room on schedule. Corneal transplant surgeons can request that limbal conjunctiva be retained for keratolimbal autografts; that the eye bank leave an adequate scleral rim diameter on the excised corneoscleral donor tissue, permitting the use of artificial anterior chambers for the preparation of lamellar endothelial donor grafts; and that accurate endothelial cell evaluation through slit-lamp biomicroscopy and specular microscopy has been performed prior to tissue being offered for transplantation.

Eye bank personnel have become increasingly professionalized, partly in response to the increased regulation by government agencies such as the Food and Drug Administration in the USA and as documented by training and certification through local, state, and national organizations. The main objective, of course, is to ensure that the recipient of corneal donor transplant tissue can expect that the donor cornea will function in an expected optical and physiologic manner and that the donor will not be the source of any potentially transmissible disease. The self-regulation of eye banks through national organizations, such as the Eye Bank Association of America (EBAA), provides additional assurance of quality and safety to transplant surgeons and the public.

Unlike many manufactured items, a donor cornea supplied by an eye bank to a corneal transplant surgeon has no warranty or guarantee. Indeed, most eye banks print a disclaimer on the donor information form, which states that the using ophthalmic surgeon is ultimately responsible for evaluating the donor tissue and determining its suitability for use. Most receiving surgeons, however, do not have access to a slit lamp in the operating room. The surgeon can only view the tissue in its storage chamber against background light to rule out gross infiltrates and under the objective of the operating microscope. Since most operating microscopes have coaxial illumination and do not have a slit-lamp attachment, this type of evaluation is not very satisfactory. This less-than-ideal examination would not usually allow the surgeon to detect a donor Descemet's membrane detachment or a low endothelial cell count. The tissue evaluation by the eye bank is, therefore, the only relevant one for most surgeons. It is also a given that the most diligent surgeon cannot examine a donor eye or excised corneal sclera rim and determine if the donor may have been septic or infected with a transmissible fatal virus (e.g. rabies or Creutzfeldt–Jakob disease), that antibiotics had not been added to the excised corneoscleral rim storage media, that storage and shipping conditions were less than optimal, etc. The surgeon's review of the donor information form is useful, therefore, only if all of the appropriate information has been actively sought and recorded by eye bank personnel. The using surgeon must trust the care, precision, and thoroughness of the eye bank team. This has been the goal of the Medical Advisory Board and the Accreditation Board of the EBAA in the USA to make sure that this trust is well placed.[1] Eye Bank organizations in other countries or regions play a similar role.

All eye banks certified by the EBAA must have an extensive procedure manual. The procedure manual must contain standard operating procedures (SOPs) for all aspects of operations of the individual eye bank. This includes operations such as 'potential donor screening,' 'procurement,' 'processing and preservation,' and 'evaluation.' Within these operations would be found SOPs for various procedures such as whole-eye enucleation, in situ corneal excision, whole-eye slit-lamp examination, laboratory corneal excision, slit-lamp biomicroscopy of the excised cornea scleral rim, endothelial specular microscopy of the excised corneal scleral rim, etc. Each procedure is a detailed document containing the purpose, responsibility, scope, definition, references, materials and equipment, policy, and the procedure written in such detailed fashion that a competent technician could ideally perform the procedure using only the manual as a guide. Such documents can be obtained on request from most EBAA-certified eye banks.[2]

PROCUREMENT

Donor corneal tissue may be obtained and stored before transplantation using the following techniques:

1. In situ corneoscleral rim excision with immediate transfer into storage media

2. Whole-globe enucleation with moist chamber storage
3. Whole-globe enucleation followed by laboratory corneoscleral rim excision with transfer to the following:
   a. Media for hypothermic storage at 4°C
      (1) Short term (e.g. M-K medium)[3]
      (2) Intermediate term (e.g. Optisol GS)[4–9]
   b. Media for organ culture at 30°C to 37°C[10–13]
   c. Cryopreservation[14–16]

All methods require a careful examination of the donor as well as an in situ examination of the donor eye and the orbit. When tissue has then been transported to the laboratory, an examination of the donor globe or excised corneoscleral rim, including a detailed slit-lamp examination and any additional studies such as endothelial specular microscopy, should then be recorded on an evaluation form prior to offering the tissue to a requesting surgeon.[17]

Whole-globe enucleation has long been the standard procurement procedure for donor eye tissue. However, with the increased number of well-trained eye bank technicians, in situ corneoscleral rim excision is becoming more common. In situ corneoscleral excision, rather than enucleation, often creates less friction with morticians since cosmetic restoration is less of an issue and is also sometimes more acceptable to donor families. The time from procurement to storage of the excised corneoscleral rim in preservation media, especially if the procurement site is in a location remote from the eye bank laboratory, is also significantly decreased if in situ excision is performed. The increased use of in situ corneoscleral rim excision does have some disadvantages. Most eye banks do not provide portable slit lamps for in situ evaluation of the anterior segment. If the donor tissue is judged unacceptable for transplantation on the basis of a slit-lamp examination of the whole globe in the laboratory, then the eye bank saves the cost of the preservation media, as well as the cost of a corneal storage viewing chamber(s) that would have been used if an in situ excision had been performed. The whole globes judged unacceptable for transplantation because of scars, corneal guttata, etc., which would not have been detected during an in situ evaluation, can also be offered for research protocols or practice surgery, an option not available if an in situ excision had been performed. Corneoscleral rims removed from whole globes in the laboratory also allow use of the posterior part of the globe for scleral preservation for transplantation, or for research protocols that only require the posterior globe, whereas an in situ excision obviously leaves the posterior part of the eye with the donor.

PHYSICAL EXAMINATION OF THE BODY

The eye bank technician must first ensure that the donor has been identified, that consent for tissue donation has been obtained, that eye and medical history screening has been performed and the appropriate forms filled out, and that the location for tissue procurement is appropriate. Screening for behavioral and medical high-risk factors by physical examination of the body is required. The technician should don personal protective equipment such as a gown, examination gloves, protective eyewear and a surgical cap. Visual inspection from donor head to toes involves looking for needle tracks, injection sites, and scars in all areas for evidence of IV drug abuse or high-risk behavior, paying close attention to the following areas: tattoo areas and/or skin lesions, brachial/radial veins and arteries, hands, and feet including the area in between the webs of the toes and fingers, external jugular, abdomen, thigh, calf, forearm, and upper arms. The rectal area should be examined for physical evidence of anal intercourse including perianal condyloma. The male and female genitalia should be examined for physical evidence of risk of sexually transmitted diseases such as genital ulcerative disease, herpes, syphilis, and chancres. All tattoos should be evaluated for possible age and origin. Evidence of acupuncture or body piercing, including pierced genitalia, should be evaluated. Comprehensive examples detailing some sexually transmitted diseases, homemade tattoos, and other pathology and their appearance are available for view by watching the EBAA—Physical Inspection CD-ROM.[18]

IN SITU EXAMINATION OF THE EYE AND ORBIT

The eye bank technician should perform a careful inspection of the orbital area of the donor. Examination of the periorbital and orbital tissues in cases involving facial trauma (e.g. vehicular accidents and homicide) may indicate how severely the eye itself may have been traumatized before death. The lids, lashes, and periorbital tissues should be carefully examined for signs of infection, such as styes, skin pustules, or accumulation of mucopurulent material on the lid margins and lashes from conjunctivitis. Details of the gross examination may help explain asymmetric findings on later slit-lamp examination and should be carefully recorded. Obviously, examination of the enucleated eye or excised corneoscleral rim in the laboratory cannot reveal any of these associated findings, which can be detected only by direct examination of the donor. The eye bank technician must be diligent, therefore, in seeking and recording this information.

When an enucleation is performed, in situ examination of the anterior segment of the eye is less important because careful gross and slit-lamp examinations are performed in the laboratory. However, a careful in situ gross examination may allow the enucleator to supply an educated guess as to the suitability of tissue for transplantation. For in situ corneoscleral rim excisions, however, a careful gross examination is very important. Since few eye banks include a portable slit lamp for in situ examination in their protocol, the technician must be adept at a careful penlight examination for two major reasons: (1) There may be important conditions involving the eye that could not be detected by laboratory examination of the excised corneal scleral rim alone. Some examples might include an eye that has undergone anterior segment surgery, such as cataract surgery, cataract intraocular lens implant surgery, and laser surgery involving the iris. Other conditions that might affect donor suitability (e.g. scleral rupture and congenital anomalies of the iris or lens) cannot be detected on subsequent laboratory examination of the excised corneoscleral rim. In addition, tumors of the anterior segment of the eye that would preclude transplantation must be identified.[19] (2) An evaluation of the degree of stromal folds and stromal edema can be more precisely assessed before placement in storage media containing osmotic agents, such as dextran, which decreases the stromal hydration of a previously swollen cornea. If an in situ gross evaluation of the eye raises any questions about transplant suitability, and if consent allows for either whole-globe enucleation or in situ excision, a whole-globe enucleation may be the safer choice since a more detailed slit-lamp evaluation can be conducted in the laboratory.

GROSS EXAMINATION

IN SITU

A penlight with fresh batteries is used to provide oblique illumination of the donor eye so that the technician, without magnification, can detect the following:

1. Epithelial edema (haze) and epithelial defects (exposure, trauma, and foreign bodies)
2. Stromal opacities:
   a. Arcus senilis
   b. Central corneal stromal scars
   c. Nonulcerated anterior stromal infiltrates
   d. Microbial infiltrates
3. Estimate of stromal edema:
   a. Clarity of cornea
   b. Number and severity of deep stromal folds (light, obvious, and heavy striae)
4. Keratitic precipitates
5. Abnormal corneal shape:
   a. Keratoconus
   b. Microcornea or megalocornea
6. Condition of the anterior chamber
   a. Formed, shallow, or flat
   b. Evidence of gross blood
   c. Abnormal anterior segment anatomy:
      (1) Congenital
      (2) Acquired (e.g. from intraocular surgery)
   d. Haziness of aqueous humor
7. Any evidence of corneal, lens, or other anterior segment eye surgery or injury

ENUCLEATED EYE

The examination is conducted in the same manner as described for the in situ examination except that the external posterior area of the globe can also be examined for abnormalities such as previous retinal detachment surgery. In addition, evidence of poor enucleation technique as manifested by traumatic corneal epithelial abrasions, retention of excessive orbital tissue, or lacerations of the globe may alert the laboratory to the possibility of a poorly trained enucleator. An excessive amount of corneal stromal edema may be explained if a globe has been improperly transported immersed in saline solution and may not necessarily negate use of the eye if adequate endothelial function can be inferred (e.g. through the use of specular microscopy).

SLIT-LAMP EXAMINATION

A careful slit-lamp examination of the donor globe or excised corneoscleral rim is the sine qua non quality control of a first-class eye bank before the release of tissue to the accepting surgeon. The major skill that eludes many technicians is the ability to adequately evaluate the corneal endothelium. The improved optics of a corneal storage viewing chamber will allow even the neophyte, however, to rapidly acquire the ability to evaluate the corneal endothelial cell layer in its entirety, which in turn will improve the detection of abnormalities that may require interpretation by the medical director. With acquired experience, the technician feels more confident in evaluating the corneal endothelium of whole globes or excised corneoscleral rims stored in bottles in which the optics and view make endothelial evaluation much more difficult even for the experienced technician or surgeon.

WHOLE-GLOBE EXAMINATION

1. Remove the eye jar lid and place it upside down in a sterile area such as a laminar flow hood or an ultraviolet lamp tissue transfer hood if the whole eye is to be shipped in the same container. Decant any excessive fluid from the jar and then clamp the jar in a viewing brace attached to the slit lamp. The eye in its holding cage should be brought forward using a sterile hemostat, sterile forceps, or sterile cotton-tipped applicators.
2. Using low magnification and either the diffuse illumination provided by a filter or a wide slit-lamp beam angled at 45°, examine the anterior globe. Major defects, which might be missed at higher magnification, are more easily identified at low magnification and then subsequently studied using higher magnification. In general, after an overall view of the eye has been obtained, the examination should proceed in a systematic fashion from the corneal epithelium back to the anterior surface of the iris, using first a broad and then a more narrowed slit beam for each aspect of the examination.
3. Adjust the microscope head and the slit beam so that they are almost coaxial, creating retroillumination which, with searching, may reveal defects or opacities in the stroma that may not have been noticed with an oblique slit.

Corneal epithelium

Microcystic edema, abrasions, and retained foreign bodies should be identified. Nonvital epithelium may have lost its adhesion to the underlying stroma and may have been rubbed off by lid action. If the epithelium is missing, it is necessary to carefully rule out stromal injury. Foreign bodies embedded in the epithelium should be carefully examined with a narrow slit beam to determine if they have penetrated into the corneal stroma. The interpalpebral area of the corneal epithelium, which may have been exposed before and after death, should be carefully examined for the presence of missing epithelium (Fig. 33.1), underlying evidence of stromal

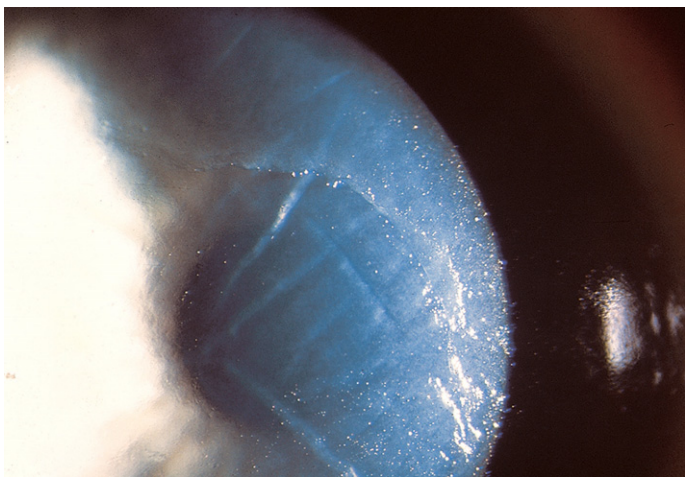

Figure 33.1. Edges of epithelial defect as shown in broad slit illumination. Mild stromal corneal folds also visible.

opacification, or inflammatory infiltrate. It is not always possible to distinguish between stromal scars, noninfectious stromal infiltrates and microbial infiltrates. In general, stromal scars have a more slate gray appearance without adjacent stromal edema, whereas microbial infiltrates have more discrete borders, adjacent stromal edema, and a white or yellowish white appearance. If the stromal opacity involves the central cornea, the cornea should not be offered for transplantation, whereas marginal opacities are primarily of concern if microbial infection cannot be ruled out. Unless it is obviously an inactive stromal scar, the medical director and using surgeon should make the final decision regarding acceptability for transplantation.

Corneal stroma

Major stromal opacities are identified with the gross examination, low-magnification scan, and retroillumination. Higher magnification using a narrow slit beam is used to define the extent, depth, location and appearance of stromal opacities in an attempt to characterize them as congenital or acquired inactive scars or as inflammatory infiltrates (Fig. 33.2, *A* and *B*). Corneal stromal folds are associated with stromal edema. There is a complex interaction between the barrier and pump function of the corneal endothelium that determines the degree of stromal hydration.[20] At 4°C, the pumping action of the endothelium ceases and the normal cornea swells. The anatomy of the cornea is such that most of the increased stromal hydration is accompanied by increased thickening of the cornea toward the endothelial cell layer, throwing the elastic Descemet's membrane into folds, which in turn lead to folds in the deeper corneal stroma. Thus, the number and severity of stromal folds depend on factors such as ante mortem endothelial function, traumatic disruption of the barrier function of the endothelium, and postmortem conditions such as temperature, elapsed time from death, and the integrity and hydration of the overlying corneal epithelium. An appreciation for what is normal helps the technician identify tissue that may have been improperly labeled by an outlying collection station or induces suspicion that the estimated time of death to examination time may be longer than indicated.

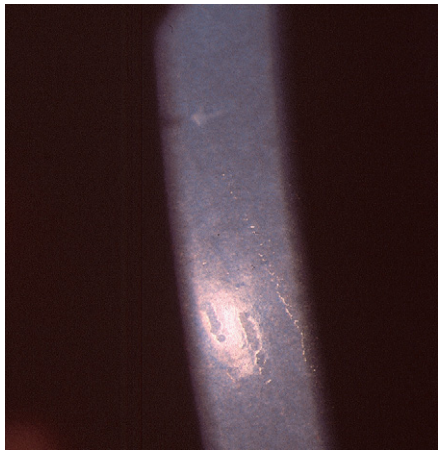
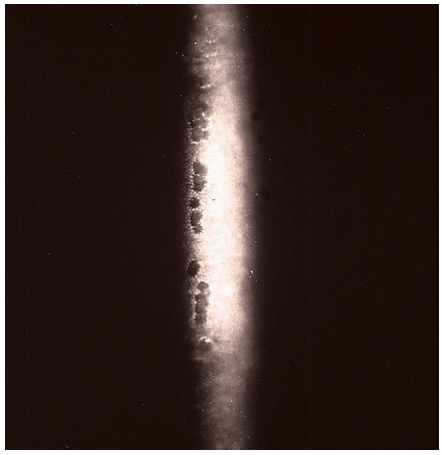
Corneal endothelium

The use of the slit-lamp technique of specular reflection for examination of the corneal endothelium in the whole globe is a skill acquired with practice and experience. The beginning eye bank technician can rapidly acquire experience by examining live subjects,[21] particularly those with Fuchs' endothelial dystrophy. The experience the technician gains in identifying the abnormal endothelial appearance of these eyes becomes invaluable when later attempting in vitro endothelial assessment in the eye bank laboratory. If the epithelial surface is dried out or irregular, placing a drop or two of an antibiotic solution on the anterior surface of the enucleated eye improves viewing conditions. The slit lamp is the most efficient and rapid means for the technician to determine the quality of the endothelial layer with respect to density of cells, the degree of cell uniformity, the intactness of the endothelial sheet and Descemet's membrane, and the detection of cornea guttata, endothelial vesicles, Descemet's tears, and stress fractures in the endothelial sheet from the trauma of excision (Fig. 33.3, *A* and *B*).

In general, eye banks do not determine the refractive status of the donor cornea, except in a research protocol, because it is not clear how that information would be used. Acquired disorders of corneal shape (e.g. keratoconus in its earlier stages) can be almost impossible for the eye bank technician to detect in the laboratory, although central cornea stromal thinning, deep stromal striae, and stromal scars should all be diligently sought on slit-lamp examination. A donor history of contact lens wear should prompt an even more exhaustive search for such slit-lamp signs of keratoconus. Of more concern is the increased prevalence of donors who may have undergone refractive corneal surgery with procedures such as radial keratotomy, epikeratoplasty, keratomileusis, LASIK, and excimer laser photorefractive ablation. The incisional scars of radial keratotomy, epikeratoplasty, and keratomileusis are usually visible on slit-lamp examination, although the change in corneal contour may be much more subtle. However, the anterior stromal scarring from laser ablation surgery and the very faint circular anterior stromal scars of LASIK surgery may be almost undetectable by ophthalmologists using the slit lamp to examine the eye in vivo, and so it is unlikely that an eye bank technician will be able to detect all such cases in the laboratory.[22,23] A donor history of refractive corneal surgery or keratoconus remains the most reliable means for screening out eye donors with abnormally shaped corneas. It is possible that topography techniques for either the in situ cornea or the excised corneoscleral rim can be adapted to screen for undesirable refractive properties of the donor cornea.[24–26] Viewing the excised corneoscleral rim in a viewing chamber against a light background using the unaided eye or low-power slit-lamp examination may be



A



B

used to detect unrecognized stromal opacities or the unequal transmission of light caused by corneal refractive procedures. Additional techniques for detecting corneas that have had refractive surgery such as LASIK or photoablation surface surgery have been evaluated, but there is yet no foolproof method for identifying such corneas.[27–29]

Anterior chamber

A crystalline-appearing aqueous in the anterior chamber may indicate that the eye has been frozen, and it should not be offered for use. The iris should be evaluated for evidence of prior trauma, laser surgery, intraocular surgery, or iris tumors. The presence or absence of the crystalline lens should be determined, and an intraocular lens implant, if present, should be identified.

Excised corneoscleral rim

Short-term storage containers are usually provided either as glass bottles or as a plastic viewing chamber, each holding approximately 20 mL of storage medium. Before corneoscleral rim excision and transfer, the expiration date and the clarity and color of the manufactured corneal storage media should be confirmed on slit-lamp examination. If there is an excessive amount of ciliary body debris in the medium after transfer of the excised corneoscleral rim, the

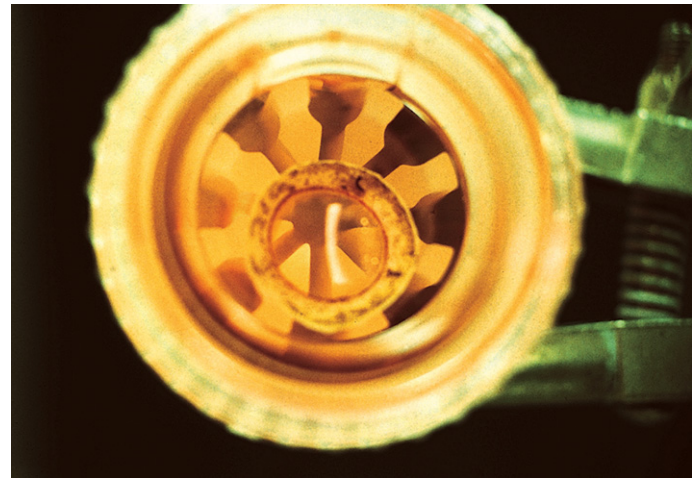

Figure 33.4. Excised corneoscleral rim in a corneal storage viewing chamber.

corneoscleral rim should be transferred to a new storage container. In a humid environment, condensation of moisture on the walls of the container may prevent adequate viewing if the container has been refrigerated. The glass vials may be clamped so that the cornea may be viewed through the bottom directly with a viewing mirror. Many technicians and surgeons prefer a corneal viewing chamber because the superior optical qualities allow more precise evaluation of the donor cornea, especially the corneal endothelium (Fig. 33.4).

The slit-lamp evaluation of the excised corneoscleral rim proceeds in the same fashion as described for the whole globe beginning with the epithelium and scanning back to the endothelium. If the same technician has performed the whole-eye slit-lamp examination and corneoscleral rim excision, the major effort is directed at detecting any evidence of epithelial or endothelial trauma as a result of the excision. Particular attention should be directed toward detection of Descemet's membrane detachments, which may be too small to be of any significance but should be pointed out to the accepting surgeon (Fig. 33.5, *A* and *B*).

EVALUATION FORM

Finally, a laboratory pro forma should be completed, detailing the findings noted.[17] Details regarding time of death, time of death to refrigeration, time of enucleation, transport time, warming time in the laboratory for specular microscopy or slit-lamp examination, and endothelial cell density determinations with an estimation of variation in cell shape (pleomorphism) and size (polymegathism) should be recorded on the donor information form along with the name of the examining technician or medical director and forwarded with the tissue to the receiving surgeon.

SPECULAR MICROSCOPY

Specular microscopy is very appealing to eye bank technicians because it allows for a seemingly precise determination of endothelial cell density and allows cornea guttata to be easily identified (Fig. 33.6). However, the area of the central corneal endothelium in a typical 8–8.5 mm donor button is much larger than any area that can be sampled by the specular microscope even with multiple-field examinations.[30] In addition, there may be a significant amount of rewarming time needed to allow viewing of the corneal endothelial

mosaic. A careful slit-lamp examination remains the most important means for assessing the overall character of the endothelial cell layer, and specular microscopy should be regarded as a supplementary tool. However, many eye banks and corneal transplant surgeons consider specular microscopy to be an essential part of donor corneal evaluation. In addition, specular microscopy may increase the willingness of surgeons to accept tissue from older donors and is required by the EBAA if the donor eye has had anterior segment surgery.[31,32] Standardization of endothelial cell density determinations is an issue for eye banks.[33,34]

Because many eye banks have a significant turnover in part-time personnel, the publications listed in the bibliography[35–38] are particularly didactic for the novice and can be recommended as permanent additions to the eye bank laboratory library.

Bonnie C. Weston

INTRODUCTION

Corneal transplantation has undergone numerous changes since Zirm performed the first successful human penetrating keratoplasty in 1905.[1] Incredibly, the graft remained clear, possibly due to the use of a human donor cornea from an enucleated eye. Although most early cases were not this successful, over time the procedure grew increasingly more predictable due to better operative techniques, instrumentation and suture material. Eventually, there was enough demand for tissue that Townley Paton opened the New York Eye Bank in 1959.[2] With the introduction of McCarey–Kaufman medium in 1974, tissue could be kept viable for days, making keratoplasty an elective procedure. These improvements have almost eliminated primary graft failure, and the most common reason for a failed graft is now immunologic rejection.[3] In turn, as techniques and medications improve, a greater number of high-risk transplants are being performed today. This has led to increased interest in the nature of corneal graft rejection and how it is affected by the donor tissue itself.

BASIC TRANSPLANTATION IMMUNOLOGY

When an animal receives a solid tissue allograft, unless the donor and recipient are genetically identical the tissue is recognized by the immune system as non-self. A process called rejection ensues, which involves the formation of specific antibodies and lymphocytes directed against the tissue. The cellular antigens causing this response are determined by a group of genes called the major histocompatibility complex, or MHC. In humans, these genes are called the human leukocyte antigens or HLA genes. The HLA system is a multigene family consisting of more than 10 loci coded on the short arm of chromosome 6.[4]

There are two major subclasses of HLA genes. HLA Class I comprises the HLA-A, HLA-B, and HLA-C loci. The antigens produced by these genes are found on almost all nucleated cells. These are transmembrane glycoproteins consisting of a small beta2 microglobulin associated with a heavy chain which has three globular domains on its extracellular portion. These domains are recognized by cytotoxic (CD8-positive) T cells.[5] HLA-A and HLA-B are considered the classical transplantation antigens. HLA-C is expressed at much lower levels and is not thought to play a role in rejection. HLA Class II includes the HLA-DP, HLA-DQ, and HLA-DR loci. The antigens these genes produce are found only on immune cells that cooperate with or present antigen to T helper cells. This includes B lymphocytes, monocytes, macrophages, and activated T cells as well as dendritic cells and Langerhans cells. Each molecule consists of two glycoprotein chains, both having an extracellular immunoglobulin-like domain. HLA Class II antigens are recognized by CD4-positive T cells. They are required for antigen presentation to Class II-restricted T cells, and thus they control the level of the immune response.[6]

The HLA system is important in solid tissue transplant rejection. Despite extensive study, rejection is still poorly understood for all types of organ transplants. Briefly, the immune response has two portions: the afferent arc and the efferent arc. There are multiple pathways for activation of both parts of the response. Sensitization of the host to the graft is initiated when dendritic cells, which display both Class I and II antigens, present antigen to recipient T helper cells.[7] The interaction causes release of lymphokines, which induce the formation of specific cytotoxic T cells and stimulate B cells to produce serum antibodies against the donor tissue. In transplant rejection, most of the damage is a result of cellular immunity, rather than serum antibodies.

HLA typing of donors was initially performed on serum with the microlymphocytotoxicity assay. Very small amounts of both lymphocytes to be typed and antisera of known HLA specificity are mixed and observed for cell viability. The test is done in a large microtiter tray to allow for the large number of known HLA alleles.[8] Due to some inaccuracy of this technique particularly for Class II antigens and cadaver blood samples, newer techniques were developed. Molecular typing with polymerase chain reaction (PCR) can detect much smaller DNA variations and is considerably more accurate than serology.[9] It has also led to a large increase in the number of known alleles at each locus. Molecular typing has since become the standard for HLA-DR typing.

IMMUNOLOGY OF CORNEAL TRANSPLANTATION

Corneal transplants represent a unique case immunologically. As corneal transplantation improved technically in the early 20th century, it was recognized that donor corneal tissue did not always opacify with time. Autografts were used if possible, as it was observed that they did well. Postoperative rejection was recognized as a distinct entity, differing from other types of graft failure, by Paufique and colleagues in 1948.[10] It was further described by Maumenee[11] and other authors. The phrase 'immune privilege' was introduced to describe the lower frequency and severity of corneal transplant rejection compared with other solid tissue transplants.[12] Multiple theories were proposed to explain this, but in 1948 Medawar provided evidence that it is primarily due to the lack of direct vascular supply,[13] and this has been supported by subsequent research. In addition, there are no lymphatic channels in the cornea. Combined, this delays both the afferent and the efferent arc of the immune response. It has also been proposed that anterior chamber-associated immune deviation (ACAID) plays a role in the low rate of rejection. However, this usually leads to suppression of delayed-type hypersensitivity, which does not appear to play a major role in experimental models of graft rejection.[14] More recently, there is evidence that the lack of antigen-presenting (Langerhans) cells in the central cornea may be an important reason for the low immunogenicity of the cornea.[15]

Despite these advantages, rejection does occur in a significant percentage of grafts. Rejection rates have declined from a high of 60% in early reports[16] to between 10 and 20% for most authors, but some of these are irreversible. The cornea expresses HLA antigens as well as minor histocompatibility antigens. HLA Class I antigens have been demonstrated in the corneal epithelium, stroma, and endothelium.[17] Class II antigens have been found in Langerhans cells within the epithelium, and many other corneal cells can be induced to express them in the setting of inflammation.[18] It is not known whether sensitization occurs in the recipient bed or the graft tissue, but Langerhans cells are a key component of the response. The activated T helper cells produce lymphokines that induce the formation of T lymphocytes targeted against the donor tissue. The mechanism of graft rejection must be extrapolated from experimental models and chronically rejected grafts. In corneal transplants, as in other transplants, cell-mediated immunity is thought to be most important.[19] However, humoral immunity probably plays a role in the tissue damage.

RESEARCH STUDIES ON HLA MATCHING

Tissue matching for keratoplasty was proposed on the basis of positive results for renal transplantation. The Collaborative Transplant Study was able to demonstrate increased survival for both new kidney grafts and regrafts. The improvement in transplant half-life was also significant.[20] If HLA matching of corneas were to decrease the incidence of rejection, it would be a goal worth pursuing. Rejection can lead to graft opacification and loss of vision, vascularization of the host bed, and sensitization of the host to foreign antigen. Irreversible rejection with loss of vision occurs in some patients, requiring repeat transplantation. If this could be prevented, the risk and cost of further surgery could be avoided in these patients.

HLA matching in corneal transplantation has been studied since the 1970s but remains controversial. Some early papers failed to show a benefit for HLA matching[21–23] but just as many demonstrated increased graft survival. Batchelor et al showed better graft survival with increasing number of HLA-A and HLA-B matches.[24] Ehlers and Kissmeyer-Nielsen[25] as well as Gibbs et al[26] showed that matching two or more HLA-A and HLA-B alleles led to a lower rate of graft loss due to rejection. Unfortunately, most early studies were retrospective, small and uncontrolled. Often these high-risk patients had very high failure rates due to other causes of graft failure, which tended to confound the results.

To address this, a number of small prospective studies followed, which again showed a benefit to HLA-A and HLA-B matching.[27–29] Boisjoly et al added HLA-DR matching to their protocol, which suggested a benefit to matching in high-risk transplants.[30] In 1985, a much larger, multicenter study, the Collaborative Cornea Transplantation Study (CCTS), was designed to clarify whether tissue typing is beneficial in high-risk keratoplasty. It was a double-blind prospective study, which investigated the role of crossmatching and HLA matching in graft survival.[31] In the Antigen Matching Study, patients received either a high antigen-matched (3–4 HLA-A or HLA-B or 2 HLA-DR), medium-matched, or unmatched cornea. At 3 years, the rates of graft rejection and survival were similar for both high and low HLA-A- and HLA-B-matched groups and for high and low HLA-DR-matched groups. In the crossmatching study, patients who had lymphocytotoxic antibodies on entering the study received either a negatively or a positively crossmatched cornea. After 2 years, both groups had a similar rate of graft rejection and survival.

The CCTS also investigated the importance of ABO blood group. The results showed similar rejection rates for ABO-compatible and ABO-incompatible corneas, but a higher failure rate from rejection for the incompatible group.

The results of the CCTS were not expected and were analyzed extensively. The most plausible explanation for the lack of effect is that the intense postoperative steroid regimen and follow-up schedule negated any benefit of tissue matching. There is a similar precedent in the solid organ transplant literature, where success can be heavily dependent on postoperative immunosuppression protocols. Recent evaluation of heart[32] and liver[33] transplants still does not support HLA matching, and thus allocation is often determined by need and tissue viability factors. It has also been suggested that studies carried out on homogeneous populations differ significantly from those done in the USA, where the ethnically diverse patients are not adequately matched by matching only major histocompatibility antigens. Minor histocompatibility antigens are expressed in the cornea[34] and can induce graft rejection experimentally even when major histocompatibility antigens are matched.[35] In addition, the HLA-DR testing in the CCTS was performed with serology, which has since been replaced by DNA techniques due to poor accuracy in cadaver blood samples. Later, repeat HLA typing of CCTS samples showed poor agreement with the original data.[36] A simulation by Volker-Dieben et al discusses the effect of errors in HLA typing on statistical results and demonstrates that even small errors in HLA typing can cause the effect of matching to be lost.[37]

Since the CCTS, the results of the crossmatch study have been upheld by Borderie et al. They followed 100 keratoplasties over 5 years. Twenty-eight percent of recipients had donor-specific anti-corneal stroma antibodies, but this did not affect rejection rate.[38] Roy et al were able to show a benefit to matching Lewis blood group antigens, but not ABO group antigens in unvascularized recipients.[39]

Not only high-risk patients have been shown to benefit from tissue matching. In 1990, Boisjoly et al were able to show a benefi-

cial effect of HLA matching (A, B, and DR) for low-risk patients.[40] In over 400 normal-risk patients controlled for other variables, Reinhard and coworkers were able to show that recipients matched for HLA-A, HLA-B, and HLA-DR had a rejection-free survival of 92% at 4 years versus 66%[41] for unmatched recipients. However, only combined matching was beneficial in this group.

The question of tissue typing is still a subject of study around the globe. Some of these studies were done in more localized areas in Europe and involved fewer surgeons, centralized testing, and more homogeneous populations. More recent studies also have the advantage of newer technology for tissue typing and matching. The majority have continued to show a benefit for HLA Class I matching. Volker-Dieben and colleagues performed a large study in the Netherlands. HLA Class I matching was performed prospectively and HLA-DR typing performed retrospectively on 1681 recipients done by one surgeon and typed serologically by one laboratory. Graft survival was significantly better in HLA-AB- and HLA-DR-matched grafts.[42] A small group of grafts was typed retrospectively using corneal tissue and DNA techniques by Bartels et al, and, again, HLA typing at the A, B, and DR loci improved graft survival.[43] Using DNA typing, Morita et al from Japan found a lower risk of rejection in grafts matched for HLA-A and HLA-DPB1[44] but not for HLA-B, HLA-DRB1, or HLA-DQB1.

The role of HLA Class II matching is less clear. A significant study, the Corneal Transplant Follow-up Study, examined data about 2777 grafts registered with the UK Transplant Support Service between July 1987 and June 1991. Vail and coworkers found that while there was a higher risk of rejection with a poor HLA Class I mismatch, those mismatched at HLA-DR had a lower rejection rate.[45] It is plausible that HLA Class II matching could lead to a higher risk of rejection because these molecules are necessary for antigen presentation. More efficient activity of antigen-presenting cells could possibly enhance the immune response in some cases.

CURRENT PRACTICE AND FUTURE TRENDS

In the USA, tissue typing is not routinely carried out for corneal grafts (personal communication, EBAA). The most significant reason is that the CCTS, which was carried out in North America, did not show a benefit to HLA typing. The time required to match donor and recipient is significant in a system that relies on liquid tissue preservation medium that lasts for 7–10 days; many surgeons are concerned about using tissue near the end of this period when it has suffered more potential oxidative damage or contamination. As well, the substantial increase in waiting time for the patient to find a tissue match is also a detriment in the USA, where waiting time for corneal transplantation is relatively short. However, as healthcare costs increase in the USA, services may be rationed and waiting times may increase. As well, the savings in repeat transplantation outweigh the cost of HLA typing. A few surgeons do wait for an HLA-matched donor for high-risk keratoplasty patients who have had multiple failed grafts. These are usually located through the Multiple Organ Retrieval Program.

In contrast, most eye banks in Europe use organ culture to sustain donor corneas.[46] This can maintain corneal viability for 4 weeks or more, which affords more time for tissue matching and locating the proper recipient. Approximately 50% of European eye banks perform tissue matching on a regular basis, for a small percentage of high-risk keratoplasty patients. Two German eye banks match all donors and recipients (personal communications, 2007). Although the wait for an HLA match can be significant, the lower number of failed grafts as a result of matching prevents these patients returning to the already long waiting list. Recently, more emphasis is being placed on the length of the wait and the ability to estimate it for patients.[47] This wait can approach years, and, for some patients with rare HLA types, a good match may never be found. The number of known alleles for each HLA locus has increased tremendously since the introduction of molecular tissue typing, increasing the difficulty of finding a good match. Recently, the concept of acceptable HLA mismatch has been introduced. Patients with certain HLA phenotypes mount stronger immune responses. Based on HLA phenotype, certain HLA mismatches may be well tolerated whereas others will be more immunogenic.[48] A computer algorithm, called HLAMatchmaker, examines the exposed portions of the HLA molecules and matches amino acid triplet sequences rather than entire HLA alleles. This allows matching without extensive serum screening.[49] When used to match a group of normal-risk keratoplasty patients, those with lower than 13 triplet-string mismatches (equivalent to 1 HLA allele mismatch) had a better graft survival than those with more. The advantage is a reduced waiting time for matched tissue, as more potential donors are identified with this method.[50]

SUMMARY

Graft rejection is now the leading cause of corneal transplant failure. Since tissue type plays an integral role in the immune response to allografts, tissue typing and matching would seem to be beneficial. However, studies have not shown this to be the case in all settings. As our limited understanding of the histocompatibility system grows, the reasons for this may become more clear. There is evidence that improved immunosuppression reduces the need for accurate tissue typing, which in turn may allow increased use of statistical tools to optimize acceptable mismatches. The rising cost of healthcare dictates that efficient allocation of resources be a priority in the future. Graft rejection leads to significant cost to society in terms of tissue preparation, surgical cost, and lost productivity for the patient. Minimizing this complication should be a priority for all transplant surgeons.

35 Corneal trephines, cutting blocks and artificial anterior chambers

Thomas John

INTRODUCTION

This is a very exciting time in the world of human corneal replacement surgery. There appears to be a tsunamic trend that is gradually gaining in momentum and driving the surgical techniques of corneal transplant surgery from full-thickness penetrating keratoplasty (PKP) toward sutureless corneal transplantation, with all its advantages of an intact host cornea without the full-thickness corneal wound and the absence of surgically induced corneal astigmatism. Further, the continued improvements and refinements in the surgical techniques bring sutureless corneal transplantation to the front stage. The new terminology introduced by the author, namely, selective tissue corneal transplantation (STCT), is defined as the selective removal of the diseased portion of the patient's cornea and its replacement with anatomically similar healthy donor corneal tissue.[1–3] With STCT, for endothelial decompensation, posterior lamellar keratoplasty (PLK) is performed, namely, descemetorhexis with endokeratoplasty (DXEK), while in corneal stromal and/or epithelial diseases with healthy endothelium, requiring surgery, an anterior lamellar keratoplasty (ALK) is performed.[2]

Whether it is PKP, which is the current gold standard of corneal transplantation (at the time of writing this chapter), or the sutureless (no corneal sutures) corneal transplantation, the need for trephines, cutting blocks, and artificial anterior chambers (AACs) continues to exist. These instruments transcend the borders and are useful for both techniques of corneal transplantation. This chapter will describe these surgical instruments and their surgical applications.

CORNEAL TREPHINES

The word 'trephine' refers to a circular or cylindrical saw,[4] a surgical instrument for cutting out circular sections, as of corneal tissue or bone.[5] By definition the use of laser technology, such as the femtosecond laser, to perform PKP is not to be considered a trephine and will not be covered in this chapter.

Trephine blades are used on both the donor and the recipient corneal tissue. It is used for both PKP and PLK procedures such as DXEK. These trephines can be broadly divided into two groups, namely those with suction and the others without suction. Although, historically, there are several types and models of trephine blades developed during the evolutionary stages of corneal transplantation, this chapter will mainly focus on the current trephines that are more popular and widely used among the corneal surgeons worldwide.

SUCTIONLESS TREPHINE

Suctionless trephines consist of a cylindrical metal blade that is sharp on one end and blunt on the other end (Fig. 35.1). These blades are used between two fingers of the surgeon, usually the thumb and index finger, and rotated in clockwise–counterclockwise directions to cut the recipient corneal tissue. It can be used on both the donor and the recipient corneas. On the donor corneal tissue, such trephines are used to cut the cornea from the endothelial side using a guillotine-type corneal punch. However, these trephine blades can also be used to cut the donor corneal disc from the epithelial side using an AAC (see below under AAC). When cutting the donor cornea from the corneal surface, the use of the trephine blade is terminated upon entry into the AAC and the rest of the cut is carried out using corneal microscissors. It is important to continually protect the donor corneal endothelium during the preparation of the donor corneal disk.

Although these suctionless trephines can be successfully used even on irregular, scarred host corneas, where suction trephines may fail to establish good suction, it is essential to remain perpendicular to the central cornea during the trephination. Maintaining a perpendicular orientation by viewing through the central opening in the trephine blade, while cutting the recipient cornea, will help minimize faulty angulation of the trephine and thus decrease the chances of an irregular cut-edge of the recipient cornea. A similar approach should be taken when trephining the donor corneal tissue from the epithelial side using an AAC. However, when trephining the donor corneal tissue from the endothelial side, it is helpful to use a guillotine-type corneal punch to obtain a more uniform cut-edge in the donor corneal disk. The wound edges, the cut-margin of the donor and recipient corneas, and the differences in the diameter of the donor corneal disk and the recipient corneal opening created with the trephination process

Figure 35.1. Photograph displaying multiple, suctionless trephine blades of varying diameters. (Photograph courtesy of Katena Products, Inc., Denville, NJ.)

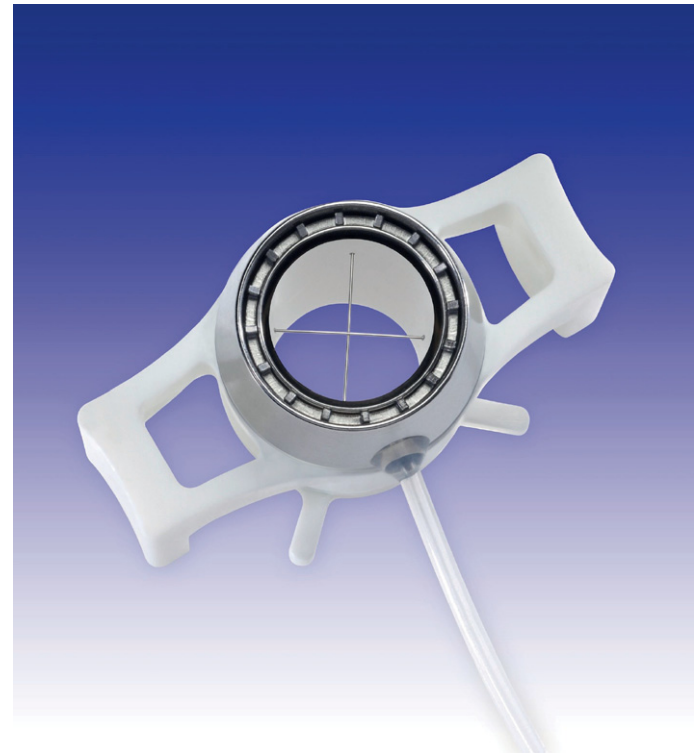

Figure 35.2. Barron radial vacuum trephine. (Photograph courtesy of Katena Products, Inc., Denville, NJ.)

will all play a role in the surgically induced postoperative corneal astigmatism.

These suctionless trephines can also be used with a handle. The handle is inserted into the blade opening from the end that is blunt, and the handle is tightened and then rotated to carry out the trephination. However, when a handle is used with these trephines, the central viewing of the cornea is no longer possible.

These disposable, individually packaged, sterile, donor trephine blades are distributed by the manufacturers for a single-time use. They are available in increments of either 0.25 or 0.5 mm, and the range of diameters will vary depending on the manufacturer.

SUCTION TREPHINES

Suction trephines are held in place by the vacuum and steadied by the surgeon's fingers during the trephination of the corneal tissue. Examples of suction trephines currently in use by corneal surgeons include the Barron radial vacuum trephine (Katena Products, Inc., Denville, NJ) (Fig. 35.2) and the Hanna trephine (Moria S.A., Antony, France) (Fig. 35.3).

CUTTING BLOCKS

Cutting blocks are used to prepare the donor corneal tissue for both PKP and DXEK. Similar to the trephines, the cutting blocks are also available with and without a vacuum device. The vacuum cutting blocks have the added advantage of holding the donor corneal tissue while the trephine makes the circular cut on the donor cornea. The cutting blocks are also available as a punch, where the trephine blade makes a vertical guillotine-type cut on the donor cornea. Figure 35.4 shows a Barron vacuum punch (Katena Products, Inc., Denville, NJ) that can be used on the donor corneal tissue.

ARTIFICIAL ANTERIOR CHAMBERS

The creation of an AAC[6] is a major milestone in the field of corneal surgery. The pre-AAC era dealt with using whole globes or a corneoscleral button that was wrapped tightly around a glass orbital implant for the lamellar graft dissection.[7] These AACs are used for both LKP and PKP. For PKP, the AAC is used to trephine the donor

Figure 35.4. Barron vacuum punch. (Photograph courtesy of Katena Products, Inc., Denville, NJ.)

cornea from the epithelial side such that a similar corneal circular cut is made both on the donor and on the recipient cornea if the same-diameter trephine blade is used.

The AAC was first described by Ward and Nesburn in 1976.[6] They described a way to trephine the donor cornea from the anterior surface when the donor corneal-scleral tissue (DCST) was mounted on an instrument that formed a seal around the scleral rim of the excised donor cornea, allowing the endothelium to be supported physically by the liquid storage medium.[6] Hence, the AAC protected the donor endothelial cells from damage as if they were still in the intact globe.[6] Since the initial description, various modifications and improvements in the AAC have been made, giving ophthalmic surgeons the ability to trephine to any desired donor corneal depth.[7–21] For lamellar corneal surgery, AACs may be utilized for both manual and automated lamellar dissection of the donor cornea using a microkeratome and the Moria ALTK system (Moria SA, Antony, France).

This chapter describes the various AACs that are currently available in the USA at the time of this writing.

SURGICAL OBJECTIVE

Lamellar corneal surgery

The surgical objective is to obtain a lamellar corneal disc of the desired thickness and diameter, an even surface with a uniplanar cut to augment the donor–host corneal interface, ease of operation, and avoidance of disc perforation.

Full-thickness PKP

The AAC is used to prepare the donor corneal disk, with the trephine cut being made from the corneal surface and protecting the donor endothelium within the AAC.

TYPES OF AAC

1. Reusable AAC
2. Disposable AAC

Reusable AAC

Reusable AAC, as the name suggests, can be used repeatedly provided care is taken not to damage the AAC unit by improper handling.

Types:

1. Moria AAC (manual), and Moria ALTK system (automated with microkeratome)
2. Bausch & Lomb (B&L) AAC (manual)

Moria AAC

The Moria unit for lamellar surgical procedures is called the ALTK system. It utilizes the Evolution3 console (Moria, Inc.) that is fully compatible with all Moria microkeratomes including the LSK, M2, and the CB units. However, currently, Moria is distributing only the CB unit with the Moria ALTK system, and it works very well with this AAC. The Evolution3 console has built-in safety features and provides ease of use for the surgeon and operating room staff. It runs on wall current and has a battery back-up for uninterrupted use. It has two high pumps that provide a quick and stable vacuum for the procedure.

The Moria ALTK system can be used for ALK (extraocular procedure) or for deep lamellar endothelial keratoplasty (DLEK) or for DXEK (intraocular procedures).

The DCST can be used for ALK using, preferably, the automated technique for the best interface (with microkeratome use) or alternatively if the ALTK system is not available in the operating room; then, the Moria AAC can be used for manual dissection of the donor lamellar disc. When using the AAC with manual dissection, the partial-thickness anterior lamellar dissection of the donor cornea can be performed after partial trephination to the desired depth using the Moria AAC and the Hanna trephine (Moria, Inc.) that is set to the required depth in microns. The Hanna trephine (Moria, Inc.) seats well on the Moria AAC and allows for stable partial-thickness trephination of the donor cornea from the epithelial side. This is followed by manual lamellar dissection of the donor corneal tissue. The same trephine with the same blade can be used on the recipient cornea for the same-diameter disc resection as that of the donor lamellar disc. Unlike the Moria ALTK system, with the Moria AAC there is no control of the amount of corneal tissue that is exposed within the ring. Hence, the diameter of tissue resection is determined by the diameter of the blade in the Hanna trephine. The Barron vacuum trephine does not seat optimally on the Moria AAC and hence proper trephination cannot be carried out with the Barron trephine in a Moria AAC.

For automated donor corneal lamellar disc, the Moria ALTK system is used, which utilizes both the Evolution3 console and the microkeratome described above. The Moria ALTK system utilizes a different design for its AAC (Fig. 35.5). This AAC has the capability of raising or lowering the mounted donor corneoscleral button (Fig. 35.5), thus altering the final diameter of the resected donor tissue. The diameter can be approximated by using the applanating lenses. The diameter by measurement on the donor cornea does not necessarily match exactly with the final resected donor lamellar disc. Hence, it may be better to resect the donor tissue first before using the microkeratome on the recipient cornea.

The Moria ALTK system consists of an artificial chamber that has a central post on which the donor corneoscleral button is placed with the endothelial side down, after applying viscoelastic material on the receptacle and the metallic rim and injecting corneal storage media (Optisol GS, Bausch & Lomb Surgical, Irvine, CA) from the donor corneal vial. Next the encasing cylindrical unit with the

Figure 35.5. The Moria ALTK system utilizes an AAC that has the capability of raising or lowering the mounted donor corneoscleral button, thus altering the final diameter of the resected donor tissue. (Reproduced with permission from Jaypee Brothers Medical Publishers (P) Ltd.)

Figure 35.6. Moria ALTK system showing sequential assembly for the Moria LSK microkeratome (left) and the Moria CB microkeratome (right). (Reproduced with permission from Jaypee Brothers Medical Publishers (P) Ltd.)

central opening for the cornea is moved into place, such that the three posts descend into the corresponding slots in the base of the AAC unit, taking care to maintain the central position of the donor cornea. Turning this encasing unit in a clockwise fashion locks it in place, and the donor corneoscleral button is now firmly mounted on to this AAC, with uniform pressure being applied to 360° of the scleral rim. The surgeon then titrates the intraocular pressure by injecting additional fluid from the attached syringe into the chamber and locking the valve if the pressure is low, or alternatively aspirating fluid from the chamber if the intra-chamber pressure is too high. The pressure can be checked by finger palpation or by using a Barraquer tonometer as needed. Next, depending on whether an LSK or CB microkeratome is used with this unit (currently only CB heads are distributed by Moria for the ALTK system), the appropriate ring is chosen and screwed on to the unit. The amount of corneal tissue being exposed is then adjusted by turning the rings and raising or lowering the central post (Fig. 35.5). The applanation lenses provide an estimate of the diameter to be resected, ranging from 6 to 11 mm. Figure 35.6 is a composite showing the set-up for the LSK microkeratome on the left and for a CB unit on the right. The LSK microkeratome or a CB microkeratome (Fig. 35.7) can be used to complete the lamellar excision of the donor corneal disc.

In summary, the three steps to the use of Moria ALTK system are as follows (Fig. 35.8):

1. The donor cornea is sealed within the AAC, and the intra-chamber pressure is adjusted to the required level.
2. The surgeon selects the desired diameter of the cut.
3. Lastly, perform the donor corneal resection.

The ALTK's adjustability and versatility reduce the incidence of induced corneal astigmatism. In this system the high-speed, high-power turbine (30000 cuts/min) creates a smooth keratectomy for a seamless-edge margin. The single-piece construction of the microkeratome heads are precalibrated for various depths of cut (130–400 μm).

Moria AAC for PKP

The Moria AAC is used to mount the donor corneoscleral rim with viscoelastic protection of the donor corneal endothelium. The intra-

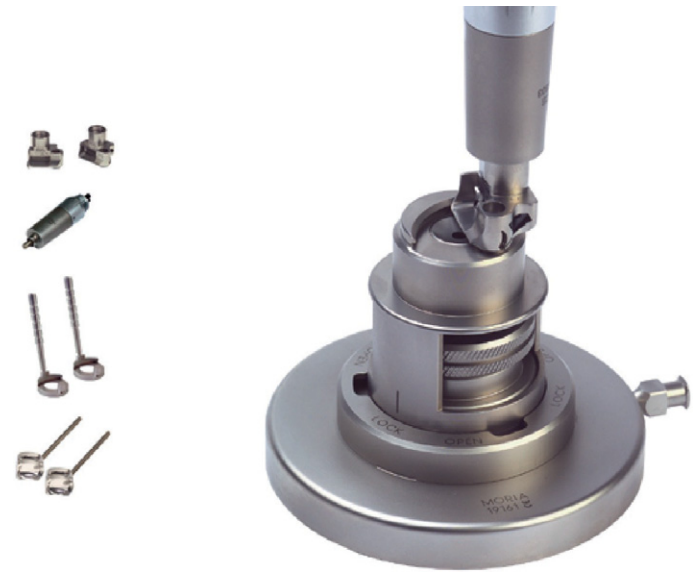

Figure 35.7. Moria CB microkeratome being used with the Moria ALTK system. (Reproduced with permission from Jaypee Brothers Medical Publishers (P) Ltd.)

chamber pressure is increased and checked with digital palpation (see above). Next, the Hanna trephine (Moria, Inc.) is used to make the full-thickness cut of the donor corneal tissue from the epithelial side. The Hanna trephine (Moria, Inc.) seats well on the Moria AAC. The same trephine with the same blade can be used on the recipient cornea for the PKP procedure. Alternatively, different-diameter trephine blades can be used on the donor and recipient cornea depending on the surgeon's preference.

Bausch & Lomb AAC

The B&L AAC (Fig. 35.9) can be used for manual dissection of the donor lamellar corneal disc. It is not designed for use with a microkeratome. The B&L AAC can be used for both PLK and ALK.

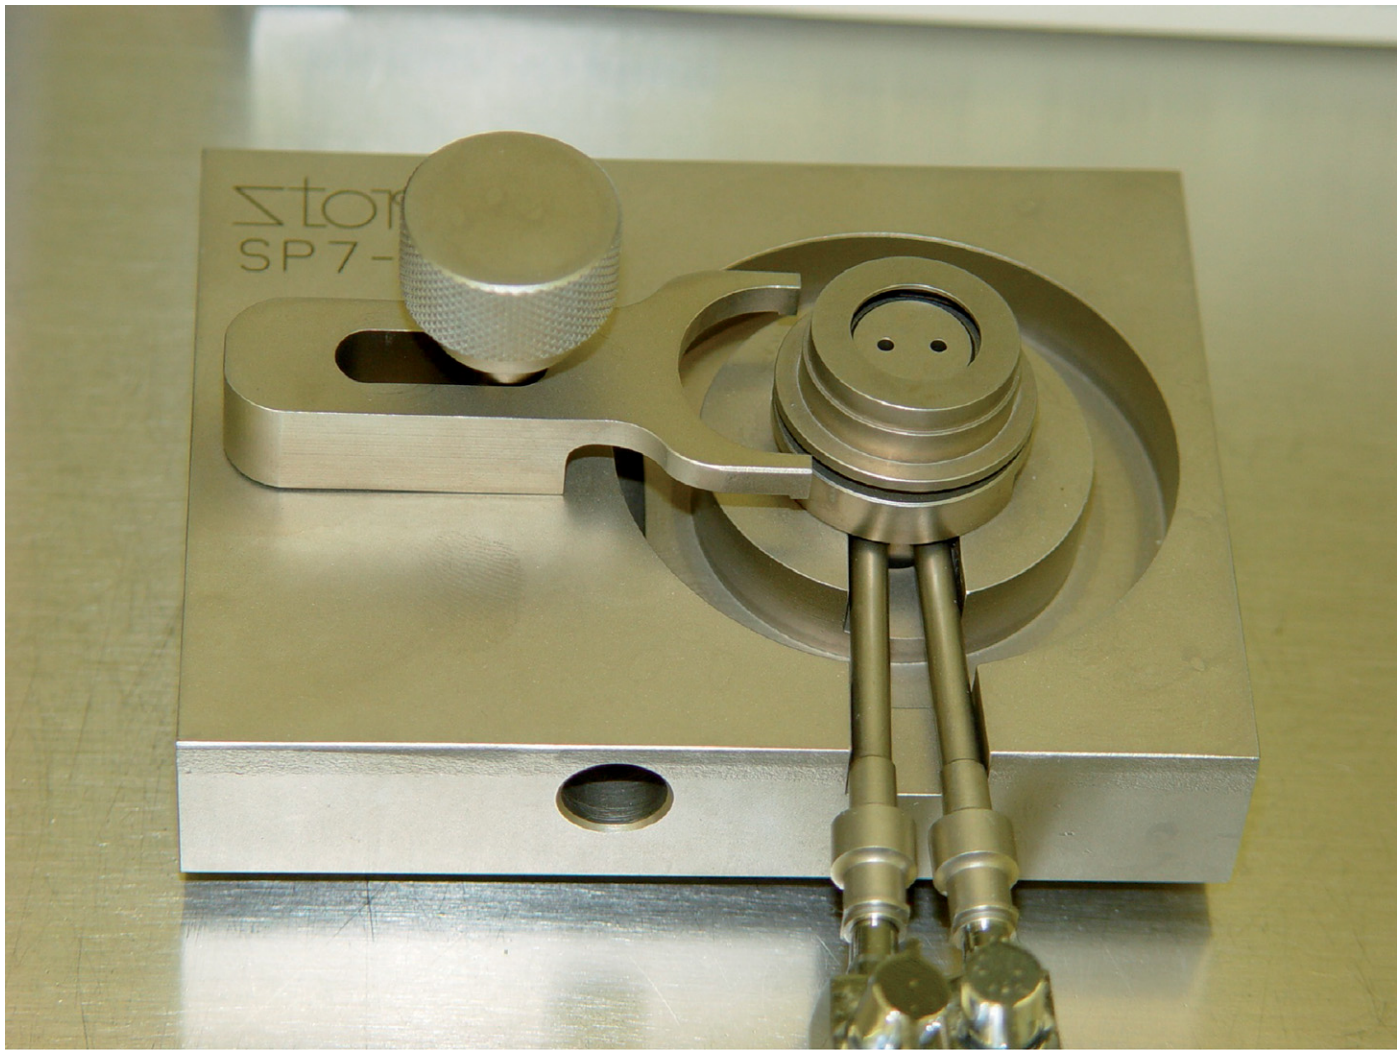

Figure 35.9. Bausch & Lomb AAC (Reproduced with permission from Jaypee Brothers Medical Publishers (P) Ltd.)

It consists of a solid metallic rectangular base with a central post on which the donor corneoscleral rim is placed with the endothelial side down, after applying viscoelastic material and fluid from the donor corneal vial. The central post has two openings for egress of fluid used to alter the intra-chamber pressure. The metallic base has a circular space surrounding the central post for collecting the fluid that egresses out of the two openings in the central post. Two metallic channels are attached to the central post on one end and to metallic valves on the other end where corneal storage media (Optisol GS, Bausch & Lomb Surgical, Irvine, CA) can be attached. Once the donor corneoscleral rim is placed on the central post and the intra-chamber space is primed with corneal storage media (Optisol GS, Bausch & Lomb Surgical, Irvine, CA), the circular fixation ring is placed over the donor corneoscleral rim and the C-arm is moved forward such that it is above the flange of the fixation ring. Once the C-arm is in its extended position, the screw is tightened and this fixates the donor cornea within the B&L AAC. The intra-chamber pressure is optimized by injecting fluid from the attached syringe and closing the valve to maintain the chamber pressure. The unit is now ready for lamellar dissection or for full-thickness cut. Unlike the Moria AAC where the fixation pressure on the donor corneoscleral rim is applied 360° directly from the top, in the B&L AAC the C-arm applies pressure only on the proximal 180° of the flange of the fixation ring, which in turn transmits the pressure to the scleral rim.

A Barron radial vacuum trephine (Katena, Inc.) of the desired diameter is placed on the moistened, epithelial surface of the donor cornea, and suction is applied to fixate the trephine. Partial-thickness trephination to the desired corneal depth is followed by lamellar dissection of the donor cornea to obtain a lamellar donor corneal disc. With the full-thickness cut, once the chamber is entered the trephine is removed and the circular cut can be completed with corneal microscissors.

Disposable AAC

Barron disposable AAC (Katena, Inc., Denville, NJ, USA)

The Barron AAC (Figs 35.10 and 35.11) is sterile, disposable, and comprises three pieces: a base with tissue pedestal, a tissue retainer, and a locking ring. The base has two parts with silicone tubing: in-line pinch clamps and female luer-lock connectors. Either port may be used to inject or aspirate balanced salt solution (BSS) and solution from the donor corneal vial, namely, corneal storage media (Optisol GS, Bausch & Lomb Surgical, Irvine, CA) viscoelastic, or air.

This AAC is a companion to the disposable Barron radial vacuum trephine. This AAC allows for trephination from the epithelial side. It is designed to hold a donor cornea (14–18 mm) on a bed of viscoelastic. The bright blue color of the unit provides a high-contrast background to view the donor cornea.

USEFUL SURGICAL SUGGESTIONS AND AVOIDING COMPLICATIONS

1. The corneoscleral rim that is obtained from the eye bank should have adequate scleral rim 360° (see below) for proper housing and fixation within the AAC of any kind. If the scleral rim is short on any one side, this will lead to tissue slippage, loss of intra-chamber pressure, fluid leakage from the unit with inability to perform an adequate lamellar dissection of the donor cornea, and a suboptimal full-thickness cut of the donor cornea.

Figure 35.10. Barron disposable AAC (Katena, Inc.). (Reproduced with permission from Jaypee Brothers Medical Publishers (P) Ltd.)

Figure 35.11. Barron disposable AAC (Katena, Inc.). (Reproduced with permission from Jaypee Brothers Medical Publishers (P) Ltd.)

2. If possible, the surgeon should have a back-up cornea available in the event of inadvertent damage to the first donor.
3. First dissect the donor cornea before operating on the recipient cornea.
4. If general anesthesia is used for surgery, the donor cornea can be prepared even before the patient is anesthetized. This will reduce the total time that the patient is under general anesthesia. Additionally, it will ascertain that a suitable lamellar corneal disc for LKP or full-thickness disc for PKP is ready for use even before the patient is anesthetized.
5. If there is tissue slippage and significant loss of intra-chamber pressure, then it may be advisable to abandon the lamellar dissection and use the back-up cornea. Dissecting without proper stabilization of the donor cornea within the AAC can result in multiplanar lamellar dissection, uneven interface, and, more importantly, possible perforation of the lamellar disc.
6. If using the Moria ALTK system, check the blade and the microkeratome head before use and lubricate with BSS to limit any mechanical epithelial damage to the donor cornea. However, in LKP procedures, the surgeon often will remove the epithelium prior to the microkeratome cut.
7. If using the Moria ALTK system, the surgeon should have prior experience with its use (e.g. LASIK surgery) or be trained and be familiar with its use for the donor cornea.
8. The Barron radial vacuum trephine usually does not fit on a Moria AAC, and hence use the appropriate matching units to facilitate and complete the procedure. A Hanna trephine will fit the Moria AAC and can be used routinely for this purpose.
9. The depth of cut on the Hanna trephine can be set in microns. With the Barron radial vacuum trephine, the depth is set by the number of quarter turns on its post.
10. For LKP, suitable lamellar dissection blades and knives should be available for the procedure.
11. In manual dissection, maintain a uniplanar lamellar dissection, by staying in the same plane of dissection until the disc is fully excised. This will help in attaining a better donor–host interface.
12. The intra-chamber pressure should always be checked before any trephination or lamellar dissection of the donor cornea. Adjust the intra-chamber pressure as needed by injecting or aspirating fluid via the attached syringe.
13. Maintain the intra-chamber pressure by closing the valve or applying the clamps provided with the unit.
14. The intra-chamber pressure may be checked digitally or with the Barraquer tonometer. Inadequate intra-chamber pressure will result in potential complications with the donor corneal tissue.

RESULTS AND CONCLUSIONS

We compared three AACs to determine the optimal sizes of DCST.[22] Twenty DCSTs were evaluated. The AACs tested were Bausch & Lomb, Moria AAC, and Moria ALTK. Twenty DCSTs were evaluated. The scleral skirt was measured from the limbus to the cut edge at four cardinal points (mean rim size 3.14 ± 0.61 mm; range 2.07–4.19). Donor corneoscelar tissues were mounted in the AACs; a target pressure of 65 mmHg was set using Barraquer tonometer. Tissue slippage with seal rupture before reaching the target pressure was considered a failure. The mean scleral rim sizes that maintained a seal and failed to maintain a seal, respectively, were 3.4 ± 0.7 mm (range 2.1–4.2) and 2.99 ± 0.51 mm (range 2.13–3.5). Using Optimal Data Analysis (ODA) techniques, we found that the DCST should have a minimal scleral skirt of 3.6 mm for successful use in an AAC for lamellar or PKP (epithelial approach).[22]

In summary, the currently available trephines, cutting blocks, and AACs greatly facilitate and improve the surgical outcomes for both full-thickness PKP procedures and lamellar grafts, namely both ALK and PLK surgeries. The introduction of the AACs into the field of corneal surgery has advanced the success rate of lamellar corneal surgery. Eye bank awareness and standardization of the required scleral rim size for lamellar corneal surgery are essential for successful outcome of the donor corneal tissue dissection and transplantation.

36 Viscoelastic materials

Matthew J. Thompson
Author Past Editions Jeremy E. Levenson

Viscoelastic materials (now referred to as ophthalmic viscosurgical devices, OVDs) have added a new dimension to corneal surgery. Although originally introduced into anterior segment surgery as a means of protecting the corneal endothelium during intraocular lens implantation,[1] these materials have now found an ever-expanding role in corneal transplantation. They offer an exquisite tool for both coating and protecting surfaces, for separating tissue spaces, and for avoiding adhesions after surgery. These features make OVDs an indispensable tool in the modern corneal surgeon's armamentarium, because they assist in the surgeon's overall goal of maximizing the survival of donor graft endothelium.

PROPERTIES OF VISCOELASTICS

Fechner[2] listed the following necessary characteristics of suitable OVDs:

1. Inert and isosmotic, sterile, nonpyrogenic, and nonantigenic.
2. Free of corpuscular elements (clumps) and optically clear.
3. Viscous enough to satisfy clinical needs.
4. Hydrophilic and able to be diluted so that most of the material can be irrigated out of the eye at the end of the operation and that the remains can leave the anterior chamber through the natural outflow channels.

Viscosity measures the resistance to flow of a solution. OVDs have a high internal friction caused by molecular attraction. At rest the long molecular chains coil on themselves. These spheroidal-shaped molecules resist movement when a force is applied. The degree of viscosity is a function of concentration, molecular weight, and the size of the flexible coils of the polymer in solution. Viscosity is the property of a viscoelastic that allows it to maintain space against vitreous (posterior) pressure. The viscosity of OVDs also varies with the rate of movement of the material, known as shear rate. In most cases, the viscosity decreases as the shear rate increases. Some viscoelastics, such as chondroitin sulfate, maintain nearly the same viscosity despite having varying degrees of force applied to them.

Pseudoplasticity is the ability of an OVD to transform, when under pressure, from a semisolid (gel) to a liquid state. As a force is applied, the spheroidal molecules unfold and, as soon as the initial resistance (viscosity) is overcome, the OVD flows with increasing speed as the shear rate increases. The pseudoplasticity of OVDs, like sodium hyaluronate, allows them to be injected through relatively small cannulas.

Viscoelasticity is the ability of a solution, once deformed, to return to its original shape, that is for the unfolded molecules to assume their spheroidal shape. Molecules with longer chains have greater elasticity than shorter-chained molecules. *It is the interaction of viscosity, plasticity, and elasticity that make OVDs such useful surgical tools for tissue manipulation.*

Cohesiveness is a measure of the degree to which a material adheres together. Highly elastic OVDs with a high molecular weight and large intertwined molecules are more cohesive. Cohesiveness is advantageous when attempting to irrigate an OVD from the anterior chamber during keratoplasty. Solutions of smaller molecules, such as chondroitin sulfate, are less cohesive and are often referred to as dispersive viscoelastics. As a mass, they tend to fracture easily, making them difficult to irrigate from the eye. The preference of cohesive or dispersive properties depends on the particular surgical application.

Coatability, that is the ability of an OVD to coat a solid, is a function of its surface tension and the contact angle formed by a drop of the substance on a flat surface. Solutions with low surface tension (Viscoat, Alcon) coat intraocular structures and surgical instruments better than high-surface-tension substances (Healon, AMO). Coating of tissue can be protective so long as the coating substance is not toxic. A low surface tension, however, results in a tendency for bubbles to form and can make the OVD difficult to irrigate from the eye.

The properties described above affect the clinical behavior of an OVD in terms of endothelial protection, tendency to increase intraocular pressure, ease of removal, space maintenance, coating ability, and flow characteristics (Table 36.1).[3–5] An ideal OVD would maintain space well, protect the corneal endothelium, and remain in the eye during surgery, yet be easy to remove at the conclusion of surgery. No one material is universally ideal. The unique properties of each material make it more or less suitable for a particular surgical application.

OPHTHALMIC VISCOSURGICAL DEVICE COMPONENTS

SODIUM HYALURONATE

Sodium hyaluronate was introduced into ophthalmic surgery as a vitreous substitute.[6] It is a polysaccharide with a high molecular weight composed of repeating disaccharide units of sodium glucuronate and N-acetylglucosamine. Sodium hyaluronate is found ubiquitously throughout the body and is present in high concentrations in the vitreous humor. It is obtained from several sources, including the dermis of rooster combs, umbilical cords, and cultures of streptococci. Each commercial preparation has the same structure but may vary in molecular weight, concentration, and shear rate.

Sodium hyaluronate has the highest molecular weight—in excess of 1 million—of the available OVD molecules. It is relatively viscous and pseudoplastic, allowing for good space maintenance and ease of both injection and removal. It is nonantigenic, nontoxic, and relatively noninflammatory and does not interfere with wound healing. Some studies indicate that it may actually facilitate wound healing through the modulation of various inflammatory cells.[6] The disadvantages are its low coating ability, tendency to elevate intraocular pressure, need for refrigeration, and high drag force on removal, which can damage endothelium.[7,8] All the viscoelastic materials tend to elevate intraocular pressure. Sodium hyaluronate elevates intraocular pressure as much as other viscoelastic materials and by some accounts more so.[9,10] Sodium hyaluronate has gained widespread acceptance by corneal surgeons, as attested by the many published reports of its use in corneal transplantation.[11–16]

The first commercially available OVD was sodium hyaluronate (Healon, AMO), introduced in 1980; it remains the standard by which newer materials are judged. Currently, there are several formulations of sodium hyaluronate (Table 36.2).

CHONDROITIN SULFATE

Chondroitin sulfate is a polysaccharide found naturally in harder connective tissue of the body, such as cartilage and the cornea, where it is bound to a protein as a proteoglycan. Unlike sodium hyaluronate, it is sulfated, resulting in an extra negative charge. This negative charge allows chondroitin sulfate to coat the positively charged tissue, intraocular lenses and surgical instruments more effectively and thus decrease the electrostatic interaction between the implant, instruments and endothelium.[17,18] Its safety and efficacy have been documented for the human eye.[19] It has a molecular weight of approximately 22 500 Da and is extracted from shark fin cartilage.

Chondroitin sulfate 20% was initially used successfully in coating intraocular lenses but, because of its low viscosity, was poor in space maintenance.[18] Increasing the concentration to 50% resulted in a hyperosmotic solution that caused endothelial dehydration and damage.[18,20] A 1 : 3 mixture of 4% chondroitin sulfate derived from shark fin cartilage and 3% sodium hyaluronate (Viscoat, Alcon) seeks to combine the advantageous properties of each individual material.

METHYLCELLULOSE

Methylcellulose 1% was introduced into anterior segment surgery by Fechner[21] as a coating for intraocular lenses. A 2% solution was found to be more effective in space maintenance[2] and is available as Ocucoat (Bausch & Lomb). The main ingredient is a highly purified brand of hydroxypropyl methylcellulose (HPMC) derived from wood pulp. Although the human enzyme systems supposedly cannot metabolize methylcellulose, this does not appear to be of any clinical significance when used in small quantities in the eye. It has been used in many combination cataract extraction and lens implantation operations without deleterious results.[2,22,23] The use of methylcellulose in keratoplasty with equally satisfactory results has also been reported.[16]

Methylcellulose has a low surface tension and contact angle, which increases coating ability, but has a lack of elasticity, which makes it more 'viscoadherent' than viscoelastic. It has been shown not to damage the endothelium.[20] Other advantages are its availability, ability to be autoclaved, low cost and ability to be stored and shipped at room temperature. Disadvantages include poor pseudoplasticity requiring a large cannula, difficulty in removal, and poorer space maintenance.

AIR

Intraocular air has some of the features of an OVD and, before the introduction of sodium hyaluronate, air was used to move tissues and separate spaces within the anterior chamber. It can be sterilized

Table 36.2 Properties of some viscoelastic materials

when it is passed through a millipore filter. However, air passes much more readily through a partially sutured wound and cannot maintain the anterior chamber against even moderate posterior pressure. It has been shown to have at least a slightly detrimental effect on the endothelium.[24–26] Although potential uses for air during corneal transplantation are discussed in this chapter, its use has been largely superseded by other OVDs.

COMMERCIAL VISCOELASTICS AND CLASSIFICATION

Each commercial preparation varies in (1) the chemical properties of molecular structure, molecular weight, concentration, pH, buffering agent, and osmolality and (2) the rheologic properties of viscosity, pseudoplasticity, viscoelasticity, and surface tension.[3,4,27] OVDs can be classified by material, viscosity, or cohesion dispersion. Previously there was a high correlation between viscosity and cohesiveness. With the introduction of several viscoadaptive OVDs, a new classification system that takes into account both viscosity and cohesion is necessary, as these two characteristics are not always correlated. Such a system of classification was proposed by Arshinoff and Jafari, which creates six classes of viscoelastics (see Table 36.3).[28]

HIGH-VISCOSITY COHESIVES

Healon (AMO) was the first commercially available viscoelastic, and its introduction revolutionized anterior segment surgery. Healon is a cohesive, high-molecular-weight and high-viscosity sodium hyaluronate derived primarily from rooster combs.

Provisc (Alcon) is a highly purified sodium hyaluronate obtained from fermentation and prepared to a specific target viscosity. It is equally useful and as safe as other sodium hyaluronate products derived from rooster comb dermis.[29]

Table 36.3 Viscoelastic materials

Zero-Shezr Viscosity Range	Cohesive OVDsCDI 30 (%asp/mm Hg)	Dispersive OVDsCDI 30 (%asp/mm Hg)
$7–18 \times 10^6$ (ten millions)	I. Viscoadaptives	I. Ultra high viscosity dispersives

Healon GV (AMO) has a high viscosity because of its higher concentration (1.4%) and higher molecular weight (5 million), making it more efficient at maintaining space.[30] However, the difficulty in removing this agent from the anterior chamber during keratoplasty combined with its high viscosity increases the possibility of serious postoperative glaucoma.[31] Consequently, it should probably be used during keratoplasty only under unusual circumstances.

Amvisc and Amvisc Plus (Bausch & Lomb Surgical) are both sodium hyaluronate products. Amvisc plus has a higher viscosity for improved space maintenance.

LOWER-VISCOSITY DISPERSIVES

Viscoat (Alcon) is a 1:3 mixture of 4% chondroitin sulfate derived from shark fin cartilage and 3% sodium hyaluronate that seeks to

combine the advantageous properties of each individual material. Viscoat is a dispersive viscoelastic that readily coats intraocular structures and remains in the eye.

Vitrax (AMO) is a low-molecular-weight, high concentration of sodium hyaluronate, dispersive OVD. AMO vitrax does not require refrigeration, which may be an advantage.

Ocucoat (Bausch & Lomb) is a preparation of 2% HPMC. Ocucoat has excellent coating ability and very little pseudoplasticity.

Cellugel (Alcon) is a preparation of 2% HPMC. Cellugel has a higher molecular weight than Ocucoat, which results in a greater viscosity and an improved ability to maintain space.

HIGH-VISCOSITY COHESIVE VISCOADAPTIVES

Healon 5 (AMO) is a viscoadaptive agent that seeks to combine cohesive and dispersive properties. It consists of 2.3% hyaluronic acid. It has a very high zero shear viscosity and pseudoplasticity. However, unlike other hyaluronic acid-based viscoelastics, under higher flow rates Healon 5 fractures, allowing it to remain in the eye during phacoemulsification. By using appropriate aspiration techniques, it can still be effectively removed from the eye.

HIGH-VISCOSITY DISPERSIVE VISCOADAPTIVES

Discovisc (Alcon) is a mixture of sodium hyaluronate and chondtroitin sulfate. This OVD has a high viscosity but also has dispersive qualities. This allows it to coat intraocular structures and remain in the eye during phacoemulsification, but it is easier to remove at the conclusion of the case with irrigation.[32]

OTHER VISCOELASTIC AGENTS

Other viscoelastic agents are available, and new agents are being tested or will be developed in the future. An understanding of their physical properties, as outlined above, will permit a good prediction as to their behavior during keratoplasty.

SURGICAL APPLICATIONS OF OPHTHALMIC VISCOSURGICAL DEVICES

An ideal OVD for penetrating keratoplasty would protect the new donor endothelium, maintain the space between the donor tissue and the rest of the anterior segment, and either be able to be left in place at the end of surgery without producing a rise in intraocular pressure or be easily irrigated from the eye.

Although the use of several OVDs in corneal transplant surgery has been reported in the literature, cohesive sodium hyaluronate-based agents such as Provisc or Healon appear to be the agents of choice for corneal transplantation. Their high viscosity provides good space maintenance, and there pseudoplasticity allows them to be introduced through a small cannula. Their cohesiveness aids in removal from the anterior chamber. The superior endothelial coating provided by other OVDs is not as great an advantage as with cataract surgery, because as soon as the donor corneal button is placed in the recipient bed, additional manipulation in the anterior chamber is minimal. However, one retrospective study by Miyata et al suggested that the placement of Viscoat on the corneal donor during and after trephination, along with the use of Healon to maintain the chamber intraoperatively, resulted in less endothelial cell loss than the use of Healon alone to coat the donor endothelium over a 12-month follow-up period.[33] The following potential application for these materials during surgery are based on published reports and on our experience and are summarized in Box 36.1.

BOX 36.1 APPLICATIONS OF VISCOELASTIC MATERIAL IN CORNEAL SURGERY

- Fill anterior chamber of whole donor globe to facilitate trephination
- Fill anterior chamber of recipient globe to prevent tissue damage and loss of aqueous fluid
- Firm whole eye before lamellar dissection
- Coat donor button to retard swelling
- Synechiolysis
- Tamponade hemorrhage
- Fill anterior chamber before placing donor cornea to protect endothelium, to prevent donor from falling into vitreous and to aid in suture placement
- Leave in eye after surgery to help avoid synechiae and prevent keratolenticular touch
- Aid in placement of posterior or anterior chamber intraocular lens
- Tamponade vitreous
- Assist in sealing corneal perforations by reforming anterior chamber before tissue adhesive is applied
- Protect epithelium while suturing

TREPHINATION AND PREPARATION OF DONOR CORNEAL BUTTON

Although it is much less common to trephine the donor button from a fresh, whole eye since the onset of widespread use of preservation media, an OVD can assist in the maneuver. Filling the anterior chamber with an OVD (less ideally, air) through a paracentesis opening allows more complete trephination without involving the underlying intraocular tissues. Alternatively, placing an OVD in the anterior chamber through the wound after initial trephination assists in the final cutting of the donor button with corneal scissors or a diamond knife.[16] In a like manner, an OVD can be used to firm up a whole eye before a lamellar corneal button is dissected.

Before the donor button is punched out from the endothelial surface of an excised cornea, an OVD used to coat the barrel of the trephine after the obturator has been retracted 4–5 mm from the cutting edge of the blade provides a protective cushion and a coating for the endothelium (Fig. 36.1).[34] If an OVD has not been used on the trephine, it can be placed directly on the donor button after punching and before placing balanced saline solution (Fig. 36.2). The viscoelastic material retards swelling of the button and thus assists in approximating tissues accurately during the suturing procedure, particularly if there has been a significant delay while the recipient eye is prepared.

TREPHINATION OF RECIPIENT EYE

After the initial trephination and just after the anterior chamber is entered, an OVD can be placed through the wound (Fig. 36.3). By helping to maintain the anterior chamber, the material also helps in making completion of the excision of the recipient button with scissors or a diamond blade easier and safer by offering some

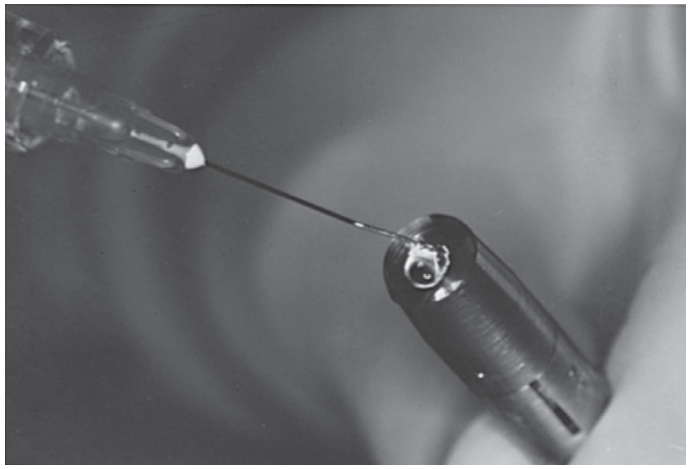

Figure 36.1. Viscoelastic material is placed in a barrel of trephine.

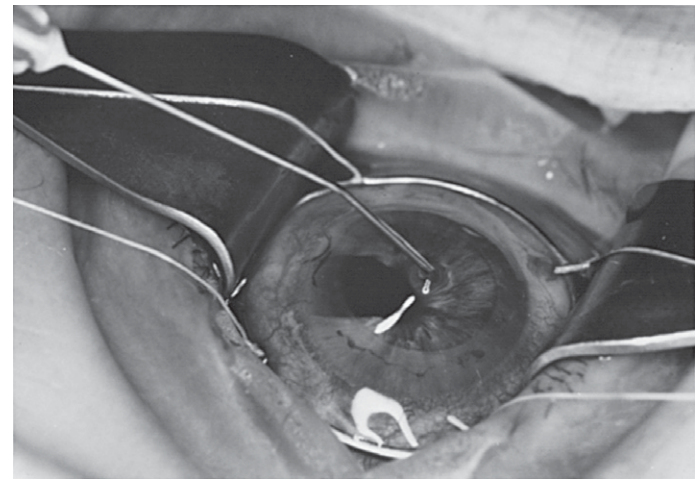

Figure 36.4. Anterior chamber is filled with viscoelastic before the placement of a donor button in the recipient bed.

protection to the underlying iris and lens. Such a technique is particularly helpful in cases such as keratoconus, where the floppy cornea tends to collapse posteriorly, distorting the wound.

Gruber et al[35] have recommended filling the entire anterior chamber through a paracentesis opening before trephination. With the chamber filled with an OVD, it is much safer to perform a through-and-through, 360° trephination with less risk of damaging the underlying tissues.

A relative disadvantage in placing an OVD in the anterior chamber at this stage of the procedure arises in an aphakic eye where it is not certain beforehand that a vitrectomy will be necessary. In general, formed vitreous can be distinguished from a viscoelastic by the tendency of the former to adhere to a cellulose sponge producing signs of traction, whereas the latter drops away. With an OVD present, a small prolapsing vitreal strand in the anterior chamber may be hidden, giving the false impression that a partial vitrectomy is not needed.

PHAKIC GRAFTS

Studies have shown that the manipulation of the donor button during suturing and the rubbing of the button against the iris diaphragm cause endothelial cell loss, especially in phakic grafts.[35,37] Filling the anterior chamber with an OVD before placement of the donor button in the recipient bed (Fig. 36.4) has a beneficial effect on postsurgical graft edema and therefore presumably on endothelial survival.[11–16] An OVD material tends to stabilize the donor button, making suturing easier and preventing contact with the iris.

PSEUDOPHAKIC GRAFTS

Corneal transplantation over a previously implanted intraocular lens, particularly of the anterior chamber variety, requires special precautions, because even transient contact between a polymethylmethacrylate lens and the posterior surface of the graft produces immediate damage to the endothelium because of the adherence of the cell membranes to the plastic.[38,39] In the past, the use of various transanterior chamber struts and stay sutures to hold the intraocular lens posteriorly and to allow an air bubble to be maintained between the lens and the endothelium of the graft proved helpful in these cases.[40] A much simpler and more effective method involves coating the lens with a layer of an OVD before placement of the donor button in the recipient bed (Fig. 36.5).[14–16]

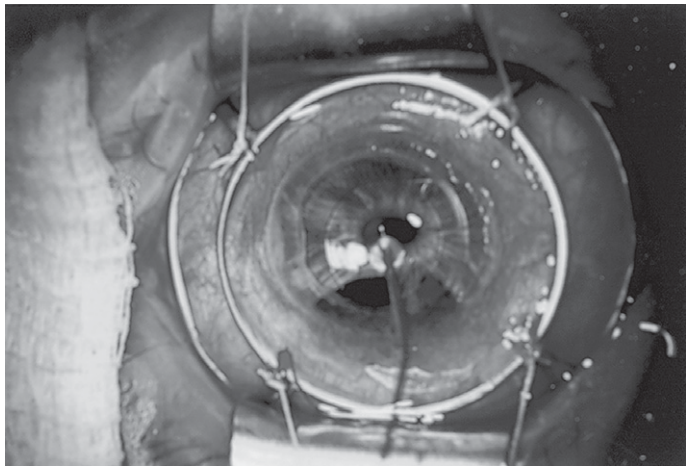

Figure 36.5. The anterior chamber of the intraocular lens is coated with viscoelastic before suturing in the donor button.

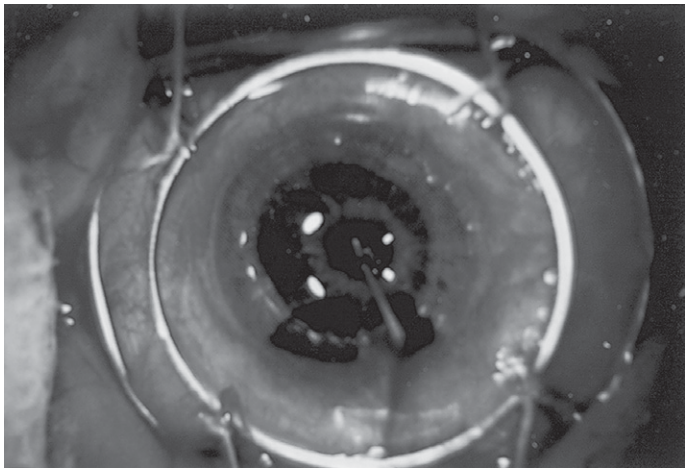

Figure 36.6. Viscoelastic is placed over the pupil and iridectomy sites.

Alpar[11,41] showed that the use of sodium hyaluronate in pseudophakic corneal transplants produced thinner grafts with less cell loss when compared with a control group in which air and balanced saline solution were used. In the author's experience, an OVD placed over an intraocular lens has allowed successful corneal transplantation even when the anterior chamber has collapsed because of posterior pressure, a situation that may otherwise require removal of the implant if an OVD had not been used.

TRIPLE PROCEDURES

Cataract extraction with intraocular lens implantation at the time of corneal transplantation can be facilitated by an OVD, both to protect the graft from the lens after it is in place and to assist with the lens implantation itself. As in a standard cataract operation, in-the-bag placement of an intraocular lens at the time of keratoplasty is greatly facilitated by use of a capsulorrhexis procedure to perform the anterior capsulotomy. If the opening cannot be made large enough to allow expression of the nucleus safely, an open sky emulsification can be performed. An OVD can be helpful in assisting in removal of the nuclear fragments after the nucleus has been fractured into smaller pieces. After removal of the nucleus and cortical cleanup, an OVD can be used to elevate the anterior capsular flaps, facilitating in-the-bag insertion of the posterior chamber lens. If sulcus fixation is considered desirable, or if too much posterior pressure causing anterior displacement of the posterior capsule makes sulcus fixation the safest alternative, an OVD can be used as a tool to separate the iris from the posterior capsule. This makes lens insertion easier and safer. Other uses in cataract extraction are reviewed elsewhere and include tamponading breaks in the posterior capsule before placing an intraocular lens, removal of intraocular lenses, preventing and repositioning iris prolapse, hydrodelineation of nucleus and cortex, keeping the pupil dilated, and repositioning or repairing a detachment of Descemet's membrane.[42,43]

APHAKIC KERATOPLASTY WITH AND WITHOUT SECONDARY LENS IMPLANTATION

In aphakic keratoplasty with an intact, posteriorly positioned vitreous face, placement of an OVD in the anterior chamber either before trephination through a paracentesis opening or just after trephination helps to reduce the chances of vitreous prolapse and the need for an anterior vitrectomy. When an anterior vitrectomy has been performed, an OVD can be placed over the pupil and iridectomy sites (Fig. 36.6). The weight and viscosity of the material act like a cork in a bottle, pushing back and keeping the vitreous posterior to the iris, thus preventing a stray strand of vitreous from prolapsing into the anterior chamber and possibly adhering to the wound during suturing of the graft. An air bubble in the anterior chamber can be used for the same purpose. However, care must be taken because accidentally trapping a large air bubble in the posterior chamber behind a constricted pupil can make adequate reformation of the anterior chamber impossible.

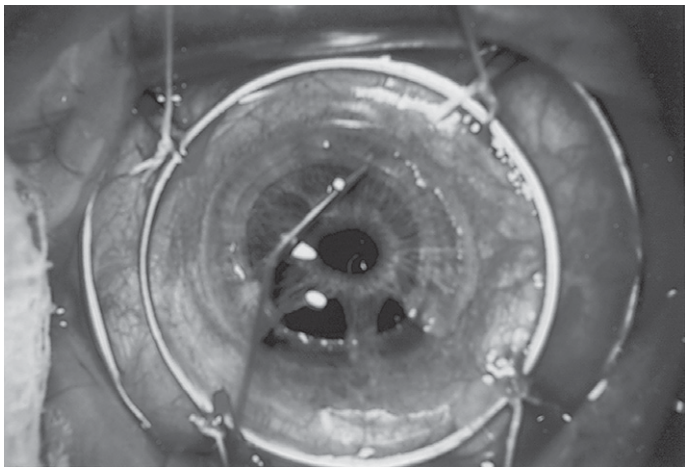

Figure 36.7. Viscoelastic is placed into the chamber angle.

If secondary lens implantation is performed, an OVD in the posterior chamber helps prevent vitreous prolapse and traction during the maneuvers necessary in the placement of an anterior chamber lens through the central trephine opening. A small amount of an OVD placed in the chamber angle assists in the proper placement of the 'feet' of the anterior chamber lens to prevent entrapment of the iris with consequent pupillary distortion (Fig. 36.7). Placing an OVD in the posterior chamber is also helpful before suturing in a posterior chamber lens to avoid vitreous traction and prolapse. A layer of the material should also be placed over the implant before placement and suturing of the donor button.

SPECIAL SITUATIONS

An OVD can be helpful in several special situations that may arise during the operative procedure. Bleeding may occur in such situations as lysing synechiae or removing an intraocular lens, particularly a flexible anterior chamber lens whose haptics have become enmeshed in fibrous adhesions. OVDs tend to localize blood in the angle and keep it from passing through the pupil into the vitreous in aphakic eyes. They also appear to tamponade oozing from capillaries, although it is not effective against more pronounced bleeding.[43,44] Such bleeding should be controlled before an OVD is introduced because the presence of blood mixed with sodium hyaluronate in the anterior chamber is prolonged.

When anterior synechiae to the wound are noted after suturing of the graft and filling of the anterior chamber with balanced saline solution, it is important to release these adhesions before surgery is finished because they may be progressive and lead to compromise of the angle. A fine cyclodialysis spatula or a cannula attached to a syringe filled with balanced saline solution or air can be used to sweep away the synechiae, but this is not without some risk to the endothelium of the graft and to the lens. A much more elegant method is to use an OVD introduced through the wound or through a paracentesis opening as a tool to push the iris away from the back of the cornea.

A situation that involves elements of both the aforementioned problems and where an OVD may make the difference between successful surgery and a disaster arises when a graft is placed on an inflamed eye. The irides of such eyes tend to ooze blood and, more significantly, fibrin, which causes the iris to adhere to the peripheral area of the cornea. If not released, these adhesions lead to difficulty in controlling glaucoma. An OVD can be used to separate the 'sticky' iris from the corneal rim and reform the angle before placement of the donor button in the recipient bed. Although not completely effective, a layer of such a material between the iris and the cornea in the immediate postoperative period may decrease the incidence of late-forming anterior synechiae. Usually, it is best to leave the material in the eye at the end of surgery and deal with any secondary glaucoma medically.

An OVD combined with a cyanoacrylate tissue adhesive can be used to restore the anterior chamber after a corneal perforation.[45] Introducing the OVD through a paracentesis tract, if possible, or directly through the wound allows repositioning of the iris, releasing of anterior synechiae, and the reformation of the anterior chamber. After removal of any excess material appearing about the surface of the cornea, which would interfere with adherence, the opening is sealed with a tissue adhesive. Maguen et al[46] used this technique to obtain normotensive eyes after perforation. A primary corneal transplant can then be safely performed, giving a better tectonic result and shorter visual rehabilitation. A lamellar graft at this point is another option.[47] Other uses of OVDs in anterior segment trauma have been reviewed[48] and include restoring the pressure and shape of the globe, evacuating hyphemas, removing foreign bodies, controlling bleeding, and manipulating tissues to restore anatomy.

OPHTHALMIC VISCOSURGICAL DEVICES IN LAMELLAR GRAFTS

Several papers have described the use of an OVD such as Healon to separate Descemet's membrane from the overlying stroma in deep anterior lamellar keratoplasty. The maintenance of the space overlying Descemet's membrane with an OVD reduces the risk and anterior chamber entry.[49,50] Prolonged detachment of Descemet's membrane resulting in need for penetrating keratoplasty has been described as a complication of this technique with OVD retention.[51] The use of air has also been described to separate Descemet's membrane from the overlying stroma.[52]

PREPARATION OF TISSUE WITH INTRALASE FOR POSTERIOR LAMELLAR KERATOPLASTY

An OVD can be used when preparing the donor disk in a hand dissected posterior lamellar keratoplasty (PLK). When preparing a donor button Descemet's stripping automated endothelial keratoplasty (DSAEK) with the femtosecond laser from the endothelial side, the use of an OVD to protect the endothelium from being damaged by the applanation process was described by Sikder and Snyder.[53] They utilized Ocucoat, Viscoat, and Healon in the study.

PROTECTION OF EPITHELIUM

Placement of an OVD on the donor button during suturing is very effective in protecting the epithelium (Fig. 36.8). Although it may make suture material more difficult to manipulate and may decrease visualization, it relieves the need for constant irrigation of the donor button with balanced saline solution, which can be traumatic to the epithelium.

GENERAL PRINCIPLES AND TECHNIQUES

Materials with less elasticity, such as Viscoat, require a larger cannula (such as = 25 gauge) for injection. These are generally supplied commercially with the material. Only syringes with a Luer-Lok system should be used to avoid the cannula being inadvertently propelled into the eye. The material should be flowing and all air bubbles expressed from the syringe before entry into the eye. A slow injection tends to avoid trapping air, fluid or debris. If an air bubble is desired, it should be placed anterior to the material. Intraocular medications should be instilled posterior to the viscoelastic material to minimize endothelial toxicity. Avoid over-

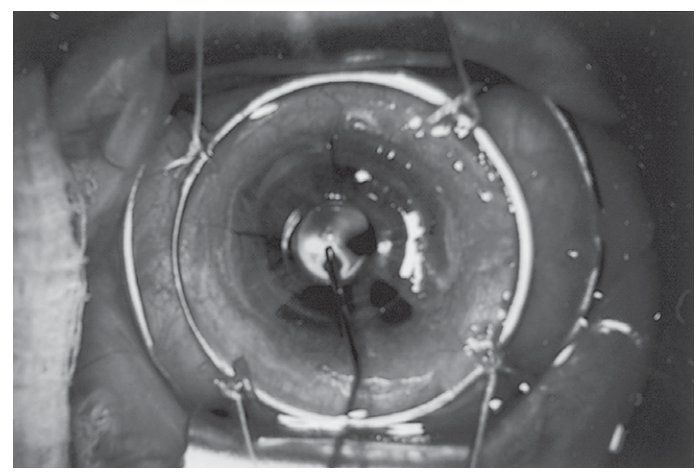

Figure 36.8. The donor epithelium is coated for protection during suturing.

filling the eye and placing the viscoelastic where it cannot be removed easily.

POSTOPERATIVE COMPLICATIONS AND REMOVAL OF OPHTHALMIC VISCOSURGICAL DEVICES

The major complication from the use of OVDs is the development of postoperative intraocular pressure rise.[14,15] The mechanism is complex and related to decreased outflow facility.[6] It may be modulated by individual variations in trabecular pore size and charge, by the amount of fibrin and inflammatory debris present that are pushed into the trabecular meshwork, or by simple mechanical blockage.[4]

Clinically, intraocular pressure peaks at 4–7 h and generally returns to preoperative levels by 24 h.[6,20,54] Alpar[11] reported an average pressure rise of 10 mmHg in a group of cases in which sodium hyaluronate had been used when compared with a control group. This amount of intraocular pressure elevation is fairly typical for most OVDs. The literature comparing the relative pressure elevating effect of all the available OVDs conflicts somewhat.[9,10] The variability of the reported results probably reflects differences in case selection, aggressiveness of agent removal, time interval at which the initial pressure measurement is taken, and other factors. The best consensus seems to be that despite their differences in physical properties, most of the available OVDs have a similar likelihood of causing elevated intraocular pressure.[55] In those studies where a difference has been reported, the higher molecular weight agents, such as Healon[56] and Healon GV,[57] have caused a greater and longer sustained pressure rise in some patients. In a study by Burke et al comparing IOP rise at 4, 10, 24, and 72 h in patients undergoing PKP with Healon or Viscoat, both groups had a similar rise in IOP at 4 and 10 h, with the Healon group continuing to have an IOP rise at 24 h, while the Viscoat group had returned to baseline. Both groups were at baseline after 72 h.[58]

The volume of an OVD left in the eye appears to be one of the factors that influence the postoperative pressure response. If 0.3 mL of sodium hyaluronate or less are used in the anterior chamber, the occurrence of postoperative pressure elevation is rare. As a general rule, the smallest amount of an OVD possible, consistent with clinical objectives, should be used. In a phakic patient for whom coating of the iris is the only objective, as little as 0.1 mL of OVD may be all that is needed. In addition, excessive sodium hyaluronate in the anterior chamber can give the false impression of a watertight wound closure with the result that, after surgery, an unappreciated wound leak is found.[59]

Another factor influencing the postoperative response of an eye to an OVD is the preoperative status of its outflow capacity. An eye with diminished outflow and pressure problems before surgery is very likely to have postoperative pressure problems even without the use of such a material. Such patients and all in whom an OVD is not removed, unless medically contraindicated, should be given an oral carbonic anhydrase inhibitor prophylactically in the immediate postoperative period and have their intraocular pressures closely monitored. This can blunt but may not eliminate the increased intraocular pressure.[60] Using topical hypotensives alone or in addition to a carbonic anhydrase inhibitor may provide equal or superior blunting of intraocular pressure elevation.[61]

Removal of OVDs at the end of surgery is technically more difficult after keratoplasty than after cataract surgery. However, in cases where relatively large amounts have been used, it is advisable to remove at least some of the material. Removing an OVD may only reduce or shorten the rise in intraocular pressure and not eliminate it.[22] The earlier in the suturing process this can be carried out, the easier it is to remove the material. In cases where there is relatively little posterior pressure, after the anterior chamber is stabilized with four to six cardinal sutures, a cannula with balanced saline solution placed deep into the chamber in each of the quadrants while the wound is slightly separated allows a good proportion of the material to be irrigated from the eye. Cohesives such as Healon and Provisc are more easily removed than other less cohesive materials such as Viscoat and Ocucoat, which require direct aspiration at the site of the OVD.[62] Placement of an air bubble in the anterior chamber before tying a running suture has been suggested as a way of pushing an OVD into the chamber angle from where it can be directly aspirated.[35] The air bubble can then be replaced with balanced saline solution. Maneuvers to remove an OVD should not be too vigorous, especially with the more viscous materials such as sodium hyaluronate, so as to avoid shear stress on the endothelium.[8]

37 Sutures and suturing technique

David H. Haight

The goals of modern penetrating keratoplasty are to achieve a clear graft and to minimize postoperative refractive error. Attention to the details of adequate wound closure are also imperative to achieve the best possible wound strength to guard against postsurgical wound rupture and also to attempt to minimize postoperative epithelial down-growth syndrome.[1] The long-term survival of graft clarity is dependent on factors such as preoperative pathology, the quality and viability of donor tissue, and postoperative events, all of which are to some extent beyond the control of the surgeon. However, minimizing postoperative refractive error is within the scope of the surgeon's control, provided attention is paid to proper surgical technique and postoperative manipulation. Large ametropias, often including high degrees of astigmatism, have historically plagued otherwise successful transplant surgery. Contributing factors include distortions induced by fixation rings, mismatches between donor and recipient trephinations induced either by poor trephine technique or by recipient pathology (e.g. keratoconus), undetected astigmatism in the donor cornea, irregularities induced by suture technique or removal practices, and other postoperative events such as trauma, infection, or graft reaction. For example, de Toledo and colleagues have reported on a series of successful keratoplasties for keratoconus and found that, despite retention of clear grafts and an initial period of stabilization of astigmatism, there was a late increase in astigmatism from year 10 and beyond. The authors attributed this to progressive disease in the host cornea and noted a correlation, on slit-lamp biomicroscopy, of a peripheral crescent-shaped thinning at the graft–host junction.[2] The roles of trephination technique and suture removal are discussed in other chapters. The following pages address the role of suture materials, pattern of placement, and intra- and postoperative adjustment techniques in the quest for emmetropia.

SUTURE MATERIALS

Before the introduction of nylon in the 1970s, braided silk was commonly used for both cataract and keratoplasty closure. However, the rapid degradation and high tissue reactivity of silk makes it unacceptable for modern keratoplasty. It does, however, have an ancillary role as a material for securing scleral support rings. Absorbable sutures are also unsuitable because of their loss of tensile strength long before healing of the keratoplasty wound occurs. Tissue adhesives, although often used for temporary closure of perforating injury, or melts have not yet been adequately developed for long-term keratoplasty closure. Likewise, staples, which have become routine in other surgical closures, have thus far been unsuitable for keratoplasty. Hence, wound closure must be effected using nonabsorbable monofilament threads.

NYLON

Soon after its introduction to ophthalmic surgery, nylon became the suture of choice for keratoplasty closure. The monofilament thread passes easily through corneal stroma and incites very little tissue reaction. The tensile strength is maintained for more than 1 year, thus allowing ample time for wound healing to occur. Nylon does not absorb, but over a period of years it undergoes a gradual hydrolysis that causes late relaxation of tension and eventually breakage of threads. It is therefore not a permanent suture and, because of the possibility of broken strands precipitating an infection or graft reaction, it is preferable to remove nylon sutures at an appropriate postoperative interval.[3,4] Nylon possesses a moderate amount of elasticity, which must be considered when tensioning and tying the material. It can be stretched up to 25% of its original length.[5] Sutures that appear tight visually may actually have inadequate tension to appose the wound, whereas over-tightening can produce an excessively flat wound with a drum head configuration and possible 'cheesewiring' of the nylon through the stroma. The latter is a result of the postsurgical contraction of the overstretched nylon. Some degree of experience is needed to obtain a feel for the correct amount of tension required for wound closure, particularly when a continuous suture is used.

Notwithstanding the idiosyncrasies of elasticity and hydrolysis, nylon remains the most widely used material for keratoplasty closure. Most commonly, the 10-0 size is used because it offers the best compromise between ease of placement and tensile strength. The 9-0 nylon is generally too large for efficient placement and manipulation, whereas 11-0 nylon lacks the strength to effect wound closure adequately by itself. The 11-0 nylon is used in

combination with other sutures, particularly 10-0 nylon, where its role is to assist in long-term wound stability.

POLYPROPYLENE

Polypropylene is a nonabsorbable material that does not undergo the process of hydrolysis. It also possesses high tensile strength and elicits very little tissue reaction. It has been successfully used for years as a haptic material for intraocular lenses, and its introduction in the 10-0 size prompted an investigation of its use for keratoplasty. In practice, polypropylene has been difficult to handle; it is negatively impacted by elasticity and can stretch up to 38% of its original length.[5] It is also quite stiff and can easily become kinked. The problems of over- or under-tensioning, as seen with nylon, exist to a greater extent with polypropylene. Given enough patience and practice, results have been reported to be good because of the low reactivity, high tensile strength, and permanence of this thread.[6] However, it is rarely used alone in keratoplasty closure. Some surgeons do use it in a continuous pattern in combination with interrupted 10-0 nylon. In this application, the nylon sutures are selectively removed to modify postoperative astigmatism while the polypropylene maintains permanent wound support. Perhaps the most important roles of polypropylene in keratoplasty are adjunctive. Its permanence and biocompatibility make it the suture of choice for iris repair and the scleral or iris fixation of posterior chamber intraocular lenses in the absence of capsular support.[7] In the latter application, long transchamber needles, both curved and straight, are armed with 10-0 polypropylene (e.g. Alcon's SC-1, SC-5, and AUM-5/SC-5 combination and Ethicon's CIF-4, STC-6, and CTC-6/CS160-6 combination).

POLYESTER

The quest for a permanent and nonelastic suture for keratoplasty led to the development of monofilament 10-0 and 11-0 polyester threads. Braided polyester materials had been previously used with good success in strabismus and retinal surgery, and the introduction of monofilament threads over 15 years ago immediately attracted the attention of corneal surgeons. Monofilament polyester is truly nonabsorbable and is inelastic, with a stretch factor of only 1%.[5] In theory it could be placed with the desired wound tension, and as soon as the tension is set and stabilizes in the corneal tissue, the corneal curvature and refraction should be permanent for the life of the graft. Thus, intraoperative or early postoperative adjustment could control astigmatism and potentially eliminate the need for suture removal or secondary astigmatic procedures. Likewise, the permanence of the thread could decrease the number of postoperative visits and avoid the infection, infiltrates, graft rejections, and refractive shifts associated with late hydrolysis of nylon. These potential benefits have led to the exploration of polyester in both running and interrupted patterns either alone or in combination with nylon for both keratoplasty and wedge resections.

The experience with polyester has fallen short of expectations. Although the material has maintained its tensile strength in situ for up to 4 years, numerous problems have been reported. Because of its inelasticity, handling is difficult and intraoperative breakage is common for those accustomed to nylon. Additionally, the lack of elasticity demands precise tensioning; slightly loose sutures result in wound leaks, and tight sutures cause cheesewiring. Although these problems can be seen with nylon and polypropylene, their elasticity leaves a greater margin for error. Also, there have been numerous reports of sterile infiltrates surrounding the threads. In one series of 14 grafts using 11-0 Mersilene, Frucht-Perry[8] reported some scarring in all cases and excessive amounts in 11 of the 14. The cause of the reaction may be particulate material attracted to the polyester during surgery, and strict avoidance of foreign body adherence may decrease the incidence of such reactions.[9] Adjustment of a continuous polyester suture after surgery is also difficult with numerous complications, including loose or broken loops, neovascularization, and wound leaks.[10] The difficulties of handling and tissue complications have caused many surgeons to abandon the material altogether. In a recent study, Bartels and coworkers compared complication rates for a polyester suture (Mersilene) with nylon.[11] The study confirmed an increased rate of early complications with the Mersilene compared to nylon including infiltrates, scarring along the suture line, and cheesewiring. However, at 2 years and beyond, the complications associated with suture retention actually decreased with Mersilene as compared to nylon. Therefore, for those surgeons who prefer to leave sutures in place with the hope of avoiding late changes in refraction, polyester remains the suture of choice. Its use, however, demands careful intraoperative manipulation in a particle-free field with precise control of wound tension and little or no postoperative adjustment.

NEEDLES

To commence our discussion of needles in keratoplasty, a review of basic nomenclature is in order.

The *point* is the sharp, penetrating end of the needle.

The *swage* is the back end of the needle to which suture material is attached.

The *length* is the total distance from point to swage before bending.

The *chord* is the straight-line distance from point to swage after bending.

The *diameter* is the diameter of the original wire from which the needle is made. Historically, this has been measured in mils (1 mil = 0.001 inches). Recently, most manufacturers have adopted millimeters as the standard. Typical wire sizes for keratoplasty are 6 or 4 mil (0.15 and 0.12 mm).

The *curvature* is that portion of a circle to which the needle is bent (e.g. one-half of a circle = 180°).

Regular cutting refers to a needle whose cross section is a face-down triangle.

Reverse cutting refers to a needle whose cross section is an apex-down triangle.

A *spatulated* needle is one with a flattened, reverse cutting point, with the third cutting edge on the bottom removed (also known as *side cutting*).

A *tapered* needle is one with a circular cross section tapering evenly to a point.

Various needle and point configurations are illustrated in Figures 37.1–37.3. The needles of choice for keratoplasty are small in diameter, ranging from 0.15 to 0.10 mm. They should also be of the reverse-cutting, spatulated type. This flattened configuration easily splits the corneal lamellae and is minimally traumatic. Additionally, the small wire size permits easy passage and leaves smaller needle tracts that are less prone to leakage. Ethicon's CS design features a concave spatula configuration that displaces more mass in a horizontal direction and produces a wide, thinner tissue tract. Alcon's A and S series needles feature a deeper triangular cross section,

creating a more radially symmetric cross section to the tract, which is advantageous for suture burial. The N series apogee needles from Alcon offer an extremely flattened spatula that is perhaps best used when shallow bites are required, such as in lamellar procedures or in secondary suture placement when there is a need to avoid preexistent deeper sutures. Alcon's C series is an earlier spatulated design, which is generally less suited for keratoplasty because of its tendency to lose both sharpness and curvature on multiple passes. Both Ethicon CS and Alcon A needles work quite well for keratoplasty, and personal preference ultimately directs the choice of needle for each surgeon.

FULL-CURVE NEEDLES

Full-curve needles (Fig. 37.4, *A*) are the most frequently used in ocular surgery. The bevel of the needle is circular with a curvature of 140–180°. The bite produced is somewhat long and shallow. The main advantage of this needle is the ease of handling and familiarity afforded by virtue of its use in most anterior segment procedures. This has made it a logical choice for both beginning and experienced corneal surgeons. It is the needle of choice for those who use an intentionally nonradial suture pattern. Efficient suture placement begins with proper placement of the needle in the needle holder. Ideally, the needle should be grasped in an area about one-quarter to no more than one-third of the distance from the swaged area to the point. Additionally, the needle should be grasped as close as feasible to the tip of the needle holder, while still maintaining an adequate grasp upon the needle. This positioning will allow the maximum length of the needle to be passed through both the donor and the recipient sides of the corneal tissue and will also prevent the tip of the needle holder from impinging on the corneal tissue during passage. This positioning is illustrated in Figure 37.5, *A*. If the needle is grasped close to the midpoint of the body and/or too far back in the jaws of the needle holder then there will be insufficient length to make an efficient pass across both sides of the wound, and, additionally, the end of the needle holder may physically interfere with the passage of the needle. This inappropriate positioning is illustrated in Figure 37.5, *B*. The needle is manipulated by first grasping the tissue with a toothed forceps and elevating it with a slight backward bend. The point of the needle is driven into the tissue immediately behind the forceps. Passage through the tissue is completed with either a pronation of the wrist if a standard curved needle holder is used or by twirling the fingers for a round-bodied, straight-jawed needle holder. Care must be taken, however, to achieve adequately deep bites, especially in the presence of edematous tissue where a bite that seems deep

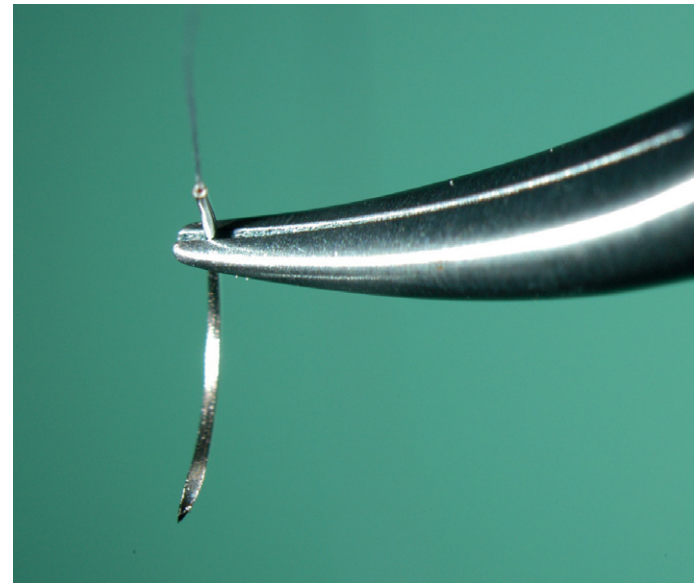
may actually penetrate only half thickness. Failure to take deep, equal bites on both sides of the wound can result in a lambda effect or a posterior wound gape (Fig. 37.6). This wound configuration can cause late slippage, excessive astigmatism, or even frank wound dehiscence. With the full-curve needle, deeper bites must be obtained at the expense of increasing the length of the tract. This in turn causes a reduction of the optical zone of the graft and allows for greater tissue compression, resulting in undesirable distortions when the suture is tensioned. The exact length and depth of the bite are a function of the curvature and length of the needle. Short, deep bites result from short chord lengths and larger curvatures, and longer, shallower bites are associated with large chord lengths and smaller curvatures. Examples of full-curve needles include Ethicon's CS-160-6, Alcon's AU-5, and US Surgical's SE-160-6.

MINICURVE

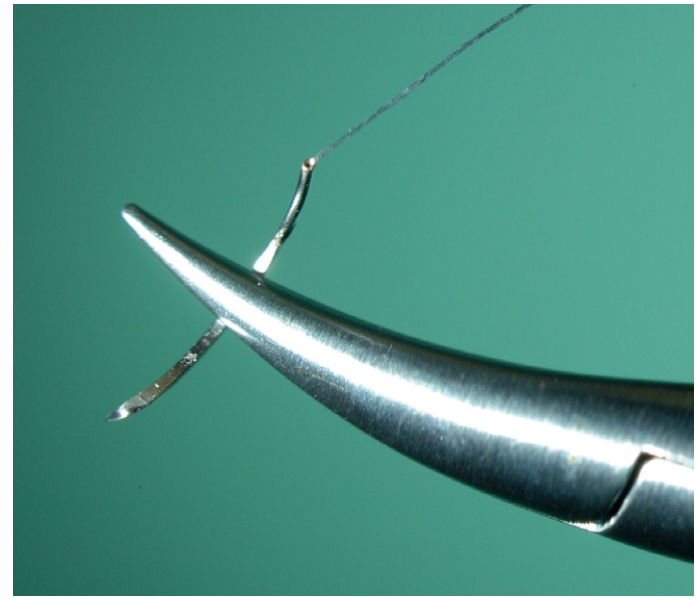
The minicurve needles (see Fig. 37.4, *B*) were developed to facilitate shorter and deeper bites. Like the full-curve needles, they have a continuous, nonchanging radius and their curvature is specified in degrees. However, their total length, chord length, and radius of curvature are all significantly smaller than their full-curve counterparts. This allows for a deeper bite while traversing less distance across the wound. In theory, this should afford better wound closure while avoiding excessively long suture bites. In practice, the small size and tight radii make handling difficult, and they are not commonly used as a primary needle for keratoplasty. They may, however, be useful when suture placement must take place in a confined space such as in repair of corneal lacerations, suturing of keratotomy incisions, or adding additional sutures to a previously sutured wound. Examples include Ethicon's CS-M-6 and Alcon's AUM-5.

BICURVE

The bicurve needle (Fig. 37.4, *C*) is another design aimed at achieving short, deep bites while improving on the handling of mini-curve



A



B

Figure 37.5. *A*, Shows the proper positioning of the needle in the jaws of the needle holder. *B*, Shows poor positioning of the needle in the jaws of the needle holder, with the needle being held too close to the mid-position of the body and too far from the tip of the jaws of the needle holder.

designs. Sometimes dubbed a 'fishhook,' this needle features an average to flat radius from the swage to the mid-portion and a steeper radius from the mid-portion to the point.

The initial flat portion toward the swage facilitates handling, and the tighter radius toward the tip permits rapid turnout after a deep bite is achieved. In practice, these needles allow for more efficient placement of deep or penetrating bites equidistant from both sides of the wound without requiring excessively long bites. The short bite avoids compromise of the optical zone, and the depth provides more secure closure. These needles are best driven with a short, straight-jawed needle holder. The technique involves grasping the flatter portion of the needle, placing the point perpendicular to the corneal surface, driving the needle down to the desired depth, and

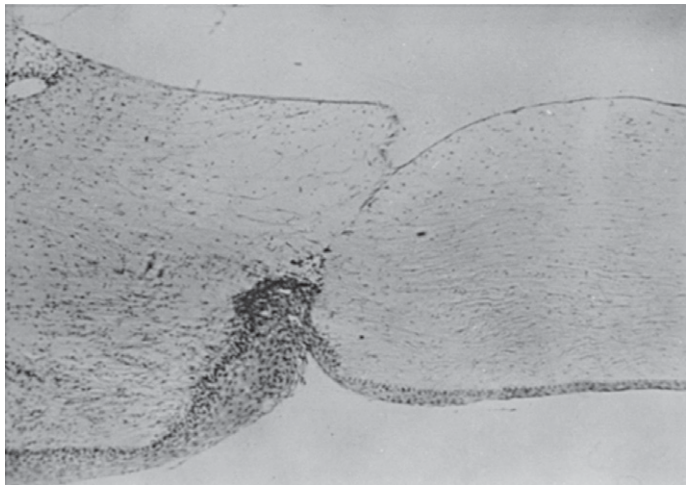


Figure 37.6. Posterior wound gape or lambda effect. Sutures placed at level of Descemet's membrane migrate anteriorly within a few days and therefore result in a posterior wound gape.

then rotating the point out by rolling the needle holder in the fingertips. This manipulation is substantially different from that used for full-curve needles but is easily learned and affords efficient, reproducible closures. Examples of the bicurve include Ethicon's CS-B-6 and Alcon's AU-6 and AU-8.

COMPOUND CURVE

The compound curve needle is a further development of the bicurve design. This needle has an initial flat curve changing to a steep curve at the midpoint and ending in a sharp, straight point. The straight point further facilitates initial entrance and penetration to desired depth, while rapid turnout is assured by the steep curve immediately behind the point. Examples of this needle are Ethicon's CS-C-6, TG6-C, and US Surgical's SE-CC-6. Needle geometry is shown in Figure 37.4, *D*.

Ultimately, the choice of needle is a matter of individual preference, but certain principles must be observed. Suture bites must be of sufficient depth to afford secure closure without posterior wound gape. This is especially important if secondary astigmatism surgery such as wedge resections or relaxing incisions are required. The effective 'optical zone' of the corneal graft with sutures in place is a diameter that lies somewhat inside the ring defined by the ends of the suture bites on the donor side. Excessively long bites shrink this optical zone and degrade the optics of the new cornea and thus the potential vision of the patient. Additionally, the tensioned long bites will have a more profound effect on tissue compression and can lead to excessive and unequal tension across the wound. Therefore, shorter and deeper bites are preferable; the author's preference is for full-thickness suturing with compound, curve-needle design. Selected needles for keratoplasty from Alcon, Ethicon, and US Surgical are listed in Table 37.1.

SUTURE TECHNIQUES

As soon as the surgeon has determined the appropriate needle and suture material to use, the strategy for wound closure must be selected. Each strategy has certain attendant features that must be properly managed both during and after surgery to achieve a successful result. Common goals for all techniques involve secure closure without over-ride or posterior wound gape, control of astigmatism and overall curvature, avoidance of tissue distortion that could decrease sutures in acuity, and prompt redressing of suture-related tissue complications.

The first decision that must be made regards the use of a ring for scleral support. At one time it was routine to use such a ring in all keratoplasty cases. The ring can maintain scleral rigidity and contour after excision of the recipient button, especially in aphakic eyes that have undergone vitrectomy. However, the ring itself can distort the scleral and corneal shape, thereby leading to irregular trephination and an ill-fitting donor button. If a ring is used, it should be sutured with care equal to the keratoplasty itself. Interrupted sutures are less desirable because of the greater risk of unequal tension, causing distortion. A running suture of six episcleral bites evenly spaced with even and light tensioning should be used. 8-0 or 9-0 silk armed with a circle spatulated needle is effective for this purpose. With the rising popularity of limbal-suction trephines such as the Krumeich and Hanna systems, which preclude the use of a scleral ring, many keratoplasties are now successfully performed without any scleral support. Thus far, there are no comparative studies that demonstrate deleterious effects attributable to the absence of scleral support, and the use of a ring in keratoplasty may be regarded as an optional step.

Trephination technique is another factor that impacts wound closure. This subject is discussed in Chapter 16, but it should be mentioned here that the type of trephine used and the graft–host disparity selected bear on wound closure. Most manual trephines require some oversizing of the donor to obtain a good fit and postoperative keratometry in the average range.[12] Limbal suction trephines such as the Hanna or Krumeich generally use the same size for donor and recipient to achieve emmetropia.[13] Special situations such as keratoconus also call for same sizing or undersizing the donor to modulate postoperative keratometry.[14] Conversely, in cases of a shallow anterior chamber, oversizing may be appropriate. The amount of tensioning required varies according to these factors; in general, same- or smaller-size buttons need tighter closure than oversize buttons. In this respect, one size (tension) definitely does not fit all. Appropriate tension for an oversize button may lead to wound leaks in a same or undersize situation, whereas sufficient tension to close a same-size keratoplasty can lead to excessive wound compression in oversize buttons. Thus, care must be taken to learn the specific cutting characteristics of each trephine. Another area in which trephination may affect the corneal power and regularity of post-keratoplasty astigmatism has been pointed out by Seitz and coworkers. Their study included 489 eyes with sutures in and 308 eyes with all sutures out, for a variety of pathology, including Fuchs and stromal dystrophies and aphakic and pseudophakic bullous keratopathy. The study included grafts done with diameters of 8.0, 7.5, and 7.0 mm with a graft oversize of 0.1 mm with trephinations performed by a Meditec Excimer Laser. They concluded that small graft diameters resulted in overall flatter K-readings and also greater corneal irregularity as evidenced by corneal topography, whereas larger grafts tended to have steeper overall keratometry and lower degrees of topographic irregularity. However, there was no significant difference with respect to the overall magnitude of the astigmatism among the different graft sizes.[15]

INITIAL GRAFT PLACEMENT AND SUTURING

The process of wound closure begins with the placement of the donor button over the recipient bed. The ideal of a perfectly round

button and bed are seldom realized. Therefore, it is important to place the button so as to optimize the fit. The use of a surgical keratometer to identify the placement that maximizes sphericity has been shown to lead to lower sutures-out astigmatism.[16] To effect this, the donor button is rotated in the recipient bed while simultaneously regarding tissue apposition and keratometric reflex. The end point for rotation of the button should be the position that yields the most spherical reflex from the keratometer (Fig. 37.7, *A*). Suturing should begin with the cornea in this position. The sutures should be passed using a small-toothed (0.12 mm) or cupped forceps to hold the button securely. The needle should be driven directly behind the fixation point, with care taken to achieve deep or penetrating bites. The exact entry point varies with the geometry of the needle but will be approximately 0.75 mm from the wound edge. The spacing should be equal on both the donor and the recipient sides unless contraindicated by local tissue factors.

Suturing of the cornea begins with placement of interrupted cardinal stitches. The first pass should be made with care not to displace the position of the cornea. A double fixation forceps such as the Polack or Bores will hold the button securely while preventing any rotation (see Fig. 37.7, *A*). The needle should be driven directly behind the fixation point. The first suture is then tensioned and tied. The location of the first cardinal is not critical, although most surgeons begin at the 12 o'clock position. Placement of the second cardinal is critical because it in effect divides the cornea into two halves that must be equidistant from the recipient bed. The bite must be 180° away from the first, and during placement the alignment of the button to the bed must be observed (Fig. 37.7, *B* and *C*). If an oversize button is used, the overlap must be equal on both sides; conversely, for an undersized button, the space or gap must be equal. The second suture should be tied with the same tension as the first cardinal. Next, additional cardinals are added, as a minimum of two additional bites are made, each 90° away from the first two, yielding four total sutures. These sutures stabilize the button, but there can be large gaps between them that make accurate closure difficult. Therefore, six or eight cardinals are preferable, and they should be spaced evenly and tensioned equally. The cornea is now ready for definitive closure.

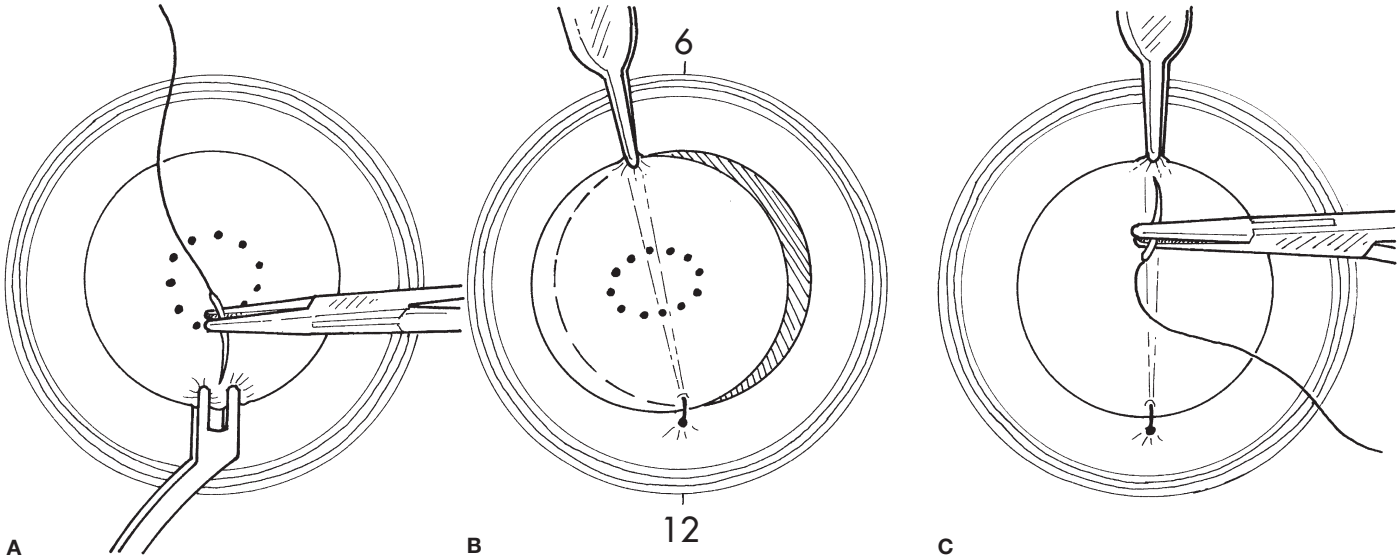

Figure 37.7. *A*, The cornea has been rotated to achieve a 'best fit,' and the first cardinal will be placed. The cornea is securely held with a double fixation forceps and the needle is driven immediately behind the forceps. *B*, The cornea is being aligned for the second cardinal. The button must be manipulated to divide the tissue precisely on both sides. *C*, The button is properly aligned, and the second suture bite is driven behind the fixation forceps.

THE SLIP KNOT

Precise control of wound tension is a key element in successful keratoplasty, and the usefulness of a slip knot for this purpose has previously been reported.[17] The slip knot offers several advantages, including exquisite control of suture tension, the ability to hold that tension temporarily while other adjustments are made followed by re-tensioning, and smaller knot size that facilitates burial. The slip knot is also helpful in ancillary procedures including placement of additional sutures for astigmatism control, relaxing incisions with compression sutures, and wedge resections. Therefore, a brief description of the tie may prove useful. There are several versions of the tie, and it is beyond the scope of this chapter to describe them all. Thus, the discussion is limited to the single slip knot with parallel sutures method (Fig. 37.8).

This knot is begun by placing the short and long sutures parallel to each other on the tissue surface (Fig. 37.8, *A*). The surgeon may wish to fixate the short end with the straight forceps held in the nondominant hand. The curved forceps are first placed over the two parallel sutures. These forceps are then sequentially brought under (Fig. 37.8, *B*) and over (Fig. 37.8, *C*) both sutures. The straight forceps are used to place the short suture into the grasp of the curved forceps (Fig. 37.8, *D*). The curved forceps are brought through the loops formed by the parallel sutures (Fig. 37.8, *E*). Again, this maneuver may be facilitated by fixing the long suture with the straight forceps. The loop is closed by pulling on the long end. This step should be performed before tensioning the suture to allow proper sliding of the suture and to minimize knot size. The suture can be tightened by pulling on the long end and loosened by pulling on the short end (Fig. 37.8, *F* and *G*). This adjustment may be performed multiple times if needed to achieve the desired suture tension. The knot is then secured with two single throws.

KNOT BURIAL

Knots of permanent sutures should always be buried and should be left in the donor button. All suture materials can incite some tissue reaction, and knots, because of their bulk, do so to a greater extent. Burying knots on the recipient side places them closer to limbal vessels and increases the risk of vascularization at the site with the attendant problems of graft rejection or suture abscess. Burial of interrupted sutures is accomplished by grasping the suture 1 mm behind the knot, elevating slightly, and moving the loop briskly in a radial direction toward the donor. If resistance is met, a toothed forceps can apply countertraction to the donor edge. A small amount of viscoelastic may also help lubricate passage of the knot. The use of the slip knot also aids burial because of its smaller size. The knot should be left in anterior stroma to facilitate later removal. The technique for burial of the knot of a continuous suture is slightly different. First, enough slack must be generated behind the knot to permit advancement into the cornea. A forceps is used to lift and slightly advance loops beginning about four to five loops behind the knot. The slack should be carried to the loop just beyond the burial site, so there is no tension immediately on either side of knot. The suture loop is then grasped with tying forceps on both sides of the knot and advanced into the cornea with a simultaneous push and pull motion. Because in this pattern the suture may not be crossing the cornea radially, it is helpful to lift and straighten the loop just behind the knot to prevent it from having to turn as it enters the cornea. This maneuver keeps the forces acting along the direction of travel and decreases the chance of suture breakage.

SUTURE PATTERNS

The preceding sections described the basics of anchoring the donor button in place with cardinal and mid-cardinal interrupted sutures. As soon as this is carried out, the anterior chamber should be reformed with saline or viscoelastic, with the latter used particularly if an intraocular lens is present to protect against inadvertent endothelial damage. A small amount of viscoelastic placed on the surface of the button helps preserve the epithelium to improve a keratometric reflex for later suture adjustment. Wound closure is then completed with one of a number of patterns. The following sections present some of the pros and cons of each technique.

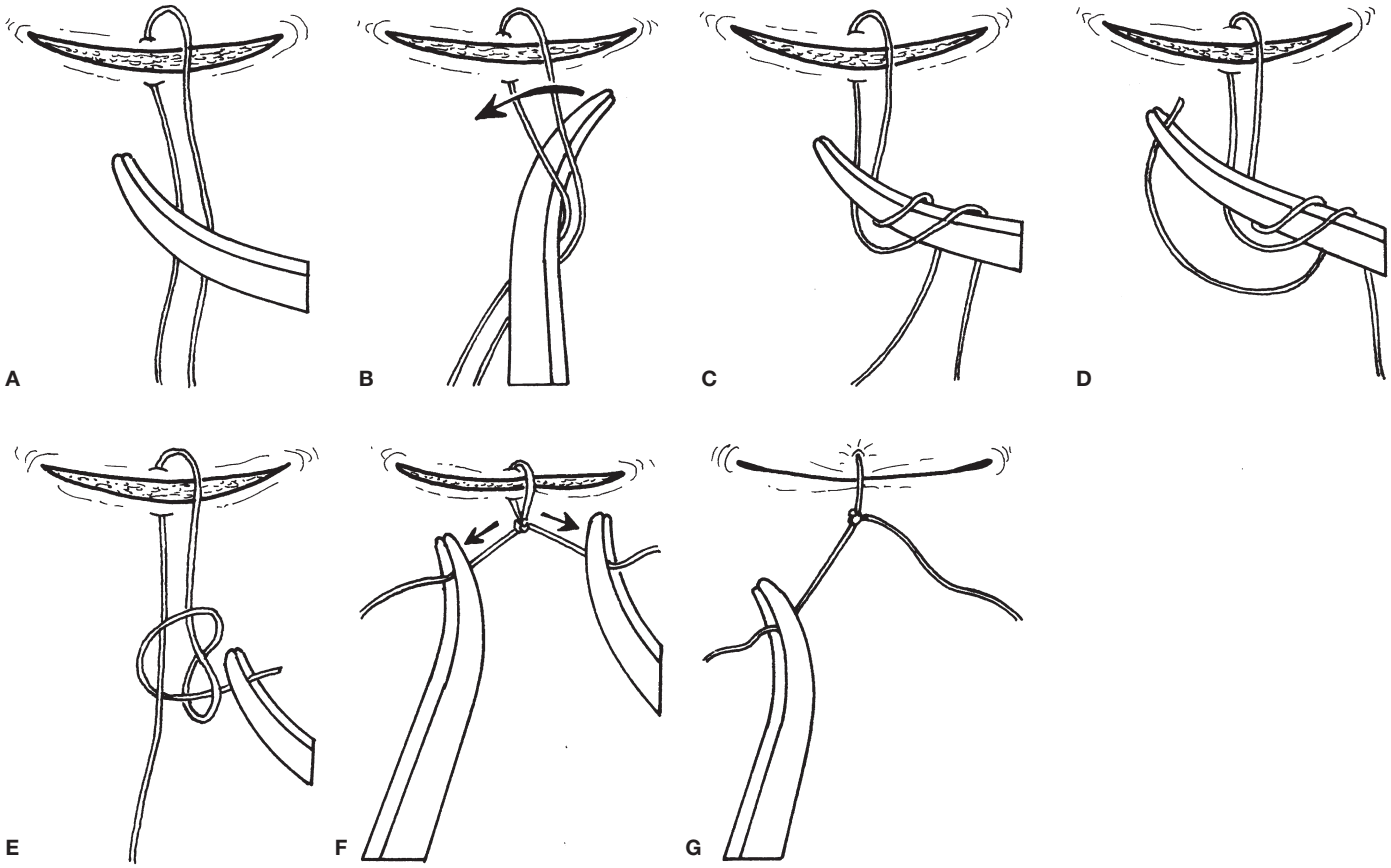

Figure 37.8. The drawings show the sequential steps for tying the 'parallel sutures' type of slip knot.

SINGLE CONTINUOUS TECHNIQUE: RADIAL PLACEMENT

The single continuous technique with radial placement (Fig. 37.9, *A*) uses a single suture of 20–24 bites to close the wound. Placing more than this number of bites or placing the bites too close to the limbus is associated with an increase in corneal neovascularization and should be avoided.[18] The pattern may be started anywhere, but the 6 or 12 o'clock positions are most common. The bites are made radially across the wound with equal spacing between bites and equal bite lengths. Deep or full-thickness bites should be taken. Initially, the donor edge is held with the toothed forceps, and the needle is driven into the cornea immediately behind. The forceps may then be moved to the recipient side to apply counterpressure at the planned site of egress of the needle. Usually, the needle need not be regrasped, but if a long bite is required or if facial features make access difficult, the needle may be passed first through the donor, drawn out of the wound, regrasped, and then passed through the recipient bed. Because the wound is not closed until the last bite is taken and the suture tied, periodic reformation of the anterior chamber is required. Viscoelastic may help maintain the chamber better, but complete filling is not desirable because of difficulty in subsequent removal, leading to postoperative pressure increases. It is preferable to use small amounts in the periphery to push back the iris where needed and rely on saline as the primary fluid for chamber maintenance. If the suture breaks during passage, a new needle may be spliced on using the slip knot. The knot does not compromise the tensile strength of the suture and may be left as part of the continuous suture; however, it must be buried. Alternatively, a very long section of new suture may be spliced on and then pulled backward loop by loop to the beginning of the pattern until the original suture and splice are removed. On completion of the pattern, the suture should be tied with a slip knot and tensioned. Tensioning should take place after the chamber is fully reformed with saline. Tensioning a flat chamber can lead to an excessively tight suture with a distorted drumhead configuration. It may be useful to use a hand-over-hand technique where one forceps holds the distal loop and maintains tension while the other pulls up slack on the proximal loop. This is then repeated loop by loop until the starting point is reached. Adequate tension should be just enough to approximate wound edges and prevent leakage. As soon as this is achieved, the knot is secured with two additional throws and buried in the donor cornea. The cardinal sutures are generally loose by this point and should be removed. The application of liquid fluorescein helps in identifying any wound leaks. It is not uncommon to see leaks through suture tracks if penetrating bites are used; these need no action and usually seal within 24 h. If the leak persists beyond 24 h then the application of a bandage contact lens, collagen shield, or patching, may be helpful. If the leak persists beyond 2–3 days, despite the implementation of these measures, there is some risk of development of a permanent fistula. Persistent leaking loops must be resutured because they may act as a site for epithelial down-growth.

The single continuous technique is easily and rapidly placed. Other advantages include the ease of intra- and postoperative suture adjustment to modulate astigmatism. Also there is usually only one knot present, and this minimizes the chance of vascularization of the graft. On the negative side, because only one

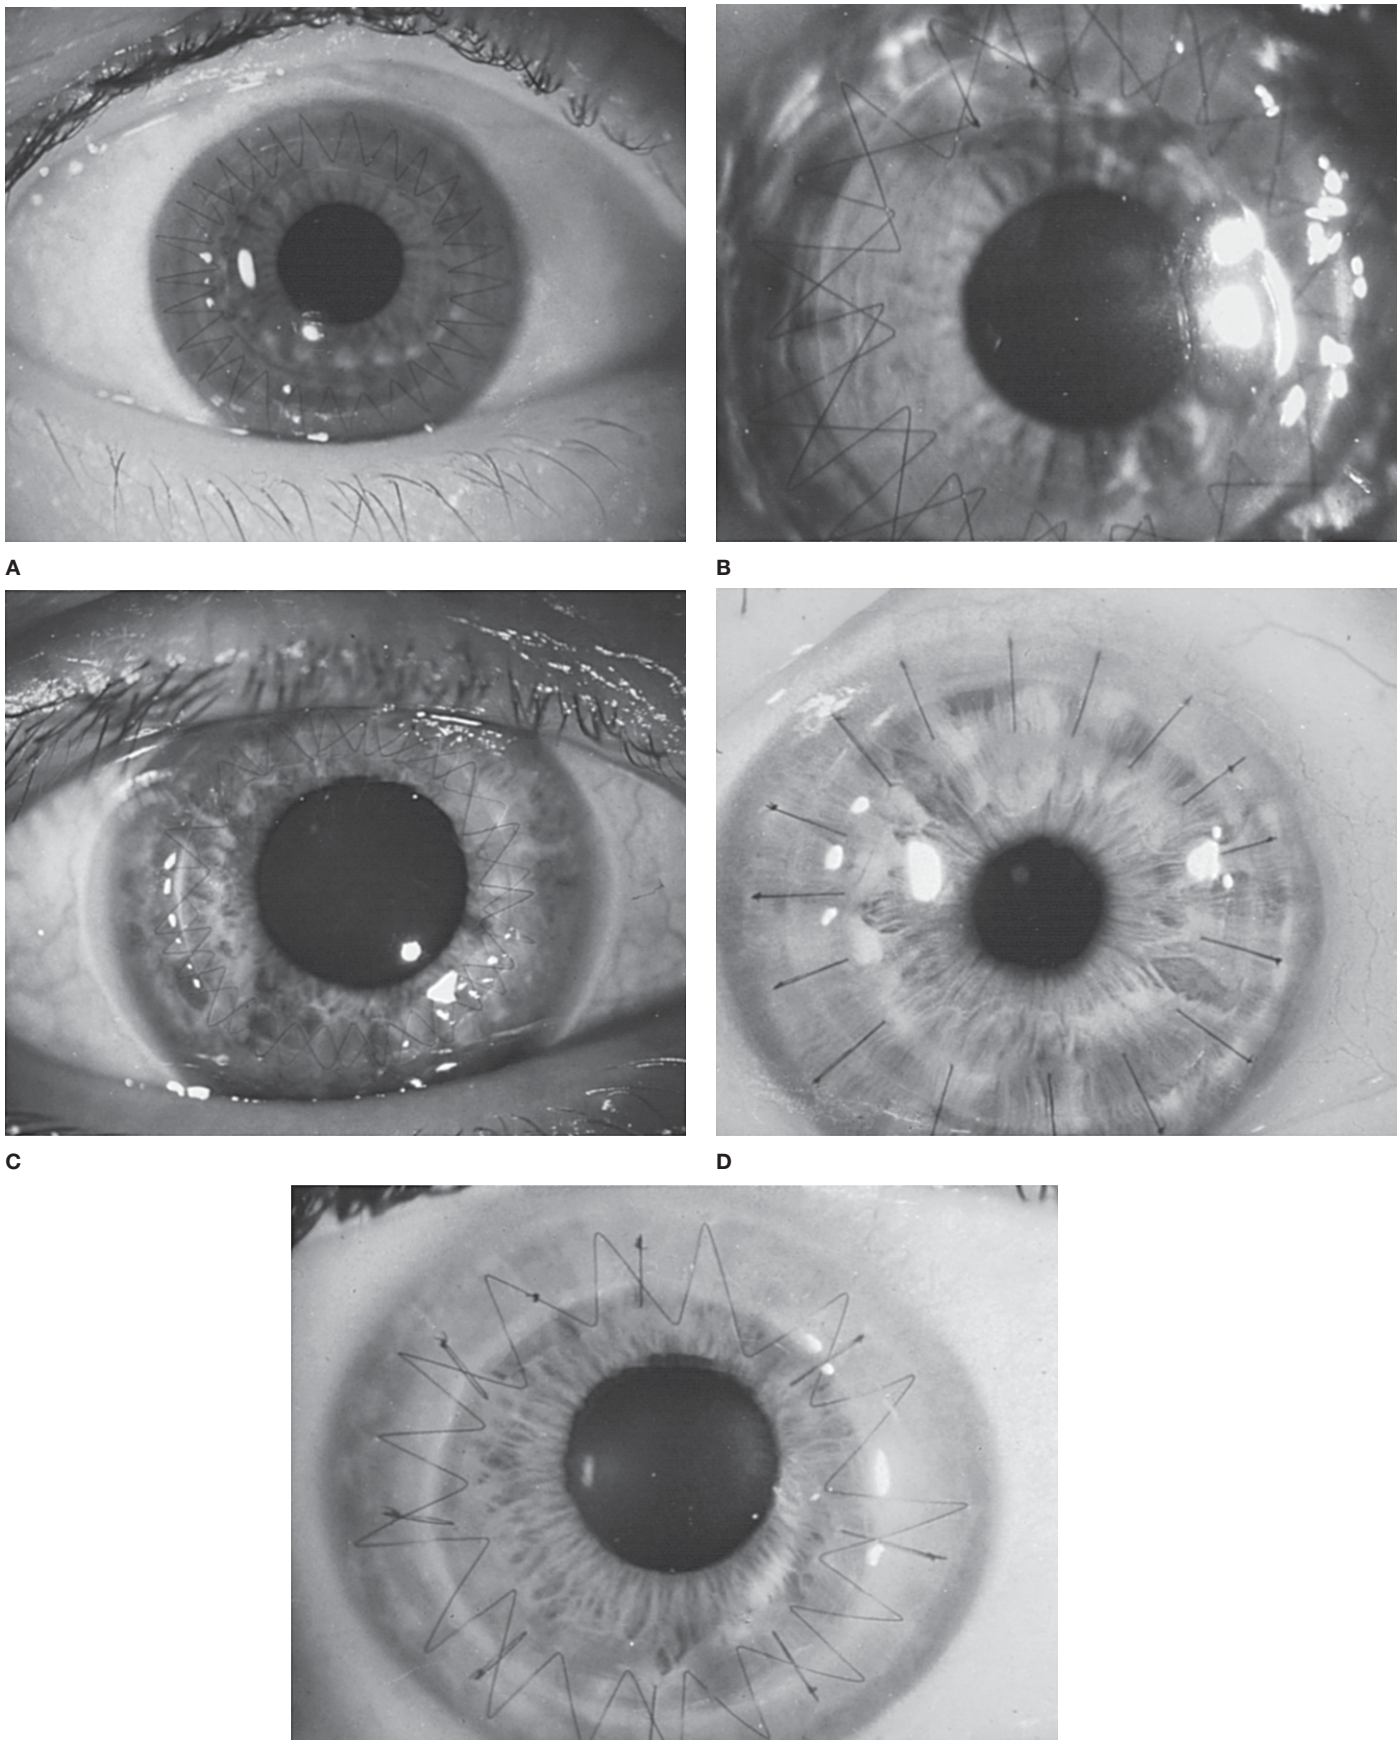

Figure 37.9. *A*, Single continuous, no torque. *B*, Double continuous torque–antitorque pattern. *C*, Double continuous, 10-0 and 11-0 nylon placed in same clockwise direction. *D*, All interrupted pattern. *E*, Combination interrupted and single continuous sutures.

needle is used for many bites, the point may become dull and in some cases must be replaced by attaching a new needle to the distal end of the suture. Also the wound is not fully secure or the chamber continuously formed until the completion of the pattern, thereby leaving the eye vulnerable in the event of any medical misadventures. After surgery, any trauma or severe tissue reaction or infection involving the solo suture may require surgical repair. A recent review of this technique revealed an average sutures-out astigmatism of 3–4 D with an average keratometry of 45 D.[19] Other studies have reported late and/or sutures-out astigmatism in the range of 3–5 D.[20–24] Another potential advantage of the single running technique versus all interrupted sutures was demonstrated in a cadaver study by Au and coworkers.[25] In this cadaver eye study, the water tightness of wound integrity in keratoplasty was evaluated by hydrostatically increasing the intraocular pressure. The results indicated that either a single running technique or a combined running and interrupted pattern produced a more secure closure than interrupted sutures alone. While there is no comparable human study, the conclusions drawn from the cadaver study do follow the logic that the continuous pattern with its suture loops overlapping the cornea between bites would provide a more secure closure. Another benefit to the single continuous was outlined by Filatov and coworkers, who compared a single continuous pattern versus a combined continuous and interrupted pattern. Although they noted no difference in the final postoperative astigmatism out to 4 years, they did observe that the single continuous pattern yielded a more rapid visual rehabilitation and less early astigmatism.[21] Furthermore, Ramirez and coworkers compared a single continuous suture versus a double running technique and concluded that the single running technique with postoperative adjustments produce less keratometric astigmatism during the first year, when sutures were still in place.[22]

SINGLE CONTINUOUS TECHNIQUE: NO TORQUE PLACEMENT

A disadvantage of the single continuous technique is that the portion of the suture that crosses over the top of the wound imparts a torque to the wound when tensioning is performed. This torque may be released when the suture is removed or breaks and may account for the late changes in astigmatism that can be seen.[26] To circumvent this torsion, some surgeons use a continuous, no-torque pattern. The classic no-torque pattern used in lamellar refractive keratoplasty is comprised of eight bites placed across the wound at 45° from the radial direction and angled in the direction of suture advancement. This placement creates a series of isosceles triangles that theoretically negates torsion. This pattern has been adopted for keratoplasty by a few surgeons by increasing the number of bites to 20–24 required for wound closure. The 45° angulation requires a greater overall length for each bite to bring the point out at an adequate distance from the wound on the recipient side, thus necessitating a full-curve needle and ample suture length. Otherwise, placement and adjustment are similar to radial single continuous patterns. Several publications have shown favorable results using this technique.[27,28] Another interesting observation was made by Sharma and coworkers, who found that the antitorque suturing pattern tended to produce a high proportion of prolate topographic maps postoperatively.[29] As the normal corneal contour is prolate, it would seem that obtaining a prolate pattern post keratoplasty would be optically desirable, but more studies will be required to establish the superiority of this suturing technique to that of other patterns in producing this type of topography.

Vajpayee and colleagues have also described an 'antitorque' pattern of continuous suturing.[30] The authors describe the antitorque pattern as being one in which the suture bites are again angled across the wound instead of being radial to it. In contradistinction to the no-torque placement described above, the angulation of the pass is made in the opposite direction of the advancement of the suture. For example, if a suture pattern is being advanced in a clockwise direction and a bite is taken through the donor button at the 12 o'clock position, the pass would be angled backward toward 11 o'clock instead of forward toward 1 o'clock, as would be the case in the no-torque pattern. Vajpayee and colleagues performed 53 keratoplasties and divided them roughly equally into three groups: one using the classic radial or torque placement, another the antitorque placement, and finally the no-torque pattern. The study concluded that at 3 and 6 months postoperatively there was no significant difference in astigmatism among the three groups. This study went on to mention that postoperative suture adjustment was helpful in reducing postoperative astigmatism in all three groups. Thus, the literature is unclear as to whether the no-torque or antitorque placement is actually better than the radial placement.

DOUBLE CONTINUOUS TORQUE–ANTITORQUE TECHNIQUE

Another approach to circumvent wound torsion is the double continuous torque–antitorque placement (Fig. 37.9, *B*). The first suture is placed with radial bites proceeding in a clockwise direction. After this suture is tensioned and tied, a second suture of the same size and material is run in a counterclockwise direction. The bites of the second suture fall between and parallel the direction of the bites of the first suture. When the second suture is tensioned, the torque it imparts compensates for that of the first suture, thus leaving only radial forces acting across the wound. Each suture is comprised of 12–14 equally spaced bites. The overall effect is a tighter, more secure wound closure with the added safety factor of two sutures.[31] Additionally, the first suture usually results in a closed chamber, thus facilitating placement of the second suture. Dolorico and coworkers have reported that, using this technique, they were able to achieve a mean postoperative manifest cylinder of 3.42 D within the 1–3 month post suture-removal period and that this astigmatism remained stable for follow-up ranging from 18 to 66 months.[32] Spadea and coworkers compared a single continuous versus a double continuous suture pattern, employing each technique in approximately 35 keratoplasties. With all sutures out at about 3 years, each group averaged approximately 3.5 D of astigmatism, and there was no statistically significant difference between the groups. However, the double running group appeared to have a faster restoration of visual function due to earlier stability of the astigmatism.[23] Solano and coworkers also compared a single continuous versus double continuous suture pattern and found that following suture removal there was no statistical difference between the techniques with respect to either mean keratometry or mean astigmatism, which in this study was 4.6 D for the double running group and 5.2 D for the single running group.[24] Thus, this technique has demonstrated advantages of a more secure wound closure, good control of postoperative astigmatism, and the possibility of earlier stability of the astigmatism versus a single continuous approach but has not been demonstrated to show a lower overall sutures-out

astigmatism. Disadvantages include a somewhat longer closure time and greater difficulty in both intra- and postoperative suture adjustment because of the necessity of simultaneous manipulation of two sutures in close proximity traveling in opposite directions.

DOUBLE CONTINUOUS-SAME DIRECTION TECHNIQUE

In the double continuous-same direction technique (Fig. 37.9, *C*), both sutures are placed with radial bites and proceed in the same direction. The goal is not to achieve a torque-free wound but to use different materials. Usually, one suture is 10-0 nylon and the second may be 11-0 nylon, polypropylene, or polyester. Ten to sixteen bites of 10-0 nylon are placed, tensioned, and tied. The 11-0 is then placed between the 10-0 bites. The 10-0 nylon is placed with deeper bites and is tensioned to close the wound. The second suture is placed more superficially and tensioned just enough to take up slack. The 10-0 nylon supplies the bulk of the support for initial wound healing. However, as previously noted, a tight 10-0 nylon may distort the cornea or produce excessive astigmatism. With this pattern, the 10-0 nylon may be removed as early as 2–3 months after surgery in the expectation that the 11-0 nylon will maintain wound support and provide a better optical surface. Thus, the overall goal of this technique is to produce faster visual rehabilitation; if the 11-0 nylon is a permanent suture, the refraction could be stable as early as a few months after surgery. Disadvantages include a slightly longer surgical time and difficulty in performing suture adjustment.

INTERRUPTED TECHNIQUE

Some surgeons prefer closing the wound with 16–24 radial interrupted sutures (Fig. 37.9, *D*). This may be the best technique for pediatric grafts where wound healing is rapid, for heavily vascularized corneas, or for corneas with segmental vascularization in which differential suture removal may be required. The closure may be more rapid, especially if the cardinal sutures can be maintained; the speed can also recommend this approach for patients who cannot remain long in the surgical position. Because of multiplicity of sutures, wound security in the presence of accidental suture breakage is the greatest of the aforementioned techniques. Postoperative astigmatism may be controlled via selective suture removal. However, intraoperative astigmatism is more difficult to modulate, and the unsupported tissue between bites leads to less even distribution of tension across the wound. The multiple knots increase the risk of vascularization, and removal may be difficult and may subject the patient to multiple periods of change in refraction. Nevertheless, Murta and coworkers have reported that an all interrupted closure compared to a single continuous closure resulted in lower post-keratoplasty astigmatism at 6- and 12-month postoperative intervals. There was, however, no statistically significant difference at 24 months post surgery. This allowed them to conclude that the interrupted pattern allowed better early control of postsurgical astigmatism and a more rapid recovery of vision.[33]

INTERRUPTED AND CONTINUOUS COMBINATION TECHNIQUE

The interrupted and continuous combination technique (Fig. 37.9, *E*) attempts to marry the benefits of selective postoperative suture removal afforded by the interrupted technique with the long-term support offered by a single continuous technique. Eight to twelve interrupted sutures are placed first, followed by a 12–16 bite running. The interrupted sutures stabilize the cornea, maintain the anterior chamber early, and facilitate placement of the continuous sutures. All bites are radial, and the continuous sutures bisect the interrupted sutures. A variety of materials and sizes may be used. Most commonly, the interrupted sutures are 10-0 nylon, and the running sutures may be 10-0 or 11-0 nylon, polypropylene, or polyester. In theory, the interrupted sutures are removed early to achieve a minimal astigmatism, while the continuous sutures maintain the wound. This approach is most valid when polyester or polypropylene is used for the continuous sutures because they may be left in place permanently. If nylon is used for the continuous sutures, late breakage can cause refractive shifts. Earlier reports showed good results with low sutures-out astigmatism,[34] but the more recent popularity of suture adjustment may point to decreasing usefulness of this technique. Filatov and coworkers[21] compared the sutures-in and sutures-out astigmatism with single continuous to continuous–interrupted combinations. They found the sutures-in astigmatism was lower in the continuous cases, but final sutures-out astigmatism was similar for both. Thus, the continuous offered a more rapid rehabilitation when compared to the combined technique. Karabatsas and coworkers also compared a combined technique to a single continuous with postoperative adjustment and also concluded that there was no significant difference at 3, 6, 9, or 12 months post surgery between either of the groups.[20] Dursun and coworkers reported on attempts to use the combined technique to control astigmatism as well as postoperative myopia and anisometropia.[35] In this technique, 92 keratoplasties were performed using 12 interrupted 10-0 nylon sutures and a tight 12-bite continuous suture. This was then followed by selective removal of the interrupted sutures. In this particular study, however, the use of the tighter continuous sutures and selected removal of fewer interrupted sutures resulted in an actual increase in final postoperative astigmatism and had no significant impact on the final spherical equivalent. In a review of factors associated with graft failure, Vail and coworkers found an increased risk with the combined continuous–interrupted pattern.[36]

SUTURE ADJUSTMENT

INTRAOPERATIVE SUTURE ADJUSTMENT

The final element in wound closure should be the minimization of astigmatism by suture adjustment. As described earlier, the donor button should be placed under keratometric control. A variety of surgical keratometers ranging from small disposable units to sophisticated qualitative and quantitative devices are available. They share a common principle of operation. A light is projected onto the wound surface, and its reflex is altered by the corneal curvature. An initially circular image appears elliptical in the presence of an astigmatic surface, with the short axis of the ellipse corresponding to the steeper meridian. When a continuous suture is used, it should be adjusted after tensioning and tying to yield a more spherical reflex (Fig. 37.10). Before starting, the chamber should be filled, cardinal sutures and scleral rings removed, and any viscoelastic rinsed from the field. The net effect is redistribution of tension from the steep meridian to the flat meridian. One or both sides of the suture may be adjusted as needed. This process may be used for single and double continuous patterns. Keratometric control may also be used with interrupted patterns but is more difficult. In these

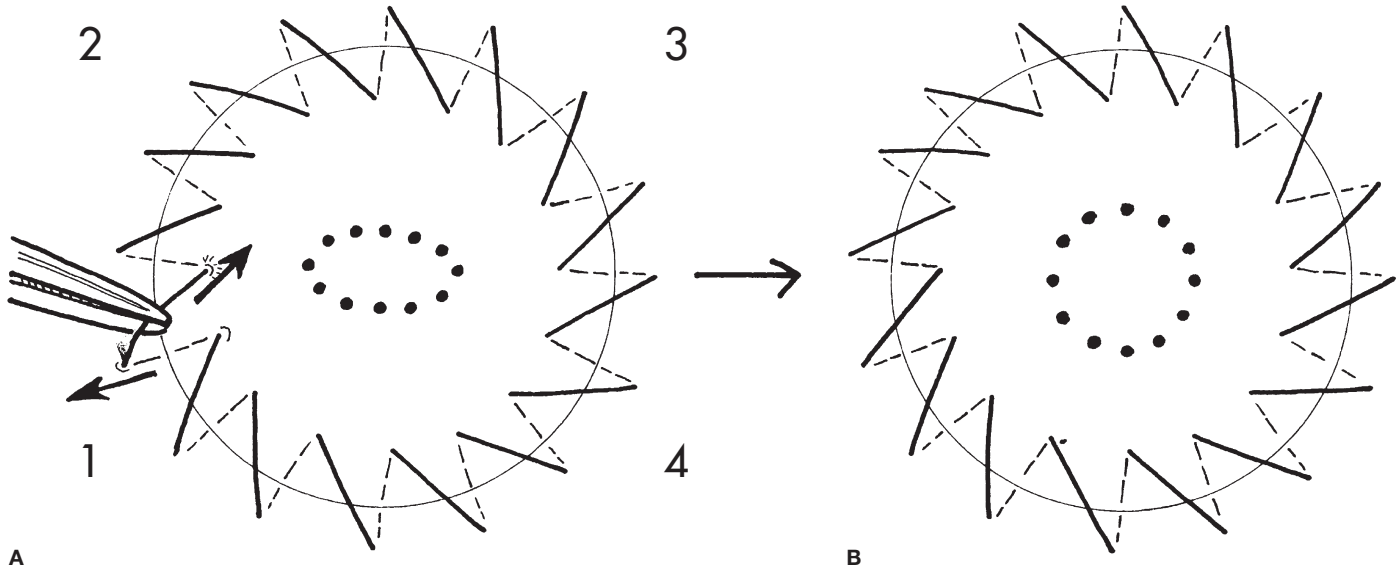

Figure 37.10. *A*, A large, with-the-rule astigmatism is shown by the oval keratometric reflex with short axis from 6 to 12 o'clock. This is adjusted by successively pulling each loop across the wound and advancing from position 1 to position 2. The slack generated is then distributed among the loops from position 2 to position 3. If needed, tightening can be performed from position 3 to position 4, and the slack distributed from position 4 to position 1. The end result will be a circular reflex as shown in *B*.

cases, sutures must be added or replaced with varying tension to influence the keratometric reflex. In all cases, the final integrity of the wound must be confirmed.

Serdarevic et al performed a randomized trial comparing long-term effects of intraoperative adjustment with no adjustment.[28] The intraoperatively adjusted group had less astigmatism, more regular topography, and better best spectacle corrective acuity than the control group. Shimazaki and coworkers corroborated this result in their analysis of 53 patients undergoing keratoplasty with a continuous suture technique, who had either intra- or postoperative adjustment at varying time periods. They concluded that intraoperative suture adjustment significantly reduced final astigmatism and, in some cases, eliminated the need for further postoperative manipulation.[37] Thus, a relatively rapid and easily performed step can significantly improve postoperative results.

POSTOPERATIVE SUTURE ADJUSTMENT

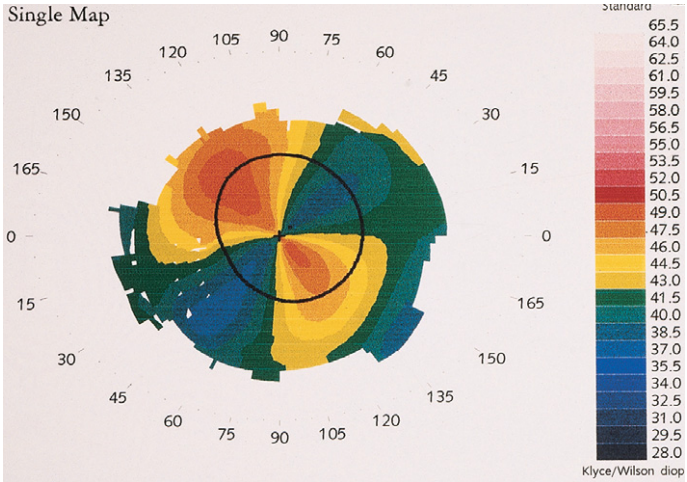
Despite efforts at intraoperative adjustment, some astigmatism may still be present in the postoperative period. In general, a cylinder of greater than 3–5 D can be a visual impediment for the patient and should be addressed. Clinical keratometry has been the mainstay for identifying astigmatism and is still useful. However, photokeratoscopy and computerized topography yield additional information including identifying tight sutures and asymmetric astigmatism. These instruments should be used if available. Postoperative adjustment is carried out much in the same manner as described for intraoperative adjustments and has been shown to be effective in numerous studies.[38–40] It may be performed as early as readable keratometry or topography can be obtained and is most effective in the first 3 months after surgery, although later adjustments may still be fruitful.[37]

The suture may be adjusted at the slit lamp using a Tennant tying forceps after administration of topical anesthetic. If feasible, somewhat better control is afforded by a surgical microscope and keratometer with the patient in a supine position. Frequently, the epithelium has closed over the loops and must be broken before adjustment. This is accomplished with a small-diameter spatula such as the Johnson. The spatula is gently inserted under each loop and swept back and forth to break the epithelium. This should be performed in sequence for all loops. The adjustment is limited by the position of the knot. Unlike the intraoperative scenario, it is best not to externalize the knot because reburial may be quite difficult. After adjustment, appropriate antibiotic and corticosteroid coverage should be used as prophylaxis against either infection or graft reaction. This technique is effective in reducing both sutures-in and ultimate sutures-out astigmatism.[41] It may be used for both single and double continuous patterns but is more easily effected with the single continuous technique. Compared with selective removal of interrupted sutures, which is done sequentially over many months, this approach affords more effective and rapid stabilization of vision because usually only one adjustment is required.[42] An example of topography of an adjusted cornea is shown in Figure 37.11, *A* to *C*.

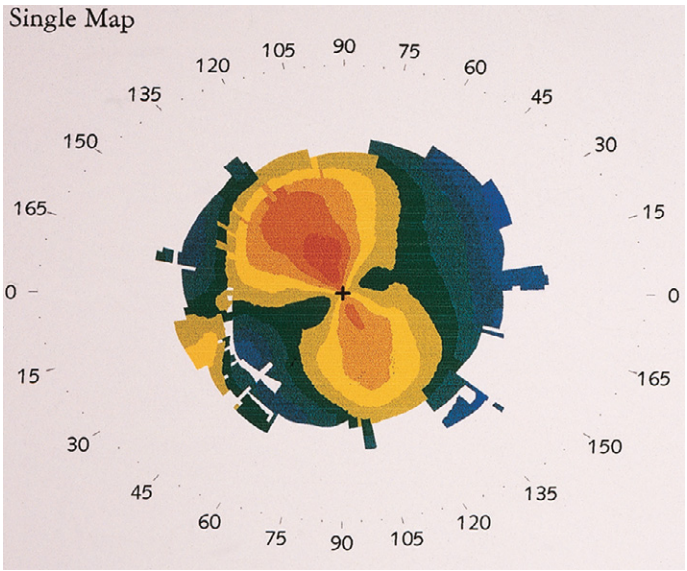
An additional technique for modulating postoperative astigmatism was proposed by Buzard.[43] Based on examination of keratoscope mires, it may be possible to identify flat meridians of 'microdehiscence' of the wound that are causing astigmatism. By placing additional interrupted sutures under keratometric control, the wound is strengthened and the surface is made more spherical. If performed early in the healing phase, the effect can persist even after suture removal. Additional sutures can be effective even in the absence of demonstrable microdehiscences and can be adjunctive to suture adjustment.

SUMMARY

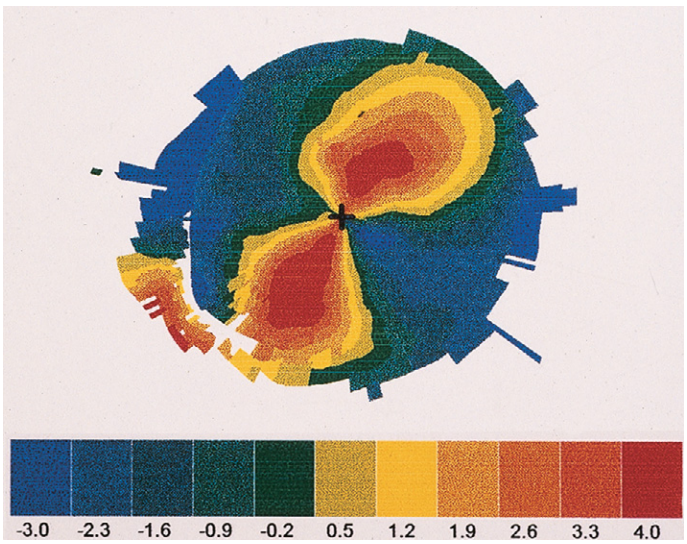
This chapter has presented information on commonly used suture materials and needle types for keratoplasty closure and comments regarding their effective use. Additionally, the pros and cons of the different types of suture patterns have also been reviewed. Ultimately, each surgeon must decide which combination of suture



A



B



C

Figure 37.11. A, Topography of a cornea 2 months after keratoplasty with a steep astigmatic band at 130°. Sim K is 48.52 × 132/38.23 × 42. The suture was adjusted with some limitation imposed by the buried knot. **B**, Post-adjustment topography. The steep axis is shifted slightly to 120° and the Sim K is reduced to 47.78 × 121/42.03 × 31. **C**, A digital subtraction of the preadjustment from postadjustment maps shows the steepening of the flat axis *(red colors)* that has resulted from the adjustment. Note the scale in **C** is not diopters of curvature but rather diopters of keratometric change. Difference = A − B.

material, needle design, and suture pattern will best serve the goals of effective keratoplasty closure. Although this chapter has referenced numerous articles reflecting the experience of a variety of corneal surgeons with the differing techniques, it should be noted that no closure technique may be definitively cited as optimal. In fact, in a recent review article Frost and coauthors reviewed 27 randomized trials of differing penetrating keratoplasty techniques.[44] The authors concluded that among the trials reviewed there was little convincing evidence to demonstrate the superiority of one suturing pattern over another for an effective control of final sutures-out astigmatism. It will take yet further studies on larger numbers of keratoplasties before a definitive best technique may be identified.

In the final analysis, even if an optically clear graft is to be obtained but functional acuity is prevented by high astigmatism not readily correctable by spectacles or contact lenses, it may be appropriate to perform a repeat keratoplasty operation, and such operations have been noted to be accomplished with some success.[45]

38 Indications and contraindications for anterior lamellar keratoplasty

Sanjay V. Patel, H. Kaz Soong

INTRODUCTION

Although the first human lamellar keratoplasty (LKP) was performed in the 19th century,[1] the surgery never gained immense popularity or prevalence because it eventually was superseded by the technically easier penetrating keratoplasty (PKP) in the latter half of the 20th century. With improved methods of corneal preservation and increasingly successful outcomes of PKP,[2] lamellar grafting became relegated to the removal of superficial central lesions in the cornea and to tectonic repair. In this chapter, 'LKP' will refer to traditional, anterior lamellar corneal transplantation. Posterior lamellar transplantation (DLEK, DSEK, and DSAEK), a more recent development, is discussed in a subsequent chapter.

In LKP, only the anterior part of the cornea is transplanted, leaving the recipient posterior stroma, Descemet's membrane, and endothelium intact. Although technically more demanding than PKP, lamellar grafting has several advantages. The wound strength in lamellar grafts is considerably superior to that of PKP, because recipient Descemet's membrane and deep stroma are left intact. The entire lamellar interface between donor and recipient cornea comprises the graft–host junction in LKP, whereas in PKP it is limited to the extremely weak peripheral trephination wound. Accordingly, PKP wounds are much more susceptible to dehiscence, occasionally with devastating clinical consequences. LKP is in essence an extraocular procedure, and therefore it is less likely to cause glaucoma, cataract, uveitis, cystoid macular edema, retinal detachment, infectious endophthalmitis, expulsive choroidal hemorrhage, and phthisis bulbi. Since the endothelium is not transplanted in LKP, donor corneal requirements are not as stringent as in PKP. Eye bank tissue with unhealthy endothelium or with preservation times in excess of 2 weeks may thus be used in LKP. It is a practical and perhaps safer alternative to PKP in regions of the world not served by eye banks and without easy patient access to postoperative care.

PKP may have certain advantages relative to LKP. One limitation of LKP is that the lamellar interface is a source of light scattering, optical attenuation, and wavefront aberrations,[3] all contributing to reduced visual acuity. Lamellar interfaces are a frequent nidus for (1) centripetal in-growth of blood vessels from the periphery of vascularized recipient corneas, (2) lipid deposition, (3) leukocyte migration (diffuse lamellar keratitis), and (4) entrapment of blood or particulate debris, such as fibers from cotton-tipped applicators, lint from cloth drapes or gauze pads, secretions from meibomian glands, and powder from gloves. When the forward-bulging cornea in advanced keratoconus is flattened by the donor lamellar overlay, visually significant folds in the recipient side of the interface may result. If the lamellar dissection is insufficiently deep, the residual stromal opacities may preclude visual improvement. If a tear or hole is present in host Descemet's membrane, it is not uncommon for a 'double anterior chamber' or 'pseudochamber' to result from aqueous humor gaining access into the lamellar interface.[4] From a technical standpoint, LKP is more time consuming and difficult than full-thickness keratoplasty and generally does not have as good a visual result as PKP. With improvements in microkeratome technology[5–7] and the advent of the clinical femtosecond laser,[8] however, LKP is undergoing a renaissance and resurgence. These newer technical innovations have aided in both the improvement of the lamellar interface smoothness and the reduction of the technical difficulty of LKP (Fig. 38.1).

Broadly, preoperative criteria for LKP include adequate recipient corneal endothelial function, a healthy ocular surface, and anterior corneal opacity/disease that spares Descemet's membrane. If possible, ocular surface disorders, such as dry eye, trichiasis, meibomian gland disease, entropion and ectropion, lagophthalmos, limbal stem-cell insufficiency, and pemphigoid should be eliminated or at least aggressively treated prior to LKP. Lamellar transplantation is advantageous in patients with poor compliance and patients who are young and physically active and therefore at greater risk of postoperative trauma.

LKP is used for both optical and tectonic indications: (1) optical LKP for improving vision in patients with anterior corneal opacities or irregular astigmatism from surface pathology and (2) tectonic LKP for reinforcement of structural integrity in corneas weakened and distorted by thinning, perforation, or descemetocele. LKP may also be used for a combination of optical and tectonic indications. Prior to performing PKP on a very thin cornea, LKP could be done first to restore a normal corneal thickness to allow safer and easier suturing of the future penetrating graft.[9,10] Lamellar grafting should generally be avoided in the removal of malignant corneal tumors

or deep corneal infections, as the possibility of subtotal extirpation or recurrent disease exists.

OPTICAL INDICATIONS

Clinical indications for optical LKP may vary among regions of the world, reflecting the differences in the relative prevalence of endemic corneal diseases. For example, there are noticeable dissimilarities in preoperative indications for LKP between India (Table 38.1)[11,12] and the USA (Table 38.2).[13]

Although dystrophies of Bowman's layer and anterior stroma are common indications for optical LKP in the USA (Table 38.2), LKP may also be considered in some cases of macular and lattice dystrophies if the deep stroma is mostly or entirely spared.[11] Corneal dystrophies recur frequently in grafts,[13] usually more so in the anterior stroma;[14] thus, LKP is a favorable option to PKP, because the procedure could be repeated multiple times without violating the intraocular anatomy.[13,15]

LKP may be preferred over PKP in aniridic keratopathy, because of the high incidence of intraocular complications, such as glaucoma, endothelial rejection, and cataract with full-thickness keratoplasty.[16,17] Combination of LKP with limbal stem-cell transplantation may improve its long-term survival, corneal graft clarity, and visual prognosis.

Corneal scars or leukomas in the anterior corneal stroma, usually resulting from infection or trauma, may be successfully treated with LKP. Corneal scars that result from infection account for a large proportion of LKPs in the developing world,[11,12] and many of these infections may be directly or indirectly related to trachoma.[12] Most scars from infectious keratitis can be successfully treated with LKP, but scars from Herpes simplex keratitis carry a risk of recurrent disease, corneal melting, and subsequent graft failure. Of the four LKPs done for scars resulting from herpetic infection in our series,[13] two grafts failed after severe stromal ulceration. One ulcer began as a nonhealing epithelial defect 3 months after surgery, while the other developed dendritic keratitis 9 years postoperatively.

Lamellar transplantation in keratoconus may be done for both optical (Fig. 38.2, *A* and *B*) and tectonic indications. The main purpose of LKP in keratoconus is to flatten the cone and to reduce the irregular distortion, but a secondary benefit is the removal of

stromal scars from the visual axis. Contact lens fitting and tolerance are also improved. As many keratoconus patients tend to be young, physically active, and prone to trauma, LKP may be a safer alternative to PKP. LKP is the procedure of choice for patients with Down's syndrome in whom eye rubbing and self-induced trauma may preclude PKP.[18,19] In our series, five of the six patients who underwent optical LKP for keratoconus had Down's syndrome.[13] The visual results in LKP for keratoconus are, however, not as good as in PKP,[2,20,21] especially when deep stromal scars are present. Consequently, some surgeons advocate deep dissection to Descemet's membrane (deep anterior LKP) for the surgical treatment of keratoconus.[22–28] To facilitate the baring of Descemet's membrane in these procedures, lamellar injection of air (big-bubble),[28] fluid,[24] or viscoelastic may be employed to physically separate the membrane from posterior stroma.

Degenerations of the anterior cornea comprise another relatively frequent indication for optical LKP, especially in the developing world.[11,12] Climatic droplet keratopathy accounted for 45% of LKPs at one referral center in India.[11] Although Salzmann's nodular degeneration[11–13] and band keratopathy[11–13] may also be treated by LKP, simple peeling of the nodules or chemical chelation of the calcium, with or without diamond drill polishing of the Bowman's layer, is usually sufficient and may preclude the necessity for transplantation. Other indications for optical LKP include chemical burns,[12] pterygia over the central visual axis,[12,29] and benign superficial tumors, such as dermoids.[12,13]

TECTONIC INDICATIONS

LKP in the surgical management of acute corneal ulceration, with or without perforation, is sometimes called patch grafting. When urgent reparative or reconstructive surgery must be performed à chaud in these acutely inflamed eyes, LKP is safer than a more invasive procedure such as PKP. A reconstructive patch graft serves as a temporary stop-gap measure to stabilize the globe, allowing it time to quiet down before a vision-restoring PKP is performed at a later time. Tectonic LKPs are thus helpful in the treatment of corneal melts, not only by providing structural support, but also by buying precious time until systemic immunosuppressive therapy has a chance to arrest the underlying collagenolytic activity. Tectonic lamellar grafts are structurally superior to cyanoacrylate tissue adhesive or amniotic membrane inlays and overlays and are definitely the therapy of choice in large (>1 mm) corneal ulcerations or perforations. Furthermore, in central corneal ulcers or perforations, LKPs usually do not obscure the visual axis as much as opaque cyanoacrylate tissue adhesives or amniotic membrane. Lamellar transplantation may also help resolve inflammatory keratitis that is refractory to medical therapy by debriding necrotic tissue that contains inflammatory cells, toxic debris, and collagenolytic compounds. Less invasive corneal surgery, such as tarsorrhaphies and conjunctival flaps, may also be considered. Whenever possible, therapeutic LKP should be delayed for as long as possible, unless the corneal disease appears to be worsening despite maximal medical therapy and the integrity of the globe is threatened.

Inflammatory corneal ulceration with underlying systemic autoimmune disease is a frequent indication for tectonic LKP, accounting for 50 out of 80 cases in our series.[4] Of the systemic diseases associated with sterile ulcerative keratitis requiring tectonic lamellar grafting, rheumatoid arthritis is the most common in our experience (Table 38.3). Autoimmune systemic diseases are frequently associated with severe keratoconjunctivitis sicca, and accordingly attention should also be directed toward aggressive control of the dryness through the use of artificial tears, ointments, cyclosporin, and punctal occlusion. Tectonic lamellar grafting is successful in the long term only if the underlying immunological disease is adequately controlled through the use of systemic medical therapy. Good systemic control of the disease is necessary not only for the successful salvage of the globe and the preservation of vision,[4] but also for reducing patient mortality associated with systemic vasculitis.[30] Tectonic LKP in the treatment of peripheral ulcerative keratitis[4] often requires technically difficult freehand, eccentric, crescentic, or fan-shaped (Fig. 38.3) lamellar dissections.[31]

Infectious corneal ulceration accounts for 18.8% of the tectonic lamellar grafts in our series,[4] with bacterial and herpetic infections predominating (Table 38.3). Fungal infections have traditionally been considered a contraindication for lamellar procedures,[32–34] because of the depth of penetration of organisms in the cornea.[35] Although PKP is usually preferred in fungal keratitis, LKP may be done if there is a reasonable chance that all infected corneal tissue could be extirpated.[35]

Noninflammatory indications for tectonic LKP include keratoconus,[18,19] pellucid marginal degeneration,[36] keratoglobus,[9] and

Terrien's marginal degeneration.[37] Lamellar grafting in these diseases may improve vision by restoring a more normal, less astigmatic corneal contour.[13,38] LKP may also be used, as mentioned previously, as the initial step to structurally reinforce a thin cornea prior to PKP.[9,10]

Other indications for tectonic lamellar grafting include the reinforcement of an excessively thin cornea after excision of a deep dermoid[12,13,39] and for the removal of other benign neoplasms.[12] Rarer indications include neurotrophic, exposure, and radiation keratopathies (Table 38.3). Small, tectonic lamellar ('snowman' or 'piggyback') grafts are also used to repair focal sterile ulcerations or perforations at the graft–host junction in PKP (Fig. 38.4).[40] The use of these small piggyback grafts preserves the central portion of the PKP and is also a safer alternative to an oversize PKP, which carries an increased risk of rejection, glaucoma, and cystoid macular edema.[41,42]

SUMMARY

The success of optical LKP has varied in the past, but the procedure is a good alternative in select cases and possesses numerous advantages over PKP. Although it is a safer alternative to PKP, it is limited by vision-reducing interface problems and by being a more technically challenging procedure. The visual results of LKP may be improved by deep LKP baring recipient Descemet's membrane and the use of a mechanical microkeratome or femtosecond laser for cutting the lamellar button in both donor and recipient corneas. Tectonic LKP is an effective procedure for reinforcing and repairing the integrity of the eye damaged by corneal melting. It is less invasive than PKP and is the preferred keratoplasty method in acutely inflamed and unstable eyes. It also provides structural support while allowing systemic immunosuppressive therapy time to take effect and for the eye to become quiescent before future vision-restoring surgery.

39 Epikeratoplasty

Ayad A. Farjo, Michael D. Wagoner

INTRODUCTION

Epikeratoplasty (EKP) is a form of onlay lamellar keratoplasty (LKP) in which a lens made of human corneal tissue is sutured onto the anterior surface of the cornea to change the anterior curvature and refractive properties of the cornea.[1] It was originally introduced by Dr Herbert Kaufman at the Jackson Memorial Lecture at the American Academy of Ophthalmology[1] as an extension of the pioneering work of Joaquin Barraquer[2] in the development of keratophakia for aphakia and keratomileusis for myopia.

The objective of EKP is to provide the refractive benefits of keratophakia and keratomileusis with less cost, less technical complexity, fewer complications, and without requiring dissection and removal of a portion of the central cornea.[2] To accomplish this, Kaufman recommended suturing of cornea donor tissue that was commercially prepared by cryolathing to a prespecified dioptric power onto a recipient eye from which the central epithelium had been removed but Bowman's layer had been left undisturbed (Fig. 39.1, *A* and *B*).[1] The use of commercially prepared EKP 'lenticules' eliminates the need for the operating surgeon to purchase the expensive equipment required to perform the technically difficult cryolathing procedure. The elimination of central corneal dissection step greatly reduces the complexity of the procedure, along with the risks of complications such as interface opacification and stromal scarring. Finally, EKP is potentially reversible because the central cornea is not disturbed by the procedure. The use of a commercially prepared lenticule of precise power (or 'living contact lens') and the utilization of a surgical technique that provides for 'complete reversibility' in a worst-case scenario resulted in optimistic claims that EKP would become the ideal refractive surgical procedure for the correction of both myopia and hyperopia.

INDICATIONS

Epikeratoplasty was originally introduced for contact lens-intolerant, monocularly aphakic adults, in whom secondary intraocular lens implantation was contraindicated.[1,3,4] The indications were later expanded to include the correction of keratoconus,[5,6] pediatric aphakia (Fig. 39.2),[7,8] and myopia.[9] Between 1985 and 1988, a nationwide study was conducted by 234 'general ophthalmologists,' who had received an intensive 2-day training course, to evaluate the use of EKP for all four indications in preparation for market approval by the US Food and Drug Administration (FDA).[10–14]

The original optimism after the introduction of EKP was not fully realized in the original clinical trials or subsequent studies. As a result of data generated from a nationwide study, the FDA did not approve the use of EKP for myopia due to poor predictability and an unacceptably high rate of refractive regression.[10] Although FDA approval was obtained for use of EKP for adult aphakia, the advent of improved anterior chamber intraocular lens designs and the development of techniques for intraocular lens fixation in the absence of capsular support provided a more simple solution for the treatment of adult aphakia.[15] Secondary intraocular lens placement with anterior chamber, iris-sutured posterior chamber, or scleral-sutured posterior chamber intraocular lenses is associated with more rapid visual rehabilitation, better visual acuity, better contrast sensitivity, and superior refractive accuracy than EKP and has led to abandonment of this procedure for adult aphakia.[14,16,17] Despite FDA approval for pediatric aphakia, favorable results with pediatric intraocular lenses, as well as increasing acceptance of intraocular lens insertion in children offered an attractive alternative to EKP in children.[18,19] Today, the excellent safety record of secondary intraocular lenses[19] has largely eliminated the need for aphakic EKP. The only remaining FDA-approved use of EKP that is currently used is for the treatment of contact lens-intolerant keratoconus and for tectonic reinforcement of the globe for corneal thinning disorders, such as keratoglobus, Terrien's marginal degeneration, and pellucid marginal degeneration. [11,20–26]

Epikeratoplasty for keratoconus

Lamellar keratoplasty has long been used to reinforce thin, ectatic corneas in eyes with keratoconus and other corneal thinning disorders (Fig. 39.3). Compared with penetrating keratoplasty (PKP), LKP is an extraocular procedure that reduces or eliminates many of the serious complications of intraocular surgery such as expulsive hemorrhage or endophthalmitis. By preserving the recipient endothelium, which is almost invariably normal in young patients with keratoconus, the likelihood of maintaining normal corneal hydra-

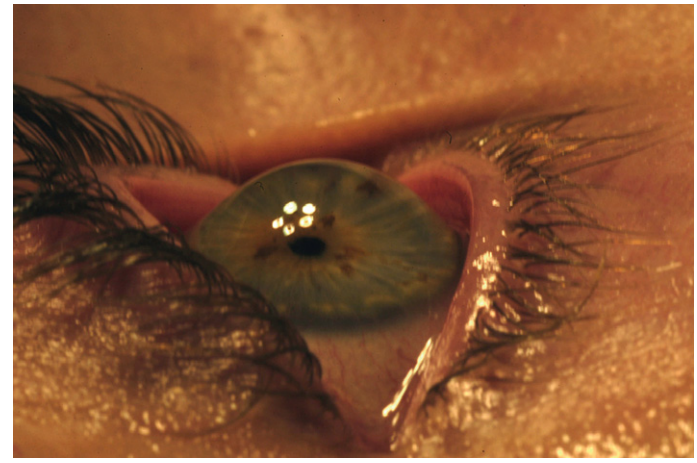

Figure 39.3. Intraoperative view of an eye undergoing EKP for keratoglobus.

tion and clarity for many decades is much higher after LKP than with PKP. In addition, the risk of endothelial rejection, which is seen in 8–39% of PKP for keratoconus, is eliminated.[27–29] While the risk of stromal rejection is probably identical with PKP and LKP, this complication is far less serious than endothelial rejection.[30] Despite the potential advantages of LKP, it was largely abandoned due to the superior visual results of PKP for keratoconus,[29] especially since overall graft survival remains high after PKP despite the incidence of endothelial graft rejection episodes.[27,31,32]

As originally described, EKP was best suited for keratoconus patients with poor spectacle acuity, absence of scarring in the visual axis, best-corrected visual acuity with a hard contact lens of 20/40 or better, and contact lens intolerance.[11] Because of the flattening and slight shift of the position of the cone, EKP was not recommended in eyes with paracentral scars within 1 mm of the visual axis.[11] Exceptions were made in cases such as Down's syndrome, where the advantages of an extraocular procedure outweighed the disadvantages of a 'less than perfect' visual result following EKP in eyes with mild to moderate central corneal scarring. Similar reasoning was applied to a large population with keratoconus in Saudi Arabia in which concerns about postoperative compliance and access to follow-up care were felt to offer a significant risk of graft failure due to neglected endothelial rejection episodes.[20] While some observers felt that better results could be obtained with cones less than 60 D in steepness,[16,21] this observation was not supported by later studies.[20]

Epikeratoplasty may be performed as part of a 'staged' tectonic procedure (T-EKP) in the treatment of corneal thinning disorders such as keratoglobus, pellucid marginal degeneration, or Terrien's marginal degeneration.[25,26] Large custom-made lenticules, up to 12.5 diameters and approximately 300 µm in thickness, may be ordered and used to reinforce the entire cornea in the first stage. If the postoperative improvement in corneal contour results in acceptable visual acuity with spectacles or a contact lens, no additional therapy is needed. If the visual acuity remains inadequate, a central PKP can be performed to complete visual rehabilitation. The reinforcement of peripheral corneal tissue by EKP greatly facilitates proper suturing of the donor cornea.

SURGICAL TECHNIQUE

Epikeratoplasty lenticules are prepared from corneal tissue that meets the criteria of the Eye Bank Association of America for trans-

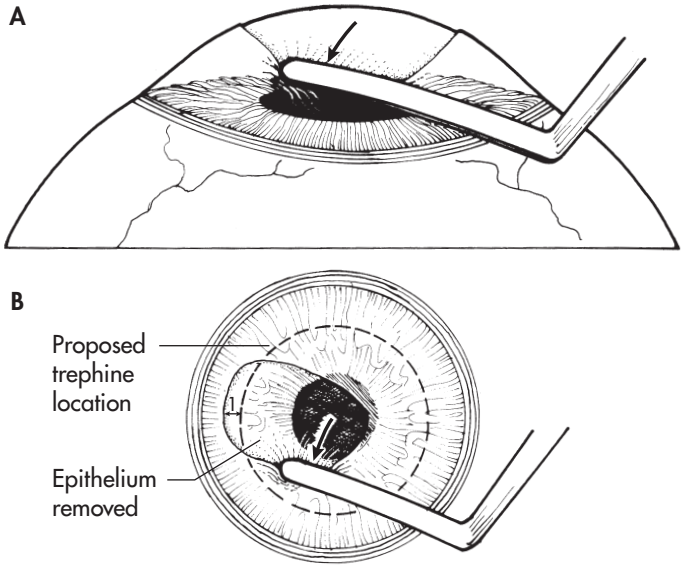

Figure 39.4. Technique for epithelial removal, side view (*A*) and surgeon's view (*B*), with blunt debridement with a spatula or blade.

plantation but does not qualify for use for PKP due to factors such as poor endothelial cell counts, long death-to-preservation times, or excessive length of time in storage media. Originally, corneal tissue was cryolathed and lyophilized prior to shipment to the operating surgeon. Today, fresh corneal stromal tissue is cut to a specific thickness and diameter, as requested by the operating surgeon, by participating eye banks and provided in standard storage media utilizing the same protocol that is used for other eye bank tissue. For treatment of keratoconus, donor stroma with a diameter of 9.0 mm and a thickness of approximately 225 µm is recommended. In the absence of prepared lenticules, alternatives include manual dissection of a donor anterior stromal disc using an artificial anterior chamber or using pre-cut corneal tissue originally intended for endothelial transplantation.

Epikeratoplasty may be performed with general anesthesia, retrobulbar or peribulbar anesthesia, or topical anesthesia (in extremely cooperative adults). The central corneal epithelium is debrided at least 1.0–1.5 mm beyond the edge of the anticipated trephination with a dull spatula, facilitated by topically applied 4% cocaine, if necessary (Fig. 39.4, *A* and *B*). Although 20% ethanol can also be used to remove the epithelium, its use should be judicious, as it has been suggested to contribute to poor postoperative epithelial healing. All epithelium should be removed from the surgical field and fornices to prevent accidental retention of epithelial nests in the interface during lenticular suturing.

After epithelial removal, an 8.5 mm (or one that is 0.5 mm less in size than the donor size requested by the surgeon) manual or Hessburg–Barron trephine is centered on the visual axis and trephination is performed approximately 225–250 µm into the corneal stroma (Fig. 39.5). Many surgeons perform a 0.5-mm annular keratectomy on the axial side of the trephine incision to facilitate suturing of the lenticule, although this is not mandatory (Fig. 39.6, *A* and *B*).

If lyophilized tissue is used, the lenticule is rehydrated for 20 min in balanced salt solution containing antibiotics. If fresh corneal donor tissue is used, it is transferred directly to the recipient eye from the donor storage media. Edge-to-edge approximation of the donor tissue and the recipient cornea should be performed with

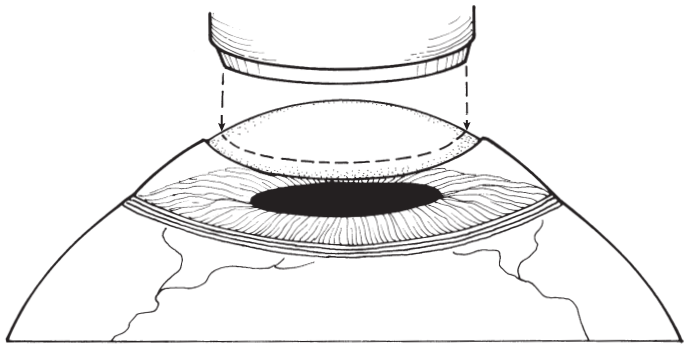

Figure 39.5. Partial thickness trephination can be accomplished with a manual or vacuum-assisted trephine.

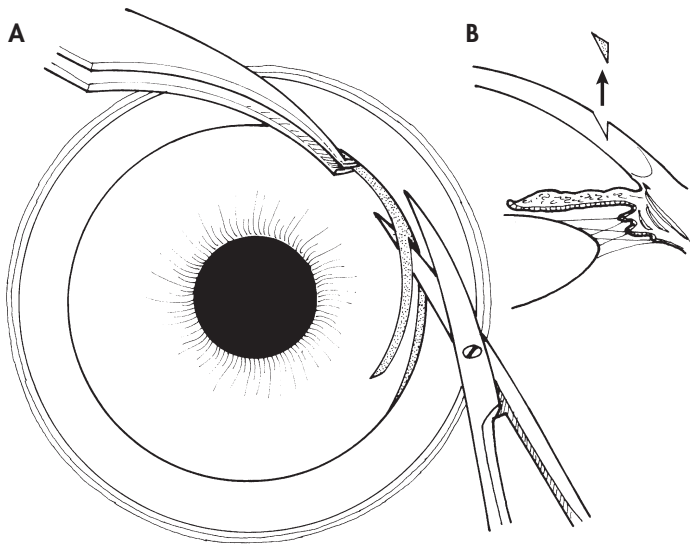

Figure 39.6. An optional partial-thickness annular keratectomy of the host cornea, side view (*A*) and surgeon's view (*B*), can facilitate suturing of the donor lenticule.

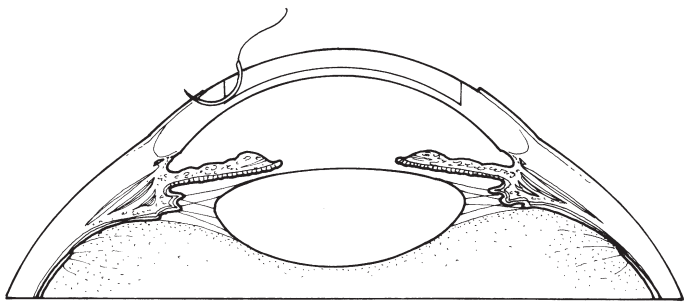

Figure 39.7. Edge-to-edge donor to host approximation is essential to a successful outcome. Care should be taken to avoid donor override of the host that may delay epithelialization.

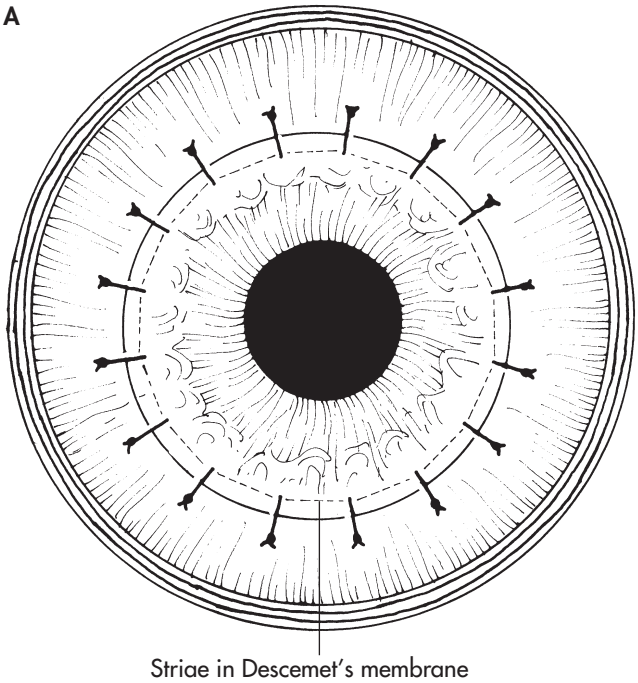
suture placement as posterior as possible in the donor tissue without inadvertent through-and-through bites and at the base of the recipient trephination groove (Fig. 39.7). A total of 16 or 24 sutures-interrupted 10-0 nylon sutures are placed, after which all knots should be rotated and buried. To obtain maximum flattening of the cone, some surgeons utilize a 9-0 silk suture for the four cardinal sutures and replace them with 10-0 nylon sutures at the conclusion of the case. Cardinal sutures should be tied as securely as possible

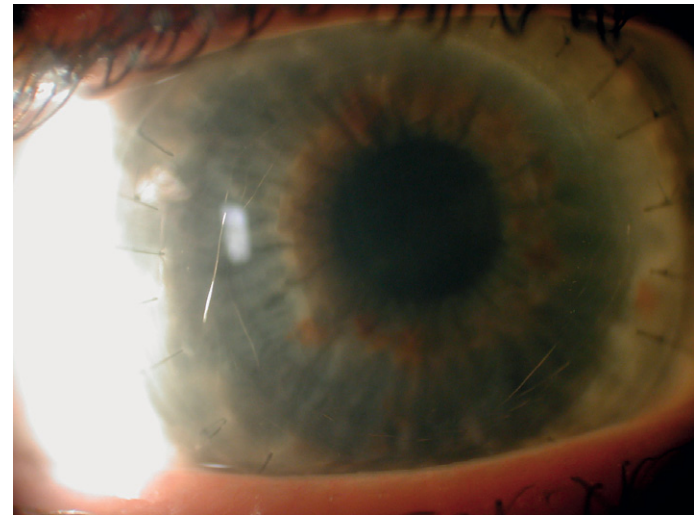
while the assistant flattens the cone with a flat spatula. Alternatively, or additionally, to aid in flattening the cone, an anterior chamber paracentesis can be performed to remove aqueous humor and lower the intraocular pressure. Concentric folds should be present in Descemet's membrane at the conclusion of the procedure, indicating that the cone has been flattened significantly (Fig. 39.8, *A–C*). These vanish after suture removal and have no permanent effect on visual outcome.

POSTOPERATIVE CARE

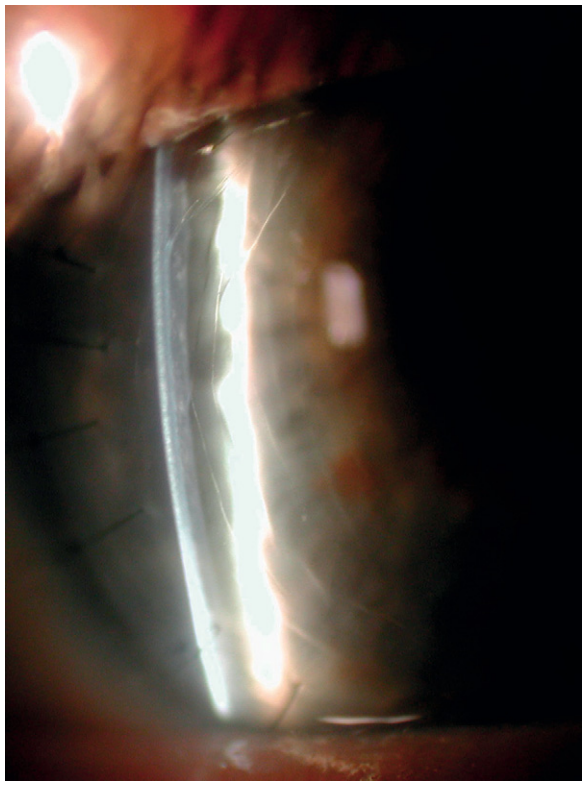
The success of EKP for keratoconus is highly dependent upon facilitating prompt re-epithelialization of the donor tissue and control of inflammation to prevent premature suture and interface vascularization. To facilitate re-epithelialization, most surgeons use bandage soft contact lenses or pressure patching. In the past, when lyophilized donor tissue was used, delayed re-epithelialization was

A





B



C

Figure 39.8. Appropriately tightened sutures will result in concentric striae (*A–C*).

common. Loss of graft clarity almost invariably occurred when epithelial defects persisted for more than 2 weeks with lyophilized issue, often in association with sterile corneal ulceration due to the lack of viable keratocytes essential for proper wound repair in the donor tissue (Fig. 39.9, *A–C*).[33] Removal of the lenticule was essential in such cases to restore the original status of the recipient cornea and prevent permanent scarring and visual loss.[34] One study demonstrated that placement of a temporary tarsorrhaphy at the conclusion of the surgical procedure reduced the mean time of re-epithelialization to 4.61 days, compared to 8.03 days with pressure patching ($p < 0.01$) and 13.2 days with bandage soft contact lenses ($p < 0.005$).[35] Since delayed re-epithelialization of 2 weeks or more is often associated with irreversible loss of lyophilized lenticular clarity, prophylactic placement of a temporary suture tarsorrhaphy at the conclusion of every EKP procedure became routine practice for many clinicians.[35] Today, persistent epithelial defects after EKP are unusual due to the use of fresh corneal donor tissue, so it is acceptable practice to utilize pressure patching or bandage soft contact lenses in the early postoperative period and to reserve temporary tarsorrhaphy for those cases in which re-epithelialization is delayed beyond the first week or in cases where delayed healing is expected. Topical prophylactic antibiotics should be utilized until re-epithelialization is complete. Removal of the EKP lenticule is occasionally necessary in the early postoperative period due to loss of graft clarity or sterile ulceration due to persistent epithelial defects (Fig. 39.10, *A* and *B*) or due to secondary microbial keratitis.[33,34,36,37]

Proper suture management is essential to achieve the desired result. Maintenance of tight corneal sutures for a minimum of 3 months, and preferably at least 6 months, is necessary to achieve maximum permanent corneal flattening and reduction of irregular astigmatism. Topical corticosteroids should be used to prevent

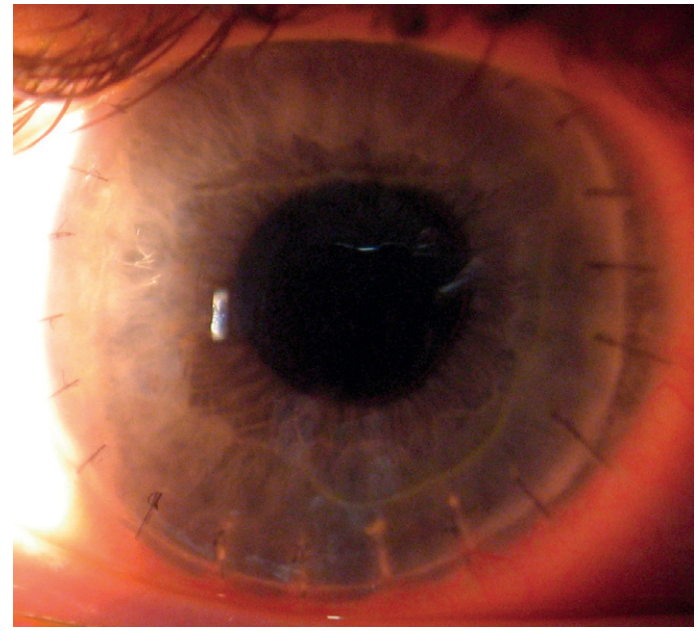
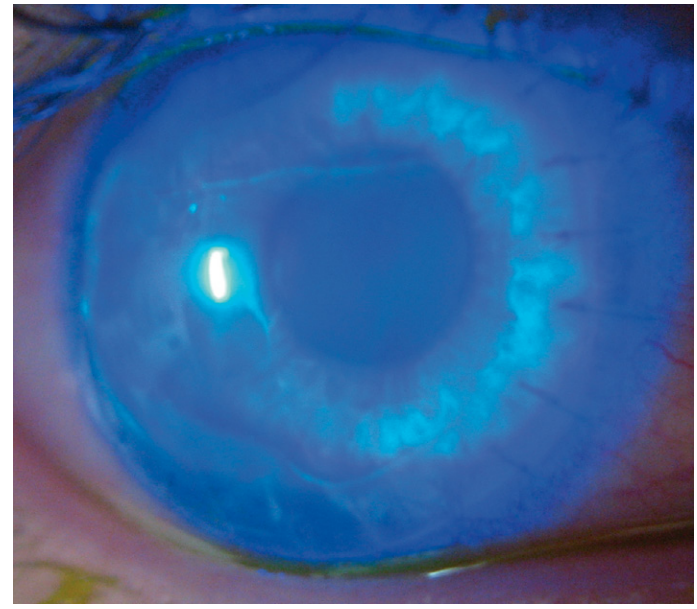
premature suture vascularization and loosening as well as epithelial and/or stromal rejection (Fig. 39.11, *A* and *B*). A reasonable regimen is prednisolone acetate 1.0% four times daily for 2 weeks, three times daily for 2 weeks, twice daily for 3 months, and once daily for 3 months. Loosened sutures should be removed to prevent vascularization (Fig. 39.12) and secondary microbial keratitis as well to avoid compromising the prognosis for future potential LKP or PKP. Suture removal should always be performed so that the knot exits from the host corneal side of the wound to avoid dehiscence of the wound. If the lenticule does dehisce during suture removal, it is important to tuck the lens back into position either at the slit lamp or in the minor treatment room. If the edge of the lenticule does not remain in proper position, it is essential to resuture the wound to avoid compromising the surgical result. Sutures that are removed within the first month should be replaced to prevent development of irregular astigmatism in the meridian of suture removal even if the graft appears to be in proper position, unless there is significant neovascularization or keratitis in the area of suture removal.

Removal of the lenticule may be necessary in the late postoperative course due to suboptimal visual acuity related to persistent irregular astigmatism, poor lenticular clarity, or interface haze or opacification (Fig. 39.13). If PKP is planned, it is best to combine



A



B

it with EKP removal in a single procedure. The most efficient method of removing the lenticule at the time of a combined procedure is simple trephination of the central cornea. Anecdotally, the prognosis of PKP does not seem to be compromised by prior EKP, but there are insufficient data in the literature to firmly support this observation.

RESULTS

When EKP was introduced, there was optimism that it would provide visual results comparable to PKP and fewer complications than LKP. Unfortunately, the results of the initial nationwide study and

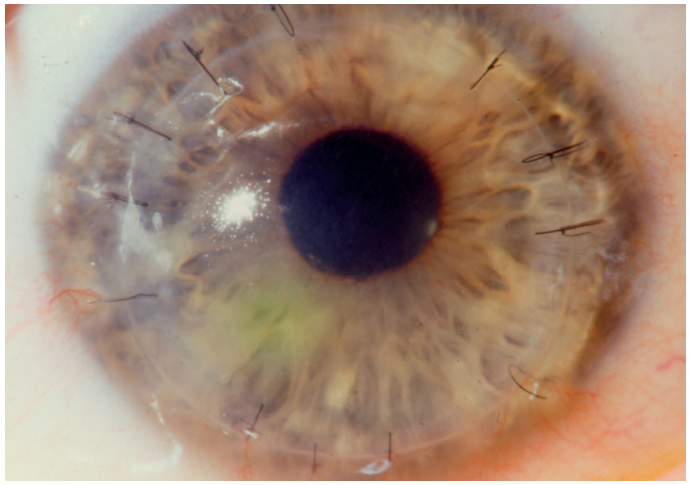

Figure 39.12. Loosened sutures (at 4:30 and 8:30) are a nidus for neovascularization and can lead to infection. These should be removed whenever identified.

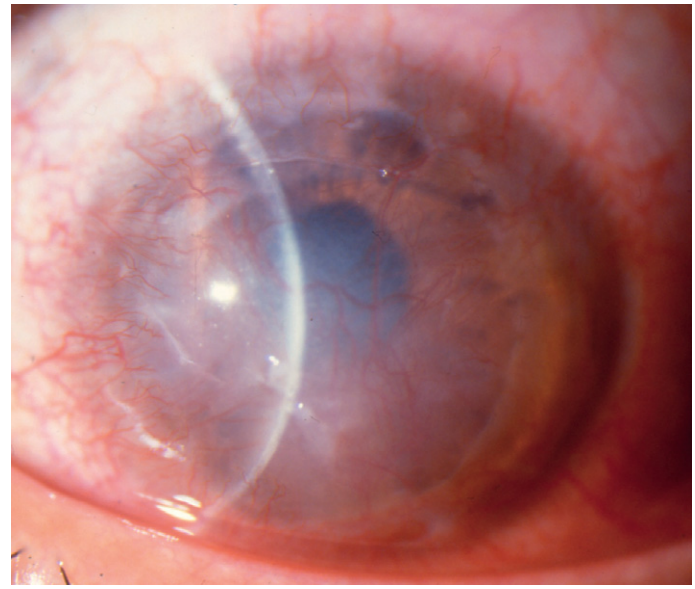

Figure 39.13. Failure of EKP in a noncompliant patient who did not use topical steroids or have sutures removed in a timely fashion.

subsequent studies confirmed that EKP does not meet these expectations.[11,20–24]

The nationwide study of EKP for keratoconus reported satisfactory results of 82 cases in which more than 30 days of follow-up was available following suture removal.[11] Uncorrected visual acuity improved in all but two patients. Whereas only 9% of eyes had an uncorrected visual acuity of 20/100 or better preoperatively, 64% had an uncorrected visual acuity of 20/100 or better postoperatively. All but two patients achieved a best-corrected visual acuity within one line of the preoperative best-corrected contact lens visual acuity. In most cases, the reduction in irregular astigmatism permitted this outcome to be achieved with spectacle correction (Fig. 39.14, *A* and *B*). For patients who chose to continue contact lens wear, the flattening of the cone permitted more satisfactory fitting, comfort, and wearing time.

Several other investigators have compared the results with EKP and PKP in small, nonrandomized series. Fronterre and Portesani reported similar mean uncorrected visual acuity (20/63 vs. 20/52), spectacle-corrected visual acuity (20/23 vs. 20/22), and contact lens-corrected visual acuity (20/21 vs. 20/20) in a comparison of EKP and PKP, respectively.[23] Steinert and Wagoner reported a mean best-corrected spectacle acuity of 20/32 vs. 20/27 after 2 years with EKP and PKP, respectively, although no eyes with EKP achieved 20/20 acuity.[21] Goosey and associates observed that while 93% of eyes achieve best-corrected acuity of 20/40 or better after either EKP or PKP, only 23% with EKP obtained 20/20 vision, compared to 73% with PKP.[24] Contrast sensitivity is reduced with or without glare after EKP when compared with both rigid gas-permeable hard contact lenses and PKP.[38]

The largest comparative study came from Saudi Arabia where 161 eyes with keratoconus treated with EKP at the King Khaled Eye Specialist Hospital (KKESH) in Riyadh were compared to 443 eyes treated contemporaneously with PKP at the same institution by the same surgeons.[20] A minimum of 24 months of follow-up was available, with a mean follow-up period of 54 months for EKP and 52 months for PKP. Among patients who chose either spectacle or contact lens rehabilitation, the median visual acuity was 20/50 for 77 eyes treated with EKP compared to 20/30 for 209 eyes treated with PKP ($p = 0.0003$). Over 75% of eyes achieved a best-corrected visual acuity of 20/40 or better after PKP, compared to only 25% after EKP. Among patients who did not choose to use optical correction postoperatively, the median visual acuity was 20/60 in 84 eyes treated with EKP and 234 eyes treated with PKP. The large series of patients treated with EKP was generated, in part, because of logistical concerns about the ability of many of the patients to have access to prompt intervention for graft-related complications, due to long distances required to travel to the tertiary eye care facility in Riyadh. Despite logistical concerns that previously existed about access to postoperative care and patient compliance, the prognosis for PKP in the latter group was found to be excellent, with a high rate of clear grafts and an acceptably low complication rate.[31]

SUMMARY

There has been limited enthusiasm about utilizing EKP as an alternative to PKP in eyes with keratoconus because of statistically significant poorer visual results.[20] Deep anterior lamellar keratoplasty (DALK) has become the alternative procedure of choice for eyes with scarring in the visual axis for which PKP is undesirable or contraindicated.[39] Visual outcomes comparable to those achieved with PKP may be possible with DALK due to the virtual elimination of interface scarring that often occurs after LKP. Epikeratoplasty may still be considered as an option if there are concerns about self-induced trauma from rubbing (e.g. Down's syndrome) or external trauma related to professional or athletic activities, especially if the alternative is withholding surgical therapy. Although both LKP and DALK maintain some extraocular advantages of EKP, they can make the eye more vulnerable to trauma, although not to the same degree as PKP, thereby preserving a limited role of EKP for this indication. From a surgical standpoint, EKP is also technically easier than DALK.[40] Finally, for contact lens-intolerant patients with clear corneas and mild to moderate keratoconus, intracorneal ring segments may supplant EKP due to acceptable visual results and greater likelihood of achieving complete reversibility in failed cases.[41,42]

Originally, EKP was expected to become the treatment of choice in countries without eye bank programs because of logistical difficulties in obtaining donor tissue before the expiration of donor endothelial viability and concerns about access of many patients to prompt and reliable postoperative care. The current use of donor storage media with donor endothelial viability of up to 2 weeks[43–45] has made it possible for countries, such as Saudi Arabia, that obtain donor tissue from abroad to offer patients a prognosis for graft survival that is comparable to that obtained in Western countries, despite the difference in media storage time.[29,31,45] The alternative use of EKP because of concerns about patient compliance and access for follow-up care remains applicable in some areas.

FUTURE DIRECTIONS

SYNTHETIC EPIKERATOPLASTY

Synthetic epikeratoplasty (S-EKP) is an investigative procedure whereby a biocompatible synthetic lenticule is attached to the anterior surface of a de-epithelialized recipient cornea in a manner identical to that described for EKP.[46–48] The impetus to develop S-EKP originated from a desire to overcome the shortcomings of the use of fresh or lyophilized donor tissue for EKP, while retaining the benefits of providing a potentially reversible extraocular procedure. Whether using fresh corneal tissue, lyophilized corneal tissue, or synthetic tissue, an ideal donor lenticule must (1) be readily available, (2) be of predictable size and dioptric power, (3) have optical clarity, (4) support epithelial migration and adhesion, (5) be permeable to solute, and (6) resist enzymatic digestion.

The anticipated success of EKP as a refractive procedure raised concerns about potentially compromising the availability of donor tissue for patients needing optical or therapeutic keratoplasty. This concern was partially offset by the requirement that tissue used for EKP should be unsuitable for corneal transplantation, but this did not address the issue that the potential demand for hundreds of thousands of donor corneas per year would impose upon eye bank networks. Successful development of an S-EKP lenticule offers the potential for a limitless supply of lenticules, thereby eliminating concerns related to both ethics and supply of donor tissue for the procedure.

Collagen-containing or collagen-derived materials and copolymers consisting of 2-hydroxyethyl methacrylate (HEMA) and collagen are good candidates for biomaterials for S-EKP.[46] Both materials are biocompatible, are adequately permeable to aqueous nutrients and metabolites, and can be accurately cut to precise diameters, thickness, and dioptric power. Reliable in situ excimer modulation is theoretically feasible with either material, since haze and collagen remodeling would not be expected in an acellular matrix. Lenticules containing type I, III, or IV collagen offer the advantage of good potential for epithelial migration and adhesion, but the disadvantage of susceptibility to enzymatic degradation by naturally occurring collagenase. Copolymers containing HEMA have better resistance to enzymatic degradation, but potential problems supporting epithelial migration and adhesion.

Thompson and coworkers reported limited in vivo success with S-EKP in nonhuman primates.[46–48] S-EKP lenticules were prepared with type IV collagen extracted from the supernatant of human placenta that was cross-linked with glutaraldehyde. Lenticules were 7.5 mm in diameter and 250 μm thick, and had an optical power ranging from +10.00 to −10.00 D. In vitro studies demonstrated that these synthetic lenticules were capable of supporting epithelial spreading and attachment. In vivo studies were performed on seven eyes of seven monkeys who were selected as an experimental model due to similarity of rhesus monkey eyes to human eyes. Failure of re-epithelialization in the first four eyes with lenticular loss due to expulsion or erosion was attributed to eye rubbing. Success of re-epithelialization in the last three eyes was attributed to hand restraints that were used for the first 7 postoperative days. Among the three eyes with successful re-epithelialization, two had focal erosions at 4 months, while one remained stable until the animal was sacrificed 42 months postoperatively. Histopathological examinations demonstrated evidence of formation of satisfactory

hemidesmosomes, anchoring fibril components, and new basement membrane.

As with EKP, other advances in the treatment of keratoconus and refractive disorders of the eye has dampened the enthusiasm for further development and implementation of S-EKP in humans. Sufficient fresh corneal donor tissue is available for the rather limited indications of EKP for KC, and most of the shortcomings of the procedure related to the use of lyophilized tissue have been eliminated. The advent of modern, reliable, and relatively simple and safe keratorefractive procedures,[49,50] and the availability of safe intraocular lenses and implantation techniques for all age groups[15,18,19] make further development of S-EKP for the correction of ametropia in humans unlikely to occur in the foreseeable future.

40 Deep anterior lamellar keratoplasty

Sheraz M. Daya, Samer Hamada

The goals of corneal transplantation are to provide corneal clarity with minimal irregularity to permit good vision indefinitely. Penetrating keratoplasty (PKP) may be complicated by endothelial graft rejection and failure, with poor prognoses for regrafts.[1] Lamellar keratoplasty or partial-thickness corneal grafting retains the patient's own endothelial layer, eliminating corneal blindness from allograft rejection. The procedure does, however, require some technical skill to obtain consistently good outcomes. Several advances in technique, combined with improvements in instrumentation, have made the procedure a worthwhile consideration in those with a normal endothelium.

HISTORICAL PERSPECTIVE

The concept of creating a lamellar corneal dissection leaving Descemet's membrane was first postulated by Von Walther in 1830 and further advocated by his student Muhlbauer in 1840.[2] During the late 19th century and first half of the 20th century, Von Hippel, Dürr, De Wecker, Füchs, Filatov, and Paufique all performed lamellar grafts and developed surgical techniques.[3] Deep dissection into the recipient cornea was pioneered by Hallermann in 1959 using full-thickness donor material.[4–6] The motivation to develop and perform lamellar techniques was to avoid penetration of the eye rather than endothelial preservation, of which there was little understanding at the time. Better outcomes were observed with deep dissection, and several hypotheses to account for this observation were proposed. These included McCulloch's theory that deep dissection left minimal host edematous tissue posterior to the graft[7] and the Descemet's membrane (DM) on the donor would act as a barrier to aqueous influx. Deep anterior lamellar grafts were performed with full-thickness donor tissue in conditions including bullous keratopathy!

Stocker suggested that the outcomes of deep anterior lamellar grafts with full-thickness donors were better as 'Descemet's membrane provides a smoother line of separation between donor and recipient, which may encourage the formation of thin solid connective tissue barrier which acts as a barrier to aqueous humor.'[7] Malbran and Stefani in1972 described better results by peeling off stroma from Descemet's centrally.[8] In the same year, Anwar described deep dissection under direct visualization. He found that deeper dissection down to DM level created a very smooth surface.[9] Anwar used full-thickness donor tissue but stripped off Descemet's membrane before transplantation and demonstrated less inflammation and interface scarring. This was supported by histopathologic evidence by Morrison and Swan.[10] Archila in 1984 described a new technique of injecting intrastromal air to facilitate deep lamellar dissection.[11–16] Hydrodelamination of Descemet's membrane was later introduced by Sugita and Kondo (1997),[17] with many adopters of the technique.[15,18,19] Hirano et al, however, demonstrated that delamination does not in fact take place at the Descemet's–stroma interface as initially thought but rather between the anterior and posterior banded zones of Descemet's membrane, reducing the tensile strength of the remaining tissue even further.[20] Melles et al described a novel method to aid deep dissection by injecting air into the anterior chamber to optically delineate Descemet's membrane.[21,22] Finally, in 2002, Anwar and Teichmann introduced the 'big bubble' technique to separate DM by injecting air close to deep stroma.[23,24] The surfaces produced with this technique provide a smooth interface with good early visual outcomes.

PRE-DESCEMET'S AND DESCEMET'S DISSECTION

The variety of techniques developed has now culminated in two possible levels of dissection for deep anterior lamellar keratoplasty (DALK), namely pre-Descemet's, where a small amount of posterior stroma is left on the recipient, and Descemet's, where the membrane is exposed with no residual stroma. The accomplishment of this dissection depends on whether manual dissection is performed or a delamination using either water or air. Although exposure of Descemet's possibly provides the best chance of visual outcome, a small amount of residual posterior stroma does provide more tensile strength, reducing complications, and is unlikely to significantly affect visual outcome. An alternative is a combination of pre-Descemet's dissection peripherally and peeling of stroma centrally to the level of Descemet's membrane as advocated by Malbran.[6] Ultimately, surgeons should select the technique that they are most comfortable with and that is reproducible in their own hands.

INDICATIONS

The indication for DALK is in all cases where the endothelium is normal and where pathology involves deep layers of the corneal stroma. Such indications include keratoconus ocular surface disease and corneal perforations.[25,26]

Outcomes of DALK are often related to the underlying diagnosis and indication for surgery. A proposed classification is to use the indication for performing the procedure and broadly divided into visual, tectonic, ocular surface disease, and miscellaneous (Table 40.1). Ocular surface disease is a special category in that factors that contribute to graft failure include persistent inflammation and corneal necrolysis from persistent epithelial defects. Graft survival was found to be better in those that had a lamellar graft rather than penetrating grafts in association with keratolimbal stem cell transplantation.[38] This categorization enables appropriate comparison of outcomes among authors.

SURGICAL PLANNING

Careful planning is necessary along with appropriate patient counseling. A useful list of questions for surgeons to ask themselves includes: (1) Is the endothelium normal? (2) What level does the pathology extend to and might it involve Descemet's membrane? (3) Will leaving minimal posterior stroma affect visual outcome? (4) What dimensions are required and is dissection technically possible? (5) Are there any issues that may influence the choice of technique, such as previous history of hydrops and a break in Descemet's membrane that might make a delamination technique a relative contraindication? (6) Finally, which dissection technique should be used?

Table 40.1 Indications for lamellar keratoplasty

Visual (optical)
• Keratoconus
• Corneal stromal dystrophies
• Corneal stromal degenerations
• Deep corneal scarring (traumatic, post infection, and other stromal scars)
Tectonic
• Corneal ectasia (focal such as pellucid marginal degeneration, diffuse, or post full-thickness grafting)[4,27]
• Corneal melt (autoimmune,[28,29] neurotrophic, or infectious[30,31])
• Traumatic corneal perforation[32–34]
• Peripheral corneal thinning (Mooren's ulcer, Terrien's marginal degeneration,[35] collagen disease, and other autoimmune diseases)
Ocular surface disease
• Stevens–Johnson syndrome (SJS)
• Chemical or thermal burns
• Ectodermal dysplasia
• Ehler–Danlos syndrome
• Corneal stromal scarring or thinning from an ocular surface disease
Miscellaneous
• Postexcision of corneal lesions (pterygium,[36] dermoid,[37] and tumors)

PATIENT COUNSELING

Patients must be counseled regarding the procedure, with special emphasis on the technical challenges and the possibility of a macroperforation and conversion to PKP. It is probably wise to include the possibility of conversion in the consent form. Other complications, including a double anterior chamber and early intervention and injection of air or isoexpansile gas, should also be conveyed. This is often balanced out by detailing the advantages of the procedure, including the safety of a relatively closed system and the reduced long-term risk of visual loss from rejection. Patients should understand the need for spectacles or contact lenses following surgery and possibly even refractive surgery for high levels of astigmatism.

ANESTHESIA CONSIDERATIONS

Lamellar keratoplasty can and often is performed under local anesthetic; however, monitoring by an anesthesiologist or designate is advised. General anesthesia is useful for a surgeon learning the technique; however, as air may be used in the anterior chamber, the anesthetist must be informed that no nitrous oxide should be used, as this will result in expansion of the air bubble within the eye. The latter may have unexpected and serious consequences, including high pressure and loss of vision.

SURGICAL TECHNIQUES

Vertical trephination and peripheral undermining in the recipient helps good graft–host apposition, accommodation of a thicker donor, and avoidance of graft slippage after suture removal. This improves the visual and refractive outcomes by reducing astigmatic error. Dissection should be as deep and smooth as possible, close to Descemet's membrane to minimize the risk of interface haze and reduced vision due to bed irregularity and consequent irregular astigmatism.[39]

A variety of surgical techniques will be described, commencing with ones that involve dissection and classified as pre-Descemet's followed by others that involve delamination and exposure of Descemet's membrane.

DIRECT DISSECTION

This technique involves initially performing a partial-thickness trephination in the recipient. The corneal stroma is then dissected using a lamellar spatula or crescent knife under direct visualization. Once accomplished, a full- or partial-thickness donor is sutured in place. This technique can be used in situations where the eye is soft, such as a perforation. The disadvantages of this technique include unreliable depth of dissection and possible tilt with a thicker area of remaining stroma on one side of the donor compared to the other, resulting in high levels of astigmatism. Irregularity of the host bed may also be translated to the anterior surface and compromise

vision. The incidence of interface haze can also be high, resulting in reduced vision.

MELLES TECHNIQUE

Melles and coworkers described a technique to visualize the depth of lamellar dissection in DALK. The technique involves exchanging the aqueous with air through a long paracentesis, creating an optical air–endothelium interface.[21] This interface acts as a convex mirror, reflecting back the posterior stroma and instrument to the viewer. A limbal incision is made, and Melles' red dissector (DORC Instruments, Rotterdam, Netherlands) is used to advance posteriorly. A black band is visualized in front of the dissecting instrument, which represents twice the residual posterior stroma (Fig. 40.1). As the instrument advances posteriorly, the black band disappears rapidly and wrinkles become apparent in Descemet's membrane. At this point, the correct depth has been reached close to Descemet's membrane and the red dissector is exchanged for the silver dissector to separate the tissue further through the limbal incision. A longer and more curved blue dissector is used to dissect the cornea in the far periphery opposite the incision. The whole cornea is dissected and, once accomplished, air is partially removed from the anterior chamber and viscoelastic is injected into the lamellar plane to push the posterior lamellar layer posteriorly.[40,41] Trephination is then performed anteriorly, perforating the anterior cornea. The anterior recipient tissue is removed, and the viscoelastic removed by irrigation followed by suture of a full donor with Descemet's membrane removed (see Donor preparation, below).

This technique has the advantage of being reproducible; however, dissection of the whole cornea is unnecessary. Additionally, with such a large area of dissection, tears in Descemet's membrane can occur diagonally opposite to the limbal incision or possibly involve the cone if excessively steep.

The author (SMD) has modified Melles' technique (Fig. 40.2, *A–D*) and commences by performing partial-thickness trephination to 75% depth. A paracentesis is created peripheral to the trephined area for air injection. Dissection takes place using Melles' optical delineation technique in the area central to the trephination along with some peripheral undermining. The anterior lamellar tissue is removed with curved corneal scissors with the bevel angled outward in order to avoid a ledge, and the donor is then sutured. The greatest advantage of this technique is its reproducibility. Deep dissection can be achieved in almost all corneas whether or not there has been previous hydrops. The author has also used this technique to perform lamellar keratoplasty on eyes with previous PKPs that have developed thinning in peripheral host tissue from residual keratoconus. The rationale is to add tissue to the host, permitting a future smaller graft centrally. In six of seven cases performed, no further graft was required, with all patients gaining vision (Fig. 40.3). One case obtained good vision (20/30) for 2 years and then developed endothelial decompensation.

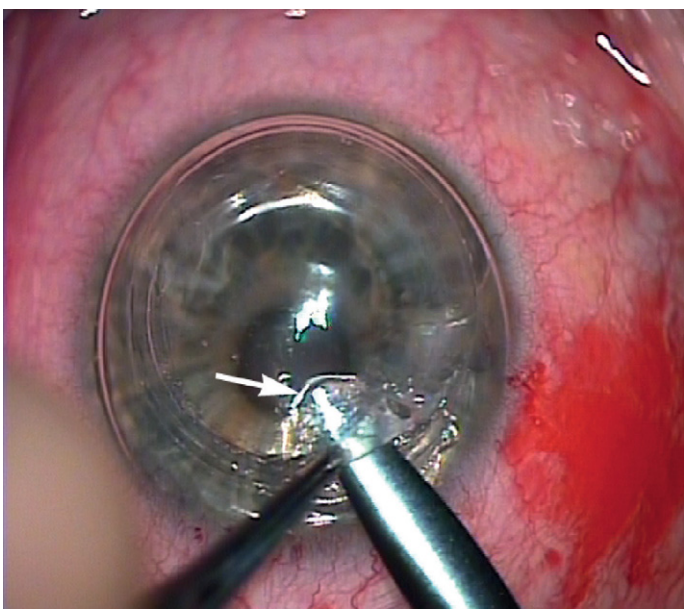

Figure 40.1. Author's modification of Melles technique, using a partial-thickness trephination to commence dissection. Arrow illustrates the 'black band,' representing twice the residual posterior stroma.

FERRARA'S CIRCULAR RING TECHNIQUE

A more recently described technique by Ferrara uses a wider channeling ring similar to that used for implantation of intracorneal ring segments. The curved blade has an eyelet at its tip through which a 6-0 monofilament nylon suture is passed. A mark is placed on the cornea, and the corneal thickness is measured at the point of incision. A micrometer diamond knife is set to 90% and a vertical incision made. A pocketing knife is used to create space posteriorly to allow entry of the curved blade with suture attached. The ends of the suture are held outside the incision with enough slack to allow the blade to rotate. The blade is slowly rotated in the corneal stroma 360° until the tip reaches the radial incision. The leading end of the suture is then removed through the incision. The two ends of the suture are now held, one that remained outside at the entry point and the other passed through the corneal channel and retrieved at the incision. The two ends of the suture are then pulled gradually toward the incision, acting like a cheesewire and creating an ultra-smooth dissection through the cornea. Once the suture is pulled out of the corneal stroma, trephination is performed and an appropriate-sized full-thickness donor is sutured in place.[42]

INTRASTROMAL AIR INJECTION

Archila, Price, and Chau described injection of air into the corneal stroma to opacify and thicken the cornea to facilitate dissection and identification of Descemet's membrane.[11,12,16] As corneal thickness increases the margin of error improves. Furthermore, any tissue left behind subsequently thins out following absorption of air. The technique involves injection of air in the midperiphery of the cornea using a 26-guage needle. This turns the cornea white. A partial trephination is performed and followed by lamellar dissection as close as possible to Descemet's membrane. Once the correct depth is achieved, a blunt spatula is used to complete the dissection of stroma. A paracentesis is usually performed after the injection of air to decrease intraocular pressure, especially if air has entered the anterior chamber as often occurs, possibly through the trabecular meshwork.[12] Occasionally injected air accumulates as a bubble in between stroma and Descemet's; this observation furthered the development of the 'big bubble' technique of Anwar.

A disadvantage is that this technique is not possible in corneas that have had previous breaks in Descemet's membrane. Additionally, dissection can be difficult to accomplish successfully through a scarred opaque cornea or with opacification created by stromal air.

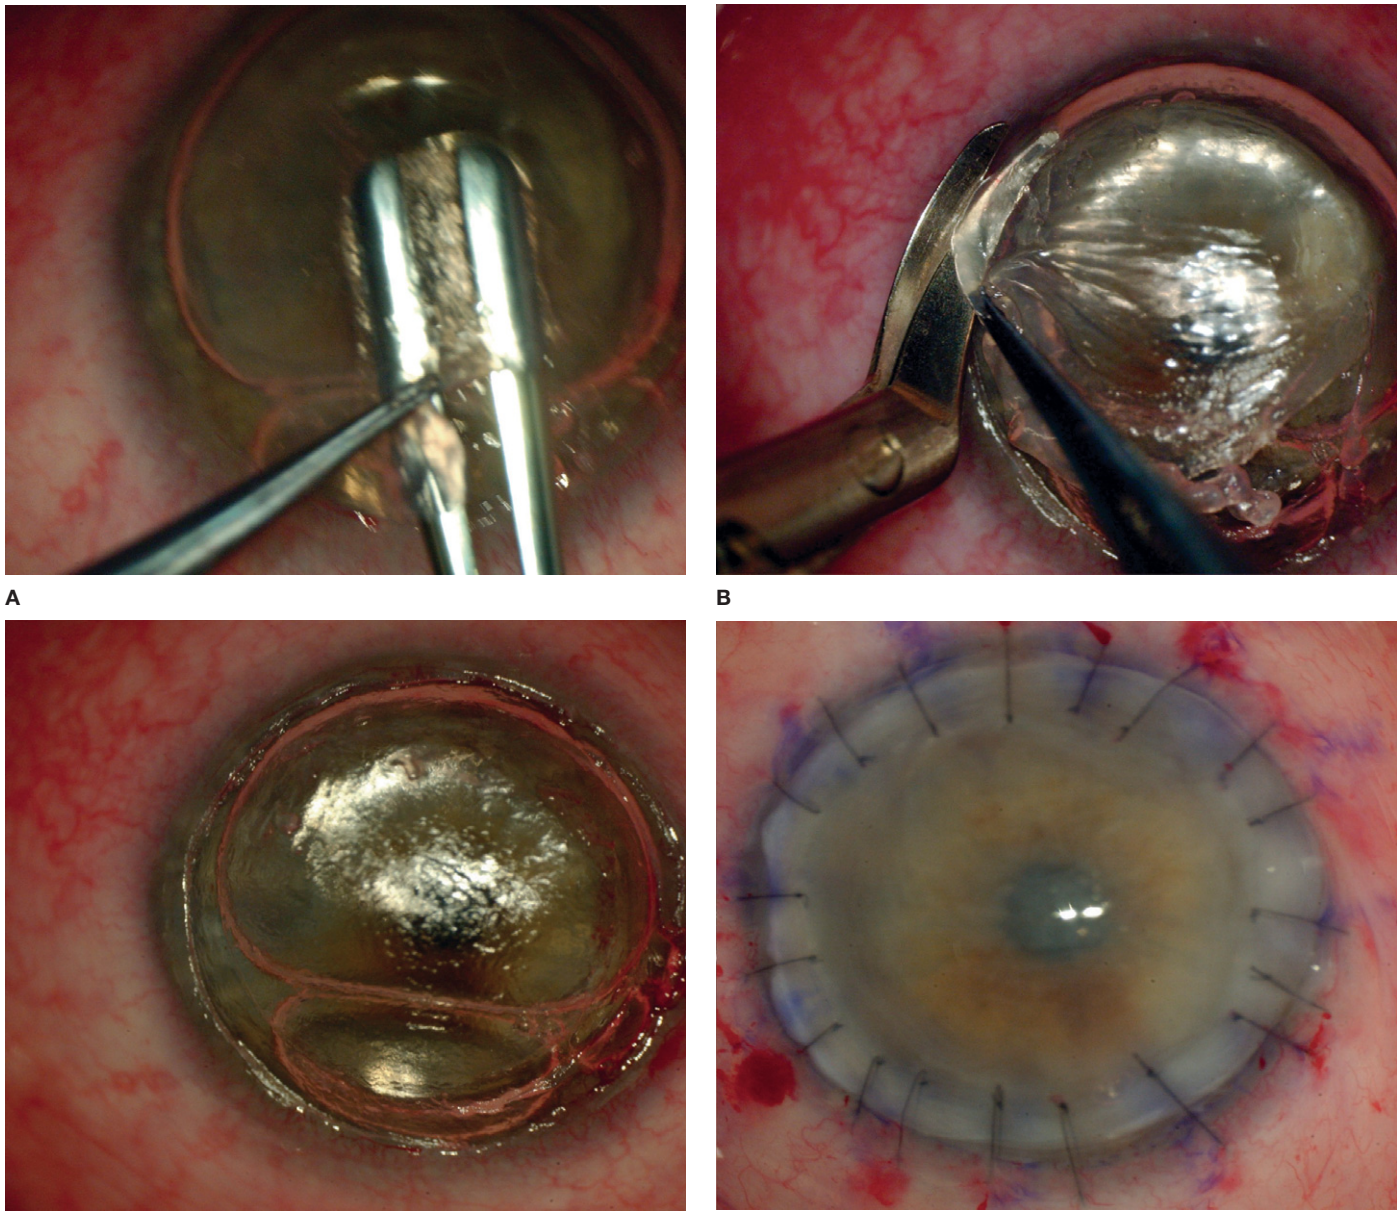

Figure 40.2. Large 10 mm DALK. Following optical delineation of Descemet's membrane, *A*, dissection performed using Daya Lamellar Separators (Duckworth & Kent, Herts, UK), *B*, removal of anterior lamellar tissue using curved corneal scissors, *C*, exposed posterior lamellar bed, and *D*, graft sutured in place.

AIR DISSECTION OR 'BIG BUBBLE' TECHNIQUE OF ANWAR

The occasional observation of a big bubble in the stroma after intrastromal injection led Anwar to develop a technique to achieve the big bubble more consistently.[9,23,24,43] The technique has the advantage of exposing Descemet's free of overlying stroma. A partial-thickness trephination is performed aiming at 60–80% depth. A 27- or 30-gauge bent needle, bevel down and attached to a syringe filled with air, is introduced deep in the stroma (about 3–4 mm from entry site) and air is injected (Fig. 40.4, *A*). In most cases, the air forms a big bubble between Descemet's membrane and the stroma. The bubble is a sharply defined whitish semiopaque disc (Fig. 40.4, *B*). A paracentesis is performed outside the area of trephination to allow the eye to be softened if necessary. Partial anterior dissection is performed, leaving a thin layer over the big bubble. A final dissection removing the remaining anterior lamellar tissue is performed with a protective spatula in the space immediately anterior to Descemet's membrane (Fig. 40.4, *C* and *D*). This portion of the procedure is potentially hazardous, as the fragile Descemet's membrane can easily tear if it comes into contact with any sharp-edged instrument or barb from a damaged instrument.

A disadvantage of this technique is that a big bubble is not always achieved. If this occurs, further air injections can be considered at sites where the cornea is still clear. Should this also not be successful (9% in Anwar's hands[23,24]), then anterior lamellar dissection will need to be carried out similar to the intrastromal air injection technique described above. While the technique is rapid when successful, it is limited to those who have not had previous injury to Descemet's membrane (laceration or hydrops). In the case

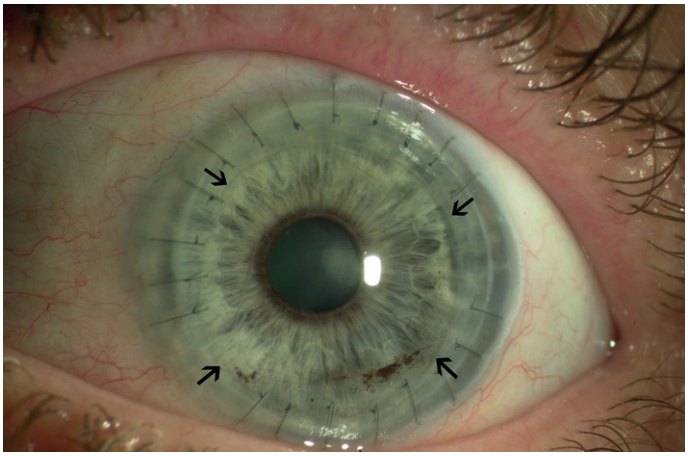

Figure 40.3. Large lamellar graft on a previously grafted (PKP) keratoconus eye with severe corneal thinning peripheral to the graft. Arrows indicate the edges of the retained posterior aspect of the old PKP.

of a previous Descemet's tear, injection of air could lead to dehiscence of the previous wound and perforation.

HYDRODELAMINATION

This technique was originally described by Sugita and Kondo[17] and involved injection of balanced saline solution into the deep stroma to swell stromal collagen fibers, thus thickening the cornea and facilitating deep dissection. Like stromal injection of air, the technique reduces the risk of DM perforation. Unlike air, which opacifies all tissue, scarred stroma does not easily swell and is relatively easy to differentiate from normal clear corneal stroma, enabling a dissection sufficient to resect corneal pathology. Panda and Singh compared the results of hydrodelamination with other techniques (air injection, viscoelastic dissection, and dry dissection) and found this technique to be less time-consuming and easier to perform, although visual and refractive outcomes were similar in all groups.[15]

VISCOELASTIC DISSECTION

In 1999, Manche et al utilized the observation of Descemet's membrane detachment after inadvertent injection of viscoelastic material in the cornea to design intentional DM detachment by injecting viscoelastic material in the deep corneal stroma.[41] Later, Melles et al described a quicker method using viscoelastic but optically defining Descemet's membrane using air in the anterior chamber as described above. When the 30 G needle is at the correct position, viscoelastic material is injected into the cornea to separate Descemet's membrane.[2,40,41,44,45] The stroma is excised and the interface is washed before suturing the donor cornea. It is important to remove all viscoelastic material, reducing the possibility of entrapment of material at the interface and a persistent double anterior chamber.[45] This method, however, has a high rate of perforation (25%).[40]

MISCELLANEOUS AND ADJUNCTIVE TECHNIQUES

Microkeratome-assisted deep lamellar keratoplasty has been previously described by Azar et al.[46] A microkeratome is used to create a hinged anterior stromal flap in the host cornea. This is followed by a manual deep lamellar stromal dissection and resection of diseased tissue. The donor graft is prepared in a similar fashion on an artificial anterior chamber. The donor button is then grafted, and the flap is repositioned and sutured. While there is a theoretical advantage of this technique in the ability to correct postoperative refractive error by lifting the flap and applying excimer laser treatment, it requires the use of expensive technology, and no studies have been performed to demonstrate any major advantage over other techniques.

Malbran's peeling technique,[6,47] described in 1972, pays attention to the visual axis, exposing Descemet's membrane centrally and leaving posterior stroma in the periphery, providing a clearer axis and thus better acuity. The technique can be used in situations where very large grafts are required for conditions such as keratoglobus.

DONOR PREPARATION

The donor can be created using a regular donor punch cutting from the endothelial side down. In keratoconus, using the same size helps to flatten the cornea and reduce myopia. Ideally, both the recipient and the donor surfaces should be as smooth as possible, and this can be accomplished by peeling Descemet's membrane. Removal can be accomplished by simply peeling Descemet's membrane using dry surgical spears on the edge of the posterior surface of the donor. Once the membrane edge starts to peel, complete dissection can be accomplished with nontoothed forceps or dry spear sponges (Fig. 40.5). To facilitate identification of Descemet's membrane Trypan blue can be used to stain the surface, and this can be useful in young donor tissue where Descemet's membrane is thinner.

COMPLICATIONS—INTRAOPERATIVE

MICROPERFORATION

Inadvertent penetration of Descemet's membrane often occurs during the process of dissection. This can also result from shear forces on an old scar or from the edge of a dissecting instrument. This is usually evident by sudden softening of the eye and the excursion of fluid or air into the interface. Should this occur, it is best to reform the anterior chamber with air and continue to dissect the cornea at a site remote from the area of perforation, leaving this to the end. Leaving a small amount of stromal tissue above the area of perforation (if in the periphery) helps minimize chamber collapse after removal of the anterior lamellar tissue. The occurrence of microperforation can be as high as 39%[11,16,17,22,48] and can occur in the best surgical hands. To minimize the chances of a postoperative double anterior chamber, leaving an air bubble is useful, as is positioning the patient in a supine position in the initial postoperative period.

MACROPERFORATION

This typically occurs at the site opposite the point of entry. In very steep keratoconic eyes, to avoid this complication, the author suggests leaving the dissection of the apex and the area opposite till later. Progressive dissection can be accomplished by sequentially cutting the recipient along the line of trephination, enabling access for dissection of the remaining cornea. Central dissection can be

accomplished more reliably under direct visualization. Should a macroperforation occur, the situation is still retrievable if most of the cornea has been dissected. An air bubble can be used to position the posterior lamellar layer against the anterior donor. If this cannot be performed, then conversion to a PKP may be necessary.

PUPILLARY BLOCK GLAUCOMA

This can occur whenever air is left in the anterior chamber. The air bubble can block the pupil, leading to posterior accumulation of aqueous and angle closure. This is best avoided by pupil dilation whenever air is used or by limiting the size of the air bubble and also periodically examining the eye in the hours immediately after surgery. One consequence of transient high pressure is Urrett–Zavalier syndrome,[49] where the pupil can become atonic and dilated.

COMPLICATIONS—POSTOPERATIVE

DOUBLE ANTERIOR CHAMBER

This is a result of a microperforation or from sutures that have been passed through the posterior host cornea, providing a channel for aqueous to enter the interface[50] (Figs 40.6 and 40.7). Another cause is entrapped viscoelastic material at the interface if viscoelastic, when used, is not sufficiently irrigated from the host bed. Varying rates of double anterior chambers have been reported with up to 30% of cases in one report.[17] Spontaneous resolution usually does occur; however, healing may be accelerated by injecting intracameral air or isoexpansile gas (e.g. sulfa-hexafluoride, SF6) and drainage of interface fluid through the graft host incision. This can be accomplished at the slit lamp through a paracentesis

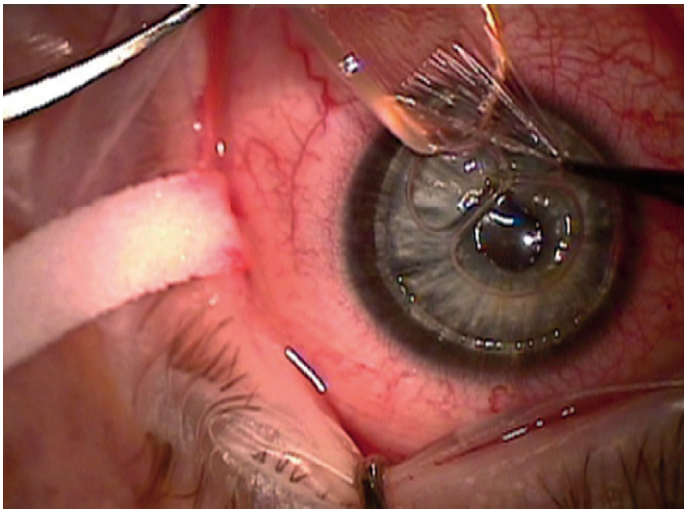

Figure 40.5. Following punch trephination removal of Descemet's membrane with fine nontoothed forceps after the edge is identified.

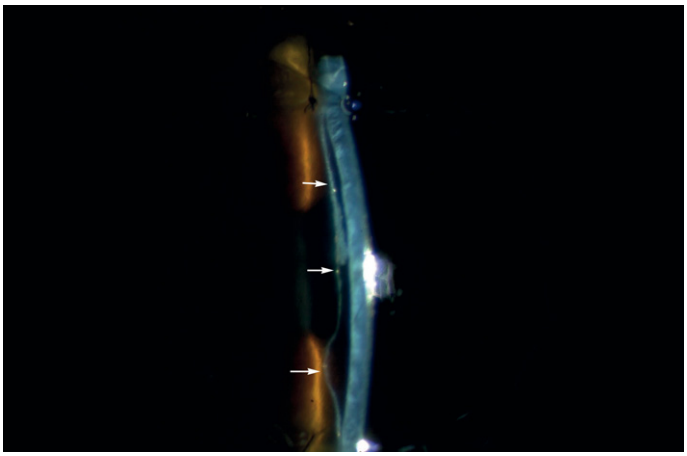

Figure 40.6. Double anterior chamber, arrows showing the posterior lamellar layer dislocated from the donor, day 1 postoperatively.

incision. Early management may decrease the chance of interface haze.

FOLDS AND WRINKLES

Descemet's folds and wrinkles often occur secondary to compression at the interface in cases where there is a disparity between the posterior lamellar surface area and donor cornea as in keratoconus. The wrinkles are typically concentric and outside the visual axis, and have no visual consequence (Fig. 40.8). Sometimes folds occur in the visual axis and these can be induced by sutures. These are best identified at the time of surgery using air in the anterior chamber. If not related to sutures, the folds can be removed by using closed forceps at the graft–host wound to pull the posterior lamellae peripherally. Should folds persist, they are likely to affect vision; however, we have observed them to disappear over several years.

EPITHELIAL, SUBEPITHELIAL OR STROMAL REJECTION

Allograft tissue can reject at different levels anatomically with the exception of endothelium. Stromal, epithelial, or subepithelial graft

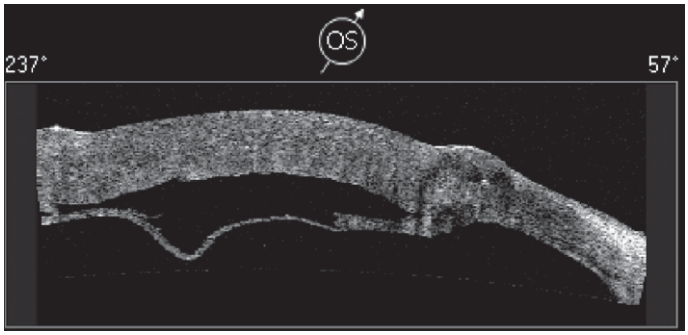

Figure 40.7. Visante (Zeiss-Meditec, Jena, Germany) ocular coherence tomography (OCT) image of an eye with a double anterior chamber prior to injection of air.

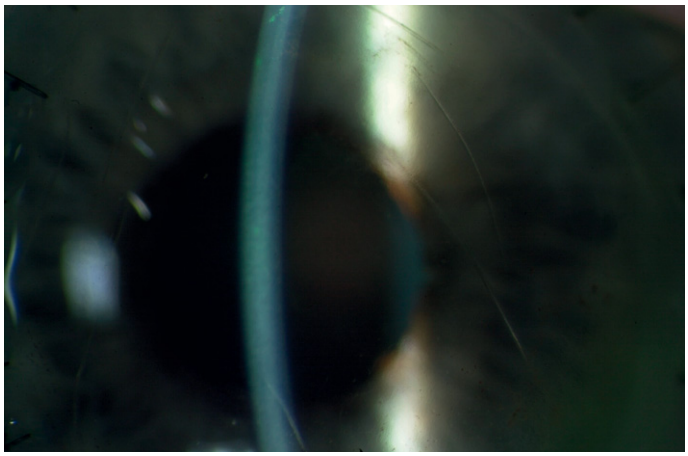

Figure 40.8. Descemet's membrane compression folds, concentric superiorly.

rejections have been reported,[51,52] and the time to rejection can vary. Epithelial rejection manifesting as an advancing line of edema often inferiorly usually occurs in the first year. Subepithelial infiltrates indicating subepithelial rejection also often occur in the first year and like epithelial rejection can be treated with increased frequency of topical steroids. Stromal rejection (Fig. 40.9) is rare (1.4%[53] and 1.9%[39]) and manifests as stromal edema along with vascularization, later clearing and leaving ghost vessels. Stromal rejection can occur at any time. Al Torbak et al reported a case of stromal rejection 16 months after DALK for keratoconus in a 13-year-old girl,[51] and Watson et al reported this as late as 41 months.[52]

POSTOPERATIVE CARE

SHORT TERM

Management of a DALK in the immediate postoperative period includes topical steroids and a broad-spectrum antibiotic. Specific therapy may be required depending on the underlying diagnoses. Where a lamellar graft is performed for herpes simplex, prophylactic indefinite use of acyclovir 400 mg twice daily is advised. Steroid use can be reduced earlier than for a PKP; however, rejection can occur as indicated above and patients must be informed to return if symptoms or signs of redness, sensitivity to light, visual loss, or pain (RSVP) occur. In the context of ocular surface disease, rapid epithelialization is the goal and all measures to achieve this must be undertaken to preserve graft clarity and integrity.

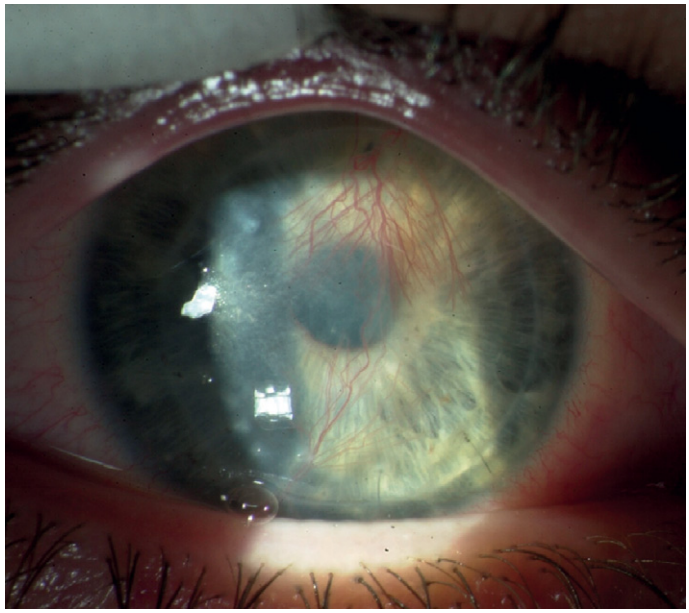

Figure 40.9. Stromal rejection of donor 12 months after DALK.

Figure 40.10. Visante OCT image of a well-apposed DALK. Note the thin dimensions of the posterior lamellar layer (arrowheads).

SUTURES

Sutures can be removed as early as 9 months, depending on how aggressively the wound has healed and how quickly steroids have been tapered. The author prefers to leave sutures in for at least 18 months if possible and until a strong fibrous ring at the interface is observed. This decreases the chances of graft dehiscence and high astigmatism.

VISUAL REHABILITATION

Visual rehabilitation can take a year or longer; however, patients, especially those with keratoconus, notice a dramatic improvement quite early from corneal flattening and reduction of myopia alone. In the authors' own series of 119 eyes who received grafts for visual rehabilitation, at last follow-up the spherical equivalent was –0.96 D. Spectacle correction and sometimes contact lenses are needed. Laser refractive surgery can also reduce anisometropia and high astigmatism. Once all sutures have been removed and vision rehabilitation accomplished, patients in low-risk categories can often be discharged from care altogether.

OUTCOMES

ENDOTHELIAL CELL LOSS

Several reports have demonstrated normal endothelial cell counts in recipients of DALK.[54–57] The progressive decline in endothelial cell density that is seen following PKP does not occur at the same rate in DALK. The percentage of endothelial loss after DALK varies from 10 to 25% depending on the surgical technique.[17,54,55] Long-term (10 years or more) outcomes in terms of endothelial cell counts are not available for DALK. The initial drop in endothelial cell count after PKP is up to 33% at 2 years and 50% after 5 years. Cell loss in PKP continues at a rate of 4.2% 5–10 years postoperatively.[58] In DALK by comparison, endothelial cell loss is 11% at 6 months, 2% at 1 year, and 1.2% at 2 years.[55] As the cells are not allogeneic, it is expected that cell loss will in time decline to reach the physiologic rate of normal adult human eyes (0.6 ± 0.5%).[55,59,60] Complications, especially those needing surgical intervention or manipulation of the graft, might adversely affect the cell count; however, Sugita and Kondo[17] found that the difference in cell count between those who developed a double anterior chamber requiring intervention and a group of uncomplicated cases was not statistically significant at 12 months postoperatively.

VISUAL OUTCOMES

There is usually a significant improvement in the visual acuity after a year.[16–18,48,61] Soong et al reported that 79% of patients required at least 1 year to achieve vision of 20/50 and that there was progressive improvement in visual acuity with time.[39] Limitations to visual improvement can be from interface haze causing light scatter. Folds in Descemet's membrane can also have an effect. Compression folds occur because of disparity between the posterior lamellae and the graft. The folds are typically concentric and outside the visual axis in keratoconus. Smoothness of the interface may also have an influence, and, as posterior lamellae are less compact, the deeper the dissection, the less the impact of irregularity (Fig. 40.10). Visual outcomes vary from report to another (Table 40.2). However, best visual results have been documented using the big bubble technique, supporting the concept that smoother is better.

REFRACTIVE OUTCOMES

Postoperative astigmatism influences visual rehabilitation with DALK. Lamellar grafts are sutured with 10-0 nylon, and a variety of suture patterns can be used. Uninterrupted (running) sutures facilitate adjustment to minimize any induced astigmatism. On the other hand, interrupted sutures allow for selective removal of sutures. The magnitude of residual astigmatism ranges from 2.00 to 4.00 D in most studies (Table 40.3), easily correctible with spectacles. Irregular astigmatism can occur, and contact lenses may be necessary for visual rehabilitation.

COMPARISON TO PKP

Penetrating keratoplasty and DALK result in comparable visual and refractive outcomes (Tables 40.2 and 40.3).[62] Deep anterior lamellar keratoplasty is more advantageous in high-risk situations, including

Table 40.2 Comparison of reported best-corrected visual acuity after deep anterior lamellar keratoplasty and penetrating keratoplasty in different studies

Study	No. of Eyes	BCVA ≥ 20/40	BCVA ≥ 20/30

young recipients, large grafts, and highly vascularized corneas and in those who are mentally subnormal such as Down's syndrome.

Intraoperative complications that threaten vision are less likely to occur in DALK, as the procedure is essentially in a closed system. Risks of expulsive choroidal hemorrhage and infection are theoretically lower.

Postoperative care requires less use of topical steroids, thus reducing the likelihood of developing steroid-related glaucoma or cataract. There is also no need to use systemic immunosuppression following anterior lamellar keratoplasty. Retaining host endothelium eliminates the risk of endothelial graft rejection responsible for graft failure following PKP.[51,65,66] Epithelial, subepithelial, or stromal rejection has been observed; however, it is less intense and easily treatable.[51,52,62,65] Follow-up can thus be less frequent; however, patients need to be cautioned about the possibility of problems and must return to the transplant center immediately should these occur.

Visual outcomes have been reported to be better in full-thickness grafting.[39,66] However, recent studies have demonstrated comparable visual outcomes of DALK to PK.[56,62,67] Visual recovery, however, tends to take longer with DALK. Although glare test results at 6 months favor PKP, the difference is not statistically significant.[67] Guell and coworkers also reported better visual quality in eyes with a PKP in an intraindividual study comparing PKP to DALK.[68] Snellen acuities, however, have been reported to be comparable, and the impact of this difference in visual quality patients who have had very poor vision requires further evaluation.

A further advantage of DALK is the ability to perform very large limbal to limbal grafts in keratoglobus and even in those who have previously had a PKP and developed a thin residual periphery. This provides some comfort in being able to accomplish a large graft without the increased risk of visual loss through immunological rejection as might occur following a large PKP.

Finally, DALK has great application in developing countries where there is considerable shortage of corneal material. Outdated material not suitable for PKP can be used for lamellar techniques in this environment. Freeze-dried methods[12] enable long-term storage of lamellar tissue, which can be effectively used in this setting.

There is increased interest in deep anterior lamellar techniques. Regrafting following failed PKP is becoming a more common indication and, considering the poorer prognosis of regrafts, DALK for long-term visual rehabilitation is a more desirable option and should be considered whenever the endothelium of the recipient is normal.

41 Indications and contraindications of penetrating keratoplasty

John E. Sutphin

Penetrating keratoplasty (PKP) is the most frequent and most successful organ or tissue transplant, with the exception of blood transfusions, performed in the USA. Table 41.1 indicates the relative frequencies of transplantations for 2006. These statistics refer to allografts or homografts, which are transplants from one member of a species to another. Penetrating keratoplasties may also be isografts using a donor from the fellow eye (autograft) or by rotating the transplant within the same eye (rotating autograft) or, less frequently, from a genetically identical twin. Xenografts are transplants between species and have not been done since the advent of transplant in the 19th century.

The exponential growth in the frequency of PKP is due to two principal developments. Prior to the mid-1930s, corneal transplant was reported infrequently and in small numbers because the requirement for diseased eyes with clear corneas as sources of tissue limited the availability of the operation. During the 1930s, Filatov in Odessa, Russia, popularized the use of cadaveric donors. The use of refrigerated donor eyes was expanded by the organization of eye banks with the first American bank established by R. Townley Paton in 1944 in New York City as the Eye Bank for Sight. The Eye Bank Association of America (EBAA) was organized in 1961 and reported 2000 transplants done that year. In 2006, the EBAA reported about 77 135 corneas donated and 45 035 transplanted.[1] The majority, 79%, were used for PKP, 13% for endothelial keratoplasty, 0.2% for anterior lamellar keratoplasty, and 0.0030% for keratolimbal allograft.[1] The second major contribution to this rapid growth has been the availability of preservation media, allowing for the maintenance of the donor cornea for periods up to 1 week with satisfactory clinical results.[1a] The first description of preservation was by Magitot in 1911,[2] but the modern era began with the use of McCarey–Kaufman media described in 1974.[3] There have been numerous improvements in the technology and technique of PKP since Zirm's first patient in 1905, but there have been no major changes in the underlying principles.[4]

INDICATIONS

Indications for a procedure are the reasons making that surgery particularly desirable for the condition to be treated. The decision to perform the surgery balances benefit versus risk in the specific patient. This section will cover the general benefits of corneal transplantation, including the common diagnoses for which it is performed.

Indications for keratoplasty fall into four broad categories:[5,6]

1. Optical: Prime purpose is to improve visual acuity.
2. Tectonic: Prime purpose is to restore altered corneal structure, including extreme thinning, perforation, and traumatic loss of tissue.
3. Therapeutic: Prime purpose is to relieve pain, to remove tissue for progressive keratitis after failure of specific antimicrobial or anti-inflammatory therapy or as an adjunct to other surgery, such as temporary keratoprosthesis and pars plana vitrectomy for ocular trauma.
4. Cosmetic: Prime purpose is to restore a normal appearance to an eye with limited vision potential.

Optical or visual indications for transplantation have become the principal reason, accounting for 74% of 5281 transplants in the Australian Graft Registry.[7] Therapeutic indications, primarily pain relief, were one of the immediate reasons for grafting in 20%; tectonic indications were listed in 3%; and cosmesis was included as an indication in 3%. Figures 41.1–41.4 show examples of the general indications. In the first series of transplants reported by Elschnig, 35 out of 174 (20%) of the grafts were for staphylomas or frank corneal perforations (tectonic).[8] With the advent of more specific diagnoses as the indication, the general indications are not always reported in large series.[9–12] Typically, a transplant done for visual reasons will have salutary effects to restore the appearance of the eye or to reduce comorbidity such as pain. But more importantly, transplants done to preserve the globe both tectonically and therapeutically will often have the benefit of improved clarity and subsequently improved visual acuity. Eighty per cent of all transplants showed at least one Snellen level of improvement, but only 66% of patients over 80 years old achieved improved postoperative vision.[7] Therapeutic keratoplasties will often have secondary effects of restoring a more normal appearance.

Optical indications for PKP generally follow the same guidelines as cataract surgery. There is no absolute level of vision below which

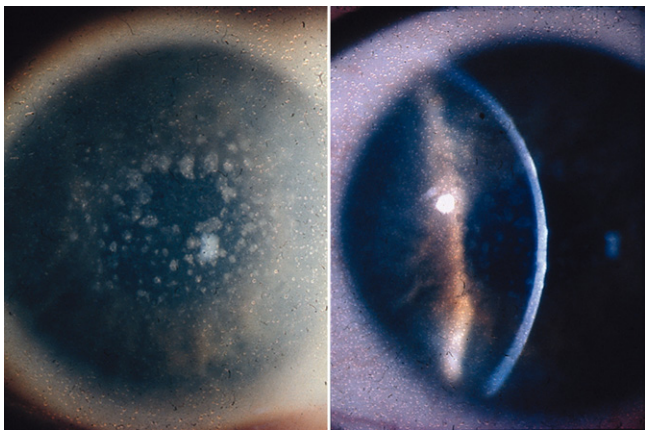

Figure 41.1. Optical Indication for PKP. This montage shows two views of an eye of a patient with macular corneal dystrophy and decreased vision from opacity and irregular astigmatism.

a patient requires cataract surgery. The indication for surgery is based on the patient's visual function and visual needs, intrinsic disease of the lens, or need for visualizing the fundus. Recently, there has been clarification of the indications in cataract surgery by several national organizations.[13] If both eyes are impaired by the underlying disease and the recipient is an acceptable candidate, then the indication for surgery is usually unequivocal. However, with the advent of managed care and the economic considerations of third parties, all indications for surgery have come under increasing scrutiny. Javitt and others showed the correlation between improved quality of life and improved visual function in a prospective nationwide trial of 1021 patients with cataract and other degenerative eye diseases measuring visual, social, and psychological endpoints.[14,15] Others have also shown unequivocally the benefit of improved visual function in improving the overall health of the elderly.[16–20]

Although PKP shares visual indications with cataract surgery, the prognosis for corrected visual acuity is less. The Australian Graft Registry reports, in a series of 5281 records, overall 1-year survival of 94% and 5-year survival of 74% with best Snellen vision of 20/40 in 48% of recipients.[7] Fifty-nine per cent had acuities of 20/60 or better and 24% were worse than 20/200. Better visual outcomes occur when indications are limited to dystrophies (20/40 in 66% with Fuchs' dystrophy[21] and 20/40 in 83% with keratoconus).[7]

Patients' perceptions of the value of PKP to themselves was rated in a smaller series showing 75% of patients had overall satisfaction with the operation and results. Satisfaction was associated with better vision in the grafted eye versus the other eye, clarity of the graft, and improvement in lifestyle. Dissatisfaction was primarily related to graft failure or problems with contact lens wear.[22]

In unilateral cases or in the case of the second eye after successful first eye transplant, there is more controversy regarding the positive impact of surgery. Javitt and others confirmed the value of second eye surgery for cataract in a preliminary study but that study did not look at individual patient outcomes.[14] In a subsequent study, the value of second eye surgery for cataract was confirmed with a 61% increase in the VF-14 (a validated measure of visual function), a 27% decline in trouble with vision, and a 24% improvement in satisfaction with vision.[23] These find-

The image on the right shows the clear corneal transplant. *B*, Same cornea as in *A*. The ongoing inflammatory nature of the infection required a therapeutic transplant to reduce the load of organisms and allow the immune system to contain any residual infection from the amoeba. *C*, Corneal button from *A*. The relative absence of *Acanthamoeba* in the anterior stroma with an intact epithelium and a concentration of trophozoites and cysts in the deep stroma suggest poor drug penetration. There is artifactual loss of Descemet's membrane. The inset shows *Acanthamoeba* cysts and macrophages.

ings are generalizable to the situation involving corneal transplant, although there is a longer rehabilitation involved with corneal transplants.

Indication for the second eye to receive a transplant involves assessing the specific risk of a second graft. Early work indicated a possible trend toward more rejections in keratoconus patients who underwent surgery in the second eye.[24–32] Others have found no change in risk to either eye.[33–37] Two large graft registries have recently reported, using multivariate analysis, an increased survival of the second eye graft.[38,39] One center did report an increased risk for rejection and failure in the first eye,[39] but the risk to both eyes fell the longer the time between surgeries, with best survival if there was no rejection for 3 years in the first eye prior to surgery on the second. The explanation for increased survival in the second eye is unclear, and possibilities can be proposed: patient selection bias and underlying good prognosis for many bilateral conditions (corneal dystrophies), negative bias in avoiding second eye surgery with poor outcome in the first eye, patient education and experience with medications, use of steroid in second eye and not first at time of second surgery, immune modulation following first eye, or relative anergy in patients who accept one graft without rejection.[39] At this time, second eye surgery indicated by the patient's visual requirements is not contraindicated by the risk of rejection with proper education and management, including topical steroids in both eyes perioperatively.

Therapeutic and tectonic reasons for doing surgery are almost always imperative and are not subject to the same controversy. Therapeutic indications may be involved in the rare circumstance where visualization of the posterior segment is required, for example following temporary keratoprosthesis for complicated retinal detachment repair including pars plana vitrectomy or to allow for photocoagulation of diabetic retinopathy. Alternatives to corneal transplant should be sought where applicable. Hard or soft contact lenses may be used in circumstances of irregular astigmatism for thin scars subject to glare and photophobia. Lamellar keratoplasty or use of tissue glues may be appropriate in the management for tectonic indications. Limbal autografting or allografting may be appropriate for primary restoration of the ocular surface or as preparation for subsequent PKP.[40] Optical iridectomy for Peters anomaly or other central scarring may provide better long-term visual results for PKP with poor prognosis.[41] Corneal tattooing has been used to improve cosmesis as well as to reduce glare and pho-

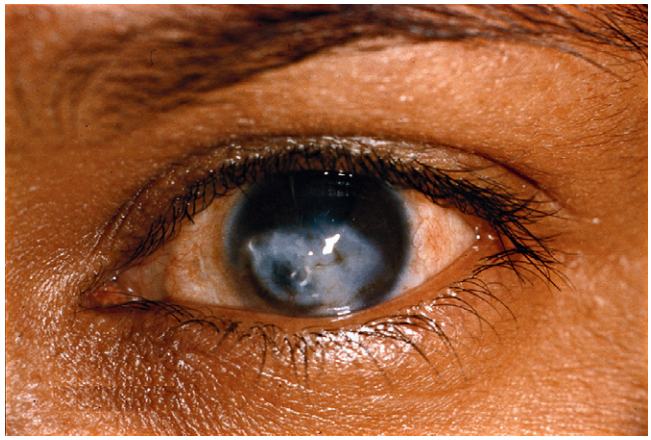

Figure 41.4. Optical indication for PKP. This young Asian female with a history of a fork injury to the left eye at the age of 2 years for which she received minimal medical intervention desires improvement in her appearance. Improvement in vision from corneal transplant is unlikely due to amblyopia.

tophobia from corneal scarring. Tarsorrhaphy and conjunctival flaps can be successful in treating persistent corneal ulceration. Pharmacological means have also been used, including metalloproteinase inhibitors, growth factors, antivirals, and oral antibiotics, such as tetracycline, with varying degrees of success.

Transplants done for cosmetic reasons are very rare with the advent of the Narcissus Foundation Program to provide painted soft contact lenses and other sources of tinted contact lenses or painted cosmetic shells. Although rare, cosmesis may still be justifiable in circumstances where the cornea is white from a long-standing injury and vision potential is limited by amblyopia.

RECIPIENT DIAGNOSIS

In 1994, the EBAA introduced a grouping of recipient diagnosis in order to improve the tracking of the indications of keratoplasty.[12] The intent was to identify trends early to allow for planning at the level of the EBAA and to direct research to appropriate areas. Table 41.2 lists the diagnoses as updated by Lindquist at the Annual Meeting of the Eye Bank Association, Santa Barbara, CA (personal communication, 1996). Many patients fall into more than one category, and it is difficult for surgeons to know precisely which is the principal indication. A prime example is pseudophakic bullous keratopathy in the presence of Fuchs' corneal dystrophy. The EBAA indicates that such a patient should be coded with Fuchs' dystrophy.

Medical advances leading to the aging of the population and the advent of intraocular lenses, which led to a rapid rise in the performance of cataract surgery, have led to changes in the indications for transplant. In the 1950s, the more common indications for grafting were regrafts, herpetic scarring, and keratoconus.[9–10] Indeed, until Max Fine reported success in 49 eyes at the Corneal World Congress in 1964, PKP was infrequently performed for aphakic bullous keratopathy or Fuchs' corneal dystrophy.[42]

In the 1980s, pseudophakic bullous keratopathy became the leading indication for corneal transplant in the USA, peaking at approximately 29% in 1988.[43,44] Table 41.3 shows that through 2004, excluding non-specified causes, pseudophakic corneal edema remained the number one cause but was decreasing in frequency. There was an increase in the number of regrafts, both those related to rejection and those after graft failure for other causes. The rise in regrafting may reflect the larger pool of completed grafts, as the total number of transplants and the longevity of the population have increased. The rates of regrafting have increased particularly at tertiary-care centers.[45] The decline in aphakic and pseudophakic corneal edema is probably related to improvements in technique of lens extraction and in the design of intraocular lenses. In 2004, a new category dedicated to postrefractive surgery patients contained 46 patients, representing 0.1% of the total.

Although grouping of indications are not precise from study to study, European authors report increases in grafting for pseudophakic bullous keratopathy from the 1970s to the 1990s.[46–48] UK registries indicate, however, that keratoconus remains the number two reason for transplant at one center behind regrafting.[46,49] In a similar-sized series involving more than tertiary-care hospitals, keratoconus was the number one reason for grafting at 20%, with regrafts in 16% and pseudophakic bullous keratopathy in 15%.[46] In Denmark, pseudophakic bullous keratopathy was most frequent at 28%, followed by keratitis and endothelial dystrophy at 14% each and regraft at 11%. As in the USA, keratoconus was an infrequent indication for transplantation, perhaps reflecting the underlying populations. In Canada, the leading indications were regraft, keratoconus, and pseudophakic bullous keratopathy (Maeno et al).[49a] The Australian Graft Registry found that keratoconus was the most common indication at 31%, followed by bullous keratopathy at 25% and regrafts at 14%.[22] These indications affirm the similar genetic makeup of Australia and the UK. Despite improvements in the diagnosis and therapy of viral and other microbial keratitis, there has not been a substantial decline in the relative percentage of corneal transplants done for these indications.

In the developing world, the leading indications for corneal transplant remain corneal scar (due to infection, chemical injury, or trauma), acute infection, regrafting, and aphakic/pseudophakic bullous keratopathy.[50–53] Indications may vary within a country. For example, in Brazil, keratoconus is the main indication in San Paulo, whereas trachoma and scarring account for the majority of grafts in Amazonas.[54] In Israel and Saudi Arabia, ocular infections and scarring accounted for the majority of grafts in the 1970s and 1980s but have steadily declined. Since the 1990s, keratoconus has been the major indication for corneal transplant in each of these countries.[55,56]

CONTRAINDICATIONS

ABSOLUTE CONTRAINDICATIONS

Absolute contraindication to PKP would be the absence of any indication to do the procedure. Patients with high probability that they would not survive the operation should not be done. The patients' or their legal surrogates' decision not to have surgery should be respected. Situations such as no light perception vision with no hope for return of vision should not be attempted unless there is psychological contraindication to either enucleation or evisceration and there are no other suitable alternatives. Patients who are satisfied with current vision with their usual type of correction (glasses or contact lenses) or whose lifestyles are not compromised should not have surgery.

RELATIVE CONTRAINDICATIONS

Relative contraindications include the risk factors for failure of the PKP to remain clear or for the patient to obtain significant improve-

Table 41.2 Clinical indications for penetrating keratoplasty, 1996

1. Pseudophakic corneal edema	**7.** Viral/postviral keratitis	Thyroid eye disease
Pseudophakic bullous keratopathy	Herpes simplex virus	Rheumatoid disease
Anterior chamber lens implant	Varicella zoster virus	Rheumatoid arthritis
Iris-fixated lens implant	Epstein–Barr virus	Cocaine-induced keratopathy
Posterior chamber lens implant	Adenovirus	**11.** Corneal degenerations
2. Aphakic corneal edema	Epidemic keratoconjunctivitis	Terrien's marginal degeneration
Aphakic bullous keratopathy	**8.** Microbial/postmicrobial keratitis	Calcific band keratopathy
Vitreoendothelial touch syndrome	Bacterial	Polymorphic amyloid degeneration
3. Stromal corneal dystrophies	Infectious crystalline keratopathy	**12.** Chemical injuries
Granular and Avellino dystrophies	Spirochete	Alkaline
Lattice dystrophy	Luetic (syphilitic) interstitial keratitis	Acid
Macular dystrophy	Chlamydial	Petroleum
Central crystalline dystrophy of Schnyder	Trachoma	Tear gas
Central cloudy dystrophy of Francois	Fungal	**13.** Mechanical trauma, nonsurgical
Recurrent stromal dystrophy	Parasitic	Traumatic opacity
4. Primary corneal endotheliopathies	*Acanthamoeba*	Traumatic corneal edema
Fuchs' endothelial dystrophy	**9.** Optical/refractive	**14.** Regraft related to allograft rejection
Congenital hereditary endothelial dystrophy	Ammetropias	(Include triggers as a secondary indication)
Posterior polymorphous dystrophy	High and/or irregular astigmatism	**15.** Regraft unrelated to allograft rejection
Iridocorneal endothelial syndrome	Myopia	Primary tissue failure
Chandler's syndrome	Hyperopia	Vitreo-endothelial touch
5. Ectasias/thinnings	Previous refractive surgery	Glaucoma
Anterior keratoconus	epiK, RK, AK, ALK, PRK, LASIK, etc.	(Include indications listed elsewhere)
Pellucid marginal degeneration	**10.** Noninfectious ulcerative keratitis or perforation	**16.** Other causes of corneal opacification/distortion
Keratoglobus	Keratoconjunctivitis sicca	Uveitis
Posterior keratoconus	Sjogren's syndrome	Glaucoma
6. Congenital opacities	Neuroparalytic/neurotrophic keratopathy	Detached Descemet's membrane
Peter's anomaly	Exposure keratopathy	Thermal injury
Glaucoma/buphthalmos	Systemic vasculitides	Fundus laser keratopathy
Aniridia	Bullous oculocutaneous diseases	Intraocular silicone keratopathy
Sclerocornea	Mooren's ulcer	Epithelial downgrowth

epiK, epithelial keratoplasty; RK, radial keratotomy; AK, astigmatic keratotomy; ALK, automated lamellar keratoplasty; PRK, photorefractive keratoplasty and LASIK; laser in situ keratomileusis.

Data from Eye Banking Statistics for 1991 and 1995. Eye Bank Association of America.

ment in vision. Many of these risk factors have been based on clinical experience.[43,57] Several large, either single or multicenter trials have applied univariate and multivariate analyses to the more commonly considered causes of graft failure.[38,46,58–64] Not every study assessed the same risk factors and not all potential risk factors have been studied rigorously. Most studies found that, when adjusted for various factors, many of the commonly accepted risk factors were not significant. Table 41.4 outlines many of the risk factors found to be significant by authors of large trials.

In the largest study, from Australia, the factors that influenced survival in a univariate analysis were the transplant center (centers with more than 20 grafts per year showed increased survival);

Table 41.3 Corneal transplant recipient diagnoses

Recipient Diagnosis	1991 (%)	Relative Rank	1995 (%)	Relative Rank	2004 (%)	Relative Rank
Non-specified	18.9	2	21.5	1	21.9	1

indication for the graft (keratoconus shows the best survival); graft number in the ipsilateral eye; history of pregnancy or blood transfusion; inflammation before or at the time of the graft; corneal vascularization at the time of the graft; history of raised intraocular pressure; the source of the donor cornea (eye bank eyes showed a poorer survival than those obtained by individual surgeons); death to donor enucleation time (cutoff at 6 h); graft size less than 7 mm in diameter or greater than 8.5 mm in diameter or with more than 0.5 mm difference between host and recipient, and lens status (aphakic grafts have the shortest survival followed by pseudophakic and then phakic, and PC-IOL had the best survival followed by anterior chamber IOL, iris clip, or other style).[38] Evaluation of risk factors for failure in the postoperative period disclosed that increasing failure occurred with early removal of the graft sutures, neovascularization of the graft, herpetic recurrence in the graft, and rejection episode. Following adjustment for the various factors using Cox proportional hazards regression analysis, the Australian Corneal Graft Registry found the significant factors to be aphakia or the presence of an anterior chamber or iris clip lens, very small or very large grafts, prior history of transplant on the ipsilateral side, an indication for transplant other than keratoconus or corneal dystrophy, active inflammation at the time of the transplant, and a postoperative rise in intraocular pressure. They found specifically that there was no effect on outcome by donor age, donor cornea storage medium, or whether the transplant was performed simultaneously with cataract surgery or in a staged manner.

Yamagami et al found six preoperative risk factors that were associated with poor outcome using Cox multiple regression analysis. These were corneal endothelial damage, the presence of anterior synechiae, glaucoma, older donor, area of vascularization, and aphakia or pseudophakia.[62]

Price et al in a consecutive series of transplants from a single practice found immunologic allograft reaction as the most common cause of failure followed by problems with the external surface of the transplant.[60,63] They indicated that the risk of failure decreased with increasing postoperative time. The significant risk factors for secondary failure included previous failed graft, race, age, iris color, use of preoperative glaucoma medicines, deep stromal vascularization, and horizontal diameter of the host cornea.[63] Price further indicated that the risk factors for immunologic allograft rejection included horizontal corneal diameter of the patient, donor size, and the difference between the host cornea and the donor diameters and between the host diameter and recipient trephine size.

Williams et al, in one of the largest multivariate analyses based on the Australian Graft Registry, followed 10 952 PKPs up to 18 years.[64] Preoperative risk factors for graft failure identified by Cox regression analysis included donor age, preoperative diagnosis, previous ipsilateral grafts, lens status, corneal neovascularization, ocular inflammation, or raised intraocular pressure. Surgical factors influencing graft survival included requirement for anterior vitrectomy, graft size, and transplant center. Postoperative events including graft neovascularization, rise in intraocular pressure, rejection episodes, and surgical intervention for intraocular pressure were

Table 41.4 Risk factors for graft failure

Risk Factor	Australian Graft Registry[50]	Collaborative Corneal Transplant Study[43]	UK Transplant Study[46]	Indiana Study[45]	Japanese Study[47]
Number of transplants in study	3608	457	2242	1819	698

Viscoelastic substance—not used		Yes			
Blood group ABO incompatibility		Yes			

Risk factors assessed by univariate analysis. Yes refers to statistically significant risk factor in the reference. No refers to tested risk factor that is not statistically significant in that study. Blank means risk factor not reported.

PKP, penetrating keratoplasty; IOL, intraocular lens.

associated with a higher rate of graft failure. They also found no improvement in graft survival over a 15-year time period.

In a study of high-risk transplant patients, Maguire et al, using multivariate survival analysis, found that many risk factors did not show a significant association in the very-high-risk recipient.[58] They found young recipient, number of prior transplants, history of prior anterior segment surgery, preoperative glaucoma, quantity of anterior synechiae, quantity of stromal vascularization, diagnosis of chemical burn, and blood group ABO incompatibility to be the strongest risk factors identified for graft failure. They found no association between donor and corneal preservation characteristics with outcome. Vail et al found the following risk factors after multifactorial analysis to be significant: surgeons with fewer than 50 transplants during the study period (1986–1992); recipients under 10 years of age; prior failed transplant; grafting for nonvisual indications; vascularization of the corneal bed; eccentric edema of the cornea as opposed to central edema; smaller trephine diameter, and differences between the donor and recipient of greater than 0.25 mm.[61]

HLA matching is discussed in another section of the book (Chapter 34). Other factors considered to be detrimental to good prognosis but not specifically assessed in these various analyses were corneal anesthesia, exposure keratitis, severe dry eye, systemic conditions of the patient, and patient compliance. Many of these conditions would fall under the sobriquet of inflammation at the time of the transplant and are associated with poor outcome. The mechanism by which many of the ocular surface conditions have interfered with long-term success of transplantation has been clarified with better understanding of the limbal stem cell.[40,65–68] Stem cells are lost from alkali and severe acid injuries and following Stevens–Johnson syndrome or other severe conjunctivitides and in specific ocular conditions such as aniridia and ectodermal dysplastic syndromes. To date no study has examined the absence of limbal stem cells as a separate risk factor for PKP failure in part due to the lack of a good clinical marker. Absence of the Palisades of Vogt and superficial conjunctival vessels crossing the limbus and presence of goblet cells on the corneal surface are non-specific markers for loss of stem cells and conjunctivalization of corneal epithelium. Holland and others have suggested improved outcome when the stem cells are replaced before PKP.[40]

Table 41.4 shows the relative risks of different characteristics in the long-term success of transplantation, as determined in five large studies using univariate analysis. Not all potential risk factors have been studied and these reports vary widely in definitions, length of follow-up, baseline characteristics, number of surgeons, and number of factors assessed. These risk characteristics are based on a much larger experience than the early pioneers who grouped corneal prognosis primarily by anatomic factors. However, there is much in common between Paton's and Buxton's groupings and these later studies. Some authors have reduced the confounding variables and biases of these uncontrolled studies using stepwise, multivariate analysis. Table 41.5 shows the quantification of the relative risks, confidence intervals, and per cent failed grafts, as determined in two studies related to the accepted prognostic groupings.

Table 41.6 outlines a modified prognostic chart generated from these large registries. Figures 41.5–41.8 show the morphologies and corresponding prognoses for a 1-year survival of corneal transplants. Prognosis can further be reduced by the presence of cofactors described in Table 41.7. Combining these estimates can provide a useful estimate of initial success for a clear transplant to a patient considering transplantation.

CONSENT

When explaining the risk and benefits of PKP to the patient and in assessing the risk factors for determining the best operation, the surgeon must keep in mind that risk is not the same as risk factors. The risks of corneal transplant surgery include nonimmunologic allograft failure, allograft rejection, expulsive choroidal hemorrhage, infection (both keratitis and endophthalmitis), loss of the eye, donor to host transmission of disease, glaucoma, retinal detachment and retinal cystoid macular edema, repeat transplant, fixed pupil, and astigmatism. In addition, there are major risks of anesthesia including stroke, myocardial infarction, and death, which have to be considered but rarely play a role in the patient's decision for surgery. Benefits represent the positive outcome and risk represents the negative outcome of transplantation or failure to transplant. In balancing these opposing forces, the surgeon makes a recommendation to the patient and when both are in agreement to proceed, a long-term relationship of careful attention and nurturing ensues.

42 Phakic penetrating keratoplasty

Joel Sugar, Satya Reddy

TECHNIQUE

When performing penetrating keratoplasty in a phakic patient, the surgeon must account for a few differences from aphakic keratoplasty. The lens and lens capsule create a shallower anterior chamber. Contact with the anterior lens capsule can lead to a premature cataract. There is a greater risk of iris prolapse from the posterior pressure of the vitreous and/or lens complex. Also, phakic keratoplasties tend to be performed in younger individuals, which may add another set of considerations. We present a step-by-step approach of addressing these concerns. The frequency of phakic penetrating keratoplasty has decreased with the recently increased use of lamellar procedures.

ANESTHESIA WITH AKINESIA AND HYPOTONY

In patients with no planned lens procedure, the use of miotics is helpful in iris management, usually 2% pilocarpine, every 10 min for three doses starting 1 h preoperatively. This dosage serves to sufficiently constrict the pupil so that the risk of injury to the anterior lens capsule is minimized. Once in the operating room, local anesthesia is often chosen because of its greater convenience and because of the rapid postoperative patient mobilization that this technique allows. There is no evidence from a corneal standpoint that either approach, local or general anesthesia, is preferable. Adequate anesthesia and akinesia of both eyelids and the globe are essential and can readily be achieved with peribulbar or retrobulbar injection. However, these patients tend be younger and may need more intravenous sedation or be more comfortable under general anesthesia. An uncomfortable patient who is moving during the procedure or a patient whose eyelids squeeze or whose globe moves induces a greater risk of chamber shallowing and inexact suture placement. When local anesthetic is used, it is important to look for periocular hemorrhage. Retrobulbar hemorrhage or a pronounced preseptal hemorrhage causing increased pressure on the globe compromises the safety of the procedure. In those patients in whom general and peribulbar anesthesia are contraindicated, Price reported successful outcomes under topical anesthesia. Patient comfort and pain seem comparable to other forms of local anesthesia.[1,2] However, topical anesthesia carries a much higher risk of intraoperative complications secondary to patient-related and anatomic factors, and we believe it should only be used when other methods of anesthesia are contraindicated. Preoperative hypotony can be obtained through digital massage or the use of a mechanical balloon pressure maintainer preoperatively. This lack of posterior pressure appears to play a significant role in reducing endothelial and lens complications intraoperatively.[3,4]

EXPOSURE AND GLOBE FIXATION AND SUPPORT

Adequate exposure of the anterior segment of the eye and adequate fixation and support of the globe are exceedingly important and need to be established before proceeding with keratoplasty. In unusual circumstances, this approach may require lateral canthotomy, lysis of symblephara, and excision of fibrotic scar to provide such exposure. Although a closed-blade speculum and double adult or pediatric fixation ring may be used in phakic keratoplasty, a combined supporting ring and speculum, the McNeill–Goldman blepharostat,[5] also provides both globe support and exposure. These are fixated to the superficial sclera with four 5-0 Dacron or polyglactin 910 sutures. Adequate studies have to be carried out to demonstrate the most appropriate suturing technique. Many surgeons use more than four sutures, and many place sutures on both the anterior and the posterior rings of the device. The effect of such sutures is uncertain, but sutures that are too long or too tight distort the globe, presumably leading to distortions in wound shape and ultimate postoperative astigmatism.[6] One study found that sutures in the axis of the rectus muscles had a greater effect on postoperative astigmatism.[7] The presence of a supporting ring, however, appears to allow easier maintenance of the anterior chamber during both phakic and aphakic keratoplasties.

DONOR PREPARATION

Several questions arise in choosing a technique of donor preparation. Brightbill et al[4] have demonstrated that punching the donor

material from the endothelial side against a firm surface leads to less endothelial damage and cleaner cuts than corneal preparation from the epithelial surface. Various cutting blocks have been described for this purpose,[8,9] and they are discussed elsewhere in this text. Various punches have been developed for holding the trephine blade, and a handheld disposable trephine may also be used for cutting the donor. Great controversy has existed concerning the size of the donor material to be cut relative to the size of the recipient bed prepared. Troutman[10] and Olson[11] have demonstrated that a larger trephine is necessary to prepare tissue from the posterior surface than is needed to prepare the recipient bed. In aphakic eyes, a 0.5 mm larger donor led to less hyperopia in two of three studies.[12–14] In a study comparing a relatively small number of phakic eyes, Perl et al[14] showed more myopia in eyes using oversized donor material than same-sized donor material, but this difference was not statistically significant. Many surgeons use 0.25 mm larger trephines in preparing donor material in phakic eyes rather than 0.5 mm larger donor material in the hope of reducing myopia in these usually myopic persons. Others have used donor material of the same size or even smaller than that of recipient material to reduce myopia in keratoconus patients.[15–17] The effect of varying donor size on glaucoma does not appear to be an important issue in phakic keratoplasty. An additional issue is the question of retaining epithelium on the donor tissue. Although Tuberville et al[18] suggested that removing donor epithelium reduces the frequency of immune graft reactions, others have failed to confirm this finding,[19] and most surgeons maintain donor epithelium because of the greater ease of postoperative patient management.

Marking of the recipient and donor corneas to allow symmetric suture placement can be carried out using vacuum cutting blocks with marking holes or by marking directly on the anterior surface of the donor material using a radial keratotomy marker dyed with gentian violet.[20]

PREPARATION OF RECIPIENT BED

The recipient bed is prepared with a trephine that is large enough to surround the diseased tissue and escape the papillary axis while not being so large as to encroach upon the limbus. In eyes with keratoconus, the biomicroscopically abnormal cornea is surrounded with the trephine. Numerous trephines have been developed—both manual and automated—that have varying degrees of complexity.[21] An open-bladed, disposable trephine may be used for cutting the recipient bed. The advantages to this trephine include the ability to directly sight down the barrel of the trephine through the operating microscope to aid in accurate positioning and its lack of a central guard, which may distort tissue shape during trephination.[22] A forceps is used to grasp the fixation ring, and the trephine blade is held in the opposite hand and first pressed on the cornea and then gently rotated. Experience allows reasonable estimation of the depth of the cut being made. Automated trephines and suction trephines may be used as well. Various authors have compared automated trephines. Uniformity of cuts varies with the trephine type, and the ideal trephine that provides straight cuts without tissue distortion has yet to be found. van Rij and Waring[23] found a nondisposable suction trephine and a free disposable blade the most uniform. Other groups have compared various suction trephines and found graft curvature to be greater with suction trephines than with handheld trephines.[24] Visual recovery in one study was more rapid and complete using the Hanna vacuum trephine compared to the Hessberg–Barron system.[25] Ovoid cutting trephine systems have been suggested in the past for astigmatic corneas, but their usefulness has never been confirmed.[23]

Radial marks may be made on the recipient bed prior to trephination using a radial keratotomy marker and gentian violet, or marks may be made with a suction trephine, such as the Barron radial vacuum trephine, which leaves impressions in the cornea after the use of the suction trephine. This approach allows equal spacing of suture placement and matching of the donor and recipient markings.

CHAMBER ENTRY

The anterior chamber may be entered using the trephine while cutting the recipient bed. This technique is safe to do if the surgeon is aware of the need to immediately release pressure when the chamber is entered. It usually leads to a perpendicular cut and allows easier removal of the host cornea. Many surgeons prefer the more controlled entry that is allowed when they trephine approximately three-fourths of the way into the recipient bed and then use a sharp disposable blade to enter the anterior chamber. At this stage, many surgeons will inject viscoelastic material into the anterior chamber to both counteract posterior pressure and create space between the cornea and the iris–lens complex. Some surgeons have suggested the use of trypan blue staining in aiding depth of trephination and visualization of recipient endothelium in excison of the posterior lip.[26] A small portion of the posterior cornea may be left intact, creating a hinge to allow the recipient cornea to be reflected out of the way but leaving it available for restoring the chamber should a suprachoroidal hemorrhage take place prior to the time that the donor cornea is in place.[27]

HOST CUTTING AND REMOVAL

The host button is removed by cutting with curved, fine corneal scissors. The recipient cornea is grasped with a fine forceps during this maneuver, and the scissors are held perpendicularly or sloped to allow a posterior bevel of the tissue. This approach creates a slightly smaller posterior than anterior opening in the recipient bed, which may allow for easier wound apposition. The disadvantage of this technique is that an uneven posterior lip may lead to tilting of the graft and resultant astigmatism. When a posterior tag of stroma and Descemet's membrane is left in just one area, this area may be the site of graft displacement at the time of suture removal and subsequent induced astigmatism. For this reason, tags should be removed perpendicularly when they are present. Pulling too strongly on a tag while cutting it out may lead to actual undercutting of the recipient bed, which may also lead to astigmatism.

There is ongoing research into the use of excimer or femtosecond lasers to cut both the donor and the recipient corneas. Early studies suggest that the excimer laser induces less corneal neovascularization; however, the data are best considered preliminary.[28,29] The femtosecond laser may allow for a more precise, perpendicular edge and prevent damage to the iris–lens structures. However, this research is still in its early stages and further investigation is necessary.

IRIS MANAGEMENT

As mentioned earlier, constriction of the pupil in phakic keratoplasty protects the lens. For routine phakic keratoplasty, iridectomies do not appear to be necessary. In patients who have a history

of inflammation, it may be necessary to lyse posterior synechiae by gentle sweeping with viscoelastic or a cyclodialysis spatula through the pupil. In such patients, as well as in patients who are undergoing keratoplasty for herpes simplex keratitis or other disorders that may be associated with future anterior segment inflammation, a peripheral iridotomy may be appropriate. Extensive anterior synechiae may be lysed with a cyclodialysis spatula, but broadly adherent synechiae are often better managed when they are transected with a sharp scissors. Highly vascularized peripheral synechiae that do not extend to the region of the graft are often best left alone.

CONTROL OF POSTERIOR PRESSURE

As discussed earlier, preoperative hypotony can be obtained through digital massage or the placement of a mechanical balloon maintainer. Some surgeons also use either topical medications or intravenous mannitol preoperatively to further reduce intraocular pressure. In spite of these efforts, vitreous pressure may still be present, sometimes nearly prolapsing the lens out of corneal wound. In these cases, a vitreous tap or limited vitrectomy can be beneficial. The prior placement of external globe support is highly beneficial in these cases. A vitreous tap can be attempted using a 21 gauge sharp needle on a 1 cc syringe. A caliper is used to measure 3.5–4.0 mm posterior to the limbus. Then, a limited peritomy is performed, hemostasis as required is achieved, and the needle is inserted into the eye while aiming the needle at the center of the globe. Proper fixation of the globe is imperative during this step, otherwise the surgeon can cause an iatrogenic cataract through violation of the posterior lens capsule. Vitreous taps tend to be of limited utility in younger patients secondary to the consistency and adherence of the vitreous, therefore a limited dry vitrectomy usually provides a greater benefit. Similar to the vitreous tap, a limited peritomy and hemostasis are achieved. An 18 gauge MVR blade is inserted into the previously demarcated site, once again aimed at the center of the globe. Then, a vitrector handpiece (typically the one from a phacoemulsification unit can be used) without the irrigation sleeve is inserted into the wound. The machine should be set at a low vacuum with a high cut rate (>400 cpm). Typically, a very limited vitrectomy is all that is necessary. Upon resolution of the posterior pressure, the vitrector handpiece is removed and the wound checked for vitreous strands with a cellulose sponge. Once cleared of vitreous, the wound is closed with an absorbable suture. Caution is paramount so that the surgeon does not touch the posterior lens capsule or the peripheral retina. The fundus should be examined either at the conclusion of the case or the next day, with either direct visualization or ultrasonography.

GRAFT MANAGEMENT AND CHAMBER MAINTENANCE

The next step is to place the donor cornea onto the recipient bed for suturing in place. A viscoelastic substance is placed over the anterior lens capsule, and the anterior iris surface and then the donor cornea is placed over this layer. One comparison of viscoelastic materials demonstrated that a dispersive viscoelastic coupled with a cohesive viscoelastic in a 'soft-shell' technique resulted in less endothelial cell loss.[30] The combination of the preoperative massage, scleral fixation ring, and viscoelastic material appears to prevent forward movement of the iris–lens diaphragm and trauma to the donor corneal endothelium.[3] Saline solutions or air can be used for anterior chamber maintenance as well, but they are not so effective during the initial graft placement. Rotation of the graft for best alignment has been suggested in the past but has not been demonstrated to be effective. During subsequent portions of the procedure, much of the viscoelastic material may be lost from the chamber, but the chamber is still maintained. Many corneal surgeons prefer irrigating this material out after sufficient interrupted sutures have been placed because of the pronounced pressure elevations, which have been demonstrated with retention of viscoelastic materials in keratoplasty.[31] Removal can also be carried out through a paracentesis track following completion of graft placement. Some transplanting surgeons, concerned with potential endothelial damage from such maneuvers, discourage viscoelastic removal and treat anticipated ocular hypertension prophylactically.

SUTURING

Suturing is an area of perhaps the greatest inter-surgeon variability. Suturing techniques range from the use of multiple interrupted sutures to double running sutures and to combinations of running and interrupted sutures. With all techniques, it is first necessary to place four initial interrupted sutures so as to achieve fixation. The first suture is placed at the 12 o'clock position, followed by a suture at the 6 o'clock position. In placing the 6 o'clock suture, it is important to attempt to align the donor tissue so that there is equal distribution to both sides of the suture. Marking the donor and recipient corneas, as described earlier, aids in this effort. Additional sutures are then placed at the 3 and 9 o'clock positions. Subsequent suturing may consist of the placement of 12 additional interrupted sutures, four or eight additional interrupted sutures, a running suture, or a double running suture with removal of the interrupted sutures.[32] One option is to use 10-0 nylon for all interrupted sutures and 11-0 nylon when interrupted sutures are followed by a continuous suture. When all the interrupted sutures are to be removed before the end of the procedure, the first continuous suture may be of 10-0 nylon whereas the second may be of 10-0 or 11-0 nylon. It is appropriate to place the interrupted sutures as deep as possible without perforating Descemet's membrane. A continuous suture, when used in addition, is placed more superficial. Avoid through-and-through suturing because of the potential of endothelial damage.[33]

Suture tension is an important issue. With interrupted sutures, tight suturing may provide a more secure wound but leads to more epithelial difficulties postoperatively and greater difficulty in achieving optical correction while the sutures are in place. Sutures that are too loose may lead to wound displacement. All sutures are trimmed close to the knots, and all the knots are buried. The knots may be rotated into the host or the donor tissue. Knots buried in the host tissue may be more likely to stimulate vascularization when compared to knots buried in the donor tissue. This area requires further study.

FINAL CHECKS

The wound is checked for its integrity by deepening the chamber with balanced salt solution and checking the wound margins for fluid leaks using sponges and gentle pressure on the globe. When necessary, additional interrupted sutures are placed. If the iris is adherent to the wound, it is either swept free with a cyclodialysis spatula placed through the wound 90° from the adherent iris or forced posteriorly by the use of irrigation with either balanced salt solution or a small amount of viscoelastic material. At this point, some surgeons recommend the use of intraoperative keratometry to

ascertain anastigmatic positioning of the graft. Studies suggest earlier visual rehabilitation but no difference in the final visual outcome with intraoperative suture adjustment.[34,35]

MEDICATIONS

At the end of the procedure, antibiotics may be injected subconjunctivally. Evidence for the benefits of drug treatment and for optimal antibiotics to be used is lacking.[36] Subconjunctival soluble corticosteroids may be injected, but the ultimate benefit is also undetermined.

ALTERNATIVE APPROACHES

Lately, there has been renewed interest in lamellar procedures. Posterior lamellar procedures, such as Descemet's stripping endothelial keratoplasty (DSEK), are being increasingly used in situations of primary endothelial disease. These endothelial lamellar procedures need a substantial amount of space in the anterior chamber and are difficult to perform in phakic patients. Also, the use of air tamponade may cause premature cataracts in these patients.[37] Anterior lamellar procedures, such as deep anterior lamellar keratoplasty (DALK), are being used in situations with healthy endothelium, such as keratoconus and partial-thickness corneal scars. These procedures are discussed elsewhere in this text.

43 Combined keratoplasty and lens removal: the triple procedure

Matthew J. Thompson, Timothy B. Cavanaugh
Authors of Past Editions: John D. Hunkeler, Daniel S. Durrie

Combined penetrating keratoplasty, cataract extraction, and lens implantation has been the treatment of choice for patients with combined corneal and cataract disease. The combined procedure reduces surgical and visual morbidity by reducing the number of procedures necessary to rehabilitate the eye and may be more effective than performing surgery in two or more stages. Early and recent clinical results have been extremely encouraging, as reported by multiple authors over the past 25 years.[1–16] The long-term results continue to be encouraging, as reported by Hunkeler and Hyde[17] in 1983, Erb et al[18] in 1996, and Das et al[19] in 2005. Casey[13] reported the surgical techniques in the triple procedure, describing the implantation of the anterior chamber (AC) IOL, the iris-supported lens, or the posterior chamber (PC) IOL.

ADVANTAGES OF EXTRACAPSULAR TECHNIQUE AND POSTERIOR CHAMBER INTRAOCULAR LENSES

Acceptance of the triple procedure as the treatment of choice for patients with combined corneal and cataract disease has not been without controversy. The success of penetrating keratoplasty and long-term graft survival has improved dramatically along with the understanding of corneal function in relation to graft survival. Furthermore, the refinement of extracapsular surgical techniques combined with PC IOL implantation has served as a breakthrough to allow more surgeons to perform the triple procedure.

With the extracapsular technique, the posterior capsule functions as a protective barrier between the anterior and posterior compartments of the eye and as a platform of support for a PC IOL.[16] With the optic of the PC IOL behind a small pupil of a constricted iris, the endothelium is naturally protected during corneal suturing, an advantage that makes the operation much simpler. For this reason we prefer PC IOLs whenever possible. If there is inadequate capsular support, suture fixation to the iris is preferred. With AC IOLs more IOL material is exposed to the endothelial surface with the attendant risk of endothelial damage. With older flexible closed-loop AC IOLs, there is a greater risk of forward vaulting than with the less-flexible, solid, open-loop polymethylmethacrylate (PMMA) AC IOLs. Scleral sutured PC IOLs are a fourth option, although the long-term complication rate may be high with this technique.[20] Additionally, there have been reports of using the Artisan iris-fixated intraocular lens behind the iris. The long-term stability of this technique is unknown.[21]

VISCOELASTIC SUBSTANCES

The triple procedure was much more difficult to perform from a technical standpoint before the advent of viscoelastic substances. Viscoelastic substances allow us to expand the capsular bag and coat the endothelium, the implant, and the host rim to maintain tissue–plane separation throughout the surgical procedure. This approach is critical for preventing endothelial cell trauma during graft suturing and ensuring accurate placement of the PC IOL in the capsular bag. Prior to viscoelastic substances, mild-to-moderate pressure on the posterior lens capsule threatened to force the implant forward against the endothelium of the donor cornea. When this complication happened, the lens implant portion of the operation was abandoned, necessitating either spectacle or contact lens fitting postoperatively, or a later secondary IOL implantation.

INDICATIONS FOR SURGERY

The indications for the triple procedure are relatively straightforward. Patients with combined corneal and cataract disease who require improvement in vision within their own reasonable life expectancy are excellent candidates for the procedure. If the improvement in visual function can be achieved by either cataract and lens implant surgery or corneal surgery separately; the simpler procedure should be the procedure of choice. The assessment of the extent of corneal disease and lens opacity should be based on the preoperative evaluation; however, occasionally the surgeon may not determine the severity of the cataract until the cloudy cornea has been removed and the lens can be inspected intraoperatively. If the cataract appears to be sufficiently dense to decrease the vision to 20/40 or worse postoperatively, the lens should be removed at the time of keratoplasty. When the patient with a cataract is being assessed, if the surgeon believes the vision will be 20/50 or worse because of corneal opacification postoperatively, a triple procedure

Table 43.1 Published indications for triple procedures, 1976–2004

Corneal Disease	Range of Incidence (%)
Fuchs' endothelial dystrophy	31–80
Leukoma	19–35
Keratoconus	1–21
Herpes simplex keratitis	4.5–14
Interstitial keratitis	4–20

should be performed. Some patients with mild nonprogressive regular corneal scarring, as in eyes with inactive interstitial keratitis of luetic origin, may regain excellent visual activity after cataract surgery alone; in these cases, the opinion of a corneal specialist regarding single versus combined procedures is valuable. The corneal specialist will have to make a judgment call based on clinical appearance, potential acuity measurements, specular microscopy, and pachymetry.

In our center, most patients who undergo the triple procedure have Fuchs' corneal endothelial dystrophy combined with cataract. Evaluation of the patient with Fuchs' dystrophy and cataract requires careful evaluation to assess the need for combined corneal and cataract surgery. A critical evaluation of the endothelial function is necessary, as the presence of cornea guttata alone is not an indication for the triple procedure. Symptoms and manifestations of early-morning corneal edema certainly indicate endothelial decompensation, and epithelial edema in the contralateral eye should arouse suspicion of impending corneal decompensation. A documented increase in central corneal thickness, the presence of Descemet's folds, and central epithelial edema indicate possible impending corneal decompensation. We give weight to clinical signs when deciding if corneal transplantation will be necessary, but in the endothelial dystrophy patient with less than 1000/mm^2 healthy endothelial cells or a corneal thickness greater than 0.64 mm, there is a greater chance of corneal decompensation,[22] although patients who fall outside of these parameters have had cataract surgery alone with acceptable visual outcomes. When there is generalized epithelial edema, gross thickening of the cornea, extensive formation of bullae, and peripheral corneal vascularization, the diagnosis and suggested management are straightforward; more subtle cases require good clinical judgment.

Corneal scarring caused by prior injury or infection, keratoconus, and hereditary corneal dystrophy make up the bulk of the remaining indications. Brady and coworkers[23] reported on clinical indications for keratoplasty and found that 26% of all transplants at their center from 1983 to 1988 were triple procedures and that the incidence of triple procedures increased from 11% in 1983 to 26% in 1988. Published indications for triple procedures from 1976 to 2004 are outlined in Table 43.1.

COMBINED VERSUS SINGLE PROCEDURES

Several authors have examined the success of combined versus nonsimultaneous surgery and have found the results to be comparable.[24,25] There is controversy, with some surgeons preferring triple procedures while others favor sequential PKP followed by cataract extraction at a later date. The arguments for staged procedures center around a reduced need for open sky time and a greater accuracy in calculating IOL power. It is intuitive that IOL calculations should be better if these can be made after the corneal power has stabilized, but it has been difficult to show definitively that staged procedures produce superior refractive results compared to triple procedures in which surgeons have used IOL formulas with individualized constants and corneal powers. It is likely that measurement of true central corneal power and the prediction of IOL power in atypical eyes such as post-penetrating keratoplasty patients will continue to improve in the future with more advanced corneal imaging systems and IOL formulas that take into account a greater number of variables.

One concern in staged procedures is that there will be endothelial failure following cataract extraction. Modern case series have reported a low rate of graft failure following cataract surgery, similar to the control rate of failure in grafts not undergoing additional procedures.[26]

The eye is open longer in a traditional triple procedure compared to penetrating keratoplasty alone. The prolonged operating time increases the risk of posterior capsule rupture, vitreous loss, and the most devastating complication of corneal transplantation, expulsive choroidal hemorrhage. Although the complication can occur with corneal transplant or cataract surgery alone, it is more likely to occur in triple procedures. Most cases seem to occur in patients who move, cough, or squeeze the eyelids during the 'open sky' portion of the operation, and the importance of an adequate lid block cannot be overemphasized. The surgeon may consider staging the procedures or performing the cataract extraction in a more closed system for patients who are at risk of expulsive choroidal hemorrhage (advanced age and glaucoma) or who are likely to be restless during surgery.

In patients in whom adequate visualization of the lens is possible through the cornea, a small incision self-sealing phacoemulsification can be done followed immediately by keratoplasty. Authors have also described performing the capsulorrhexis only prior to removing the corneal button.[27] Menapace et al[28] described the use of a temporary keratoprosthesis as a modification of the triple procedure to perform the cataract portion with small incision surgery in a closed system. Farjo described a technique of non-coaxial illumination to aid visualization through cloudy corneas.[29] In our practice, if the cataract extraction or a significant portion of it can be performed under a closed system, we do so.

CONTRAINDICATIONS

Contraindications for triple procedures are identical to those for noncombined keratoplasties. For example, if a corneal transplant is contraindicated in an eye with uncontrolled ocular cicatricial pemphigoid or infiltrative keratitis with corneal melting, then a triple procedure should not be performed either. Patients with proliferative diabetic retinopathy, uncontrolled glaucoma, and uncontrolled recurrent episodes of moderately severe or severe uveitis are poor candidates for the triple procedure. Patients with a history of severe herpetic stromal keratitis or prior active keratouveitis may have complicated postoperative courses and will require pre- and postoperative oral antiviral prophylaxis and intensive follow-up.

INTRAOCULAR LENS POWER CALCULATIONS

After the decision has been made to proceed with the triple procedure, the lens-implant power calculation should be performed. Binder[9] and Crawford and coworkers[3] have evaluated the parameters

Table 43.2 Hoffer technique for intraoperative lens power calculation

Axial Length (mm)	Formula	Percentage Used
<22	Hoffer Q	8
22.0–24.5	Average of all three	72
24.5–26.0	Holladay 1	15
>26	Sanders–Retzlaff–Kraff/T	5

that assist in proper lens-implant power selection and have developed linear-regression formulas based on their clinical experience. Retzlaff[30] reported a linear-regression formula that has been used for cataract extraction with lens implantation.

$$\text{IOL power} = A(\text{constant}) - 2.5 \times \text{axial length} - 0.9 \times \text{average } K \text{ in diopters}$$

Several authors have reported that the choice of IOL power formula does not affect IOL power predictions in triple procedures, but others assert that IOL power calculation using theoretical formulas are most likely to be accurate with formulas chosen based on the axial length as recommended by Hoffer[31] (Table 43.2). The more important factor in postoperative refractive accuracy of triple procedures is the use of personalized constants within a given formula.[32,33] In the SRK formula this would be the *A* constant. Each IOL has a manufacturer-recommended *A* constant. Personalizing the *A* constant by analyzing postoperative outcomes will yield greater accuracy. When using the Holladay formula the surgeon factor (*S* factor) should be modified, and in the Hoffer Q formula it is the postoperative AC depth that should be personalized.[33]

Each corneal surgeon should also individualize IOL power calculations by noting the average keratometry readings for a series of patients after keratoplasty. The keratometry value selected is based on results of numerous triple procedures with the same trephine and suture techniques by the same surgeon. For example, using the same trephine and suture techniques an average value close to 44.5 D at 12 months postoperatively was found in a series of triple procedures. In order to attempt to further improve accuracy, one group analyzed the correlation between preoperative peripheral cornea power, as measured by computerized videokeratoscopic analysis (Corneal Analysis System, EyeSyS Laboratories, Houston, TX). In patients with flat peripheral corneas (40 D or less), a value of one was subtracted from the surgeon's average central corneal power in calculating the IOL power. This modification resulted in a statistically significant better postoperative refractive outcome.[34]

SURGICAL TECHNIQUE

SOFTENING THE GLOBE

On the day of surgery, pupillary dilatation is achieved with 1% cyclopentolate and 2.5% phenylephrine given 15, 30, 45, and 60 min preoperatively. A topical nonsteroidal anti-inflammatory drop can also be used to prophylax against premature intraoperative miosis. Some surgeons use preoperative antibiotics for 1–3 days preoperatively, although at this time there is not good evidence to support this. Either a local or a general anesthetic may be used. If general anesthesia is selected, endotracheal anesthesia is preferred. A lower rate of suprachoroidal hemorrhage is reported with penetrating keratoplasties done under general anathesia.[35] In our practice, most cases are done under local anesthesia with minimal preoperative sedation. Prior to retrobulbar injection the eye can be anesthetized with proparacaine. Some physicians prefer a combination of bupivacaine and lidocaine anesthetics. Equal parts of 0.75% bupivacaine and 4% lidocaine are mixed to give a solution that is 0.375% bupivacaine and 2% lidocaine. Hyaluronidase is also incorporated with the anesthetic to aid in tissue spread. This local anesthesia gives a rapid onset with the lidocaine, long staying power with the bupivacaine, and few adverse reactions. We always perform a lid block with retrobulbar anesthesia. Following injection, we use a Honan pressure cuff at 20–25 mmHg to soften the eye for 10 min. Some surgeons prefer to use the Honan device for 20–30 min preoperatively.

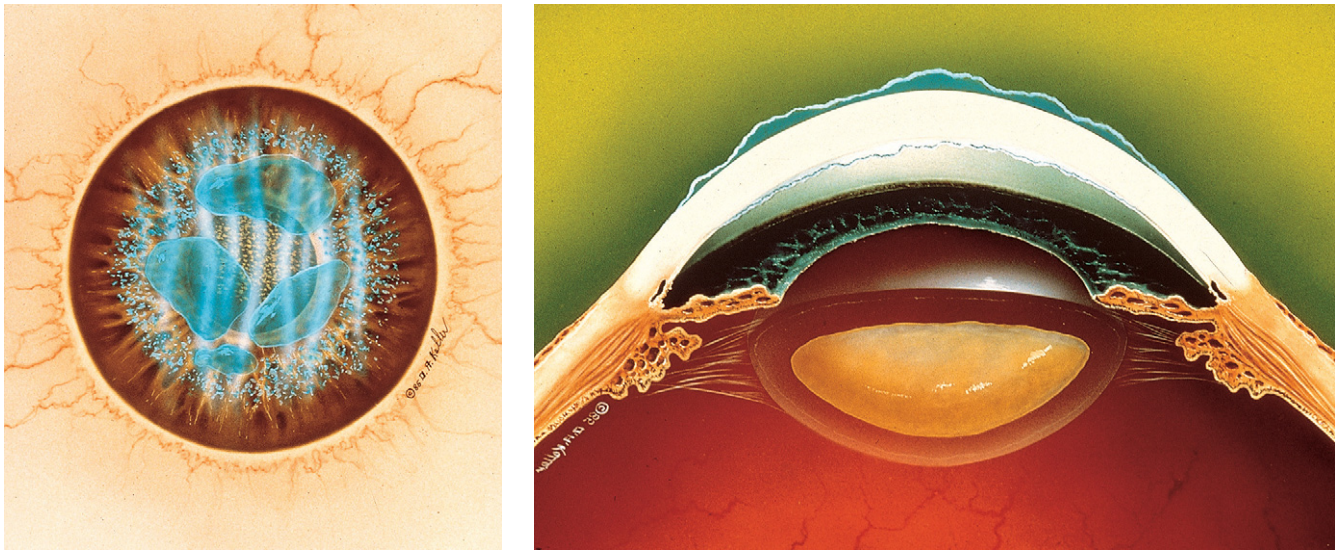
PREPARATION

The patient is positioned with the iris and facial features in a flat plane, the head in an apparently comfortable position, and the body relatively flat with some break at the knees for patient comfort. Some surgeons use a wrist rest system. The lids and lashes are prepped with betadine, including a drop of 5% solution in the eye. A paper drape is used to cover the head and the body, with a solid patch of adhesive plastic in the center. The lids are retracted by the scrub-nurse assistant, and the adhesive surface is applied directly to the retracted lids and exposed host cornea (the sticky adhesive will not adhere to the cornea but adheres nicely to the lids and lashes). A central cut is made in the drape adhesive plastic to allow the insertion of a wire lid speculum. The lashes remain everted and out of the surgical field.

It is important that the speculum system that is chosen does not apply pressure to the globe. We routinely use the McNeill–Goldman blepharostat ring, which is a combined speculum and scleral support ring. Some surgeons do not use a Flieringa ring routinely except in pediatric cases or when the eye has had or is scheduled to undergo vitrectomy. The ring is secured to the globe with four 5-0 silk or vicryl sutures. The tails of the suture can be left long to assist in maneuvering the globe during the operation. The speculum and ring should be inspected throughout the operation to ensure minimal pressure on the globe. Vitrectomy instrumentation should be available in case a vitrectomy becomes necessary.

REMOVAL OF EPITHELIUM

In cases in which no minimal peripheral epithelial edema exists, removal of healthy peripheral recipient epithelium is unnecessary. In eyes with Fuchs' corneal dystrophy (Fig. 43.1, *A* and *B*), several pathologic changes may have occurred by the time of surgery including epithelial edema, bullae, and striate keratopathy (resulting in significant corneal thickening); frank corneal decompensation; dense, nuclear cataract formation; and, occasionally, tremendous epithelial hypertrophy (associated with superficial vascularization). Edematous corneal epithelium with or without fibrovascular pannus can be removed with a #64 Beaver blade, decreasing the chance of trephine slippage and irregular cutting of Bowman's membrane and the anterior lamellae of the cornea. In addition, this step ensures that sutures will be passed securely into corneal stroma rather than into thickened fibrous tissue or epithelium. Occasionally, some cautery is required for prolific vessels, but bleeding normally ceases



A B

Figure 43.1 *A*, Cornea with advanced Fuchs' dystrophy showing microsystic and bullous epithelial edema, striate keratopathy, and circumciliary flush. *B*, Dense nuclear cataract in eye with advanced Fuchs' corneal dystrophy. Slit-lamp evaluation of lens changes may be difficult when significant corneal edema is present.

on its own. If phacoemulsification is to be performed prior to removing the corneal button, removal of edematous epithelium often improves visualization. Phacoemulsification can be performed at this stage and may be done via a scleral tunnel or clear cornea approach. The wound should be sutured at the conclusion of the case. Some surgeons prefer to perform a partial-thickness trephination prior to phacoemulsification.

DONOR TISSUE PREPARATION

Donor tissue should be prepared before trephination of the patient's cornea to ensure that adequate donor tissue is available immediately upon entry into the AC. There are a variety of techniques for the trephination of donor tissue. Most surgeons cut the donor tissue endothelial side up with an Iowa, Troutman, or Hanna corneal trephine punch. The disposable trephine selected should be 0.25 or 0.5 mm greater than the opening to be made in the recipient cornea. The slight oversize of the button allows for some tissue compression effect of the sutures without significant flattening of the central graft curvature.

When using the Iowa trephination system, the donor is placed epithelial side down and is centered on the cutting block. The trephine is then passed through the guide and is pushed straight down through the cornea, producing a crunching sound. Before withdrawing the trephine, the donor rim can be grasped, lifted, and turned to ensure complete separation. If the trephine does not cut full thickness for 360°, a blade or corneal scissors is used to complete the cut. The donor button is placed epithelial side down on a polytef punch block with a few drops of Optisol storage solution and covered before transplantation.

Some surgeons prefer to use a trephine such as the Hanna trephine with an artificial AC. The donor corneoscleral tissue is placed endothelial side down (epithelial side up) (see Fig. 43.2) over viscoelastic, and the artificial chamber is sealed by screwing the top down. Sterile balanced salt solution is then injected to fill the artificial chamber to an estimated intraocular pressure of approximately 50–60 mmHg. The donor center is marked by making an impression through the gunsight of the Hanna trephine with the tip of a cannula. Suture placement may be marked on the epithelial side of the donor with a 12-incision radial keratotomy marker. The Hanna trephine self centers and is then used to cut the donor tissue from the epithelial side in the same fashion as the patient's cornea is to be cut (see Fig. 43.3). The advantage of trephination from the epithelial side with an artificial AC is that the surgeon is cutting both the donor and the recipient corneas from the epithelial side. This approach eliminates the opposite beveled cut and tissue mismatch seen with traditional trephination and allows the surgeon to mark suture placement on both donor and recipient for more precise suture alignment.

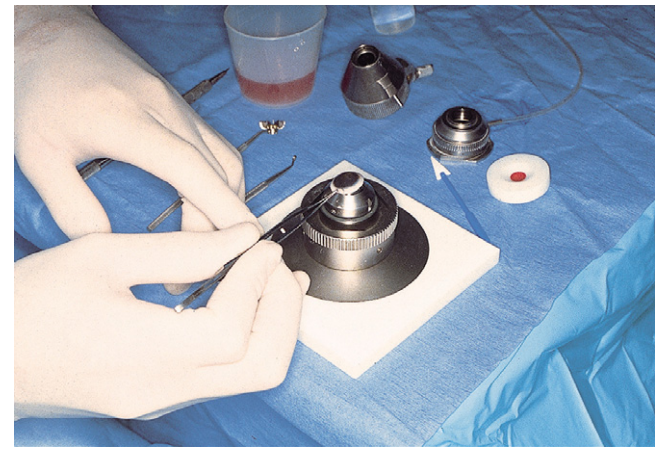


Figure 43.2. Donor corneal-scleral rim resting on Hanna artificial anterior chamber.

Another approach involves using an excimer laser to cut both the donor and the recipient tissue. Graft oversize need not be as high with this technique because of greater precision in cutting.[36] Enhanced precision should lead to better surgical results, especially

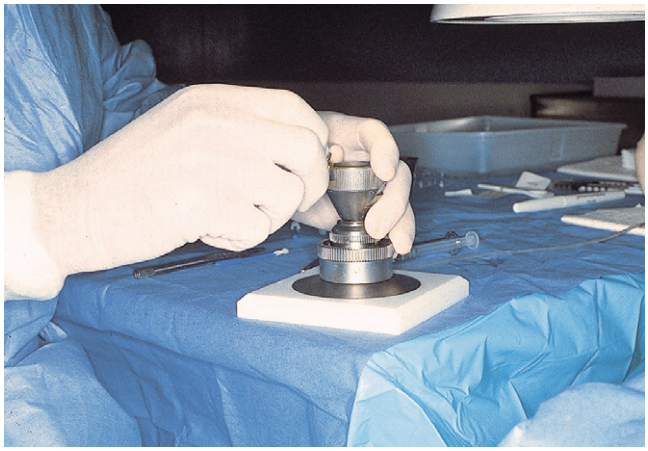

Figure 43.3. Hanna trephine on artificial anterior chamber cutting donor cornea.

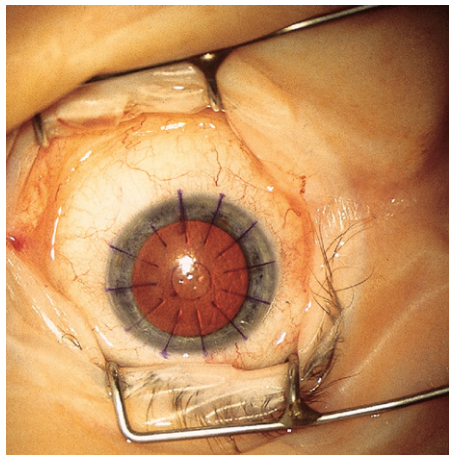

Figure 43.4. 3.0 mm optical zone mark and 12 radial marks of recipient cornea.

regarding postoperative astigmatism. Cost and availability may limit this technology in the near term, however.

RECIPIENT CORNEA TREPHINATION

The center of the patient's cornea is marked by measuring with 6 mm calipers from periphery to center at 3, 6, 9, and 12 o'clock positions. The cornea can be marked to assist in even spacing of sutures by marking the central optical zone with a 3 mm optical zone marker marked with gentian (Fig. 43.4). An inked 12-incision radial keratotomy marker is centered around the 3 mm and 12-radial marks to guide interrupted suture placement (Fig. 43.4). A limbal paracentesis incision is made between suture marks, and a moderate amount of viscoelastic is injected to protect the intraocular structures from the cutting action of the trephine blade. Both handheld and suction trephine systems are available. The most popular system is the Hessburg–Barron vacuum trephine to incise the recipient cornea. The blade is aligned with the edge of the trephine housing under operating microscope guidance (Fig. 43.5), and the blade is then retracted three quarter turns. The cross-hairs in the trephine are centered on the cornea with the syringe plunger held in. When the trephine is in the proper position, the plunger is released and the resultant vacuum suctions the trephine mechanism in place. The blade is then advanced 6.5 quarter turns, which corresponds to a corneal incision of approximately 0.30 mm, and is then removed. Alternatively the AC may be entered. The incision depth is checked with 0.12 mm tooth forceps, and dissection is carried deeper with a slight inward beveling by either a diamond knife or a disposable 15° blade. The AC is then entered, and the incision is extended 360° with right and left cutting corneal transplant microscissors. There is often an inner bevel to the incision.

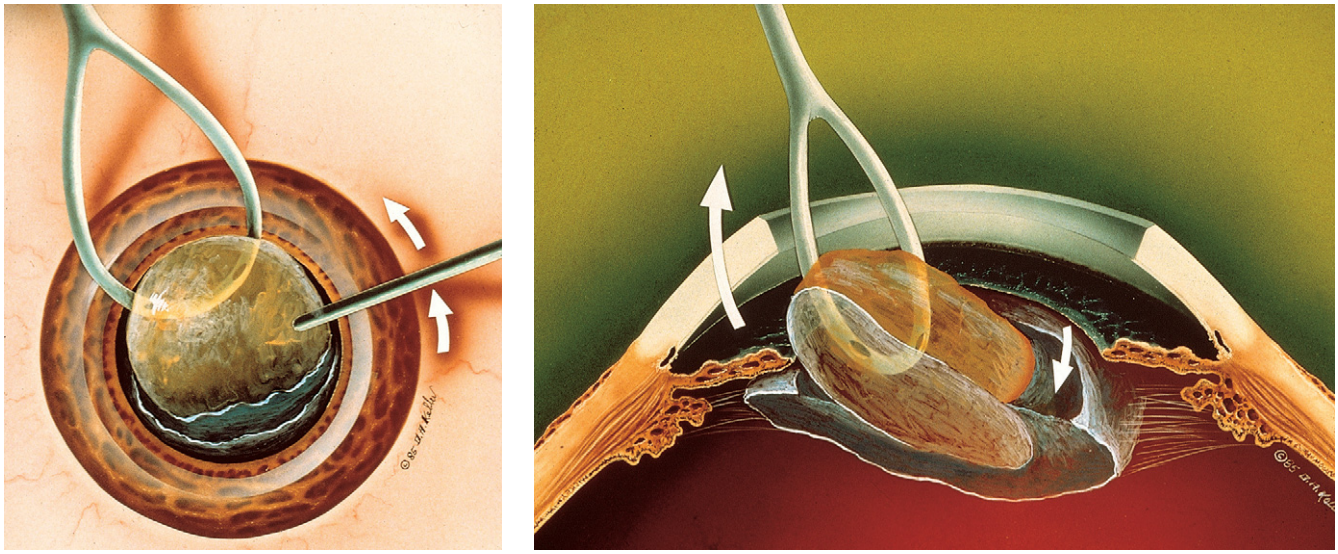
In the Hanna trephine system, suction is applied peripheral to the limbus and the central cornea is supported by a central obturator. This arrangement allows for trephination 100% through the cornea without significant bevel formation or chamber shallowing. In contrast, the Hessburg–Barron trephine suctions directly onto the cornea and lacks central support, which allows for beveled cuts and suction pressure to transmit to the AC once initial entry is achieved. The Hanna trephine also centers more precisely, as it contains a central gunsight target that rests directly on the cornea in contrast to the Hessburg–Barron's cross-hairs that are elevated off the corneal surface.

With either system, once the chamber is entered, it is imperative that suction pressure be removed to avoid rapid chamber shallowing and inadvertent cutting of the iris or lens capsule by the blade. We often use an 8 mm diameter blade. If the same marks are made on both donor and recipient corneas and the same Hanna trephine is used to cut both from the epithelial side, excellent alignment of tissue results in both the anterior–posterior and the circumferential aspects.

CAPSULOTOMY AND LENS REMOVAL

After excess viscoelastic and fluid are removed, a round capsulotomy is performed by capsulorrhexis. Staining the capsule can assist with visualization.[37] If there is any posterior vitreous pressure, the capsule edge often begins to tear radially. If this complication occurs, completion is best done with scissors. Some surgeons have suggested that depressing the center of the lens with a second instrument can assist in flattening the anterior capsule and completing a capsulotomy. It is wise to avoid contact with the iris to prevent premature miosis before removal of the nucleus. The central piece of anterior capsule is removed, leaving a round opening preferably around 6 mm in diameter.

One method of nucleus removal involves hydrodissection until one pole of the nucleus prolapses from the capsular bag and then



A B

Figure 43.6. Lens loop and irrigating cannula used to deliver nucleus after anterior capsulotomy.

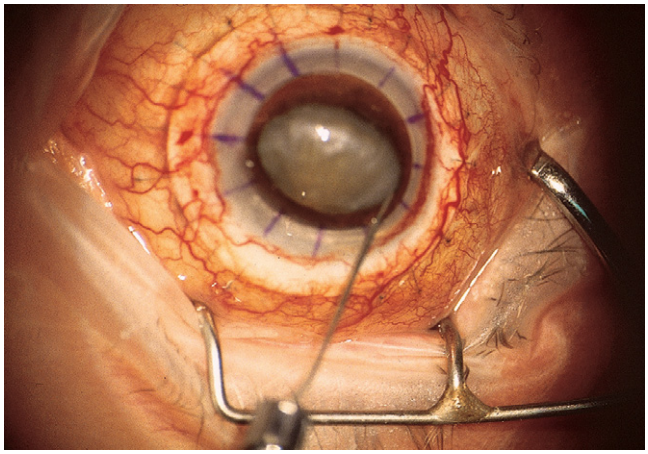


Figure 43.7. Open sky hydroexpression of cataractous lens nucleus.

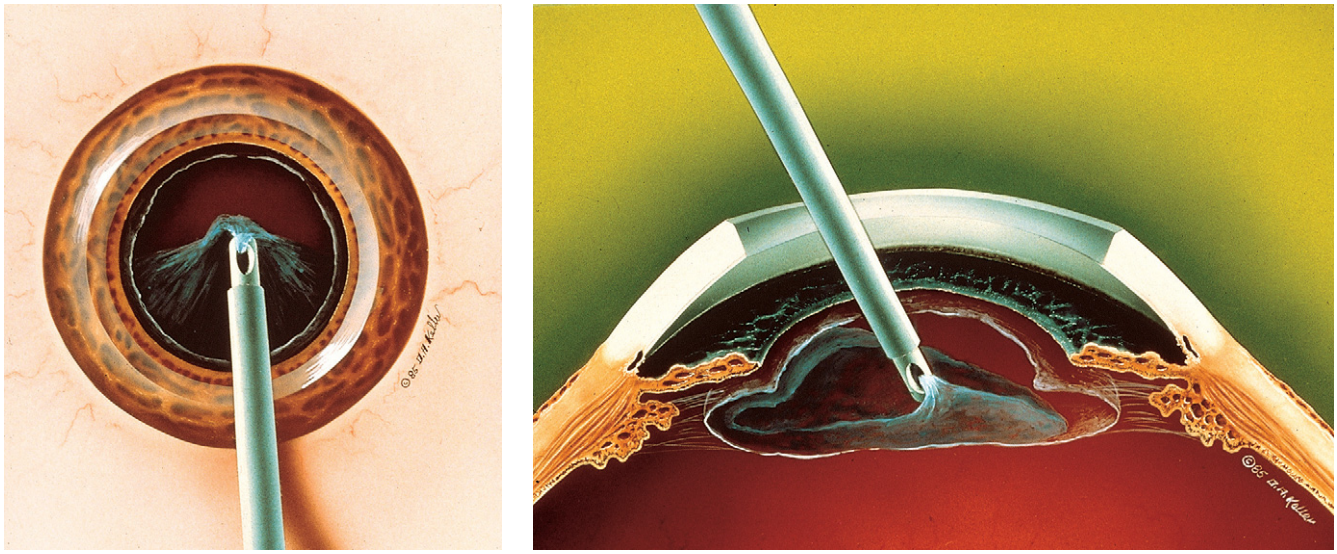
placing a lens loop under the inferior pole of the elevated nucleus (Fig. 43.6, *A* and *B*). The nucleus is raised superiorly and anteriorly with a 25-gauge irrigating cannula placed just above the inferior pole, then forced superiorly and anteriorly. The cleavage plane develops, allowing insertion of the lens loop with or without an irrigating component. Once this cleavage plane has been established, a counterclockwise rotary movement with a 25-gauge irrigating cannula spins the nucleus out of the capsule bag. If this approach fails, for whatever reason, the nucleus can be brought forward with posterior pressure on the peripheral cornea in the 5 o'clock meridian, which raises the intraocular pressure and brings the nucleus forward. At this point, the 25-gauge irrigating cannula can fix the nucleus, and the lens loop can be slipped underneath the nucleus before its removal. It is also possible to remove the nucleus by application of a cryoprobe to the dried central nucleus and to gently pull it up. The current preferred technique is more elegant and simply uses hydrodissection and hydroexpression to gently express the nucleus from the bag (see Fig. 43.7). A 27-gauge cannula is used to sweep the anterior capsule aside while injecting balanced salt solution posterior to the equator of the nucleus. This step usually results in the nucleus prolapsing anterior to the capsulorrhexis and standing on end. It is then gently rotated out of the eye by the cannula. If the lens cannot be prolapsed a phacoemulsification handpiece may be used to fragment the lens for removal.

IRRIGATION AND ASPIRATION

The remainder of the lens cortex can be removed with conventional cortical clean-up, irrigation, and aspiration systems (Fig. 43.8, *A* and *B*). Mechanical irrigation and aspiration and manual technique are equally effective. Excessive irrigation obscures the surgeon's view of the red reflex and creates multiple-mirrored images from the fluid surface, obscuring the view of the cortex and posterior lens capsule. The anterior cortical tissue is engaged with the aspirator and stripped toward the center (Fig. 43.9). Relatively high vacuum levels must be used for most irritation/aspiration systems to maintain purchase on the cortex in the open system. There is no special technique required for cortical stripping in the soft eye. Occasionally, with positive posterior pressure and a convex posterior lens capsule, aspiration in the fornix of the capsule bag is difficult but can be facilitated by applying gentle posterior pressure on the peripheral posterior lens capsule while the cortical material is stripped away. The gentle posterior pressure develops the cleavage plane, allowing engagement of the anterior cortex peripherally. Once most of the cortex has been removed, a Kratz sandblasted capsule polisher or silicone sleeve squeegee polisher is used to clean off the central posterior capsule.

POSTERIOR INTRAOCULAR LENS INSERTION

The 7-mm optic one-piece all-PMMA ultraviolet-absorbing PC IOL is our choice for placement within the capsular bag (Fig. 43.10, *A* and *B*). Viscoelastic is used to separate the anterior and posterior lens capsules to facilitate in-the-bag loop placement. Constant, gentle downward pressure should be maintained on the IOL during insertion as the vitreous pressure tends to push the IOL back out of the bag. If necessary, the lens position can be inspected with a hook,



A B

Figure 43.8. Aspiration of residual lens cortex after removal of nucleus. Stripping is best accomplished when the peripheral anterior cortex is engaged and gently pulled toward the center, with improved red reflex being noted.

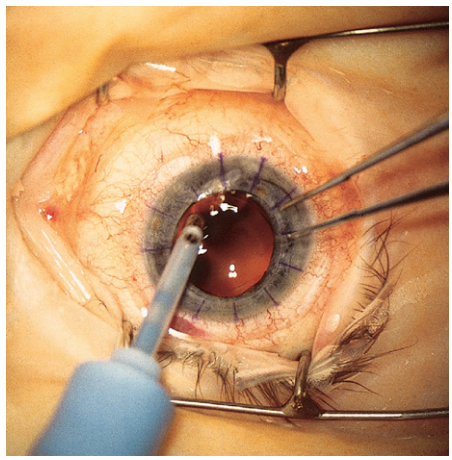


Figure 43.9. Automated irrigation/aspiration cortical clean-up.

and the lens implant rotated to achieve centration. A small peripheral iridotomy is optional, but it is not routinely done.

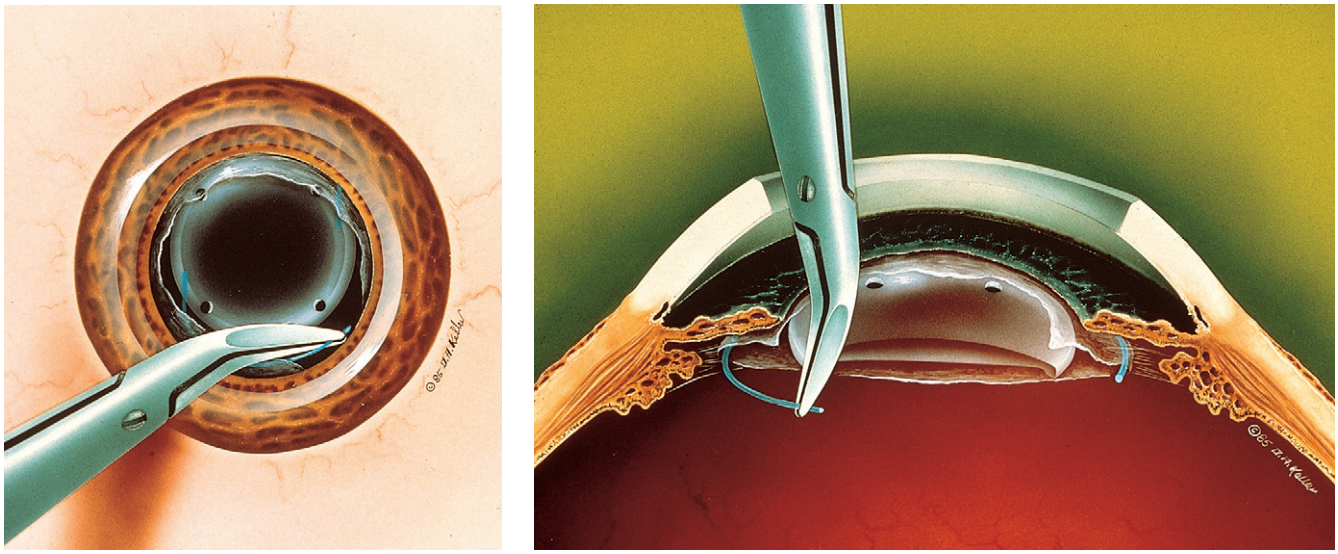
After the IOL is positioned, acetylcholine chloride is used for miosis and to ensure final placement of the lens behind the iris. Residual viscoelastic material is then evacuated out of the AC with irrigation and aspiration and the AC is left filled with balanced salt solution. Viscoelastic can be left in the AC to protect the donor endothelium during suturing. A cohesive agent is preferred at this point to aid in complete removal at the conclusion of the case, minimizing the potential for significant intraocular pressure rises. In all cases, a coating of viscoelastic should be placed along the rim of the recipient cornea to guard against endothelial damage from tissue sliding during placement of the four cardinal sutures.

INADVERTENT CAPSULAR RUPTURE

If the posterior lens capsule is inadvertently broken during the procedure with a small tear either centrally or peripherally in a small sector, a PC IOL may still be inserted. Provided that there is a stable capsular platform, the lens can be gently inserted within the capsular bag or in the ciliary sulcus. However, if significant capsular support is lost or extensive vitreous surgery is required, it is advisable to suture fixate a PC IOL to the iris, to insert a flexible AC IOL, or to suture fixate a PC IOL to the sclera. This can be accomplished through the keratoplasty opening, avoiding a second incision at the limbus. Iris fixation is preferable due to its rapidity, ease, dependability, and safety. Scleral fixation is used if there is inadequate iris to provide support and an AC IOL is contraindicated. In the past a PMMA AC IOL with four positioning holes in the optic was available for iris fixation, but lenses with positioning holes are no longer widely available. Alternatively a three-piece PC IOL can be fixated to the iris by passing a 10-0 prolene suture through the mid-peripheral iris, under the haptic of the IOL, and back through the iris. The exit points on the iris should be about 1 mm apart—less will allow for cheesewiring of the suture through the iris and more will 'bunch up' the iris and distort the pupil. A peripheral iridectomy is not routinely done, and postoperatively the pupil still dilates nicely. Complications such as iris chafing, pigment dispersion, pupillary block, and dislocation are rare with this technique. It is important to have alternative lenses available in an appropriate power should the need arise.

SUTURING THE GRAFT

A small amount of viscoelastic material (we currently use Provisc, Alcon) is placed in the AC and around the recipient rim to protect the donor endothelium. The donor cornea is removed from the polytef block with a corneal spatula and placed over the recipient hole (Fig. 43.11), where it is secured with four cardinal sutures placed sequentially at the 12, 6, 3, and 9 o'clock positions (Fig. 43.12). The chamber can be deepened with balanced saline solution at this point and if necessary supplemented with air or viscoelastic material. With a nice coat of viscoelastic material, it is possible to use air, which reduces the amount of viscoelastic material needed to give a firm eye for excellent suture placement. We have also used Viscoat (Alcon) in the past and have not experienced significant



A B

Figure 43.10. Following use of viscoelastic to separate anterior and posterior lens capsules, in-the-bag placement of posterior-chamber intraocular lens facilitates using needle-holder guidance of the superior loop.

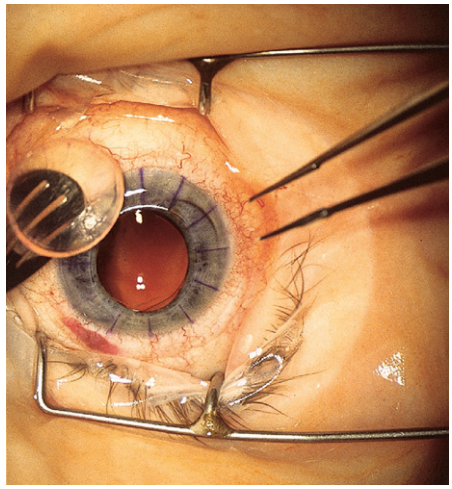


Figure 43.11. The donor button is brought onto the patient's eye with a spatula.

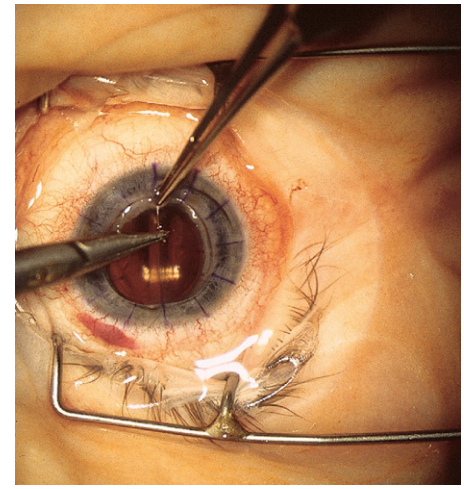

Figure 43.12. 11-0 Mersilene suture placement along previously placed radial marks.

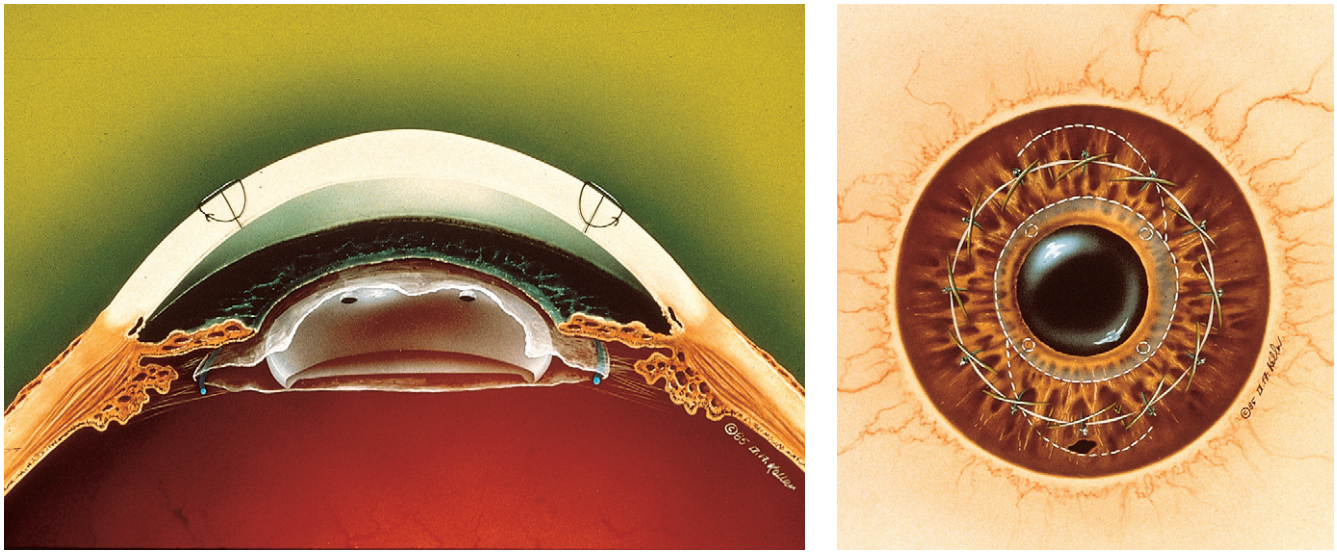
postoperative intraocular pressure rises despite often leaving much of the material in the AC at the close of surgery.

The surgeon then completes suturing with interrupted sutures alone, combination of interrupted and running sutures, or single or double running sutures. Good results can be obtained with a variety of suturing techniques. In our current technique, eight additional interrupted sutures are placed equally spaced between the four cardinal sutures on each of the 12 radial keratotomy marks. All the knots are tied evenly and securely in a 3-1-1 fashion before being trimmed on the knot and buried in the peripheral host cornea (Fig. 43.13, *A*). Suture depth placement is at the 90% or greater level. Ideally, sutures are deep enough to directly approximate Descemet's membrane, but we avoid full-thickness sutures because of concern for postoperative endophthalmitis. Suture bites of approximately 0.75–1.0 mm are preferred to minimize tissue compression centrally, with a larger central optical zone being achieved. A 12-bite continuous running suture is then placed with bites between each of the 12 interrupted sutures in a slight antitorque direction (Fig. 43.13, *B*). Suture slack is taken up once around the circumference with nontoothed forceps while the AC is somewhat shallow and the eye moderately soft. The suture begins and ends in the incision so that the knot is already buried on the host side. Tying the continuous suture more gently than the interrupted sutures allows for effective reduction of graft astigmatism by selective removal of the interrupted sutures postoperatively. When the AC is filled at the end of the case, tension of the sutures tightens to the appropriate level.

Some physicians have reported using 11-0 polyester sutures for closure with the combined 12 interrupted and 12-bite running technique. The 11-0 polyester is a monofilament permanent suture material that can be left in place indefinitely. A theoretical benefit of this technique is enhanced long-term wound integrity provided by permanent sutures. Graft incisions heal very little, and wound dehiscence or trauma after suture removal is not uncommon even years postoperatively. In addition, at the time of regraft, most wounds can easily be separated using minimal blunt dissection with



A B

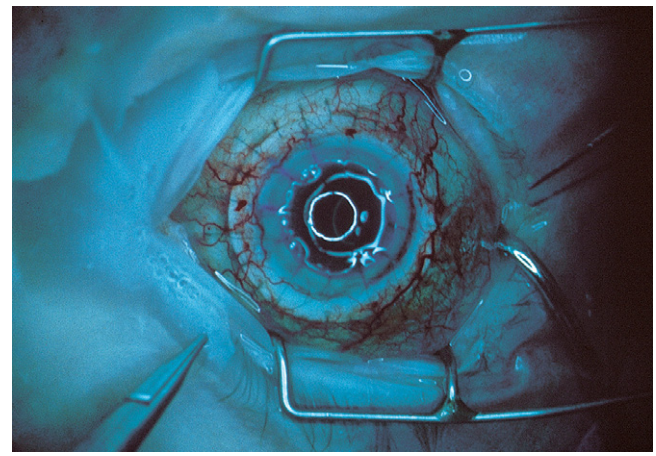

Figure 43.15. Round keratometry reflection on patient's cornea at the end of surgery.

jewelers' forceps. Unfortunately, one study showed that the short-term complications with polyester sutures were higher than with nylon.[38]

ADJUSTMENT OF SUTURE TENSION

Intraoperative adjustment of suture tension to minimize postkeratoplasty astigmatism is useful. Suture tension is adjusted twice during the operation: once after the interrupted sutures are in and again after the running suture is tied. A simple instrument such as the Hyde astigmatic ruler can be used to project a circular keratoscopic image onto the cornea.[39] The coaxial light of the operating microscope is directed toward the vertically aligned eye. A circular image is created as the coaxial light reflects off the inner circular ring of the astigmatic ruler, projecting such a ring onto the corneal surface, which can be monitored by the surgeon viewing through the oculars of the microscope system (Fig. 43.14). The round end of a sterile safety pin can be used in a similar fashion. More advanced instrumentation is also available. A Nidek qualitative and quantitative intraoperative surgical keratometer projects a continuous circle of light onto the corneal surface and can be brought in and out of the operative field mechanically using foot pedal control (Fig. 43.15). Examples of other surgical keratometers available include the Serdervaric Circle of Light, Terry keratometer, and Polack keratometer (Jed-Med). The interrupted or continuous suture can be relaxed in the steep meridian and tightened in the flat meridian. The oval mire can be converted to a circular configuration, which is the desired end point. Although this solution does not solve the long-term problems, it helps to minimize postkeratoplasty astigmatism until selective suture removal can be performed[40] and may obviate the need for such suture removal. This approach allows earlier visual rehabilitation for the patient with less cylindric correction in the short term and hopefully in the long term.

CONCLUSION OF PROCEDURE

Once the suture has been adjusted to minimize astigmatism, remaining viscoelastic has been irrigated from the eye, and eye inflated to

the appropriate pressure with balanced salt solution, the procedure is essentially complete. The Flieringa ring is removed, and subconjunctival injections of 0.3 mL betamethasone and 0.3 mL cefazolin (50 mg/mL) are given in the inferior temporal quadrant. To anticipate and prevent postoperative wound healing and re-epithelialization problems, preoperative basal tear secretion tests are performed on every patient and we have a low threshold for performing inferior punctal occlusion prior to or at the end of the procedure. In addition, the donor epithelium is inspected pre- and intraoperatively, and temporary tarsorrhaphies are done if the patient is at high risk of healing problems. This proactive approach has saved countless grafts from problems and is a quick adjunct to the surgical procedure. A patch and Fox shield is applied to the eye after instillation of an antibiotic–corticosteroid ointment. The procedure is typically performed on an outpatient basis, and the patient is then prepared for discharge. Rarely is a 1-day hospital stay necessary.

CLINICAL RESULTS

Many surgeons have reported clinical results of triple procedures with generally favorable outcomes.[1,2,4–8,11,12,14–18] Summaries of results compiled from the literature are outlined in Tables 43.3–43.5. Transplant studies have not usually evaluated uncorrected visual acuities but, as techniques improve, patients may be able to achieve excellent unaided vision. Triple procedures were reviewed by one author using his standard method (standardized suturing and suture removal techniques with the 12 interrupted and 12-bite running 11-0 polyester suture technique and intra- and postoperative suture adjustment, trephination diameters, the Hanna trephine and artificial AC, and an assumed keratometry value of 44.50 D). Data were gathered over a 1-year period on 49 consecutive patients with normal macular examinations who met the indications for triple procedure. Refractive data reflect selected sutures remaining given the assumed permanency of Dacron polyester suture. The results are detailed in Table 43.6. Both refractive and keratometric astigmatism values were excellent with refractive cylinder consistently under 2.25 D from 3 months onward and keratometric cylinder under 3.5 D after 3 months. Mean keratometric power was relatively consistent and shows gradual steepening from 43.06 D at 3 months to 44.21 D at 12 months, reflecting wound healing and suture removal events. This 12-month value is the basis for the 44.5 D keratometry value that we use in triple procedure IOL calculations. Finally, the mean spherical equivalent data show excellent targeting of IOL calculations in triple procedures using the standard technique, with an initial hyperopic overshoot of +1.56 D at 3 months but gradual steepening to +0.13 D at 12 months. Excellent refractive results were obtained in this series with the triple procedure, and visual rehabilitation may be very rapid with good refractive stabilization

by 12 months. Complication rates are quite acceptably low, as outlined in Table 43.7.

DESCEMET'S STRIPPING AUTOMATED ENDOTHELIAL KERATOPLASTY WITH CATARACT, THE NEW TRIPLE PROCEDURE

In an eye that is a good candidate for one of the many forms of posterior lamellar keratoplasty and also has a visually significant cataract, the surgeon should consider the alternative triple procedure of phacoemulsification followed by Descemet's stripping automated endothelial keratoplasty (DSAEK). In most cases of DSAEK the view into the AC is adequate to allow phacoemulsification. The cataract wound (scleral tunnel or limbal incision) can be made in a fashion to allow for DSAEK through the same wound. We try to have the internal aspect of our incision remain peripheral to the area of Descemet's stripping, but others prefer for the donor cornea to overlay the internal aspect of the incision. For the cataract

portion of the procedure, a cohesive viscoelastic should be chosen, which can be completely removed from the eye such as Provisc or Healon. Capsular staining can aid greatly in the completion of the capsulorrhexis in this procedure. Phacoemulsification may then be carried out by the surgeon's usual technique, and an IOL can then be inserted into the capsular bag. The viscoelastic can then be completely removed from the eye prior to the stripping of Descemet's membrane. This minimizes the amount of viscoelastic left in the eye that can potentially interfere with donor adherence. Some surgeons prefer to leave the viscoelastic in the eye until after the stripping of Descemet's membrane. The donor button can then be inserted into the eye through the phacoemulsification incision, which may not even need to be enlarged.

CONCLUSIONS

Posterior capsular opacification occurs with about the same frequency in simple extracapsular cataract extraction and is treated by yttrium–aluminum–garnet laser capsulectomy (Fig. 43.16) with minimal threat to the graft. Certainly, variations on technique can give equally good results. Different suturing techniques with continuous or interrupted sutures alone (Fig. 43.17) or in combination using either 10-0 and 11-0 nylon or 11-0 polyester (Fig. 43.18) work very nicely. However, the combination of 12 interrupted sutures with a continuous 12-bite suture is our preferred method. The long-term results in the expanded series of triple procedures include 80% at 20/40 or better. The graft survival

rate is comparable to the results with keratoplasty in the absence of a lens implant (Fig. 43.19). The triple procedure continues to be the treatment of choice for most patients with combined corneal and cataract disease requiring surgery to restore functional vision.

44 Pseudophakic and aphakic penetrating keratoplasty

Richard L. Abbott, Maria D. Bernal

Pseudophakic corneal edema continues to remain the leading indication for penetrating keratoplasty (PKP) in the USA.[1–3] There are several reasons why this is the case: (1) there is an overall increase in cataract surgery and increasing patient age;[4–7] (2) despite newer cataract surgery techniques, intraocular lens (IOL) implants and viscoelastic materials, cataract surgery continues to cause significant endothelial cell loss[8] documented even 10 years after surgery;[9] (3) there are more donor tissues available[10] and surgeons trained to perform keratoplasty surgery; (4) the techniques and instrumentation for pseudophakic and aphakic penetrating keratoplasty have significantly improved, resulting in a more favorable prognosis for a clear graft and possibly improved vision.[6,11–14]

Aphakic corneal edema, on the other hand, is decreasing as an indication for PKP[1–3] due mainly to technological advances and widespread use of intraocular lenses.

In the last few years, transplantation of the posterior layers of the cornea for pseudophakic and aphakic corneal edema has been described[15–17] and is now being implemented in tertiary-care cornea practices with excellent results being reported.[18]

This chapter reviews the current surgical techniques and instruments used for pseudophakic and aphakic penetrating keratoplasty.

SURGICAL CONSIDERATIONS FOR PSEUDOPHAKIC AND APHAKIC KERATOPLASTY

Before keratoplasty is performed on a patient with pseudophakic or aphakic corneal edema, careful preoperative planning and attention must be given to the following potential problems:

1. Presence of irregular thinning or thickening and neovascularization of the host cornea
2. Presence of loose vitreous in the anterior chamber
3. Presence of anterior and posterior synechiae
4. Status of pupil and size and location of peripheral iridectomy
5. Increased incidence of elevated intraocular pressure (IOP)
6. Increased incidence of cystoid macular edema
7. Status of opposite eye (phakic, aphakic, or pseudophakic)

The surgical technique of pseudophakic or aphakic keratoplasty may vary depending on many of these findings. It is the obligation of the corneal surgeon to recognize these potential problems preoperatively so that the surgical approach can be appropriately tailored for best results. In addition, thorough familiarization with anterior vitrectomy techniques and instrumentation should be accomplished before this type of surgery is performed.

TECHNIQUES IN PSEUDOPHAKIC AND APHAKIC KERATOPLASTY

Surgery may be done under general endotracheal anesthesia or with retrobulbar or peribulbar and seventh-nerve regional anesthesia combined with intravenous analgesic and hypnotic medication administered by a standby anesthesiologist. If general anesthesia is used, a nonpolarizing muscle relaxant (e.g. pancuronium bromide) may be used to prevent any 'bucking' or possible movement of the patient during surgery. Before draping, attention should be given to the positioning of the patient on the operating table. Tilting the table in a slight reverse Trendelenburg position and avoiding significant hyperextension of the neck help to decrease positive vitreous pressure in the eye. Turning the patient's head slightly to the side opposite the eye to be operated on increases exposure and helps decrease any interference from the patient's nose during surgery (Fig. 44.1). Applying compression to the globe before surgery with either a mechanical device or a digital massage can lower the IOP, but excessive softening will hamper trephine cutting. In some cases, intravenous mannitol may be started 1 h before surgery to minimize vitreous bulging once the cornea has been trephined. The operating microscope is then positioned over the patient and adjusted to the surgeon's need for height and surgical field. A microsurgical vitrectomy instrument is brought into the operating room and prepared for possible use during the surgery. After routine preparation of the surgical field with 5% povidone-iodine and two drops of 5% povidone-iodine placed in the inferior fornix, sterile draping of the patient is performed and the operation is ready to begin.

A wire or solid blade lid speculum is inserted between the lids and carefully checked to ensure that there is no pressure on the globe. Either a single or a double Flieringa ring may be fixed to the

globe with sutures of 6-0 polyglactin 910 on a spatula type of needle. The 12 and 6 o'clock sutures are left long for stabilization of the globe by the assistant during the trephination. Extreme care must be taken in the placement of the scleral support ring because unequal placement of the fixation sutures can cause irregularity in the graft recipient bed and considerable graft astigmatism. Because of this problem, many corneal surgeons have discontinued using the Flieringa ring and simply place a bridle suture beneath the superior and inferior rectus muscles using 5-0 silk suture. These two sutures provide a means for stabilization of the globe during trephination (Fig. 44.2). If proper care has been taken in the preoperative positioning of the patient and placement of the lid speculum, there seems to be less need for the scleral support ring.

At this time, the eye is carefully inspected through the operating microscope. Attention is specifically directed to the status of the cornea and presence of neovascularization or anterior synechiae. The anterior chamber and iris are examined to confirm preoperative findings of vitreous involvement, secondary membranes, posterior synechiae, and the status of the pupil. Using a handheld trephine of suitable diameter (either disposable or reusable), a mark is made on the surface of the cornea to serve as a guide to help choose the appropriate graft size. This mark is best seen if the cornea is blotted dry. If the epithelium is edematous and loose, it should be removed to the periphery with a cellulose sponge or blade at this time. The graft size should be large enough to replace a significant portion of the edematous cornea, but not so large that peripheral anterior synechiae and secondary glaucoma become an increased postoperative risk. In addition, attention must be paid to other important findings (position of the pupil, presence of peripheral iridectomy, and location of deep corneal neovascularization) in the determination of the final size and position of the new corneal graft. Commonly used trephine diameters in pseudophakic and aphakic cases range from 7.5 to 8.5 mm.

At this point, a corneal protector is placed over the patient's eye, the microscope light is turned off, and attention is directed away from the recipient eye to a separate table where the donor cornea is prepared (Fig. 44.3). The donor cornea with scleral rim is trans-

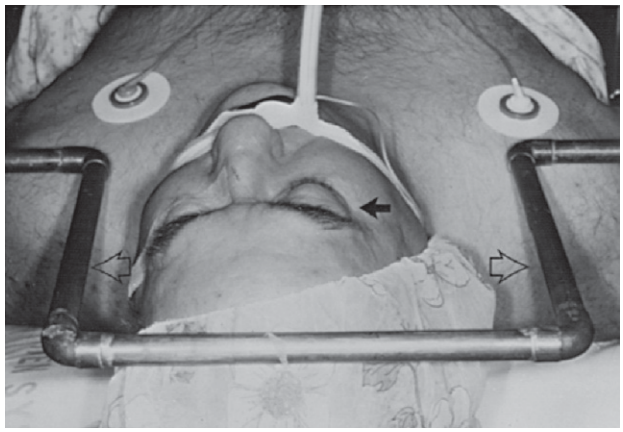

Figure 44.1. Slight rotation of patient's head to side opposite the eye to be operated (dark arrow) improves exposure. Light arrows are the surgeon's wrist rest.

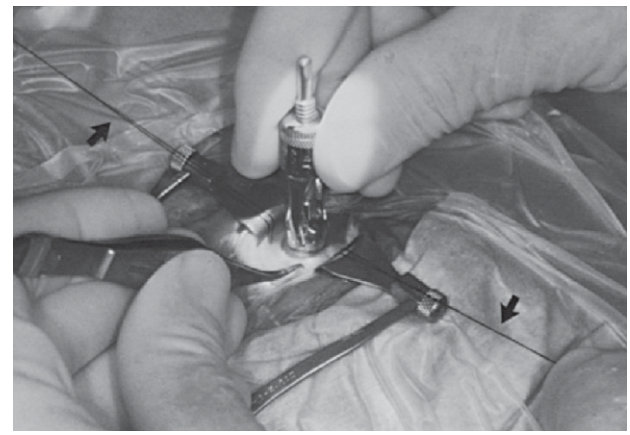

Figure 44.2. Bridle sutures (arrows) placed beneath superior and inferior rectus muscles help provide stabilization during trephination.

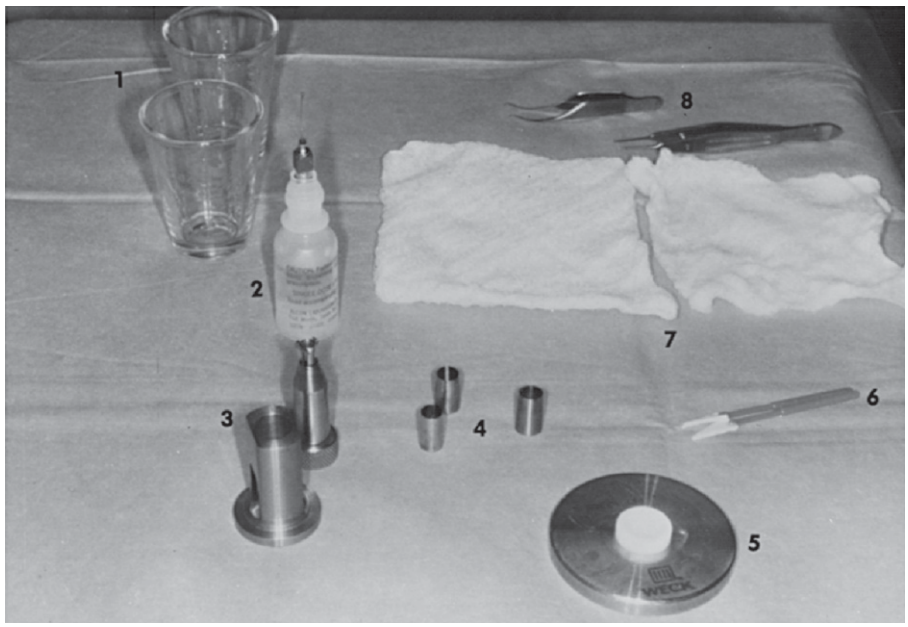

Figure 44.3. Donor preparation table includes the following: 1, two medicine glasses; 2, balanced salt solution; 3, corneal punch; 4, disposable trephine blades (different sizes); 5, polytef block and punch base; 6, cellulose sponges; 7, moistened gauze pads; and 8, 0.12- and 0.3-mm forceps.

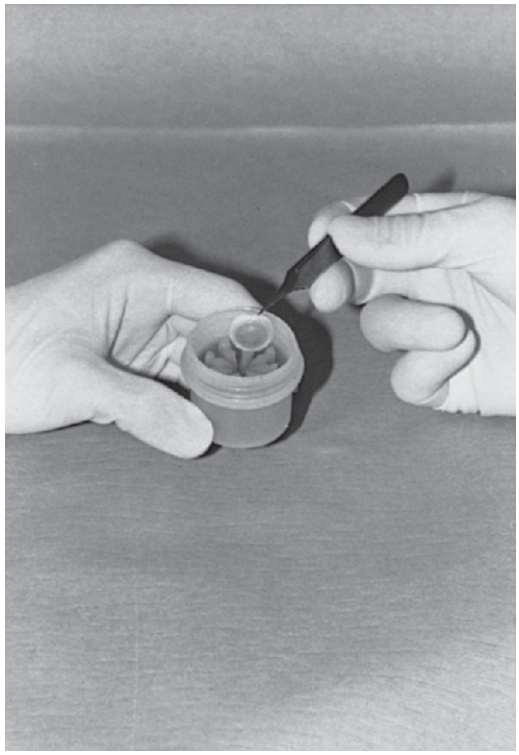

Figure 44.4. Donor corneal tissue is removed from its storage vial for transfer to the cutting block.

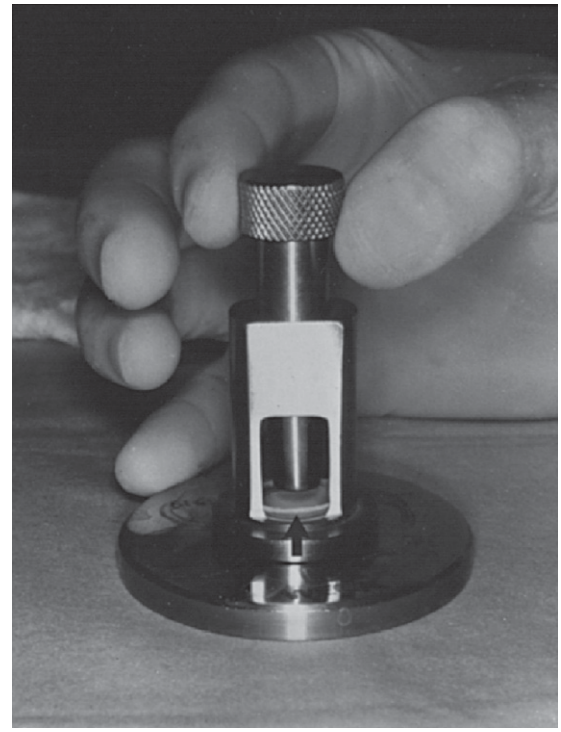

Figure 44.5. Donor corneal tissue (arrow) is centered on the polytef block before the button is cut.

ferred from a small vial containing Optisol GS (Bausch & Lomb, Irvine, CA) (Fig. 44.4) and placed on a polytef cutting block with the epithelial surface facing down. Extreme care is taken to minimize trauma to the endothelial cells. The donor cornea is carefully centered on the polytef block beneath the punch trephine to avoid cutting an oval button or creating a shelved edge (Fig. 44.5). A disposable trephine blade is used, usually 0.2–0.5 mm larger than the recipient graft bed. A slightly larger donor button is punched to avoid the disparity that is created by trephination of the recipient from the epithelial surface and donor from the endothelial surface with the same-size blade.[19,20] Firm, steady pressure is applied to the punch trephine to allow it to pass through the donor tissue into the polytef block (Fig. 44.6). When the trephine has passed through the donor corneal tissue and engages the cutting block, there is a sudden change in resistance and a distinct 'crunching' sound is heard. If a clean through-and-through cut has been made, the donor button should remain on the polytef block when the punch trephine is removed (Fig. 44.7). A drop of balanced salt solution, donor storage medium, or viscoelastic material is carefully placed on the endothelial surface to prevent drying. The donor button is placed into a moist chamber for temporary storage by covering the polytef block with a moistened medicine glass or transferring the donor tissue into a moistened petri dish (Fig. 44.8). The tissue is then brought back to the recipient table for later use.

Attention is now directed back to the patient in whom the corneal protector is removed from over the eye and the recipient cornea is once again carefully inspected. A handheld or a vacuum trephine can be used to trephine the recipient cornea. Although some studies have shown a slight increase in endothelial cell loss adjacent to the cut and slight beveling of the cut with vacuum trephines, many surgeons preferred them because they are easier to use and long-term results appear not to be different than with handheld trephines.[21,22] We prefer handheld trephines, and this is the technique

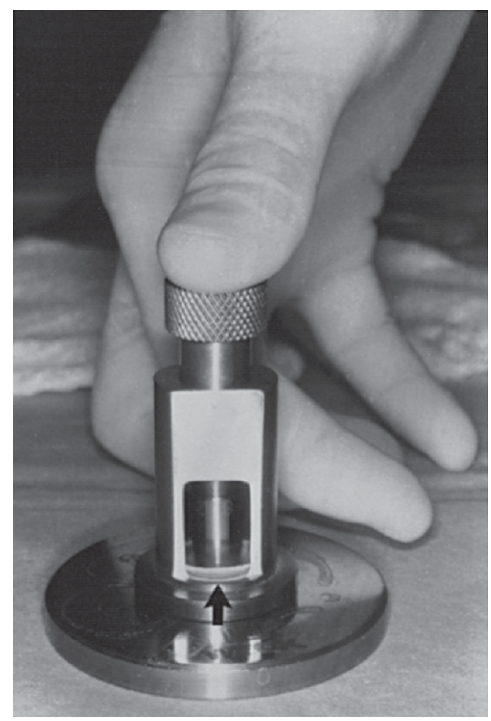

Figure 44.6. Firm pressure is applied downward on the punch trephine to allow it to pass through corneal tissue (arrow) and engage the polytef block.

described. If a guarded trephine is used, it should be set for cutting at 80% depth. The assistant holds the superior and inferior rectus sutures, and the surgeon grasps the horizontal limbal tissue at the 9 or 3 o'clock position with 0.12 or 0.13 mm tooth forceps to stabilize the globe (see Fig. 44.2). If a scleral fixation ring has been applied, it is grasped with large-toothed forceps during trephination.

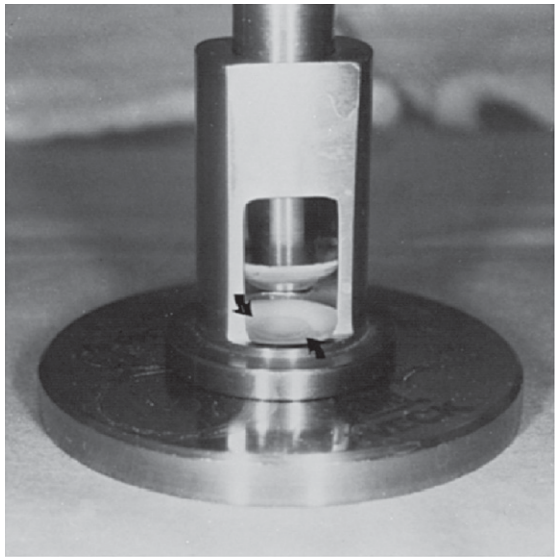

Figure 44.7. If a clean cut has been made, the donor button should remain on the polytef block (arrows) when punch trephine is withdrawn.

Figure 44.8. A medicine glass is moistened with balanced salt solution and placed over the corneal button and polytef block for temporary storage of donor tissue.

The trephine blade is then set within the previous mark on the corneal surface. After ensuring that there is not any undue pressure on the globe and the trephine is perpendicular to the corneal surface, the cutting of the corneal tissue is carefully begun. The surgeon gently rotates the trephine in a circular motion, attempting to apply equal pressure on all edges of the cutting surface so that uniform depth is obtained. While some surgeons will enter the anterior chamber with the trephine, our technique involves carefully avoiding uncontrolled entry into the anterior chamber at this time.

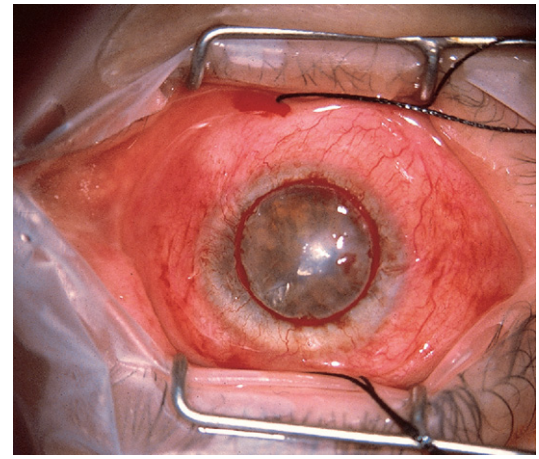

Figure 44.9. Initial partial-thickness trephination in vascularized corneas avoids hemorrhage into anterior chamber. Bleeding stops spontaneously within a few minutes.

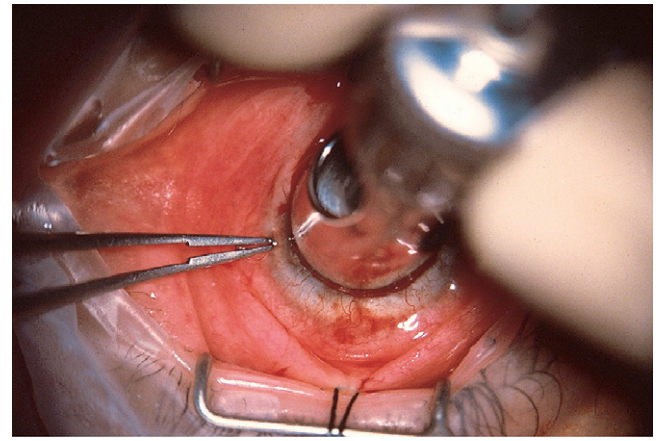

Figure 44.10. Handheld trephine may be placed within the previous cut to deepen the incision. Three-point fixation is used to stabilize the globe.

The trephine is removed, and the depth of the incision is checked with the microcyclodialysis spatula. In vascularized corneas, partial-thickness trephination allows bleeding and rapid spasm of the superficial and midstromal blood vessels, avoiding hemorrhage into the anterior chamber (Fig. 44.9). If the incision depth is found to be unequal, the trephine may be placed within the previous cut by 'skating' the trephine on the corneal surface and feeling the blade enter into the deeper portions of the incision (Fig. 44.10). Extreme care must be taken to avoid creating a 'double cut' in the corneal tissue. This step can be repeated as often as necessary until a deep cut is obtained in all areas. Beveling of the incision through the stroma should be avoided to allow precise fitting of the donor button within the recipient bed.

After trephination of a symmetrically deep wound, the anterior chamber is slowly entered with a microsharp blade within the incision close to the point of fixation. A 3–4 mm incision is made to allow easy entrance of the angulated curved microcorneal scissors. The blades of the scissors are kept perpendicular to the plane of the iris, leaving a narrow rim of endothelium and Descemet's membrane on the posterior margin of the recipient bed (Fig. 44.11). As the cutting of the cornea is completed, attention should be directed to

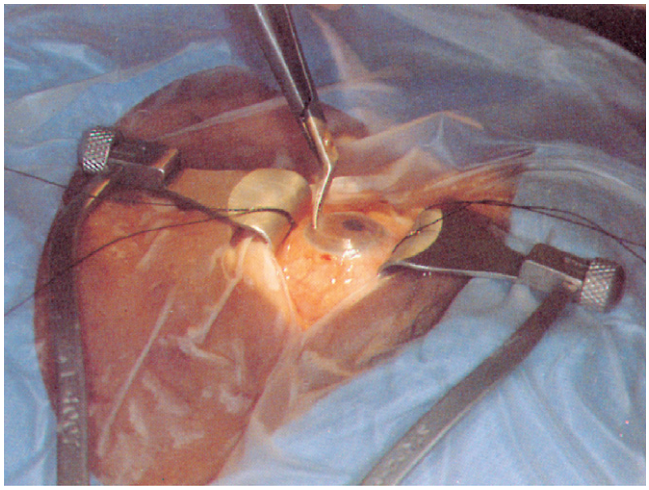

Figure 44.11. Blades of angulated curved microcorneal scissors are kept perpendicular to the plane of the iris to avoid creating a large posterior bevel in the wound.

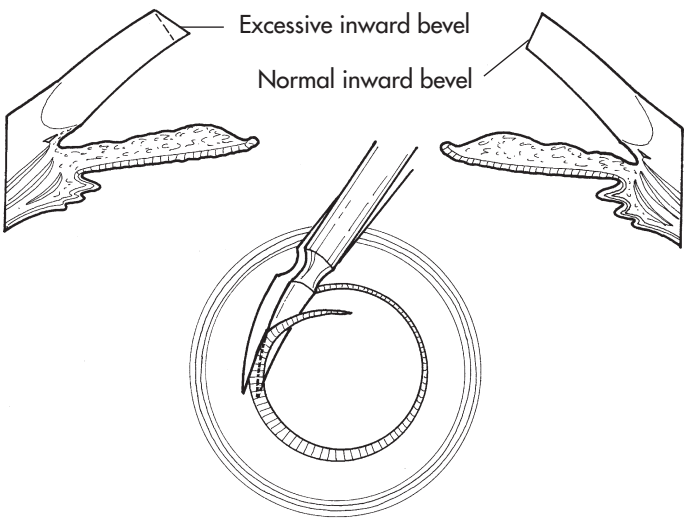

Figure 44.12. Excessive inward beveling from initial scissors cut is trimmed with a Vannas or Castroviejo scissors to achieve more gradual inward bevel.

its endothelial surface where vitreous attachments or iris adhesions may have to be cut before removal of the corneal tissue. In addition, any adventitious tissue should be removed from the wound with the Vannas scissors (Fig. 44.12). If the hyaloid face is intact and away from the cornea, the pupil may be constricted with acetylcholine chloride 1 : 100 (Miochol-E) to help maintain this state. Once the recipient cornea has been removed from the eye, several different approaches may be taken depending on the preoperative and intraoperative findings. These approaches may be divided into four separate groups and are discussed separately:

1. Pseudophakia with ruptured or absent posterior capsule
2. Pseudophakia with intact posterior capsule
3. Aphakia with loose vitreous in the anterior chamber
4. Aphakia with hyaloid face intact

PSEUDOPHAKIA WITH RUPTURED OR ABSENT POSTERIOR CAPSULE

The presence of an intraocular lens in a patient with corneal edema requires careful clinical examination and planning of the surgery before transport to the operating room. In most cases, plans should be made for removal of the pseudophakos combined with a partial anterior vitrectomy at the time of keratoplasty. The style of the implant and its position in the eye will help determine the surgical approach.

There are several important factors that must be considered when performing surgery on these patients. The following are the indications for removing the intraocular lens at the time of keratoplasty:

1. Patient history of pain and signs of recurrent hyphema, uncontrolled glaucoma, or persistent uveitis
2. Endothelial touch
3. Dislocated or subluxated haptics and unstable intraocular lens
4. Presence of chronic cystoid macular edema
5. Metal haptic materials
6. Iris sphincter erosion

Depending on the lens style and length of time that it has been in place, frequently there are strong adhesions to the angle, iris, vitreous, capsular bag, or ciliary sulcus. Removal of AC IOLs and iris-supported PC IOLs can be extremely difficult and traumatic to the eye and requires familiarity with the many styles of lenses (such as the Leiske, Azar 91Z, Stableflex, Sputnik, Copeland, etc.) that have been available for insertion over the years.[23,24] Various forms of iris clips and loops must be opened or cut before lysis of iris and vitreous adhesions that surround the implant. The use of blunt and sharp dissection in the removal of these lenses is required, and care must be taken to preserve as much iris tissue as possible. In some cases, supporting haptics must be cut from the lens optic and then carefully rotated free from dense fibrous tissue in the angle or ciliary sulcus. After removal of the implant, the anterior vitrectomy is performed (see description below in the section 'Aphakia with loose vitreous in anterior chamber'). Consideration for implantation of a different style of pseudophakos can be given.

The more recent use of posterior chamber lenses has decreased the incidence of uveitis, secondary glaucoma, and cornea-related problems, and frequently PC IOLs located in the capsular bag or ciliary sulcus cause no problems and can be left in place. Considerations for leaving the intraocular lens in place are summarized as follows:

1. Lens is in excellent position and appears stable
2. Eye is quiet
3. Pupil is mobile

PSEUDOPHAKIA WITH INTACT POSTERIOR CAPSULE

When the posterior capsule is intact or the hyaloid face is unbroken, the style of the implant and its effect on the eye primarily determine the surgical approach. The posterior capsule should be left intact, and preoperative yttrium–aluminum–garnet capsulotomy avoided if keratoplasty surgery is planned. In general, iris plane lenses should be removed; however, anterior chamber lenses that appear stable frequently can be left in place. Nonetheless, in cases where the posterior capsule is intact, many, if not all, of these eyes have a PC IOL implanted in the eye. Newer PC IOLs implanted into the capsular bag rarely cause any problems. Potential problems include decentration, inaccurate lens power, or glare problems. In these cases, repositioning or exchange of the IOL could be considered. An attempt to open the fibrosed capsular bag can be performed with

viscodissection[25] and a gentle surgical technique. Similarly, when the PC IOL is located in the ciliary sulcus, unless the implant is thought to be causing inflammation by rubbing on the iris or is associated with any of the problems listed above, it can be left in place.

If the pseudophakos can be retained, the operation is less complicated. Application of miotic drops such as pilocarpine prior to surgery or injection of acetylcholine chloride 1 : 100 (Miochol-E) into the anterior chamber during surgery will help maintain a PC IOL in place.

APHAKIA WITH HYALOID FACE INTACT

A decision to insert an intraocular lens into this eye is based on the following factors:

1. Phakic or intraocular lens in other eye
2. Aphakic and contact lens in other eye
3. Physical needs and activities of patient
4. Inability to wear a contact lens
5. Overall health of the involved eye to tolerate a secondary implant
6. Relative risk of insertion and possible vitreous involvement
7. Status of the capsular bag and or sulcus of the eye

If an intraocular lens is to be inserted into the eye, and there is adequate sulcus support or an intact capsular bag, a PC IOL should be implanted in the bag or the sulcus. If an intraocular lens is to be inserted into the eye, but there is no capsular or sulcus support, the options are to suture a PC IOL to the iris or sclera or insert a flexible open-loop AC IOL. We believe that if there are no contraindications for placement of an AC IOL (such as angle abnormalities), implantation of a flexible open-loop AC IOL is considerably less difficult and equal, if not better, results can be obtained compared to suturing a PC IOL to the iris or sclera.[11,12] To implant a flexible open-loop AC IOL, the pupil may be constricted with acetylcholine chloride and a small amount of viscoelastic material placed over the pupil and on the surface of the iris to help act as a 'cushion' for the underlying vitreous. Using a flexible open-loop anterior chamber-style lens with three-point or quadriflex fixation, insertion through a 7.5 mm or larger recipient bed opening can be accomplished without difficulty. Once the lens is in an adequate position, additional viscoelastic material and balanced salt solution are used to fill the remainder of the anterior chamber. The donor button is then transferred to the recipient bed and sutured in place.

APHAKIA WITH LOOSE VITREOUS IN ANTERIOR CHAMBER

During the preoperative evaluation of the patient, attempts should be made to determine the presence of loose vitreous in the anterior chamber. If vitreous is present or highly suspected, plans should be made before beginning the surgical procedure to prepare and have ready the use of a guillotine type of vitreous cutting and aspirating instrument. Use of a mechanical vitreous cutting instrument in these cases reduces vitreous traction and iris inflammation associated with the technique of removal by cellulose sponge absorption. Some surgeons have also advocated the evacuation of fluid vitreous through the pars plana[26] or the use of bimanual vitrectomy[27] before entry into the anterior chamber.

If formed vitreous is encountered in the anterior chamber at the time of removal of the corneal button, care must be taken to cut any adhesions from the posterior surface of the cornea. Once the cornea has been removed, an open-sky vitrectomy is performed with the mechanical vitreous instrument held within the center of the pupil or in the peripheral iridectomy using low suction (4–6 mmHg) and a rapid cutting rate (300–400 cuts/min) (Fig. 44.13). Balanced salt solution may be gently dripped into the anterior chamber as needed during vitrectomy. Recently, triamcinolone acetonide suspension (Kenalog 40 mg/mL) filtered and diluted 1 : 10 has been applied before performing the vitrectomy to better visualize the vitreous by staining it.[28] The vitrectomy is considered adequate when the iris has dropped posteriorly well back from the recipient bed and there is no formed vitreous left in the anterior chamber. A cellulose sponge is used to carefully touch the surface of the iris. Attempts should be made to free the pupil from vitreous adhesions and secondary membranes and to remove any strands of vitreous adherent to the peripheral cornea. After this step has been completed, the anterior chamber is filled with balanced salt solution before placement of the donor tissue within the recipient bed. If indicated, consideration for a secondary lens implant may be given before placement of the donor graft tissue.

A vitrectomy should not be performed if the vitreous face is unbroken and does not protrude anteriorly because there is an increased risk of cystoid macular edema and retinal detachment occurring after this procedure.

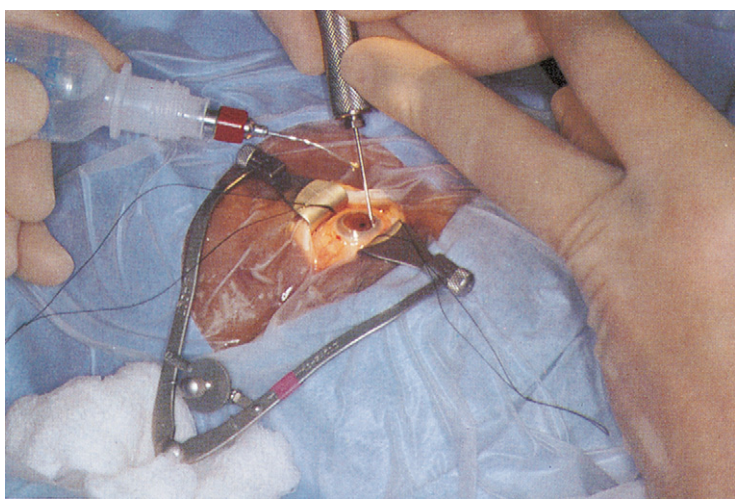

Figure 44.13. 'Open-sky' vitrectomy is performed with a mechanical vitreous cutting and aspirating instrument held within the pupil or in the peripheral iridectomy. Balanced salt solution may be dripped into the anterior chamber during vitrectomy.

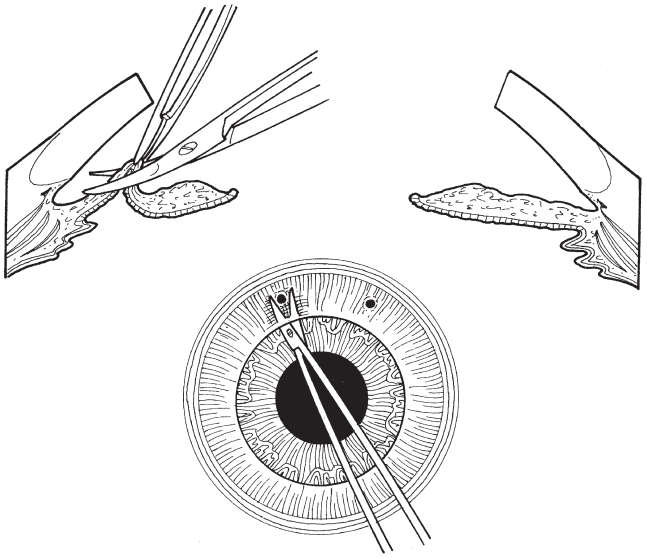

Figure 44.14. Creation of peripheral iridotomies with an open-sky approach using scissors to prevent focal pupil block and peripheral anterior synechiae.

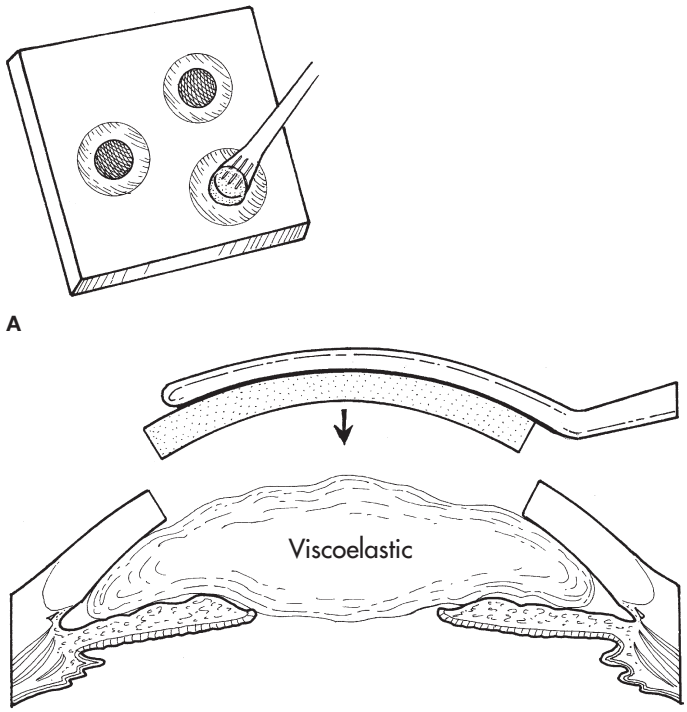

Figure 44.15. A Paton spatula is used to transfer the donor button from the polytef block to the recipient defect.

IRIDOTOMY

Aphakic and pseudophakic eyes with anterior chamber lenses should have one or two peripheral iridotomies performed to avoid later development of either focal or diffuse peripheral synechiae and a pupil block-like syndrome.

Technically, the iridotomies are more easily made in the mid-iris periphery between 4 and 8 o'clock positions using a Vannas, Fine stitch, or Castroviejo scissors and 0.10 or 0.12 mm forceps to partially 'tent up' the iris (Fig. 44.14). The iridotomies should be checked for patency to assure complete removal of posterior pigment. The use of viscoelastic to deepen the iridoendothelial distance will facilitate the iridotomy and contain hemorrhage.

SUTURING OF DONOR BUTTON

The donor graft, which has been temporarily stored in a moist chamber on the Mayo stand, is now transferred by the surgeon to the recipient bed. This transferal is accomplished either by grasping of the anterior edge of the button with a fine 0.12 mm forceps (Fig. 44.15) or by use of a corneal spatula to invert the graft onto the recipient bed. Depending on the condition of the anterior chamber, a large air bubble, balanced salt solution, or a viscoelastic substance will be present beneath the graft. If a pseudophakos is present, it is imperative that the endothelium not come into contact with it during the suturing of the graft. Care must be taken in the placement of the first corneal suture at the 12 o'clock position because the graft is freely mobile and can easily be displaced so that possible damage to the endothelium is caused. It is recommended therefore that this first suture be placed primarily to anchor the graft in position and can easily be removed and replaced with a deeper suture if necessary. All sutures should be placed deeply within donor and host tissue without too long a bite being taken.

The most important suture to be placed by the surgeon is the second cardinal suture at the 6 o'clock position. It is this suture that most affects the final position of the donor graft within the recipient bed, and careful attention should be paid to the alignment of this suture. It is recommended that the surgeon leave the needle in place after it has been passed through both the donor and the host tissue to check the graft edges at 3 and 9 o'clock positions for over-ride or gaping of the wound (Fig. 44.16). If this complication is detected, the needle can easily be backed out of the wound and repositioned; thus, the surgeon can correct the possible wound disparity (Fig. 44.17). The 3 and 9 o'clock sutures are then placed equidistant between the 12 and 6 o'clock sutures. The graft surface is dried to better observe the diamond crease that forms between the four cardinal sutures. If the sutures have been placed equidistant from each other, each side of the diamond will be equal and additional sutures may now be placed. Cardinal sutures may have to be repositioned, however, if the sides of the 'diamond' are not aligned, causing malposition of the donor graft

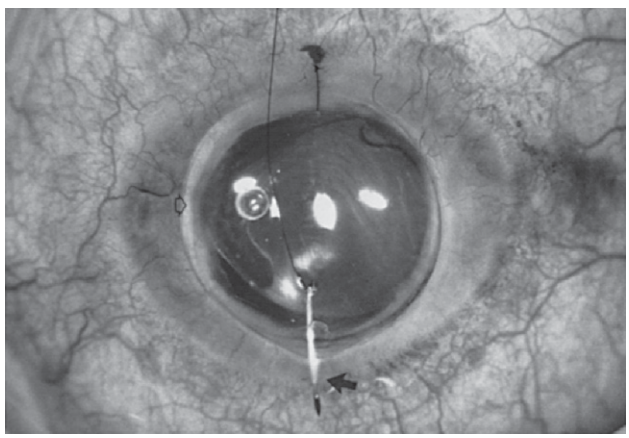

Figure 44.16. After 6 o'clock suture (solid arrow) is placed, graft edges are checked at the 3 and 9 o'clock positions for over-ride or gaping of wound. In this case, there is over-riding of graft at 9 o'clock (open arrow).

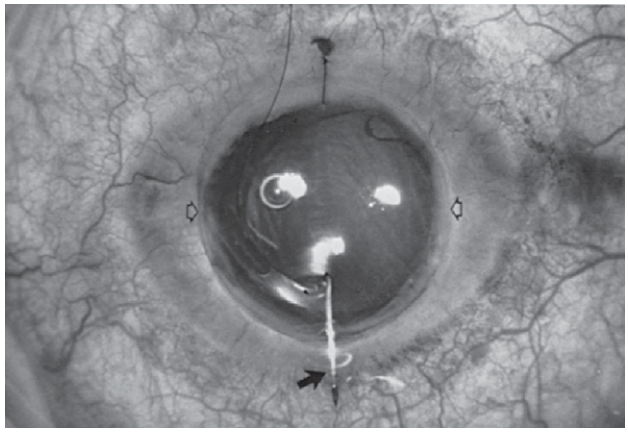

Figure 44.17. The 6 o'clock suture is removed and placed slightly to the right (solid arrow). New position of graft at the 3 and 9 o'clock positions (open arrow) is now better aligned.

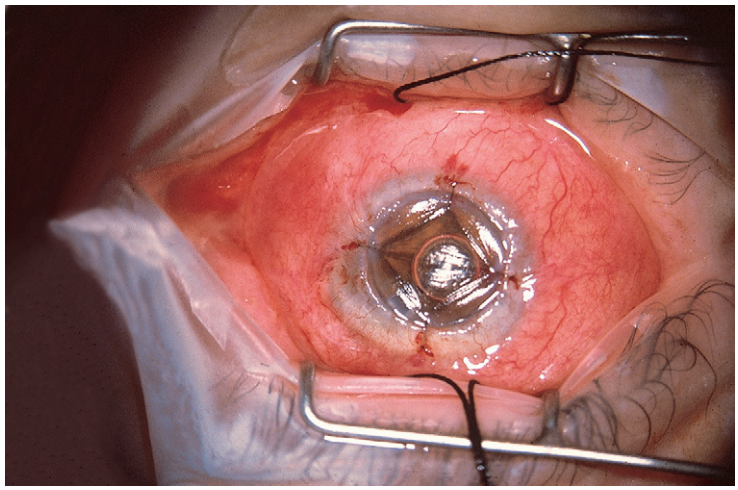

Figure 44.18. Once the four cardinal sutures have been placed, a diamond crease will be apparent on the graft surface. Wound alignment should be checked at this point before additional placement of sutures.

(Fig. 44.18). Once satisfactory placement of the initial four cardinal sutures has been completed, the anterior chamber should be redeepened with either balanced salt solution or viscoelastic material using a 2 mL syringe attached to a 30 gauge angulated cannula. Closure of the wound is now complete with either additional interrupted sutures of 10-0 nylon or a continuous suture of the same or finer nylon suture.

On completion of suturing, the anterior chamber is carefully examined to make sure that there are no synechiae present, the pseudophakos is in good position (if present), and large amounts of air or viscoelastic substance have been removed. The integrity of the wound is checked with topical fluorescein dye or by application of gentle pressure with a dry cellulose sponge between each suture on the host cornea. If any fluid escapes, a suture is either added or replaced to achieve satisfactory wound closure. The eye is left normotensive at the completion of the case. The bridle sutures are removed, and subconjunctival injections of antibiotic are given inferiorly. Subconjunctival injection of a corticosteroid is optional but encouraged when there has been a vitrectomy or significant manipulation of the iris at the time of surgery. Several drops of a topical steroid and a broad-spectrum antibiotic are given. Finally, the lids are closed and a monocular bandage and eye shield are applied.

45 Anterior chamber-type intraocular lens replacement during penetrating keratoplasty for pseudophakic bullous keratopathy

Terrence J. Doherty, Jonathan H. Lass

The choice of an intraocular lens (IOL) for IOL exchange in pseudophakic penetrating keratoplasty or secondary IOL implantation in aphakic penetrating keratoplasty remains debatable. The poor graft and poor endothelial survival observed with closed-loop anterior chamber (AC) IOLs in the early 1980s[1,2] led to a strong interest in the use of sutured posterior chamber (PC) IOLs, either iris- or scleral-fixated in these settings.[2–14] This interest was based on the assumed advantages of an IOL situated in a more physiologic position, posterior to the pupil and closer to the nodal point of the eye; improved visual results because of less cystoid macular edema from a possible barrier effect on the vitreous; less secondary glaucoma because of less trabecular meshwork damage; and, most importantly, reduced endothelial cell loss because of the posterior pupillary IOL location. There are disadvantages, however: the operating time is longer, vitrectomy is needed in all cases, iris or ciliary body suturing is required, and there may be increased potential for endophthalmitis, retinal detachment, and vitreous hemorrhage.

Experimental[15] and clinical evidence[1,2,5,7,8,16–22] indicate that a one-piece open-loop polymethylmethacrylate (PMMA) AC IOL, based on the Kelman design in the early 1990s, performs more favorably than the closed-loop IOL for AC insertion and is associated with improved long-term graft survival. The major advantages of this type of AC IOL technique over the sutured PC IOL technique are ease and speed of IOL insertion and fixation, lack of suturing for IOL fixation, and avoidance of vitrectomy in many cases. Although there is still some recent evidence[13] that insertion of an AC IOL is associated with higher incidence of secondary glaucoma, cystoid macular edema, and endothelial cell loss, these potential greater risks have not been supported in multiple studies comparing these techniques.[6,8,9,11,16]

TECHNIQUE

PSEUDOPHAKIC

The technique for pseudophakic penetrating keratoplasty with IOL exchange for a Kelman-style, open-loop PMMA AC IOL has been well described.[2,5,7,8,16–23] This chapter does not discuss IOL exchange during Descemet's stripping automated endothelial keratoplasty (DSAEK)[24,25] whose closed-chamber technique requires a limbal approach for the lens exchange. Preoperatively, a Honan pressure balloon is applied. The pupil is constricted with 1% pilocarpine hydrochloride applied three times, 5 min apart, 1 h before surgery. Surgery is performed under local anesthesia. The use of a single Flieringa ring is optional. If chosen for better anterior segment support, the ring is sutured to the episclera with six interrupted 6-0 polyglactin 910 sutures. The lid speculum is subsequently removed, and the polyglactin 910 sutures are anchored to the drape. Before trephination of the recipient bed, the size of the new AC IOL is determined by measurement of the horizontal limbal diameter and the addition of 1 mm. One method for determining power of the new AC IOL is to take the original AC IOL power and subtract 1 D, based on the assumption of an average of 1 D of corneal steepening postoperatively. Few remaining iris-plane-style IOLs are left in pseudophakic bullous keratopathy survivors, but if the original IOL is an iris-plane style, 2 D are subtracted. The graft is cut from the endothelial side, 0.25 mm larger than the recipient bed; we favor an 8.25 mm donor in an 8 mm recipient bed. The Barron system vacuum trephine (Katena Products Inc., Denville, NJ) is preferred, since it enables alignment of the donor with the recipient bed and a well-centered vertical cut on the donor. After partial trephination to two-thirds depth with the recipient trephine part of the Barron system, the AC is entered with a 67 Beaver blade and the host corneal button is excised with Castroviejo scissors, with a small shelf of Descemet's membrane being left. Lysis of any anterior or goniosynechiae is then performed in areas apart from the old AC IOL with a Barraquer cyclodialysis spatula.

Any closed-loop AC IOL, iris-plane IOL, as well as any lens that is unstable or associated with inflammation should be removed at the time of penetrating keratoplasty. Multiple techniques have been described for removal of closed-loop AC IOLs, most commonly the Stableflex lens.[1,17,21,23,26] Briefly, the optic is first removed by cutting each double closed-loop haptic two-thirds of the distance from the optic to the angle with Vannas scissors. The double-loop haptics are then slid out of the tunnel formed by peripheral anterior synechiae by pulling them with a curved hook placed in

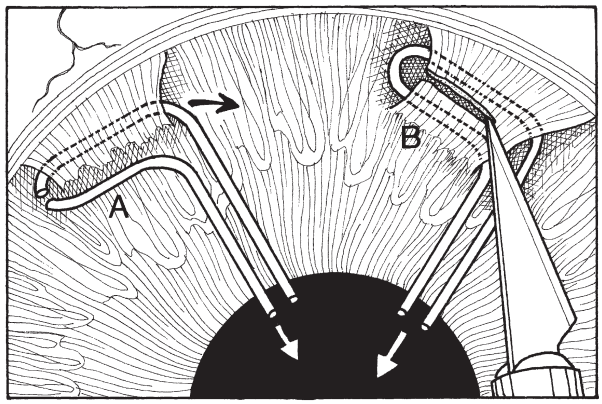

Figure 45.1. Removal of a double-loop intraocular lens (Stableflex) may involve A, cutting the loop in half and removing each arm separately, or B, cutting the iris adhesions then removing the loop in one piece.

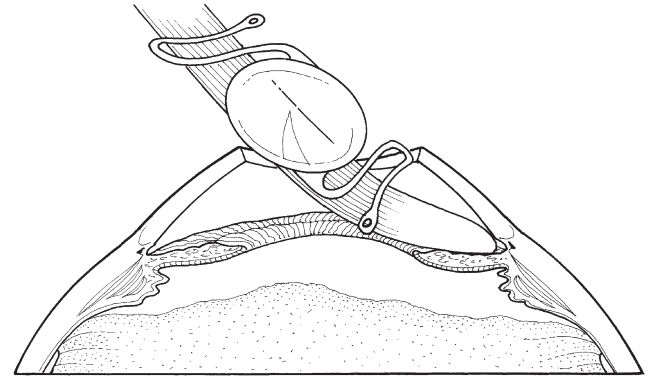

Figure 45.2. Insertion of a Kelman-style, one-piece, open-loop polymethylmethacrylate anterior chamber intraocular lens with a lens guide during pseudophakic penetrating keratoplasty.

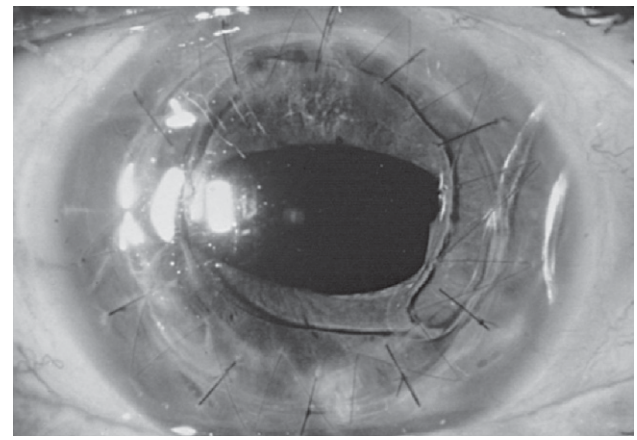

Figure 45.3. A horizontally placed open-loop anterior chamber intraocular lens 6 months after pseudophakic penetrating keratoplasty (Cilco Multiflex II, Alcon, Fort Worth, Tx).

the closed end of the loop, or they could be cut free (Fig. 45.1). Care should be taken not to leave a burr on the end of the loop that could tear the iris and produce bleeding or to allow excessive traction to result in dialysis of the iris root. Any bleeding is controlled by use of sodium hyaluronate viscoelastic in the angle or compression with a cellulose sponge soaked with epinephrine 1:1000. If excessive bleeding is encountered, any residual haptic material should be left within the angle, severing any exposed material at the iris root. After removal of the lens, the angle should be inspected by dental mirror gonioscopy or by inversion of the limbus using scleral depression.[26] Once the original AC IOL is removed, the eye is examined for any vitreous in the anterior segment. Using a vitrector with a fast cutting rate (400–500 cuts/min) and a low-medium aspiration pressure (150–200 mmHg) without irrigation, an anterior vitrectomy is performed to remove any vitreous strands from the AC, angle, iris, and ciliary body. A dry cellulose sponge is used to detect any residual vitreous, which should then be removed. The few survivors with pseudophakic bullous keratopathy associated with a rigid, PMMA AC IOL may either be left in place, if there is no history of cystoid macular edema, or be removed through a corneoscleral incision before corneal trephination. Iridoplasty is performed to repair pupillary deformities, if necessary, with a 10-0 polypropylene suture on a tapered needle. The pupil is then further constricted with intraocular acetylcholine, and the angle is deepened with sodium hyaluronate viscoelastic.

If an AC IOL is to be implanted, an all-PMMA, open-loop, four-point fixation AC IOL (our preference: S122UV Equiconvex, Bausch & Lomb, Rochester, NY) should be used. Previously it was argued that the positioning of the new AC IOL should be determined by the presence of residual peripheral anterior synechiae, but a comparative study[9] fails to support this hypothesis. Therefore, we recommend placing the new AC IOL in the orientation of the previous AC IOL. Once an adequate vitrectomy, if necessary, has been performed leaving the AC free of vitreous, sodium hyaluronate viscoelastic is injected into the AC to cover the pupil and deepen the angle. A lens guide is inserted in the direction of the original IOL haptic orientation and then the new IOL, held with fine tying forceps, is inserted with the leading haptic placed in the angle. The guide is then removed. The trailing haptic is placed under the corneal wound by retracting the corneal bed beneath the trailing haptic with 0.12 forceps and using a tying forceps to hold the optic and gently compress the leading haptic into the angle. This enables the trailing haptics to spring into the angle below the corneal wound. In the setting of a pre-existing sector iridectomy, the AC IOL should be positioned horizontally from the 3 o'clock to the 9 o'clock position within the angle with or without a lens guide (Figs 45.2 and 45.3). With proper placement, the pupil should remain round with no tenting of the iris. After implantation, the AC is filled sufficiently with sodium hyaluronate viscoelastic to protect the donor endothelium as the button is sewn into place. The viscoelastic may be left in the eye at the end of the case.

APHAKIC

The technique for aphakic keratoplasty with secondary AC IOL implantation is essentially the same as that described above, except that anterior vitrectomy is required in all cases and IOL power calculation differs. Power calculation can be determined based on the keratometry and axial length measurement of the fellow eye along with comparison of the previous spectacle correction of both eyes, or it may be based on the axial length measurement of the operative eye and an average keratometry reading (e.g. 43 D) determined from previous keratoplasty experience.

ANTERIOR CHAMBER INTRAOCULAR LENS VERSUS SUTURED POSTERIOR CHAMBER INTRAOCULAR LENS IN PSEUDOPHAKIC PENETRATING KERATOPLASTY

In the absence of capsular support during penetrating keratoplasty, the surgeon has three procedures that can be chosen: (1) implantation of a one-piece, open-loop, flexible AC IOL into the angle, (2) suture fixation of a PC IOL to the iris, and (3) trans-scleral fixation of a PC IOL. In recent years, trans-scleral fixation of a PC IOL has become the most commonly employed posterior change IOL fixation approach, if chosen. Iris fixation of an IOL has also been reconsidered in recent years using the Artisan-style IOL (Ophtec, Groningen, Netherlands), with one study showing comparable results to the former methods with an argument that the safety of these lenses and simplicity of the insertion may have an advantage.[27]

The numerous retrospective studies[28–37] that have directly and indirectly compared the three methods were recently compared in a comprehensive meta-analysis to determine the safety and efficacy of open-loop AC and scleral- and iris-sutured PC IOL in eyes with inadequate capsular support.[38] A subset of the analysis included eyes that underwent concurrent penetrating keratoplasty. Studies were evaluated and rated according to relevance and statistical power before being included in the meta-analysis. Table 45.1 summarizes portions of the pooled data from the seven, nine, and five studies that published data on the safety and efficacy of AC IOL and scleral- and iris-sutured PC IOLs, respectively. Graft survival rates were found to be between 82 and 100% for the AC IOL group, 90–100% for the iris-fixated group, and 87.5–100% for the scleral fixated group. Visual acuity better or equal to 20/40 was similar among the groups as well, with a slightly better result (47%) in the iris-fixated group, largely based on the disproportionately high success rate (60%) of a large study done at one site.[40] In addition, the percentage of patients with vision equal to 20/200 was also similar among the groups (~35%) with no increased incidence of graft failure regardless of lens type. Interestingly, these individual case series demonstrated that the incidence of glaucoma with secondary IOL insertion was much higher in the cases involving penetrating keratoplasty and PBK compared to secondary IOL insertion from complicated cataract surgery. The rates ranged up to 45% for AC IOL groups, 43% for the scleral-sutured PC IOL groups, and up to 62% for the iris-sutured PC IOL groups. Only one group has published long-term outcomes of penetrating keratoplasties and open-loop, flexible AC IOLs.[39] This retrospective study showed the probability of graft survival at 1, 2, 4, 6, and 8 years to be 93, 87, 78, 65, and 65%, respectively.

There have been, however, few studies performed at the same site comparing open-loop, flexible AC IOLs versus iris- or scleral-fixated PC IOLs. Our site studied 25 patients with an open-loop AC IOL and 24 patients with an iris-fixated PC IOL 1 year after penetrating keratoplasty.[8] Graft clarity, visual results, control of intraocular pressure, and endothelial survival were compared. The average best-corrected visual acuity was comparable between the two groups; 29% of the eyes were 20/40 or better in the AC IOL group and 25% in the iris-fixated PC IOL group. Comparable intraocular pressure control also was shown for the two IOL types, contrary to previous postulation.[6] In this study, average intraocular pressure did not differ for the two groups at 1 year (AC IOL 19 ± 6 mmHg versus PC IOL 20 ± 5 mmHg). In addition, no new cases of glaucoma occurred in the AC IOL group and only one new case (4%) in the iris-fixated group. Most importantly, the two IOL groups experienced the same average endothelial loss at 1 year (AC IOL 32 ± 26% versus PC IOL 27 ± 26%), disputing the assumed advantage of the posterior pupillary location of the PC IOL in protecting the endothelium, at least when the posterior capsule is absent.

Two other sites have also reported retrospective comparisons of open-loop, flexible AC IOLs versus either iris- or scleral-fixated PC IOLs.[6,10,11,16] Both sites showed no difference in clinical outcome when comparing graft clarity, visual acuity, and intraocular pressure. Furthermore, one site showed a significantly lower average endothelial cell loss at 1 year with the Kelman-style AC IOL (11.5%)[16] than that with an iris-fixated PC IOL (19.0%).[10,11] This site extended its observations to 2 years for 35% of its initial patient population and, surprisingly, found 38% cell loss in its iris-fixated PC IOL group[12] compared with 21% in its AC IOL group.[16] However, Brunette et al[4] advocate sutured PC IOLs over AC IOLs during penetrating keratoplasty. Comparing the AC IOL technique to both scleral and iris-fixated PC IOL techniques, they reported that the visual acuity during the first 12 months was similar between the two groups, but eyes receiving PC IOLs had significantly better visual acuity at periods greater than 1 year. They also argued that there is a greater increase in intraocular pressure (29.6%) with the AC IOLs versus PC IOLs (5%). Unfortunately, this study was retrospective and the numbers too small to accurately compare iris- versus scleral-fixation techniques.

To date, the study done by Schein et al[9] remains the only prospective randomized multicenter trial comparing the three techniques. In this study, 176 consecutive patients with pseudophakic corneal edema who underwent penetrating keratoplasty with IOL exchange were randomly assigned into one of three implantation techniques (AC IOL, $n = 60$; iris-fixated PC IOL, $n = 56$; scleral-fixated PC IOL, $n = 60$). There were no exclusions of patients or assignment to an IOL implantation technique on the basis of ocular history or anatomy, and all groups were similar in age, sex, and ocular morbidity. Evaluations were performed at baseline and at 6, 12, and 18 months postoperatively. Life-table methods were used to compare escalation of glaucoma therapy, loss of graft clarity, iridocorneal synechiae, adequacy of lens centration, and cystoid macular edema. At 12 months, the spectacle-corrected

Table 45.1 Results of penetrating keratoplasty in pseudophakic bullous keratopathy with intraocular lens exchange

Intraocular Lens (IOL) Type	Mean Follow-Up (mo)	Clear Grafts (%)	Visual Acuity (20/40 or better) (%)[a]
Anterior chamber (AC) IOL[4,8,16,18,22,23,39]	12–50	82–100	35.2
Iris-fixated posterior chamber (PC) IOL[3,5,36,37,40]	7.6–30	90–100	47.2
Scleral-fixated PC IOL[4,8,28,30–35]	12–26.8	87.5–100	40

[a] Average from pooled data.

visual acuity was 20/40 or better in 16.3% of the AC IOL group, 15.7% in the iris-fixated PC IOL group, and 20.0% in the scleral-fixated group. Survival analysis showed no significant difference in the escalation of glaucoma therapy and loss of graft clarity. The cumulative risk of iridocorneal synechiae ranged from 24.7% for the AC IOL group to 44.9% for the scleral-fixation group, although this finding was not statistically significant. Three scleral-fixated lenses required refixation because of either partial dislocation or visually significant tilt. There were no cases of dislocation in the iris-fixation group. The cumulative risk of cystoid macular edema was significantly less for the iris-fixated group than for either of the other two groups. According to their complication index, the chances of developing one of the major adverse outcomes was significantly higher in the scleral-fixated group compared to the iris-fixated IOL group. The AC IOL group complication index was intermediate and indistinguishable statistically. In this study, endothelial survival was not examined. However, a longitudinal cohort study done at a different site[6] did compare the endothelial attrition rates at 1 and 2 years of corneal grafts with secondary AC IOL and iris-sutured PC IOL implantation. For the AC IOL group ($n = 19$) the attrition rate was 16.5% and 28.4% at 1 and 2 years, respectively, with a 5.3% graft failure rate compared to the 19.0% and 38.2% attrition rate and 8.3% survival rate for the iris-sutured PC IOL group ($n = 60$).

CONCLUSIONS

Although the wave of pseudophakic and aphakic bullous keratopathy continues to decline with the advent of better surgical techniques and lens technology, one site[41] has recently demonstrated in a large, long-term, longitudinal review that in the setting of penetrating keratoplasty, insertion of a secondary IOL in aphakic eyes, as well as exchange of an IOL in eyes with PBK, led to a significantly higher graft survival rate in both cases when compared to eyes that were left aphakic or whose previous PC IOL was retained ($p = 0.0051$ and $p = 0.0031$, respectively). Therefore, understanding of secondary lens exchange in the setting of PK remains an important surgical issue. Careful consideration of the patients' ocular anatomy plays a large role in the choice of which IOL insertion technique to use. According to the largest meta-analysis comparing all the available literature to date,[38] all three IOL insertion techniques demonstrate comparable safety and efficacy in eyes with no anatomic contraindications. However, scleral-sutured IOL fixation involves a longer operating time and additional complications of lens tilt, suture erosion, and necrotizing scleritis.[42] Therefore, scleral-sutured PC IOL implants should only be considered for instances in which extensive peripheral anterior synechiae, iris atrophy, distortion, or absence, makes implantation of an open-loop, flexible AC IOL or iris-fixated IOL problematic. With the advent of deep lamellar endothelial keratoplasty (DLEK) and DSAEK increasingly replacing penetrating keratoplasty as the procedure of choice with endothelial failure in pseudophakic bullous keratopathy, implantation of AC IOLs in the setting of ABK and PBK may have a decreasing role. Amayem et al[43] described several successful cases in which DLEK was successfully combined with IOL exchange and secondary IOL placement in patients with ABK and PBK. At their site and ours, the technique of endothelial transplant involves the removal of all implanted AC IOLs and the implantation of secondary sutured PC IOLs in most cases to facilitate insertion of the endothelial graft and to prevent postoperative damage to the graft. There are currently no published reports comparing PK and DLEK associated with PBK or ABK and the management of the IOL. In any event, the need for additional long-term data and prospective analysis still remains if one technique is to emerge as superior in both safety and efficacy.

46 Lens replacement in pseudophakic bullous keratopathy: iris-sutured posterior chamber lenses

W. Stanley Muenzler

In 1985 Roger Hall and I presented the first series[1] of iris-sutured posterior chamber lenses at the time of keratoplasty for pseudophakic bullous keratopathy (PBK). At that time PBK was the leading indication for penetrating keratoplasty (PK).[2–5] We have seen patients as long as 21 years after this procedure with clear grafts, stable lenses, and stable vision, with no serious long-term effects. Others[6,7] have had similar results in large numbers of cases. For example, Akpek et al[6] reported, in 2003, on 264 eyes followed for an average of 5 years (up to 11). Eighty-one per cent of grafts were clear 5 years postoperatively. In 2004, Farjo[7] reviewed 366 eyes with similar iris-sutured lenses during a 9-year period with similar results. Vision improved, grafts remained clear, and complications were minimal, comparable for corneal transplantation in other types of PK.

There has been an ongoing controversy over the best surgical management of these patients. The choice was of whether to replace the lens explanted with another anterior chamber lens, or to suture the lens in the iris or with scleral fixation. One prospective randomized trial reported that the risk of complications was less for the iris fixation cohort than either the anterior chamber intraocular lens or the scleral fixation group.[8] Also, sulcus-fixated[8] and posterior chamber lenses fixated by posterior capsule or Soemerring's ring remnants have been reported, but with no long-term results (Gelender, personal communication).[9–10]

Recent reports have indicated a significant reduction in the number of cases of PBK; however, as recently as 2003, Thompson et al[11] reported a series of 3992 consecutive PKs from 1982 to 1996 with 32% PBK. Others reported, in 2004, only 13.5% of 8318 PKs from 1983 to 2002,[12] and in a group of 784 cases from 1990 to 1999, PBK represented only 7.6% of the total.[13] This reduction is obviously from improved technique, instrumentation, lenses, and, perhaps, better recognition of the importance of the appearance of the endothelium.

SURGICAL TECHNIQUE

Details of the procedure have been described elsewhere.[14] Most cases are done under local anesthesia. A Flieringa or McNeil–Goldman ring is used to stabilize the eye. Donor corneas are trephined with a Barron punch and made 0.25 to 0.5 mm larger than the recipient cornea, where sizes range from 7.5 to 8.0 mm. The posterior chamber lens used is an alcon model SKR21RU. This lens has four positioning holes. Two 10-0 polypropylene sutures (ethicon BV-100-4) are placed up through the holes on each side. The lens is placed aside, ready to suture in (Figs 46.1 and 46.2).

The cornea is trephined to a depth of about 90% and then entered and slowly decompressed. The pupil is contracted with miochol. The anterior chamber lens is removed, and goniolysis and repair of any large iridectomies that might cause glare in the optical axis. An anterior vitrectomy is usually needed. The lens is then placed behind the iris with the haptics placed in the ciliary sulcus. The optic is sutured to the iris, using a double throw square knot, with one extra loop to avoid pinching of the iris tissue. The sutures are placed at about the mid-iris. Additional miochol is instilled. A viscoelastic is utilized to coat the lens–iris diaphragm, and the corneal button sutured in place. Postoperative care is as usual for PK.

The manufacturer (ALCON Laboratories, Fort Worth, TX) no longer produces the lens we prefer to use in this procedure. Akpek et al[6] reported using three other lens types. My recommendation to surgeons who now wish to use our technique with currently produced lenses is to use lenses available from your suppliers.

DISCUSSION

Although the methods mentioned above have stood the test of time through many years and with many different surgeons, it appears that a new method of keratoplasty variously called, posterior lamellar keratoplasty,[15] deep lamellar endothelial keratoplasty (DLEK) championed by Terry et al,[16–18] or Descemet's stripping endothelial keratoplasty by Meles et al[19] and Price and Price,[20] will replace PK for most disorders of the corneal endothelium. Only Descemet's membrane and the endothelium are replaced. A donor containing posterior stroma, Descemet's, and endothelium are obtained with a Moria automated keratome and trephined to the size needed. The advantages of this procedure over PK are significant, including a much smaller, stronger wound; little if any change in the refractive error (avoiding the high and changing astigmatism); and more rapid recovery of vision. A 5 mm sutureless incision may be used and

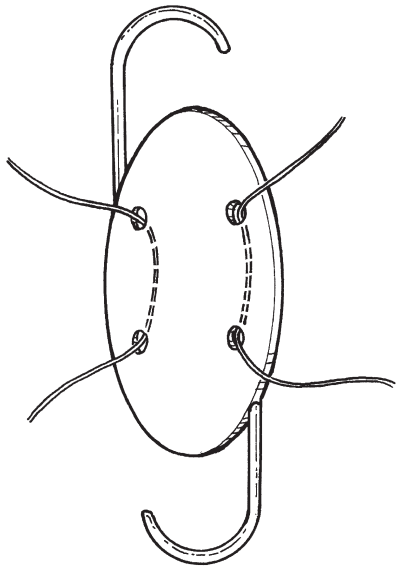

Figure 46.1. Before entering recipient eye, a four-hole posterior chamber lens is prepared on a tissue wipe with use of two 10-0 polypropylene sutures double-armed with tapered needles. Two needle ends of the first suture are passed upward through positioning holes on one side, and then a second suture is similarly placed through the opposite-side holes. Later, lenses with needles and sutures are transferred to the eye and viewed against the iris for best positioning.

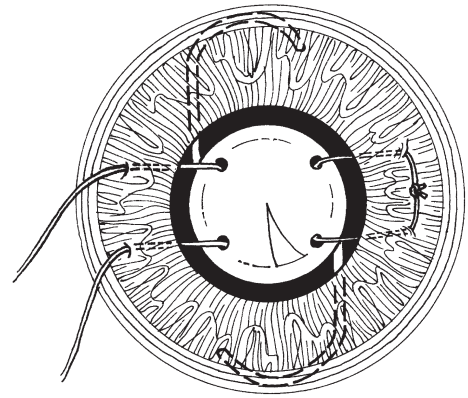

Figure 46.2. The first needle is placed up through the mid-peripheral iris in the lower quadrant and the other end through the mid-peripheral upper iris. Similar maneuvers are then carried out on opposite side. The inferior loop is then placed behind the iris, and the superior loop is last to be positioned behind the iris. The two ends of the right suture and the two ends of the left suture are tied together with knots in front of the iris.

has more recently been combined with lens explantation, vitrectomy, sulcus-sutured intraocular lenses, and cataract surgery.

Patients with vitreoretinal disease have had pars plana vitrectomy procedures within 4 months of DLEK.

Although it appears that these new procedures of endothelial transplantation are revolutionary and offer a safer, more predictable procedure (almost like intracapsular cataract surgery versus small incision phacoemulsification), the number of cases is relatively small and follow-up (especially in complicated cases) is relatively short. Therefore, as in all new procedures, these will have to stand the test of time and are certain to evolve into even better procedures.

SUMMARY

Iris-sutured intraocular lenses have been used in conjunction with PK since 1985.

Several reports have shown this procedure to be quite predictable, with clear grafts, improved visual acuity, and minimal long-term complications.

Recent developments in endothelial corneal transplantation may make these procedures obsolete.

47 Intraocular lens replacement in pseudophakic bullous keratopathy: scleral-fixated type

Thomas D. Lindquist

For the past several years, corneal edema following cataract surgery has been the most frequent indication for penetrating keratoplasty.[1,2] The management of the intraocular lens (IOL) during corneal transplantation, therefore, becomes a very important issue. At the time of penetrating keratoplasty, all iris-fixated IOLs and all small-diameter, round-loop, and closed-loop anterior chamber (AC) IOLs should be removed.[3–5] Flexible, open-loop, one-piece, all polymethylmethacrylate (PMMA) AC IOLs have had complication rates comparable to either iris- or scleral-fixated IOLs.[6,7] Some surgeons may elect, therefore, to retain this type of IOL at the time of corneal transplantation in eyes with less than 90° of peripheral anterior synechiae and controlled intraocular pressure.[8]

At the time of corneal transplantation for aphakic or pseudophakic corneal edema, a thorough anterior vitrectomy should be performed, taking particular care to remove the vitreous from the anterior and posterior surfaces of the iris as well as from the angle itself.[9] Retention of a previously placed AC IOL may make complete removal of the vitreous difficult. In any eye that has a history of persistent macular edema after cataract extraction and IOL insertion, the IOL should be removed, followed by a thorough anterior vitrectomy.

In the absence of capsular support, trans-scleral fixation of posterior chamber (PC) IOLs can be a safe and effective technique during penetrating keratoplasty with IOL insertion or exchange.[6–8,10] Perceived advantages of a trans-sclerally sutured PC IOL include reduced endothelial cell loss because contact with the corneal endothelium is avoided, less secondary glaucoma because contact with the trabecular meshwork is avoided, and decreased cystoid macular edema because contact with the iris is minimized. Trans-sclerally sutured PC IOLs have greater applicability in cases of distorted pupils, sector iridectomy, disrupted anterior segments, pre-existing anterior synechiae, or shallow ACs.[8,11]

Disadvantages of trans-sclerally sutured PC IOLs encountered during the development of this procedure included technical difficulty, increased operative time, the possibility for PC IOL dislocation, and the potential for endophthalmitis secondary to the erosion of the polypropylene suture through the conjunctiva.[10,11] These disadvantages have largely been obliterated by innovative designs in the IOL as well as by specialized needles and techniques[10,12–14] for trans-sclerally sutured PC IOLs that can now be safely, efficiently, and effectively performed in conjunction with penetrating keratoplasty.

INTRAOCULAR LENS REMOVAL

Removal of an IOL during corneal transplantation is considerably less difficult than through a limbal incision. However, the tendency for fibrosis to develop around the haptics[15] can make IOL removal difficult even from an 'open sky' approach.

Once the recipient button has been trephined and excised, the haptics of AC IOLs may be amputated with either Westcott scissors or a haptic amputator. When removing looped haptics, one arm of the loop should be amputated near the iris root to facilitate removal of the remainder of the haptic through the tunnel of fibrosis, which is frequently encountered. The haptics may be amputated individually, thereby freeing the optic, which is removed from the field. If vitreous is wrapped about the haptic or the optic, a limited anterior vitrectomy may be performed prior to amputation of the optic and haptics. Alternatively, as the optic portion is being removed, any attached vitreous may be amputated with a Westcott scissors. Bleeding from the iris root may be successfully managed by application of 1 : 1000 epinephrine or thrombin.

PC IOLs need not be removed unless there has been optic decentration or the lens power needs to be adjusted. PC IOLs that lack manipulating modifications of the haptic can generally be removed by clockwise rotation into the AC. IOLs that have manipulating modifications near the tip of the haptic may be removed by amputating the haptic near the lens optic followed by counterclockwise rotation, which generally frees the haptic.

TECHNIQUE FOR TRANS-SCLERAL FIXATION OF A POSTERIOR CHAMBER INTRAOCULAR LENS DURING PENETRATING KERATOPLASTY

Conjunctival peritomies measuring approximately 3 mm in length are created at the 2 and 8 o'clock positions or at the 4 and 10 o'clock positions of the limbus to avoid the ciliary blood vessels

and the long posterior ciliary nerve in the horizontal meridian. Bipolar cautery may be applied to the episcleral vessels to control any bleeding. In younger patients with prolific Tenon's fascia, the episclera may be scraped with a #64 or #69 Beaver blade to facilitate rotation of the knot at the conclusion of the procedure.

A Flieringa ring is attached to the episclera with 7-0 polyglactin 910 suture to provide scleral support, particularly during mechanical anterior vitrectomy and passage of the 10-0 polypropylene needle through the ciliary body. Placing sutures at each margin of the conjunctival peritomies securely stabilizes the sclera while burying the knot of the polypropylene suture fixating the sutured PC IOL (Fig. 47.1).

The recipient button is then trephined and excised. If necessary, previously placed IOLs are removed. A careful and thorough mechanical vitrectomy is completed, taking care to remove any vitreous from the anterior and posterior iris surfaces and from the ciliary sulcus.

The selection of an appropriate PC IOL is critical to the success of this technique and furthermore minimizes potential complications. The recommended PC IOLs include biconvex, large optic (6.5–7 mm), and one-piece, all-PMMA construction. Oversized eyelets are located 180° apart on the inside curve of both haptics. Eyelet-to-eyelet diameter is 12–12.5 mm, and the haptics are angled posteriorly to further minimize iris contact.

One needle of a double-armed 9-0 polypropylene suture is passed through the inferior eyelet of the PC IOL, taking care not to twist the newly created loop around itself (Fig. 47.1). A curved 9-0 polypropylene needle may be straightened using a second needle holder such that only a ski edge remains at the tip. The needle is passed through the pupil, underneath the iris, and through the ciliary sulcus, exiting perpendicular to the sclera approximately 0.75 mm posterior to the surgical limbus at the site of the previously prepared inferior conjunctival peritomy. The second needle of this suture is passed in a similar fashion a minimum of 2 mm adjacent to the first suture, but again 0.75 mm posterior to the surgical limbus. Ultimately, the two ends of the suture are tied together, allowing for the creation of a continuous trans-scleral loop whose knot may be buried beneath episclera. Another double-armed 9-0 polypropylene suture is placed through the second eyelet, and the needle is passed in an identical fashion 180° from the previously placed sutures, exiting sclera through the superior conjunctival peritomy (Fig. 47.2). Marking the recipient cornea with an eight-incision radial marker dipped in Gentian violet greatly facilitates placement of the second suture precisely 180° from the first.

While gentle traction is applied to the polypropylene sutures, the inferior lens haptic is inserted posterior to the iris and is directed into the ciliary sulcus. The superior lens haptic is then similarly positioned using a superior haptic compression technique. Lens centration, stability, and pupil contour are assessed (Fig. 47.3). Each end of the double-armed 9-0 polypropylene suture is then 'milked' to be sure that it slides freely and that the knot may be buried beneath episclera (Fig. 47.3, *inset*).

The ends of the double-armed 9-0 polypropylene sutures are tied together and cut short. The knot is then buried in a manner similar to limbal or corneal sutures (Fig. 47.4). Placement of a drop of viscoelastic on the suture just before burying the knot will facilitate rotation of the knot beneath the sclera. The knot is buried prior to securing the donor cornea; otherwise the time delay may allow for

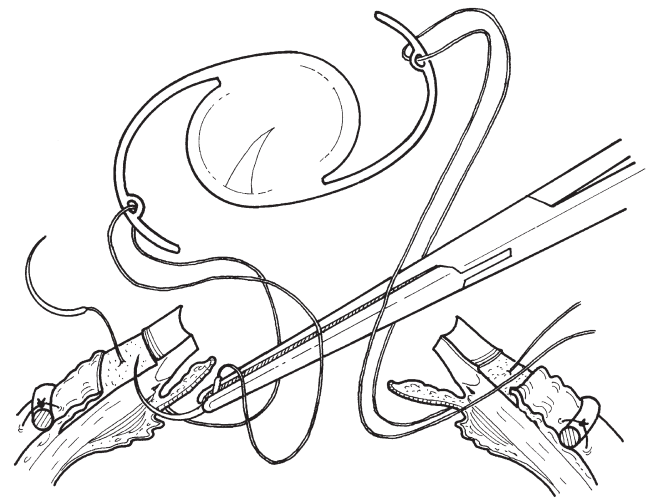

Figure 47.2. The needles are passed through the pupil, underneath the iris, and through the ciliary sulcus, exiting perpendicular to the sclera about 0.75 mm posterior to the surgical limbus at the site of the inferior conjunctival peritomies.

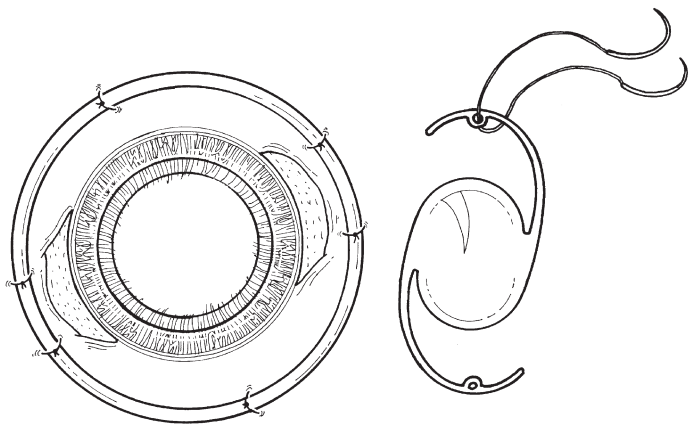

Figure 47.1. Securing the Flieringa ring at each margin of the conjunctival peritomies stabilizes the sclera for trans-scleral passage of the 9-0 polypropylene sutures and for burying the knot after the suture is tied to create a continuous loop. One needle of a double-armed polypropylene suture is passed through the inferior eyelet of the lens, taking care not to twist the newly created loop around itself.

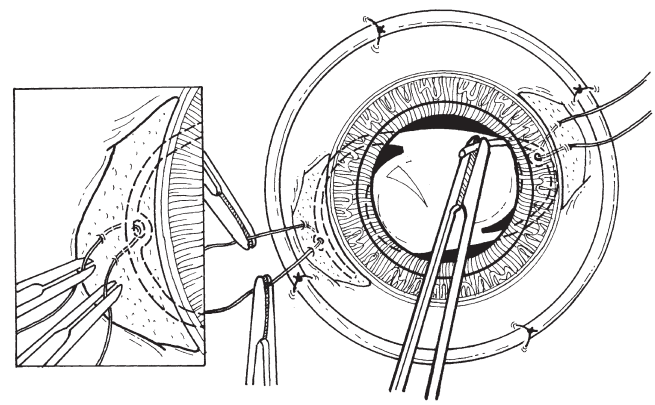

Figure 47.3. The inferior lens haptic is inserted behind the iris, and with gentle traction on the trans-scleral polypropylene sutures, it is directed into the ciliary sulcus. The superior lens haptic is positioned using a superior haptic compression technique. Each end of the double-armed suture is then 'milked' to be sure that it slides freely (*inset*).

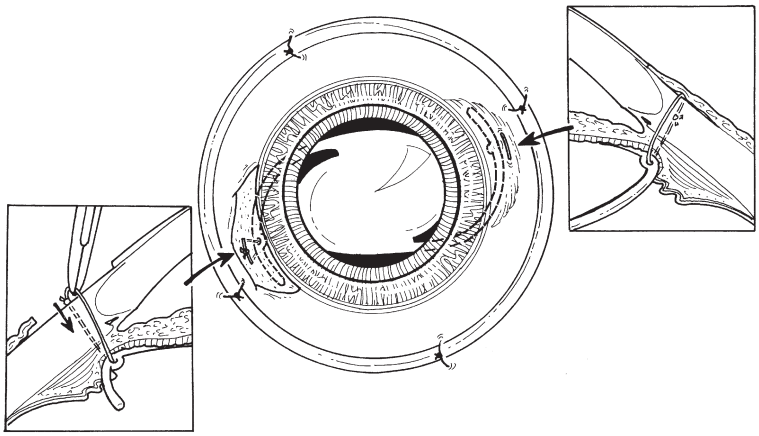

Figure 47.4. The ends of the double-armed sutures are tied together and cut short. The knot is then buried in a fashion similar to interrupted corneal or limbal sutures.

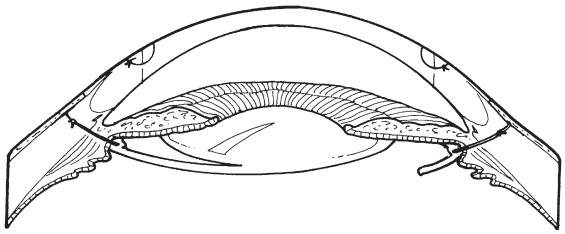

Figure 47.5. The donor cornea is then placed on a bed of viscoelastic and secured. Conjunctival flaps are closed over the trans-scleral sutures using 10-0 nylon or 8-0 polyglactin 910 sutures.

tissue swelling, which makes burying the knot considerably more difficult.

Viscoelastic is placed on the surface of the IOL optic. The donor cornea is then floated on this bed of viscoelastic and secured with 10-0 nylon suture. The conjunctival flaps are closed over the trans-scleral sutures using 10-0 nylon or 8-0 polyglactin 910 suture (Fig. 47.5).

AB EXTERNO SULCUS FIXATION

An alternative that has greater applicability for limbal insertion of a trans-scleral PC IOL is the ab externo technique.[16,17] During secondary lens insertion or IOL exchange in the absence of penetrating keratoplasty, this technique does not require the placement of a Flieringa ring.

A small conjunctival peritomy is performed at the 8 and 2 o'clock positions or the 4 and 10 o'clock positions as previously described. A straight transcorneal needle with 10-0 polypropylene suture penetrates the scleral bed parallel to the iris 1.5 mm posterior to the surgical limbus. The needle tip is passed through the ciliary sulcus posterior to the iris and is visualized in the pupillary space. A 28-gauge needle on a standard insulin syringe is passed through the sclera 180° from the straight transcorneal needle and is visualized in the pupillary space. The straight needle is threaded into the barrel of the 28-gauge needle and is maximally advanced (Fig. 47.6, *A* and *B*). The insulin syringe is then removed from the eye, carrying with it the straight needle and its attached suture. This approach creates a taut segment of 10-0 polypropylene suture extending from sulcus to sulcus. The straight transcorneal needle is then passed back across the sulcus in the opposite direction parallel to the initial pass but separated by a minimum of 2 mm on the scleral bed. A 28-gauge needle is passed through the sclera into the pupillary

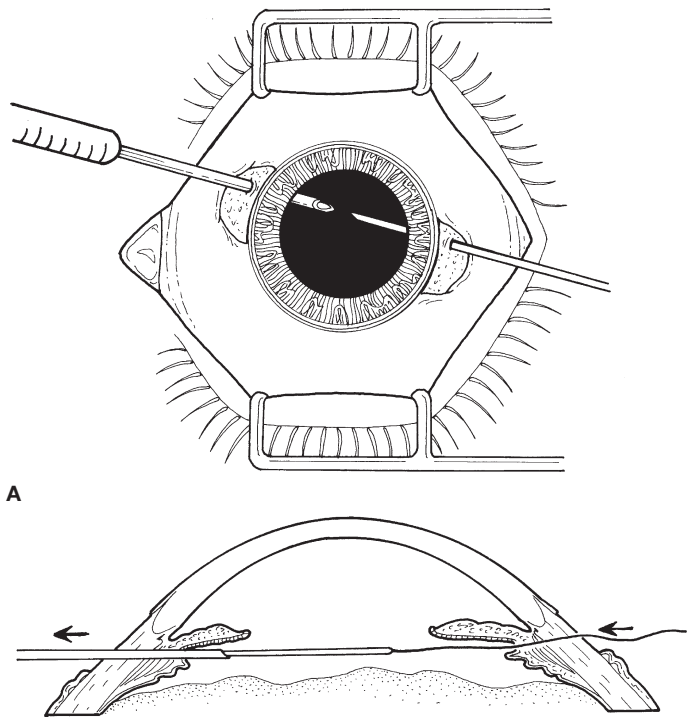

Figure 47.6. *A*, A straight transcorneal needle with 10-0 polypropylene suture penetrates the scleral bed parallel to the iris 1.5 mm posterior to the surgical limbus. The needle tip is passed through the ciliary sulcus posterior to the iris and is visualized in the pupillary space. *B*, A 28-gauge needle on a standard insulin syringe is passed through the sclera 180° from the straight transcorneal needle and is visualized in the pupillary space. The straight needle is threaded into the barrel of the 28-gauge needle and is maximally advanced.

space. Again the straight transcorneal needle is threaded into the 28-gauge needle and removed from the eye (Fig. 47.7).

The recipient button is then excised. A mechanical anterior vitrectomy is performed. The 10-0 polypropylene sutures are cut. One end from each pair is threaded through the eyelet of a specialized PC IOL. The sutures are secured to themselves (Fig. 47.8) and rotated out through the ciliary sulcus. The IOL is inserted within the ciliary sulcus while gentle traction is applied to the sutures. The sutures are tied to themselves creating a continuous loop (Fig. 47.9, *A*). The knot is rotated into the eye (Fig. 47.9, *B*). The overlying conjunctiva is then closed with 10-0 nylon or 8-0 polyglactin 910 suture.

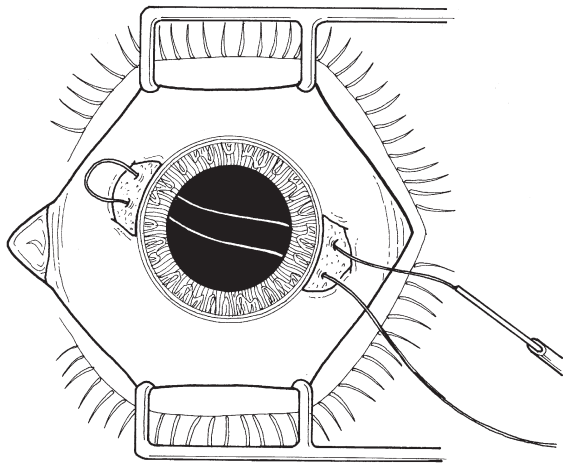

Figure 47.7. The straight transcorneal needle is passed back across the sulcus in the opposite direction parallel to the initial pass but separated by a minimum of 2 mm on the scleral bed. A 28-gauge needle is passed through the sclera into the pupillary space. Again, the straight transcorneal needle is threaded into the 28-gauge needle and removed from the eye.

COMPLICATIONS

EROSION OF THE POLYPROPYLENE SUTURE THROUGH THE CONJUNCTIVA

Prior to the availability of eyelets on the haptics of PC IOLs, erosion of the polypropylene suture knot through the conjunctiva created the potential for epithelial downgrowth or endophthalmitis. In two studies, erosion of the knot was noted in 20%[12] and 24%[18] of cases in which only a conjunctival covering was used. When the polypropylene knot was buried beneath a scleral flap, suture erosion developed in 15% of cases.[18] Suture erosion has not occurred when the knot has been covered by a portion of the donor cornea, which included Descemet's membrane.[19,20]

One case of epithelial downgrowth has been reported following trans-scleral fixation of a PC IOL; however, an interrupted nylon suture leak from the corneal transplant was implicated as the source rather than the polypropylene suture securing the IOL.[18]

Endophthalmitis has been reported following erosion of a 9-0 polypropylene knot through a conjunctival flap 5 months postoperatively[21] as well as following erosion of a 9-0 polypropylene knot through a partial-thickness scleral flap 6 years postoperatively.[22]

To minimize potential problems from suture-knot erosion, various techniques have been developed. When the polypropylene suture is tied to itself, the loop can be left intact, rather than cut, and the

free end may be passed beneath the sclera and cut flush with the surface such that no barb is left exposed. The knot itself, however, may erode through the conjunctiva in time. A similar technique can be used beneath a partial-thickness scleral flap, although the overlying sclera atrophies with time. This approach is supported by the finding that knots that were previously not visible in time become visible beneath partial-thickness scleral flaps. Half-thickness corneal autografts containing Descemet's membrane have been successfully used to cover polypropylene knots at the time of combined keratoplasty and trans-scleral fixation of a PC IOL.[19,20]

However, the availability of PMMA PC IOLs with islets on each haptic has allowed for fixation with a continuous polypropylene loop in which the knot may be buried beneath the episclera. This technique virtually eliminates the chance of knot erosion. Lewis[12] found no cases of suture erosion in 40 eyes using this technique. No conjunctival inflammation has been noted overlying the polypropylene suture lying on the episclera. The only drawback of this approach is that two needles must be passed through the pars plicata at each site of fixation to create a complete loop of polypropylene by tying a knot, which can then be buried. This technique virtually eliminates the potential for polypropylene knot erosion and the associated complications.

INACCURATE PLACEMENT OF HAPTICS WITHIN THE CILIARY SULCUS

In two eyes studied histopathologically after penetrating keratoplasty with trans-scleral IOL implantation, only one of four haptics were found to be within the ciliary sulcus.[23] When needles were passed perpendicular to the sclera, Duffey and coworkers[24] found that the relationship of the ciliary sulcus to the surgical limbus varied between the horizontal meridian and the vertical meridian. In the vertical meridian, the ciliary sulcus was found to be 0.83 mm posterior to the surgical limbus, whereas in the horizontal meridian the ciliary sulcus was 0.46 mm posterior to the surgical limbus. Oblique meridians are preferred for trans-scleral fixation, as this method minimizes the possibility of encountering the ciliary arteries or the long posterior ciliary nerves. When PC IOLs are trans-sclerally fixated in the oblique meridian, the 9-0 polypropylene suture should exit the sclera 0.75 mm from the surgical limbus. When trans-scleral needles are passed from an ab externo approach, the trajectory parallels the iris plane and requires a more posterior placement of the needles in the sclera to achieve sulcus penetration. It is recommended to initiate the ab externo pass 1.5 mm posterior to the surgical limbus in the oblique meridian.[12,16,25]

The mean diameter of the ciliary sulcus ranges from 11[26] to 11.25[27] mm. The haptic-to-haptic diameter of PC IOLs with eyelets on the inside haptic ranges from 12.0 to 12.5 mm. This diameter is more in keeping with the true anatomic diameter of the ciliary sulcus. When larger haptic-to-haptic diameters were used previously for trans-scleral fixation, there may have been an increased tendency for the haptics to slip out of the ciliary sulcus during insertion.

Knowledge of the precise localization of trans-scleral suture placement relative to the surgical limbus coupled with the improvement in PC IOL design for trans-scleral fixation should allow for consistent placement of haptics within the ciliary sulcus.

INTRAOCULAR LENS TILT

IOL tilt has been recognized as one of the most common postoperative complications of trans-scleral PC IOL implantation. In a randomized study comparing IOL fixation techniques during penetrating keratoplasty, Schein and coworkers[28] found IOL dislocation and tilt to be present in 7% of the trans-sclerally fixated group. This report did not include PC IOLs having eyelets on the haptic for trans-scleral fixation.

One-piece, all-PMMA technology gives the PC IOLs used in trans-scleral fixation marked stability in the anteroposterior dimension. Although the haptics are quite flexible when compressed, they resist tilting because of the one-piece technology uniting the haptic to the optic. The complications of IOL dislocation and tilt have been minimized by the improvements in PC IOL design, namely the presence of positioning eyelets and the stability incurred by one-piece, all-PMMA technology. Implanting foldable trans-sclerally sutured lenses[29] cannot provide the same stability of one-piece, all-PMMA PC IOLs.

Histopathologic evaluation of sutured PC IOLs has shown that the long-term position of the IOL is derived primarily from the trans-scleral suture and not from fibrous encapsulation of the haptic.[23] In one reported case, the trans-sclerally fixated PC IOL fell into the vitreous cavity after the external fixation suture was cut at the time of surgical removal.[18] However, gonioscopic evaluation of the haptic position in trans-sclerally sutured PC IOLs demonstrated a fibrotic membrane around the sutured haptic in 83% of lenses located within the ciliary sulcus, whereas no fibrosis was seen surrounding haptics outside the ciliary sulcus.[30] Although positioning the haptics within the ciliary sulcus may lead to fibrotic encapsulation, it is advisable to retain the polypropylene suture indefinitely.

DISLOCATION OF SUTURED PC IOLS

Dislocation of sutured PC IOLs has occurred years after trans-scleral fixation with 10-0 polypropylene suture.[31–33] Therefore, 9-0 polypropylene suture is now recommended to minimize suture dissolution and IOL dislocation.[33] Nevertheless, the possibility of PC IOL dislocation needs to be addressed in younger patients giving informed consent.

RESULTS

In a retrospective study of 122 eyes that underwent secondary IOL implantation at the time of penetrating keratoplasty, survival analysis showed the probability of a clear graft at 1 year to be 80% for eyes with an AC IOL and 90% for eyes with a PC IOL sutured to the iris or the ciliary sulcus.[34] Visual acuity was better than 20/200 in 48% of eyes with an AC IOL and 68% of eyes with a PC IOL.[34] Intraocular pressure rose by 5 mm Hg or more in 30% of eyes with an AC IOL and 5% of eyes with a PC IOL.[34]

In another study of 49 eyes that underwent secondary IOL implantation at the time of penetrating keratoplasty, the probability of a clear graft at 1 year was 88% for eyes with an AC IOL and 96% for eyes with a trans-sclerally sutured PC IOL.[35] At 1 year postoperatively, best-corrected visual acuity of 20/40 or better was noted in 25% of eyes with an AC IOL and 29% of eyes with a trans-sclerally sutured PC IOL.[35] No statistically significant difference in endothelial cell loss was noted between the two groups 1 year postoperatively.[35] Overall, in eyes that underwent secondary IOL implantation at the time of penetrating keratoplasty, eyes with a trans-sclerally sutured PC IOL had better results compared to eyes with an AC IOL.[34,35]

SUMMARY

Trans-scleral fixation of PC IOLs has applicability for IOL implantation in cases lacking capsular support. Improvements in lens design and modifications in technique have improved reproducibility of the procedure and greatly minimized potential complications. One-piece, all-PMMA PC IOLs with positioning eyelets on the haptics markedly reduce the likelihood of lens decentration and dislocation. The positioning eyelet also allows for the creation of a complete loop of polypropylene suture, which then allows the knot to be buried beneath the sclera, further minimizing any potential for knot erosion through the conjunctiva. Nevertheless, the long-term stability of trans-scleral fixation is derived from the polypropylene suture, which remains a limitation of this procedure. 9-0 polypropylene suture is now advised for trans-scleral fixation of PC IOLs to minimize degradation of the suture with possible lens dislocation years after insertion.

48 Regrafting

Linda Rose, John D. Gottsch, Frank M. Jakobs, Walter J. Stark

The patient with graft failure who is a candidate for repeat corneal transplant requires a thorough examination so that the cause of the graft failure can be determined, the post-regraft visual potential may be predicted, and a rational surgical approach can be devised to maximize graft survival. This chapter focuses on the causes and relative risks of failed keratoplasty, the indications and contraindications for repeat penetrating keratoplasty, and surgical techniques that can maximize survival of the corneal regraft. Additionally, we review endothelial keratoplasty as an alternative to a full-thickness regraft.

CAUSES OF CORNEAL GRAFT FAILURE

Corneal graft failure is the inability of the transplanted cornea to retain sufficient transparency for adequate vision. Functional graft loss usually can be attributed to one of two causes: mechanical graft failure that is caused by endothelial cell dysfunction or immunologic rejection by the recipient's immune system. Both mechanical and immunologic graft failure can occur at any time following transplantation.

PRIMARY DONOR FAILURE

Primary graft failure is defined as corneal edema that is present from the time of keratoplasty, does not clear, and is not associated with rejection or secondary causes of graft failure. The cause of primary graft failure is endothelial decompensation. In contrast to some other vertebrates, the human endothelium is not able to regenerate. Incorrect donor cornea removal, use of insufficient storage medium, intraoperative endothelial damage, and implantation of grafts of borderline quality all contribute to graft failure. To ensure that the donor material is of adequate quality, slit-lamp examination of the cornea, and especially of the endothelium, is essential before surgery.[1] Screening of donor endothelium using specular microscopy is performed by most eye banks today. Because of advances in surgical techniques and materials and improved donor tissue preservation, the relative risk of primary graft failure is low. Previously, Arentsen reported an incidence of 4% in a series of failed corneal grafts.[2] A more recent review of the literature reports more optimistic numbers; Price et al reported a 0.5% incidence of primary graft failure in a case review of 3640 initial grafts.[3] In the authors' experience, primary donor failure has occurred in less than 1% of cases. When it occurs, available options for restoring corneal clarity involve either regrafting with a full-thickness keratoplasty[4] or a posterior lamellar graft as is done in endothelial keratoplasty (see Section 4 of this text).

LATE DONOR FAILURE

Late graft failure seems to occur most often in corneal grafts in which a marginal endothelium proceeds to complete endothelial dysfunction. In the early postoperative period, the graft is clear, but it may become edematous months to years later without apparent predisposing causes. Accelerated endothelial cell attrition has been reported after keratoplasty.[5–8] One study found an overall 15-year risk of developing late endothelial failure of 12%.[9]

Nishimura et al observed that grafts with late endothelial failure had lower cell counts prior to transplantation and more loss of cells in the first 2 months postoperatively, but the subsequent cell loss was not accelerated compared to those in grafts that survived.[10] Thus, even after years, grafts seem to fail due to an initial endothelial cell count that is low, rather than from accelerated loss of endothelial cells at the time graft failure appears. In general, any grafted cornea has a higher basal rate of endothelial cell loss than the normal cornea. Bourne examined 500 corneas for changes in endothelial cells in the 20 years following penetrating keratoplasty and found that the rate of endothelial cell loss was 4.2% annually in grafts, whereas it is only 0.6% annually in normal corneas. If such cumulative cell loss is responsible for endothelial failure, it may be possible to prolong the life of a graft by setting criteria for higher donor endothelial cell counts.[8] Endothelial decompensation may also manifest following secondary events such as pseudophakic or vitreous touch, recurrent inflammation, glaucoma, or rejection. Even though there is slow, continuous cell loss over time, corneal grafts generally have a favorable prognosis for long-term clinical stability.[6,11]

Another rare but devastating mechanism for late donor failure is epithelial downgrowth, caused by a fistulous tract that allows

surface epithelium to migrate into and proliferate in the anterior chamber.[4] Clinical signs include a scalloped edge at the posterior graft surface that advances from the periphery toward the central cornea. Epithelial cells may be seen floating in the anterior chamber. Epithelial downgrowth can occur at any time postoperatively. Special caution should be taken with a suture track leak that persists for greater than 2 weeks. The suture should be removed as a fistulous track may be forming. Downgrowth may also appear many years after penetrating keratoplasty, often in the setting of graft dehiscence,[12] repeated surgery, or one involving iris manipulation.[13] Differentiation of epithelial downgrowth from the classical endothelial rejection line, which has been described by Khoudadoust, may be difficult[6,14]; therefore, any endothelial rejection that does not respond to steroid treatment should lead to suspicions of epithelial downgrowth and should be observed and documented closely using slit-lamp photography.[15] When the iris is involved, application of low-dose argon laser can be used to induce a diagnostic blanching effect on the ectopic epithelium.[16,17] Epithelial downgrowth has been treated by repeat keratoplasty,[18] or intraoperative peeling and excision of involved tissue,[12] but it is our experience that it is not easily corrected with either surgery. Cryotherapy has been used to limit further growth of the membrane but restoration of a clear cornea often requires regrafting.[13,17]

ALLOGRAFT REJECTION

Allograft rejection is the most common cause of corneal graft failure.[3,19–21] Early studies demonstrated that corneal graft failure can be caused by sensitization of the recipient to donor material.[22] Later, Khodadoust and Silverstein[23,24] showed that the epithelium, stroma, and endothelium each could exhibit an immune reaction. The clinical manifestation and frequency of the three types of corneal graft rejection have been described;[25–27] they may be characterized by epithelial and endothelial rejection lines (Fig. 48.1), subepithelial infiltrates, keratitic precipitates, and graft edema. Endothelial graft rejection is the most common, whereas isolated stromal rejection is rare.[28] In general, stromal involvement indicates a strong immune response; if it is not treated at an early stage, this can result in severe rejection episodes and graft loss caused by stromal necrosis.

Corneal graft rejection is an ophthalmic emergency that requires immediate attention because the time interval within which ongoing rejection may be reversed effectively is limited to a few days. Early symptoms include inflammatory signs such as conjunctival redness, ocular discomfort, photophobia, blurred vision, and tearing of the eye. Although these symptoms are not necessarily pathognomonic, in the grafted eye they must be considered as signs of rejection until proven otherwise. The Collaborative Corneal Transplantation Study (CCTS) demonstrated a significant correlation between patient-reported symptoms and apparent allograft reaction.[29] Patients who were diagnosed with reactions at scheduled visits during the first postoperative year were two and a half times more likely to report symptoms than were those without reactions; red eye and vision loss were reported most frequently.

HIGH-RISK PENETRATING KERATOPLASTY

Uncomplicated penetrating keratoplasty is a form of transplantation that enjoys a highly favorable prognosis,[30,31] currently with a 5-year survival rate of 90% and a 10-year survival rate of 82% in first-time grafts.[32] As Price et al point out, this is dependent on the preoperative diagnosis, with the most favorable graft survival rates in keratoconus (97.4%) and Fuchs' dystrophy (96.9%).[3] Any local (inflammation and neovascularization) or systemic (pre-sensitization) alteration of the recipient's responder status may affect this outcome, resulting in rejection rates as high as 50–70%. Regrafting in this situation therefore requires careful planning of the operation and thorough evaluation of the multiple risk factors involved.

IMMUNOLOGIC RISK FACTORS

Vascularization

Corneal vascularization potentiates allograft rejection because it creates a functional link between the antigenic material represented by the graft and the afferent and efferent arms of the immune system. Vascularization may be evident as preoperative recipient vascularization, as secondary graft neovascularization, or as both.

In vascularized recipient corneas (Fig. 48.2), rejection occurs at a significantly higher rate than in nonvascularized corneas.[2,3,19,21,33,34] Khodadoust[20] reported rejection rates up to 65% in densely vascularized corneas, with a significantly decreased time interval between the surgical procedure and allograft reaction compared with avascular conditions. Deep stromal neovascularization, especially, has been shown to increase rejection rates.[3,35] In the CCTS, stromal vascularization in four quadrants nearly doubled the risk for

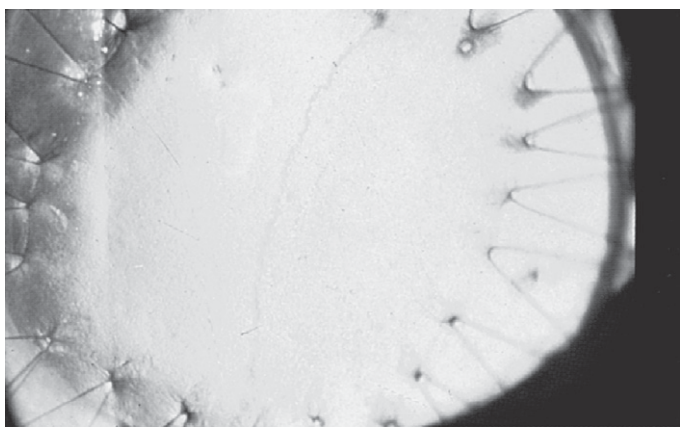

Figure 48.1. Retroillumination of endothelial rejection line.

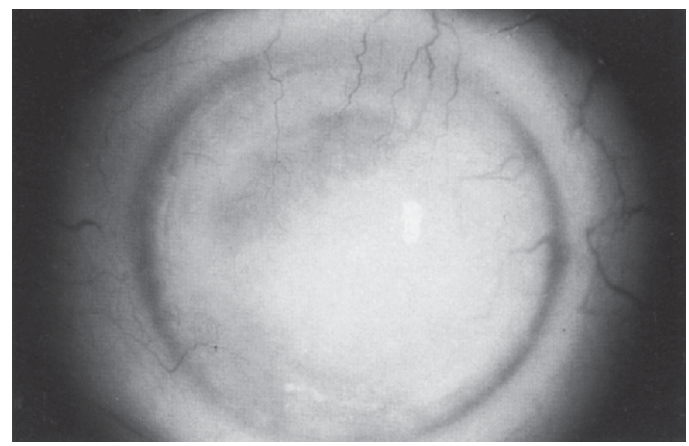

Figure 48.2. Corneal opacification with vascularization after herpes zoster keratitis.

allograft rejection,[36] which was confirmed by Hill,[37] and Price et al reported that deep stromal vascularization increased the risk of failure due to rejection by 2.7-fold.[3] Depth, extent, and density of graft neovascularization seem to be the critical factors for corneal allograft survival in prevascularized graft beds. Residual ghost vessels caused by old inflammatory disease did not appear to influence graft survival significantly.[37] Attempts to eliminate recipient vascularization preoperatively using argon laser or cryocoagulation show no lasting benefit.[38,39]

Postoperative graft vascularization can be induced by mechanical or inflammatory irritation of the corneal surface, such as suture abscesses, exposed knots, and contact lenses worn incorrectly.[2,34] Suture site neovascularization appears to be a trigger for corneal graft rejection. In the CCTS, the risk for rejection failure was doubled in eyes with interrupted sutures as compared with eyes with a running suture.[36] Additional suturing techniques that have been reported to increase risk of neovascularization include burying suture knots in the host stroma[40] (although the authors of this chapter do not find this to be the case in their practice), and a short limbus-to-suture distance. Lam et al performed serial photographs on transplants postoperatively, documenting the progressive development of neovascularization and allowing measurements of the distance between potentially angiogenic sutures and the limbus. They reported that 90% of postoperative corneal neovascularization occurred in grafts in which the distance between the sutures and the limbus was <406 μm. Graft to limbus distance of <1000 μm was another risk factor for neovascularization in this study.[41]

Inflammation

Corneal graft rejection represents an inflammatory event mediated by cellular and humoral immune mechanisms. The local pathology shares the classical features of a non-specific inflammatory response (i.e. vascular dilatation, edema, and cellular infiltration). Clinically, this correlates with conjunctival injection, chemosis, corneal edema, and the presence of circulating cells in the anterior chamber. Foulks notes that often circumcorneal vascular injection due to ciliary flush is the earliest sign of rejection, and it may occur before cellular infiltrates appear in either the cornea or the anterior chamber.[16]

Pre-existing inflammatory conditions such as herpetic keratouveitis[42–44] or bacterial suppuration resulting from a suture abscess (Fig. 48.3) may incite an allograft reaction. Inflammation at the time of transplantation is a risk factor for corneal graft rejection and failure.[45–47] From experience with the transplantation of solid organs, it is known that nonspecific inflammation can induce highly active cytokines that promote both endothelial adhesion and migration of immunocompetent lymphocytes, monocytes, and neutrophils, thus triggering specific graft rejection. A recent study showed that cytokines induce apoptosis in cultured endothelial cells, which may be the mechanism of damage to donor endothelium in graft failure.[48]

Previous graft loss

As with vascularized organ transplantation, previous graft loss is one of the leading predictors of corneal graft failure. Khodadoust[20] described a 50% loss rate following failed primary graft. The prognosis for repeat keratoplasty (Fig. 48.4) has improved, and success rates of 42–68% have been reported, with follow-up observations ranging from 1 to 12 years.[2,32,49–53] The CCTS[36] assigned a statistical risk of approximately 1.2 for each additional graft. Although Kirkness and coworkers[50] determined that allograft rejection appears to be the most common cause of graft failure in patients with repeat transplant, this is not necessarily related to the number of keratoplasties done in a given eye. In a single-surgeon series of 702 grafts, Hill found no significant difference in survival between repeat grafts into avascular corneas and first-time grafts into avascular corneas, suggesting that it is vascularization that triggers the rejection risk in repeat keratoplasty.[37]

The role of donor-specific allosensitization in corneal transplantation and its relative contribution to immunologic graft failure are still unclear. In the transplantation of vascularized organs, previous graft loss, preoperative blood transfusion, and pregnancy are known as potentially presensitizing factors.[54,55] In the case of corneal transplantation, while previous graft loss does remain a strong risk factor for immunologic graft failure,[46] blood transfusion and pregnancy do not.[36] Additionally, as discussed below, studies have failed to establish a clear benefit to histocompatibility matching.

Because corneal graft failure usually is accompanied by a certain degree of corneal neovascularization, it is likely that regrafted patients acquire an elevated level of donor-directed humoral immunity, which may account in part for the increased rejection rates that are reported for this patient collective.[36] Although Roy and coworkers found that corneal transplant recipients who developed post-transplant antibodies had a high risk of undergoing endothelial

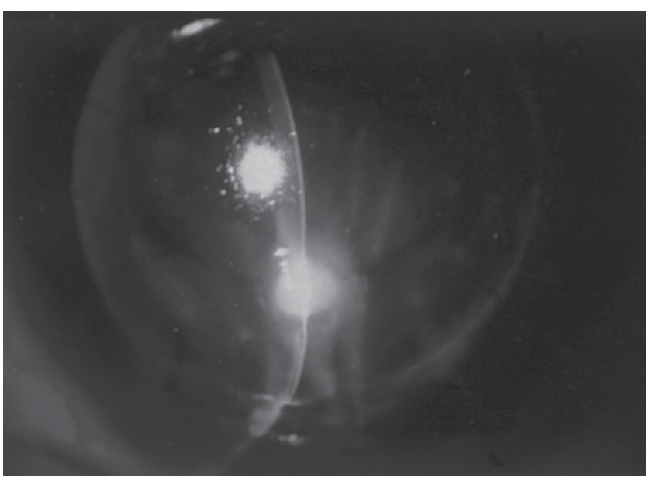

Figure 48.3. Allograft reaction 1 week after presentation with suture abscess caused by *Streptococcus pneumoniae*.

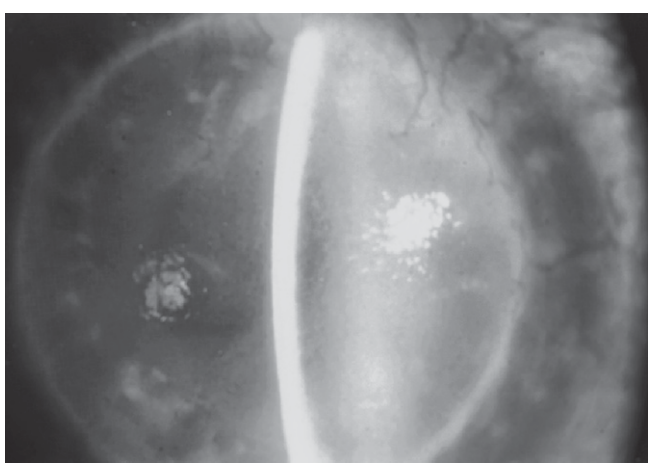

Figure 48.4. Recurrent lattice dystrophy 5 years after keratoplasty.

allograft rejection,[56] analysis of the CCTS and other data[36,57] does not establish a clear benefit to either histocompatibility or ABO matching. This finding was confirmed recently, with one exception: in the case of previous graft failures,[59] positive cross-matching significantly increased the risk of rejection. The lack of benefit of donor–recipient cross-matching in general is in clear contrast to the outcomes of solid organ transplantation[54,55] and indicates an as yet incomplete understanding of basic immunologic features regarding corneal graft rejection.

SURGICAL RISK FACTORS

Previous and subsequent anterior segment surgery

Corneal graft failure is associated with previous anterior segment surgery, including non-cornea-related operations such as lensectomy and vitrectomy.[36] A study of 2242 corneal transplants registered by the UK Transplant Service confirmed that surgical risk factors have a highly significant influence on the outcome of penetrating keratoplasty.[60] Previous implantation of a glaucoma drainage device is an independent risk factor for graft loss irrespective of control of intraocular pressure.[61] Postoperative clouding of clear corneal grafts following additional cataract surgery was reported in 16% of patients by Stark and Maumenee,[62] 20% by Lemp and coworkers,[63] and 25% by Binder.[64] As phacoemulsification has improved, cataract surgery after penetrating keratoplasty has become more successful; in a study of 29 postkeratoplasty patients undergoing cataract extraction, only one developed graft failure during an average follow-up of 44 months.[65]

Graft diameter

Increased graft size has been reported in some studies to be a significant risk factor for rejection.[45,66,67] Other studies, however, refute this and point to smaller grafts as more likely to be rejected.[36,60] Price et al found an increased risk of rejection and endothelial failure in small grafts (recipient size less than 7 mm) and an increased risk of rejection in large grafts (recipient size >8.5 mm).[3] These considerations do not include very large grafts (>9 mm), which usually are restricted to special indication such as severe infectious keratitis, corneal melting diseases,[68] and advanced keratoconus/keratoglobus[69,70]; these show a clear disadvantage compared with conventional graft sizes. The risk factor with regrafts may become critical if the surgeon increases the graft size successively so that opaque areas may be completely excised.[67]

Anterior synechiae

Iridocorneal synechiae are a significant risk factor for corneal graft failure.[2,3,36,71,72] Anterior synechiae may result from chronic inflammation or previous anterior segment surgery; they may predispose the patient to both immunologic graft failure through exposure of the endothelial layer to iris blood vessels and mechanical failure through direct traction on the graft endothelium.[71,73] In addition, anterior synechiae are often associated with elevated intraocular pressure.[73,74]

EPIDEMIOLOGIC RISK FACTORS

Recipient-related factors

The strongest risk factor for graft failure in the CCTS was the age of the recipient at the time of keratoplasty.[36] Recipients younger than 40 years of age had approximately twice as many graft failures from all causes and twice as many failures from immunologic rejection as did recipients older than 40 years. No difference in graft outcome was found within the three subdivisions of older patients up to 89 years of age. Similar findings have been reported by Musch and Meyer[75] and Boisjoly et al,[66] and others,[28,45,76] but Price et al did not find that age influenced graft failure rates.[3]

In the CCTS, male corneal graft recipients had a higher failure rate than female recipients, but they had similar rejection failure rates. No significant difference was found between black and white or other groupings of recipients,[36] but Price et al did report that African Americans were significantly more at risk than whites for endothelial failure and graft rejection and that sex did not influence graft failure.[3]

In the CCTS, current smokers had a substantially higher reaction rate than nonsmokers and a higher failure rate from all causes, whereas the rejection rate was similar.[36] Diabetes was a risk factor for endothelial failure, but not rejection in Price's series.[3]

Donor-related and other factors

The corneal donor study recently reinvestigated the effect of donor age on outcome of PK and found no difference in the 5-year graft survival rate with donors aged 66–75 years compared with donors aged 12–66 years.[76a] They did, however, find a slightly higher rate of endothelial cell loss in subjects receiving tissue from older donors. Patients that received a cornea from donors aged over 65 had a 5-year endothelial cell loss of 75% with a final endothelial cell count of 654 cells/mm^2. When the donor's age was 65 years or less, the endothelial cell loss at 5 years post-PK averaged only 69%, and the final endothelial cell density was 824 cells/mm^2.[76b]

Previously, the CCTS data revealed little systematic variation in outcome rates by donor age, donor race, or times either from donor death to corneal preservation or from donor death to surgery.[36] A waiting time of longer than 9 months until corneal transplantation increased the failure rate from 33 to 45%.[36] Evidence has been produced that bilateral grafts increase the risk for allograft rejection.[77]

SPECIAL CONSIDERATIONS

Chemical injuries

The prognosis for penetrating keratoplasty in eyes with chemical injuries, severe alkali burns in particular, is poor.[78,79] This most likely results from a combination of immunologic and nonimmunologic factors. The immunologic risk is attributed to the extensive vascularization that is seen in most cases of chemical burn. Nonimmunologic graft failure can be caused by tear deficiency, symblepharon, and trichiasis,[79] or by limbal stem cell loss that leads to persistent epithelial defects and chronic corneal ulceration.[80] Regrafting in this situation usually is contraindicated until these problems are controlled.

In the case of chronic surface disease, a conjuctival flap performed first may be used to quiet the inflamed eye. Penetrating keratoplasty can then be performed months or years later with an improved prognosis.[81]

In eyes with repeated graft failure due to severe ocular surface disease such as Stevens–Johnson syndrome, chemical burns, ocular cicatricial pemphigoid, or limbal stem cell deficiency, a keratoprosthesis may offer improved prognosis[82,83]; however, the long-term compliance of the patient is more critical, and the consequences of visual loss can be more severe.[83,84]

Limbal stem cell transplants, from stem cells cultivated on membranes[85] or from conjunctivolimbal allografts or autografts,[86] have

been performed prior to repeat keratoplasty to address surface disease from stem cell loss. The long-term outcomes of these are not yet clear and often require systemic immunosuppression.

Glaucoma

Elevated intraocular pressure has been called the single most serious complication that accompanies penetrating keratoplasty.[87,88] In two series,[2,89] uncontrolled glaucoma accounted for up to 20% of all failed penetrating keratoplasties. Postkeratoplasty glaucoma is clearly multifactorial in origin and varies with preoperative conditions and the indications for keratoplasty. The likelihood of developing glaucoma after penetrating keratoplasty is highest with aphakic and pseudophakic bullous keratopathy, up to 50%[89,90]; overall the cumulative 15-year risk of developing glaucoma is 20%,[9] and in repeat transplants, postoperative glaucoma occurred in 34–47% of cases.[50,52,91] Although elevated intraocular pressure may cause endothelial dysfunction,[92] the use of glaucoma drops has been identified as an independent risk factor for corneal graft failure,[3] possibly due to adverse effects on the ocular surface and stem cells.

The management of postkeratoplasty glaucoma is difficult and requires careful evaluation of the surgical and nonsurgical options that are available for pre- and postoperative pressure control. Failure of medical therapy indicates the need for surgical intervention.[93] For many years, cyclocryotherapy was the treatment of choice for medically intractable postkeratoplasty pressure control, with success rates ranging between 80 and 100%.[94,95] However, a significant percentage of eyes in these series developed phthisis and other serious complications, leading to final graft failure.[96]

A number of advanced techniques have been reported, which avoid the disadvantage of affecting structures adjacent to the ciliary body. The procedures are usually based on one of two principles: the implantation of aqueous shunts (as was described by Molteno,[96] Schocket et al,[98,99] and other authors[98–100]) or the elective application of contact or noncontact laser energy, such as trans-scleral neodymium : yttrium–aluminum garnet (Nd : YAG) cyclophotocoagulation.[101,102] Transvitreal endophotocoagulation of the ciliary processes[103] potentially provides similar success rates in achieving pressure control, but with fewer complications.

Trabeculectomy with antimetabolites performed at the time of penetrating keratoplasty can successfully control IOP.[93] Although glaucoma may be controlled with a glaucoma drainage device, the presence of a shunt predicts a poor long-term graft prognosis and is an independent risk factor of graft failure.[61]

Determining which technique to apply is an individualized decision. Surgical intervention of any kind following penetrating keratoplasty can be detrimental to graft survival. When intraocular pressure is controlled poorly with all types of therapy, regrafting may be contraindicated.[52]

Herpes simplex keratitis

Herpes simplex may cause primary graft failure even in the absence of prior known herpetic disease. One recent study found evidence of HSV DNA in 33% of cases of primary graft failure.[104] The source of this may be latent viral infection of either the host or the donor.

Recurrence of herpetic keratitis (Fig. 48.5) after keratoplasty ranges from 15 to 47%.[42–44,105–107] Although a history of preoperative inflammation does not appear to influence graft survival rate or the incidence of recurrent herpes keratitis in the graft,[42] grafts performed during active recrudescence may be complicated by defective wound healing, a flat anterior chamber, anterior synechiae, or glaucoma.[44,101,107–109] Ideally, keratoplasty should be postponed until the herpes keratitis has been quiescent for an extended period (6 months).[4]

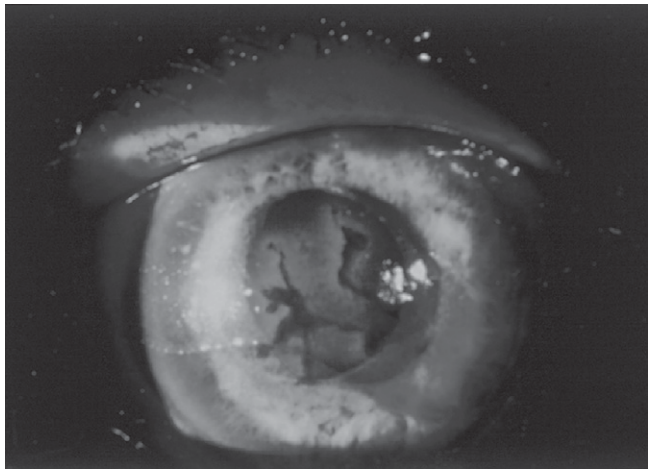

Figure 48.5. Recurrent herpetic dendrite 20 years after keratoplasty.

Allograft reaction may be difficult to distinguish from recurrent herpetic disease.[21] If the typical dendritic ulcers are not clinically apparent, it can be impossible to define the phenotype of corneal reaction, even with diagnostic methods such as rose bengal staining.[109] Fine and Cignetti[43] indicate that large keratitic precipitates in the presence of corneal edema with donor and recipient cornea involvement probably represent recurrent herpetic disease. Because these precipitates are not pathognomonic,[42] the authors recommend treatment with both topical steroids and topical antivirals. Ficker and coworkers[42] determined that rejection episodes complicated 23% of herpes recurrences, indicating that immunologic rejection can be induced by herpetic inflammation. Older studies[43,44] indicated that 50–60% of corneas with herpes recurrence develop graft failure.

Rejection rates are higher in grafts performed for herpetic disease, 29% at 1 year and 46% at 2 years in one recent study, but with reasonably optimistic graft survival rates of 84% at 1 year and 67% at 2 years.[106]

Topical steroids and antivirals have improved graft survival in herpetic keratoplasty. Ficker and coworkers[42,105] found long-term survival rates up to 70% over a follow-up period of 10 years, with herpes recurrence accounting for less than 20% and immunologic rejection representing the major cause of final graft failure. Similar tendencies are reported for repeat herpes simplex keratoplasties. Although subsequent regrafting usually decreases the overall survival rate,[42,105] one study reported decreasing regraft percentages of about 50% in the 1970s,[44] 22% in the 1980s,[51] and 6% in the 1990s.[110] This decline was ascribed to the improved medical treatment of herpes simplex keratitis.[111]

Prophylactic use of antiviral medications after keratoplasty for herpes simplex keratitis is common, and the literature reports support a beneficial effect of topical[111] and systemic[112,113] long-term treatment with trifluridine and acyclovir following penetrating keratoplasty.[111] Antiviral prophylaxis reduces the recurrence rate of herpes simplex, as well as the incidence of corneal graft failure. More recent studies have emphasized systemic prophylaxis over topical, and the authors use only systemic prophylaxis.

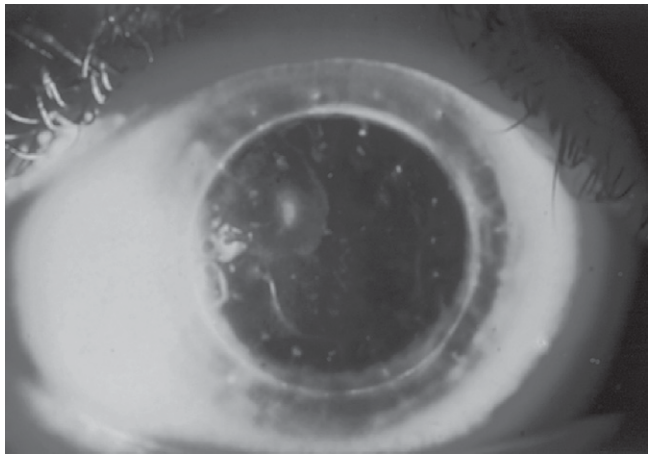

Figure 48.6. Recurrent hereditary stromal dystrophy after keratoplasty.

Recurrent corneal dystrophy

The recurrence of hereditary stromal dystrophy (Fig. 48.6) after keratoplasty has been reported in Reis-Bücklers',[114] granular,[115] lattice,[116,117] and macular dystrophies.[118,119] Recurrences occur most commonly in grafts for lattice dystrophy, with 25–48% of these grafts demonstrating recurrence within 25 years.[117,120] Regrafting may be necessary in 15% of patients in whom primary corneal transplantation has been performed.[117] Phototherapeutic keratectomy has been successfully employed on recurrent corneal dystrophies after penetrating keratoplasty.[121]

REGRAFT INDICATIONS, SURGICAL CONSIDERATIONS, AND VISUAL PROGNOSIS

INDICATIONS FOR REGRAFTING

Primary graft failure

Corneal grafts with gross stromal edema and large broad folds immediately after keratoplasty should be suspected of having endothelial decompensation. Intensive topical steroids may be of some benefit, but if no reversal is noticed within several days, irreversible graft failure is inevitable, and regrafting within 3 months is recommended. Stromal edema may also be caused by ocular hypotony, which may clear when ocular hypotensives are discontinued and intraocular pressure increases.

Graft rejection

Despite evidence that the risk of allograft rejection is increased with repeat keratoplasty, advances in corneal preservation techniques, operating methods, and medications have improved the prognosis for high-risk keratoplasty substantially. With advances in topical and systemic immunosuppression, even the small population with a history of multiple graft failure may enjoy useful vision because prolonged periods of graft survival can now be achieved.

Recurrence of host disease

Although many grafts with recurrent herpes keratitis remain clear, 23–30% require regrafting.[42,51] Recurrent corneal dystrophy, particularly lattice dystrophy, may reduce graft clarity.[117] A soft contact lens is usually of some benefit in reducing epithelial erosion symptoms; however, some patients require regraft.

CONTRAINDICATIONS FOR REGRAFTING

Uncontrolled glaucoma

An eye with increased intraocular pressure that is uncontrolled by medical or surgical therapy will likely have difficulties after a keratoplasty procedure. Before surgery, the pressure should be controlled through cyclocryotherapy, shunt, or filtering procedures, if necessary. In desperate situations, penetrating keratoplasty combined with a filtering procedure may be justified.

Inadequate tear function

Eyes with severe keratitis sicca or severe cicatrizing diseases should be considered for keratoplasty only rarely. The postoperative prognosis for these eyes is extremely poor.[36,78,79] If keratoplasty is attempted, tarsorrhaphy and punctal occlusion may be necessary to enhance the surface lubrication postoperatively.

Unsatisfactory lid margins

Trichiasis, ectropion, entropion,[122] extensive symblepharon, and scarred lid margins[80] are relative contraindications for keratoplasty. These conditions should be corrected before keratoplasty is undertaken.

SURGICAL CONSIDERATIONS

Principles

Fine states that two principles must be considered before regrafting is undertaken:[49]

1. The graft should be sized so that its margins lie in the most normal tissue, whether recipient or donor.
2. The graft margin should not be in proximity to the limbus.

The corneal surgeon should avoid successive increases of the donor size with each regraft. If the recipient bed includes a previous donor of excessive diameter and the tissue is of sufficient consistency, a penetrating keratoplasty may be performed within the boundaries of the original donor.

Suture technique

In the CCTS, the risk for rejection failure increased considerably for eyes with interrupted sutures as compared with eyes with a running suture,[36] but this could be because interrupted sutures are often used in grafts that have a poorer prognosis to begin with. Interrupted sutures are recommended in highly vascularized recipient beds that promote inflammatory responses during the early postoperative period, allowing selective suture removal when necessary.

VISUAL PROGNOSIS

Although it is difficult to compare visual acuity data across studies, the overall impression is that regrafts lead to improved visual outcomes.[123] Studies with prolonged follow up report clear regrafts at 2 years ranging between 64 and 85%, and for 5 years from 46 to 53%.[32,51,53,110,123,124] Rapuano and coworkers found a visual acuity of 20/20 to 20/40 in 32%, 20/50 to 20/100 in 40%, and 20/200 to 20/400 in 21% of regrafted patients.[110] Statistical analysis of this cohort revealed a relative accumulation of rejection failures within the first 18 months, whereas later onset of graft failure was decreased significantly.[51] It appears that regrafts that remain clear for a certain initial time period have excellent overall visual and survival prognoses. The long-term stability of corneal (re)grafts

confirms the idea that chronic rejection pathways do not contribute to functional graft declines, as was reported by researchers on solid organ transplantation. Specific investigations of this issue have not been reported.

REGRAFTING: DESCEMET'S STRIPPING ENDOTHELIAL KERATOPLASTY

Regrafting was the leading indication for PK in a recent study[125] accounting for 40.9% of all grafts performed. In the regraft subgroup of this study, endothelial failure was the most common indication. A new option has emerged for the management of regrafting due to endothelial failure: endothelial keratoplasty. DSEK surgery removes or strips the host's diseased Descemet's membrane and transplants donor Descemet's membrane with a small amount of posterior stroma.[126] When DSEK is performed for endothelial failure in a graft, the stripping of Descemet's membrane is omitted to prevent excess traction at the old graft–host junction. New posterior lamellar host tissue is positioned posterior to the old graft which is left in place unaltered.

Fig. 48.7 demonstrates a DSEK performed for graft failure. This patient was a 76-year-old male who was 3 years postop traditional keratoplasty for pseudophakic bullous keratopathy, now with endothelial failure. Preoperative best-corrected visual acuity (BCVA) was 20/400 and pachymetry was 0.938 mm. Ten weeks postoperatively, BCVA was improved to 20/60 despite history of a vein occlusion and glaucoma treated with a tube shunt.

The benefits of electing DSEK over full-thickness traditional keratoplasty for Fuchs' dystrophy or pseudophakic bullous keratopathy are superior tectonic strength, no induced astigmatism, and no corneal sutures. When DSEK is performed secondarily after a full-thickness graft has failed, it still offers the benefits of a sutureless graft that does not introduce astigmatism. Additionally, the immediate postop tectonic strength is more secure than if the full-thickness graft had been replaced. However, there is no reduced risk of rejection.

At this time it is not clear that regrafting by DSEK is preferable to full-thickness regrafting. DSEK can be considered as an alternative for regrafting, especially in candidates at risk of falls and trauma, as the smaller wound in a DESK may likely offer a lower risk of postoperative dehiscence.

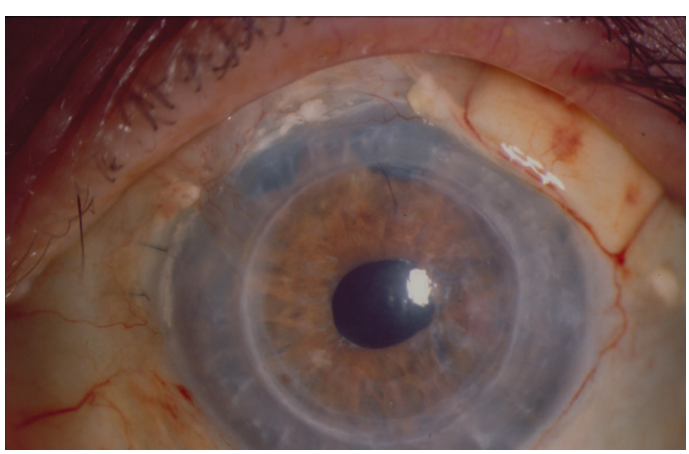

Figure 48.7. Regrafting with DSEK: photograph taken 10 weeks postoperatively.

APPROACHES FOR THE PREVENTION OF CORNEAL GRAFT REJECTION

Immunologic rejection remains the most common cause of corneal graft failure, particularly within the first 6 months following transplantation.[3,50,127] Although the primary corneal allograft enjoys a certain degree of immune privilege,[128] which is thought to be promoted by passive anatomic sequestration (avascularity) and active mechanisms that downregulate the number of attacking T lymphocytes by inducing apoptosis (Fas/FasL-System),[129,130] evidence has accumulated that the effector mechanisms responsible for corneal graft rejection are not principally different from those described for vascularized solid organ transplantation.[48,130,131]

The Cornea Donor Study, currently in progress, is again exploring the benefits of blood group compatibility in corneal transplantation. Until now, many studies have shown that in high-risk grafts, rejection is lower if there is ABO matching,[58,132] but the differences have often been statistically insignificant or simply not present in the case of low-risk grafts.

49 Pediatric keratoplasty

Gerald W. Zaidman

Visual and surgical results in pediatric penetrating keratoplasty have seen significant improvement. At one time, corneal transplantation in children was considered to have a very high chance of failure and was contraindicated.[1,2] Advances in surgical technique and postoperative care now enable surgeons to frequently obtain a clear transplant in an infant or a child. Currently, prompt penetrating keratoplasty is the first step in averting irreversible loss of visual function due to amblyopia.

Corneal surgeons understand that many aspects of an infant's or a child's preoperative, intraoperative, and postoperative care differ from those of an adult undergoing a corneal transplantation. The difficulty in assessing the visual function of an infant or a young child, a child's inability to cooperate with the eye examination, and the great variability in outcome make the physician's decision regarding surgery more difficult than in an adult. It is for these reasons that these children are amongst the most challenging for corneal surgeons.

INDICATIONS

In North America the most common cause of a congenital corneal opacity is one of the anterior segment dysgeneses.[3–7] This is a group of disorders comprising Peters anomaly (Types I and II) (Figs 49.1 and 49.2), sclerocornea (Fig. 49.3), corneal dermoid (Figs 49.4–49.8), and congenital anterior staphyloma (Fig. 49.9). This group makes up nearly 60% of congenital corneal opacities in North America. The next most common cause is congenital glaucoma (Figs 49.10 and 49.11), comprising 10–15% of the patients. The third group, also consisting of approximately 15% of the patients, is the congenital corneal dystrophies (Figs 49.12 and 49.13). This includes congenital hereditary endothelial dystrophy, congenital heredity stromal dystrophy, and posterior polymorphous dystrophy. Finally trauma, infection, and metabolic and genetic disorders make up less than 10% of the patients.

Acquired pediatric corneal opacities (Figs 49.14–49.19) can be divided into two groups—acquired nontraumatic or acquired traumatic.[5,6] These two groups, separately, are less common than congenital corneal opacities. Although the etiologies in all three groups of children with corneal opacities are different, the difficulties in managing these children are similar.

DIFFERENTIAL DIAGNOSIS OF PEDIATRIC CORNEAL OPACITIES

Congenital

- Peters anomaly (Figs. 49.1 and 49.2)
- Sclerocornea (Fig. 49.3)
- Corneal dermoids (Figs. 49.4–49.8)
- Congenital anterior staphyloma (Fig. 49.9)
- Glaucoma with corneal edema (Figs. 49.10 and 49.11)
- Congenital corneal dystrophies (Figs. 49.12 and 49.13)
- Metabolic

Acquired, nontraumatic

- Herpes simplex keratitis (Fig. 49.14)
- Microbial keratitis (Fig. 49.15)
- Keratoconus
- Neurotrophic keratitis
- Interstitial keratitis
- Ophthalmia neonatorum

Acquired, traumatic

- Corneal or corneoscleral laceration
- Birth trauma (Figs. 49.16–49.19)
- Nonpenetrating injury with scar

SURGERY

PREOPERATIVE EVALUATION

The diagnosis and treatment plan are made after an office visit, family history, consultation with a pediatrician (to rule out systemic, genetic, and metabolic disorders) and pediatric ophthalmologist, and most importantly an examination under anesthesia (EUA). An EUA is done on all children with congenital corneal opacities and on many younger children with acquired opacities.[8] This is the most

accurate way to do a complete eye examination including slit-lamp examination and tonometry. During the EUA, the corneal diameter is measured and A-scan and B-scan ultrasonography are performed. At the same time refraction, VER, ERG, or ultrasound biomicroscopy can be done.[9,10]

After the EUA is performed and before surgery is scheduled, the parents are extensively counseled regarding the risks of surgery. They are taught the difference between surgical success (clear graft) and visual development. We teach the parents about amblyopia and its treatment. Finally, we tell the parents that the goal is functional and ambulatory vision and that they should not expect perfect vision.

Before surgery is scheduled one more factor is considered—the child's social situation. Supportive and motivated parents or caregivers are a necessity. In an unstable social environment surgery is doomed to fail and should not be undertaken.

Finally, intraocular pressure control is required before corneal transplant surgery. In my experience, except in patients with congenital glaucoma, if the untreated intraocular pressure is less than 30 mmHg it can usually be controlled medically. Patients are treated with prostaglandin inhibitors, beta blockers, or topical or systemic carbonic anhydrase inhibitors. Alphagan is not used because of reports of pulmonary side effects in infants. If medical control is unsuccessful glaucoma surgery is required prior to penetrating keratoplasty (PKP). Filtering surgery is generally preferable to tube shunts.[11]

TIMING

Because of the small size of the neonatal eye and the high risk of intraoperative complications, a PKP for a congenital corneal opacity is not done before the child is 2 months of age. In an ideal situation, the child is first seen in the office at 7–14 days of age. The EUA is scheduled for 3–6 weeks of age. In a unilateral congenital corneal opacity, the corneal transplant is then done at 8–12 weeks of age. With a bilateral opacity surgery, the first eye is done between 2 and 3 months of age. In bilateral cases, the more severe eye is not necessarily done first. Because of the risk of amblyopia and the need for the child to develop vision, the less severe eye is often done first. In bilateral cases, the second eye is usually done 6–8 weeks after the first. This allows at least 4 weeks of postoperative care to remove sutures, control glaucoma, avoid infection, and validate parental compliance. Once these have been accomplished, the second eye is done. For an acquired corneal opacity in an older child, surgery is performed once the eye has stabilized and all inflammation has resolved.

TECHNIQUE

Surgery is done under general anesthesia. A pediatric lid speculum is inserted, and a scleral support ring is sewn to the sclera with interrupted 7-0 silk suture. A weight-appropriate dose of intravenous mannitol (25%) is given before surgery commences, and all children are hyperventilated by the anesthesiologist.[12] Donor tissue is obtained from donors between 4 and 18 years of age. The recipient corneas are trephined between 5.0 and 7.0 mm, and the donor between 5.5 and 7.5 mm, thereby consistently creating a 0.5 mm difference between donor and recipient corneal buttons. The anterior chamber is entered with a 15° angled knife and reformed with a viscoelastic. Viscoelastic or a spatula is used to lyse any synechiae between the iris and the cornea. During these maneuvers, any bleeding can usually be controlled by sodium hyaluronate, topical epinephrine drops (in a concentration of 1/10000), gentle pressure, or microcautery to the bleeding vessels. Excision of the recipient corneal button is performed with pediatric corneal transplant scissors (STORZ E 3230 R, L). During excision of the patient's cornea, infants and children can develop significant amounts of positive pressure. The surgeon has to be experienced in handling this to avoid loss of the lens or vitreous loss. Grafts are sutured into position with 12–16 interrupted 10-0 sutures. All suture knots are buried. A subconjunctival injection of 0.5 mL of gentamicin (40 mg/mL) and 0.5 mL solumedrol (40 mg/mL) is given at the end of the procedure. At the end of surgery indirect ophthalmoscopy can be performed.

POSTOPERATIVE REGIMEN

Routine postoperative care includes a topical antibiotic four times a day, aggressive topical corticosteroids, and glaucoma therapy as needed. A topical corticosteroid (prednisolone acetate 1%) is used 10 times a day for the first month after surgery, 8 times a day for the second month, 7 times a day for the next month, and then tapered by one drop per month, every month (6 times/day for 1 month, 5 times/day for 1 month, etc). Therefore, patients are treated with topical corticosteroids for a minimum of 10 months after surgery.

For the first month after surgery patients are examined 2–3 times per week. In the second postoperative month, office examinations are done weekly (or more often if necessary). Office examinations are then slowly decreased from a frequency of once every 2 weeks to once every 6–8 weeks. Examinations under anesthesia are frequently performed, initially in the operating room and occasionally in an office setting (under chloral hydrate sedation) as needed. The first EUA is 2–3 weeks after surgery and then repeated in the operating room every 2–3 weeks until all sutures are removed. For infants all sutures are usually removed by 6–10 weeks postoperatively (see below). Office EUAs are usually done every 3 months using a portable slit lamp and a pneumotonometer or tonopen. Finally, parents are instructed as to how to examine the grafted eye (with a light and a magnifier) to note any signs of a loose suture or a graft rejection.

Both before and after all the sutures have been removed, patients are examined by a pediatric ophthalmologist, who dispenses a spectacle correction and a regimen for patching the unoperated eye. In patients with unilateral disease, patching is done for approximately 6 h/day. In bilateral cases, the second eye has surgery 2 months after the first eye and the same postoperative routine is followed.

Finally, the parents are warned that the graft is at risk whenever the child develops any severe febrile illness or is to be vaccinated. At these times, the corticosteroid drops are increased in frequency for a short time. For example, vaccinations are delayed until 1 year after surgery. When it is time to vaccinate the child the corticosteroid drops are increased to four times a day for 1 week before and 1 week after the vaccination.

SUTURE REMOVAL

For children who have their corneal transplant during their first year of life, sutures are removed by 5 weeks after surgery, in 1-year olds within 6–7 postoperative weeks, in 2- and 3-year olds by 3–4 postoperative months, in 4–6-year olds within 4–6 months, and in 7–10-year olds at 5–6 months postoperatively.[13,14] Patients 10–18 years of age are treated the same as adults.

CONCOMITANT SURGICAL PROCEDURES

If the lens is cataractous, adherent to the cornea, or abnormal in size or location, it is removed. If possible a standard extracapsular cataract extraction is done, the posterior capsule is kept intact, and a surgical capsulotomy is done at a future time. If the posterior capsule breaks (or if the lens is small or subluxed) then a generous anterior vitrectomy is performed. If cataract surgery is required, heparin, 2500 units in 500 cc, and epinephrine is added to the irrigating bottle.

A peripheral iridectomy is indicated if there are posterior synechiae to a clear lens. This is also performed when lensectomy and vitrectomy are undertaken.

Because of the high risk of intraoperative complications, it is not advisable to do a corneal transplant on a child's eye with uncontrollable glaucoma. The intraocular pressure should be controlled prior to transplant surgery. If medical control is not possible, a filtering procedure is done a few weeks prior to the transplant. Glaucoma tube shunts are not generally used because of the potential risk to the clarity of the lens or cornea.[11]

ALTERNATIVES TO PENETRATING KERATOPLASTY

Some children with corneal opacities can be treated without a PKP. These alternative operations consist of an optical iridectomy, rotating keratoplasty, or lamellar keratoplasty.[15–18]

The first two can be used when the child has a peripheral opacity that just impinges on the visual axis. Surgically enlarging the pupil (in an optical iridectomy) or moving the scar out of the way (rotating keratoplasty) can enable the child to see around the opacity.

In some children, especially those with corneal dermoids or scarring from corneal ulcers, the corneal opacity is not full thickness and the posterior cornea is relatively clear. In these cases, the opacity can be removed with a lamellar dissection. The lamellar dissection can be done manually or, as has been recently reported, using the microkeratome.[19]

The main problem with any of these three procedures is that they can result in unpredictable amounts of astigmatism. Also interface haze may be present after a lamellar graft, preventing the development of 20/20 vision. However, since a lamellar procedure is an extraocular procedure and not a full-thickness procedure, it lessens the chance of a wound dehiscence. It also eliminates the risk of an endothelial graft rejection.

OPTICAL CORRECTION AND AMBLYOPIA THERAPY

Without effective optical correction and amblyopia therapy, a pediatric PKP may be of limited benefit. Therefore, co-management with a pediatric ophthalmologist is mandatory in all children who have corneal transplants. Amblyopia can be reversed in younger patients if treated promptly and appropriately.

Correction of refractive error is a vital part of amblyopia therapy. At about the second postoperative week, the epithelium has generally healed and the graft has cleared sufficiently to perform cycloplegic retinoscopy. Retinoscopy may be difficult, and the refraction will change as the wound heals and sutures are removed, but the correction of a moderate and large refractive error can be prescribed at this time. The refraction should be repeated periodically until the sutures have been out for several months. Refraction of an aphakic eye can be confirmed if the axial length is known. The following formula is an approximation for an aphakic eye and assumes a keratometry measurement of 45 D and a vertex distance of 10 mm:

$$\text{distance spectacle power} = 63.7 - (2.28 \times \text{axial length in mm})$$

The results from this formula can be modified by keratometry measurements. For an aphakic eye, an infant is generally prescribed a near correction, which is +1.00 to +2.50 D sphere over the distance correction. The aphakic child should be put in a bifocal, with the top of the segment at the inferior border of the pupil. Contact lenses are also useful in visual rehabilitation of pediatric keratoplasty patients, especially in monocular aphakes. Silicone lenses offer the highest oxygen permeability of all lenses and are often well tolerated in aphakic patients with normal corneas.

If the contralateral eye is normal, occlusion therapy should be started as soon as the graft is partially cleared and correction of any refractive error is being worn. Ideally, this should not be later than 2 postoperative weeks. Occlusion during the first 6 months of life is usually limited to one-fourth to three-fourths of infant's waking hours. If the child is older than 6 months, full-time occlusion therapy can be started. The vision in both eyes is monitored carefully to check for improvement of the amblyopic eye or worsening of the normal eye.

RESULTS

For many years, ophthalmologists believed that the results of PKP in children were poor and surgery was doomed to failure. In earlier, now outdated, studies done between the 1970s and the early 1990s, a graft clarity rate of between 29 and 75% was reported after corneal transplant surgery for congenital corneal opacities. In these studies, the average graft survival was 49%.[5] Patients with grafts for acquired traumatic or acquired nontraumatic disorders generally did better with a graft clarity rate of between 64 and 81%.

Since then, with improved surgical techniques and better peri- and postoperative care, the success rate has improved. For example,

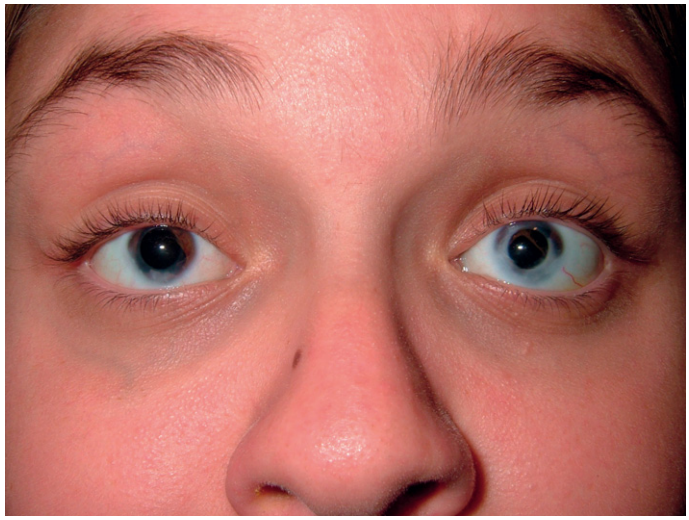

Figure 49.20. Postoperative photo of a teenager 15 years after bilateral PKP for Peters anomaly Type I.

Figure 49.21. Higher-power photo of Figure 49.20.

in our study of children with traumatic corneal lacerations, clear grafts were obtained in all of the patients and all had improved visual acuity.[20] Similar excellent results were obtained in other studies[21] with visual improvement in more than 80% of children. Frueh and Brown in 1997[22] determined that the probability of a clear graft is 75% in 1 year and 58% at 2 years in children with congenital corneal opacities. Dana et al in 1997[23] reported 61% graft clarity at 38 months after surgery in a diverse group of children. Yang et al in 1999[24] reported that about 50% of all grafts done in children with Peters anomaly were clear 1 year postoperatively. The authors of this paper also gave us a 'profile' of an eye with a clear graft. It had mild-to-moderate disease, a donor cornea less than 8 mm, a running suture and no intraoperative lensectomy, vitrectomy, or retinal detachment. Comer et al in 2001[25] reported a 61% rate of graft clarity in infants with a variety of disorders. Michaeli et al in 2005[4] reported clear grafts in 88% of their patients with Peters anomaly 1 year after surgery.

Our surgical techniques and our perioperative and postoperative care have been modified and designed using knowledge gained from these prior studies. Since 1988, the author has operated on 30 eyes with Peters anomaly Type I. These patients have been followed an average of 6.5 years; many of them are now more than 3 years of age and their vision has been tested (Figs 49.20 and 49.21).[26] A graft clarity rate (including regrafts) of 90% has been achieved in these patients. More than 50% of the patients have achieved vision of better than 20/100 and two-thirds were 20/400 or better. In this group of patients, the major risk factor for graft failure or poor vision was poorly controlled glaucoma (as has been shown by other authors).[27]

CONCLUSIONS

Although the prognosis still remains somewhat guarded, corneal transplant surgery can be successful in children with acquired or congenital corneal opacities. After surgery, useful vision can develop in these patients, especially in the absence of glaucoma or, if glaucoma is present, it is either transient or easily controllable with medical therapy.

Corneal surgeons can advise the parents of infants and children who require corneal transplant surgery that their children have a good chance of graft clarity if they are intensively managed (with frequent examinations, high-dose topical corticosteroids, and aggressive control of glaucoma) during their peri- and postoperative period. Furthermore, if the amblyopia is aggressively co-managed with a pediatric ophthalmologist, more than 50% of them can develop good or functional vision.
