**MARS:** The SPAD method was further developed into a combination of dialysis, filtration and adsorption (= **m**olecular **a**dsorbent **r**ecycling **s**ystem). (103). The patient's blood is fed through a hollow-fibre filter and dialyzed against an albumin dialysate. The ABS (s. tab. 20.5) pass through the pores in the filter and become bonded. Plasma proteins, hormones and vitamins are not lost. The albumin dialysate is recirculated in a closed circuit where it is fed through a second dialyzer and two adsorber columns which bind the ABS. The albumin dialysate is returned to the hollow-fibre filter. It is dialyzed against a bicarbonate solution in order to remove the excess water and water-soluble substances (ammonia,

creatinine, urea, iron, copper) as well as to stabilize the electrolyte and glucose levels and the pH value. The results obtained to date are promising. (93, 101, 104) (s. fig. 20.4)

*Fig. 20.4:* Diagram showing the molecular adsorbent recirculating system (MARS)

**FPSA:** **F**ractioned **p**lasma **s**eparation and **a**dsorption is a very efficient and multifactorial method, employing membranes and adsorbants. (86) It is additionally characterized by the use of microparticles (2.0−3.5 μm), which are recirculated in suspension using high-speed flow (2−4 l/min) to optimize the in-line filtration process. In a further development, a special sulfone filter is applied.

**Prometheus:** In the meantime, the Prometheus method has been introduced. (97) Here, the plasma is separated out by an albumin-permeable filter and cleaned in a secondary circuit via an adsorber together with conventional high-flux haemodialysis. Direct contact between the albumin plasma and the adsorber helps to increase the efficiency of this method.

► These liver support methods serve to detoxify the organism for a limited period of time. They are regarded as **supportive measures** in intensive care. Survival time has often been prolonged, yet only in isolated cases has the overall life-span of the patient been extended. These methods of treatment, which are costly and involve considerable resources, can only be carried out in medical units that are equipped with all the facilities of intensive care and thus in a position to effect epidural brain pressure measurement, blood purifying processes and liver perfusion methods. • Only young patients between the ages of 15 and 25 have a real chance of survival (40 to 50%), provided they receive optimum intensive care. With patients over 30, supportive techniques should only be applied to bridge the time period until a liver transplantation can be carried out.

However, **conservative treatment** may be attempted for 4 or 5 days under the following conditions irrespective of *age*: (*1.*) there may be a chance of regeneration during this period that can be made use of; (*2.*) this period of time does not preclude the patient's chances of liver transplantation (which generally calls for 2 to 4 days' preparation time); (*3.*) should there be no signs of recovery or regeneration, not even in younger patients (< 30 years), transplantation is nevertheless indicated. • After 4 or 5 days, however, severe *complications* develop, also

in younger patients, which render transplantation difficult or even impossible. Especially, older patients (> 30 years) should always undergo liver transplantation without delay.

### 5.3.2 Bioartificial systems

**Temporary substitution** of the liver function using hepatocytes (e.g. in haemofiltration systems or bioreactors) is conceivable in acute liver failure, possibly in conjunction with activated charcoal filtration or with plasma separation. The importance lies in bridging the phase of acute liver failure until compensation of the liver function or liver regeneration is achieved.

The bioreactor is filled with capillaries in which the patient's blood circulates; some of this blood has already been oxygenated extracorporeally. The efficacy of the system depends on an efficient exchange of the corresponding substances in both directions as well as stable hepatocyte functions. It is possible to use human (allogeneic) or animal (xenogeneic) hepatocytes as well as cell cultures (immortalized cells or tumour cell lines). If human cells are taken, $10^{10}$ hepatocytes per patient are required − as would be needed for a conventional liver transplant. With regard to the use of animal hepatocytes, there is a possible risk in that no solution has yet been found to the question of zoonosis transmission and there may be an immune reaction to foreign antigens. Bile flow also remains a problem. (90, 98, 99, 107, 108)

1. The so-called "artificial liver" system was first developed by K. N. Matsumura et al. (1978). This procedure comprised haemodialysis across a **suspension of vital hepatocytes.** • Such semi-artificial liver was first used clinically in 1987 on a patient with bile-duct carcinoma and acute liver failure (K. N. Matsumura et al.).

2. The binding of microsomal **liver enzymes to synthetic carriers** is a promising method of temporarily compensating important liver functions (G. Brunner, 1981).

3. **Bioartificial liver (BAL):** Freshly isolated hepatocytes of pigs, immobilized on collagen-coated microcarriers, remained vital invivo and in-vitro over a longer period of time in a perfusion system; they were able to conjugate bilirubin and synthesize proteins. These results provided the basis for developing an extracorporeal bioartificial liver (A. A. Demetriou et al., 1986). In more advanced systems, plasma was perfused through an activated charcoal column and a fibre system with cultured pig liver cells. (90, 95, 98, 108) • With the help of a BAL, the plasma is separated by centrifugation and directed into a reservoir in order to increase both the plasma and metabolite flow. By integrating an activated charcoal column, it is possible to effect a greater elimination of toxins. The separated plasma reaches the hollow-fibre bioreactor, where it is perfused through the previously inserted hepatocytes (7 ± 1 hours). • Such a system yielded increased production of coagulation factors in a patient with alcohol cirrhosis (D. F. Neuzil et al., 1993). (s. fig. 20.5)

4. **Extracorporeal liver assistance device (ELAD):** Attention has recently focused on temporarily replacing the liver function with hepatocytes which have been cultured in the extracapillary space of a cellulose-acetate hollow-fibre unit. Each unit contains ca. 200 g C3A cells, an amount which is necessary for successful perfusion. ELAD has proved efficacious in clinical use. (106)

**Fig. 20.5:** Diagram showing a bioartifical liver (BAL) (98)

5. **BLSS:** The **b**ioartificial **l**iver **s**upport **s**ystem is made up of a blood pump, a heat exchanger to control the blood temperature, as well as an oxygenator and a bioreactor. The hollow-fibre bioreactor generally contains 70−100 g of porcine liver cells. Initial experience with BLSS is encouraging. (92)

6. **BELS:** The **B**erlin **e**xtracorporeal **l**iver **s**upport system consists of a three-dimensional accumulation of approx. 500 g pig liver cells. These cells are linked by means of capillaries and provided with oxygen independently of the patient's blood, so that they function and stay vital for several weeks. (89)

**MELS:** The **m**odular **e**xtracorporeal **l**iver **s**upport system was developed from BELS. In contrast to BELS, however, it consists of three modules: (*1.*) a cell module with human hepatocytes, (*2.*) single-pass albumin dialysis and (*3.*) a dialysis module for constant venovenous haemofiltration. (100)

The clinical significance of bioartificial systems will largely be dependent upon whether it is possible (*1.*) to keep functional hepatocytes alive in extracorporeal systems for an adequate period of time and (*2.*) to make such systems available at short notice for use in emergencies.

### 5.3.3 Extracorporeal liver perfusion

The idea of extracorporeal liver perfusion (ECLP) for removing toxins by way of perfusion using an animal liver goes back to Andrews (1953), who used this technique for liver substitution in dogs. In 1958 J. J. Otto et al. applied this method and demonstrated a clear reduction in pathologically elevated serum ammonia values in the dog. • In 1965 B. Eiseman et al. first treated hepatic coma in humans by perfusion using a pig liver. • The use of baboon livers yielded further progress (S. Saunders et al., 1968; T. S. Lie et al., 1976). Treatment was reported to be successful in isolated cases. This procedure has been successfully taken up again, using human livers which, for medical or organizational reasons, could not be transplanted. • Vital pig livers are now also used. The fresh liver is kept in a sterile chamber where it receives the patient's blood via the portal vein and, if necessary, via the hepatic artery. There have been no reports of xenogenous infection or rejection. Although

the procedure is relatively safe, the results obtained with perfused livers from humans or baboons would appear to be better than is the case with livers taken from pigs.

## 5.4 Liver transplantation methods

Liver transplantation is the method of choice in all patients with acute liver failure whose spontaneous survival rate without a transplant is <20%, taking into account all the parameters. Criteria proposed by King's College or Clichy provide a useful basis for assessment. The crucial factor, however, remains the choice of the appropriate time for carrying out the transplantation: (*1.*) the possibility of eliminating decompensation by means of regeneration should be exploited; (*2.*) delayed indications should not result in complications which would prevent a transplantation from being carried out (e. g. brain-stem herniation, sepsis).

### 5.4.1 Orthotopic transplantation

▶ The **survival rate** following orthotopic transplantation in acute liver failure is 50 to 80% after 1 year and about 60% after 5 years. When the **indication** for transplantation is given, it is impossible to foresee to what extent the patient's life might be lengthened. The decision as to whether and when a transplantation is indicated continues to be arbitrary. The question of which patients will benefit most from transplantation is still unresolved − particularly since liver diseases are in general potentially reversible. However, acute liver failure due to Wilson's disease or the Budd-Chiari syndrome is an indication for liver transplantation, because these conditions are always lethal otherwise. Of all liver transplantations in Europe, a constant 10−12% are carried out due to ALF. In patients under the age of 45, this figure is 20%. Meanwhile, OLT has already been carried out on four adolescents for Ecstasy-induced liver failure. • With an isoelectric line in the electroencephalograph and with irreversible cerebral oedema, transplantation is no longer possible. The prognosis is likewise poor for decompensated liver insufficiency as a result of "acute-on-chronic failure" (e. g. acute virus infection or intoxication in cirrhosis), even after conservative and invasive intensive care therapy or indeed after liver transplantation. (20, 44, 109−111, 119, 120, 123, 124) *(see chapter 40.7)*

The following *criteria* are indicators for an **ultima ratio transplantation** in cases where the probability of survival without transplantation would be <20% (T. E. STARZL et al., 1989):

1. Foudroyant deterioration of the general state of health
2. Severe coagulation disorders
3. Coma stages III to IV
4. Metabolic acidosis
5. Liver atrophy
6. Circulatory insufficiency requiring catecholamines
7. Manifestation of septic multiple organ failure

**SLT: S**plit **l**iver **t**ransplantation was developed as an alternative to OLT (118). The transplanted split should be around 1% of the body weight of the recipient. SLT has a higher complication rate than OLT.

**LDLT:** With regard to **l**iving **d**onor **l**iver **t**ransplantation, SLT has become particularly important in cases where no cadaver organ is readily available. Living donor liver transplantation was first carried out on children. The left lateral segment, usually segments II and III, of the donor's liver is used. Around 5% of OLT candidates are also suitable for LDLT. More than 2,500 living donor liver transplantations have been carried out worldwide. The donor mortality rate is 0.2−0.3%. (115, 116, 122)

### 5.4.2 Auxiliary partial orthotopic liver transplantation

In 1991 auxiliary partial orthotopic liver transplantation (APOLT) was successfully carried out for the first time in acute liver failure, with the subsequent possibility of dispensing with the transplant after regeneration of the patient's own liver. (112) The corresponding part of a donor liver is transplanted orthotopically as left lateral segments II and III into the acutely diseased liver. The requisite partial resection of the liver is considered difficult. (121) A European multicentre study (12 centres) achieved equally good results in 30 patients compared to orthotopic liver transplantation with the removal of the native liver (M.-P. CHENARD-NEU et al., 1996). APOLT is intended as a temporary measure in acute liver failure with the aim of discontinuing immunosuppressive therapy after the patient's own liver has regenerated. So far, results imply that more complications are experienced in APOLT than in OLT.

### 5.4.3 Heterotopic transplantation

The concept of heterotopic transplantation of a complete or even partial ("spliced") donor liver should also be pursued further. Heterotopic transplantation involves placing an auxiliary (additional) organ in the right upper abdomen (O. T. TERPSTRA et al., 1988). In surgical terms, this technique is considered to be demanding due to the application of the piggy-back method (= anastomosis of the donor liver with the appropriately prepared ostium of the hepatic veins to the infrahepatic caval vein, generally cranial to the opening of the renal vein). • These two methods (APOLT and auxiliary heterotopic liver transplantation) are particularly suitable for juveniles with acute liver failure because they bridge the critical time span preceding the regeneration of the diseased liver. Immunosuppression is thus only required for a restricted period of time. The transplant shrinks or is surgically removed. Acute liver failure induced by Ecstasy was successfully overcome using this technique. (113) It allows the liver function to be compensated and gives the diseased liver time to regenerate. (117)

### 5.4.4 Xenotransplantation

Pigs with human immune system genes are expected to facilitate the production of transgenic donor organs (D. WHITE, 1992). This is the basis of all endeavours to use transgenic pig liver for the purpose of xenotransplantation (J. PLATT, 1993). In the future, genetic engineering should make it possible to eliminate the immunobiological risk of complement-activated, hyperacute rejection. However, the problem regarding the transmission of zoonoses has not yet been resolved. To date, a survival period of 70 days has been achieved with three xenotransplants in ALF and chronic liver insufficiency (J. FUNG et al., 1997).

## 5.5 Transplantation of hepatocytes

Liver cells were successfully transplanted for the first time in experiments on rats (A. J. MATAS et al., 1976; C. G. GROTH et al., 1977). The requirements for transplantation include absolute care in the

production of an adequate quantity of **vital liver cells** of utmost purity as well as the possibility of cryopreservation and in-vitro culturing. The cells are injected locally into the implantation area or infused selectively into the organ through a vascular catheter. Special adhesive-supporting substances can be used in this process (agarose gel, micro-encapsulation into thin membranes, etc.). (125–130)

Among the experimentally tested **transplantation sites** are the spleen, kidneys, lungs, pancreas, peritoneum, greater omentum and fatty tissue. Up to now, the spleen has proved to be the most suitable. The transplantation of foetal liver cells into the spleen may even culminate in a liver lobule-like formation with bile ducts and veins – however, the functional results have (so far) been no better than with normal hepatocytes.

The question of the required **number of hepatocytes** has still not been resolved: the collapse of a certain liver function (e.g. normalization of factor VIII values in serum) can be compensated by a far lower number of hepatocytes than is the case with total liver failure (e.g. acute liver failure). Calculations made up to now have claimed that there are at least $10^7 - 10^8$ liver cells in partially resected liver parenchyma.

**Indications** for the transplantation of hepatocytes predominantly involve those liver diseases in which functional failures occur in the liver cells (not in the bile ducts). • Permanent transplantation would be indicated, for example, in order to eliminate *congenital metabolic disorders* of the liver cells. In this case, hepatocytes from the patient could be used, with subsequent elimination of the defect by gene technology, as well as hepatocytes from healthy donors. A few years ago, a therapeutic effect lasting for over one year was achieved for the first time in a girl suffering from the Crigler-Najjar syndrome (I.J. Fox et al., 1998). • Human hepatocytes are most definitely more suitable than animal liver cells. The latter may well meet the requirements for a provisional substitute, but not for permanent transplantation.

## Future prospects

► Looking to the future, it can be expected that the next few years will witness advances in gene technology (e.g. transgenic animal liver) and molecular biology (e.g. targeted blockade of the immune system against the liver transplant) or even produce new concepts of liver and hepatocyte transplantation.

► It is no longer too bold to pin legitimate hopes on the development of an artificial liver. The preliminary objective hereby must be to replace the most important liver functions for a longer period of time, thus affording the diseased liver of the patient a greater chance to regenerate.

# Clinical Aspects of Liver Diseases

## 21 Clinical and morphological principles

# 21 Clinical and morphological principles

## 1 Attempt at a systematic approach

Any attempt at setting up a systematic approach to liver disease has to incorporate the correlation between *morphological* and *functional* changes. At the same time, such an approach has to take account of *aetiological* and *pathogenic* factors. • However, any classification made is provisional by its very nature, since there is no uniform standpoint in this respect, and advances in medical knowledge can alter any such classification. (*see references* 2, 4, 9, 20)

### 1.1 Difficulties of systematization

► It must be borne in mind that only relatively minor morphological changes might be evident in functional liver insufficiency. • Moreover, apparently normal hepatic functions may also prevail despite pronounced morphological changes in the liver.

► Further consideration has to be given to the fact that different pathogenic factors may also trigger similar or even identical morphological changes as well as identical biochemical reactions.

The term **hepatopathy** (G. v. BERGMANN, 1936) (s. p. 74) − which cannot be defined precisely − must be viewed as a noble attempt to classify all liver diseases with their respective morphological and functional changes as one single entity. It should be noted that in those days there was little chance of making a detailed diagnosis of a liver disease during the patient's life.

### 1.2 Need for systematization

As early as 1947, H. KALK strongly emphasized the need to systematize liver disease in line with morphological aspects. Initially, his approach was founded on laparoscopic criteria, i. e. size, colour and superficial structures of the liver. • Pathohistological examination, however, is indispensable in the classification of most liver diseases. Liver diagnostics is based on four essential pillars, of which histology is still the most important and, in cases of doubt, the decisive factor in determining the diagnosis. (s. pp 75, 76)

Even though it is still difficult today to systematize liver diseases, any such attempt can be of help, providing it takes due account of the aetiology, the clinical picture and the morphological changes. This facilitates an overview of the different liver diseases, including their variants and complications, and makes for a better understanding of certain individual forms of disease and the way in which the various forms are interrelated.

## 2 Clinical forms of liver disease

### 2.1 Primary and secondary liver diseases

All liver diseases can be classified into two groups with diverse clinical, therapeutic and prognostic relevance:

1. Primary liver diseases
2. Secondary liver diseases

**Primary liver diseases**

The liver is primarily affected, and the involvement of the liver in the disease is paramount. A typical example would be acute viral hepatitis resulting from primary hepatotropic viruses. (s. tab. 5.16)

It is not possible to make a reliable *clinical* differentiation between the primary hepatotropic types of hepatitis; there are, however, certain distinctive hints derived from *histology* or immunohistology (e. g. HAV, HBV or HCV infection). Modern methods of *serology* and *immunology* render precise differentiation possible. • *Acute viral hepatitis does not exhibit any isolated specific morphological findings; it is the sum of the individual phenomena which results in the diagnosis.* (s. tab. 22.1)

**Secondary liver diseases**

The liver is secondarily affected by a systemic disease or shows a coreaction to extrahepatic organ processes. Involvement of the liver in the disease is not obvious. • Occasionally, the aetiology of the underlying disease can be diagnosed from liver biopsy material by means of characteristic morphological substrates or by the detection of pathogens. • In the majority of cases, these findings are ambiguous and are thus grouped together under the generic term "non-specific reactive hepatitis".

**Non-specific reactive hepatitis**

Concomitant hepatic lesions can occur as a consequence of a number of viral, bacterial, parasitic and mycotic infections as well as due to toxic effects. Owing to their ambiguity, however, these lesions do not allow closer aetiological specification. • *Therefore, the term "non-specific reactive hepatitis" is not actually considered to be a pathological entity in its own right.*

From the **pathohistological point of view,** the findings are (*1*.) degenerative liver cell changes with single focal liver cell necrosis, (*2*.) concomitant reaction of the Kupffer cells and formation of Kupffer cell nodules with a generalized reaction of the mononuclear phagocytosis system, usually inside dilated sinusoids, (*3*.) histiocytic and portal round-cell infiltration, and (*4*.) cholangitic reaction with sparse infiltrations of neutrophilic granulocytes around small bile ducts. (s. fig. 21.1)
**Fig. 21.1:** Non-specific reactive hepatitis in sepsis due to cervical lymph node abscess: sparse single cell necrosis and periportal inflammation

► The *pluriaetiological spectrum* involved in this condition already suggests the problematic nature of the generally accepted term non-specific reactive hepatitis. • The *confusion in terminology* is rendered all the more complex because the diagnosis of a non-specific reaction does not necessarily justify using the rather implicative term "hepatitis". • Moreover, an individual who is affected by non-specific reactive hepatitis cannot really be referred to as a "liver patient". We are also familiar with inflammatory secondary phenomena, such as leucocyte cellulations in alcoholic hepatitis or mesenchymal reactions due to drug abuse. In these cases, it can be equally problematic to apply terms like "non-specific", "hepatitis" or "liver disease".

This is why the **pathologist** will deliver a purely morphological description depending on the facts of the case, whereas it will be the task of the **clinician** to categorize these "non-specific" inflammatory secondary phenomena with respect to their aetiology and clinical significance.

## 2.2 Diffuse and focal liver diseases

In concordance with the morphological pattern associated with the liver condition, two further groups of diseases may be distinguished (s. tab. 4.1!):

1. **Diffuse liver diseases**
   The disease of the liver is largely diffuse; its occurrence can be either primary or secondary.

2. **Focal liver diseases**
   The liver only exhibits focal processes of disease, which may be primary or secondary and of non-specific or specific genesis.

**Diffuse liver diseases:** Certain *problems* with morphological definitions arise from the term diffuse liver disease. Individual cases present a genuine form of diffuse liver disease (e. g. in acute viral hepatitis), or portal-peri-

portal lesions of different degrees of diffusion are witnessed (e. g. in bacterial cholangitis), or there are intraparenchymal diffusely localized changes (e. g. in cases of listeriosis). • In diffuse liver diseases, the bioptic histological finding is representative in 80−100% of cases. (s. pp 157, 160)

**Focal liver diseases:** In contrast, it is frequently impossible to detect localized findings in the biopsy material, which is 1.5−2 cm in length and generally comprises up to 20 portal fields, especially since percutaneous biopsy can only reach a certain area of the right liver lobe. *Consequently, "negative" biopsy findings do not necessarily rule out the presence of localized hepatic changes!* (s. p. 160) • Larger focal lesions are detected by imaging procedures and can be assessed by guided biopsy, fine needle biopsy or laparoscopy.

## 2.3 Acute and chronic liver diseases

With regard to the time period involved in the course of a liver disease, distinction has to be made between two further groups, excluding the prodromal stage and the healing process (s. tab. 4.1) (s. p. 75):

1. **Acute liver diseases**
   In the individual case of acute liver disease, it is necessary to differentiate between *peracute* (i. e. *fulminant*), *subacute-necrotic* and *protracted* courses.

2. **Chronic liver diseases**
   Chronic liver diseases may show *protracted (subchronic)*, *"persistent"* or *"aggressive"* courses. The new classification of chronic hepatitis emphasizes its respective aetiology while at the same time categorizing the degree of inflammatory and necrotic activity as well as any fibrosis and additional changes in the hepatic architecture.

**Chronic liver disease** is characterized by inflammatory infiltrates and/or degenerative changes which have persisted for 6 to 12 months or longer; its prognosis is dubious. Chronic liver disease is thus defined by the following **triad:**

1. Prolonged course of disease (>6 months)
2. Inflammatory and/or degenerative morphological findings
3. Dubious prognosis
   − no general healing tendency
   − tendency towards progression
   − occurrence of complications

Chronic liver diseases (congenital or acquired) can be classified (schematically) into 10 groups depending on their **aetiopathogenesis.** However, due to the close spatial intercalation of the mesenchymal and epithelial hepatic systems, the transition between the groups is

fluent. As a result, chronic liver diseases can be classified according to their aetiopathogenesis as follows:

| | |
|---|---|
| 1. infectious | 6. vascular |
| 2. toxic | 7. cardiac |
| 3. autoimmune | 8. malignant |
| 4. metabolic | 9. haematological |

## 2.4 Aims of liver diagnostics

### 2.4.1 Rational and expedient diagnostics

A diagnosis can only be regarded as expedient (i.e. thrifty and economical) if it has been reached by rational (i.e. logical and targeted) measures. Any irrational form of diagnostics will always be too expensive, even if it appears to be economically reasonable or is indeed presented as being cost-effective. (s. p. 74)

### 2.4.2 Diagnostic and clinical issues

In nearly every single case, the main diagnostic and clinical issues can be resolved, provided all the necessary (rational) diagnostic channels are pursued. (s. p. 75) (s. tab. 4.1) • This always includes the major differential diagnoses of **hepatomegaly** *(see chapter 11)*, **jaundice** *(see chapter 12)* and **cholestasis** *(see chapter 13)*. It is likewise of great clinical importance to establish the aetiopathogenesis of **portal hypertension** *(see chapter 14)*.

▶ During the course of acute or chronic liver disease, it may be difficult for the liver to fulfill all biochemical tasks (s. p. 32) due to a profound impairment of its functional capacity. The result is inadequate functioning (= insufficiency) − this **liver insufficiency** is, however, still **compensated.** (s. pp 277, 381) In the individual case, just a few liver functions may be affected to varying degrees (= *partial insufficiency*), or the functions of the liver can be extensively impaired in their entirety (= *global insufficiency*). The condition of compensated liver insufficiency may go unnoticed both subjectively and clinically − it is generally only revealed by laboratory analysis of the liver function. At this stage, the liver is still capable of maintaining the viability of the organism. • For this reason, the state of compensated liver insufficiency must be stabilized and maintained by the patient, on the one hand by preventing damage and on the other hand by establishing the best possible living conditions.

▶ In the course of acute or chronic liver disease, the biochemical functions of the liver may be compromised indefinitely; the outcome is **decompensated liver insufficiency.** (s. pp 277, 381) (s. tab. 20.4) The stage of decompensation is synonymous with the onset of life-threatening complications. These mainly take the form of *hepatic encephalopathy* with transition to hepatic coma *(see chapter 15)*, *oedema* and *ascites* with imbalance of the electrolytes and the acid-base equilibrium *(see chapter 16)* through to the *hepatorenal syndrome (see chapter*

17*)*, the hepatopulmonary syndrome *(see chapter 18)* and/or the development of *coagulopathy* as well as *bleeding oesophageal varices (see chapter 19)*.

The clarification of the diagnosis and the various clinical issues provides **statements** on (*1.*) course of disease (regressive, stationary, progressive), (*2.*) success of therapy, (*3.*) healing process, and (*4.*) prognosis. (s. p. 75)

# 3 Basic morphological processes of the liver

Despite the tremendous scope of morphological changes in liver diseases, the *pathomorphological reactions* of the liver can be attributed to four main processes, which form the basis of **morphological diagnostics:**

1. Cell damage / degeneration (and sequelae)
2. Cell death / necrosis (and sequelae)
3. Regeneration
4. Fibrogenesis

*Pathobiochemical hepatic reactions* can likewise be classified (schematically simplified) into four main disfunctional mechanisms, which form the basis of **biochemical diagnostics:**

1. Enzymopathies
2. Cholestasis / jaundice
3. Metabolic insufficiency
4. Immune reactions

## 3.1 Cellular adaptation

### 3.1.1 Membrane hyperplasia

During the course of biotransformation (s. p. 53), the need for *cell adaptation* often goes far beyond the normal scope of physiological activity as a result of excessive strain. This can lead to **membrane hyperplasia** (or agranuloreticular hypertrophy) of the smooth endoplasmic reticulum. (s. pp 55, 524, 544) The result is a considerable increase in liver cell volume, so that **hepatomegaly** is even clinically detectable. (s. p. 210) This in turn may cause increased glycogen deposition suppression of the mitochondria and of the granular reticulum in the cell periphery as well as an extremely fine-grain or net-like cytoplasm which is seen to be more eosinophilic and brighter. • This form of biotransformational proliferation of the smooth endoplasmic reticulum is easy to distinguish from the virus-induced (inflammatory) form − e.g. by aldehyde-thionine staining or through localization in the liver lobule. • *Membrane hyperplasia will persist as long as there is a surplus of substrate and will regress once the substrate pressure is relieved.* (s. fig. 21.2)
**Fig. 21.2:** Adaptive changes of hepatocytes due to hyperplasia of the smooth endoplasmic reticulum. Several binuclear hepatocytes (BH). Small Kupffer cell nodule following cell necrosis (arrow)

### 3.1.2 Hyaline drops

*In long-standing membrane hyperplasia, the affected membranes show regeneration and degradation.* Electron microscopy reveals them to be so-called cytoplasmic whorls, and light microscopy displays them as pale eosinophilic, occasionally layered homogeneous hyaline drops. • When persistent for a long period of time, this (physiological) cellular adaptation may gradually take on the form of cellular damage.

### 3.1.3 Lipofuscinosis

*The peroxidation of unsaturated fatty acids from membrane hyperplasia remnants can cause lipofuscinosis.* This consists of fine-grained, iron-free, yellowish-brown polymeric residual bodies (phospholipid protein complexes) within the lysosomes. These pigments are principally found in perivenular hepatocytes, in particular at the biliary pole (= pericanalicular). Because of their delayed breakdown, they are detectable for a longer period of time than membrane hyperplasia. • Lipofuscinosis is found in older hepatocytes, at an advanced age in life ("wear-and-tear pigment"), in hepatic (brown) atrophy, malnutrition, cachexia, vitamin E deficiency, and with the Dubin-Johnson syndrome. In cases of analgesic abuse, panlobular localization is found. (s. figs. 21.3; 24.9)

**Fig. 21.3:** Lipofuscinosis (metachromatic-red cytoplasmic pigments) following abuse of analgesics of the phenacetin type (Ladewig)

## 3.2 Hepatocellular degeneration

As a form of sublethal, yet generally reversible damage depending on the noxa, hepatocellular degeneration presents multiple changes in the cell and nucleus as well as cellular metabolic disorders.

### 3.2.1 Cellular changes

**Hydropic-cell swelling:** Disorders in the energy homeostasis in the hepatocyte biomembrane, with the associated failure of the ion pumps, leads to an increased influx of fluid from the extracellular space into the interior of the cell. This osmotic cellular oedema results in increased *cytoplasm transparency* in addition to a reduction or even complete loss of cytoplasmic basophilia. The endoplasmic reticulum is dilated and the liver cell is enlarged. Collectively, a picture of *cellular hydrops* develops. • In later stages, a vacuolar swelling of the smooth ER is evident, and the organelles diminish. The cytoplasm is light-coloured, stringy or honeycombed, and in places optically "empty". There is a loss of glycogen as well as reduced chromatolysis, whereas protein accumulates. Such **ballooned hepatocytes** are deemed to be an early stage of a rapidly developing cellular lysis, as a result of which empty lattice fibres become visible. The ballooning is considered to be a severe, yet still reversible form of cell damage. (s. fig. 21.4)

**Fig. 21.4:** Ballooned hepatocytes with intracellular bilirubinostasis ($\rightarrow$)

**Granular-cell swelling:** In cases of turbid and/or granular swelling of the cell, usually toxin-related, the cell interior, which comprises numerous homogeneous eosinophilic granules, becomes lighter. This process is actually based on a swelling and proliferation of the mitochondria. At the same time, there is a substantial glycogen overload of the rough ER, which is subsequently displaced to the pole of the hepatocyte adjacent to the bile duct. • In some instances, this may lead to the development of **giant mitochondria**, which can reach a size comparable to that of the nucleus itself. These present as pale eosinophilic, well-defined, PAS-negative hyaline bodies. They appear in cases of chronic alcohol

and/or medicament abuse, dermatosclerosis and local hypoxia. (s. fig. 28.3)

**Feathery degeneration:** Due to the detergent effect of retained bile acids, particularly in cases of long-term cholestasis, a net-like degeneration of the hepatocytic cytoplasm develops. The hepatocytes are hydropically swollen and appear foamy. They are also permeated with feather-like cytoplasmic filaments, which are often impregnated with bilirubin. Under an electron microscope, vorticose accumulations of membrane material can be seen. The smooth ER is dilated. Feathery degenerated cells are predominantly located in the periportal regions of the liver; being typically solitary, they are seldom found in groups. (s. figs. 13.4; 22.4)

**Hyaline bodies** are observed as round, eosinophilic, occasionally layered acidophilic corpuscles in the cytoplasm of degenerated hepatocytes. Diffusely distributed in the lobule, they are particularly evident in acute viral hepatitis A and B. • It was, in fact, in yellow fever that they were first described as **Councilman bodies** (W. T. COUNCILMAN) in 1890. • So-called **pin cells,** i. e. dehydrated, pin-shaped, compressed liver cells, may be regarded as precursors of the hyaline bodies. As a rule, they can be fully restored.

**Ground-glass cells** can be identified as enlarged liver cells with pale eosinophilic, turbid cytoplasm resulting from hyperplasia of the smooth ER. The nucleus is displaced to the cell margin. These cells are randomly distributed throughout the liver lobule. They are found in viral hepatitis B, glycogenosis (type IV) and hypofibrinogenaemia or can result from the impact of foreign substances. (s. figs. 5.7; 22.7) • From a differential diagnostic standpoint, they must be distinguished from **induced cells,** which may develop as a result of biotransformation stimuli. These cells are reversible, but can remain as hyaline droplets if noxic agents persist.

### 3.2.2 Nuclear changes

Nuclear changes are frequently observed in the form of **large nuclei** or **double nuclei** and reflect impaired reparatory nuclear division. The nucleoles are enlarged and basophilic. • This category likewise includes the so-called **glycogen vacuolation of the nuclei,** such as is found in diabetes mellitus, Wilson's disease and glycogenosis. (s. fig. 31.1) • It is often possible to observe cytoplasmic **intranuclear inclusions,** such as iron-containing inclusions (e. g. in haemochromatosis), protein-containing viral DNA (e. g. in cytomegaly), basophilic inclusions surrounded by a clear halo (e.g. in cytomegaly), eosinophilic *Cowdry type A* or basophilic *Cowdry type B* (e.g. herpes simplex virus) (s. fig. 23.2), herpes zoster virus, HB particles, and *Torres bodies* (e. g. in yellow fever). • **Sanded nuclei** (L. BIANCHI, 1976) are finely granulated ("sand-like"), pale eosinophilic hepatocyte nuclei, stuffed with HB core particles, as found in chronic hepatitis B.

### 3.2.3 Cellular metabolic disorders

**Cholestasis:** The cytoplasm becomes brighter at the sinusoidal pole, and together with reinforced basophilia at the peribiliary pole, it points to toxic intrahepatic cholestasis. These changes often precede the deposition of bile. Histologically, bilirubin is normally not visible. Under pathological conditions, it appears yellowish-brown in the liver cells and greenish in the canaliculi. Bilirubin deposits are referred to as **bilirubinostasis**. (s. figs. 13.1; 22.4; 29.4) • In a histological context, the term **cholestasis** is generally used. Thus the morphological definition of cholestasis (= bilirubin deposition) differs from the clinical definition of cholestasis (= increase in bile acids and alkaline phosphatase, yet without hyperbilirubinaemia). Depending on its location, the bilirubin stasis is classified as *hepatocellular* (= intracellular), *canalicular* (= inspissated bile plugs in more or less dilated intercellular bile canaliculi, first appearing in acinar zone 3 and extending to zone 1) and *ductular* (= inspissated bile plugs in dilated bile ductules, especially in long-standing extrahepatic bile duct obliteration.) • In localized liver damage, **focal cholestasis** may also be detectable.

**Lipid accumulation:** The increased deposition of *triglycerides* in hepatocytes is deemed to be the most common morphological change in the liver. It begins within the endoplasmic reticulum, increasingly displacing the nucleus and organelles to the periphery of the cell. In lipid accumulation, fatty infiltration can be differentiated from fatty degeneration. The latter manifests as microvesicular or macrovesicular steatosis. (s. fig. 31.3) Fat deposits can both support and perpetuate liver cell damage. In addition, fatty liver cells are more vulnerable to damage from free radicals, endotoxins and hypoxia. • *Acute alcoholic foamy degeneration* of the liver is a particular form of microvesicular steatosis which diffusely affects the entire liver parenchyma. This rare and severe disorder was first described in 1983 by T. UCHIDA. (50) • *Labrea fever* is an equally uncommon and serious liver disease with microvesicular steatosis. It was first observed by B. BUITRAGO et al. in the Amazon River basin in 1986. Hepatitis D superinfection in chronic carriers of hepatitis B is considered to be the cause; the correspondingly modified hepatocytes are termed morula cells or spongiocytes. (7) • Cholesterol deposition mainly in the lysosomes is typical of *cholesteryl ester storage disease* (s. figs. 21.5; 31.13) and of *Wolman's disease*, while in *Tangier disease* (familiar HDL insufficiency), the cholesterol deposits are found free in the cytosol of these cells. • In *Gaucher's disease*, deposits of glucocerebroside are present. The pale cytoplasm contains PAS- and diastase-resistant material, which resembles folded paper. Such hepatocytes are called Gaucher cells. (s. fig. 31.15) • Similar cells are also encountered in chronic myeloid leukaemia, plasmacytomas and malignant lymphomas (= *pseudo-Gaucher cells*).

**Fig. 21.5:** Cholesterol ester storage disease (CESD). Micro-/macrovesicular fat droplets in hepatocytes and foam cells in a portal tract (Sudan III)

**Glycogen accumulation:** Large-scale deposition of glycogen gives hepatocytes a plant-like structure. The cells appear bright, are enlarged and have compressed sinusoids. These variations are found in glycogenosis IV (Anderson's disease), whereas in glycogenosis II, the cytoplasm contains fine, PAS-positive vacuoles. • *Lafora bodies* are characterized as round-to-oval-shaped, well-defined, slightly eosinophilic cell inclusions, which give the cytoplasm a fine-granular, homogeneous appearance. They are presumably composed of acidic mucopolysaccharides and mainly located in the periportal hepatocytes. Similar inclusions are found following the intake of disulfram and INH (= *pseudo-Lafora bodies*).

**Pigment accumulation:** Pigments are coloured substances which are produced in the body (endogenic) or are introduced from the outside environment (exogenic). • Noteworthy here are *lipofuscine* (see above) and *ceroid pigment*. (s. fig. 21.6) The latter is a coarse brown pigment found in hypertrophied Kupffer cells and macrophages. Ceroid pigment is both diastase-resistant as well as acid-fast. It derives from the phagocytosis of lipids released from dead hepatocytes (heterophagia). • In addition, *malarial pigment* (s. fig. 25.3), *schistosomatic pigment*, *melanotic pigment* and the *porphyrin pigments* are worthy of mention.

***Fig. 21.6:*** Brownish ceroid ("decomposition pigment") in nested macrophages together with posthepatitic late-phase nodule (HE) (s. p. 415)

**Protein accumulation:** The intracellular storage of protein can be an expression of both adaptive processes and metabolic disorders. While such deposits are often quite harmless, they may also facilitate or even directly cause damage to the cell. • *Fibrinogen* or *albumin* are occasionally deposited in this way. Proteinocholia reflects a hepatocellular metabolic disorder as well as a disturbance in bile acid excretion with marked feathery degeneration. (s. fig 22.4) • In $\alpha_1$-antitrypsine deficiency, deposits of the altered proteinase inhibitor are found in hepatocytes, appearing as globular, eosinophilic, PAS-positive, diastase-resistant inclusions, predominantly located in zone 1. (s. fig. 31.10) • *Mallory bodies* were first identified in alcoholic cirrhosis in 1911 by F. B. MALLORY, but they are not specific to alcohol abuse. These inclusions are also found in PBC, Wilson's disease, HCC, FNH, NASH, van Gierke's disease, abetalipoproteinaemia and chronic cholestasis as well as after intestinal bypass surgery and the use of certain medicaments (e. g. amidaron, diltiazem, nifidipin). Mallory bodies are aggregated, hyperphosphorylated cytoceratine filaments. They are irregularly shaped (branched, cord-like), thick, eosinophilic cytoplasmic inclusions, which can be detected immunohistochemically with antibodies to ubiquitin. Their pathogenesis is unclear. Up to now, no negative effects upon the existing liver disease are known. (11) (s. figs. 28.1, 28.2)

**Inorganic substances:** *Ferritin* represents the primary storage form of iron in hepatocytes. In the case of iron overload, ferritin is bro-

ken down into haemosiderin. It is a golden-brown, granular, iron-containing pigment which appears as blue granules when treated with Prussian Blue stain. (s. fig. 31.25) • *Haemosiderin* is mainly located in lysosomes, but can also be found in the cytoplasm. In haemolysis, haemosiderin granules are chiefly stored in Kupffer cells and macrophages, where iron from necrotic liver cells is also present. • An increased storage of *copper* occurs in Wilson's disease, cholestasis and Indian childhood cirrhosis. The cytoplasmic copper granules can be displayed with rhodanine or orcein dyes. The periportal hepatocytes are mainly affected. (s. fig. 31.22) • In patients with pronounced anthracosis, *carbon* can also be detected in the liver cells. (s. fig. 21.7)

***Fig. 21.7:*** Carbon pigment deposits in portal macrophages. Clinical diagnosis: pronounced anthracosis

## 3.3 Mesenchymal reactions

As a result of degenerative changes, there may be mesenchymal reactions such as the formation of *stellate cell nodules* (s. fig. 22.2), which reflect previous cellular decay, or a diffuse spread of *retothelial nodules* in toxic hepatosis. Portal *cellulations*, eosinophilic *pericholangitis* and *peliosis hepatis* as well as *granulomas* also belong to this group. • Eosinophilic depositions (antigen-AB precipitates) which accumulate in the immediate surroundings of fungi, parasites or bacterial colonies (i.e. perifocally) are classified under the term **Splendore-Hoeppli phenomenon** (E. SPLENDORE, 1908; R. HOEPPLI, 1932). (s. p. 497)

▶ The occurrence of mesenchymal or even "inflammatory" lesions depends on the type of noxa and the respective exposure time. Turbid swelling, for example, can be either an expression of enhanced cellular activity or indeed a sign of impaired protein metabolism. Perhaps the deposits of minute fat droplets are a counter-regulatory mechanism. With degenerative changes, thought should therefore always be given to the question of whether a finding is a compensatory mechanism or whether it constitutes damage and might, as such, evoke (secondary) mesenchymal reactions. Transitions may be fluid, just as epithelial and mesenchymal lesions of differing intensities can also combine. • *Histological terminology always depends on the respective findings at the various stages of change.*

In this context, it is reasonable to address the long-standing rejection of the term **hepatosis.** Even if the objections to the term hepatosis as defined by R. Rössle (1929) (s. p. 404) are absolutely justified, it is nevertheless true to say: *the primary degenerative lesions of the liver cell are of central significance — they can be considered as the key to the development of multiple functional and structural patterns of damage.*

### 3.3.1 Peliosis hepatis

When portal processes of varying aetiology spread, sinusoidal structures and cellular systems are damaged. (52, 54) Toxic effects or local increases in pressure in the sinusoids, for example, can lead to their dilation with concomitant epithelial lesions and the destruction of reticular fibres. The invasion of erythrocytes results in diffusely distributed cavities filled with blood (so-called "globoid bleeding") of 0.5 − 2.0 mm, even up to 1.0 cm, in diameter. They were first described by E. Wagner in 1861 and termed peliosis hepatis by F. W. Schönlanck in 1916. Such cavities possess no endothelium. They are mostly disseminated, but sometimes arranged focally. All age groups and both sexes are affected equally. Peliosis hepatis is diagnosed with the help of ultrasound, CT or MRI. The diagnosis can be confirmed histologically with a liver biopsy. (s. figs. 21.8; 36.15) • The blood-filled cavities of the **parenchymatous type** are linked with the sinusoids; their walls consist of trabeculae formed from flattened hepatocytes. In contrast, the blood-filled cavities of the so-called **phlebosclerotic type** communicate with the sinusoids and the central veins. Indistinct sinusoidal dilations, so-called *hepatic spongiosis* (P. Bannasch et al., 1981), are a possible precursor of peliosis hepatis. • Peliosis can lead to bleeding into the parenchyma or abdominal cavity. It is nearly always found in adenomas and FNH. Secondary thrombi may appear at the centre of the peliotic foci. In the subsequent course of disease, fibrosis may develop. Despite elimination of the root cause, a regression is rarely possible. Intra-abdominal haemorrhages are often fatal. (s. p. 763)

***Fig. 21.8:*** Peliosis hepatis with dilated sinusoids and small trabeculae (▶) after intake of contraceptives containing oestrogen (HE)

The **causes** of peliosis hepatis are varied and include anabolic or androgenic steroids, oestrogens (52), azathioprine, arsenic, vinyl chloride, tamoxifen and danazol as well as tuberculosis, histiocytosis, leishmaniasis, leprosy, carcinoma, sprue, liver abscess, cytomegalovirus infection, glycogenosis (type I) (14) and marasmus. (46) • Congenital (angiomatous) abnormality of the vessels may also be a contributory factor. (5) The respective development of peliosis hepatis is still unclear.

▶ **Bacterial peliosis hepatis** has been determined in cases of HIV infection and cat-scratch fever, where it is caused by Rochalimaea quintana bacteria (Bartonella henselae). (s. p. 482) It presents as a proliferation of blood-filled cystic sinusoidal cavities, which are surrounded by fibromyxoid stroma (M. J. Dolan et al., 1993). Sometimes it is possible to identify the causative organism using PCR or staining with a silver dye (Warthin-Starry). Treatment can then follow with antibiotic agents, such as erythromycin, doxycyclin or clarithromycin.

### 3.3.2 Granulomas

Granulomas develop as a knot-like collection of macrophages, plasma cells, lymphocytes, histiocytes, fibroblasts and multinuclear giant cells of the Langhans' or foreign-body type. They are considered to be a particular form of chronic inflammation. In principle, two forms are differentiated: (*1.*) immune granulomas and (*2.*) foreign-body granulomas. • In the case of immune granulomas, macrophages can, following antigen stimulation, transform into epithelioid cells, which produce large quantities of cytokines. The centre of these epithelioid granulomas are populated with CD4$^+$ cells, whereas the periphery is predominated by CD8$^+$ cells. *Immune granulomas* can also have a lymphohistiocytic structure. Due to the high turnover rate of their cells, immune granulomas are extremely dynamic entities, whose morphology can vary greatly. • *Foreign-body granulomas* typically contain the causative substance (e. g. starch, silicone, mineral oil, beryllium). Lipogranulomas are also included here. (13) • Granulomas can sometimes completely degenerate. However, in cases where the causative agent remains, they may also persist or scar over. (s. figs. 21.9, 21.10; 24.4, 24.8, 24.14; 29.6, 29.7)

Granulomas are generally distributed focally throughout the liver, mostly within the liver lobules and less frequently in the portal fields. As a rule, the normal lobular architecture is not affected. Granulomas located on the surface can be visualized laparoscopically as small, greyish-white foci, which can be conveniently collected by forceps biopsy for histological examination.

In **genuine granulomas**, it is often possible to identify the underlying causative disease (e. g. tuberculosis, syphilis) as a specific form of reaction with typical tissue structures; one can sometimes also demonstrate the presence of pathogenic organisms in the granuloma. • **Genuine, unspecific granulomas** constitute a largely uniform reaction of the liver to different causes. • **Lipogranulomas** result from the destruction of fatty liver cells. They are composed of phagocytizing and epithelioid cells and surrounded by ring-shaped histiocytes. In particular, they are found in alcoholic liver damage.

(13) • With certain limitations, it is possible to distinguish **sarcoid-like granulomas,** which are considered to be a resorption phenomenon. They are made up of round cells and histiocytic epithelioid cellular tissue, occasionally with ceroid-containing macrophages or foreign-body giant cells; sometimes central necrosis or caseation is evident. Although the borders of the parenchyma are indistinct, they can still be identified. The healing process takes place with fine cicatrization. • **Eosinophilic granulomas** are seen as an expression of hyperergic immune reactions. They contain epithelioid cells and eosinophilic leucocytes. (8, 10, 12, 13, 18, 21, 25, 51, 53)

**Fig. 21.9:** Sarcoid granulomas (miliary type, up to the size of a lentil) on the liver surface (right liver lobe)

**Fig. 21.10:** Fibrosing epithelioid cell granuloma containing giant cells in sarcoidosis

| Medicaments | Parasites |
|---|---|
| Acetylsalicylic acid | Amoebiasis |

| Rickettsiosis | |
| Toxoplasmosis | |

**Tab. 21.1:** Possible causes of the formation of granulomas in the liver (s. figs. 21.9, 21.10; 24.4, 24.8, 24.14; 29.6, 29.7)

In over 80% of patients, tuberculosis, sarcoidosis and medicaments are the main causal factors. (51) In most cases, granulomas are discovered accidentally during liver biopsy. They cause no discomfort, and there are no clinical findings or any deviations from normal laboratory parameters. However, they sometimes give valuable hints of the underlying disease. It should be mentioned that therapy can only be directed at the underlying disease itself. (s. tab. 21.1)

From the pathologist's point of view, the term **granulomatous hepatitis** is incorrect: the detection of granulomas never represents a histomorphological picture of "hepatitis", even in cases where the granulomas are densely accumulated in the portal fields or indeed diffusely distributed in the parenchyma. Granulomas are considered to be harmless findings in the sense of a local mesenchymal or hyperergic concomitant reaction of the liver to toxic lesions as well as to extrahepatic causes − they do not actually constitute a liver disease, nor can they be seen as a liver disorder of any significance. (36)

It has indeed been postulated that **granulomatous hepatitis** exists as a disease in its own right with fever of unknown origin, an increase in transaminase activity, lymphocytosis, splenomegaly, myalgia or arthralgia, weight loss, fatigue and malaise (M. ELIAKIM et al., 1968). • Yet, the concomitant increase in the blood sedimentation rate as well as the rise in alkaline phosphatase may

well be assigned to rheumatic polymyalgia or autoimmune vasculitis (s. tab. 5.9!) — in the same way that the positive response to glucocorticoids points to an *immunopathy* which may really exist.

## 3.4 Cell death and necrosis

### 3.4.1 Programmed cell death

Like practically all other tissue cells of the organism, hepatocytes are subject to **physiological ageing,** a process that is controlled by specific biochemical signal substances. The normal, genetically determined **life-span of hepatocytes** is 200 (150−400) days. This programmed cell death or death due to ageing (C. VOGT, 1842) is known as **apoptosis**, which in Greek means "falling of the leaves from the trees" (J. F. R. KERR et al., 1972). (28) Apoptosis is of great significance for the homoeostasis of tissues and for the removal of old, injured or mutated cells. • It is a genetically programmed and regulated, active, energy-consuming process, whereby the liver cell controls its own death. Both physiological and pathological stimuli can initiate apoptosis. It is important that the integrity of the plasma membrane remains intact. Despite the death of individual liver cells, the tissue structure is not affected. The remaining apoptotic bodies are later phagocytized by macrophages. (4)

A cell surface receptor (CD 95/APO-1/Fas) that can trigger apoptosis was described for the first time in 1989 (S. YONEHARA et al.). In addition to Fas, there are further receptors which mediate the apoptosis of hepatocytes, such as TNF-δ, TGF-β and TRAIL (= TNF-related apoptosis-inducing ligand). (16, 41) *Pro-apoptotic proteins* include Bcl-2, Bcl-w, Mcl-I and Brag-1; *anti-apoptotic proteins* include Bax, Bad, Bak and Bag. Only isolated cells are affected by apoptosis, usually 40−60 per $10^5$ hepatocytes, mainly in the area of two cellular columns around the terminal liver vein. The process of apoptosis appears to be irreversible. At first the cell disengages from the neighbouring cells, showing "wild movements" (so-called *boiling stage*). The stability of the cell membrane declines, and evaginations of the cell appear (so-called *zeiosis*). Finally, vesicles encompassed by membrane are discharged (so-called *blebbing stage*). The cell nucleus ruptures, and chromatin is condensed; the DNA is split. The organelles are not changed, and no lysosomal enzymes are released. No inflammatory or fibrotic reactions occur. The remnants of the apoptotic hepatocytes form eosinophilic *acidophilic bodies*. They are then expelled from the cell aggregate and later phagocytized by Kupffer cells. These residual bodies are additionally found in cases of viral hepatitis, drug-induced toxic liver damage and yellow fever; they are also called *Councilman bodies*. The shrunken cell or other cellular residues are likewise phagocytized. • The decomposed liver cells are replaced by new hepatocytes ("moulting"). It can be assumed that the **normal values of liver enzymes** (with their relatively low range of varia-

tion) are largely based upon this programmed cell death. (4, 32)

> The genetically determined normal life-span of hepatocytes is, however, impaired by the negative effects of an unhealthy lifestyle, exogenous and endogenous noxae, or pathological processes. • *In such instances, the physiologically programmed death of cells due to ageing is prematurely triggered by provoked cell death.*

### 3.4.2 Provoked cell death

▶ Provoked cell death is not genetically regulated, but is a passive, incidental process triggered by pathological stimuli. This is a non-energy-consuming process, whereby the integrity of the plasma membrane and of the organelles is destroyed, as is the overall tissue structure. The result is cellular disintegration with subsequent release of the cell contents into the extracellular space. This is followed by a concomitant inflammatory response, later progressing to tissue regeneration or fibrosis. Possible **causes** are: (*1.*) severe disorders of the mitochondrial energy metabolism with loss of ATP, (*2.*) loss of protective cellular substances, such as reduced glutathione, and (*3.*) release of lysosomal enzymes and toxic oxygen products (such as $H_2O_2$, hydroxyl radicals and singlet oxygen) by activated macrophages. (4) • These causal pathobiochemical factors affect hepatocytes in various modes and combinations as well as over different time sequences. The degenerative reactions are correspondingly variable and intensive. Provoked cell death always affects larger accumulations of liver cells. At the outset, the organelles are usually damaged, with a number of noxae initially causing harm to certain components of the cell (mitochondria, membranes, cytoskeleton, lysosomes, etc.). Lysosomal enzymes are released from the liver cells at an early stage. As a rule, inflammatory and scarring reactions are witnessed. • *Thus the degenerative changes, which are in themselves always reversible, can indeed ultimately become irreversible and hence cause cell death.*

### 3.4.3 Cell necrosis

Cell necrosis in the form of coagulation necrosis or colliquation necrosis can be detected approximately 6 hours after the death of a liver cell. • **Coagulation necrosis** is characterized by a loss of water with subsequent concentration of the cytoplasm and shrinkage of the cell. This is also termed *acidophilic necrosis*. Shrinkage leads to eosinophilic, elongated and unevenly frayed hepatocytes, so-called *stift cells*. This break off its connection to adjacent cells. The nucleus becomes pyknotic and caryolytic. The remaining cytoplasm is strongly eosinophilic owing to the breakdown of RNA and denaturation of protein. • **Colliquation necrosis,** nowadays known as *lytic necrosis*, becomes evident in cases of water uptake and cell swelling (ballooning). It is caused

by the impact of hydrolytic enzymes (proteases, nucleotidases). Cytolysis, which is focused on the lobules, leads to patchy or string-like parenchymal loss. Inflammatory infiltrates occur as a reaction to lytic necroses. Various patterns of necrosis are differentiated according to the degree and distribution of cell destruction in the acinus. The liver cells disappear as a result of enzymatic lysis, and empty reticular fibre nets (s. p. 19) (s. fig. 2.7) or even collapsed fibre areas are the outcome. (3)

Programmed cell death (apoptosis) and cell necrosis can be differentiated by morphology. However, liver diseases are often accompanied by a combination of both processes, so that there is mostly no clear borderline. Therefore, the term **necrapoptosis** was introduced. (30) This coexistence of apoptosis and necrosis can often be explained with the help of calcium-induced mitochondrial permeability transition (MPT) (D.R. HUNTER et al., 1976).

A prerequisite for the development of cell necrosis is the loss of cellular ATP reserves. However, 15−20% of the normal ATP reservoir are sufficient to prevent cell lysis. In the same way, fructose (a glycolytic ATP donor) has been shown to inhibit cell necrosis in laboratory experiments. This could be an explanation for the fact that fructose infusion was formerly considered to be effective in liver diseases.

**Single-cell necrosis:** Necrotic hepatocytes are found both as groups and in isolation. Initially, they either form small patches or are disseminated throughout the liver. The reticular fibres at first remain, but are later removed.

**Cell-group necrosis:** Lytic necrosis comprising larger groups of hepatocytes can be located at certain positions within an acinus (= *zonal necrosis*) or throughout the entire lobule (= *panlobular necrosis*). • So-called *surgical necrosis* occurs mainly during abdominal operations and can manifest in single-cell or cell-group forms. It results from surgical trauma or hypoxia and is principally found in centroacinar areas.

**Confluent necrosis:** Cell-group necroses can merge within a lobule (= *submassive necrosis*) or connect affected areas in several different lobules (= *multilobular necrosis*).

**Bridging necrosis:** These are extensive types of confluent necroses lying within a single acinus or connecting neighbouring lobules (J.L. BOYER et al. 1970). The reticular fibre network collapses. Bridging necrosis can appear between the central veins (= *venovenous*) or the portal tracts (= *portoportal*) of neighbouring lobules. Once they have been removed, it is possible to identify a strand-like collapse of the reticular fibres of the sinusoids.

**Piecemeal necrosis:** This is the fundamental element of a progressive, chronic-inflammatory process. The necrosis is brought about by cytotoxic T lymphocytes, which may be located within a recess of the hepatocyte (=

***Fig. 21.11:*** Degenerated hepatocyte with either an intracellular located lymphocyte, often surrounded by a narrow clear halo (= emperipolesis) or a lymphocyte invaginated in the cell membrane (= peripolesis) − it is perhaps a T lymphocyte. This condition points to immunologically induced liver damage in florid virus hepatitis B (HE)

*peripolesis*) or inside the hepatocyte itself (= *emperipolesis*). (s. fig. 21.11) • The necrotic process takes place at the crossover between mesenchyma (portal tract, septa) and parenchyma, whereby mononuclear cells (primarily lymphocytes, plasma cells, macrophages) penetrate the boundary and infiltrate the acinus (= *interface hepatitis*). The interface between parenchyma and mesenchyma becomes blurred. Kupffer cells are hypertrophied and there is a proliferation of the ductuli. So-called *liver cell rosettes* are also occasionally found near piecemeal necroses. (31) These are light-coloured, hydropic hepatocytes which are arranged around a central lumen and often surrounded by fine connective-tissue fibres. Liver cell rosettes are deemed to be an expression of regenerative activity.

The progressive course of cell damage through to **cell death** is mainly characterized by *two biochemical metabolic processes:* (*1.*) oxidative stress and (*2.*) disruption of intracellular $Ca^{2+}$ homoeostasis. These two processes interact, so that the oxidative stress induces the disruption of calcium homoeostasis; there are also, however, other reciprocal actions/effects involving further cellular metabolic processes. (27)

▶ **Oxidative stress** is occasioned by the dominance of pro-oxidants (= *reactive oxygen intermediates*) over anti-oxidants (= enzymatic or non-enzymatic anti-oxidants as well as auxiliary reactions supporting anti-oxidants). (s. p. 67) Several pro-oxidants possess properties of radicals, rendering them particularly reactive and unstable; some reactive oxygen intermediates (ROI) are not radicals. ROIs are indispensable to many metabolic processes − yet if they predominate, they precipitate severe damage to various biological substances. They are able to evoke the particularly important oxidation of polyunsaturated fatty acids (= *lipid peroxidation*) (s. p. 68) or address target areas in carbohydrates and proteoglycans, proteins or enzymes, and nucleic acids. The disruption of totally different cellular substrates in a variety of intensities and combinations can produce a multifaceted picture of biochemical damage and its outcome. In contrast, cell damage may not only be the upshot of oxidative stress, but also the cause of it, so that a *vicious circle* is set up, whereby the cellular damage is reinforced. An

imbalance between pro-oxidants and anti-oxidants with a predominance of reactive oxygen intermediates or free radicals can therefore culminate in hepatocellular degeneration and provoke cell death. (15, 24, 44, 45) (s. fig. 21.12)

▶ **Disrupted calcium homoeostasis:** Normal concentrations of ionized calcium in the cytosol ($0.05-0.2$ μM), in the overall liver cell ($0.5-2.0$ μM) and in the extracellular space ($1.0$ μM) maintain the function of numerous Ca-dependent enzymes and structural elements of the liver cell. Calcium homoeostasis is maintained by the regulatory functioning of all $Ca^{2+}$ transportation systems, energy supply in the form of ATP and intactness of the biomembranes. Defective calcium homoeostasis can cause an increase in calcium in the cytosol, which in turn activates calcium-dependent enzymes, alters the metabolic functions of the cell and disrupts the gap junctions and tight junctions. These biochemical changes result in various forms of hepatocellular degeneration and ultimately in cell death. (s. fig. 21.12)

## 3.5 Regeneration

Our present knowledge concerning the extraordinarily complex process of liver regeneration stems almost exclusively from experiments on animals and isolated hepatocytes in culture. • *In principle, this exceedingly complicated concept depends on the close collaboration of hepatocytes, non-parenchymal cells and elements of the extracellular matrix as well as the fine coordination between proliferative and anti-proliferative factors.*

*Physiological liver regeneration* follows the physiological ageing of the liver cells (= programmed cell death). (s. p. 400) *Reparative liver regeneration* results from a loss of liver tissue or cell death caused by damage. *Complete regeneration* leads to normal histo-architecture and return of all cell-specific functions. *Incomplete regeneration* is given if the defective area is filled with replacement tissue.

In the process of regeneration, irreversibly damaged or surgically removed liver tissue is replaced as far as possible by new growth. The *regeneration* of the liver (s. p. 5!) is a most important process in (*1.*) overcoming necrosis, (*2.*) determining the course of a liver disease, (*3.*) liver resection, (*4.*) partial liver transplantation, and (*5.*) liver cell transplantation. (29)

The morphological signs of liver regeneration mainly include (*1.*) increase in cell proliferation (= bright cytoplasm of the hepatocytes) and mitoses, (*2.*) appearance of hepatocytes containing $2-3$ nuclei with greater variability (= dyskaryostasis), (*3.*) formation of $2-3$ rows of liver cell trabeculae, (*4.*) occurrence of liver cell rosettes around a central lumen, and (*5.*) proliferation of cholangiocytes. • The hepatocytes of a cirrhotic liver react to a significantly smaller extent to growth-stimulating factors than those of the normal liver (S. KISO et al., 1994).

The regenerative processes can largely be attributed to *enhanced cellular division,* i.e. compensating hyperplasia (= increase in the tissue volume through a rise in the number of cells), and to the differentiation and multiplication of *liver stem cells*, particularly in those cases where the remaining liver tissue is insufficient to induce adequately compensating hyperplasia. Thus a loss of $<15\%$ of liver tissue does not induce compensating hyperplasia, whereas a loss of $>75\%$ of liver tissue means that DNA synthesis does not suffice to compensate such extensive tissue damage. • With a loss ranging between 15 and 75%, DNA synthesis and the mitotic index are enhanced in the remaining liver in relation to the reduction in tissue volume. (39)

Liver regeneration takes place in **three phases:** (*1.*) *pre-replicative phase*, with preparation for mitosis, (*2.*) *proliferative phase*, with wave-like mitoses at $6-8$ hour intervals, and (*3.*) *restitution phase*, with reconstitution of the liver structure. • There are **two stages** to this whole process: (*1.*) *priming*, which is the transition of latent hepatocytes ($G_0$) into the mitotic cycle ($G_1$) − this reversible process is triggered by cytokines, hormones or other permissive substances, whereby the cells proliferate due to stimulation by the growth factor; (*2.*) *progression* is the transition from $G_1$ to DNA synthesis (S) − this transition point from $G_1$ to S is marked by the expression of cyclin $D_1$.

▶ DNA synthesis commences just 10 to 12 hours after partial liver resection, and after another 10 to 20 hours, mitotic division reaches maximum activity. Replication in the endothelial cells and bile duct epithelia follows within 1 to 3 days. Consequently, 3 or 4 weeks subse-

quent to a right-sided hemihepatectomy, the size, structure and function of the liver are largely restored, and 6 months later, regeneration is generally complete. • *After restoration of the normal organ size (with a fluctuation range of only 5−10%), the regenerative processes come to an end − there is no "overregeneration". Nor is there any formation of hepatomas or malignant transformations.* The best conditions for regeneration are found in young patients (10 to 45 years of age).

**Regulation:** The course taken by regenerative processes is regulated by **cyclins** and **CDK** (= cyclin-dependent kinases). The regenerative cycle is also controlled by cell-specific **regulator proteins.** They are designated by the letter "p" (protein) and their respective molecular weight (given in kD), e.g. p16, p21, p24, p27, p53, p107. • There are numerous **signal compounds** which are essential to the regeneration of the liver, acting in a stimulating or inhibiting capacity in accordance with the respective regeneration phase. They likewise consist of small protein particles which have a wide range of action. These signal substances act through receptors attached to the cell membrane. As a result, biochemical signals are directly transmitted to certain organelles in the cell and the nucleus, where the transcription of specific genes is controlled.

**Stimulators** such as *HGF* (= hepatocyte growth factor), *TGF-α (= transforming growth factor), EGF* (= epidermal growth factor), *FGF-1 and 2* (= fibroblast growth factor), *CT-1* (= cardiotrophin 1) and *HSS* (= hepatic stimulatory substance) affect DNA synthesis and the replication of hepatocytes. • The so-called **permissive substances**, which are considered to be essential for the effectiveness of the growth factors, are glucagon, insulin, IGF-I and II, $T_3$ and $T_4$, calcitonin, ACTH, oestrogens, vasopressin and interleukins. • *HGF is regarded as the most effective mitogen, whereby this effect is enhanced by noradrenaline.* Merely 1 or 2 hours after a partial liver resection, the plasma levels of HGF increase to 15−17 times their normal value; 10 to 20 hours later, the rise in DNA synthesis commences. In fulminant liver failure, the HGF levels were found to be elevated, as they were in 80% of patients with CAH or cirrhosis; this is probably due to the insufficient hepatic clearance of HGF or to its increased formation in the extrahepatic cells. • *TGF is of importance in stimulating the proliferation and differentiation of hepatocytes.* In contrast, *FGF-2 and plasminogen are mainly responsible for the proliferation of non-parenchymal cells and for angiogenesis.*

**Inhibitors** of DNA synthesis and cell replication are *TGF-β* and *HPI* (= hepatic proliferation inhibitor). Their function is to block the growth-promoting factors once the nominal size of the liver has been reached. • The regeneration course is, however, also linked to a complex **network** of biochemical processes, including the polyamines (putrescine, spermidine and spermine) as well as the precursors of nucleic acids (orotate, thymidine and uridine). (17, 33, 47−49, 55, 56)

> The coordinated and regulated **regeneration of the liver** can thus be regarded as one of the most outstanding features in human life − no other organ possesses this ability to regenerate, with the complete restoration of size, structure and function. • *Why −* one may ask − *was this ability attributed only to the liver as far back as antiquity, and not to any other organ?* Was this just a product of the imagination projected into this mantically meaningful organ, or had the repercussions of liver injury really been observed? ***After all, the first two hints of the regenerative capacity of the liver go back almost 3,000 years! (s. p. 5)***

## 3.6 Fibrogenesis

▶ The process of fibrogenesis results in an increase in the extracellular matrix, i.e. all insoluble organic constituents of the interstitial space. This represents an uniform, dynamic and potentially reversible reaction of the liver to chronic injury. Fibrosis is considered to be a possible forerunner of liver cirrhosis.

The **functions of the extracellular matrix** are manifold: (*1.*) stabilization of the tissue and organ structure, (*2.*) structural linkage of cells, (*3.*) transmission of information between the various types of cells within the tissue and the extracellular milieu, (*4.*) adhesion or migration of cells, and (*5.*) influence on the development and differentiation of cells and their polarity. • In fibrogenesis, collagen fibres build the framework in which the other components of the extracellular matrix are embedded. In line with this wide scope of functions, the extracellular matrix is not only organ-specific as regards its architecture, but it also displays variations at different locations within the liver, e.g. in Disse's space, in the periportal fields and within the acinus zones. • The extracellular matrix is a dynamic structure, i.e. there is a constant equilibrium between build-up (by matrix-metalloproteinases = **MMP**) and break-down (by tissue inhibitors of matrix metalloproteinases = **TIMP**).

The **main constituents of the extracellular matrix** are (*1.*) *collagen*, particularly the fibrillary types I (36%), III (36%) and V (16%) as well as the non-fibrillary types IV (9%), VI (0.2%) and to a minor degree also type VII, (*2.*) *glycoproteins* (fibronectin, tenascin, laminin, undulin, elastin, entactin), and (*3.*) *proteoglycans* of both the core protein and the glycosaminoglycan type (e.g. chondroitin, heparan sulphate, hyaluronic acid, dermatan sulphate).

**Profibrogens:** These matrix substances are produced in a variety of ways in the liver and sinusendothelial cells. The Ito cells, which are activated into myofibroblasts, are deemed to be the most important site of synthesis for virtually all types of matrix. Stellate cells take in apoptotic hepatocyte remnants. As a result, they produce 10 times more collagen I and 8 times more $TGF_{β1}$. The latter activates fibroblasts and keratinocytes. Furthermore, perivenular myofibroblasts, portal fibroblasts, sinus endothelium and bile duct epithelium can take over the synthesis of matrix proteins. Production of the matrix substances is stimulated by signal substances and controlled by regulatory factors. (s. tab. 21.2)

**Antifibrogens:** Some cytokines and peptides have an inhibitory effect on fibrogenesis. Formation and breakdown of the extracellular matrix are regulated by collagenases, stromelysin, proteases,

| Profibrogens | Antifibrogens |
|---|---|
| Endothelin-1 | HGF |
| FGF | Interferon-γ |
| ILGF | Interleukin-10 |
| Interleukin-1, -4, -6 | TNFα |
| Leptin (in ASH and NASH) | *etc.* |
| PDGF | |
| TGFα | |
| $TGF_{β1}$ | |
| **Drug-related antifibrogenesis** | |
| Canrenone | Baicalen |
| Captopril | Colchicine |
| Interferon-α | Glyzirrhicin |
| Pentoxyfilline | Halofuginone |
| Silymarin | $PGE_2$ |

***Tab. 21.2:*** Some cytokines and peptides as well as chemical or herbal substances with profibrogenetic and antifibrogenetic effects

endoglycosidases, etc. These *enzymes*, which are responsible for breaking down the components of the matrix, are mainly produced in Kupffer and endothelial cells as well as in fibroblasts. • A number of *substances* also have an antifibrogenic effect under clinical conditions. In this context, pentoxyfylline and silymarin are worth mentioning; of equal interest are halofuginon and baicalen extracted from the Chinese plant sho-saiko-to. (35) (s. tab. 21.2)

**Pathologic fibrogenesis:** As a rule, there are no abnormal matrix components in pathological fibrogenesis; the tendency is for the total mass to increase as much as 8 to 10 times the normal amount, albeit in varying proportions for each individual substance. There is an excess of collagen types I and IV as well as of hyaluronane, chondroitin sulphate and dermatan sulphate, with a relative reduction in heparan sulphate. The collagen content (with a normal level of 0.5%) may rise to 50% of the protein fraction of the liver, which is equivalent to 3 to 6 times the normal level of approximately 7 mg/g wet weight. Acetaldehyde produced during the metabolism of alcohol considerably stimulates fibrogenesis by enhancing the transcription of genes for matrix components, in particular collagen type I and fibronectin. Reactive oxygen intermediates as well as non-protein-bound iron in haemochromatosis also have a stimulating effect on fibrogenesis.

**Standstill:** It can be assumed that fibrogenesis will initially come to a standstill upon cessation of the causative factors or stimulating signals. When the extracellular matrix is only moderately increased, the lobular structure, the vascular supply and the bile flow from the periportal fields are undisturbed. A balance between the stimulation and inhibition of fibrogenesis can develop, stopping "liver fibrosis" at the point which has been reached.

**Regression:** It is of clinical relevance that an enzymatic breakdown occurs as well in order to cope with the augmented production of matrix components, thereby resulting in regression of fibrosis. Whether, on the other hand, pathological fibrogenesis progresses even after the causative factors cease to be present has not yet been clarified, even though this has been demonstrated in vitro. (6, 19, 23, 35, 37, 42)

# 4 Hepatitis and hepatosis

## 4.1 Hepatitis

▶ It was Diogenes of Appolonia who first used the term "hepatitis" when referring to the so-called "liver vessel". (s. p. 6) • In his "Historia hepatica" (1725), J. B. Bianchi later grouped the various types of diffuse inflammation of the liver under the term "hepatitis".

In histomorphological terms, **hepatitis** means "inflammation of the liver". The factor causing the disease may spread from the initially or predominantly affected **mesenchyma** to the liver cells (such as in kala-azar and malaria), or the primarily or mainly affected **liver cells** may subsequently incorporate the mesenchyma into the damaging process (as for example in yellow fever). • In leptospirosis and herpes virus infection, the morphological finding is determined almost exclusively by changes in the parenchyma, while mesenchymal reactions are hardly or not at all present.

▶ As long as the interaction between the liver and the causative factor (viruses, toxins, noxae, etc.) is restricted to the *mesenchyma* or the connective tissue (particularly within the periportal field), i.e. if directly adjacent hepatocytes have not as yet been damaged, no rise in transaminase levels (GPT, GOT) is to be expected in laboratory examinations. These mesenchymal reactions range from signs of portal inflammation (cellulation, oedema,

activation of fibroblasts) to Kupffer cell reactions (changes in shape, swelling, proliferation or pseudoproliferation) through to proliferation of the bile ducts and fibrotic processes.

▶ The spread of the damaging processes to adjacent *hepatocytes* is signalled by an increase in transaminase activity; the liver cell membranes are also affected. The result is an enhanced release of cytoplasmic enzymes (GPT, to a lesser extent also GOT) into the serum. Ultimately, cell necrosis must be expected with a rise in mitochondrial enzymes in the serum (GDH, mGOT). From the point of view of biochemistry, the term hepatitis presupposes an increase in indicator enzymes once when the hepatocytes have been damaged or destroyed. (s. pp 93−95) (s. tabs. 5.3−5.5)

The term hepatitis is frequently used with a variety of **differentiating attributes**, such as acute, necrotic, chronic, cholestatic − as well as with attributes which are not quite correct from a pathohistological viewpoint, such as diffuse, non-specifically reactive, granulomatous or focal. • Taking a histological and biochemical approach, the complex process of hepatitis can indeed be accepted as such and allocated to a larger group of clinical pictures. • This interpretation might make it easier to understand the terms *"serous inflammation"* (R. Rössle, 1929) and *"acute interstitial serous hepatitis"* (H. Eppinger, 1937).

The classical **inflammation criteria** such as *exudation, cellulation* and *proliferation* can only be applied to the liver with some reservations, since the emphasis in this instance is on the sinusoids, which already display maximum permeability under normal conditions. The increase in capillary permeability, required by the definition of inflammation, is really only applicable to the area of the vascularized portal fields, e.g. in purulent cholangitis. The definition of inflammation can only be applied to classic acute viral hepatitis. (s. p. 415)

*It is to be expected that the current criteria of inflammation in hepatology will be reviewed and revised.*

## 4.2 Hepatosis

The term *hepatosis* was used for the first time (according to our research) by F. Pielsticker in 1921 (34) in analogy to the nephrosis-nephritis concept before being subsequently adopted by A. Géronne. (22) It was then made generally known on a large scale and became the subject of controversial discussion as a result of the frequently quoted publication by R. Rössle (1929). (38) Especially H. Kalk (1957) showed a commitment to this concept. • Hepatosis can be defined as a *"metabolic disorder of the hepatocyte in the widest sense"* (L.-H. Kettler, 1965), which is the focal point for the morphological approach during the entire course of disease (G. Holle, 1967; H. U. Zollinger, 1968; W. Doerr, 1970; O. Klinge, 1984).

▶ *Non-inflammatory, primary degenerative changes in the liver, which mostly affect only the parenchyma, are known under the term hepatosis.* The causative damage can be of an exogenous or endogenous nature. Electron microscopy has yielded a better understanding of the primary degenerative alterations of the liver parenchyma, which in turn has been the reason for a revival of the term hepatosis. (s. p. 398)

**Endogenous hepatosis** comprises endogenous metabolic disorders of the liver cell; as a rule, the terminology used in this context refers to the accumulated substances (e. g. glycogenosis), the harmful substrate (e. g. fructose-1 phosphate) or the enzyme defect (e. g. $\alpha_1$-antitrypsin deficiency).

**Exogenous hepatosis** is caused by numerous and varying substances, which are made up externally and transported to the liver cell, such as alcohol, medication, chemicals, toxins, etc. Its pathogenesis is still unresolved, which is why the nomenclature remains subject to debate.

# 5 Fibrosis and cirrhosis

## 5.1 Fibrosis

Fibrosis is defined as local or diffuse augmentation of the extracellular matrix together with an additional disproportionate increase in its individual components. It is not possible to detect any structural or functional abnormality concerning the respective matrix substances, which are now being generated to a growing extent. The lobular structure remains intact. Fibrosis is a dynamic process which is potentially reversible.

Fibrosis is usually the consequence or concomitant symptom of a chronic hepatobiliary disease, the course of which can itself in turn be unfavourably influenced by the fibrosis. The matrix substances, which are being produced in greater quantities, are increasingly deposited in Disse's space in the portal field and periportal area as well as around the terminal liver vein.

**Morphological changes** result from the increasing deposition of matrix components: more pronounced portal and periportal formation of connective tissue, constriction of lobular areas by connective tissue, narrowing or obstruction of small vessels, neovascularization within the connective tissue septa, and disorders in the lobular structure. • **Functional disorders** are likewise witnessed: the haemodynamic system is impaired to an increasing extent, resulting in portal hypertension with its own specific complications; the metabolic exchange of substrates, the oxygen supply and the clearance of toxic substances are considerably impeded; the bile flow from the portal fields is reduced. • Hepatic fibrosis can come to a *standstill* at any given level, either temporarily or permanently, yet can even be *accelerated* by the activation of Ito cells. It is also possible for the fibrosis to *regress* as a result of enzymatic breakdown. (1, 6, 23, 35, 40)

▶ In line with the differences in **aetiopathogenesis**, there are various *mechanisms of fibrosis development:* (*1.*) fibrosis due to changes in preformed intralobular and portal fibres, (*2.*) fibrosis resulting from the destruction of liver cells (= *substitute fibrosis*), (*3.*) fibrosis as a consequence of the collapse of the reticulin-fibre scaffolding (yet without an increase in collagen fibres) with complete or partial lobular necrosis or bridging necrosis (= *collapse fibrosis*), (*4.*) enhanced neoformation or diminished breakdown of the extracellular matrix, and (*5.*) fibrosis resulting from the proliferation of bile ducts (= *periductal fibrosis*). (s. fig. 32.12)

**Serum markers of fibrosis:** The clinical validation of possible serum markers of fibrosis or fibrolysis causes great difficulties, since this condition generally shows only slow changes over a long period. Furthermore, the ubiquitous presence of molecules of the extracellular matrix in other organs can produce false values in liver fibrosis. • The propeptide of type III procollagen **(P-III-P)** is taken as a serum-related marker for assessing the metabolism of collagen. The P-III-P value is a criterion for measuring the turnover of extracellular matrix components. (s. p. 112) (26, 43) In the meantime, it is possible to measure several markers of matrix deposition (e. g. P III C, P III N, tenascin) or matrix removal (e. g. P IV C, P IV N, collagen IV, undulin) with the help of reproducible and relatively sensitive **sandwich ELISA tests**. Similarly, an elevated serum value of TGFβ$_1$ can point to increased fibrogenesis. (1, 35) • A decrease of the **prothrombin index** less than or equal to 80% points to severe fibrosis. (8) The introduction of useful markers for connective-tissue metabolism would be of great importance for detecting progressive and regressive fibrosis as a result of antifibrotic therapy. (s. tab. 21.2)

In line with the morphological **activity,** a distinction can be made between *progressive* and *stationary* fibroses, which appear either as mild or severe with regard to their intensity and can be reversible or irreversible in terms of their course. Depending on the extent of the inactive stationary fibrosis, the hepatic function is only slightly or not at all impaired. In contrast, active progressive fibrosis gives rise to portal hypertension, which can actually become reversible once the fibrosis is inactivated. • Fibrosis can be differentiated according to its **localization**: (*1.*) portal/periportal, (*2.*) perisinusoidal, and (*3.*) perivenous. In the case of (*4.*) diffuse fibrosis of the liver, all three areas are typically affected, but to varying degrees of intensity. Furthermore, there is (*5.*) periductal fibrosis. An exact discrimination of the various types is often impossible. • **Intralobular focal fibrosis** can be caused by minor losses of parenchyma, formation of granulomas, recovery of abscesses, obliteration of a cavernous haemangioma, reaction of parasites in the liver parenchyma, etc. • A **regression of fibrosis** is possible: this process could be demonstrated in successfully treated haemochromatosis, during abstinence following alcohol abuse, after IFN therapy in chronic hepatitis C, and in Indian childhood cirrhosis after penicillamine therapy.

### 5.1.1 Scarred liver

A scarred liver (H. KALK, 1957) develops as a result of a large-scale loss of parenchyma, which is replaced by scar tissue without bulbiform metaplasia. Outside this scar,

the lobular architecture is retained. During laparoscopy, these multilobular necroses of the parenchyma are visible as concave greyish-white to greyish-red scars with deep retractions, giving the picture of the so-called *funnel liver.*
• The left liver lobe in particular can shrink to a slender scarred disc as a result of its poor blood supply. (s. figs. 21.13; 22.16; 35.1, 35.14!)

***Fig. 21.13:*** Atrophy of left liver lobe due to acute viral hepatitis B

### 5.1.2 Portal/periportal fibrosis

A fibrotic widening of the portal fields (with differing intensity and often variable regional distribution) is a frequent finding in chronic hepatitis, and it plays an important role in staging. (s. p. 694) However, it may also be a remnant of previous hepatitis. In many cases, strands of connective tissue extend into the periportal parenchyma. Mostly, there is portal/periportal fibrosis with an irregular star-shaped pattern. (s. fig. 21.14)

***Fig. 21.14:*** Periportal and septal fibrosis following severe acute viral hepatitis B: liver architecture clearly disrupted; older collapse fields with condensed reticular fibres; (Gomori's reticulin stain)

The reticular fibre structure of the sinusoids breaks apart, while liver cells attempt to remedy the parenchymatous defects from the area of the lobules. In chronic, alcohol-

induced liver disease, *brushwood-like fibrosis* is often evident. In hereditary haemochromatosis, there is usually evidence of a *holly-leaf fibrosis*: thickened portal fields and finger-like fibrosis with flat ends. Such a fibrotic pattern can also be seen in cholangitic processes with biliary portal fibrosis. The portal bile ducts become encircled by connective tissue in an onion-like manner, which is termed *periductular fibrosis.* Occasionally, *portal-centrolobular fibrosis* as well as *portal-perilobular fibrosis* can be detected. Particular mention should be made here of a special form in schistosomiasis, the so-called *pipe-stem fibrosis.* (s. fig. 25.14)

---

**Portal/periportal fibrosis can be found in:**

| | |
|---|---|
| α$_1$-AT deficiency | haemochromatosis |
| alcohol abuse | hepatoportal sclerosis |
| Byler's disease | methotrexate |
| chronic cholangitis | obstructive jaundice |
| congenital fibrosis | PBC, PSC |
| cystic fibrosis | schistosomiasis |
| galactosaemia | thorotrastosis |
| graft-versus-host | Wilson's disease, *etc.* |

---

### 5.1.3 Perisinusoidal fibrosis

In perisinusoidal fibrosis (also called intermediate fibrosis), fibres develop along the sinusoids, or they encircle the individual hepatocyte in a pericellular manner. These forms either affect the whole lobule equally or they show a tendency to invade the periportal or central region of the lobule. Initially, the lobular structure is not affected, nor is the vascular supply restricted. • The progressive fibrogenesis leads to a **capillarization of sinusoids** (F. SCHAFFNER et al., 1963): the deposition of glygoproteins and collagen fibres in Disse's space causes the formation of a basal membrane below the endothelial cells. The sieve plate-like structure is lost, mainly due to alcohol and endotoxin. The endothelial cells express CD34, factor VIII, endothelin-1, etc. These factors induce the perisinusoidal cells to contract, supporting the development of portal hypertension. Such capillarization impedes the metabolic exchange of substrates, i.e. between plasma and the sinusoidal surface of the hepatocytes. • *Chicken-wire fibrosis* is a characteristic finding in chronic, alcohol-induced liver disease. (s. fig. 21.15) A particular example of a sinusoidal/pericellular fibrosis is connatal syphilis, which is termed *brimstone fibrosis.* (s. p. 479)

---

**Perisinusoidal/pericellular fibrosis can be found in:**

| | |
|---|---|
| arsen intoxication | myeloproliferative disease |
| Budd-Chiari syndrome | osteomyelosclerosis |
| chronic alcohol abuse | portal vein thrombosis |
| chronic blood congestion | Schönlein-Henoch |
| connatal fibrosis | vinyl chloride |

---
*Fig. 21.15:* Pericellular trabecular fibrosis showing a wire mesh pattern (so-called chicken-wire fibrosis) due to chronic alcohol abuse (Sirius red)

### 5.1.4 Perivenous fibrosis

Central venules only contain a small amount of collagen, with the result that in this form of fibrosis, perivenous sinusoids are always involved as well. A typical example is perivenular fibrosis in chronic alcohol abuse. (s. fig. 21.16) • Centrolobular fibrosis may also be detectable in healed viral hepatitis or following slight liver damage (e. g. Meulengracht's disease). *Central hyaline sclerosis*, which is due to chronic alcohol abuse with intermittently recurring alcohol hepatitis, is known to be a particularly severe form of fibrosis. (s. p. 526)

| Perivenous fibrosis can be found in: | |
|---|---|
| Budd-Chiari syndrome | healed hepatitis |
| chronic alcohol abuse | Meulengracht's disease |
| chronic blood congestion | |

*Fig. 21.16:* Perivenular and perisinusoidal fine-meshed fibrosis and discreet cellular inflammatory reaction as a result of chronic alcohol abuse (CV = central vein) (Ladewig)

### 5.1.5 Septal fibrosis

In persistent confluent and bridging necrosis, the development of correspondingly located **fibrotic septa** can be observed. • *Portoportal septa* connect neighbouring portal tracts, such as in progressive piecemeal necrosis and in

chronic cholestasis with an extensive ductular reaction. • *Centrocentral septa* connect adjacent central veins as a result of confluent cell-group necrosis. • *Portocentral septa* join portal tracts with central veins following corresponding bridging necrosis. • *Active septa* display inflammatory infiltrates of mononuclear cells and are therefore difficult to differentiate from the neighbouring parenchyma. These inflammatory cells are able to stimulate further fibrogenesis. • *Passive septa* display no inflammatory infiltrates and are therefore easily differentiated from the adjacent parenchyma. They represent a cicatricial process in the healing of confluent necrosis. Septa older than 6 months can contain elastic fibres.

### 5.1.6 Liver collapse fibrosis

Liver collapse fibrosis must be differentiated from proper liver fibrosis, which displays increased deposition of a qualitatively altered extracellular matrix. It results from a collapse of the reticular fibres following liver cell necrosis. • A *primary collapse* arises subsequent to confluent cell-group necrosis in a previously normal parenchyma. • A *secondary collapse* develops as a result of extensive necrosis in previously damaged parenchyma (e. g. cirrhosis).

Inactive, stationary or even regressive liver fibrosis hence constitutes the healing of a pathological event by means of connective tissue. Such a more or less pronounced *partial (fibrous-defective) recovery through the formation of connective tissue* may often be regarded as a therapeutic success.

## 5.2 Cirrhosis

► *The elimination of the lobular structure is the essential component of all forms of cirrhosis.* • Pronounced necrosis or extensive proliferation of connective tissue do not serve as adequate criteria for liver cirrhosis. Nor are inflammatory processes an absolute prerequisite for the development of this condition. The aetiology nor the presence of regeneration nodes are criteria for liver cirrhosis. *(see chapter 35)*

### 5.2.1 Basic criteria

The criteria for the development and completion of liver cirrhosis can be assessed according to their importance:

1. Pronounced parenchymal necrosis, not balanced by reparative mechanisms
2. Diffuse increase in connective tissue
3. Varying degrees of nodular regeneration

4. *Elimination and metaplasia of the lobular structure, in principle covering the entire liver*
5. *Disruption of the intrahepatal (venous, portal and arterial) haemodynamic system*

### 5.2.2 Systematic approach

**Aetiology:** It would be beneficial to establish a systematic approach to cirrhosis based on the underlying aetiology, since this would allow both preventive and therapeutic measures to be initiated. Only some forms of cirrhosis allow aetiological identification from morphological criteria. Nevertheless, given the simultaneous application of all laboratory parameters, clinical findings and imaging procedures, it is nearly always possible nowadays to clarify the aetiology of cirrhosis – *the frequency of "cryptogenic" cirrhosis has been continually reduced in relation to the improvements made in detailed diagnostics. (see chapter 35)*

*However, a systematic approach to cirrhosis can only be founded to a limited degree on aetiological principles,* since (*1.*) it has not (as yet) been possible to define the cause in many cases of cirrhosis, (*2.*) one specific cause can trigger different morphological forms of cirrhosis in different patients, (*3.*) several causes can result in the same form of cirrhosis, and (*4.*) several causes often merge in a variety of combinations.

**Morphology:** A systematic approach to cirrhosis based on morphology has so far found the widest acceptance and consequently given rise to various principles regarding classification. (2, 20) Any such approach should, however, focus on the processes which are evident in each individual case:

---

1. *Formation of regeneration nodes*
   - macronodular (> 3 mm)
   - micronodular (< 3 mm)
   - mixed nodular
   - "smooth" surface cirrhosis

2. *Postdystrophic* (monophasic) *cirrhosis*
   (= incomplete postnecrotic cirrhosis)

3. *Pathogenic development*
   - regular forms of cirrhosis
   - irregular forms of cirrhosis
   - biliary cirrhosis
   - vascular cirrhosis

4. *Collapsed form and development of septa*

---

Experience shows that the course of cirrhosis can be reconstructed relatively well from the morphological findings, although certain mixed forms are once again to be expected:

(1.) Atrophic, *finely nodular* cirrhosis, which is low in regenerative capacity and rich in connective tissue, generally develops if the underlying damage persists and its pronounced impact continues. (s. fig. 28.13)

(2.) Cirrhosis which is hypertrophic, *coarsely nodular*, rich in regenerative capacity and poor in fibrosis usually develops if the damage occurs in episodes with intermittent phases of respite. Consequently, the formation of regeneration nodes can be helpful in assessing the duration of the "recovery phases". (s. fig. 35.2)

(3.) *Mixed nodular* cirrhosis (s. fig. 35.6)

(4.) *"Smooth"* cirrhosis (s. fig. 14.3)

Aetiopathogenetical and morphological criteria, however, are to be considered as separate, but complementary factors. In some cases, the aetiopathogenetic cause of a cirrhosis can be diagnosed by reliable morphological findings.

The **transformation of the lobular architecture** is initiated and maintained by at least two histomorphological processes: (*1.*) piecemeal necrosis and (*2.*) bridging necrosis, which provides string-like links between the central veins and the portal fields. Portocentral shunts, which are of significance for the "fate" of cirrhosis, make use of these bridges as routes for their development. During the course of time, these channels, which acquire solid basal membranes like capillaries, carry the portal blood directly to the venous flow-off. As a result, blood is withdrawn from the respective acini; these areas become more susceptible to disruption and damage and are forced to restructure anew. *(see chapter 35)*

---

In other words: the **disruption of intrahepatal haemodynamics** due to *parenchymal necrosis + shunts + formation of septa* ultimately constitutes *"evil which will always continue to bear evil"*, thereby perpetuating lobular transformation.

---

### 5.2.3 Morphological diagnosis

It is of paramount importance for the morphological assessment of cirrhosis to know whether the **liver material** was obtained by (*1.*) post-mortem autopsy (when lymphohistiocytic inflammatory reactions are hardly detectable anymore) or (*2.*) biopsy with the aid of a Menghini needle (which only rarely yields fully assessable cirrhotic material). In contrast, biopsies carried out with a Silverman needle, for example, produce an adequately sized biopsy cylinder for assessment.

▶ Suspicion of cirrhosis is based on the following **criteria:** (*1.*) fragments of the biopsy cylinder are extensively surrounded by fibres, (*2.*) central veins have a non-eccentric arrangement, (*3.*) evidence of increased vascularization or vascular ectasia and possibly also of strikingly poor vascularization, (*4.*) variability of the nuclear pattern, (*5.*) different epithelial sizes with divergent glycogen content, and (*6.*) disordered, tubular or reticular epithelial areas.

▶ It is possible that some of the **uncertainties in diagnosis** as well as any existing differences in the systematic approach to liver cirrhosis taken by pathologists and clinicians might simply be attributable to the fact that the material used for assessment has been considered as representative although it was in fact inadequate and obtained by faulty procurement techniques.

Clinical and particularly scientific statements on the morphology of cirrhosis are most reliable if the following **criteria** are met (s. pp 157, 160):

> 1. **in-vivo examination of tissue**
> 2. **tissue specimens obtained through laparoscopic biopsy (and not by blind biopsy!)**
> 3. **sufficient compact hepatic tissue (best obtained using a Silverman needle)**
> 4. **additional documentation intended for the pathologist using colour photography of the liver surface (since the macroscopic images are frequently of greater relevance in postnecrotic, coarse-nodular transformation processes and it is obviously impossible to cover the entire process by way of biopsy)**

# 6 Liver tumours

Both benign and malignant tumours may be found in the liver. They originate in (*1.*) liver cells, (*2.*) connective tissue, (*3.*) blood and lymph vessels, and (*4.*) bile ducts. An updated systematic classification and nomenclature for nodular hepatocellular lesions was set up in line with the agreement worked out in Los Angeles in 1994. (53) The classification is based on pathogenesis, aetiology and prognosis. A determinant factor for any systematization is the question of whether the cells prove to be regenerative or can be classified as dysplastic, or possibly even neoplastic, and which characteristics are displayed by the respective adjacent stroma of the liver.

## 6.1 Benign tumours

Benign liver tumours are no rarity. As a rule, they only give rise to symptoms or biochemical findings if they have reached a critical size or if they become noticeable due to the compression of blood vessels or bile ducts. Such tumours may be of clinical importance because of their potential precarcinogenicity in individual cases as well as their tendency to massive bleeding following traumatization. Benign liver tumours can be differentiated as (*1.*) *epithelial*, (*2.*) *cholangiolitic*, (*3.*) *vascular*, and (*4.*) *mesenchymal*. It is also possible to differentiate liver cysts (congenital or acquired). *(see chapter 36!)*

*Benign epithelioid tumours* include liver cell adenoma, biliary adenoma, biliary cystadenoma, biliary papillomatosis, *etc.*

*Benign mesenchymal tumours* include angiomyolipoma, lymphangioma, haemangioma, infantile haemangioendothelioma, leiomyoma, *etc.*

*Tumour-like lesions* include hamartoma, FNH, NRH, focal steatosis, peliosis hepatis, inflammatory pseudotumour, cysts, lobular hyperplasia, postnecrotic regenerative nodes, *etc.*

**Regenerative lesions** are the result of localized proliferation of liver cells and their stroma. They are regarded as the main response to various types of liver damage.

Generally, they are circumscribed and 0.5−3.0 cm (or occasionally more) in diameter. They can grow and build up daughter nodes ("nodule-in-nodule"). The parenchyma is regular; these lesions contain portal fields, bile ducts and blood vessels. The hyperplastic hepatocytes are arranged in enlarged liver cell columns consisting of 2−3 plates. Usually, there are no cell atypias. • Congenital or acquired vascular anomalies or irregularities of the arterial blood supply with focal hyperperfusion may also cause the formation of regenerative lesions. A multitude of biochemical factors and hormones also play a key role. (53, 55) (s. p. 402) Regenerative lesions can be classified in five main groups (s. tab. 21.3):

> 1. **Monoacinar regenerative nodes**
>    • *diffuse nodular regenerative hyperplasia without fibrotic septa (NRH)*
>    • *diffuse nodular hyperplasia with fibrotic septa or within cirrhosis (DNH)*
> 2. **Multiacinar regenerative nodes**
> 3. **Lobular or segmental hyperplasia**
> 4. **Cirrhotic nodule**
>    • *monoacinar*
>    • *multiacinar*
> 5. **Focal nodular hyperplasia (FNH)**
>    • *solid type*
>    • *teleangiectatic type*
>      − *solitary*
>      − *multiple*

**Tab. 21.3:** Classification of regenerative lesions

**Dysplastic lesions:** Due to changes in the cytoplasm or the nucleus, dysplastic lesions exhibit histological characteristics such as irregular structure or growth. Genetic factors are considered to be involved (even though appropriate criteria do not as yet exist for all forms). (53) The lesions are classified as follows (s. tab. 21.4):

> 1. **Hepatocellular adenoma**
> 2. **Dysplasia**
> 3. **Dysplastic focus**
> 4. **Dysplastic nodule**
>    • **low-grade (slightly dysplastic)**
>    • **high-grade (severely dysplastic)**

**Tab. 21.4:** Classification of dysplastic lesions

## 6.2 Malignant tumours

In classifying malignant liver tumours, differentiation has to be made between primary and secondary liver tumours (J.B. Gibson et al., 1978; K.G. Ishak, et al., 1994). **Primary liver tumours** are differentiated in four groups. (s. tabs. 21.5; 37.1) *(see chapter 37)*

> 1. **Epithelial tumours**
> 2. **Mesenchymal tumours**
> 3. **Neuroendocrine tumours**
> 4. **Mixed forms**

**Tab. 21.5:** Classification of primary malignant liver tumours

Examples of **secondary** malignant liver tumours are (*1.*) liver metastases, (*2.*) myeloid metaplasia, (*3.*) myeloproliferative diseases, and (*4.*) lymphomatosis.

# Clinical Aspects of Liver Diseases

## 22  Acute viral hepatitis

# 1  History of acute viral hepatitis

Hippocrates described a potentially dangerous disease widely witnessed in young people and accompanied by jaundice. • As early as 752, Pope Zacharias wrote in a letter to St. Boniface, Bishop of Mainz (Germany), about "jaundice of a contagious nature" where those affected would have to be segregated.

▶ In 1629 Henry de Beer wrote about a **jaundice epidemic** in Spa (Belgium). In 1745 Cleghorn described the clinical picture of jaundice witnessed during the course of an epidemic in Menorca (Spain). In 1761 I. F. Herlitz (14) observed many jaundice patients in Göttingen (Germany) and gave an impressive description of the clinical symptoms of this benign illness, which mainly occurred in winter; this was all the more interesting since he himself was suffering from it. The term **icterus epidemicus** in fact stems from him (and was also proposed by A. Hennig in 1890). • Descriptions of jaundice epidemics were to follow from Bremen (Germany) (1760), Essen (Germany) (G. F. H. Bruening, 1772), Genova (Italy) (1792), Lüdenscheid (Germany) (F. Kercksig, 1799), Greifswald (Germany) (L. Mende, 1810), etc. In fact, more than 80 epidemics in Europe and 6 outside Europe were recorded by C. Köhnhorn (1877) (16), C. Fröhlich (1879) (11) and A. Hennig (1890). Numerous publications focused on the frequency of epidemic jaundice in garrisons and at theatres of war, so that the illness also became known as *"soldier's disease"*. • Its causal **origin** was deemed to be poor hygiene, vermin, overcrowding, climatic factors, monotonous and nauseating nutrition, mental trauma, physical strain and polluted water. (quot. in 4, 11, 16) H. Eppinger (1908) was of the opinion that this apparently epidemic jaundice was, in fact, an accidental accumulation of non-infectious diseases. Almost all epidemics were accompanied by severe courses of disease and many deaths. As early as 1862, R. J. Graves drew attention to the fact that "the worst was to be feared if there were any signs of nervous symptoms during the course of jaundice" (hepatic encephalopathy?). He attributed the cause of jaundice to gastroenteritis and believed that it also affected the bile ducts. This opinion was so convincing for R. Virchow (1864) (29) that he later adopted the term **icterus catarrhalis** for catarrhal jaundice, a term that had been introduced by H. Quincke (1903): the bile was thick and sticky with subsequent obstruction of the small bile ducts and development of jaundice. At a later date, he also assumed the cause to be an intercurrent mucous plug in the duodenal papilla. However, towards the end of the 19th century, it was increasingly believed to be an infectious disease (A. E. Ch. Chauffard, 1885; M. Heitler, 1887; S. P. Botkin, 1888 [it was also known as **Botkin's disease** in Russia and the Baltic countries]; A. Hennig, 1890; O. Minkowski, 1904, etc.). The main localization of the disease was already considered to be in the liver parenchyma, but the source of the infection was unknown. Airborne transmission was also postulated. (6)

▶ Reports that were drawn up by Lürman (20) and Jehn (15) on the epidemics in Bremen (Germany) and Merzig (Germany) following inoculation with smallpox vaccine are considered to be the first ever regarding the **parenteral route of infection** (i. e. HBV and HCV infections). In Bremen (Germany) 191 persons (out of 1,290 cases) and in Merzig (Germany) 144 persons (out of 510 cases) succumbed to the disease. Further reference to the parenteral transmissibility of infectious jaundice was made by A. Flaum et al. (1926), G. M. Findlay et al. (1937), A. S. McNalty et al. (1937), S. A. Propert (1938), P. Selander (1942), C. H. Grossman et al. (1946), etc. After an inoculation campaign with a measles convalescent serum involving 109 children, A. S. McNalty (1937) observed the occurrence of jaundice in 47% of cases with a mortality rate of 22%. • W. Siede (1949) reported that 19% of 125 children developed jaundice after an infusion of insulin and dextrose. • In 1943 in the USA, the term *homologous serum jaundice* was introduced, but it was also known as *serum hepatitis*. Over the following years, the terms *haematogenous hepatitis*, *inoculation hepatitis, transfusion hepatitis* and **homologous serum hepatitis** were used as well. (21, 27)

▶ In 1919 F. Lindstedt introduced the term **hepatitis epidemica** for epidemic jaundice. In 1930, however, G. Lepehne proposed the term "hepatia" to avoid emphasizing its inflammatory character. The term **icterus simplex** can be attributed to G. v. Bergmann (1931). Another term used was **infectious hepatitis,** proposed by G. M. Findlay et al. (1939). • Since the morphological studies carried out by H. Eppinger et al. (1935) revealed "acute destructive hepatitis" and the characteristics of "serous inflammation" (R. Rössle, 1929), icterus catarrhalis has also been considered morphologically as "hepatitis", and the term *"acute interstitial serous hepatitis"* is used. In 1937 H. Eppinger distinguished the parenchymal from the periacinal or cholangiolitic form of hepatitis, an idea which is reflected by the present-day term of acute *viral hepatitis with cholestatic character*. H. Eppinger was already familiar with the term *anicteric hepatitis*, which he called "icterus sine ictero" (1937). • In 1940 F. Corelli claimed icterus catarrhalis to be an allergic inflammation which could possibly be improved by desensitization therapy. He reports on a number of interesting observations of icteric patients under a variety of conditions. (7)

*First World War*: The tremendous **jaundice epidemics** witnessed during the war in practically every army and those in the thirties among the civilian population called

for a new definition. An excellent monograph was drawn up by F. v. BORMANN (1940), critically evaluating the entire material available (406 publications quoted!). (4) The clinical picture was described in great detail, all theories and doctrines quoted and observations and experiments presented with the greatest of care. The viral nature of the pathogen was postulated on the basis of the findings. The publication brought out in the same year (1940) by F. LAINER from Eppinger's hospital is an excellent supplement to the level of knowledge of that time − yet even in 1940, the opinion was still held that icterus catarrhalis occurred sporadically in the form of serous hepatitis, precipitated by endogenous or exogenous toxins and not by any specific icterogenic pathogen. (18) • T. TH. ANDERSEN et al. (1938) were the first to trigger jaundice in young swine by feeding them the **duodenal juice** of jaundice patients. This in turn could be transmitted in a second passage to other swine by feeding them the raw liver of the first icteric group. The administration of the blood of jaundice patients to swine also led to the occurrence of jaundice with microscopic liver changes. No pathogen was found and so it was generally assumed to be an invisible virus (1), as McDONALD had already postulated in 1908.

▶ *Second World War*: Large-scale **epidemics,** even **pandemics,** of hepatitis were also rife during the Second World War. Entire military units were severely depleted by the illness. *I was one of those affected in Russia in 1942.* The number of cases of hepatitis in the Second World War has been estimated at approx. 16 million. • In this period, the first transmission of an infectious agent was effected in a **self-experiment** by H. VOEGT (1941), who was later to be my tutor in hepatology. Within 3 or 4 weeks, the oral intake of duodenal juice from a hepatitis patient led to the contraction of hepatitis in both himself and in three medical student volunteers (who had not stayed in an epidemic area). Histological focus was on "capillaritis". Six other test persons, who were orally administered haemolyzed blood or urine taken from a jaundice patient (2 cases) or received serum or blood by s.c. or i.m. injection (4 cases), showed symptoms of hepatitis. The direct transmission path of an infectious virus was hence deemed proven (30) and the existence of "posthepatic residual damage" established (12). In 1952 H. VOEGT told me personally at the university in Giessen (Germany) that he had changed the term **icterus infectiosus** (K. GUTZEIT, 1942) into **hepatitis contagiosa** (1942) − also used by A. DOHMEN in 1943. The term **hepatitis infectiosa** was proposed by F. MAYTHALER in 1942. • In 1943 F. O. MACCALUM confirmed the transmissibility of an infectious agent. (22)

In 1947 MACCALUM termed hepatitis epidemica as type A and inoculation hepatitis as type B. These results were validated by further studies. (13, 23, 24) S. KRUGMAN et al. (1967) introduced the terms MS1 and MS2 for these two types of virus, which at a later date were to correspond to HAV and HBV. (17) In 1970 virus B was detected by

D. S. DANE et al. (8) − following the identification of the Australian antigen by B. S. BLUMBERG et al. (1965) (3) and A. M. PRINCE (1968). (25) In 1973 the hepatitis A virus was discovered by S. M. FEINSTONE et al. (9) In 1977 the delta virus was detected by M. RIZZETTO et al. (28) A pathogen termed hepatitis E virus was identified in 1983 in the stool of an infected volunteer (M. S. BALAYAN et al.). (2) It was assumed that another virus existed (10, 26), which was termed the hepatitis C virus after being identified by Q. L. CHOO et al. in 1989. (5) Detection of the hepatitis G virus (HGV) followed in 1996 (J. LINNEN et al.). (19)

> Infectious jaundice presents the most imposing clinical picture in hepatology and has occupied physicians for more than 2,500 years, caused epidemics and pandemics all over the world (thus significantly influencing the outcome of wars), led to innumerable experiments as well as controversial theories and culminated in absurd speculations including treatment by the oral administration of live sheep lice (a practice still occasionally found nowadays). • Today, hepatitis viruses have been (almost) fully explained down to the last molecular, biological and serological detail.

# 2 Morphology and aetiopathogenetic range

▶ Histologically, the suffix **"itis"** denotes inflammation, thus "hepatitis" can be defined as "inflammation of the liver". This term was coined by J. B. BIANCHI as early as 1725 in order to summarize various diffuse inflammations of the parenchyma.

The classical **criteria of inflammation** (*1*.) *exudation*, (*2*.) *cellulation* and (*3*.) *proliferation* can only partly be applied to the liver, since this organ is predominantly characterized by sinusoids rather than capillaries. An essential problem thus arises in the morphological context of the term "hepatitis". *Due to this specific vascular feature, the otherwise valid association between the terms "inflammation" and "infection" is only marginally true in the case of the liver.* In fact, this association is only given with infectious changes within the vascularized fibrous tissue of the portal fields. • *The problem concerning the definition of "hepatitis" has already been outlined in detail in the last chapter.* (s. p. 404)

> Macroscopically, acute viral hepatitis presents as a **large red liver** (H. KALK, 1947). The *enlargement* is probably due to hyperaemia and to the oedematization of the portal area. The *reddening* is brought about by hyperaemia and the accumulation of large quantities of stagnating erythrocytes in the empty lattice fibre network.

## 2.1 Histomorphological changes

Histologically, the parenchyma, the mesenchyma and the connective tissue are affected in an almost identical manner. The combination of all lesions together with the onset of hepatocellular regeneration gives the typically **unsettled variegated picture** of acute viral hepatitis, which is more characteristic than any single finding on its own (H.-W. ALTMANN, 1971). The liver lobules are affected as a whole and in all their components, whereby particularly the hepatocytes at the centre of the lobule are most severely damaged. For this reason, acute viral hepatitis is deemed to be **lobular hepatitis.** These changes are shown as constant or inconstant lesions. (31, 34, 36) (s. tab. 22.1)

| | Lobular | Portal and periportal |
|---|---|---|
| **Con-stant** | Liver cell degenerations (hydropic swelling, eosin-ophilic degeneration, pin cells, hyaline bodies) and cell polymorphy, single cell necrosis in the form of (acidophilic) Councilman bodies, infiltration of lympho-cytes, macrophages and activated stellate cells (yet only few plasma cells and neutrophilic granulocytes), prolifer-ation of sinusoidal cells. | Infiltration by small lymphocytes, plasma cells and other mono-nuclear cells (= lym-phohistiocytic). |
| **Incon-stant** | Confluent liver cell necro-sis, possibly developing into bridging necroses (32) or multilobular (< 3% of cases) or even massive necroses in B, B/D and C hepatitis, as well as in E hepatitis dur-ing pregnancy; collapse of the lattice fibre net-work. Formation of pas-sive septa, cholestasis, ac-cumulation of ceroid and siderin in macrophages and stellate cells. | Flow of infiltrates into adjacent lobular areas, fibroblast activity, damage to and prolif-eration of bile ducts, accumulation of ceroid and siderin in macro-phages. |

*Tab. 22.1:* Morphological changes with acute viral hepatitis

**Mitoses:** The consumption of liver cells by necroses is considerable, as is the concurrent regeneration process, particularly at the onset of acute hepatitis and during the retrogressive phase. • This also explains the remarkable observation that patients with the *Dubin-Johnson syndrome* are found to have far fewer pigment-charged liver cells subsequent to acute viral hepatitis. (s. pp 222, 421)

**Stellate cell activation:** At the climax of acute viral hepatitis, the stellate cells are diffuse and highly activated. **Stellate cell nodules** (s. fig. 22.3) are formed. The diffuse spread of the swelling and the proliferation of sinusoidal cells may recede during the retrogressive phase into more localized proliferations. These somewhat indis-tinctly contoured stellate cell nodules can often be detected in the necrotic area already at an early stage. In this event, they generally contain the liver disintegration pigment **ceroid** (s. fig. 21.6), later also **lipofuscin** (s. fig. 21.3) and **siderin.** Such so-called *residual*

*Fig. 22.1:* Acute viral hepatitis A: Periportal inflammation and periportal cell loss

*Fig. 22.2:* Subsiding acute viral hepatitis A with lytic loss of hepa-tocytes and round-cell infiltrates

*Fig. 22.3:* Kupffer cell nodules (arrow) in subsiding acute viral hepatitis B; hydropic hepatocytes, often binuclear

*nodules* (H. KALK et al., 1947) or *late-phase nodules* (W. WEPLER et al., 1968) are frequently still found 1 to 2 months after the acute hepati-tis is deemed to be clinically healed. The nodules remain diffusely distributed in the parenchyma until they gradually diminish, lose their pigment and ultimately disappear completely.

**Regeneration:** Regenerative processes overlap with the slowly dwindling inflammation. They are characterized by a proliferation of the liver cell columns, an uneven pattern of cell nuclei, an increase in mitoses and the formation of liver cell rosettes. (s. p. 229) Acute viral hepatitis usually heals completely within a period of 4−8 weeks.

**Formation of collagen:** The empty lattice fibre structure in a de-epithelialized area (with possible collapse of the lattice fibres) becomes increasingly collagenized, so that sclerosis occurs at the centre of the lobules in place of lost liver cells. This process may be completely reversible if the regenerated liver cells succeed in respreading the fibres. Otherwise, central fibre scars persist for a long period of time. This fibre production occurs far earlier and to a more pronounced extent at the periphery of the lobules. In delayed epithelial regeneration, the fibre layers or cicatrized changes remain as portal fibrosis. (s. p. 404)

## 2.2 Sonographic morphology

With the help of sonography, it is possible in acute viral hepatitis to obtain the following findings: (*1*.) hepatomegaly, (*2*.) slight increase in brightness, (*3*.) truncated lower liver margin, (*4*.) thickening of the gall-bladder wall (35), and (*5*.) increased blood flow (using duplex sonography).

## 2.3 Specific courses of disease

Various endogenous or exogenous factors can alter the histomorphological picture of acute viral hepatitis, so that specific courses of disease may become apparent.

### 2.3.1 Minimal hepatitis

The course of minimal hepatitis (O. KLINGE, 1976) is generally found in anicteric or subicteric patients and only shows minor histological lesions. It is even possible over a period of several years to detect the hyaline bodies, the activation of the sinusoidal cells and the moderate round-cell infiltration of the portal fields as well as single cell necrosis. These changes show no progression, so that histology largely corresponds to that of chronic persistent hepatitis.

### 2.3.2 Drug-induced hepatitis

Irrespective of the type of drug, acute hepatitis (so-called *"hippie hepatitis"*) prevails in drug addicts. It is characterized by portal infiltration, generally with a large number of eosinophilic leucocytes. Cholestasis is common. The lobular borders are often difficult to define. In most cases, phagocytized exogenous pigments or waste substances are found in the macrophages. • However, the extent to which primary or secondary hepatotropic viruses are involved must always be clarified. (s. tab. 5.16) • Histology, the course of disease and the prognosis are determined by the duration and intensity of drug intake, polytoxicomania or additional viral infections.

### 2.3.3 Cholestatic course of disease

▶ The "cholestatic course of disease" (W. SIEDE, 1942) is largely identical to the "periacinal form of icterus catarrhalis" (H. EPPINGER, 1937), "cholangiolitic hepatitis" (C.J. WATSON et al., 1946), "hepatitis with intrahepatic obstruction" (I. MAGYAR, 1953) and "hepatitis with a cholestatic element" (H. KALK, 1957).

Those forms of acute viral hepatitis that have a normal clinical course also present discrete quantities of bile to be found as intraepithelial drops and intercellular cylinders or deposits in the stellate cells. These findings cannot be confirmed biochemically. • A cholestatic course of disease is occasionally witnessed with a marked increase in alkaline phosphatase, particularly in older patients and in women. It is mostly accompanied by jaundice. The patient's general well-being is significantly compromised, and pruritus is pronounced in most cases.

**Histologically,** changes linked to the respective stage of hepatitis can be observed together with an abundance of bile drops in the liver cells, above all in the centre of the lobule; in addition, there are bilirubin cylinders inside the canaliculi that are often dilated and tubular in shape. Sometimes, tubular reshaping of the liver cell plates is noticeable, with a bile canal in the centre. • **Cholestatic liver cell rosettes** develop in isolated surviving hepatocytes or small groups of hepatocytes within areas of collapse. These parenchymal islands of hepatocytes are arranged in a tubular pattern resembling that of the cholestatic liver cell rosettes. Evidence of bile retention is not always obvious, but copper and copper-associated protein are often demonstrable. Bile duct proliferation is usually inconspicuous. (s. p. 229) Bilirubin cylinders can also be detected in the ductuli. In the portal fields, the picture of cholangiolitis is witnessed: small, round-cell infiltration with embedded leucocytes and degenerative changes of the portal bile ducts. (s. fig. 22.4)

*Fig. 22.4:* Feathery degeneration (arrows) of ballooned hepatocytes, massive liver cell oedema and bilirubinostasis in the canaliculi. Clinically: cholestatic course of acute viral hepatitis B

### 2.3.4 Anicteric course of disease

As early as 1904, O. MINKOWSKI observed the anicteric form, and later, in 1937, H. EPPINGER described it using the term "icterus sine ictero", i.e. the bilirubin values in the serum are not in excess of 1.5−1.8 mg/dl, with the result that no jaundice of the sclerae can develop. This is a clinical phenomenon and not a morphological one. There are even reports of fatal acute liver necrosis without jaundice. Generally, the clinical findings are less pronounced than with the icteric course of disease. Bilirubinuria is only observed in isolated cases, whereas urobilinogenuria is usually detectable. (s. pp 421, 432)

### 2.3.5 Fulminant course of disease

Hepatitis fulminans (B. LUCKÉ et al., 1946) is the most severe course of viral hepatitis, and in 80−90% of cases, it is fatal. The term is used if signs of liver insufficiency emerge within 8 weeks following the onset of disease. (If this occurs later, preference is given to the term "subacute necrotizing hepatitis".) • The clinical findings suddenly and swiftly multiply in intensity and acuity. In addition, fever, nausea, vomiting and hepatic foetor are witnessed, and the sensorium becomes dulled. Cutaneous and mucosal bleeding occurs, and there may be evidence of oliguria and oedemas. Laboratory parameters show a considerable decrease in enzyme activity, serum iron (after an initial increase), Quick's value, albumin and cholinesterase. Leucocytosis is frequently observed. The morphological picture is characterized by extensive, confluent parenchymal necrosis (*liver dystrophy*). There is virtually no sign of a mes-

enchymal reaction. Postdystrophic *scarred liver* is usually found in those surviving the disease. (s. figs. 21.13; 22.16; 35.14)

### 2.3.6 Giant-cell hepatitis

**Giant cell hepatitis in children:** During infancy, acute viral hepatitis can occur with the formation of syncytial, polynuclear balloon-like giant cells. Recessive autosomal *hereditary factors* are said to contribute to this form of hepatocyte reaction. In recurrent intrahepatic cholestasis of the Aagenaes type, giant-cell hepatitis usually develops. The **pathogens** include CMV, the herpes, varicella, Coxsackie, ECHO, HBV and rubella viruses, as well as listeriosis, toxoplasmosis and syphilis. The pattern of epithelial damage largely corresponds to classic acute viral hepatitis − however, the histological picture is dominated by giant cells. (s. fig. 22.5) (s. p. 467!)

Differentiation is made between **two types:** (*1.*) giant cells in a regular arrangement (with evenly placed giant cells around the former canaliculi) and (*2.*) giant cells in an irregular arrangement. Both types may appear simultaneously. • Their *development* is probably due to the confluence of liver cells following disintegration of the membrane − so-called confluent giant cells (O. KLINGE, 1970). This process is facilitated by the fact that in children up to the age of five, liver cells are usually still in a double epithelial plate-like arrangement. Following their cytolysis, the giant cells are replaced by regular epithelium. The prognosis is often good, but reports have also been received of severe courses of disease.

*Fig. 22.5:* Numerous multinuclear giant cells (centre of picture) as well as bile duct proliferation (arrow) in so-called giant-cell hepatitis (HE)

**Postinfantile giant-cell hepatitis:** This term was introduced by H. THALER in 1982. The form itself is rare; only about 70 cases have been reported so far. (33) Generally, it develops in a similar way to progressive cholestasis of unknown aetiology. It mainly affects zone 3. The giant cells make up > 10% of the hepatocytes. They contain large numbers of nuclei (up to 40 per cell). Numerous luminae can be detected in the cytoplasm. Pathogenetically, this is a syncytial formation (and not amitotic cell regeneration as in the infantile form). The morpho-

logical spectrum extends from acute to chronic hepatitis and ultimately to cirrhosis. The giant cells are often present to such a minimal extent that they are undetectable in a biopsy specimen. The frequency of disease is possibly greater than has been assumed up to now. It may be caused not only by infections, but also by medication or the Epstein-Barr virus and paramyxoviruses. The frequent evidence of autoantibodies (e. g. ANA) and significant increases in γ-globulin levels point to a close correlation between giant-cell hepatitis and autoimmune processes such as PSC.

### 2.4 Aetiopathogenetic diversity

The problem of working in line with morphological classification is rendered more complicated by the aetiopathogenetic diversity of acute hepatitis. The tissue changes in acute hepatitis arise not only from primary hepatotropic viruses and secondary hepatotropic or exotic types of viruses, but also from bacterial or parasitic agents. • Changes identical to these can, however, also be caused by alcohol, chemical substances, toxins or allergic and immunological reactions as well as by reactions to radiation (so-called radiogenic hepatitis), for example from cobalt − and even by the early forms of Wilson's disease or primary biliary cholangitis.

A recently discovered form of acute hepatitis was attributed to a *deficiency of lipoamide dehydrogenase* (= catalytic subunit E3 of the pyruvate dehydrogenase complex). This LAD deficiency was allocated to chromosome 7 (q31-q32). So far, about ten well-documented cases have been reported. The patients all died during early childhood. (32) • Recently, there were reports of *episodes of acute hepatitis* each with significantly increased transaminases, slight jaundice and uncharacteristic symptomatology. Between the episodes, all the liver values were normal. Histological analyses only revealed minor findings in the form of non-specific reactive hepatitis. The aetiology could not be determined even though the entire range of clinical examinations was applied. This entity is considered to be identical to benign recurrent intrahepatic cholestasis. (37)

The respective lesions in the area of the lobules and portal fields and at the hepatocytes, the mesenchyma and connective tissue differ in intensity from case to case (also depending on the respective stage of the disease) − yet the picture of "acute hepatitis" predominates. • *In each case of liver disease which remains unresolved in terms of differential diagnosis, thought must be given to the possibility of acute hepatitis with its wide range of aetiological causes.* (s. fig. 22.6)

**Acute hepatitis** *is not an entity in itself, either clinically, aetiologically or morphologically − but must be seen as a* **syndrome.**

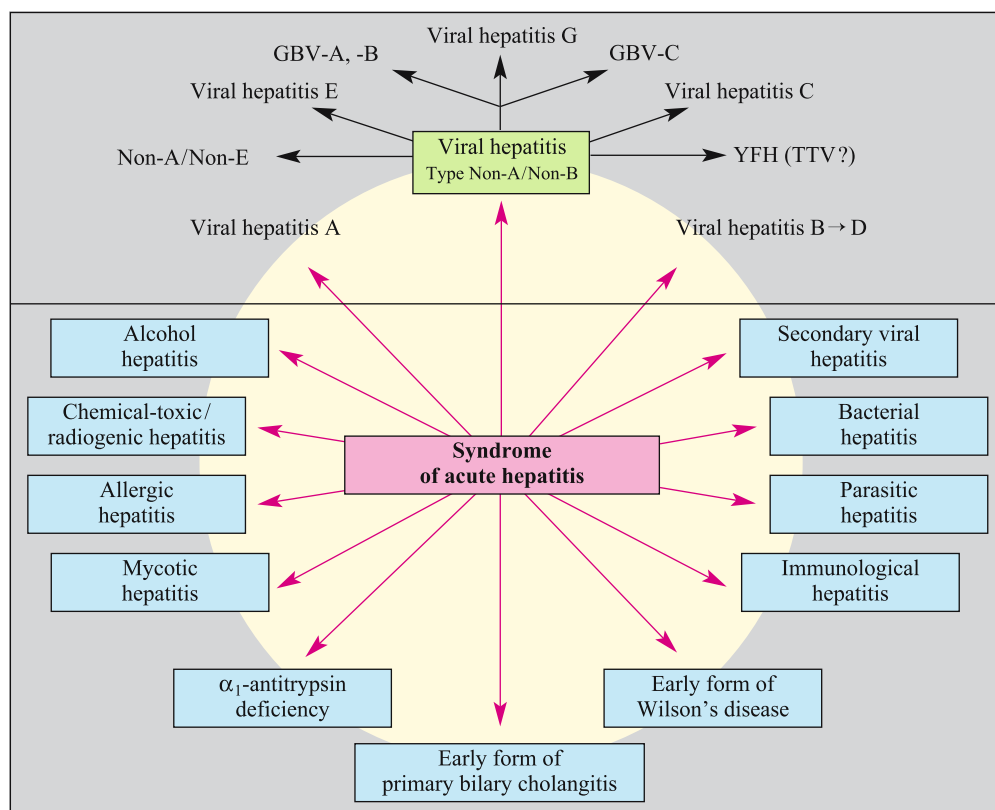
417


*Fig. 22.6:* Syndrome of acute hepatitis (s. tab. 5.16)

# 3 Acute viral hepatitis A

## 3.1 Definition

Acute viral hepatitis A is caused by an enterally transmitted RNA virus of 27 (−32) nm in diameter. It is self-limiting and usually self-healing, contracted by people lacking virus A antibodies − hence its preference for children. With good hygienic living standards, however, the tendency of infection shifts increasingly to adulthood. The disease seldom follows a biphasic or cholestatic course. A fulminant course of disease is very rare (ca. 0.01%). Transition into chronic hepatitis need not be feared. (s. p. 422!) There is no causative correlation with primary liver cell carcinoma. Healthy HAV carriers are not known. The disease leaves the patient with life-long immunity.

## 3.2 Pathogen

Up to now, **one serotype** has been identified. **Seven genotypes** of HAV are known to show serological cross-reactions. Three genotypes are deemed to be HAV strains, stemming from the *simian virus.* Recently, a new genotype 1 B variant was described. (43) By means of genotyping, it is possible to explain the geographic origin of the virus, the individual source of infection, etc. HAV since been characterized in greater detail. (74, 114) (s. p. 112!) (s. fig. 5.4!)

### 3.2.1 Inactivation

HAV survives for up to 3 months in freshwater or sea water. It is completely inactivated by **heat** at 75 °C for 20 minutes or 85 °C for 1 minute, but only partly inactivated at 60 °C for 4 hours. Boiling water (< 15 minutes) is not enough to inactivate HAV completely, particularly if the instruments have not been mechanically cleaned with due care prior to heating. **Formalin** (diluted solution, 37 °C for 2 hours), **β-propriolactone, sodium hypochloride** and **glutaraldehyde** (2%) are suitable for inactivating HAV. • *Alcohol, ether or acids (up to pH 3) do not inactivate HAV; the virus also remains stable down to −70 °C.* (105)

### 3.2.2 Detection

**Stools:** With the aid of an electron microscope, HAV is detectable in the stools 7 to 11 days before the acute phase of disease begins. The rate of detection in the 1st week in no more than 50% of cases, in the 2nd week about 29% of cases and in the 3rd week merely 4% of cases. After the 4th week, HAV can generally no longer be found in the stools at all − by means of molecular hybridization (or PCR), PCR, however, it may be possible to detect the viruses up to 3 months following onset of the disease. In the event of clinical relapse, HAV is again apparent in the stools. (107) The presence of the virus ($10^9 - 10^{11}$ particles/g stool) clearly means infectiosity − yet a negative test does not definitely rule out infectiousness. It has hitherto not been possible to validate either the replication of the virus in stools or its permanent excretion. Some two weeks after the initial occurrence of dark urine, intestinal excretion of the virus has generally ceased, and in addition, patients are no longer infectious with respect to their environment.

**Serum:** At the same time as viruses are excreted in the stools, viraemia is apparent. The highest concentrations are found shortly before the onset of the disease ($> 10^7 - 10^9$ particles/ml serum). Using PCR, it was possible to show that viraemia can exist for longer than 3 weeks, and even up to 4 months.

**Cells:** The HA antigen is detectable as granular fluorescence in the cytoplasm of the hepatocytes from the 2nd week after infection, about 1 week prior to excretion in the stools. HAV could also be detected in the spleen and lymph nodes (P. KARAYIANNIS et al., 1986).

### 3.2.3 Replication

Replication of HAV is effected within the liver cell following its transportation into the interior via a "receptor": (*1*.) the capsid proteins are removed and the RNA is released; (*2*.) both are reproduced separately in the cytoplasm; (*3*.) new viruses are assembled from the RNA copies and the structural proteins; (*4*.) these viruses are packed into vesicles and released into the biliary pole; (*5*.) the viruses are excreted via the ductuli. The viruses enter the bile by way of the ductules and are subsequently excreted into the bile and stool as early as 1−2 weeks before onset of the disease.

### 3.3 Transmission

Transmission of HAV is effected by a **faecal-oral route.** The main danger, therefore, is *poor hygiene*, as is occasionally found in communal houses or flats, children's homes, prisons, shelters for the homeless and homes for the mentally handicapped as well as among injecting drug users, etc. (45, 59, 73, 85, 91, 108) A similar danger prevails for those who are constantly exposed to material that contains viruses, such as sewage and water purification plant workers (57), medical personnel (= *nosocomial infection*) (s. pp 428, 441) (70), dentists (55) and staff in neonatal intensive care units. (97, 117) • An additional hazard exists in infected drinking water and foodstuffs, such as ice cubes, ice-cream, frozen strawberries and raspberries, raw bilberries, salads, green onions, raw milk, hamburgers, cold meat, bread, cakes and pastries. (38, 43, 52, 66, 79, 80, 86, 90, 116) The warming up of food with microwave ovens (> 1 minute) has been shown to lower the risk of infection. (87) • Even chlorinated water in a swimming pool can serve as a vehicle for HAV infection. (82) Sexual transmission is rare, although an oral infection route may be responsible for infection in such cases, especially among homosexuals. (47, 110) The hands, in particular, are vehicles of HAV transmission to animate and inanimate surfaces. (84) HAV infection of an animal keeper at a zoo, transmitted for example by the apes he cares for, is accepted as an occupational disease. (100)

**Oyster hepatitis:** The ingestion of oysters cultivated in pools or harbour basins has led to oyster hepatitis (B. Roos, 1956). This is due to their mode of life: filtration of approx. 40 litres water/hr, whereby coliform bacteria are excreted again, leading to a 100-fold concentration of HAV. Usual boiling of oysters in water does not guarantee inactivation of such highly concentrated HAV. (54, 95) The terrible epidemic in Shanghai in 1988 caused a sensation, with 292,301 cases of disease (4,083 per 100,000 inhabitants) being registered. The infection was brought on by the ingestion of inadequately boiled Venus oysters (Anadara subcrenata Lischke). (63, 112)

▶ **Posttransfusion transmission** was observed for the first time by T. Francis (1946) and A.G. Harden (1955). In isolated cases (e.g.

collection of blood and blood plasma during viraemia), a haematogenic mode of transmission is conceivable (65, 103) (see earlier observations of H. Voegt [30], S. Krugman et al. [17]). Infection of haemophiliacs from factor VIII preparations is likewise considered rare (61), as is infection in haemodialysis units. However, a total of more than 80 cases have actually been reported. • *There have been no reports of* **perinatal infection.**

### 3.4 Epidemiology

HAV is a ubiquitous virus, especially since it retains its stability in heat and cold under normal environmental conditions and is highly resistant to external influences. The risk of infection correlates with a low standard of hygiene. For this reason, a 7 to 10-fold increase in frequency of the disease must be anticipated when travelling to certain countries (some 20 cases of infection out of 1,000 travellers per month). The risk of infection is even greater with so-called adventure trips (overland trekking, backpacking) in those countries. The same also applies to persons engaged in humanitarian or development projects. Given these factors, prior active vaccination is a necessity, unless immunity already exists. (78, 109)

The **seasonal frequency** of infection in the late autumn and winter, which used to be most pronounced in the wake of dry summer months (at least in northern latitudes), is less evident today. It is possible that *closer physical contact* resulting from unfavourable weather conditions played a part here − especially since such seasonal fluctuations were not observed in southern regions.

▶ Recent decades have witnessed large-scale **epidemics** *in several countries*, generally caused by poor hygiene conditions and/or infected food or drinking water. (51, 63, 112) • This is also true of the great epidemics and **pandemics** with their impact on the battle fronts and across the frontiers during the **Second World War:** from 1939−1945, between 5 to 6 million German soldiers and 3 to 4 million civilians (i.e. about 13% of the German population at that time) contracted an HAV infection. These figures do not include the undoubtedly large number of unidentified anicteric courses of disease. • A wide-scale regrouping of troops had to be carried out as a result of the losses in manpower due to HAV infection, as *I experienced myself when I likewise contracted the disease in Russia in 1942.* (s. p. 414)

The **infection rate** among the population of a country correlates with age, hygiene standards, socio-economic status and individual risk factors (drug addiction, homosexuality, close contact with infected persons, etc.). Men and women are subject to the same frequency of infection, irrespective of age or race and seasonal or regional factors. • In Germany, there has been a rapid decrease in natural immunity, because far fewer juveniles become infected with HAV today. Consequently, when people contract the infection at a more advanced age, there is a higher complication rate and greater mortality (2.7% vs. 0.004%).

### 3.4.1 Frequency of disease

The infection rate is established by determining anti-HAV IgG in the serum. Prevalence depends upon the epidemiological situation in a particular country. At

40−50%, Germany ranks in the middle, with a clear dependence on age: some 5% of eighteen-year-olds and about 75% of seventy-year-olds are positive. Currently, 30−40% of those older than fifty are HAV-negative in Germany. The infection rate is about 4 to 5 times higher than the number of cases actually registered. (56, 76)

### 3.4.2 Obligation for notification

Germany's 4th Federal Epidemic Control Act (1992) requires that all cases involving primary hepatotropic viruses (A, B, C and others) which result in disease or death are reported to the local Public Health Department. (s. tabs. 23.1, 23.2; 24.3; 25.1)

There has been a continuously declining tendency in the number of HAV cases in numerous countries as a result of improved hygiene and active vaccination. • In *Germany*, the following **frequencies** of HAV disease were registered − although the actual figures were probably much higher. (s. pp 426, 440)

| | |
|---|---|
| 1992 = 6,990 | 1998 = 3,811 |
| 1993 = 5,839 | 1999 = 3,131 |
| 1994 = 5,488 | 2000 = 2,820 |
| 1995 = 6,639 | 2001 = 2,274 |
| 1996 = 4,911 | 2002 = 1,479 |
| 1997 = 4,596 | 2003 = 1,365 |

**Mortality** in the same period (1992−2002) was as follows:

| | |
|---|---|
| 1992 = 13 | 1998 = 9 |
| 1993 = 14 | 1999 = 13 |
| 1994 = 12 | 2000 = 11 |
| 1995 = 12 | 2001 = 17 |
| 1996 = 19 | 2002 = 11 |
| 1997 = 15 | 2003 = 4 |

## 3.5 Pathogenesis

In principle, differentiation is made between two **phases:** (*1*.) initial *non-cytotoxic reaction* with a high HAV replication rate and (*2*.) *cytopathogenic reaction* with low virus production, histological signs of inflammation and development of immunity. • **Liver cell necrosis** is caused by T lymphocytes (CD$^{8+}$) specific to the virus, with T cell-induced cytolysis occurring in the course of the immunological response. The virus is subsequently neutralized by antibodies. • Given the right predisposition, HAV is deemed capable of triggering **autoimmune hepatitis.** (96, 115)

## 3.6 Serological diagnostics

Direct detection of **HAV** and **HAAg** in the blood or stools is only necessary for scientific purposes. • Serological diagnostics is based on the specific detection of **anti-HAV IgM,** the presence of which confirms acute viral hepatitis A. In differential diagnosis, it is necessary to rule out acute viral hepatitis E, with which anti-HAV IgM may likewise occur! Anti-HAV IgM rises in the serum during the first 2 weeks of the disease, i. e. 3 to 4 weeks after infection. It persists for about 2 or 3

months, and in single cases for up to 12 months (71), with slowly diminishing titre values. A clinical relapse is usually accompanied by a renewed increase in anti-HA IgM; in protracted courses of disease, the drop in titre values is generally delayed. • A rise in **anti-HAV IgG** is observed four to six weeks after infection. This finding points to a subsiding HAV count or one which has long since run its course. The IgG specific to the virus persists for a lifetime and reflects the HAV immunity of the carrier (and the infection rate of the population or community). (78) (s. p. 113) (s. fig. 5.5)

The mere detection of **anti-HAV** only implies the presence of virus-specific IgG or IgM and offers no information on acuity or immunity. For this purpose, it is necessary to determine the antibodies of the IgG or IgM. Maternal HA-antibodies pass to the foetus via the placenta and provide the infant with postnatal immunity for a certain period of time. The most sensitive method of detecting hepatitis A is by RT-PCR. HAV-RNA can also be detected with high sensitivity using molecular hybridization (up to approximately 10$^4$ copies per ml).

## 3.7 Stages of disease

**Incubation period**
The period of time between HAV infection and the manifestation of symptoms ranges from 15 to 49 days, the mean period varying between 25 and 30 days. A shorter incubation period is often accompanied by a severe course of disease, i. e. fluctuations in the period of incubation depend on the respective quantity of the virus uptake and on the individual immune response.

**Prodromal stage**
Generally, the onset of the prodromal stage is characterized by nausea, vomiting, lack of appetite, a feeling of repletion and diarrhoea (or constipation), followed by weakness, fatigue, fever, headaches, itching, sore throat, painful joints, impaired sense of smell and taste, light sensitivity and coughing − in various degrees of intensity and frequency. These symptoms often take the form of a "febrile influenzal infection". In children and juveniles, the "gastrointestinal" symptoms predominate, whereas adults more frequently present with jaundice as well as aching joints and muscles.

**Clinical stage**
In approx. 90% of all patients, acute viral hepatitis A is subclinical, i.e. it frequently goes undetected. The end of the prodromal and the beginning of the clinical phase is indicated by a *brown colouration of the urine*. Urobilinogenuria persists for a longer period of time than bilirubinuria. Mild proteinuria and microhaematuria can develop. *Stools are usually acholic*. • With the occurrence of *jaundice* (60−70% children, 80−90% adults), most of the subjective symptoms of the prodromal stage subside,

whereas *fever* and *exanthema* often occur. There is evidence of *hepatomegaly* in 70−80% of cases (whereby the liver is sensitive to pressure due to capsular distension and has a soft consistency) and *splenomegaly* in 20−30%, more rarely also *cervical lymphadenopathy* (10−20%). • **Children** often show a moderate or asymptomatic course.

From the end of the incubation period, **laboratory parameters** show a rise in *LDH* as an expression of virocyte duplication. They reach their maximum value in the prodromal stage and decline from the beginning of the icteric stage. • Already in the prodromal phase, the *indicator enzymes* GPT, GOT and GDH begin to rise, the increase in GPT being evident at an earlier point ("liver cell damage") and that of GOT somewhat later. The transaminase values (usually between 800−1,200 U/l GPT and 500−700 U/l GOT) do not necessarily correlate with the degree of severity. In approx. 95% of cases, the transaminases show one peak. Generally, the DeRitis quotient is <1 ("inflammation type"). (s. p. 95) (s. tab. 5.6) (s. fig. 5.5) The *y-GT* rises until the end of the icteric phase and then recedes to the normal range at a slower rate than the indicator enzymes − also reflecting regeneration of the liver cells. (s. p. 97) A rise in *serum iron* is always an expression of liver cell damage. (s. p. 98) The *AP* and *LAP* only increase minimally. Conjugated *bilirubin* is elevated, where the bilirubin values − and to a far greater extent the duration of the jaundice − correlate with the degree of morphological severity. *IgM* in the serum is clearly higher. The *haemogram* initially reflects leucopenia and lymphopenia, the latter often developing into relative lymphocytosis with the production of *atypical lymphocytes*. All other parameters (electrophoresis, Quick's value, cholinesterase, autoantibodies, etc.) are normal. Zinc and selenium, which are important for the body's own defence, are often reduced; copper levels are elevated. (71) *Viraemia* may be longer-lasting than previously assumed: HAV RNA is detectable about 17 days before GPT increases and several days before HAV IgM appears. Viraemia persists for an average of 79 days after GPT increase, i.e. the main duration of viraemia is 95 days. (41)

### Convalescence phase

The icteric phase lasts for some 2 to 6 weeks. Laboratory parameters become completely normalized after 4 to 6 months. Normalization of the *serum bile acid* is also deemed to be a reliable parameter of recovery. The regression phase is often characterized by pronounced *diuresis*. (56, 76, 113)

### 3.8  Extrahepatic manifestations

Extrahepatic manifestations have repeatedly been described in viral hepatitis A. (78) They can complicate the course of disease and cause considerable clinical difficulties. (s. tab. 22.2)

Acute renal failure (60, 93, 120)
Aplastic anaemia
Arthralgia (68)
Ascites (48, 77)
Cholecystitis (39, 88, 92)
Cryoglobulinaemia (67, 68)
Encephalitis (64)
Exanthemas
Guillain-Barré syndrome (42)
Haemolysis (81)
Myalgia
Pancreatitis (50, 75, 104)
Pleural effusion (106)
Purpura (44)
Thrombocytopenia (44)
Urticaria (102)
Vasculitis (49, 67, 68)

**Tab. 22.2:** Extrahepatic manifestations with acute viral hepatitis A (with some references) (s. tabs. 22.7, 22.8)

### 3.9  Clinical courses of disease

► Acute viral hepatitis A usually pursues an uncomplicated course (in children mostly mild or asymptomatically) and heals without sequelae (90−99%). About 13% of the elderly patients need clinical therapy. • Nevertheless, some particular courses of disease are worth mentioning:

**Cholestatic course**
Characteristic of this course of disease − mainly in elderly patients − are the greatly increased bilirubin values (15−30 mg/dl) lasting between 2−5 months, accompanied by elevated AP (and LAP) values. Transaminase activity is relatively low (generally below 500 U/l). Clinical symptoms include itching, fever, malaise, bradycardia and a loss of weight. This complicated course of disease finally heals without sequelae. (46, 49, 62, 64, 101, 118) (s. pp 416, 432) (s. fig. 22.4)

**Fulminant course**
Very rarely (0.01%), albeit more frequently in elderly patients and people with a compromised immune system (0.1−1.0%), viral hepatitis A takes a fulminant course. About 1.0% of all cases of fulminant viral hepatitis are caused by HAV. The survival rate is >90%. (53, 83) (s. pp 377, 433)

**Protracted course**
Delayed courses of disease lasting between 6 and 18 months (2−3%) have been observed repeatedly (also by us in three cases). The frequency is estimated at 5−20%. (101) (s. p. 432) • This protracted course of HAV infection can, however, be a sporadic, recurrent *HEV infection*, since HAV IgM also reacts positively here! • With both a protracted as well as a cholestatic course, thought must always be given to the combination of acute viral hepatitis with the *Dubin-Johnson syndrome* when drawing up a differential diagnosis. In one protracted and cholestatic case, we observed that it was ultimately the typical histological finding which produced the diagnosis. In such cases, percutaneous biopsy is essential for differential diagnosis. (s. pp 223, 415) (s. fig. 12.1) Generalized lymphadenopathy can be considered as a marker of ongoing inflammation. (89)

**Anicteric (subclinical) course**
The anicteric course is mainly found in children. However, it generally remains unidentified due to the multifarious complaints. For this reason, the condition can give rise to a chain of infections, particularly in nursery centres and schools. (94) (s. pp 416, 432)

**Recurrent course**

For reasons that cannot be explained (reinfection? reactivation?), relapse occurs in 5−15% of cases, especially in children. There may be renewed HAV excretion in the stools (with the danger of infection for the environment) and a more pronounced increase in anti-HAV IgM in the serum. The clinical course is usually milder than in the first phase of the disease, yet is more frequently accompanied by cholestasis and extrahepatic manifestations. Despite this relapse, the disease heals completely. (40, 107)

**Chronic course**

▶ A report on the (possibly) first case of acute hepatitis A developing into chronic active hepatitis (CAH) and cirrhosis has already been published. (69)

## 3.10 Formation of granulomas

As with various viral, bacterial or parasitic diseases, with Hodgkin's disease or after the intake of allopurinol, etc. (s. tab. 21.1), acute viral hepatitis A can be accompanied by intrahepatic fibrin-ring granulomas. (99)

## 3.11 Prophylactic measures

In principle, consideration has to be given to any measure that prevents faecal-oral HAV infection, e. g. correct **hygiene procedures** − particularly in risk situations. Generally, for water and food, is required: *"Cook it, peel it or forget it!"* This includes the (worldwide) purification of drinking water and the operation of reliable sewage plants. (45, 47, 73, 78)

### 3.11.1 Passive immunization

Passive immunization by means of standard immunoglobulin (J. STOKES et al., 1945) requires an absence of HAV antibodies. The detection of anti-HAV renders immunization superfluous. Such protection is temporary, lasting approx. 2−4 months. It is effective as both a **pre-exposure** measure (almost to 100%) and **postexposure** measure (in over 80% up to 14 days after exposure and possible infection). Passive immunization should also be given to pregnant women who have been exposed to infection. • Immunization is indicated to protect HAV-antibody-free persons in their contact with diseased persons or prior to a stay in high-risk regions. The immunization of antibody-free persons also makes it possible to develop a temporary protective ring of immunity, preventing the infection from spreading when diseased persons are being cared for. This so-called *vaccination seal* is recommended for families and schools or institutions where there is close physical contact. Such passive immunization should be extended to simultaneous vaccination as well. (45, 58, 80, 111)

**Immunoglobulin A:** The specific human immunoglobulin A is injected i.m. deeply at body temperature (0.02−0.06 ml/kg BW). With continued exposure, it is necessary to repeat the injection after 6−8 weeks. Because of the known HAV IgG content, the effect is better and lasts longer than with standard immunoglobulin, in particular since batches of immunoglobulin can differ

in antibody titre. Approximately 1% of vaccinated persons display side effects in the form of fever, rash, aching joints or local soreness at the site of injection. All of them are without consequence and disappear rapidly. There are no contraindications. • Should a **pregnant woman** be suffering from an acute HAV infection at the time of delivery, the newborn should be immunized simultaneously.

### 3.11.2 Active vaccination

Active vaccination (P. J. PREVOST et al., 1975) with an HAV live vaccine as well as with an inactivated HAV vaccine has produced a higher antibody titre as well as a longer period of efficacy than passive immunization.

The usual **commercially obtainable vaccine** is highly immunogenic and low in side effects. The former 3-phase administration (i.m.) with a single dose of 720 IU can be replaced by a 2-phase administration (i.m.) at zero and 6 (−12) months with a single dose of 1,440 IU. On average, an antibody titre of >4,000 IU/l is reached. Given an annual drop in the titre of 14%, a period of protection of some 10 years can be expected. The vaccine protection expires at about 20 IU/l, which is why a booster inoculation ought to be carried out in due course. An **immunity** of almost 100% is achieved. By controlling the antibody titre, the time point for a **booster inoculation** can be established. The success rate is highest among younger people (under 40 years). If protection has to be provided sooner, both injections may be administered within a period of 2 weeks. **Side effects** are very rare and without consequence, and disappear rapidly (tendency to diarrhoea, nausea, slightly increased transaminases, local soreness). (58, 72, 80, 98, 119)

The **indications** for active inoculation are (*1.*) people who are planning a stay in areas with a high HAV infection risk, (*2.*) those who are working in such areas or have close contact with HAV sufferers (including cleaning and kitchen staff in medical facilities), (*3.*) homosexuals, and (*4.*) patients with severe or chronic HAV-negative liver disease, since a superimposed HAV infection can result in a life-threatening situation.

*In principle, hepatitis A inoculation should be a routine measure already carried out in childhood.*

### 3.11.3 Simultaneous vaccination

In a situation in which rapid protection is required and at the same time long-term immunity is to be established as well, it is possible to carry out an active-passive vaccination with immunoglobulin A and active vaccine A. This is also indicated in the case of a newborn if the mother was suffering from acute viral hepatitis A during pregnancy. After the 3rd inoculation with vaccine, all individuals displayed a good formation of antibodies to HAV.

## 3.12 Therapy

A *causal therapy* (with antiviral agents) is not yet possible. • *Bed rest* is usually kept in line with the situation of the patient and, as with other acute diseases, is recommended. • With inadequate oral intake, the *substitution* of fluid, calories (glucose infusions), electrolytes, trace elements and (water-soluble) vitamins is advisable.

*Cholestyramine* may prove necessary for severe pruritus due to a cholestatic course of disease (4−8 g prior to breakfast) − if antihistamines were unsuccessful. With such a cholestatic course of disease, the application of *ursodeoxycholic acid* (2−3 × 250 mg) is most suitable. (166) In some cases with a fulminant course, *interferon alpha* has been successfully used. *"Special diets", gluco-corticoids* or other *medication* are not necessary.

# 4  Acute viral hepatitis B

## 4.1  Definition

A 42 nm DNA virus causes acute liver inflammation, which heals in the majority of cases; in 5−15% of cases, it becomes chronic or develops into a long-term virus carrier status. Occasionally, posthepatitic cirrhosis may occur, and there is a close correlation with the development of primary liver cell carcinoma.

## 4.2  Pathogen

The hepatitis B virus **(HBV)** belongs to the *hepadna virus* group. • This includes e.g. woodchuck hepatitis virus **(WHV)** and ground squirrel hepatitis virus **(GSHV)** (= orthohepadnaviruses) as well as Peking duck hepatitis virus **(DHBV)**, and heron **(HHBV)** (or crane **[CHBV]**) hepatitis virus (= avihepadnaviruses). (205, 206, 217, 220, 224, 230, 261)

There are at least **7 genotypes** of HBV (A−G). Serologically, **9 subtypes** of HBsAg can be distinguished, all of which have component "a" in the main HBsAg. HBV can only infect mature hepatocytes in humans and chimpanzees. HBV DNA is a direct parameter of viral replication and infectivity, with a magnitude of $10^{11}$ to $10^{13}$ per day; replication of HBV is extremely high. It is possible to detect 10−100 viruses/ml using PCR. (119, 137, 164, 173, 188, 189, 199, 232, 239) • (s. p. 113!) (s. figs. 5.6, 5.9!)

### 4.2.1  Inactivation

Viruses are only deemed to be definitively inactivated once their nucleic acid has been irreversibly changed. This can be determined with electron microscopy or by a negative PCR. The individual types of virus may differ considerably in terms of morphology and biochemistry, so that the efficacy of disinfectants can vary greatly, both in mode and degree. Hepatitis B viruses number among the most resistant types of virus. This is why the hepatovirucide potential of a disinfectant is largely considered to be a criterion of its general effectiveness.

**Hepatovirucidal substances** such as aldehyde derivatives, chlorine preparations (as long as chlorine is released at a low pH), glyoxal, n-propanol and iodine have proved to be effective. Virus destruction is also achieved by **heating** (e.g. 100°C >10 minutes, or hot air 180°C >2 hours, or steam 120°C >20 minutes at 1 bar). Just as effective in inactivating a virus is the boiling of instruments or equipment in a soda solution for 15 minutes. As far as possible,

linen should be disinfected by **boiling,** e.g. in an alkaline solution (pH 9−10 >30 minutes). Linen which cannot be boiled should be decontaminated by **soaking** for 12 hours in a 16% aqueous solution of formalin or in a 1.5% chloramine-T solution. Crockery and cutlery should be boiled in a soda solution (>15 minutes) or soaked in either commercially available aldehyde compounds (2% >1 hour) or compounds of aldehyde glyoxal and ethylhexonal glyoxal (5% >15 minutes). The careful **cleaning** of instruments prior to sterilization − any remaining blood must be removed − is of great importance. Instruments sensitive to heat are sanitized by **gas sterilization** using ethylene oxide or placed in a 3% formalin solution for 6 hours. **Endoscopes** are sterilized by immersion in a commercially obtainable virucide disinfectant, by an ultrasound immersion method or in an endoscope disinfector. Frequent **hand washing** with soap (ca. 3 minutes) and subsequent disinfection using an ordinary commercially obtainable preparation (approx. 2 minutes) is deemed adequate (yet not reliable). • Reference should be made here to recognized disinfecting agents and procedures listed in the official guidelines of the individual countries.

### 4.2.2  Pathogenesis

**Virus docking:** According to current knowledge on pathogenesis, virus docking with the liver cells ensues directly via specific receptors (e.g. pre-S1 domain). This capsid protein, which contains HBV DNA, is transported into the cell nucleus with the help of a nuclear, localization signal. Now the development of the complete Dane particle starts, and the new viruses are secreted from the hepatocytes by the Golgi apparatus. About $5 \times 10^{13}$ viruses are produced per day. It is possible that new therapeutic paths could be opened up by using specific peptides to prevent the virus from docking with the target cell or to stimulate the antibody response. The uptake of the virus is effected by endocytosis; the virus DNA reaches the cell nucleus.

**Hepatocytolysis** is caused by the cellular immune response to virus-coded or virus-induced antigens of the liver cell membrane. HBV itself is not directly cytopathogenic. The T lymphocytes are of prime importance for the cellular immune response to HBcAg (or HBeAg) at the liver cell membrane. The density of the virus determinants at the liver cell surface and the concentration of the antigens, determined by the human leucocyte antigen complex, are significant. Genetic factors and the individual endogenous production of interferon also influence hepatocytolysis. The virus particles released by lysis are fixed by humoral antibodies and then phagocytized. (214, 221, 232)

## 4.3  Antigens and antibodies

**HBsAg** is coded by the pre-S gene. Pre-S$_1$ and pre-S$_2$ antigens are detected in high concentrations in the serum. HBV expresses three forms of HBsAg: large (l), medium-sized (m) and small (s) proteins. Small HBsAg is the main component of mature HBV. (appr. 90%) (153) In uncomplicated courses of disease, the elimination of these surface antigens is generally achieved well in advance of the decrease in the HBsAg titre. The elimination of HBsAg can be swift but also delayed and is usually effected within 2−4 months. Smooth endoplasmic reticulum containing HBsAg is histochemically detectable by orcein or aldehydethionine staining. However, this is only true for half of the hepatocytes. HBsAg can also be detected in the liver cells by fluorescence microscopy. The affected hepatocytes have no preference for a particular site in the liver lobule. Nor is there any correlation with the respective HBsAg serum titre.

Histologically, the HBsAg-containing hepatocytes have the appearance of so-called **ground glass cells** (S. HADZI-YANNIS et al., 1973). (163) (s. figs. 5.7; 22.8) (s. pp 114, 396)

*Fig. 22.7:* HBsAg in the cytoplasm of hepatocytes (arrows) (s. fig. 5.7). Clinically: HBsAg carrier (former drug abuse) with moderately increased transaminases (immunoperoxidase reaction). These findings correspond to the so-called ground glass cells in HE (s. figs. 5.7; 22.8)

**HBeAg** is cleared from the serum in acute disease after several days or a few weeks. The significance of HBeAg has not been clarified (viral persistence?). It is not necessary for HBV replication. It is considered to be a breakdown product of HBcAg and, in conjunction with HBsAg and HBV DNA, determines the infectivity of the patient. The seroconversion of HBeAg to anti-HBe does not guarantee the active elimination of HBV in all cases, since viruses can still be detected by PCR in clinically healthy carriers of anti-HBe. In these cases, a decrease in the titre of anti-HBe is generally accompanied by a reduction in the remaining virus load. Anti-HBe can persist for 10−20 years, even lifelong. Negativity of HBeAg can be a sign of the formation of mutants due to the occurrence of a stopcodon (TGA) between the pre-core and core region. As a result, HBeAg cannot be produced. Infections with HBeAg-negative mutants usually show a high-replicative course. (137, 138, 182) (s. p. 425) (s. tab. 22.3)

**HBcAg** is not detectable in the serum, yet can be demonstrated by immunofluorescence in the nuclei of the hepatocytes. (s. fig. 22.8) The excessive formation of **intranuclear HBcAg** is occasionally expressed in the form of a microvesicular, eosinophilic brightening of the karyoplasm and a shift of chromatin to the core membrane. As a result of the metabolic strain on the liver cells due to the viral infection, functional core swelling occurs, subsequently leading to enlargement as well as basophilia of the nucleolus. HBcAg can be seen in the affected cores as an even, dense, finely granulated fluorescence. HBsAg and HBcAg are detectable in the liver cells both together and separate from one another. With serologically unresolved chronic hepatitis, the demonstration of HBsAg and HBcAg in the liver cells can bring clarity to the clinical picture.

**Anti-HBs** is found in the serum just 2−3 months after infection ("diagnostic window") and probably remains detectable for life (due to mild, continuous boosting from persistent hepatitis B viruses?). It guarantees

*Fig. 22.8:* Immunohistochemical detection of HBcAg in the nuclei of liver cells shown by monoclonal antibody. Hepatocytes with ground glass-like homogenization of the cytoplasm, so-called ground glass cells (arrow). HBsAg in the cytoplasm is not presented immunohistochemically in this case (s. figs. 5.7; 22.7)

immunity to HBV infection. Patients with anti-HBs titres are generally also anti-HBc-positive. Some 10−15% of hepatitis B patients form no anti-HBs. In previous infections which date back a long time, titre levels can fall below the detection threshold. About 2% false-positive values are measured in the serum. (s. p. 114)

**Anti-HBc IgM** is the earliest immunological response of the body to HBV antigens. It is the most reliable marker, and once the disease is overcome, it can probably be demonstrated lifelong as **anti-HBc IgG.** In chronic hepatitis B carriers, low titre anti-HBc IgG may also be present. It is the most suitable marker for the HBV contamination rate of a population (more reliable than anti-HBs). The absence of HBsAg and anti-HBc IgM rules out acute HBV infection. In healthy patients who test positive for anti-HBc, latent viral replication is usually still to be found. This can be detected with the help of PCR. Active vaccination does not result in positive anti-HBc IgM. (s. p. 114)

**HBxAg:** The significance of the smallest coded region of the HBV genome (17 k Da) − as well as of its protein, which comprises 154 amino acids − is still unclear. It is deemed to be an early marker of acute hepatitis B. HBx reinforces the replication of HBV in the liver cell. It has possibly something to do with the development of liver cell carcinoma, especially since it is most prevalent in HBV-related liver cirrhosis and even in liver cell carcinoma. (146, 212)

Serological markers of the HBV antigens and antibodies facilitate reliable diagnostic and prognostic statements as well as an evaluation of the existing infectivity of the patient. (138, 188) (s. pp 112−116) (s. tab. 5.17) (s. fig. 5.9)

## 4.4 HBV variants

Clinically relevant *mutations* at a rate of about 1 nucleotide/10,000 bases/year can accumulate in cases of HBV infections which have existed for years. (s. tab. 22.3)

| | |
|---|---|
| **S gene:** | loss of the "a" determinant (= absence of vaccine protection) |
| **Pre-S gene:** | loss of B and T cell epitopes or loss of the pre-$S_2$ promoter region or loss of the pre-$S_2$ start codon (= no neutralization of the virus by anti-HBs) |
| **Pre-C/C gene:** | inhibition of the "e" antigen synthesis (= severe course of disease) |
| **C gene:** | loss of T cell epitopes (= tendency to fulminant hepatitis) • so-called escape mutants |
| **P gene:** | loss of polymerase (= accelerated elimination of the virus, "unfit" mutant) • so-called replication defect |

*Tab. 22.3:* Known HBV mutants and their possible biomolecular repercussions

Such mutations can be found in all genes of the HBV. After the onset of acute hepatitis, such mutants can affect the course of disease in a variety of ways, resulting in fulminant development or rapid chronicity, or indeed latent virus persistence. As a result of mutations in the pre-C/C region, formation of the e-antigen can also be prevented. Such HBV mutants might be responsible for a situation which has long puzzled physicians, namely the occurrence of severe chronic hepatitis despite a complete immune response. It is likewise possible that the development of hepatocellular carcinoma is attributable to the integration of the viral genome (with its oncogenic domain) into that of the host cell or the mutants. Mutations in the "a" determinants can effect non-response to the administration of HBV vaccine. When using active vaccines composed of the S-gene product from wild type HBV sequences, mutated viruses are indeed capable of bringing about an infection in inoculated persons (so-called S-escape mutant). (130, 132, 135, 182, 196, 244, 254, 262)

## 4.5 Specific serological courses of disease

(*1*.) **HBsAg-negative/anti-HBs-positive course:** This rare course of disease can occasionally be detected in fulminant hepatitis with rapid elimination of the virus, in cases of infection with HBV mutants, in HDV superinfection with suppression of the HBV infection and in non-apparent HBV infection in patients suffering from alcohol-related liver damage.

(*2*.) **HBsAg-positive/anti-HBs-positive course:** It is possible for this constellation to occur with vaccine *escape mutants*, with anti-HBs immune response to a subdeterminant rather than to the "a" antigen and with subsequent infection from another genotype with HBsAg positivity.

(*3*.) **Anti-HBc-positive course:** In negativity of HBsAg and anti-HBs, only anti-HBc can be identified. This constellation is found in approx. 1.5% of the population, in 0.9% of blood donors and in 15−25% of intravenous drug addicts. Anti-HBs in low titre, no longer measurable, may also be present, although positivity can occur in 35% of cases following a once-only "booster" and in 50% of cases after full vaccination. • If a healthy individual shows anti-HBc positivity, there is the possibility of a latent infection with virus replication in hepatocytes. In order to verify the interpretation of this finding, it is necessary to use HBV-DNA determination or PCR.

(*4*.) **HBsAg-positive/anti-HBs-positive/anti-HBc-negative course:** The occurrence of this rare constellation may be attributable to a selective immune defect, HBcAg/anti-HBc immune complex formation and mutation in the core gene.

(*5*.) **HBe-minus-HBV mutant:** With fluctuating increases in transaminases, the reaction to HBV DNA can nevertheless be positive in the presence of anti-HBe. HBeAg formation is not induced. These patients are particularly endangered by the rapid development of CAH and cirrhosis. (s. pp 114, 424) (s. tab. 22.3)

## 4.6 Chronic HBsAg carriers

A person is said to be an *HBsAg carrier* (*1*.) if HBsAg positivity has persisted for more than 6 months, (*2*.) if the clinical and chemical findings fail to show any signs of acute hepatitis, and (*3*.) if no (or only minimal) lesions are detectable histologically. • The *diagnosis* and differentiation of an HBV carrier can be established by PCR. Viral hepatitis B is, however, only considered to be completely cured if HBV-DNA negativity is established at least in the serum. Nevertheless, chronic hepatitis cannot be ruled out as long as HBV DNA is still detectable, even though HBsAg negativity as well as anti-HBs and anti-HBe positivity is given. • *Risk factors* involved in the development of a carrier state include youth, minimal quantity of inoculated viruses with a subclinical course, individual immune status, dialysis patients, etc. Only about 3% of carriers can recall having had acute hepatitis. • The *elimination rate* of HBsAg from the serum is about 2% per year. One case was recorded with almost 20 years of HBsAg persistence and infectivity!

Some 10% of patients with HBV infections develop a *carrier state* (men 5 or 6 times more frequently than women). With regard to vertical infection, a carrier state is witnessed in up to 90% of the affected children. • The long-standing existence of an HBsAg carrier state involves the following *dangers*: (*1*.) superinfection with HAV and HCV, (*2*.) superinfection with HDV, (*3*.) occurrence of chronic hepatitis culminating in cirrhosis (in 10−20% of cases), and (*4*.) two to four-fold risk of hepatocellular carcinoma (1 in ca. 250 carriers). • The *prognosis* is generally good for persons who become HBsAg carriers as adults. It is not possible, however, to make a long-term prediction regarding the course of a carrier state. If elevated transaminase values are detected at intervals of several months, the histological findings need to be clarified by liver biopsy. (121, 123, 143, 150, 167, 201)

HBsAg carriers are fundamentally deemed to be contagious, with the degree of *infectivity* fluctuating widely from viraemic, highly infectious carriers to non-infectious carriers. By determining the HBeAg and HBV DNA, it is possible to estimate the degree of infectivity, if necessary incorporating PCR findings. (202) Carriers can present a very real source of infection in interpersonal and intrafamilial contact (142, 150, 157, 199, 202, 229, 253), particularly since HBsAg can be found in various body secretions. (s. tab. 22.4) The newborn, too, is exposed to the danger of infection in the perinatal and postnatal phases, so that passive-active immunization is urgently recommended. (259)

Chronic HBsAg carriers must be given detailed information on how they should behave. This is particularly important with respect to their occupation, especially for persons in the medical field. Care in complying with hygiene regulations, the wearing of gloves and avoiding procedures that may cause injury are matters of course.

## 4.7 Epidemiology

The HBV infection rate in Germany is 0.3−0.8% of the population (ca. 500,000 carriers), 0.1% of blood donors and 2−6% of i.v. drug addicts. In Europe, 0.1−5.0% of the population are HBsAg-positive, with a greater frequency in countries to the south (the highest values being found in southern Italy and Greece). Among foreigners from endemic areas who are resident in Germany, the fraction of chronic HBV infected persons is 10 times higher than in the general population. In the countries of Africa and East Asia as well as in some parts of South America, up to 30% of the population (sometimes even more) are HBsAg-positive. Very high infection rates are found in isolated population groups (such as the Alaskan Eskimo with 45% and the Australian aborigines with 85%). The HBV reservoir is estimated to number about 350 million people worldwide. Some 250,000 patients die each year as a result of hepatitis B. (122, 199)

### 4.7.1 Obligation for notification

In Germany, **viral hepatitis** ranks second among infectious diseases that are subject to notification. After 1962 (passing of the Federal Epidemic Control Act), the number of cases ranged between 14,077 (minimum value, 1963) and 25,900 (maximum value, 1973), with a steady decline since that time. Nevertheless, the figures only relate to those cases which have been "registered". The actual number is probably more than 5 times higher, since anicteric cases are mostly not identified, the obligation to report the disease is possibly "forgotten" and the law can be subject to flexible interpretation. This has no doubt resulted in widespread "under-reporting". The wording of the law does not differentiate between acute and chronic diseases. • A "healthy" chronic HBsAg carrier does *not* have to be reported − *nor* does a case of "suspected viral hepatitis".

► In *Germany*, the following **frequencies** of HBV disease were registered, whereby the actual figures are about 5 times higher. The continuously declining tendency can be found in numerous countries as a result of improved hygiene, optimized testing of blood as well as of blood constituents, and active vaccination. (s. pp 420, 440)

| | |
|---|---|
| 1992 = 5,987 | 1998 = 5,232 |
| 1993 = 5,497 | 1999 = 4,570 |
| 1994 = 5,166 | 2000 = 4,601 |
| 1995 = 6,152 | 2001 = 2,427 |
| 1996 = 6,044 | 2002 = 1,425 |
| 1997 = 6,133 | 2003 = 1,304 |

**Mortality** in the same period (1992−2002) was as follows (males/females = 2 : 1):

| | |
|---|---|
| 1992 = 173 | 1998 = 158 |
| 1993 = 175 | 1999 = 96 |
| 1994 = 167 | 2000 = 98 |
| 1995 = 148 | 2001 = 93 |
| 1996 = 207 | 2002 = 108 |
| 1997 = 190 | 2003 = 119 |

## 4.8 Transmission

Acute viral hepatitis B can present with up to $10^{13}$ viruses per millilitre of blood − indeed an inconceivably high figure. The typical maximum titre is about $10^8$ viruses/ml serum. It is possible to detect $10^5−10^6$ particles by means of HBV DNA. A very small number of viruses suffices for an infection in the individual case. The PCR method identifies a very low number of HBV particles, although in practice the detection threshold of 100 to 1,000 HBV particles/ml is considered adequate. With such excessive viraemia, it must be assumed that B viruses pass into all body secretions and excretions − only their detection in the stools remains controversial. Sperm is considered to be particularly infectious. (191, 199, 221, 231) (s. tab. 22.4)

### 4.8.1 Parenteral infection

In the past, the *infection route* was assumed to be solely *parenteral*, with blood transfusions being of paramount significance, followed by the parenteral administration of plasma preparations. Present-day extraction and processing techniques for blood and blood constituents have deprived this route of its significance (1 : 150,000−200,000). • Nevertheless, it must be borne in mind that the transfusion of HBsAg-negative, but anti-HBc-positive blood can lead to an HBV infection. (168, 231) This diagnostic *risk gap* still exists when selecting blood donors (in the USA and France, for example, blood donors are already screened by means of anti-HBc).

Every 10th to 20th HBsAg-negative and anti-HBc-positive blood donor is considered infectious. This infection, which is for example caused by immune complexes (s. p. 431), has a longer period of incubation (>120 days) and generally progresses without clinical symptoms.

| | |
|---|---|
| Amniotic fluid | Pancreatic juice |
| Articular effusion | Peritoneal dialysate |
| Ascites | Pleural effusion |
| Bile | Saliva (151, 178, 203, 253) |
| Breast milk (127) | Sperm (178) |
| Colostrum (194) | Stools |
| Gastric juice (?) | Sweat |
| Lacrimal fluid (253) | Urine (178, 253) |
| Liquor (223, 255) | Vaginal secretion |
| Menstrual blood | |

*Tab. 22.4:* HBsAg and HBV-DNA detection in body secretions and excretions (with some references)

A number of *unusual parenteral infection routes* have been observed as causing the onset of viral hepatitis B in individual instances (this can be sometimes of relevance when a medical expertise has to be drawn up): spring lancets for taking blood from the finger (227), infection from the interior of a syringe, tattooing (193, 243), acupuncture (180), mosquitoes, (215), bugs (207, 218), leeches that have been used several times, infection from skin diseases such as psoriasis or eczema, manicure or pedicure, shaving, infection from blood smears on thorn bushes, etc. Contagion from needles which have been improperly and carelessly discarded must be avoided. The frequent multiple use and sharing of needles and syringes explains the high rate of contamination and subsequent contraction of the hepatitis B virus among drug addicts (70−90% after >5 years).

### 4.8.2 Sexual infection

Infection via the sexual route must be seen as more frequent than has been assumed up to now (25−30% to 68%). *Infectious body fluids* include sperm, vaginal secretion, urine and menstrual blood. (s. tab. 22.4) Apart from the main inoculation route via mucosal lesions, discussion focuses on the cellular intake of the virus through lymphocytes (in which HBV latently exists and can also proliferate) or through mononuclear cells. • Hence, viral hepatitis B can be seen as a special form of *sexually transmitted disease* (STD), and the concomitant abuse of drugs succeeds in considerably heightening the risk of HBV infection. (157) • In 19%, 44% and 56% of documented cases, prostitutes proved to be HBsAg-positive, with a 75% concurrent drug dependence. (237) • *Homosexual males* are exposed to a high risk of infection (ca. 70%), especially since anal intercourse considerably increases the danger of HBV transmission. (161) • With these risk groups, *active immunization* is the safest and cheapest preventive measure in every case. In addition, it is also generally important to encourage safer sex with the aim of preventing hepatitis B. (191, 199)

### 4.8.3 Perinatal infection and antenatal care

**Diaplacental infection** from HBsAg-positive pregnant women to their unborn children (so-called **vertical infection**) is very infrequent in the first and second trimester, yet often prevails in the third trimester. With coexisting HBeAg positivity and in acute viral hepatitis B in the third trimester of pregnancy, the child is nearly always (>90%) infected. About 10% of HBV infections are acquired in utero. It is, however, difficult to decide whether the infection is diaplacental or perinatal. Of the foetuses examined, in fact only 8% showed signs of diaplacental infection. Consequently, diaplacental transmission of HBV is considered to be of minor importance. It is remarkable that HBsAg could be detected in the gastric juice in 96% of the newborns with HBsAg-positive mothers, thus pointing to the infectivity of the amniotic fluid. The most regular development of an HBsAg carrier state in children may be caused by intrauterine exposure to HBeAg: this antigen is transmitted via the placenta and can therefore induce immunologic tolerance in the foetus. (266)

**Perinatal infection** occurs during the course of delivery. The transmission mode is either through skin injuries to the child, maternal-foetal microtransfusions due to placenta lesion or oral intake of HBsAg from maternal blood, amniotic fluid and vaginal secretion. There have even been repeated reports of fulminant hepatitis in newborns between the 2nd and 4th month of life. Chronic hepatitis must be feared in >90% of cases, and the development of liver cirrhosis has also been observed. The probability of a perinatal infection correlates with the detection of HBeAg. Each HBsAg-positive pregnant woman ought to be considered infectious on principle, so that the newborn immediately receives a simultaneous vaccination. In this way, perinatal infection of the child is almost certainly averted before it can develop, and postnatal infection is prevented. Administration of lamivudine during pregnancy to prevent HBV infection is a further alternative. (124, 128, 134, 250, 256, 259, 263)

**Postnatal infection** also poses a danger for the non-vaccinated baby/infant in terms of breast milk (127), injury to the mamilla and close physical contact with regard to an HBsAg-positive mother. (128)

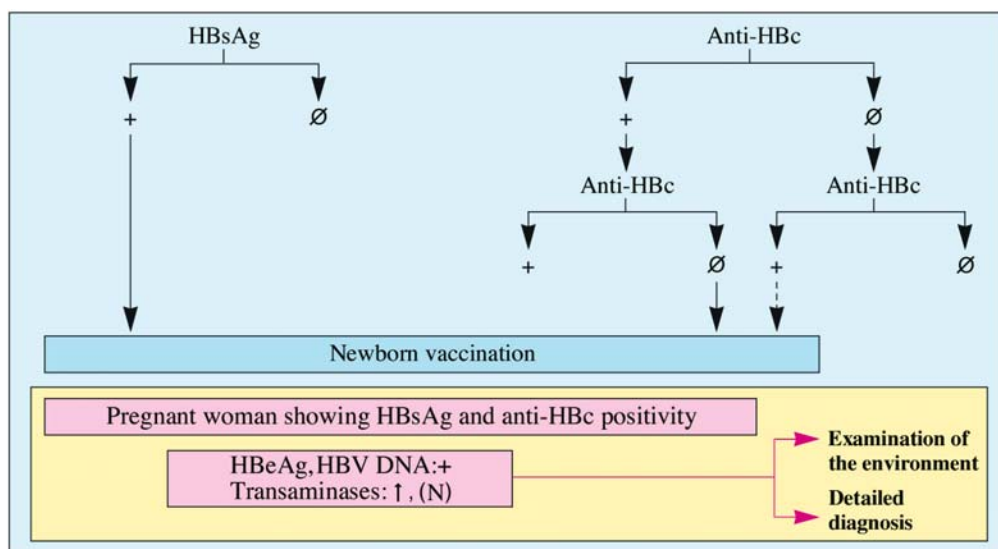
▶ **Statutory prenatal care:** Some 5,000 HBsAg-positive women become pregnant in Germany every year. In the past, only so-called risk groups were tested for HBsAg. However, it became clear that only about one third of the pregnant women who were HBsAg-positive could be assigned to a "classical" risk group, while two thirds of the pregnant carriers remained unaccounted for. This explains why the guidelines applied throughout the respective countries did not lead to a decrease in the frequency of HBV infection in newborns. The cost of routine HBsAg testing and simultaneous prophylaxis for neonates with HBsAg-positive mothers amounted to just 1/20 of the costs incurred annually for the treatment and care of those cases which were not protected from perinatally acquired hepatitis B infection. • In 1992 the respective **statutory maternal guideline** in Germany was changed accordingly and now reads: "The blood shall be examined for HBsAg in all pregnant women after the 32nd week of pregnancy and as near to the delivery date as possible." Thus general screening for hepatitis B in pregnancy has been anchored in law, and the costs, including those for simultaneous vaccination, are borne by the health insurers. (s. fig. 22.9)


*Fig. 22.9:* Screening of pregnant women in the final trimester with indications for simultaneous vaccination of the neonate

### 4.8.4 Close physical contact

*Infection during childhood* can be related to close contact within the family or in day centres and schools (258), particularly those for mentally disabled children and adults. (145) The prevalence of HBV in child molesters is high. (158) Children normally maintain close physical contact, which may involve mutual skin injuries. (151, 191, 199, 219) Initial HBV infections sustained in childhood are generally associated with a very high carrier rate (20−30%), whereas with advancing age the predisposition to carrier state decreases to about 5%. An HBsAg-positive child can, therefore, be the source of *intrafamilial horizontal infection*. From this angle, too, the necessity of *preventive vaccination* is obvious. (176)

*HBV infection in the home* mainly affects the partner. Seromarkers were in evidence in about 50% of such cases, whereas only 17% of the other members of the household were affected. In 78% of partners who presented serological evidence of HBV infection, HBsAg, HBeAg and DNA polymerase were simultaneously detected, while HBsAg and anti-HBe were found in only 25% of cases. Without doubt, contact in the family or among people sharing a flat or a house constitutes a specific risk of HBV infection from HBsAg carriers. Each individual case must, therefore, be examined as to whether passive or active or simultaneous vaccination is indicated and at what time. It should be noted that the infection rate in non-immune members of a household is about 30%. (142, 191, 203, 229)

With *travellers to the tropics*, the rather high rate of HBV infection must be attributed to close physical contact in poor hygienic conditions and possibly to insect bites as well. An unusual report was published concerning an HBV infection in four employees (out of ten) in a *butcher's shop* within one year. (155) The 100 to 200-fold frequency of viral hepatitis in *prisons* as compared to that among the general population is striking (so-called *desmoteric infection*). (59)

**Oral transmission** of HBV (S. KRUGMAN et al., 1967) requires larger quantities of substrate (about 50-fold) than parenteral infection. Usually, oral HBV transmission has a longer incubation period and almost always takes an anicteric course.

## 4.9 Hepatitis B and medical personnel

### 4.9.1 Medical personnel

The term **nosocomial infection** (s. p. 419) should not only be applied to hospitals, but also to every *doctor's surgery*. At these locations, there are basically **three paths of transmission:**

1. HBV can be transmitted from one infectious in-patient to another (so-called cross-infection).

2. Patients can be infected by contaminated blood and blood constituents as well as instruments or equipment. Here, too, cross-infections are of considerable relevance. (179, 227, 233)

3. Infected physicians and nursing staff are frequently found to be hepatitis B carriers. (190, 222, 246, 257) A considerable sensation was caused by the fact that, in one report, 41 patients had been infected by a single practitioner in the course of 4−5 years. (160, 179)

▶ Compared with the general population, physicians (7.4-fold) and other medical personnel (16-fold) are exposed to a considerably **higher risk** (200 in 100,000) of contracting acute viral hepatitis from contact with HBV-infected patients. HBsAg positivity was detected in 1.5% and 1.6% of medical personnel as a whole, 16% of physicians, 22.4% of surgeons and 36.5% of laboratory staff. Likewise, physicians and medical staff of psychiatric hospitals (10−12%) and those engaged in pathology are risk groups. The greatest danger from hepatitis is found in dialysis centres. The so-

called **Newcastle infection** clearly demonstrated the unfortunate chain of hepatitis disease when 6 members of the medical staff were infected by an HBV-positive patient who was admitted to hospital after having been injured in an accident. (234) • Of 133,000 **surgeons** in the USA, 1,900 proved to be chronically infected with HBV. In spite of this, the transmission of hepatitis B from surgeons to patients is considered unusual. Recently, however, a case was reported in which one HBV-infected surgeon had transmitted an acute HBV infection with positive HBc IgM to 19 patients who had been operated on by him (out of 144 assessable cases). (165) Similarly, a German thoracic surgeon, who had unknowingly become infected by HBV a long time before, was held responsible for the transmission of hepatitis B to 13 of his patients (1999). • The transmission of hepatitis B by **endoscopes** (provided they have been cleaned in compliance with the regulations) is considered improbable. (197)

The recommended **prophylactic vaccination** against HBV has led to a drastic drop in occupation-related HBV infections. Given an even greater acceptance of voluntary active immunization, it would be possible to prevent HBV infection almost completely in the medical sector. In accordance with the statutory regulations, non-immunized persons ought not to be engaged in HBV risk areas. With a genetically engineered vaccine available, all those whose occupations involve contact with blood, blood constituents, contaminated items or body secretions (s. tab. 22.5) should most definitely receive active hepatitis B inoculation. In conjunction with compliance to hygiene regulations, this measure would make it possible to eliminate the risk of nosocomial HBV infection almost completely (< 1%). Vaccination against hepatitis B is soon to be compulsory for medical staff according to an EU directive. • In the case of **needlestick injury,** passive immunization should be effected within 6 hours if the following *infection constellation* is established (by means of a rapid test): donor = HBsAg-positive and recipient = anti-HBs-negative. At the same time, active immunization should be initiated. (184, 204, 233)

### 4.9.2 Hepatitis B and the dialysis unit

**Physicians and medical staff** at dialysis units, as well as the patients themselves, are exposed to a particularly high risk. At 15 American dialysis centres, the physicians presented an HBsAg frequency of 2.4%, which is 5 times higher than in the general population. In 1978 a total of 752 physicians and nursing staff contracted hepatitis B with 5 fatal cases in 350 European dialysis units. The number of lethal infections recorded in the field of dialysis totalled 65 between 1972 and 1978. However, the subsequently improved preventive measures, parallel to the separation of hepatitis-positive from hepatitis-negative units and, in particular, the employment of immunized staff have resulted in the extensive elimination of HBV infection in the field of dialysis. (211)

HBsAg positivity was found in 15−20% of **dialysis patients,** about two thirds of whom were also HBeAg-positive and hence highly infectious. Chronic hepatitis can be expected to develop in about half the patients. HBsAg-negative dialysis patients must be vaccinated as soon as possible, perhaps initially with passive immunization, until they form their own antibodies. Unfortunately, however, dialysis patients show a high percentage of *nonresponders*. Our experience shows that it is in fact possible to achieve a response in some of these cases following adequate "substitution" of zinc, and in some cases selenium. (144, 170) (s. p. 436)

Moreover, the **relatives of dialysis patients** are also exposed to the risk of an HBV infection. Altogether 26% of the contact persons examined presented serological signs of hepatitis B infection. The frequency rate rose to 35% in people assisting in home dialysis. Here, too, preventive measures are to be strictly observed; non-immune contact persons must be actively immunized.

### 4.9.3 Hepatitis B and dentistry

The first report that dentists (5.3%) were exposed to hepatitis more frequently than the general population was drawn up by A. BERNSTEIN et al. (1953). • The **risk of contracting the disease** in a dental practice was calculated by G. KLAVIS et al. (1971) and by subsequent investigators as being 6−30 times higher than average. Some 80% of the hepatitis diseases contracted by dentists are considered to be related to their occupation. The number of dentists who have overcome viral hepatitis is given at approx. 14%. • Understandably, the question arises as to what extent an HBsAg-positive dentist poses a **risk** to his/her patients. The first report on this transmission mode, submitted to my knowledge by M. L. LEVIN et al. in 1974, focused on a dentist who had infected 12 patients as well as a dental nurse and a colleague. Other publications report on the infection of many patients, in one case up to 55 within a period of 4 years. (162)

Given the specific circumstances of this profession, dentistry is *ideal* for the transmission of HBV: (*1.*) to the attending dentist, the patients are a totally unknown group of persons with respect to hepatitis infectivity; (*2.*) dental treatment nearly always involves injuries in the oral cavity, where blood mixes with the saliva (which is deemed to be an infectious agent anyway) − the close contact of the dentist with blood and saliva predisposes him to HBV infection; (*3.*) the work of a dentist involves injuries to the skin from instruments as well as from nonvisible or unnoticed epithelial defects or rhagades (also caused by the frequent washing and brushing of hands); (*4.*) the application of high-speed turbine drills produces a spray of vapour comprising blood constituents, saliva and mucosal particles − in the case of an HBV carrier, this is highly infectious. It was demonstrated that the arm and hand of the dentist act as a "crash barrier", so that most of the spray is deflected and can easily be inhaled by the dentist (L. WINKLER, 1970). • There are almost 40 publications available on the subject of the high occupational *risk of infection* to which dentists are exposed and on the transmission of hepatitis B from dentists to patients. (136, 162, 169, 183, 185, 186, 225, 226)

### 4.9.4 Insurance questions

The infection of dentists or physicians and their medical staff with HBV from infectious patients presents no particular problems in terms of accident insurance protection and recognition as an **occupational disease.** In the eyes of the law, it is of no importance whether hygiene regulations have been ignored, whether a situation can be attributed to negligence or whether use has been made of the opportunity for active immunization. Active immunization of dentists (physicians) and their personnel is, however, a top priority! In addition, care

should be taken to comply with accident prevention regulations.

Nevertheless, the situation becomes more complex if patients appear to have been infected with viral hepatitis by a dentist or a doctor and claim compensation from the respective **personal liability insurance.** The decision taken here will be based on the general terms and conditions of the insurance policy itself. Likewise, the definition of "intent" and "gross negligence", as stipulated under German law, will have to be clarified once all relevant factors have been reviewed.

For the **legislator,** the question arises as to whether the (possible) infectivity of a dentist (physician) constitutes an exceptionally high risk and to what extent hygiene-related stipulations and other legal measures can provide a remedy. The legislator, however, reserves the right to "prohibit the practice of certain occupational activities in whole or in part". In some cases, this channel has already been pursued by the responsible authorities (even somewhat inappropriately).

▶ In 1978 we reported on a dentist who was given a two-year suspension. (185) The issues raised by this publication, in particular regarding the inadequacy of sometimes uncoordinated and unbalanced regulations, have still not been satisfactorily clarified by the discussions and statements that have meanwhile ensued. (186)

For chronic HBsAg carriers (s. p. 425), there are no comprehensive regulations to follow with respect to **professional conduct,** everyday routine and family life. Yet they must be well informed about their condition and should be fully aware of the danger they pose. Provided the respective hygiene measures are observed, restrictions in professional life are generally not necessary.

## 4.10 Stages of disease

**Incubation period**
The incubation period is $(25-)$ $50-90$ $(-180)$ days. This wide range depends on (*1.*) route of transmission, (*2.*) quantity of virus transmitted, and (*3.*) immunity status of the infected person.

**Prodromal stage**
The prodromal stage can last from a few days up to 2 $(-4)$ weeks. Non-specific prodromal symptoms (general, gastrointestinal, influenzal and arthritic/myalgic complaints as well as taste disorder) tend to develop more gradually, yet more severely, in hepatitis B than in hepatitis A. Otherwise, however, there are no great differences in terms of prodromal symptoms between the two types of hepatitis virus, so that it is not possible to differentiate hepatitis B from hepatitis A at the prodromal stage. (s. p. 420) Nor is this possible by establishing more pronounced enzyme activities or by means of initial histological findings. It is the presence of HBsAg (which is, however, absent from the serum in the early phase in about 5% of cases and thus usually remains

unidentified) and above all of anti-HBc IgM as well as HBeAg and HBV DNA in the serum which makes differentiation possible. In the pre-icteric phase, there is as a rule evidence of leucopenia. Subsequently, lymphocytosis and monocytosis occur. (s. p. 114) (s. fig. 5.9)

**Clinical stage**
The clinical stage commences with the occurrence of jaundice. The level of bilirubin in the serum and, especially, the duration of the icteric phase, correlate with the morphological degree of severity. Here, direct (conjugated) bilirubin mostly predominates. (s. tab. 22.5)

| Parameters | Spectrum of values |
|---|---|
| GPT<br>GOT<br>DeRitis quotient | $\uparrow\uparrow - \uparrow\uparrow\uparrow$<br>$\uparrow - \uparrow\uparrow$<br>$< 1$ |

| Quick's value<br>Colombi index<br>Cholinesterase | $N -(\downarrow)$<br>$N -(\downarrow)$<br>$N -(\downarrow)$ |
| Immunoglobulins | $\uparrow - \uparrow\uparrow$ |
| Leucopenia<br>Lymphocytosis, monocytosis | $N - +$<br>$N - +$ |
| γ-globulins | $N - \uparrow$ |

***Tab. 22.5:*** Spectrum of laboratory parameters in acute viral hepatitis B, depending on the degree of severity and specific courses of disease (N = normal)

Depending on the degree of jaundice, pruritus usually occurs, the stools are light in colour (acholic), and, at the same time, the urine takes on a dark brown shade. Even prior to the occurrence of jaundice, urobilinogen is excreted to a greater extent in the urine and remains detectable for the entire course of disease. The icteric phase lasts $3-6$ weeks; $60-70\%$ have an anicteric course. In the majority of cases, the liver is enlarged so as to be palpable and is tender upon pressure; the spleen is frequently palpable, too, and, in $10-20\%$ of patients, the lymph nodes are swollen. Arthritic pain, fever, and skin eruptions are commonly experienced. In children, an anicteric form with lymphadenopathy as well as a non-pruritic, mostly populous exanthema, known as acrodermatitis papulosa infantum (= *Gianotti-Crosti syndrome*), can develop. (s. p. 84) The laboratory param-

eters show a wide spectrum, depending on the degree of severity and the course taken by the hepatitis. Micro-haematuria and mild proteinuria are possible. The blood sugar is occasionally reduced, and isolated cases can present symptoms of hypoglycaemia. (s. tab. 22.6) (s. p. 420)

In the later course of disease, slight increases in IgA and IgG may be detected. (s. tab. 5.15). HBsAg is absent from the serum in approx. 90% of cases within 2−4 months. A lower Quick's value due to reduced absorption of vitamin K normalizes swiftly following the parenteral substitution of vitamin K (so-called Koller's test). The possible detection of antibodies (e.g. SMA, ANA, SLA, LMK) is of no significance. The return of bile acid values to normal constitutes a sensitive parameter for the regression and healing of the disease.

**Convalescence phase**
Given a natural course of disease, all laboratory values are normalized within 4−6 months. The values of γ-GT and AFP may continue to be increased for a while as an expression of the regeneration of the liver cells. Occasionally, weakness, fatigability, reduction in physical strength, etc. can persist for a considerable period of time. (150, 199)

## 4.11 Extrahepatic manifestations

The course of disease of viral hepatitis B can be changed or complicated by multiple extrahepatic manifestations. (78) They are probably caused by circulating *immune complexes* containing HBV antigens (U. E. NYDEGGER et al., 1980). Circulating antibodies are present in up to 80% of cases. It is assumed that virus antigens (HBs, HBe) constantly reach the blood from the liver cells, as do immune complexes formed in the liver. Antigenaemia triggers the production of circulating immune complexes in the blood. Inefficient clearance in the RES due to massive complement fixation then leads to the deposition of immune complexes in different organs. • Three forms of glomerulonephritis can be differentiated: (*1*.) membranous, (*2*.) membrano-proliferative, and (*3*.) endocapillary. (s. tabs. 22.2, 22.6) *(see chapter 34.7.3)*

▶ D. J. GOCKE et al. (1970) reported on the first observation of HBsAg-associated vasculitis. Hepatitis B was first associated with glomerulonephritis by B. COMBES et al. in 1971. Polymyositis was described by A. A. MIHAS et al. in 1978. Concomitant haematological reactions are relatively frequent, generally in the form of harmless haemolysis or thrombopenia. Severe complications include agranulocytosis and panmyelophthisis due to acute viral hepatitis, such as were described by E. LORENZ et al. in 1955 (at that time without the possibility of virus classification). Altogether, over 250 cases of panmyelophthisis or aplastic anaemia have been reported in the literature. (171, 181, 199, 208)

***Tab. 22.6:*** Extrahepatic manifestations in viral hepatitis B (with some references) (s. tabs. 22.2, 22.8)

## 4.12 Specific clinical courses of disease

As with HAV infection (s. p. 421), the clinical features of viral hepatitis B can be influenced by certain courses of disease. As a result, it can prove difficult to draw up a differential diagnosis, and thus further examination becomes necessary. Some of these initially unpredictable courses of disease may be a considerable impediment to the self-limiting capacity of viral hepatitis B. (s. fig. 22.10)

### 4.12.1 Subclinical course

The term *"asymptomatic"* course should not be used. Even if no subjective symptoms or clinical findings exist and HBsAg is not detectable, at least the GPT is always elevated. The existence of an HBV infection is not to be dismissed unless the remaining HBV seromarkers, including HBV DNA, are negative as well. • In contrast, the term *"subclinical"* can be applied to a constellation comprising increased GPT (and GOT) values, HBsAg negativity (low-level carrier) and elevated HBV seromarkers. • Therefore, it is quite right for persons with elevated transaminase values (despite concurrent HBsAg negativity) to be excluded from being blood donors as a precautionary measure.

### 4.12.2 Anicteric course

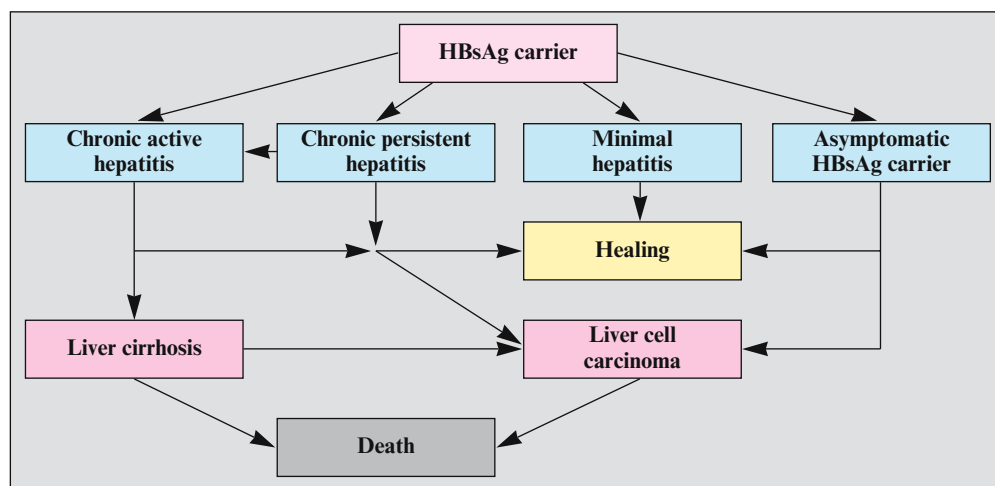
In this course of disease (s. pp 416, 421), the immune reactions are weakened; consequently, liver cell lesions are less pronounced (= lower transaminase values as a rule) and virus elimination is delayed (= protracted


*Fig. 22.10:* Clinical courses of disease in the HBsAg carrier status (s. tabs. 5.17, 5.18) (s. p. 116)

course of disease in general), with the result that HBsAg persistence is also more common. Often, these patients are only identified by chance. Because of the frequent non-diagnosis, they continue to be exposed to the daily routine strain put on them at work and to chemical noxae, alcohol or medicaments, thus furthering the tendency towards chronicity of the disease.

### 4.12.3 Protracted course

This is characterized by a delayed normalization of the laboratory parameters and also by urobilinogenuria. By contrast, the serum bilirubin has generally become normalized. Subjectively, there are no symptoms. Protracted hepatitis B can continue to be HBsAg-positive or become HBsAg-negative, or the HBsAg negativity, apparent from the very beginning, may remain unchanged the whole time. In these cases, however, HBV-DNA positivity still exists (by applying the PCR method, the sensitivity of HBV identification is increased 10 million-fold!). • Histologically, there are periportal residual infiltrates as well as late nodules and liver cell lesions with isolated cell necrosis. It is recommendable to establish morphological findings by means of percutaneous biopsy so as to have a basis for comparison with follow-up biopsies. Protracted hepatitis B is considered to be an important indicator for the further course, either towards the healing of the disease or its transition into chronic hepatitis.

### 4.12.4 Recurrent course

A renewed rise in the enzyme activities in the regular course of subsiding disease or during the posthepatitic phase of normal findings points to a relapse of hepatitis B (2−15% of cases). As a rule, the first occurrence of the disease and its relapse are only separated by an anicteric interval (H. THALER, 1982). The histological findings are generally more pronounced, since the disease has not yet morphologically healed. Routine everyday strain as already mentioned above (alcohol, chemical noxae,

medication, etc.) may be a causative factor. Physical work, however, is not considered to induce a relapse. Activation of HBV replication by means of cytotoxic therapy has been described. (198) A relapse is understandably distressing to both patient and physician. In setting up the differential diagnosis, thought has to be given to secondary viral hepatitis (A, C, and especially D) as well as to an additional infection with secondary hepatotropic viruses (s. tab. 5.16) or indeed to a general virus infection. Superimposed hepatitis infections are greatly feared.

### 4.12.5 Cholestatic course

The frequency is given at 10−15%; including the minor cases of disease, however, it may even be as high as 30%. In the main, older persons are affected. When setting up the differential diagnosis, the numerous other causes of cholestasis have to be ruled out. (s. pp 416, 421) (s. tabs. 13.4−13.6, 13.8) (s. fig. 22.4) • *Explorative laparotomy is contraindicated!*

**Fibrotic cholestatic hepatitis** in HBV infection can be found in patients following liver transplantation and reinfection of the transplant as well as after bone marrow transplantation (S. E. DAVIES et al., 1991; J. W. S. FANG et al., 1993). The prognosis is poor. Therapy with lamivudine can be tried. (175) Usually, the transplant fails or the outcome is fatal within one year. (s. p. 417)

### 4.12.6 Fulminant course

The frequency of fulminant hepatitis B (s. pp 376, 416, 421) is about 1%, yet it is clearly higher in an infection with HBV mutants and above all in a superinfection with HDV. Fulminant hepatitis B may be due to a combination of several unfavourable factors such as pre- or coexisting liver disease, coinfection with HDV (approx. 50%), virus load, virulence and route of infection (e. g. intravenous drug addicts), hormonal strain, additional infections, haemodialysis and inadequate (too fast, too

pronounced) immune reactions. With rapid HBsAg negativity and anti-HBs positivity, the survival rate is clearly better at 47% than is the case with persistent HBsAg positivity at 17%. • Therapy with lamivudin can be recommended. (126, 132, 140, 174, 182, 192, 222, 241, 242, 244, 251, 262)

### 4.12.7 Subacute course

The subacute course is rare. It is found more frequently in women than in men. The onset is acute, the symptoms are more severe and the disease progresses for months. The prognosis is serious, since chronic liver insufficiency often develops. Mortality is high.

### 4.12.8 Chronic course

About 3−5 (−10)% of cases of acute hepatitis B become chronic. Chronicity occurs in 40% of 1 to 5-year-olds and in 90% of babies. (s. fig. 22.10) Enzyme activities (GPT, GOT, GDH) usually stabilize at moderately elevated levels, the liver function values (cholinesterase, Quick's value, albumin) are normal or only minimally reduced, while the gammaglobulins stay in the normal range or only display a modest increase. The IgG value shows a tendency to rise. The persistence of HBsAg for more than 10−12 weeks may point to chronification. Serological markers can present quite different constellations in individual cases, yet anti-HBc positivity (with distinctly and sometimes greatly elevated titre values) and HBV-DNA positivity always prevail. Evidence of HBsAg/IgM complexes is considered to be a sign of chronicity. (195) A defect in the pre-S1 region may further chronification. The risk of cirrhosis is 30% in a 20-year course of disease. • Up to now, it has not been possible to prevent the development of chronic hepatitis. The idea that earlier treatment with IFα might reduce the number of chronic courses is under discussion. *(see chapter 34.6.5)*

## 4.13 Hepatitis B and pregnancy

Some 40% of all liver diseases and some 50% of jaundice occurring during pregnancy are caused by acute viral hepatitis.

The **course** of acute hepatitis B is not influenced by pregnancy. More frequent development into chronic hepatitis or reactivation of chronic hepatitis need not be feared. The **mortality rate** of 1.5% corresponds to that of acute viral hepatitis without pregnancy.

At 7.2%, the **miscarriage rate** in the event of pregnancy coinciding with acute hepatitis B is no greater than the frequency of spontaneous miscarriages. Only the **premature birth rate** at 15.7% is slightly higher than with normal pregnancies. The cause could be a greater sensitization of the uterus musculature to oxytocin as a result of higher bile acid values in the serum or an inadequate

breakdown of placental hormones because of impaired liver function. The **stillbirth rate** at 3.1% lies within the normal range. In the literature, however, there are reports of higher rates of premature birth (28.6%) and stillbirth (9.9%) if viral hepatitis occurs in the third trimester of pregnancy. There is no increase in the frequency of **embryopathy** or *foetal deformity*. • As in acute viral hepatitis A, an **abortion** is not indicated. On the contrary, each termination must be seen as an abrupt intervention in the hormone system and the immune reaction status, which considerably endangers the pregnant woman. (124) (For *statutory antenatal care* see p. 427) (s. fig. 22.9)

## 4.14 Hepatitis B and hepatocellular carcinoma

There is a causal interrelation between the development of hepatocellular carcinoma (HCC) and an HBV infection. (s. fig. 22.10) This is also shown by the geographic correlation between the high HBsAg prevalence in Asian and African countries (up to 20%) and the higher HCC rate. HBsAg carriers have a 100 to 200-fold relative risk of developing HCC compared to the controls. The probability rate of HCC was calculated at 6%/5 years. The seromarkers of an existing or past HBV infection were detected in the serum or liver of HCC patients in over 60% of cases. An increased frequency in families was demonstrated by the observation that several infected children of HBsAg-positive mothers developed HCC. The latency period is between 15 and 30 years. Under certain circumstances, the HBV protein x (HBx) acquires oncogenic qualities, triggering a cascade of intracellular events (so-called *step-wise carcinogenesis*) and thus effecting the sequential activation of oncogenes and the inactivation of tumour-suppressor genes. (123, 125, 146, 177, 228, 240, 265) (s. pp 444, 775)

## 4.15 Prophylaxis

All preventive measures are facilitated by an awareness of the serological status of infected persons, individuals with suspected infection and those generally in need of protection. • *Prevention of acute viral hepatitis has the following aims:*

> 1. **Inactivation of the pathogen**
> 2. **Interruption of the infection chain**
> 3. **Passive immunization**
> 4. **Active immunization**

*Inactivation* of the hepatitis virus is effected by suitable disinfection and sterilization measures. (s. p. 423) • Interruption of the infection chain is easier with hepatitis A than with hepatitis B as a result of its faecal-oral mode of transmission and shorter period of infectivity. Because of the costs involved, it is also difficult to build up a temporary immunization barrier around the infected patient. There is no legal obligation to have a

patient with acute viral hepatitis hospitalized. When the patient is treated at home, however, the provisions of the Epidemic Control Act have to be adhered to, preferably with the involvement of the Public Health Department. Upon admission to an isolation unit, it is recommended to separate hepatitis A patients from B and C patients, since there is no cross-immunity between the various hepatitis viruses, secondary infection is always possible and thus constituts a certain risk!

### 4.15.1 General hygiene measures

In order to *prevent* viral hepatitis and to *treat* hepatitis patients (in hospital and at home), strict compliance with **hygiene regulations** is a priority. Regular and thorough briefing of physicians and nursing staff is imperative. Eating and smoking should be prohibited in areas where a greater risk of hepatitis prevails. The sexual transmission of HBV is reliably prevented by using condoms. • *If all hygienic requirements are fulfilled, the risk of hepatitis infection can be reduced to <1%.*

### 4.15.2 Passive immunoprophylactic measures

Passive prevention is ensured by (*1*.) pre-exposure prophylaxis or (*2*.) postexposure prophylaxis. To this end, *immunoglobulin (HBIG)* with an established anti-HBs content (generally 200 IU/ml) is available. The **efficacy** of passive immunoprophylactic measures depends on:

1. the existing hepatitis B virus load in the body
2. the amount of anti-HBs administered
3. the timing of the injection
4. the mode of application of the preparation

The **protective effect** of HBIG (0.06 ml/kg BW) sets in 2−5 hours following i.m. injection. It lasts for about 2−3 months. If necessary, repeated vaccination may be advisable after 1, 3 and possibly 6 months. The application of HBIG calls for critical assessment in view of the high costs involved.

**Pre-exposure prophylactic measures** with the cheaper traditional gammaglobulin is ineffective against hepatitis. In cases of non-immunity, **immunoglobulin B** (0.06 ml/kg BW) has to be administered without delay. Non-immune persons should know their own serological status, so that suitable preventive measures can be taken immediately after any probable contact. If necessary, a serological **rapid test** can be carried out first, although this involves a certain loss of time. • The protective effect of the immunization decreases with each hour, and just 6 hours after exposure, efficacy can no longer be guaranteed.

**Postexposure prophylactic measures** are, in contrast, of tremendous practical significance. This is true for the HBV infection of non-immune persons in the medical field as well as in everyday life (e.g. needlestick injury, swallowing infectious material, sexual contact, prevention of reinfection following liver transplantation). All preventive measures must be complemented by concur-

rent active vaccination in contralateral parts of the body (= *simultaneous vaccination*). • The mere detection of anti-HBc or anti-HBe in the suspect matter (blood, for example) is suggestive of an infection and justifies vaccination of the exposed person (since HBV DNA may be present in a still unknown quantity). The demonstration of anti-HBe in the mother is an indication for the vaccination of the neonate. Newborns with HBsAg- and/or HBeAg-positive mothers are considered to be particularly at risk. For this reason, HBIG is administered immediately postpartum and repeated after 1 and 3 months. At the same time, active vaccination is initiated.

**Side effects** (e.g. local soreness, urticaria, exanthema, arthralgia) are rare or harmless and only last a short time. The administration of HBIG in cases of HBsAg positivity might, in theory, lead to the formation of immune complexes, yet this complication has not been observed so far.

### 4.15.3 Simultaneous vaccination

In approximately 95% of cases, simultaneous vaccination affords protection against HBV infection. An **indication** is given for non-immune persons if their circumstances have led to HBV exposure and there is not enough time for active prophylactic immunization:

1. newborns with HBsAg-positive (and anti-HBc-positive, possibly even anti-HBe-positive) mothers
2. accidental inoculations (e.g. needlesticks, injuries, smear contacts)
3. sexual contact, particularly anal intercourse, with potentially infectious partners
4. dialysis patients and relatives caring for them (e.g. home dialysis)
5. current exposure through close physical contact (e.g. in institutionalized homes for the mentally disabled, in shelters for the homeless, among drug addicts)

In order to prevent infection with HAV or HBV, particularly when exposed to these hepatitis viruses, various **measures** are indicated. (s. fig. 22.11)

### 4.15.4 Active protective vaccination

The **basic principle** for the development of a vaccine resulted from observations by S. KRUGMAN et al. (1970), according to which inoculation with heat-inactivated HBsAg prevented the outbreak of hepatitis B or lessened its severity in 80% of exposed persons as a result of the development of protective antibodies (anti-HBs). The first active immunization against HBV was carried out in 1973 (S. KRUGMAN et al.). • The **immunogenicity** of vaccines derived from plasma is comparable with that of gene-engineered vaccines: with $3 \times 10$ µg, anti-HBs is induced in 95−99% of children and adults (20−40 years); in older persons, the immune response is weaker.

A **vaccination schedule** involving injections (i.m. in the upper arm [!] or more effectively intradermal) at intervals of 1 and 6 months following the first injection (i.e. month 0, 1, 6) has proved successful. If an adequately high anti-HBs titre is to be attained as quickly as possible, the recommended intervals are 0, 1, 2 and 12 months.

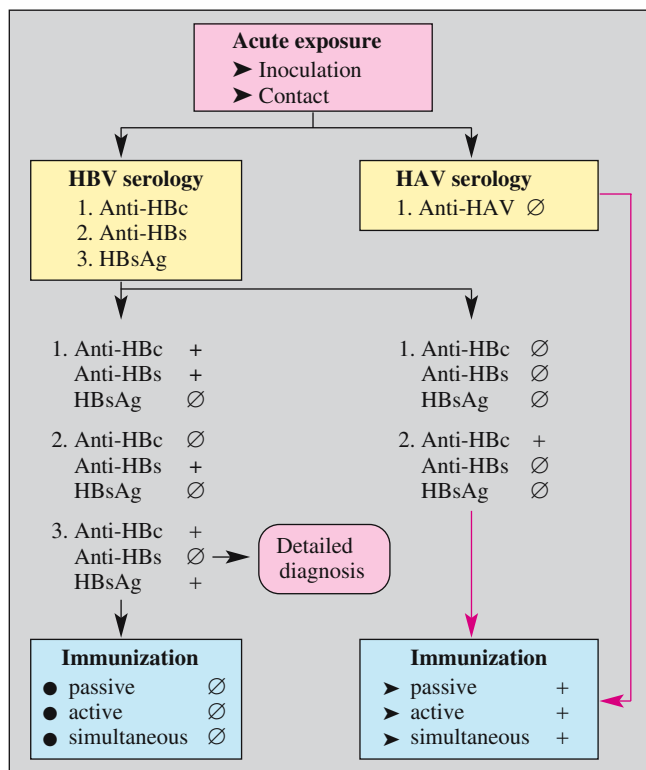
**Contraindications** include acute infections and (possibly) certain allergies. **Side effects** are minimal (<5%) and harmless (e.g. fatigue,


**Fig. 22.11:** Preliminary tests and measures in the event of exposure to or infection with HAV or HBV

rise in temperature, local reddening of the skin). In rare cases, reports have been received of thrombocytopenia, haemolysis or neuritis. • Active vaccination can be carried out during **pregnancy.** (124) (s. fig. 22.9)

The **indication** for active vaccination is given for all non-immune persons (*1.*) who are most probably exposed to the danger of infection, (*2.*) for whom the necessary time for the development of a protective anti-HBs titre is available, (*3.*) who have not previously received active vaccination because of indicated simultaneous vaccination, and (*4.*) as a general rule all children (from infancy) and juveniles. These groups include:

1. Persons working in the health sector (184, 204, 236)
2. Persons occupationally in contact with blood or blood constituents
3. Intimate partner of an HBsAg carrier
4. Homosexuals (161, 236)
5. Dialysis patients and, if necessary, the relatives caring for them (e. g. home dialysis) (144, 170, 236)
6. Care personnel or inmates
   − in homes for the mentally disabled
   − in shelters for the homeless
   − in prisons
7. Drug addicts (236)
8. Travellers to endemic areas, especially, when these journeys are repeated or if hygienic conditions are poor (such as with adventure travel)
9. Patients with coexisting liver disease who would be considerably endangered by an additional HBV infection
10. According to the WHO report of 1995, hepatitis B vaccination should be included in *vaccination programmes* for infants and juveniles − this has already been introduced in numerous countries

**Preliminary testing** prior to active prophylactic immunization against HBV is carried out in line with a well established schedule. (s. figs. 22.11, 22.12) • Active vaccination of persons who are only anti-HBc-positive usually triggers a booster effect with the development of anti-HBs.

Regarding **vaccine protection,** the efficacy threshold for anti-HBs is deemed to be a titre of about 10 IU/l. The antibody titre is determined between 4 and 6 weeks after the last vaccination. Depending on the titre attained, a *booster* may be required at various intervals. It is recommended to check the titre level some 4 weeks after the booster. In this way, it is possible to establish the effect of the previous vaccination and to fix a date for the next booster. About 25% of all successfully vaccinated persons are no longer adequately protected after 5 years.

| Anti-HBs titre (in IU/l) | Booster after |
|---|---|
| < 10 | immediately |
| 10−100 | 3−6 months |
| 100−1,000 | 1 year |
| 1,000−10,000 | 3−5 years |
| > 10,000 | 6−10 years |

▶ The **immune response** is mainly influenced by *age, gender* and *immune status*. Women usually show a better immune response than men. In almost every case, children form adequately high antibody titres (100% responders). Older people, starting at the age of about 50, show a slowly decreasing immune response. (152) Smokers, patients suffering from coeliac disease and overweight persons are more frequently non-responders, as are certain HLA types or those with IL-2 deficiency (e. g. dialysis patients). Dialysis patients or immunosuppressed persons are only capable of an immune response in about 50% of cases (or even less). • In 5−10% of cases, no antibodies are formed (non-responders). (199, 235)

**Relative non-responders** only display a good immune response after an additional 4th, 5th or 6th injection. In alcoholics, a double vaccine dose is more effective. (238) Care must be taken to ensure that the ampoule is well shaken and the injection correctly placed (i.m.) in the

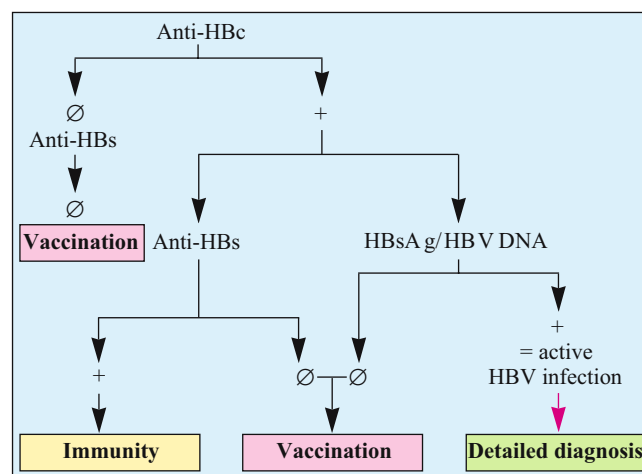

**Fig. 22.12:** Preliminary tests prior to active vaccination against hepatitis B (s. tab. 5.17)

upper arm. It must likewise be guaranteed that the vaccine storage directions are adhered to and the cooling chain is not interrupted prior to injection. • The trace elements **zinc** and **selenium**, which can be relatively or absolutely reduced under certain conditions, are also important for the functioning of the immune system. (s. p. 55) (s. tab. 3.15) In our experience, an adequately high "substitution" of zinc and selenium can prove beneficial before repeated injections (especially since the cost factor is low, and there are no known side effects). This measure is highly recommendable for cirrhotic patients, in particular those with alcohol-induced cirrhosis, and indeed for all alcohol abusers. These persons, who generally display zinc deficiency, are hardly capable of an immune response, yet are very much exposed to the risk of HBV infection.

**Absolute non-responders** are individuals who, in spite of all efforts, still show no immune response. Additional administration of interleukin-2 may open up new opportunities for treatment. (122, 238)

| Measures for non-responders |
| --- |
| 1. Compliance with storage instructions and maintenance of the cooling chain for the vaccine<br>2. Shaking the ampoule<br>3. Injection in the upper arm (i.m., intradermal)<br>4. Additionally, 4th, 5th or 6th repeat injections, in general with double dose and at shorter intervals<br>5. Possibly pre-administration of zinc and selenium |

► If there is a risk of HBV infection prior to the completion of vaccination and before anti-HBs values can give protection, the administration of HBIG is indicated. As a result, interim passive protection is provided and active vaccination can be completed. • *Active vaccination against hepatitis B is also considered to be the most effective prevention against the development of HBV-related hepatocellular carcinoma.* (265)

## 4.16 Therapy

*Causal therapy* (i.e. antiviral treatment) is not yet possible with viral hepatitis B. Both HAV and HBV are deemed to be self-restricting. • *HBV infection*, however, differs considerably from hepatitis A with regard to the following **criteria:**

| |
| --- |
| 1. Development of HBsAg carrier state<br>2. Progression to chronic hepatitis<br>3. Transmission mode<br>4. Penetration into body secretions and excretions<br>5. Correlation with HCC<br>6. Virus binding to the liver cell membrane<br>7. Mechanism of hepatocytolysis |

### 4.16.1 Aims of treatment

The spontaneous recovery rate is around 90%. The desired aims in treating viral hepatitis B can only be attained by means of therapeutic steps targeted at the pathogenesis of the HBV infection:

| |
| --- |
| 1. Shortening of the (acute and total) course of disease<br>2. Prevention of massive liver cell necrosis<br>3. Avoidance of chronic hepatitis |

### 4.16.2 Methods of treatment

**Symptomatic measures:** The only forms of treatment available (at present) are those already used in general medicine or other reasonable symptomatic measures:

| |
| --- |
| 1. Avoidance of factors (possibly) damaging to the liver, such as alcohol, chemicals, medication, toxins, *etc.*<br>2. Avoidance of factors (possibly) straining the immune system, such as operations, vaccinations, special medication, mental stress, *etc.*<br>3. Treatment and stabilization of endocrine diseases, such as diabetes mellitus, hyperthyroidism, *etc.*<br>4. Avoidance of malnutrition<br>5. Avoidance of physical strain |

**Alcohol abstinence:** Despite contradictory opinions, a period of alcohol abstinence should always be maintained during the acute course of disease as well as during the so-called posthepatitic vulnerable phase. Even if just a minimal amount of alcohol is actually permitted, the patient is nevertheless likely to increase consumption at will.

**Bed rest:** Patients who feel ill and weak will keep to bed rest of their own accord and refrain from any unnecessary physical exertion. (s. p. 7) The fact that the hepatic blood flow is improved when the body is lying flat is an additional argument in favour of bed rest during the acute phase of disease.

**Diet:** The *diet* should be evenly balanced and in accordance with the principles of present-day dietetics; it must also be tolerated by the patient. There is no special diet for viral hepatitis patients. • The *water and electrolyte balance* is often disrupted in cases of acute viral hepatitis, possibly with the occurrence of oedemas and ascites (so-called *hepatitis oedematosa*) (48, 77, 131) (s. p. 297) or impaired renal function (60, 120) − as is recognizable from the diuresis which normally develops at the onset of the convalescence phase. An even balance of water and electrolytes should be maintained − this is very much supported by the patient lying flat. • In the event of inadequate nutrition or malnutrition, particularly when nausea and vomiting occur, substitution measures are advisable (e.g. vitamins, glucose and electrolyte infusions).

**Moist warmth:** The application of moist warmth in the region of the liver is one of the oldest modes of treatment of liver disease and dates back to CAELIUS AURELIANUS. (s. p. 7) This aims at an improved circulation in the liver, something which has not, however, been proved up to now. In the case of upper abdominal complaints,

moist warmth is not only seen as beneficial, but it helps to avoid the use of splasmolytics and analgesics.

**Cholestyramine** may be advisable in cases of pronounced pruritus as a result of a cholestatic course of disease (4−8 g before breakfast).

**Ursodeoxycholic acid** was used to treat acute viral hepatitis B *without* cholestasis for the first time by our working group in 1988. (166) At the time, we attributed the markedly positive effect of treatment in 9 out of 10 patients to the potential immunomodulatory effect of UDCA. (149, 154, 216) In 1993 reports were also published by A.D. JORGE on the good results achieved in 22 patients suffering from acute viral hepatitis and cholestasis. • Administration in acute viral hepatitis is therefore recommended in controlled studies, since side effects are not to be expected and the current level of knowledge on the pharmacological effects of UDCA can be deepened. The beneficial effects of UDCA as reported so far in the cholestatic course of acute viral hepatitis are evidence of the success of this treatment.

**Medicaments:** *Glucocorticoids* are contraindicated. • Administration of *interferon α* is more dangerous than helpful. • *Other medicaments* should not be used unless this is absolutely necessary − it must be noted that the disturbed metabolism may alter in unforeseen ways. • In contrast, **misoprostol** (153) and **lamivudine** (141, 248, 250) showed remarkably positive effects. Especially in fulminant hepatitis B, administration of lamivudine (100 mg/day) proved to be effective. In patients with reactivation due to cytostatic therapy after liver transplantation, lamivudine was much more efficacious than famciclovir.

▶ The "treatment of jaundice with **sheep lice**" was first reported on by J.J. BECHER (1663). In a fascinating publication, K. QUECKE (1951) describes this topic in detail from the viewpoint of medical history. This procedure has long been common practice in folk medicine in the treatment of jaundice and involves the ingestion of a certain number of live sheep lice. There are inofficial reports that this absurd course of treatment is still practised in many regions of the world as well as in all social classes of the population, as I myself have witnessed (cf. the German expression of *"eine Laus ist über die Leber gelaufen"* or the English exclamation of *"something is biting him"* when someone is in a bad mood). (s. p. 5)

## 4.17 Healing of hepatitis B

The term **healing** means the *complete restoration* of the previous normal condition. Such a *restitutio ad integrum* in morphological and biochemical terms often cannot be achieved in the case of acute viral hepatitis B. • The term **healing up** means *recovery*, although varying morphological or biochemical *residues* may remain − as is often the case with acute viral hepatitis B.

### 4.17.1 Morphological healing process

In simple terms, the morphological healing process comprises three steps: (*1.*) phase of remittent inflammation, (*2.*) phase of regeneration, and (*3.*) phase of residual defects. Even if the healing phases are fluid in their relation to one another, each individual stage is easy to identify in the "longitudinal histological pattern". (264) (s. figs. 22.13, 22.14)

(*1.*) The **phase of remittent inflammation** shows a *variegated histological picture*, which is characterized as follows:
- increased deposition of glycogen in the hepatocytes
- accumulation of small liver cells with chromatin-rich nuclei and basophilic cytoplasm in the peripheral areas of the cleaned necrotic foci
- increase in acidophilic (and eosinophilic) single-cell coagulation necroses (= *Councilman bodies*), rejected from the cellular arrangement, so that the histological picture is often dominated by these condensed acidophilic hepatocytes with disintegrating nuclei
- rise in binuclear hepatocytes
- decrease in ballooned hepatocytes and histiocytic-lymphocytic cell elements in favour of plasmocytic forms as well as eosinophilic degeneration (= *dark liver cells*)
- reduced stellate cell reaction through to focal residues
- smoothing of the parenchymal portal field barrier, with inflammatory reactions receding to the portal fields; the liver cells grow in the direction of the central vein, making use of the intersinusoidal spaces as conveyance channels

*Fig. 22.13:* Late stage of acute viral hepatitis B: moderate round-cell infiltration of the lobular parenchyma with small aggregates of Kupffer cells and Kupffer cell activation; slight disarray of liver cell trabeculae; minimal canalicular cholestasis (→); liver cell mitosis (▶) and binuclear hepatocytes

*Fig. 22.14:* Scarred area with fragmented parenchymal islets (→) after confluent necrosis in the wake of viral hepatitis B (HBsAg+). Localized round-cell infiltration in the remaining parenchymal areas (HE)

(*2*.) The **phase of regeneration** (s. p. 402) cannot be precisely delimited − the histological picture shows the superimposition of remittent inflammatory changes and signs of regeneration. Minor inflammatory reactions in the portal field may persist for some time after termination of the clinical course of disease. The liver cell degeneration pigment ceroid (s. fig. 21.6) is no longer present, the stored iron pigment is only gradually transported away and the intralobular late nodules (s. fig. 22.3) recede slowly. Fibrocytes and fibroblasts are produced and activated, apparently developing from the histiocytes.

(*3*.) The **phase of residual defects** continues to display so-called *late nodules* (even for several months). The portal fields are freed from inflammatory elements. Only occasionally is iron-positive pigment identified; this serves as the most reliable and longest detectable sign of a past acute viral hepatitis. Parallel fibrillar production of collagen is increasingly evident in the portal field. The portal field vein, initially still dilated, normalizes its lumen. Occasionally, there are minor fibrotic portal fields, with the fibres fringed at the corners. Condensation of the intralobular lattice fibre structure or fibrous sclerosis around the central vein may still be detectable. These connective tissue residues often prove to be reversible.

In severe hepatic necrosis with large losses of parenchyma, the regenerating epithelium is not always able to restore the affected area completely. There is a development of fibrous bundles, which are in some places connected with pronounced and partly fringed fibrotic tissue in the portal field. Moreover, extensive **cicatricial areas** are formed, occasionally embedded in small parenchymal islets. (s. fig. 22.14)

► After severe viral hepatitis had been overcome, we were able to use photolaparoscopy in many cases to document extensive **parenchymal losses**, particularly in the area of the left liver lobe. We found not only (*1*.) diffusely distributed scarred retractions and defects in the connective tissue on the liver surface, but also (*2*.) circumscribed, relatively clearly defined grey-white and sunken scar plates, and even (*3*.) a largely dystrophic loss of the left liver lobe. (s. figs. 21.10; 22.15, 22.16)

*Fig. 22.16:* Large sunken scar plate in the area of the left lobe of liver (about 6 × 4 cm) subsequent to massive dystrophic liver parenchymal necrosis due to viral hepatitis B

*Fig. 22.16:* Atrophy of the left liver lobe with pronounced capsular callosity following acute viral hepatitis B (s. fig. 21.13; 35.1, 35.14)

Despite these often extensive fibrotic and scarred changes, sometimes with considerable parenchymal loss, liver function values are usually normal. The enzyme activities, likewise normalized, suggest the total disappearance of inflammatory reactions without any further liver cell damage. However, γ-GT can still be elevated, pointing to continued liver cell regeneration.

### 4.17.2 Biochemical healing process

Biochemical healing is demonstrated by the normalization of enzyme activities and liver function parameters. There are also no obvious signs of any (possibly still) increased mesenchymal activity. Occasional posthepatitic (functional) hyperbilirubinaemia is of no significance; it always disappears spontaneously. HBsAG elimination is 1−2% per year. Serologically, the occurrence of anti-HA IgG and anti-HBs IgG as well as anti-HBe (with the simultaneous disappearance of HBsAg and HBeAg) is considered to initiate a recovery phase with immunity. (264)

Nevertheless, these normalized laboratory parameters do not supply any information on the form of morphological healing; in individual cases, this can be either a *restitutio ad integrum* or a persistent *defect after healing* with pronounced parenchymal loss and fibrosis. (s. pp 404, 438) With examinations using imaging procedures, thought should be given to the possibility of such posthepatitic defect healing processes − even on a large scale! (s. figs. 22.15, 22.16) − in cases where findings are difficult to interpret. Only laparoscopy (and possibly targeted biopsy) can assess the type and severity of such morphological findings reliably and pinpoint their clinical significance in the light of laboratory tests.

# 5  Acute viral hepatitis C

## 5.1  Definition

Acute viral hepatitis C is largely (about 90%) identical with the disease formerly known as acute NANB hepatitis. The main features of HCV infection are the persistence of the virus (in >80% of cases) and a high risk of chronification (in 60−80% of infected persons). *(see chapter 34.6.6!)*

## 5.2  Pathogen

▶ As from 1981, cases of acute viral hepatitis not caused by HAV or HBV were known as non-A-non-B hepatitis (NANB) (H. Yoshizawa et al., 1981; D. W. Bradley et al., 1983). • In 1989 Q.-L. Choo et al. succeeded in isolating another pathogen of acute viral hepatitis from the serum of an artificially infected chimpanzee suffering from chronic NANB hepatitis. (5) Later in the same year, the above mentioned working group presented a radioimmunoassay with which the antibodies to the C-virus were detectable. (311) • HCV is a (+) strand RNA virus with a total of some 9,400 nucleotides (9.4 kilobases). This virus has a diameter of 30−60 nm. Its nucleotide sequence displays homologies to the flaviviruses and pestiviruses of the flaviviridae family. HCV possesses a long open reading frame encoding a *polyprotein* precursor of about 3,000 amino acids. With the help of enzymatic degradation three **structural proteins** develop: nucleocapsid C (p21), envelope E1 (gp31) and envelope E2 (gp70). A so-called region p7 forms the transition to the **non-structural proteins**. These include the regions NS2 (p23), NS3 (p70) (= protease/helicase), NS4A (p8), NS4B (p27), NS5A (p58) and NS5B (p68) (= replicase). The beginning of the structural proteins is denoted by 5'NCR, the end of the non-structural proteins by 3'NCR. (s. fig. 22.17)

The complete DNA sequence has meanwhile been clarified. HCV binds to the cell surface structure CD 81 via its envelope protein E2; for this reason, HCV can also infect other cell types (apart from hepatocytes). (318) • Virus replication can be detected very early (within the first week after exposure). The viral particle load is < $10^6$/ml serum, which is less than half of an HBV infection. The highest antibody titres are found in the pre-acute and early acute stages. • HCV can replicate extrahepatically, e. g. in leucocytes and B or T lymphocytes as well as, occasionally, in oral lichen tissue. (284) The spleen serves as a large extrahepatic reservoir for HCV. (280, 288, 313, 318, 334, 342, 355, 358, 377, 383, 404) (s. p. 115)

### 5.2.1  Genotypes

HCV shows pronounced **genetic variability.** The cause lies in the fact that HCV mutates swiftly and continuously under immune pressure, so that several variants result (known as *quasi species*). The **mutation rate** is about 10 times higher than that of HBV. Worldwide, different virus isolates have been found and characterized in great detail. The genes for the envelope proteins $E_1$ and $E_2$ seem to be particularly variable. • Up to now, **6 genotypes** and **13 subtypes** have been distin-

**Fig. 22.17:** Diagram of the genetic organization and structure of HCV.

guished. There are clear differences in their prevalence, depending on the geographic region. In Germany, for example, genotypes 1b (50−55%), 1a (18−23%) and 3a (15−18%) are most frequent, with i.v. drug dependence displaying an even higher prevalence of the HCV genotypes 2, 3a and 1a. Genotype 3a was particularly common in young patients. In cases of sporadic and post-transfusion hepatitis, there is greater correlation to type 1b, which could take a more severe course in liver transplant recipients due to the special circumstances involved. Type 1b was also frequently detected in patients with liver cell carcinoma in a non-cirrhotic liver. Furthermore, type 1b is more often associated with cirrhosis, and its response to interferon treatment is less marked, whereas types 2a and 3 display the highest responsiveness. Haemophiliac patients suffered successive infections with up to 3 HCV genotypes. • Types 4 and 5 are found mainly in Africa and type 6 in Asia. The assumption that certain genotypes are of significance for the course and prognosis of an HCV infection was not confirmed in an evaluation of 2,235 patients. • It is most probable that the course of disease and the success of therapy largely depend on the genotype and the virus load. (282, 287, 313, 341, 358, 377, 383, 389)

| Genotypes of HCV and their regional frequency | |
|---|---|
| Europe, USA | 1, 2, 3 |
| Australia | 1, 2, 3 |
| Far East | 1, 2 |
| Middle East | 4 |
| North Africa | 4 |
| South Africa | 5 |
| Southeast Africa | 6 |

**Tab. 22.7:** Main geographical distribution of the HCV genotypes

### 5.2.2 Inactivation

There are no particular measures for inactivating HCV, except for the same disinfecting procedures as applied for viral hepatitis B. Emphasis is thus placed on formalin, aldehyde derivatives and chlorine preparations as well as heating (e. g. 60 °C for 10 hours). (s. p. 423)

## 5.3 Serological diagnostics

### 5.3.1 Anti-HCV test

The anti-HCV test mainly serves to identify chronic (and thus particularly infectious) HCV carriers and blood donors. The test does not identify any acute disease or HCV infection of a newborn with an HCV-positive mother, nor does it provide any information on specific immunity or infectivity. • *Although the term anti-HCV is generally used, antibodies to the intact C-virus have not been detected (as yet).*

▶ The presence of anti-HCV affords no protection from another infection or reinfection. A reliable anti-HCV IgM test is not yet available. Experimental results, however, showed that the titre correlates with the activity of the disease and thus with the response to interferon therapy. A serum may contain HCV RNA, even though the anti-HCV test is negative. *All sera testing positive for HCV RNA proved to be infectious.*

In acute viral hepatitis C, the HCV RNA usually clears from the serum once the infection is over – although the anti-HCV test remains positive for a long time after this. However, the combination of increased GPT and a positive anti-HCV test of the first generation nearly always points to infectious HCV. Subsequent to the EIA test, 95% of the positive sera demonstrated cRNA by PCR, so that infectivity could be confirmed. For this reason, neither anti-HCV-positive blood donors nor blood units can be released for transfusion. As a check for hepatitis B-negative patients with liver cell carcinoma, the EIA test displayed positivity in 83% of cases. In patients with aetiologically unresolved cirrhosis, the EIA test was positive in 62% of cases, i. e. a large number of the cryptogenic chronic cases of hepatitis and cirrhosis were probably caused by HCV infection.

▶ False-positive HCV tests are mainly found with autoimmunopathies, in particular autoimmune hepatitis type 2 (LMK-positive form). (298, 313, 331, 350, 353, 358, 404) In cases of HCV infection which cannot be established serologically, the HCV RNA should be identified directly prior to commencement of INF therapy. In this way, the danger of deterioration in patients with autoimmune hepatitis is eliminated.

### 5.3.2 RT-PCR test

The detection of viraemia can only be carried out by determining the HCV RNA in the PCR test after prior reverse transcription (RT) (K. B. MÜLLIS, 1985). This also works in the incubation phase with patients who are still anti-HCV-negative with normal transaminase values as well as with serum that is still anti-HCV-negative in the acute phase. Thus the following **indications** are given for the PCR method:

(*1.*) identification of a possible HCV infection already during the incubation or acute phase, possibly after exposure

(*2.*) ascertainment of acute viral hepatitis C with negative anti-HCV test

(*3.*) detection of virus persistence and hence infectivity

(*4.*) measurement of the number of particles as a follow-up, particularly in patients prior to and after interferon therapy

(*5.*) testing newborns of mothers with a positive anti-HCV test

(*6.*) testing immunosuppressed patients for HCV infection

(*7.*) establishment of reinfection after organ transplantation

## 5.4 Epidemiology

The annual rate of new infections in Germany is estimated at 15,000−20,000. The prevalence of HCV infection is 0.4 (−0.7)%, which equals approx. 500,000 chronic carriers of HCV. This includes both carriers with liver disease and people with an apparently healthy liver, since HCV RNA-positive persons show normal GPT values in 50−60% of cases, yet also display the histological signs of chronic hepatitis. In the countries of south-eastern Europe, the prevalence is 1.5−4.0%. As with hepatitis B, there are regions with a particularly high rate of infection, such as for example the Pacific area with 75%. Worldwide, the number of infectious HCV carriers is estimated at 200−300 million; the number of those infected with HCV is estimated at approx. 5 million in Europe and 4 million in the USA. (313, 334, 344, 349, 358, 359, 377) *(see chapter 34.6.6)*

**Obligation for notification:** In Germany, since 2000, a differentiation has been made for notification purposes between HAV and HBV as well as HCV, HDV, HEV and "others". The following numbers for **NANB hepatitis** (including all hepatitis viruses except A and B) were registered (s. pp 420, 426):

| | |
|---|---|
| 1992 = 2,188 | 1996 = 5,178 |
| 1993 = 2,498 | 1997 = 6,272 |
| 1994 = 3,163 | 1998 = 6,174 |
| 1995 = 4,272 | 1999 = 5,987 |

The following **frequencies of HCV** were registered, whereby the real figure is 8−10 times higher:

| | |
|---|---|
| 2000 = 6,274 | 2002 = 6,745 |
| 2001 = 8,635 | 2003 = 6,961 |

**Mortality** due to virus hepatitis excluding A and B (i. e. "other viruses") was as follows:

| | |
|---|---|
| 1992 = 62 | 1995 = 98 |
| 1993 = 76 | 1996 = 156 |
| 1994 = 99 | 1999 = 173 |

**Mortality** due to virus hepatitis C was as follows:

| | |
|---|---|
| 2000 = 168 | 2002 = 127 |
| 2001 = 166 | 2003 = 110 |

## 5.5 Transmission

The hepatitis C virus can be transmitted *parenterally* or *sporadically*. **Risk groups** with a high prevalence rate are haemophiliac patients (70−90%), i.v. drug addicts (50−90%), posttransfusion patients (60−80%), dialysis patients (5−30%) and liver transplant recipients. In 40−50% of patients with a positive anti-HCV test, the transmission route is still unknown. These cases are designated *"community-acquired"* or *"sporadic" hepatitis C.* The cause is rooted in poor hygienic conditions and close physical contact. (272, 277, 334) Fundamentally, the possibility of infection depends on the virus titre in the source person − it is considerably lower than with HBV infection. Nosocomial infection between patients has also been observed. (281, 329, 390)

**Body secretions:** HCV antibodies and HCV RNA could be detected in saliva, sweat, urine, ascites, ejaculate, breast milk, bile and lacrimal fluid. It can be assumed that (as with hepatitis B) the occurrence of HCV in various body fluids is directly correlated to the HCV concentration in the serum. (268, 290, 330, 338, 343)

**Blood transfusion:** Some 90% of cases of NANB posttransfusion hepatitis are caused by hepatitis C. The risk deriving from this greatly feared transmission route could be diminished by using the anti-HCV test to screen blood donors and blood units; this caused a reduction from 4.0% to 0.6% and to <1 for every 10,000 blood units (= residual risk if a so-called serological window is present). (295, 298, 301, 386, 396)

**Blood products:** The use of blood units or blood products with haemophiliac patients as well as the administration of immunoglobulin preparations in general (322, 347) were accompanied by high HCV positivity. Today, there is only a slight risk of HCV infection in this respect.

**Haemodialysis:** HCV prevalence (5−30%) depends on the duration of dialysis and hence on the number of blood units used. Transmission is also possible via the dialysis equipment itself. (296, 317, 365, 378)

**Drug addicts:** With i.v. drug abuse, above all due to the common practice of "needle sharing", HCV antibodies can be detected in 50−90% of cases. (314, 382)

**Medical personnel:** Infection can be caused by way of *needlestick injury* (273, 316, 323, 352, 388, 399) or percutaneously, or the route of transmission may remain unknown. (407) The rate of contagion is 0.8%. Medical personnel in transplantation units were particularly exposed to risk (309), as were those in dialysis and plasmapheresis centres. (294, 406) Dentists, too, were infected 12 times more frequently with hepatitis C than a control group (1.7% vs. 0.14%). With dental surgeons, a contagion rate exceeding 9% could be detected. (290, 303, 324) In emergency admission units, the frequency rates for positive anti-HCV tests were very high. (307) An outbreak of acute hepatitis C was observed among volunteers participating in pharmacokinetic studies. (333) There was also a report regarding the risk of HCV transmission from patients to surgeons. (395) However, no serious risk of transmission emanating from an infected gynaecologist was demonstrated during a period of 7 years. (337) In other studies, the risk of HCV infection in medical staff is largely identical to that found in the normal population; in cases of injury, no (not even short-term) IF therapy is indicated.

**Transplantation:** The transfer of an infected organ led to hepatitis C in about half the cases, which, because of the required immunosuppression, mainly took a fulminant or chronic course. As with HBV infection, reinfection can occur in up to 87% of cases within a 12-month period following the transplantation of a virus-free liver. (328) This could be due to the duplication of the virus in extrahepatic cells. However, the transplanted liver only showed slight inflammatory reactions, so that HCV cirrhosis is deemed to be a clear indication for transplantation. (305, 345, 381, 400, 402)

**Skin injury:** One report was received on the parenteral transmission of hepatitis C via a bite wound from an HCV-infected person (299) and another on transmission from shaving. (397) It is not certain whether mosquito bites can also transmit hepatitis C. Large tattoos or acupuncture are considered to be another channel of infection. Worthy of mention is a report of an HCV-positive anaesthetist who infected 20 patients with hepatitis C. (292)

**Endoscopy:** There is no risk of infection provided the endoscope has been correctly cleaned. (369)

**Intrafamilial infection:** The frequency of intrafamilial infection, i.e. from close contact in the household and sexual contact between spouses, is clearly higher than with HCV-free families, yet it is still categorized as low. The notified rates of infection can vary considerably (3.2−23.0%). With children, positive anti-HCV tests were found in about 5% of cases. The sensitivity of the tests applied and the difference in the types of virus are probably responsible for the variations in the infection risk. (270, 289, 302, 321, 347, 360, 370)

**Sexual transmission:** In heterosexual partners, anti-HCV tests were positive in 5−23% of cases; a frequent change of partners seems to increase the risk of infection (some 10% of all HCV infections). Sexual transmission is more

frequent from an infected male to a female than vice versa. Homosexuals display a low infection rate of about 3% per year. In prostitutes, prevalence is 5−10%. In all, sexual transmission is of minimal significance, yet it has been validated in several studies. (278, 315, 343, 348, 370, 391, 394, 398)

**Vertical infection:** In about 0.8% of pregnant women, the anti-HCV test is positive. The likelihood of transmission from the mother to the child is 5% (−10%), yet it increases in line with the titre value of the circulating HCV RNA. The chronicity rate may be as high as 90%! However, detection is only possible by means of PCR, since anti-HCV can also be transmitted passively to the newborn, irrespective of infection. Transmission of HCV has even been demonstrated over a number of generations. HCV-positive mothers should possibly refrain from breast-feeding their infants, since HCV RNA can be present in the breast milk. Nevertheless, a doctor's order against breast-feeding is unnecessary. So far, one fatal case of HCV infection in a child has been reported. Administration of immunoglobulin to the newborn is not indicated. Pregnancy is not contraindicated in HCV-infected women. HCV screening is not required in every case. (306, 327, 367, 368, 385, 405)

## 5.6 Histological findings

On the whole, the histological picture resembles that of toxic hepatitis. As a result, it can be most difficult to make a differential diagnosis. In contrast to HAV and HBV infections, viral hepatitis C displays some *specific histological features* (310, 325, 326, 334, 358, 362, 376, 384):

(*1.*) In 30−85% of cases, the liver cells show fatty degeneration.
(*2.*) Destruction of the bile ducts is frequently detectable.
(*3.*) Hyaline cytoplasm inclusions (Mallory bodies) can often be detected.
(*4.*) Hyaline single cell necrosis (rather similar in appearance to Councilman bodies) is nearly always witnessed. This cell necrosis is the result of cytotoxicity, mediated by T lymphocytes.
(*5.*) In the portal fields, plasmacellular and lymphocytic infiltrates prevail. However, they are also present in the liver parenchyma, arranged linearly inside the sinusoids, which is why this finding can indeed be mistaken for hepatitis mononucleosa. There are no granulocytic components.
(*6.*) Epithelioid cell granuloma and liver cell ballooning are found in rare cases.
(*7.*) With a chronic course of hepatitis C, the extent to which connective tissue is formed is far less than in chronic hepatitis B. In contrast, filigree bundles of fibre and small hyalinization foci are chiefly found.

▶ **Histological diagnosis** of chronic HCV positivity is no doubt *best guaranteed by means of targeted biopsy with laparoscopy if 2 or 3 bioptic specimens are taken, possibly from the right as well as from the left liver lobe.* Percutaneous biopsies, as a primary or follow-up measure, only reach a limited area of the right liver lobe (s. fig. 7.8). One single bioptic specimen is not necessarily representative of the total liver findings, as we have repeatedly pointed out in the light of our own experience. (s. p. 160) (s. tabs. 7.3, 7.11) *(see chapters 34.2; 34.6)*

**Differential diagnosis:** Such histological findings can lead to considerable difficulties in terms of diagnostic classification. Moreover, the course of hepatitis C can occasionally be uneventful; sometimes only minor fatty liver cell degeneration, often without any noteworthy inflammatory reactions, is to be found. Even in cases of validated HCV infection, percutaneous liver biopsy can show "normal findings" (which, however, cannot in any way be seen as representative as a whole, particularly with HCV infection). Histological diagnosis is also rendered very difficult by the occasional combination of an HBV infection with hepatitis C. The following *liver diseases* are important in terms of differential diagnosis:

(*1.*) Exogenous toxic fatty liver cell degeneration with possible inflammatory reactions of fatty liver hepatitis. Especially, *alcohol-toxic fatty liver* is the most frequent false diagnosis in cases of hepatitis C.
(*2.*) False diagnosis due to a certain similarity with *autoimmune hepatitis.*
(*3.*) Histologically, suspected *primary biliary cholangitis.*
(*4.*) Morphological similarity with *hepatitis mononucleosa.*

## 5.7 Stages of disease

The **incubation period** lasts for 6−12 weeks, with extreme values ranging from 2−26 weeks. Anti-HCV can only be demonstrated 4−6 weeks after infection, whereas PCR is already positive within the first week. Current serological tests fail during the incubation phase, which is why those persons who are without clinical and biochemical symptoms can transmit HCV infection unnoticed (e. g. as blood donors).

The **acute phase** is characterized by a continuous rise in the detection of anti-HCV. Only 5−10% still test negative for a certain period of time; in suspected infection, a serological check should therefore be carried out after 4−6 weeks. With individual patients, the immune response can be delayed by several months, although there are no signs of immunodeficiency. As with HAV or HBV infections, prodromal symptoms are considerably milder or even absent. *In fact, the acute phase is clinically symptom-free in ca. 80% of cases!* Jaundice and/or hepatomegaly only occur in 15−30% of patients, whereby the jaundice is less pronounced. Enhanced fatigue may be evident. The mean transaminase activity is about half of that observed in hepatitis B, i. e. between 250−750 U/l. Often, an episodic fluctuating course ensues, alternating with transaminase values that may even be normal; therefore, normal values cannot be taken as a criterion for ruling out HCV infection. The clinical course frequently displays different episodes with monophasic (15%), biphasic (22%) or multiphasic transaminase levels as well as a plateau-like pattern of GPT values. The increase in transaminase

activity can persist for a period of 12 months in half of the cases. The inflammatory changes correspond to the extent of viraemia, i. e. the severity of the course of disease correlates with the anti-HCV titre. Often there is a significant increase in γ-GT (as much as 3 to 4 times the norm). This generally correlates with serious damage to the bile capillaries. • A *cholestatic course* is rare; generally, the disease progresses rapidly and can culminate in liver failure. Organ transplant patients are especially affected. • A *fulminant course of disease* is more frequent in Japan, yet is very rare in western countries (0.5−1.0%). (291, 311, 327, 392) This can be attributed to the higher HCV prevalence in Japan or to the divergence of HCV genotypes. • Superinfection with HAV has also been known to cause a fulminant course of disease.

▶ In acute and chronic HCV infections, various **antibodies** such as ANA, SMA, LKM-1, anti-GOR, etc. (s. pp 118−121, 679) (up to 65% of cases) as well as a positive rheumatoid factor (approx. 20% of cases) were detected. The differentiation between "genuine" autoimmune hepatitis and HCV infection with autoimmune phenomena is of paramount clinical significance.

A **symptom-free course of disease** is common with HCV infection. A subclinical course is often observed as well. It is therefore sometimes difficult to define the onset of the disease and the point when clinical healing begins. Clarity is only obtained by reliable histology based on representative samples. (279)

The clinical course can be unfavourably affected by various **risk factors** (e. g. race, gender, advanced age, immune status, genetics) as well as by alcohol abuse (275, 337, 363), toxins, coinfections and chemicals. Conversely, the course and prognosis of HBV, HDV and HIV infections as well as of metabolic diseases (e.g. porphyria cutanea tarda, $\alpha_1$-antitrypsin deficiency) can deteriorate as a result of hepatitis C.

**Course of disease:** Some 15−30% of those infected with HCV recover spontaneously; another 25% are asymptomatic with consistently normal transaminase values and only minor histological lesions. In approx. 40% of patients, sonographically determinable abdominal lymphadenopathy develops. During the further course of disease, hepatitis C displays a high chronicity rate of 60−80%. In 20−30% of cases, liver cirrhosis can be expected to develop within 10−20 years. These figures apply both to posttransfusion and to sporadic HCV infections. In 5% of cases, death occurs within 5 years. (312, 313, 334, 354, 362, 375, 380, 393, 396)

The **diagnosis** of acute viral hepatitis C is based on the following parameters, whereby especially alcoholic liver damage must first be ruled out (353, 377):

- **moderate increase in GPT, GOT and GDH**
- **noticeably higher γ-GT value**
- **repeatedly positive anti-HCV test (plus titre determination in the blood)**
- **determination of the HCV genotype**
- **positive HCV RNA test**
- **histological criteria**

**HCV carrier state:** A clinically asymptomatic carrier is demonstrated by the anti-HCV titre and HCV RNA (in serum and peripherical blood mononuclear cells) with, however, normal transaminase values. This form is naturally found most frequently in immunodeficient patients, but also in cases of infection caused by genotype 3. Histology may be non-contributory (279, 354, 365, 379, 384) − yet it can also reveal severe changes, in which case the GPT level is correspondingly elevated.

## 5.8 Extrahepatic manifestations

Just as with acute viral hepatitis A and B, an HCV infection can induce extrahepatic manifestations and syndromes. (300, 313, 357, 358) Such associations with various diseases not only make differential diagnosis very difficult, but they also have an unfavourable influence on the course of disease in certain cases. The capability of the C virus to induce autoimmunity is of special significance. (s. tab. 22.8) *(see chapter 34.6.2)*

Agranulocytosis
Aplastic anaemia
Corneal ulceration (401)
Cryoglobulinaemia (269, 346, 351)
Diabetes mellitus (type 1)
Erythema exsudativum multiforme
Glomerulonephritis (293, 339, 361, 372)
Guillain-Barré syndrome (332)
Hyperlipasaemia (403)
Lichen ruber planus (364)
Non-Hodgkin lymphoma (297, 346)
Polyarteriitis nodosa (283, 285, 366)
Polyarthritis
Polyneuritis
Porphyria cutanea tarda (304, 356, 387)
Sialadenitis
Sjögren's syndrome (271)
Thrombocytopenia
Thyreoiditis

**Tab. 22.8:** Extrahepatic manifestations in viral hepatitis C (with some references) (s. tabs. 22.2, 22.7)

Even during the acute course of disease, haematological manifestations in the form of **agranulocytosis** and transient **aplastic anaemia** have been observed. • Membranoproliferative **glomerulonephritis** is rare. HCV RNA, anti-HCV IgG antibodies and IgM rheumatoid factors are found in the immune complex deposits. At the same time, cryoglobulins and circulating immune complexes can often be identified in the serum. No association of this manifestation with a particular HCV genotype is known. HCV replication in the renal epithelium has not been detected up to now. Treatment with interferon-α has been successful in producing a clear improvement of the renal function. • HCV RNA is detected in 42−95% of patients with essential compound **cryoglobulinaemia** of type II or III (in Germany, in about 25% of cases). These findings often coincide with the identification of the rheumatoid factor and/or a decrease in complement. This extrahepatic manifestation of an HCV infection also displayed a good response to interferon-α, whereas cessation of this therapy led to the reoccurrence of the clinical and biochemical symptoms. Long-term therapy might be helpful here, possibly with low-dose interferon-α. HCV RNA is an accepted suitable follow-up parameter for the effectiveness of interferon therapy. In chronic HCV infection, a low-titre cryoglobulinaemia is often found without any concurrent signs of autoimmune disease typical for the condition. •

**Polyarteriitis nodosa** is another extrahepatic manifestation of HCV infection. • In 70−80% of cases, HCV infection could be associated with **porphyria cutanea tarda**, whereas in Germany and Ireland, the coexistence of an HCV infection with PCT could only be established in < 10% of cases. A possible explanation for this variation in prevalence might be either regional differences in the frequency of congenital uroporphyrinogen-III decarboxylase deficiency or a specific genotype. • Moreover, some reports have focused on **dermatological** and **ophthalmological** associations. Histology has shown **lesions of the salivary gland** in up to 50% of cases.

## 5.9 Hepatitis C and hepatocellular carcinoma

The prevalence of anti-HCV antibodies in patients with HCC is 13−76%, i.e. there are considerable geographic differences. High rates of prevalence are found in Italy, Spain and Japan (55−76%). A combination with a concurrent HBV infection increases the risk of carcinoma development. With posttransfusion NANB cirrhosis, the incidence of carcinoma development is > 5%. Given an appropriately long duration of HCV infection (20−30 years), primary liver cell carcinoma must be expected in up to 20% of cases, i.e. HCC occurs in 1−4% of patients with HCV cirrhosis every year. Likewise, in chronic hepatitis C, the frequency of HCC tends to be underestimated owing to the difficulty involved in making an early diagnosis. (276, 286, 297, 336, 374) (s. pp 433, 775)

### HCC diagnostics

Priority is given to **sonography**, which should be carried out at intervals of about 6−9 months in cases of chronic HCV infection. • At the same time, the **$\alpha_1$ foetoprotein** should be determined, since both results are complementary to each other. AFP values of < 20 ng/ml do not give any cause for suspicion. Increasing values, however, should be checked at shorter intervals, since a continuous rise points to a high risk of carcinoma. The AFP values correlate well with the size of the tumour and the undifferentiation of HCC. • The next diagnostic step to be taken is a **CT** scan. It is important to mention that foci of 3−5 cm in diameter are still accessible for surgical resection. • *For the histological validation of a diagnosis of suspected HCC,* **laparoscopy** *is the first priority − there is no other real diagnostic alternative.* (s. p. 155) Such a technique facilitates targeted biopsies and, when using Robbers forceps, the targeted *removal of tissue* from various areas in an adequate quantity for possible specific pathological processing. *At the same time, it supports* **staging** *through inspection of the free abdominal cavity, which is generally required in any case and cannot be replaced by any other procedure.* Percutaneous ("blind") or sonography-guided liver biopsy is not recommended, especially since it involves a considerably greater risk of bleeding in this situation than does laparoscopic forceps biopsy; moreover, percutaneous biopsy is only possible in a relatively small area of the right epigastric region (which does not always correspond to the localization of the focus). Further thought must be given to the fact that the obtained information is in itself limited, and usually the investigation has to be taken a step further by subsequent staging. *(see chapter 37.3)*

## 5.10 Prophylaxis and therapy

As with HBV infection, *prophylactic measures* include general hygiene measures and avoidance of exposure. Passive or active vaccination is not yet available. No therapy is required initially in a suspected infection with HCV due to needlestick injury. (NB: All relevant findings and facts must be carefully documented!) However, GPT and GOT as well as PCR should be checked after 2−3 weeks and again after a further 4−6 weeks. If a virus infection is now detected, interferon therapy can be applied. In terms of behaviour on the part of the patient, the *treatment* of acute viral hepatitis C corresponds to that of acute viral hepatitis A or B. During antiviral therapy, HCV RNA should be monitored every 3 (−6) months. (274, 308, 313, 350)

▶ Only an efficient **antiviral immune reaction** can eliminate the hepatitis C virus. In cases of acute HCV infection, minimal (endogenous) interferon-α values are detectable in the serum, i.e. the virus effects a poor interferon induction in the organism. • The $CD8^+$ and $CD4^+$ T lymphocytes appear to be mainly responsible for virus elimination. The problems of HCV infection lie in the fact that the patient has virtually no chance of spontaneous improvement or even healing with a *chronic course* of disease, i.e. there is practically no self-limiting factor in a disease process that has become chronic.

### Antiviral therapy

In 1992 **interferon-α** was used for the first time in acute HCV infection (3 × 3 million U/week, s.c. for a period of 3 months). The time at which therapy was commenced varied between 1 and 6 months after onset of the disease. Measured against the normalization of the transaminase values, success was attained in 70% of cases vs. 40% in the placebo group. After the end of therapy, the transaminase values may rise again. In the event of chronification, however, the course proved to be milder, and there was less histological activity. The long-term effect of interferon-α therapy in acute viral hepatitis C cannot be assessed as yet. Only in 20−25% of cases has it so far been possible to maintain remission of the disease. Patients with HCV genotypes 3 or 2 maintained remission in 30−40% of cases. • The dosage recommended is 5 million U/day for 4 weeks, then 3 × 5 million U/week for 5 months, the aim being to achieve HCV RNA negativity and normalization of the transaminase levels as well as to avoid chronification (success rate > 80−98%). (319, 320) With a negativity of HCV RNA and normalization of laboratory values, interferon therapy can be continued for another 6 months (3 × 3 million U/week). • In some 50% of patients suffering from hepatitis C, the immune reaction is sufficient to control the virus (i.e. its multiplication is suppressed). Presumably, complete elimination of the viruses cannot be achieved, even with an intact immune system. An increase in $CD4^+$ lymphocytes is indicative of an effective cellular immune response, so that the viral load is kept at a low level. • In 60−80% of people infected with HCV 2 or HCV 3, the virus load can be reduced to below the detection threshold after 6 months of combination therapy with **interferon-α + ribavirin**; with interferon monotherapy, this is achieved merely in 30−40% of cases. • The question of improving the success rate by changing the dosage or period of application is still unresolved, yet worth considering in view of the problem of HCV infection. (340, 350, 358, 371, 377) • This is also true for the (pharmacologically plausible) adjuvant use of **antioxidants,** for example in the form of *silymarin* (2−3 × 140−170 mg/day) during treatment with interferon-α. • Moreover, not enough reliable data are available regarding treatment with **amantadine** (e.g. 2 × 100 mg/day for 3−6 months) subsequent to interferon therapy. • Good results have meanwhile been achieved with **pegylated interferon**, a newly developed interferon: with a single application per week, it produces more constant efficient levels, a higher success rate and fewer side effects. *(see chapter 34.7.4)*

# 6 Acute viral hepatitis D

## 6.1 Definition

Acute viral hepatitis D/B is precipitated by an initially uncoated (incomplete, defective) human apathogenic viroid, which subsequently acquires HBsAg as its envelope protein. This hepatitis delta virus (HDV) becomes pathogenic as a result of two different infection modes: (*1.*) simultaneous infection of HBV and HDV (= coinfection) and (*2.*) infection of a chronic HBsAg carrier with HDV (= superinfection).

## 6.2 Pathogen

The **delta virus** was first detected in HBsAg carriers by M. Rizzetto et al. in 1977. (28) It was described as having a spherical form with a diameter of 36 nm. Subsequently it was characterized as a causative agent of exceptional pathogenicity. • As a **viroid**, the delta particle comprises an uncoated, single-stranded RNA in closed (circular) chain form, with 1,758 bases (1.7 kilobases). Viroids are up to 100 times smaller than viruses. The delta RNA is similar in structure to the genome of viroids from the plant kingdom. The nucleoprotein of the delta viroid is made up of the actual delta antigen (HDAg), which is composed of two larger proteins (P24 = 24,000 kD, P27 = 27,000 kD). (s. fig. 22.18) • *Because of its coating with "major" HBsAg (>95%), the delta viroid becomes a complete pathogenic virus (HDV), replicating in the host cells. In this form, it has also been shown to be transmissible in animal experiments (chimpanzees, marmosets).* It has not yet been clarified whether coating material from other hepadna viruses is used to complete the virus − in any case, replication within the hepatocytes has been demonstrated in the absence of HBV. The infectivity of HDV is essentially dependent on the presence of HBV. Pathogenic HDV also infects other body cells such as renal cells and fibroblasts. HDV can be inactivated by means of formalin. (411, 414, 415, 418, 436, 437, 440, 448)

### 6.2.1 Mutants

The presence of mutant forms has been postulated on the basis of certain observations that HDV infection can have a somewhat variable course of disease (*1.*) in animal experiments, (*2.*) in human disease, (*3.*) in various ethnic groups, and (*4.*) in different regions of the world. Only **three genotypes** (1−3) are known so far. These features of heterogeneity may all be found in a single patient. It can be assumed that mutants account for the difference in virulence of HDV and are also of significance for the clinical course, prognosis and therapy of the disease (e. g. genotype 1 is found mainly in fulminant hepatitis, cirrhosis and HCC). (422, 426, 428, 451)

## 6.3 Transmission

The transmission route of HDV corresponds to all the channels of infection of HBV, since its pathogenicity is coupled to the HBV as a helper virus. Thus HDV is mainly transmitted parenterally through blood and blood products as well as by sexual and even close physical contact. HDV infection cannot survive HBV infection. (417, 434, 443, 444, 452, 453)

**Vertical transmission** from mother to child is rare. Nevertheless, newborns with HBsAg-positive and HDV-

*Fig. 22.18:* Structure of the hepatitis D virus

infected mothers are especially at risk. Today, examinations carried out in the final trimester of pregnancy regularly identify HBV-infected women by serological testing, so that perinatal infection should, in principle, no longer occur. (421) (s. p. 427) (s. fig. 22.9)

**Posttransfusion infection** can be dangerous for the recipient (*1.*) if he/she is HBsAg-positive and if the donor blood, although proved to be HBsAg-negative in terms of the legal requirements, contains incomplete delta particles which can cause a superinfection and (*2.*) if the blood units have been obtained from an asymptomatic HDV carrier, where HBsAg synthesis in the donor is inhibited and his/her serological categorization proves to be false-HBsAg-negative. • *For this reason, blood units intended for HBsAg-positive recipients should be HDV-negative and also show normal transaminase values.*

## 6.4 Epidemiology

Retrospectively, the delta virus could be detected in Brazil in liver tissue dating back to the years after 1930 and also in blood specimens from the year 1947. Similar discoveries have been made in blood elsewhere since 1968. • HDV infection is actually present worldwide, yet there are considerable differences in frequency. The **highly endemic areas** with the greatest infection percentage are parts of Romania (ca. 80%), the Pacific Republic of Kiribati (ca. 70%) (449) and the Amazon region (ca. 60%). Other **endemic areas** include Egypt, Senegal, Gabon, Kenya and Tanzania as well as certain parts of Bolivia, Columbia and Venezuela. (412, 425) Other significantly less endemic areas are to be found in the Balkans, southern Italy (25−30%) and countries of the Near and Middle East. There are estimated to be approx. 10 million HDV-infected people worldwide, i. e. some 5% of HBsAg-positive carriers. (440, 442, 446) • Outside the endemic regions, the highest figures are found among **risk groups:** haemophiliac patients (40−60%), i.v. drug addicts (up to 80%), dialysis patients and homosexuals (40−60%). (408, 413, 429, 441−443, 452) • In Germany, HDV

infection is rare (0.5−3.0%), except in the above-mentioned risk groups. (420); there were 8 cases registered in 2001, 12 cases in 2002, and 10 cases in 2003.

## 6.5 Serological diagnostics

Because of the different modes of infection with acute viral hepatitis D, as coinfection or superinfection, serology can also reveal special features. In this respect, HDAg as well as HDV RNA can be directly detected in the serum and liver cells by PCR. (409, 424, 427, 445, 447) (s. p. 115)

An **indication** for an HDV check by means of the anti-HDV search test is given with (*1.*) an acute intermittent episode of chronic hepatitis B, (*2.*) an acute HBV infection in risk groups and patients from endemic areas, and (*3.*) a severe or fulminant course of acute viral hepatitis B. The persistence of anti-HDAg IgM can be considered as a *serological risk marker* for the development of a chronic form. A titre of $>1:1,000$ points to chronic hepatitis D. Generally, anti-HDV and HDV RNA are replication markers for an HDV infection.

### 6.5.1 Coinfection

HBsAg positivity is evident prior to the appearance of HDAg in the serum, just as HBcAg is found in the liver cell prior to the detection of HDAg. The other HBV seromarkers follow, as in viral hepatitis B when existing on its own. Anti-HBc IgM can be demonstrated at an early stage with a high titre. Some 1−2 months after an HDV infection, about 90% of the infected persons have antibodies (anti-HDV and anti-HDAg IgM), yet as a rule, the antibody titre is low. Anti-HDAg IgM can persist for 5−6 (−12) weeks. Anti-HDAg IgG is subsequently detectable − often only within a serological "window". HDV IgG remains present for a number of years and points to a past HDV infection. With the occurrence of anti-HDV, the HDV RNA disappears. As the healing of the acute HDV coinfection progresses, the titre of anti-HDAg IgG gradually drops below the detection threshold. A past HDV infection can no longer be recognized retrospectively. HDAg and HDV RNA become negative in the hepatocytes as well. With the coinfection of HBV and HDV, the HBV RNA clears more rapidly from the serum than in the case of an HBV infection on its own. (s. fig. 22.19)

### 6.5.2 Superinfection

The HDV infection of a chronic HBsAg carrier leads to the suppression of HBV synthesis, so that HBsAg, HBcAg and HBeAg are no longer detectable. By contrast, anti-HDV can be identified earlier and at a higher titre. (s. fig. 22.19)

## 6.6 Courses of disease

The course of disease is determined equally by these two modes of infection. The incubation time is (60−)

70 (−110) days. Analogous to the HBV infection, the HDV infection can likewise take on multiple forms. (409, 416, 427, 432, 441)

### 6.6.1 Coinfection

A healthy person is simultaneously infected with HBV and HDV. The pathogenic effect of HDV is usually restricted to the period of the generally self-limiting HBV infection, i.e. it can be expected to heal in approx. 90% of cases. For this reason, its clinical picture often cannot be distinguished from that of viral hepatitis B. In the event of a false-negative absence of HBV seromarkers, acute viral hepatitis D can be misinterpreted as HCV infection. Frequently (in some 30% of cases), a bimodal-like increase in the transaminase activity is registered at intervals of 3−4 weeks. This second rise in enzyme activity is probably caused by activation of HBV after synthesis was initially suppressed by HDV. (s. fig. 22.19) Such a biphasic course often correlates with the bilirubin level. The second phase of the disease can sometimes be very severe, developing into *fulminant hepatitis* in 2−20% of cases. (412) • In 2−7% of patients, *chronic hepatitis D* may follow; 30−60% of these patients develop *cirrhosis*. A *hepatocellular carcinoma* might also appear after a 30 to 40-year latency period. (450)

***Fig. 22.19:*** Diagram of the immune status in the course of coinfection and superinfection with HDV

### 6.6.2 Superinfection

A "healthy" or "diseased" HBsAg carrier is additionally infected with HDV. The incubation period is shorter than for coinfection. The transaminase values, hitherto normal or moderately increased, are now rapidly augmented, subsequently pursuing a plateau-like course. (s. fig. 22.19) As a result, superinfection normally takes a more severe course than coinfection. Consequently,

transaminase values are generally higher than is usual in coinfection (approx. 300−400 U/l). The transaminase level is only insignificantly correlated with the extent of liver cell necrosis. A modest boost in bilirubin (3−6 mg/dl, higher values are rare) is witnessed after the rise in transaminase activity. Generally, alkaline phosphatase is elevated. • *Fulminant hepatitis* must be expected more often than in coinfection (10−25%). A rapid rise in transaminase values (>1,000 U/l) points to the onset of this severe clinical picture. No distinction can be made from the fulminant course of an HBV infection. (419, 433, 434, 447) • *Chronic hepatitis D* occurs in 70−95% of cases of superinfection. Reactivation is frequent. Accordingly, the histological pattern of liver damage is more pronounced. (423) Chronic hepatitis D develops into *cirrhosis* at a higher rate and also at an earlier stage. Likewise, there is a danger of *hepatocellular carcinoma* following an appropriately long period of latency; the frequency is, however, no higher. (450) • In single cases, reciprocal viral interference can effect the *healing* of HBV and HDV infections. (416, 430, 439, 454)

## 6.7 Special features of HDV infection

The occurrence of an asymptomatic **HDV carrier state** is possible, yet rare. With immunodeficiency, there is greater proneness to HDV infection and HDV replication. • Following **liver transplantation,** increased HDV replication can result from the use of immunosuppressives. There is a danger of reinfection of the transplant and development of chronic hepatitis D. Treatment with interferon-α had no influence on the replication of HBV, yet it reduced HDV replication. (435, 438) • Disproportional to the absence or minimal presence of portal hypertension, distinct **splenomegaly** can be found in approx. 20% of patients infected with chronic HDV. (432) • **Autoantibodies** of the LKM 3 type (liver kidney microsomes) are detectable in some 20% of patients. • The **extrahepatic manifestations** are similar to those found with HBV infection. (s. tab. 22.5) The special features of the serological and clinical course, as well as of the histological changes, can possibly be attributed to the differing pathogenesis or degree of cytotoxicity. (410)

## 6.8 Prophylaxis

In terms of coinfection, prevention is only possible by means of passive or active immunization against HBV. It is imperative for chronic HBsAg carriers to avoid HDV endemic areas. However, should this not be possible, strict protective measures against HDV infection are called for.

## 6.9 Therapy

The treatment of acute viral hepatitis D is symptomatic; it is usually carried out in line with the same principles that apply to acute viral hepatitis A, B and C. • Consideration can indeed be given to the treatment of chronic hepatitis D with pegylated interferon-α in combination with lamivudine. However, the results achieved to date with interferon monotherapy have been less suc-

cessful than in cases of chronic hepatitis B or C. The relapse rate is also higher. The long-term success of the application of interferon-α is 10−20%. (431) *(see chapter 34.7.5)*

# 7 Acute viral hepatitis E

▶ The first thoroughly investigated epidemic of the disease known today as viral hepatitis E occurred in **New Delhi** in December 1955/January 1956. More than 29,000 cases of jaundice were reported. The 3 (to 4)-fold frequency among females and the prevalence in middle-aged people (30−40 years) were striking. Above all, pregnant women were particularly affected and the occurrence of the disease in the third trimester was accompanied by high mortality (15−25%). Everything pointed to contaminated drinking water as being the source of infection. (501) At the time, serological tests were not available for the differentiation of acute hepatitis. Nevertheless, after the development of HAV seromarkers, deep-frozen sera from this 1955/56 epidemic were examined, and, amazingly, no HAV positivity was established. Consequently, this large-scale epidemic in New Delhi was − at least for the most part − not caused by an HAV infection. There must have been a second type of (non-A) virus transmitted by the faecal-oral route. (487, 502) • In 1975 V. M. VILLAREJOS et al. likewise described an epidemic in **Costa Rica** with a faecal-oral transmission route which was not caused by HAV. • The evaluation of a hepatitis epidemic in **Kashmir** in November 1978 produced similar results to those found after the epidemic in New Delhi. HAV and HBV infections were not present. (476) Here, too, a faecal-oral transmission route via contaminated drinking water was found. • The greatest epidemic of all, registering about 120,000 diseased persons, was in **Xinjiang/China** (1986−1988).

## 7.1 Definition

Apart from HAV infection, acute viral hepatitis E is deemed to be a second enterally transmissible form of viral hepatitis. The incubation period and clinical picture are largely identical to those of an HAV infection, but HEV occurs more frequently in adults. Pregnant women are particularly susceptible, with a more severe course of disease, a higher abortion rate and increased mortality (15−25%).

## 7.2 Pathogen

The virus known as **HEV** was first identified in Moscow in 1983 after being recovered from the stools of a voluntarily infected person (M. S. BALAYAN et al.). In 1988 it was assigned to the *Caliciviridae* (D. W. BRADLEY et al.), to which it bears a similarity. It is also similar to that of the rubella virus, but because it lacks a protein coat, it cannot strictly be assigned to the Togaviridae. In all probability, it represents a new virus family. The genome was clarified in 1990. (489) HEV is a (+)-stranded, naked RNA virus, 27 to 34 nm in size, with a genome of 7,200 nucleotides in length and 3 open reading frames. Several isolates have already been cloned and sequenced. The processing of isolates from various geographical areas clearly demonstrated genetic hetero-

geneity. Up to now, **1 serotype** and **3 genotypes** have been identified. (456, 461, 466, 470, 472, 478, 488−490, 503)

## 7.3 Epidemiology

In all probability, HEV is a zoonosis which is transmitted to humans mainly by pigs (481), but possibly also by other animals, e.g. rodents. (468) HEV infection occurs *endemically* and *epidemically* as well as *sporadically* (because of travel). There have been many reports of epidemics and endemias of acute viral hepatitis E, such as in India (458, 488, 494, 502), Pakistan (465, 497), Nepal (474), Afghanistan, China, Indonesia, Malaysia, Egypt (467), Israel (475), Somalia (483), Ethiopia (498), Turkey (496), Syria (457), Singapore (463), Venezuela (486) and Mexico (500). Sporadic diseases have been described in seroepidemiological studies in Europe (460), the USA, Korea, Australia (482), South Africa (469), Austria (471), Spain (473), Switzerland (479), Taiwan (480), Greece (495), Belgium (499) and Italy (505). • In view of travel and tourism, particularly in the form of adventure treks in countries with poor hygienic conditions, HEV infection must be considered when faced with the task of drawing up a differential diagnosis of acute viral hepatitis. In Germany, up to 1% of the population are infected with HEV: in 2001 some 34 cases, in 2002 merely 17 cases, and in 2003 as many as 32 cases were registered. • The swine is considered to be the main reservoir of virus; in the USA, the majority of pigs were found to be infected with HEV (genotype 3) within the first year of life. (481) This strain of HEV has been transmitted from swine to chimpanzee and from humans to swine. Such an HEV reservoir in swine has meanwhile been detected in other countries, including Germany. Nevertheless, transmission from the animal reservoir to humans is extremely rare.

## 7.4 Transmission

HEV is transmitted by a **faecal-oral route.** (462, 464, 472, 491) Sources of infection are contaminated drinking water (particularly due to pigs) as well as food which is unboiled and contaminated by foul or waste water (470, 487, 492, 502) as well as eating raw deer meat (e.g. in Japan). Only rarely is close intrafamilial contact deemed to be the route of infection. (455) In contrast, an epidemic of HEV infection has already occurred in schools. (459) At one school in India, 67 children and a great number of teachers contracted the disease. (458) The risk of the environment becoming infected by an HEV patient is only 1.5−2.5%, whereas in acute hepatitis A, an infection ensues in 10−20% of cases. HEV is excreted in the stools in considerably lower concentrations than HAV. (488) As a result of this, and because HEV is less stable than HAV, the danger of contagion by HEV is lower. Transmission of HEV from an infected mother to the newborn child is possible, resulting in signifi-

cantly higher morbidity and mortality. (477) It is not known why pregnant women succumb to the disease more often, with a mortality rate of 15−25%. Possibly, a parenteral route of infection is involved. The i.v. transmission of HEV to primates led to higher transaminase values and evidence of virus particles in the blood as well as to the detection of HEV by PCR. Therefore, transmission by blood transfusion is assumed. In haemophiliacs, the i.v. risk of infection is low (504) or non-existent. Reinfection with the hepatitis E virus must be expected, since there does not appear to be lifelong immunity.

## 7.5 Serological diagnostics

The diagnosis of acute viral hepatitis E is possible through the detection of **anti-HEV IgM;** identification of **anti-HEV IgG** points to a past HEV infection. No results are as yet available on the duration of anti-HEV IgG positivity and any possible immunity associated with it. It is interesting to note that HAV IgM can be detected in acute HEV infection. This may lead to a false diagnosis of acute viral hepatitis A. (s. p. 420) The specificity of positive anti-HEV IgG or IgM test results should always be validated by means of the corresponding Western blot test. In a self-infection experiment with HEV, the HEV RNA was detectable in the serum from the 22$^{nd}$ day after infection onwards; once the maximum GPT level had been reached (on the 46$^{th}$ day), the serum was no longer HEV-positive. Anti-HEV IgG could only be identified on the 41$^{st}$ day following infection (a short time after the occurrence of jaundice), and this persisted for more than 14 years. From the onset of the icteric phase, HEV could be demonstrated in the stools; this virus was also the cause of viral hepatitis E in related animal experiments. (462) In 10−20% of cases of HEV infection confirmed by PCR, neither anti-HEV IgM nor subsequently anti-HEV IgG could be detected. A negative anti-HEV IgM finding does not exclude acute HEV infection. (456, 464, 470, 472, 503)

## 7.6 Clinical aspects and courses of disease

The incubation period is 10−56 (mean period about 40) days. The symptomatic clinical picture which is given cannot be distinguished from that of acute viral hepatitis A − especially in cases where the HAV IgM is positive. (s. p. 420) The clinical findings and symptoms are regressive within a period of 2 or 3 weeks. The course is acute and self-limiting, especially in children moderate or asymptomatic. In individual cases, severe courses of disease can occur with transaminase values above 2,000 U/l and a pronounced increase in bilirubin. (456, 460, 485) • Occasionally, a *cholestatic course* of disease occurs with clearly elevated values of the cholestasis-indicating enzymes, bile acids and serum bilirubin. Although the disease lasts longer (as in acute viral hepa-

titis A), the prognosis is still the same. • *Fulminant hepa-titis* occurs in 2−3% of cases. This severe clinical picture is to be feared quite often in children with HAV and HEV coinfection (470) as well as in pregnant women in the third trimester; mortality is high (10−25%). (470, 478, 484, 503) HEV superinfection produces severe decompensation in patients with chronic liver disease. • *Chronic courses* of HEV infection or HEV carrier state have not been observed as yet. Nothing is known about a correlation between HEV infection and hepatocellular carcinoma. The *extrahepatic manifestations* occasionally occurring in HAV infection can be anticipated in HEV infection as well. Mortality due to acute viral hepatitis E is 0.18−0.58% for a normal course of disease.

### 7.7 Prophylaxis and therapy

No immunoprophylactic measures are available. The hygienic and therapeutic measures correspond to those given for acute viral hepatitis A.

## 8  Acute viral hepatitis NA-NE

▶ In the initial course of evaluating 17 epidemics from a total of 25 waterborne epidemics in India transmitted by faecal-oral route, it originally seemed that 16 epidemics had been caused by HEV. The seroepidemiological results showed, however, that the epidemic on the Andaman Islands, and possibly also several of the remaining 16 epidemics, might have been caused by a *third non-A-non-E virus* transmitted by faecal-oral route. This presumed *NA-NE* virus has not been conclusively identified so far. It has simply been assigned to the *flaviviruses.* (506) • Acute NA-NE hepatitis is found worldwide (20−60% of sporadic acute NANB hepatitis). Non-parenteral transmission is most common. There is no gender- or age-related preference. Usually, the disease is self-limiting; its course is often severe. Fulminant liver failure and the development of chronic hepatitis were observed. (507, 508, 510)

## 9  HF virus

In 1994 N. Deka et al. detected virus-like particles of 27−37 nm in size in specimens of stools from French patients with virus hepatitis NANB. The authors provisionally named the infectious agent hepatitis French virus or HFV. (509) The patients tested seronegative for other hepatitis viruses, and no HAV or HEV was detectable in the stool specimens. Following i.v. application of such particles in rhesus monkeys, the hepatitis virus was produced and could be identified in the liver cells and stools of these primates. The genetic material was characterized as a double-stranded DNA of 20 kilobases in length. It was possible to reproduce the pathogens in cell culture. The existence of this pathogen and its epidemiological significance in relation to humans have not been confirmed up to now.

## 10  HG virus

In 1995 J.P. Kim et al. confirmed that they had identified another putative hepatitis agent in the serum of a patient with aetiologically unresolved chronic hepatitis by means of PCR. Because the letter F had already been used for the above mentioned unsubstantiated virus, the authors moved on to the next letter in the hepatitis alphabet and named this novel agent hepatitis G virus or HGV. The genomic structure of this enveloped RNA virus of the *flaviviridae* group (50−60 nm, plus strain) with its 9,125 and 9,392 nucleotides has already been clarified. (523) • In the meantime, anti-HGV (against the envelope protein E 2) has been developed as a serological marker. Up to now, 3 genotypes and 5 subtypes have been demonstrated, each with its own geographic distribution. (527) The virus seems to be spread worldwide and to have a prevalence of about 2%. HGV definitely has a long-term persistence rate (up to 16 years). (510, 512, 517, 525) Studies using frozen blood specimens demonstrated that HGV has existed in Germany for at least 20 years. (515) Patients with chronic viral hepatitis B or C are coinfected with HGV in 10−20% of cases. HGV can be detected directly not only in the serum, but also in liver parenchyma and mononuclear cells. (530) In nearly all cases, infection occurs parenterally, e. g. blood transfusion (515, 524, 532), haemodialysis (517, 519, 531) and i.v. drug addicts (528, 529); more rarely it is due to plasma products (520) and sexual contact (516, 528). Vertical infection from mother to child is also possible. The clinical course is mostly asymptomatic. In patients showing an unclarified elevation of transaminases, hepatitis due to HGV should be considered. A rise in γGT and AP was associated with lesions of the small bile ducts as a result of HGV infection. (514) Overall, laboratory parameters and histology resembled HCV. (512, 521, 522) The course of hepatitis with HAV, HBV or HCV is not influenced by an HGV infection. (510, 511, 513, 526, 530) Examination of patients with cryptogenic chronic hepatitis did not point to HGV infection as being a causal factor. (518) Treatment of persistent HGV with interferon had only a limited effect. (521, 531) Liver transplants were not affected by this virus. (511)

## 11  GB viruses

▶ As early as 1967, F. Deinhardt et al. discovered an infectious agent in the serum of a 34-year-old surgeon in Chicago suffering from acute hepatitis. It was termed **GB virus** from the initials of the first and last names of the patient. The serum was obtained on the third day

of jaundice. This GBV was successfully transmitted to marmosets. Further serial passaging in marmosets and during filtration experiments strongly suggested a viral aetiology. (535) Subsequent studies showed that the GB agent was distinct from HAV, HBV, HCV and HEV. (546)

Almost 30 years later (1995), this GBV agent was differentiated into 2 flavivirus-like genomes: **GBV A** (9,493 nucleotides) and **GBV B** (9,143 nucleotides). (548) Both virus types are simian viruses. Up to then, these 2 types had not been found in humans. However, GBV A antibodies have meanwhile been detected in 0.3% and GBV B antibodies in 1.2% of blood donors. Nevertheless, these two types of viruses are considered to be of no pathogenic significance for humans. It would, however, appear from animal experiments that GBV A potentiates GBV B infection. According to their genomic organization, the GB species A and B belong to the family of *flaviviridae*.

Recently, another genome, **GBV C** (ca. 9,200 nucleotides), was identified by means of PCR. (539, 549) It is defined as a single-stranded (+) RNA virus and forms a separate species within the *flaviviridae* family. It seems that the original serum of GB contained no (or no more) GBV A, GBV B or GBV C RNA; thus the above mentioned surgeon's hepatitis remains unclarified with regard to the causative virus type. In the meantime HCV could be differentiated into five subtypes: 1a, 1b, 2a, 2b and 3a.

It became evident that GBV-C and HGV are 2 isolates of the same virus, which is why the term **GBV C/HGV** is generally used. This virus can cause (mostly) asymptomatic as well as (rarely) acute hepatitis. Its RNA is detectable in the serum and saliva, but not in the urine, of infected patients. (547) There is a close relationship for the transmission of this virus from mother to child. (533) The incubation time is 4 to 6 months. However, the virus possesses no capability to replicate in liver cells; it can be considered as an endosymbiont. In most cases, the virus appears to be eliminated, but it can remain in a latent state in the long-term course. (538, 541, 545, 551) It was possible to demonstrate the presence of GBV C/HGV RNA in 10−20% of patients with chronic hepatitis C. (543) RNA was found in 1.2−16% of blood donors (534), in 3.0−20% of long-term haemodialysis patients (542), in 17.3% among dental personnel (544) and in 30% of polytransfused patients. In Hungary, antibodies to GBV C/HGV were found in 28% of the population over the age of 60. (550) This virus is held responsible for (mild) chronic active hepatitis. Infection has also been reported due to sexual contact. (525) However, infection with GBV C/HGV does not always lead to liver disease. Aplastic anaemia was observed in the course of GBV C/HGV infection. (537) Even after liver transplantation in GBV C-positive patients, viraemia was still detectable in 75% of cases. In contrast, GBV C viraemia was found

in 29% of HBV-positive patients and in 12% of HCV-positive patients following OLT. The occurrence of hepatitis in a liver transplant was not influenced by GBV C/HGV. There is no clear association with fulminant hepatitis.

# 12 TT virus

In 1997 another virus was detected in a Japanese patient with increased transaminases of unknown aetiology. The infectious agent was termed TT virus or TTV, based on the initials of the patient who had been infected as a result of a blood transfusion. (561) This genome is approx. 3,800 nucleotides in length. It is an antisense, circular, single-stranded DNA virus with no outer envelope. There are three conserved open reading frames. The size of the TTV is estimated to be 30−50 nm. It probably belongs to the *circoviridae* family. (559)

TTV has not been shown by electron microscopy. Up to now, the virus could only be demonstrated in the serum due to the presence of TTV DNA. A total of 16 genotypes have now been differentiated. (564) Recently, a TTV isolate from non-human primates could be identified; the authors named it s-TTV. Overall, 10.5% of Japanese patients with liver disease were found to be infected with s-TTV, whereby two different genotypes were classified. (557) There have also been reports of TTV-like mini virus DNA, which are detectable in a large number of patients. (558) TTV can replicate in various tissues, although changes in the liver are only mild. (565)

There is a high prevalence of TTV all over the world (41−93%), with striking differences in the various countries. Japan has a prevalence of 39−68%. (553) In Hungary, 18.5% of healthy persons and 50.4% of patients with hepatitis of unknown aetiology tested positive. (567) In Brazil, donated blood was shown to contain TTV in 62% of cases. (560) In Germany, a TTV viraemia could be found in 14% of healthy donors and in 16−20% of the various risk groups. (563)

TTV can be transmitted by blood products and through common parenteral routes (560, 563, 564) as well as by haemodialysis. (554, 556) TTV could also be detected in umbilical cord blood, so that a neonatal (in utero) transmission is to be considered. (558) The likelihood of enteric transmission has been shown by the finding of TTV DNA in breast milk, saliva, duodenal fluid, bile juice and faeces. There is a higher viral load in saliva than in the corresponding serum. (555, 566) TTV displays ubiquitous diffusion in human tissue and is able to invade the central nervous system. (562) A high virus load has been demonstrated in patients with HCV-associated HHC. (568) Although TTV has been found in patients with a broad range of liver diseases, current

evidence does not indicate a specific link with TTV infection in such cases.

# 13 SEN virus

In the year 2000, Italian scientists discovered a new virus isolated from an HIV-infected drug user. It was provisionally named SEN virus or SENV after the initials of the source patient, who showed elevated transaminases of unknown aetiology (D. PRIMI et al.).

This agent is also an antisense, circular, single-stranded DNA without an envelope. The genome is linear and contains ca. 3,900 nucleotides; it has at least three open reading frames. Up to now, 8 genotypes have been reported (SENV-A to -H). There are remarkable parallels between SENV and various TTV subtypes, and it may be that both viruses share a common ancestor. (575)

Genotypes D and H are thought to be linked with non-A-non-E hepatitis. Therefore investigations have focused on these two strains. SENV-D and -H strains were detected in patients with fulminant hepatitis (32%), chronic hepatitis (27%), autoimmune hepatitis (33%), cirrhosis (31%) and primary biliary cirrhosis (46%). (574) The prevalence in the population is currently estimated to be 10–20%; in risk groups with parenteral exposure, the figures are remarkably high – up to 80% in transfused non-A to non-E hepatitis. (577) Coinfection with HBV or HCV is found in approx. 20% of patients. Perinatal transmission from mother to child has also been reported. (570) • SENV infection does not affect the course of a persistent HCV coinfection. (571) It was also shown that SENV has no influence on acute or chronic hepatitis A, B or C and is not the cause of cryptogenic hepatitis. (578) Genotypes D and H were more often present in patients with a high risk of parenterally acquired viral infection. (569) SENV-H viraemia has been found mostly in patients with HIV. (573)

Infection with SENV-D and -H adversely affected the outcome of antiviral therapy for HCV (572), whereas in another study SENV did not influence the clinical or histological features of HCV at all. (577) SENV infection is not associated with increased evidence of liver disease or the risk of HCC. (576, 579) Likewise, this virus does not play any role in graft dysfunction after liver transplantation, although SENV was found in 35% of unselected liver transplant recipients. It is possible that SENV is a causative agent of posttransfusion-associated hepatitis, especially since specific DNA could be detected in liver tissue.

# 14 Other viruses

In 1994, using a total of 1,974 sera from patients with NANB hepatitis, the working group of G. BERENCSI

(Budapest) was able to identify 133 cases of a positive cross-reaction with the **yellow fever antigen** *(YF IgG)*; in 19 instances, *YF-IgM positivity* was also demonstrated. The majority of the sera were HCV-negative. These patients had had no contact with yellow fever vaccines and they had never left Hungary. • Studies carried out so far suggest the existence of an independent, but not yet identified flavivirus in the Hungarian population which produces a positive cross-reaction with the YF antigen and is associated with posttransfusion hepatitis. (576)

The evolutionary distance of flaviviridae polyproteins was used to generate an **unrooted phylogenetic tree**. The GB viruses are considered to form a group of their own with a close relationship to HCV. (s. fig. 22.20)

*Fig. 22.20:* Possible phylogenetic scheme of the HCV (*Hepaciviridae*) and GB viruses (especially GBV C/HGV) as well as other members of the *Flaviviridae* (I): DV = Dengue virus, WNV = West Nile virus, JEV = Japanese encephalitis virus, YFV = yellow fever virus, or *Pestiviruses* (II): BVDV = bovine viral diarrhoea virus, HCHV = hog cholera virus (mod. J. N. SIMONS et al., 2000)

# Clinical Aspects of Liver Diseases

## 23 Acute concomitant viral hepatitis

# 23 Acute concomitant viral hepatitis

A multitude of viruses can affect the liver as a large, filtrating and reacting organ, and subsequently cause concomitant viral hepatitis in the course of an existing systemic viral infection. Laboratory and histological findings in this case are determined by the type of pathogen, including its particular hepatotropic character, and by the immune status or reactivity of the affected organism. Concomitant viral hepatitis does not generally cause symptoms, which is why it is often recognized purely by chance due to slight to moderate elevations in transaminases; minor increases in bilirubin or cholestasis-indicating enzymes are rarely detectable. Nevertheless, rather severe courses with vast hepatocellular necrosis can occur in patients with a weakened immune response. • In infancy, concomitant viral hepatitis is frequently accompanied by a predominant cholestasis syndrome. On the one hand, an infant liver can be damaged by virus infections of a severe and even fatal course, yet on the other hand, it displays an astonishing capacity for regeneration and is indeed capable of restoring destroyed liver structures.

## 1 Secondary hepatotropic viruses

The most important virus species with regard to their ability to cause concomitant inflammatory reactions of the liver are (*1.*) herpesviruses, (*2.*) rubella viruses, (*3.*) Coxsackie viruses, and (*4.*) paramyxoviruses. (s. tab. 23.1)

| | | |
|---|---|---|
| **1. Herpesviruses** | | |
| − Epstein-Barr virus | D | E |
| − Herpes simplex virus 1, 2 | D | E |

| **5. Adenoviruses** | (S   D | E) |
| **6. Human parvovirus B 19** | | |
| **7. HIV** | laboratory test + | |

***Tab. 23.1:*** Secondary hepatotropic viruses which can cause viral hepatitis. • In Germany, **obligation for notification** is given in cases of suspicion (S), disease (D) or exitus (E). This can, however, vary from country to country. *If in doubt*, contact the Public Health Department!

## 1.1 Herpesviruses

Out of a group of approximately 40 herpesviruses (containing DNA, 100 nm in length), the following are classified as secondary hepatotropic: (*1.*) Epstein-Barr virus (types A, B), (*2.*) herpes simplex virus, (*3.*) herpesvirus-6, (*4.*) varicella-zoster virus, and (*5.*) cytomegalovirus.

### 1.1.1 Infectious mononucleosis

"Pfeiffer's glandular fever" (E. Pfeiffer, 1889) or "infectious mononucleosis" (T.P. Sprungt et al., 1920) is caused by the human herpesvirus 4 (= EB virus 4), which was discovered by M. A. Epstein, B. G. Achong and Y. M. Barr in 1964.

Infectious mononucleosis is a generalized reticuloendothelial infection, mainly found in adolescents and young adults. The total endemic infection rate in the more advanced age groups is 80−100%. • This condition is transmitted by close physical contact ("kissing disease"), sexual contact and blood transfusion. The incubation period of the orally transmitted virus is 8−21 days (up to 7 weeks). This is followed by a prodromal stage with headaches, tiredness and atypical fever. The clinical picture is defined by (chiefly cervical) swollen lymph nodes (95−100%), tonsillitis (>80%), splenomegaly (>50%), exanthema, mucosal petechiae in the oral cavity (30−50%) and leucocytosis with very large numbers of lymphomonocytoid cells. These "atypical lymphocytes" (W. Schultz, 1922) are activated T cells. Gallbladder wall thickening is found by sonography. (17)

In about 50% of cases, **hepatitis mononucleosa** with hepatomegaly (10−25%) develops, displaying an increase in transaminases of 10−20 times the normal value. (13, 15) Jaundice is witnessed in 5−10% of cases, usually due to autoimmune-based haemolysis. (2, 4, 5) There is a distinct elevation of LDH and alkaline phosphatase. (7) Hence, the following enzyme constellation can be evaluated as the *biochemical triad* of hepatitis mononucleosa:

| | | |
|---|---|---|
| **LDH** | ↑↑↑ | **(90−95%)** |
| **AP** | ↑↑ | **(75−90%)** |
| **GPT, GOT** | ↑ | **(60−90%)** |

The *Paul-Bunnel test* (J.R. Paul, W.W. Bunnel, 1932) is positive from the 4th to 10th day in about 75% of cases. Serological proof of acute infection can be successfully obtained by way of *anti-EB virus IgM*. The virus DNA is revealed by PCR. • *Hepatic lesions* are already found as from the 5th day and are most distinct between the 10th and 30th day of the disease. Portal/periportal and sinusoidal infiltrations of partially beaded lymphomonocytoid cells frequently appear in the form of small

foci. Proliferations of Kupffer cells and bile capillaries as well as isolated focal hepatocellular necroses and granulomas are present. (2, 8, 16) (s. fig. 23.1)

*Fig. 23.1:* Agglomeration of activated Kupffer cells (partially beaded), especially in the sinusoidal vessels, with single-cell necrosis. Clinical diagnosis: hepatitis mononucleosa (HE)

► *We observed a severe haemolytic course in a 23-year-old man, which took 4 months to subside: total bilirubin up to 34.8 mg/dl, haemoglobin decline to 7.7 g%, LDH up to 1,720 U/l, reticulocytosis 54‰, GPT 110 U/l, GOT 60 U/l, AP 308 U/l, γ-GT 148 U/l, increased erythropoiesis in bone marrow ++, direct Coombs' test ++, cold agglutinin ++, and incomplete cold haemolysin ++. (s. fig. 23.1)*

Some of the more *serious extrahepatic complications* are splenic rupture, thrombocytopenia, myocarditis or pericarditis, meningitis, pneumonia, nephritis and haemolytic anaemia; ascites was also reported in the course of severe hepatitis. (3) It should be noted that EBV can sometimes trigger autoimmune hepatitis. (14) • The prognosis is good. Complete recovery is generally achieved within 6−12 weeks. However, fatigue can persist for 8 to 9 months, which for athletes, for example, means an inability to train, resulting in a drop in performance. In this context, it has been suggested that the **fatigue syndrome** may indeed be caused by a variant of EBV. • In rare cases, a *fulminant course*, possibly even with a fatal outcome, is witnessed. In so-called sporadic fatal infection, the mortality rate is relatively high (40−45%). (1, 6, 10−12) A *chronic course* of EBV infection has been observed in some families, implying a genetic predisposition. Transition into chronic hepatitis or cirrhosis need not be feared because it is extremely rare. (13) In 50−70% of cases, an EBV infection developed following liver transplantation, and in 2% of these patients, *EBV hepatitis* occurred, sometimes with a lethal outcome. (9) • *Therapy* is symptomatic. Treatment with aciclovir is reported to be without success. In complicated courses, erythromycin (*cave* ampicillin!) and glucocorticoids may be indicated.

## 1.1.2 Herpes simplex hepatitis

The herpesvirus hominis is a generally widespread virus which can affect all tissues. Herpes simplex virus types 1 (mostly systemic) and 2 (genital herpes) are transmitted by droplet or smear infection. • In newborns, in patients with a weakened immune response or in immunosuppression (particularly following liver transplantation or in AIDS) as well as in chronic diseases (for example colitis) and during pregnancy, the course of disease may be severe, even lethal. • The viraemia can also cause *herpes hepatitis*. Clinical findings include fever, fatigue, abdominal discomfort (ca. 60%), hepatomegaly (ca. 35%), leucopenia and thrombopenia, marked increases in transaminases and occasionally distinct decreases in cholinesterase and albumin. Jaundice tends to be rare (with a value of < 5 mg/dl). Diagnosis can be established serologically by detecting herpesvirus antibodies of the IgM class or by demonstrating the presence of pathogens. Mucocutaneous changes are infrequent. The liver surface usually displays variable, yellow-coloured focal necrosis with red borders. • *Histologically*, microvesicular fatty degeneration is detectable; focal hepatic necroses are surrounded by hepatocytes with intranuclear inclusion bodies of Cowdry type A (surrounded by a bright area) (s. fig. 23.2) or type B (homogenous, ground glass-like).

*Fig. 23.2:* Acute herpes virus hepatitis with intranuclear bodies (Cowdry type A) (→)

The extent ranges from individual cell necroses to patchy confluent lobular necroses with irregular zoning. HSV are directly cytopathic; thus cellular necroses appear at first, followed by inflammatory infiltrates. Herpesviruses are visible by electron microscopy; they can be cultured from the liver and rendered visible through staining by means of immunoperoxidase. • The *prognosis* is dubious in high-risk patients; mortality is 10−15%. Following severe fibrosis resulting from long-standing protracted HSV hepatitis, chronic cholestasis may develop (even with a lethal course). There have been several reports of a fulminant course of disease. (24, 27, 30−34, 36) • *Therapy* is effected, even during pregnancy, using aciclovir as the agent of choice with

5(−10) mg/kg BW/8 hours as i.v. infusion or, in severe and immunosuppressed cases, with 10 mg/kg BW. Ganciclovir has also proved to be effective with 2 mg/kg BW/12 hours as i.v. infusion. (19−22, 24−26, 28, 29)

### 1.1.3 Herpesvirus hepatitis

A particular hepatotropicity causing severe herpes hepatitis is ascribed to herpesvirus 6 (HHV-6). There have even been reports of a fulminant course with this virus infection. (18, 23, 35) • HHV-8 causes *Kaposi's sarcoma*. The liver is the most common site, with dark reddish-violet tumour nodes. Histological analysis reveals endothelial cell proliferations and growths of spindle-shaped fibroblast-like cells. The bile ducts may be altered. Transaminase levels are elevated, and jaundice occurs. There may be a causal relationship between HHV-8 infection and *multicentric Castleman's disease*. The latter usually implies the presence of peliosis hepatis, perisinusoidal fibrosis and nodular regenerative hyperplasia.

### 1.1.4 Varicella-zoster hepatitis

"Chickenpox" in infancy and "shingles" in adults are caused by the same varicella-zoster virus. Very rarely and almost exclusively in immunosuppressed patients, *concomitant hepatitis* can occur with pronounced (mainly focal) hepatocellular necrosis, sometimes even with a fatal course. (37) Leucocytic portal and periportal infiltration can spread to the blood vessels and bile capillaries. Intranuclear inclusion bodies are present (s. fig. 23.2). Diagnosis is based on increased GPT, GOT, GDH and γ-GT values as well as the presence of varicella IgM antibodies; alternatively, pathogens can also be demonstrated in cultures. In children, a differential diagnosis of Reye's syndrome must be considered. As *therapy* in a severe course, aciclovir is indicated. (38−43)

**Fig. 23.3:** Herpes zoster. Pronounced concomitant hepatitis: GPT 186 U/l, GOT 132 U/l, GDH 8.3 U/l, γGT 56 U/l, cholinesterase ↓; alkaline phosphatase and bilirubin normal

Herpes zoster generally shows less severe concomitant viral hepatitis. In one particular case of zoster disease (s. fig. 23.3), we observed an unusually pronounced

form of hepatitis. After recovery, the patient revealed normal laboratory values.

### 1.1.5 Cytomegalovirus

A cytomegalic infection is transmitted perinatally or postnatally (mainly unnoticed) by the cytomegalovirus (CMV) − a DNA herpesvirus − as well as by direct body contact (droplet-smear infection, breast milk, sexual intercourse) and blood transfusion. Some 60−80% of all adults in the USA and in Europe have overcome a cytomegalic infection and are now immune. (48)

In terms of liver involvement, a **pre-/perinatal infection** usually causes hepatosplenomegaly, moderate jaundice (ca. 60%), differing degrees of cholestasis (concomitant cholangitis) and mild *cytomegaly hepatitis*. In numerous cases, the characteristic intranuclear inclusion bodies (so-called *owl's eyes*) can be found. The occurrence of *giant-cell hepatitis* (s. fig. 22.5) is considered to be an unusual event. Occasionally, *granulomatous hepatitis* with epithelioid cellular or histiocytic granulomas occurs. Histologically, the hepatic changes can persist for months or years. Therefore, non-cirrhotic portal hypertension may develop. (47) Mortality is about 20%.

**Postnatal infection,** providing it does not take a symptom-free course, displays the clinical picture of infectious mononucleosis with similar haematological findings and complicative developments (such as haemolytic anaemia, thrombopenic purpura, pneumonia) as well as retinitis, arthritis, acute portal vein thrombosis and colitis. In about 25−35% of cases, *cytomegaly hepatitis* develops with moderate jaundice, hepatomegaly, a slight increase in transaminases and varying degrees of cholestasis. Cytomegaloviruses can persist in lymphocytes and other body cells and may be reactivated under conditions of diminished immunity or immunosuppression.

In **infancy,** cytomegalic infection is mainly symptom-free. Up to 40% of cases, however, did show evidence of *cytomegaly hepatitis* with hepatomegaly. Virus excretion in the urine points to viraemia. • In **adulthood,** there is likewise evidence of *concomitant hepatitis* (52) as well as *granulomatous hepatitis* (44, 45, 51) in addition to the generally pronounced cytomegalic infection, which is witnessed to varying degrees during this phase of life. Moderately increased GPT, GOT, GDH and LDH activity is generally in evidence; this is sometimes accompanied by a distinctly pronounced elevation of γ-GT (without an equivalent rise in AP) and decreased levels of serum iron. Occasionally, marked cholestasis occurs. In most cases, there is a reduction in serum iron. Bilirubin values are moderately elevated or completely normal. (50) • *Diagnosis* of cytomegalic infection is based on the antibody titer increase of CMV IgM (sometimes with reactivation), detection in the virus by PCR, virus excretion in urine or in situ hybridization. Histologically, the typical intranuclear inclusion bodies suggest a cytomegalic infection. (54−56) CMV infection is to be feared in the

liver transplant; thus there is a danger of "vanishing bile-duct syndrome". (46, 49) • *Therapy* consists of ganciclovir (53) or foscarnet. CMV immunoglobulin is recommended for pre-exposure prophylaxis.

## 1.2 Togaviruses

### 1.2.1 Rubella hepatitis

*Connatal infection* due to the 60 nm RNA virus, which belongs to the togavirus group, is accompanied by a clearly enlarged liver and spleen as well as, on occasions, by jaundice. Histologically, cholestasis with bile pigmentation in the hepatic cells and with bile thrombi in the canaliculi is found. The portal fields are widened and irregular as a result of inflammatory infiltration, and the ductuli generally display pronounced proliferation. Occasionally, *giant-cell hepatitis* occurs. (s. fig. 22.5) • In adolescents and adults, *granulomatous hepatitis* is sometimes observed. In other cases, only slight histological changes are detectable, or the findings can be interpreted as insignificant *non-specific reactive hepatitis*. In the later stages, fine calcification foci can develop (as in Ebola hepatitis). (57, 59−64) (s. fig. 21.1)

### 1.2.2 Spring-summer encephalitis hepatitis

In spring and summer, ticks (especially Ixodes ricinus) can transmit meningo-encephalitic viruses of the togavirus family to human beings. During this disease, *concomitant hepatitis* may develop, with a moderate increase in transaminases. Histologically, pronounced focal hepatic cell lesions are found together with mesenchymal inflammatory reactions; all of these findings are attributable to non-specific reactive hepatitis. (58)

## 1.3 Picornaviruses

### 1.3.1 Coxsackie hepatitis

This virus species derived its name from the town of Coxsackie in the state of New York, where virological evidence thereof was successfully obtained for the first time. Coxsackie viruses are assigned to the picornavirus group, consisting at present of 23 A and 6 B types. • *Coxsackie hepatitis* with mesenchymal reactions, portal infiltration and focal hepatocellular necrosis sometimes occurs, especially in infants. Cholestatic, predominantly centrolobular forms of the disease, can develop in adults. A lethal course is extremely rare. (66−68) • The course of infection with the Coxsackie type B4 or B5 virus may give rise to the *Fitz-Hugh-Curtis syndrome* with the development of the typical violin string-like adhesive strands. (65) (s. fig. 24.2)

### 1.3.2 ECHO virus hepatitis

The widespread group of echoviruses, with its 31 known serotypes, has not yet been reliably categorized system-

atically or pathogenically. These viruses can also give rise to *concomitant hepatitis*, with type 4 and type 9 being held mainly responsible for this condition. (69)

## 1.4 Paramyxoviruses

### 1.4.1 Measles hepatitis

The measles virus, discovered in 1911, is a large (100−150 nm) paramyxovirus with a lipid envelope. Concomitant *measles hepatitis* occurs in 80% of all adults suffering from measles. It generally takes an anicteric, clinically bland course, and in most cases even goes unnoticed. Diagnosis is based on the elevation of transaminases and the detection of IgM antibodies. Cytologically, multinuclear giant cells are found in the nasal secretion. The prognosis for measles hepatitis is good. Despite lifelong immunity, however, the measles virus is able to persist latently in cells, especially in lymphocytes (as in autoimmune hepatitis). (70, 72, 75)

### 1.4.2 Parotitis hepatitis

The parotitis virus, an RNA virus of the paramyxovirus group, can also cause *mumps hepatitis* with corresponding minimal histological and laboratory findings.

### 1.4.3 Giant-cell hepatitis

In 1991 in Canada, J. Phillips et al. determined the presence of paramyxoviruses in patients with an infaust course of giant-cell hepatitis: out of 10 patients, only 5 survived with the help of liver transplantation. Paramyxovirus nucleocapsid protein, with a diameter of 12−17 nm, was detected in the cytoplasm of the hepatocytes. (74) Until then, this paramyxovirus had been unknown. It can cause severe acute hepatitis, which might even be fatal. (71, 73, 76) (s. p. 417!)

## 1.5 Adenovirus hepatitis

Adenoviruses can be the cause of *hepatitis* in newborns or immunosuppressed persons, sometimes even with a *fulminant course*. They bring about the formation of inclusion bodies in the hepatocellular nuclei. Adenovirus infections can be diagnosed either serologically or by virus isolation. (77−79)

## 1.6 Human parvovirus B19

HPV B19 causes erythema infectiosum in children. It may also lead to acute hepatitis. Aplastic anaemia is found in adults with simultaneous, potentially massive liver cell necroses and fulminant liver failure. HPV B19 can be detected in the liver tissue using PCR. (80)

## 1.7 HIV hepatitis

By means of virological examination methods, it was possible to demonstrate HIV-1 RNA in hepatocytes,

Kupffer cells and endothelial cells. The liver may be involved in systemic HIV disease both during primary infection and in the more advanced stages. The elevation of the transaminases, of GDH and γ-GT is highly significant. Hepatomegaly can occasionally be detected as well and is attributed to infection-related hyperplasia of the liver cells. *HIV-concomitant hepatitis* shows differing degrees of focal hepatocellular necrosis, inflammatory mesenchymal reactions, portal field infiltration, granulomas or peliosis hepatis. During the course of HIV infection, *HIV cholangiopathy*, frequently of the sclerogenic type, may also develop. Cryptosporidiosis of the bile ducts with cholangitis has so far only been observed in AIDS. (s. p. 639) • The most common opportunistic infective agents are Mycobacterium avium intracellulare (40−45%), cytomegalovirus (20−30%), cryptosporidium and various mycoses (histoplasmosis, cryptococcosis, coccidiomycosis). (81−87)

## 2 Exotic hepatotropic viruses

A large number of virus species that can be found in tropical and subtropical countries are known to be hepatotropic pathogens. They can give rise to minimal findings of so-called non-specific reactive hepatitis or fatty degeneration of the liver cells with cell necrosis, or may be the cause of severe liver disease. All of them have been categorized under the generic term exotic virus diseases. (88, 100, 102) They are pathogens from the family of (*1.*) flaviviruses, (*2.*) filoviruses, (*3.*) arenaviruses, and (*4.*) bunyaviruses. (s. tab. 23.2)

| | | |
|---|---|---|
| **1. Flaviviruses** | | |

| • Rift Valley fever (Phlebovirus) | D | E |
| • Crimea-Congo fever (Nairovirus) | | |

**Tab. 23.2:** Significant exotic hepatotropic viruses which can cause hepatic damage. • In Germany, the **obligation for notification** is given in cases of suspicion (S), disease (D) or exitus (E). This can, however, vary from country to country. *If in doubt*, contact the Public Health Department!

### 2.1 Yellow fever

The main epidemic regions are South America and equatorial Africa, i.e. the so-called *yellow fever belt* between the 15<sup>th</sup> northern latitude and the 15<sup>th</sup> southern latitude. The yellow fever virus is transmitted from human being to human being by infected mosquitoes, especially Aedes aegypti or Aedes simpsoni. There is a marked steatosis hepatis. Often a bacillary peliosis hepatis is found; it can be associated with the cutaneous bacillary angiomatosis. Rochalimaea henselae have been determined as a pathogen. In children with a coinfection of HIV and adenoviruses, fulminant hepatitis has been reported. An incubation period of 3−6 (−13) days is followed by fever with viraemia, jaundice, hepatosplenomegaly, arthralgia, myalgia, exanthema, bleeding and haematemesis ("vomito negro") as well as circulatory disorders and renal damage (largely in the form of fatty tubular degeneration). However, inapparent or bland courses of disease are equally possible.

*Hepatic lesions* in the case of yellow fever are more likely to correspond to those of hepatosis. (s. p. 404) There is also evidence of distinct acidophilic hepatocellular necrosis as well as microvesicular fatty degeneration of the hepatocytes. Hyaline, eosinophilic inclusions in the cytoplasm of degenerated hepatic cells (so-called *Councilman bodies*) are characteristic and were first identified by W. T. Councilman in 1890 in yellow fever (s. p. 396). Acidophilic inclusion bodies in the hepatocellular nuclei which are arranged concentrically around the nucleolus (so-called *Torres corpuscles*) correspond to the yellow fever virus (C. M. Torres, 1928). The liver does not present any significant signs of inflammation. The reticular fibre structure is maintained, so that the liver architecture is usually completely restored-provided the outcome of the disease is favourable. (s. fig. 23.4)

**Fig. 23.4:** Portal inflammation and acute parenchymal necrosis (N) due to shock (first periportal cell trabecula is still intact). Clinical diagnosis: yellow fever

The *diagnosis* is established by determining the specific YF IgM antibodies and/or the virus RNA. Laboratory parameters reveal an elevation of the transaminases, GDH, γ-GT and LDH as well as a reduction in leucocytes, Quick's value and cholinesterase. Albuminuria is also present. *Mortality* (5−10%) is generally due to renal insufficiency. After *recovery*, immunity is lifelong.

Chronic courses of disease are not known. When travelling to yellow fever regions, immunization (with live vaccine) is imperative; vaccine protection lasts for 6−10 years. (s. p. 451) (93, 98, 112)

## 2.2 Dengue fever

The dengue virus is also related to the flavivirus species. It is transmitted by mosquitoes (of the Aedes type). The prognosis is relatively good − despite the fact that several hundred deaths have been recorded during epidemics (such as in Java and India in 1996). Altogether, some 55 million people contract the disease every year. The worldwide mortality rate is approx. 10%. In Germany, more than 1,500 cases of infection are registered annually. Following a 5 to 8 day incubation period, the clinical picture comprises fever ("breakbone fever"), headache, nausea, haemorrhage (haematuria, melaena), myalgia and arthralgia, exanthema, lymphadenopathy, and even splenic rupture. • *Concomitant hepatitis* of different degrees of severity, often with centroacinar necrosis and microvesicular steatosis, can occur. Fulminant hepatitis is rare. Convalescence is protracted. Diffuse residual parenchymal calcifications may remain. No vaccine has been found so far. (82, 86, 87)

## 2.3 Marburg virus disease

In 1967 in Marburg (Germany), a total of 23 patients contracted a previously unknown infection caused by the "Marburg virus", which belongs to the filoviruses. Altogether, five outbreaks have been reported, with over 120 cases. It is a single-strand RNA virus, 790−970 nm in length and 80 nm in width. Infection resulted from direct, work-related contact with African apes (green guenons) as well as human transmission (partially due to sexual contact). After a 5 to 7 day incubation period, the clinical picture became serious, with fever, vomiting, diarrhoea, exanthema, conjunctivitis, myalgia, haemorrhagic diathesis with thrombopenia, renal and hepatic damage as well as disorientation. • Laboratory parameters and histological examinations pointed to severe *hepatitis* with hepatosplenomegaly. Jaundice is extremely rare. Hyaline eosinophilic liver cell necrosis, microvesicular fatty degeneration and lymphomonocytic infiltration of the portal fields predominate. The patchy necroses tend to merge and form bridging necroses. Basophilic bodies can be found in the necrotic cells. The reticular fibre structure remains intact. • The prognosis is unfavourable: in the Marburg epidemic, mortality was 28%; in epidemics in the Sudan and in Zaire, it was 53% and 88%, respectively. (89, 99, 104−106, 110, 111)

## 2.4 Lassa haemorrhagic fever

Lassa fever was first identified in 1969 in a missionary in Lassa (Nigeria). (91) The disease is also endemic in eastern Sierra Leone. Over 100,000 people worldwide contract the disease every year. A single-strand RNA virus of the arena group was isolated and characterized as the pathogen. (91) The disease is transmitted by rats. The incubation period is 3−16 days. • It manifests as haemorrhagic fever with ulcerous inflammation in the throat and mouth cavity, arthralgia, exanthema, alopecia, hearing impairment, lymphadenopathy as well as haemorrhages. In endemic areas, diagnosis is generally based (approx. 80% of cases) upon the *triad* (*1*.) fever and pharyngitis, (*2*.) proteinuria, and (*3*.) retrosternal pain. • The *liver* displays distinct acidophilic necrosis, frequently bridging necroses, and bleeding. Pronounced Kupffer-cell hyperplasia is evident. Deposits of lipofuscin are found. The transaminases and GDH are markedly increased; the blood count shows leucopenia and thrombopenia. The course is anicteric as a rule. Hepatosplenomegaly is present. The diagnosis is confirmed by the presence of IgM antibodies. Mortality is 35−40%. Ribavirin has proved successful as therapy. There is still no vaccine available. (91, 94, 97, 108, 113)

## 2.5 Ebola haemorrhagic fever

The Ebola virus disease was first observed in 1976 in Sudan (in the vicinity of the Ebola River). Altogether, 14 outbreaks have been reported. Apart from in Sudan, Ebola infections are frequent in the Congo and in Gabun. The incubation period is 7−10 days. Both the course of disease and the virus itself closely resemble the Marburg virus, although it is a virus in its own right and related to the filovirus species. Clinical findings include generalized pain, pharyngitis, conjunctivitis, bronchitis, exanthema and enanthema. Death usually occurs on the ninth day. The mortality rate of this haemorrhagic fever with pronounced hepatic damage (focal necrosis) was between 51% and 89%. (90, 95, 100, 102) (s. fig. 23.5)

**Fig. 23.5:** Portal (left) and parenchymal (right) round-cell inflammation. Clinical diagnosis: Ebola fever

## 2.6 Rift Valley fever

This severe, febrile clinical picture was first observed in 1930 in Africa, predominantly in Rift Valley (Kenya). The causative pathogen is a bunyavirus, transmitted to both animals and humans by mosquitoes. While it is generally fatal in animals, especially in sheep, the prognosis in humans is favourable; its course resembles that of influenza. Liver findings show *concomitant hepatitis*. (107, 109)

# Clinical Aspects of Liver Diseases

## 24 Bacterial infections and the liver

# 24 Bacterial infections and the liver

A number of bacterial infections may affect the liver to varying degrees of intensity. The frequently observed liver involvement is attributed to a number of **causes:** (*1.*) size of this visceral parenchymatous organ, (*2.*) multiplicity and activity of the hepatic RES as a filtering system, (*3.*) double (portal and arterial) blood supply with transport of bacteria or their toxins, and (*4.*) lymphogenous spread of pathogenic organisms.

## 1 Pathogenesis

The pathogenesis of liver involvement in bacterial infections often remains unresolved. In this respect, **four pathomechanisms,** either alone or in combination, are assumed to play a role. (s. tab. 24.1)

| |
|---|
| **1. Direct effects of pathogens**<br>• direct haematogenic spread<br>• direct lymphogenous spread<br>**2. Indirect effects of pathogens**<br>• toxins<br>• endotoxins<br>**3. Reactions due to the basic disease**<br>• hypoxaemia<br>• fever, exsiccosis, acidosis<br>• electrolyte imbalance, *etc.*<br>**4. Therapy-induced liver damage** |

*Tab. 24.1:* Pathomechanisms of liver involvement in bacterial diseases

*Tab. 24.2:* Morphological reaction types in liver involvement following bacterial infections

## 2 Types of lesion

Liver involvement may occur in both extrahepatically localized and generalized bacterial infections. Various **morphological reactions** appear depending on (*1.*) severity of infection, (*2.*) type of pathogen, (*3.*) respective morphological reaction of the liver, and (*4.*) possible previous liver damage − similar reactions also appear in viral hepatitis. Combined with the potential coexistence of scarred/fibrotic and chronic inflammatory liver changes, these additional acute infections may lead to morphological pictures that are difficult to interpret. The diversity of the morphological reaction types may also be influenced by individual factors. (s. tab. 24.2)

## 3 Bacterial pathogens

The principal pathogenic agents causing liver damage are pyogenic cocci, gonococci, enteric bacteria, myco-

*Tab. 24.3:* Major bacterial organisms causing liver damage. • In Germany, **obligation for notification** is given in cases of suspicion (S), disease (D), exitus (E), or perinatal infection (P). This can, however, vary from country to country. *If in doubt:* contact the Public Health Department!

bacteria, spirochaetes, listeriae, brucellae, rickettsiae, chlamydiae and clostridiae. (s. tab. 24.3)

## 3.1 Pyogenic cocci

**Streptococcus pneumoniae:** Infection with Streptococcus pneumoniae may cause both toxic liver damage and pneumococcal hepatitis with focal necroses, leading to the corresponding laboratory findings. In lobar pneumonia, *jaundice (= biliary pneumonia)* frequently occurs in the so-called grey hepatization stage. In addition to predominantly bacterial haemolytic jaundice, increased transaminases (20%) and cholestasis (10%) are found. The condition always regresses completely. A *liver abscess* induced by pneumococci is a rare event. (3−5, 9)

**Staphylococci, streptococci:** In sepsis, toxic liver damage and portal granulocytic infiltration may be observed. Septic bacterial invasion of the liver mainly entails periportal, circumscribed and non-suppurative *septic foci* (s. fig. 24.1), and occasionally multiple microabscesses as well. (10) Cholestasis usually suggests a severe course of disease; likewise, prolonged jaundice points to a poor prognosis as far as the underlying disease is concerned. (1, 2, 4, 6−8)

***Fig. 24.1:*** Markedly altered, swollen hepatocytes. Focal intralobular accumulation of Kupffer cells, histiocytes and leucocytes. Clinical diagnosis: streptococcal sepsis

## 3.2 Neisseria gonorrhoea

Gonococcal infection may lead to *toxic liver damage* or *concomitant hepatitis*, especially in the presence of gonococcal sepsis. Diagnosis of gonorrhoea is established by direct demonstration of pathogens (vaginal smear, liver tissue, liver capsule) or serologically by means of CFR (positive from 3rd week).

**Perihepatitis acuta gonorrhoica:** Of special relevance is a fibrinous inflammation of the subphrenic space without abscess formation, occurring as a sequel of gonorrhoeal adnexitis in women. It is also called the *Fitz-Hugh-Curtis syndrome* (A.H. Curtis, 1932; T. Fitz-Hugh, 1934),

although it was first described by C. Stajano in Montevideo in 1920. Only two cases of this syndrome have so far been reported in men. Symptoms include severe epigastric pain (nearly always dextral), local peritonitis (dependent on respiration and movement), shoulder pain due to irritation of the phrenic nerve, and occasional friction rub. There are no other major subjective complaints or clinical findings. • In the meantime, it has been demonstrated that, in addition to Neisseria gonorrhoeae, Chlamydiae and even Coxsackie virus B5 may also be responsible for this condition. (s. pp 467, 481) • A typical feature of the syndrome are the fine violin string-like adhesions between the liver surface and the abdominal wall, which are easily identified by means of laparoscopy. The syndrome can also be diagnosed retrospectively by laparoscopy through the detection of such lesions. (11−15)

▶ *In the one case that we observed, the patient was suffering from severe recurrent epigastric pain and had pathological, inflammation-related laboratory parameters. Following unsuccessful diagnostic efforts during an 8-month course, we were finally able to obtain a diagnosis by laparoscopy at once and confirm gonorrhoea as being the cause of the disease. (s. fig. 24.2)*

***Fig. 24.2:*** Fitz-Hugh-Curtis syndrome: perihepatitis with violin string-like adhesions in gonorrhoeal infection

## 3.3 Enterobacteriaceae

**Escherichia coli:** In the case of sepsis, the occasionally massive endotoxinaemia may lead to major liver cell damage, accompanied by jaundice. Histologically, focal liver cell necrosis, giant-cell transformation, inflammatory infiltrations and signs of cholestasis are detectable. Escherichia coli is the most frequent causative agent of liver abscesses, followed by Friedländer's bacillus and Yersinia enterocolitica. In the case of bacteraemia, a toxic shock syndrome can develop with a so-called cholangiolitis lenta (M. Vyberg et al., 1984).

**Ehrlichiosis:** Ehrlichia chaffeensis is an infection which is transmitted by the bite of a tick. It results in fever, myalgias and panzytopenia. Transaminases are increased in 80−90% of cases. Histologically, it is possible to detect scattered lobular lymphohystiocytic foci, various diffuse infiltrations and Kupffer-cell hyperplasia with intense phagocytosis. Occasional injuries to the bile duct epithelium may also cause elevated AP activity. Laboratory findings and histology (which often vary in severity) suggest that host inflammatory or immune responses contribute to the liver injury. (29)

**Salmonellosis:** Infection with Salmonella paratyphi A, B or C may occasionally cause suppurative *cholangitis* with cholangiohepatitis. In contrast, Salmonella enteritidis mainly gives rise to *toxic hepatitis*. • In typhus abdominalis, hepatomegaly (20−30%) as well as an increase in transaminase and alkaline phosphatase activities are invariably observed from the 2nd to 3rd week of disease. Hyperbilirubinaemia is frequent, whereas manifest jaundice is rarely witnessed. Histology may demonstrate signs of non-specific reactive hepatitis. In some cases, submiliary nodules or *granulomas* (so-called *typhomas*) are verifiable. Here, mainly intrasinusoidal proliferations of large plasma-rich cells with very small nuclei (so-called beef-like cells or typhoid cells) are found. These epithelioid cell clusters originating from reticular cells often contain multinuclear giant cells in their periphery. The toxic submiliary *typhoid nodules* (s. fig. 24.3), however, exhibit centroacinar necroses, proliferations of sinus endothelial cells and granulocytes with signs of regeneration. Apart from that, *liver abscesses* have also been identified. (16, 17, 19, 20, 22, 24−27, 30)
***Fig. 24.3:*** Granuloma-like, lymphohistiocytic infiltrate. Clinical diagnosis: typhus abdominalis (HE)

**Shigella:** Infections with shigella are rarely accompanied by hepatitis. Direct involvement of the liver in the course of shigellosis is, however, to be feared, as first demonstrated by positive shigella identification from liver biopsy as early as 1910 (J. H. N. KNOX Jr. et al.). Shigella-induced cholestatic hepatitis with jaundice and marked histological changes has likewise been reported. (21)

**Yersinia enterocolitica:** Infection with Y. enterocolitica or Y. pseudotuberculosis, together with haematogenous spread, may lead to a septic-typhoid course with hepatic and splenic abscess formation. Especially ulcerative colitis was frequently found to favour the formation of multiple *liver abscesses*. A genetic disposition is assumed in the presence of the HLA-B 27 gene. Patients with hepatic overload of iron are at special risk of Yersinia infection, since iron plays a major role in the metabolism of Yersinia. (18, 23, 28, 31, 32)

## 3.4 Mycobacteria

### 3.4.1 Mycobacterium tuberculosis

Tuberculous hepatic infections are transmitted **pre-/perinatally** via the umbilical vein or the amniotic fluid; maternal placenta tuberculosa is a precondition for both infections. • The hepatic artery and the portal vein as well as the hepatopetal lymph vessels serve as **postnatal infection routes.**

1. The **tuberculous primary complex** in the liver with caseation of the associated hepatic hilar lymph nodes may become the source of spread causing early systemic generalization. Given the clinical picture of a coarse-nodular or a miliary tuberculosis, this may result in the death of the newborn child.

2. **Miliary tuberculosis** generally results in an attack on the liver by a number of clustered miliary tubercles. They are distinctly recognizable on the liver surface by means of laparoscopy. (35, 39, 50, 54) GPT, GOT and GDH as well as alkaline phosphatase are moderately increased. Clinical manifestations include severe malaise, hepato(spleno)megaly and fever − the cause of the latter often remaining unresolved for a long time. The haematogenous spread, occurring as intermittent episodes, also provokes a number of small *tuberculous liver foci*. As a rule, they show central caseation and fibrinoid necrosis. In the periphery, a corona of epithelioid cells of variable diameter is found, in which Langhans' giant cells are embedded. (s. fig. 24.4)
***Fig. 24.4:*** Tuberculous epithelioid cell granuloma with Langhans' giant cells and small central necrosis (N); additional steatosis of hepatocytes (HE)

These granulomatous tubercles are surrounded by a loose rim of lymphocytes. Massive miliary spread to the liver may also cause acute liver failure (35, 44) as well as septic shock with multiorgan failure. (54)

3. **Tuberculomas** may develop through enlargement and subsequent confluence of the miliary foci or tubercles as well as through nodular development of tuberculous foci in the tertiary stage. They appear as nodules with a diameter of 1−4 cm. Embedded calcifications are typical features of tuberculomas. They may penetrate bile ducts and cause *tuberculous cholangitis* with bile-duct stricture. (41, 42, 50) These major tuberculous nodes become encapsulated in the course of time; the caseous necrosis may still contain tubercle bacilli in its interior. These tuberculous nodes may likewise be the source of haematogenic spread. They may also decompose as a result of caseous necrosis and thus lead to hepatic cavities such as *tuberculous abscesses* (45, 46, 50, 57) or gravitation abscesses. Diagnosis of a liver abscess therefore includes differentiation from tuberculosis. Differential diagnosis from *pseudotumoural liver tuberculosis* is very

**Fig. 24.5:** Small nodular hepatic tuberculosis: foci, the size of a millet seed up to that of a lentil, in the right lobe of liver

**Fig. 24.6:** Old intrahepatic tuberculoma. Encapsulated eosinophilic necrosis with marked caseation (HE)

difficult, even when using imaging techniques. (33, 34, 36−44, 47, 49−53, 55, 56, 58−63, 65) (s. figs. 24.5, 24.6)

In the course of healing, miliary tuberculosis or small diffuse disseminated foci give rise to scarred transformation with the morphological picture of *tuberculous pseudocirrhosis* as a result of vascularization, fibroblasts and histiocytic connective tissue. As a rule, however, no major hepatic dysfunction results from the cicatrization of the healing process, which no longer (or barely) exhibits the specific character of granulation tissue.

4. Non-specific **toxic liver damage** may be evident; in this connection, possible tuberculostatic toxic effects must also be considered. With severe courses of tuberculosis, *peliosis hepatis* is often observed. Frequently, *retothelial nodules* are detectable, as demonstrated for the first time in tuberculosis patients by H. HAMPERL in 1953. (50) In the course of chronic pulmonary tuberculosis, *fatty infiltration of liver cells* was noted, as reported in several publications. (50) It was attributed to toxic effects and/or undernourishment or malnutrition. Secondary *hepatic amyloidosis*, developing in the course of chronic lung tuberculosis, has also been postulated. (50) A restriction of *hepatic function* in chronic tuberculosis, which was first observed by E. LEURET et al. in 1922, has been described in a number of publications. (51, 60, 63) Depending on the severity and duration of the disease as well as the tuberculostatic pretreatment, we found pathological laboratory parameters in 15−20% and 25−40% of cases respectively. (50)

If laboratory tests and imaging techniques have proved unsuccessful, it is only possible to obtain a reliable *diagnosis* and differentiation of the multiple manifestations of liver tuberculosis by means of laparoscopy and targeted biopsy. (s. tab. 7.11) (s. figs. 7.11; 24.5, 24.6) Hepatic miliary tuberculosis is recognizable with the help of percutaneous biopsy in more than 90% of cases due to the dense arrangement of the foci. The aim should always be to demonstrate the presence of tubercle bacilli in the liver tissue either directly or by culture (higher sensitivity can be obtained using PCR). (37) • *Treatment* consists of a fourfold combination: isoniazid (5 mg/kg BW/day), rifampicin (10 mg/kg BW/day), pyrazinamide (25 mg/kg BW/day), ethambutol (20 mg/kg BW/day), generally for 2−4 months, subsequently isoniazid + rifampicin for 6−12 months.

### 3.4.2 Mycobacterium scrofulaceum

Mycobacterium scrofulaceum may cause **granulomatous hepatitis.** Clinical findings include a clear increase in alkaline phosphatase as well as fever and general malaise. Diagnosis is confirmed by positive culture of the pathogen in liver biopsy specimens. (61) • Other **atypical mycobacteria** may also cause liver damage, possibly in the form of granulomatous hepatitis, especially in AIDS (20−50% of cases). (58) (s. fig. 24.7)
*Fig. 24.7:* Acid-fast bazilli of mycobacterium tuberculosis in the liver of an AIDS patient (Fite staining)

### 3.4.3 Mycobacterium leprae

In lepromatous leprosy with a high germ count, the liver is affected in 50−90% of cases. Glisson's capsule is thickened and whitish. The number of *lepra granulomas* in the liver, which appear in the form of yellowish nodules, may be high enough to justify the term granulomatous hepatitis. Initially, these granulomas consist of histiocytic and lymphocytic infiltrates, which contain lepra bacteria in approximately 75% of cases. The lepra bacteria can be identified above all in Kupffer cells. Eventually, the characteristic bacteria-phagocytizing leprotic cells are formed (so-called *foam cells* or Virchow cells). These large-cell lepra granulomas are localized predominantly in the portal tract and show a tendency to central caseation. (s. fig. 24.8) • The *treatment regimen* consists of diphenylsulphone, clofazimine and rifampicin in combination for 6 to 24 months or longer (depending on the course of the disease). Thalidomide has also proved effective. • *BCG vaccination* is an effective prophylactic measure against infection induced by Mycobacterium leprae. (66−68)

*Fig. 24.8:* Lepra: granuloma-like, lymphohistiocytic infiltration in the liver parenchyma (HE)

## 3.5 Spirochaetes

### 3.5.1 Leptospirosis

In 1886 A. Weil reported 4 patients with an acute, highly feverish, infectious disease, accompanied by icterus and a high mortality rate. This disease was termed **icterus infectiosus Weil.** In 1915 R. Inada et al. in Japan and P. Uhlenhut et al. in Germany discovered virtually at the same time that the **Leptospira icterogenes** (or L. icterohaemorrhagica) were pathogenic agents (S. interrogans). So far, about 180 serotypes have been identified, all of which are generally pathogenic for humans and may provoke Weil's disease.

**Reservoir hosts** include especially rats, mice, hedgehogs, hamsters and various domesticated animals. Leptospirosis is therefore a globally distributed zoonosis. **Transmission** to humans occurs via the oral or percutaneous route with small skin or mucosal lesions serving as portals of entry for the pathogens, which are excreted in the urine of infected animals.

The incubation period for **leptospirosis (Weil's disease)** is 7 to 14 days. Subsequently, the septicaemic phase sets in with fever, chills, myalgia, arthralgia, headaches, haemorrhagic conjunctivitis, abdominal pain, vomiting and renal involvement (erythrocyturia, proteinuria). Histologically, interstitial nephritis with tubular necrosis is demonstrable. • In just a few days, icterus, hepatomegaly, an increase in transaminase activity and haemorrhagic diathesis occur, especially in severe cases. Histology reveals focal centrilobular lesions (acidophilic degeneration, turbid swelling) and lymphocytic infiltration of the portal tract, stellate cell proliferation and bile thrombi in the canaliculi as well as active hepatocyte mitosis. The histological picture corresponds to that of *cholestatic hepatitis* (cholestasis is usually not verifiable by laboratory tests). • Identification of pathogens is successfully performed in blood and CSF (1st week) and in the urine (2nd week); increasing antibody titres (up to four times the norm) are detectable in the serum as from the 2nd week. Proof of specific IgM is also possible. • As the disease advances, a typical iridocyclitis as well as meningitis or encephalomyelitis with brain oedema can appear. Convalescence may take a long time in some cases; this phase is characterized by adynamia and loss of hair. Mortality can range from 4−50%, depending on the course − anicteric or icteric − and is mostly due to renal insufficiency. The recommended *therapy* consists of penicillin (10−20 million U/day) or doxycycline (2 × 100 mg/day). (69−73)

▶ *We observed a lethal case (treatment with doxycycline was unsuccesful) showing massive amounts of leptospirae in the serum and in the centrifuged urine under dark-field examination. Maximum values were: GPT 4,200 U/l, GOT 2,290 U/l, GDH 1,080 U/l, serum bilirubin 11 mg/dl and Quick's value 17%, but with normal AP (!); such pathological levels have repeatedly been reported in the literature. Autopsy revealed severe interstitial nephritis, tubular necrosis (laboratory findings corresponding to severe renal insufficiency), brain oedema (680 g), severe*

*hepatic dystrophy with marked centrozonal necroses and diffuse small-droplet fatty degeneration of the liver cells as well as haemorrhagic organ lesions. (s. fig. 24.9)*

**Fig. 24.9:** Enlargement of hepatocytes with large nucleoles (arrow), distinct icterus with (green) bile thrombi in the biliary capillaries and hepatocytes. Multivacuolar steatosis of isolated liver cells. Groups of histiocytes (far left of picture) with phagocytized nuclear material and lipofuscin. Clinical diagnosis: Weil's disease

### 3.5.2 Syphilis

The coexistence of jaundice and syphilis was described by PARA-CELSUS as early as 1585. • In all stages of **syphilis,** congenital or acquired, liver involvement is possible. The **pathogen** (anaerobic, gram-negative) is very sensitive to environmental factors and perishes rapidly. The period of cellular fission is 36 hours. Treponema pallidum is occasionally verifiable in histological preparations as corkscrew-shaped structures, $6-10$ μm in length and 0.2 μm in diameter. (s. fig. 24.11)

**Lues connata** (congenital syphilis) is a form of syphilis transmitted to the foetus after the 4th month of pregnancy. If neither foetal death nor abortion occurs (approx. 30%), hepatosplenomegaly, "capillaritis" and *interstitial syphilitic hepatitis* develop. Splitting of the liver cell plates into small epithelial groups takes place. Subsequent swift interstitial fibrosis leads to the picture of microgranular intralobular cirrhosis. Focal cell necro-

**Fig. 24.10:** Lues connata: Severe inflammatory infiltration (especially left of picture); sinusoidal fibrosis; irregular liver cell plates (far right of picture). So-called "interstitial syphilitic hepatitis" (HE)

sis in the liver of the neonate causes the formation of miliary *syphilomas*, which contain giant cells, epithelioid cells, lymphocytes and marcrophages. (s. fig. 24.10) • Obliterative endarteritis, fine-spot bleeding and large siderin deposits lead to the picture of the so-called **brimstone liver.** (s. p. 406)

▶ *A 38-year-old patient had been suffering from subfebrile temperatures, general malaise, moderately increased GPT, GOT, GDH and γ-GT, markedly augmented alkaline phosphatase (430 U/l), reduced ChE and albumins as well as moderately elevated γ-globulins for a period of several weeks. All the other laboratory values and examinations with imaging techniques were within the normal range. Syphilis was originally not considered in the differential diagnosis. However, percutaneous biopsy provided evidence of corkscrew-shaped pathogens within lesions, now interpreted as syphilitic hepatitis. Subsequent serological tests for specific antibodies were positive. (s. fig. 24.11)*

**Fig. 24.11:** *Syphilis, secondary stage:* hepatitis syphilitica. In the liver parenchyma, massive amounts of corkscrew-shaped syphilis pathogens, $6-10$ μm in length, are visible (= treponema pallidum) (silver impregnation)

**Lues acquisita** progresses as (*1*.) *early syphilis* throughout the primary and secondary stages, lues latens seropositiva (= early latent form) and as (*2*.) *late syphilis* in the tertiary stage, lues latens seronegativa (= late latent form), and stage IV. (79, 84, 86) • From the primary complex, haematogenous dissemination of the pathogen throughout the body takes place, with development of the early stage of syphilis (primary and secondary stages). *Syphilitic hepatitis* is found in 10% of cases, with focal liver cell necrosis, infiltrates of lymphocytes, eosinophils and granulocytes, focal activation of the stellate cells and portal infiltrations. (76, 77, 80–82, 85) Epithelioid cell granulomas are mostly localized in the central lobule. The portal bile ducts are narrowed by infiltrations, resulting in pronounced cholestasis. The portal vessels show signs of vasculitis. Hepatomegaly of hard consistency is present. About 50% of patients exhibit elevated transaminases. Usually, the antimitochondrial antibody $M_1$ is positive. (74) Healing is accompanied by fibrosis. Cirrhosis may also develop. • In the *tertiary stage*, occurring in $30-40\%$ of cases after years of lat-

ency, *gumma syphiliticum* may be observed inter alia in the liver, where it is either solitary or multiple and mostly localized in the right lobe. Gummas are large, closely circumscribed, nodular structures with a diameter of a few millimetres up to several centimetres. They consist of central caseation, which is surrounded by vascularized granulation tissue resembling a capsule and by plasma and giant cells. (75, 78, 83) (s. fig. 24.12) The hepatic architecture is generally not affected. Usually, endarteritis develops. Treponemas are only rarely found in the gumma. • In the case of multiple occurrence with associated deep grooves and scar formation, the striking picture of *hepar lobatum* appears.

*Fig. 24.12:* Hepatic gumma from syphilitic hepar lobatum. Intrahepatic necrotic zones surrounded by a thin layer of granulation tissue

### 3.5.3 Borreliosis

In 1976 **Lyme borreliosis** was observed for the first time in Lyme (USA). It is caused by Borrelia burgdorferi and transmitted by insects and ticks. The multisystemic clinical picture initially includes erythema chronicum migrans with non-specific manifestations. During the following weeks and months, cardiac involvement, polymeningoradiculoneuritis and arthritis may be seen.

In isolated cases, pronounced *Lyme hepatitis* develops. The pathogen is often identifiable in liver cells and sinusoids. *Treatment* consists of doxycycline or erythromycin.

The epidemic (European) **relapsing fever** is induced by the spirochaete Borrelia recurrentis (obermeyeri), which is transmitted by lice. Following an incubation period of 3 to 15 days, there are sudden repeated (up to ten) attacks of fever separated by fever-free intervals together with parallel hepatomegaly and splenomegaly, cutaneous and mucosal bleeding (e. g. colon, nose), myalgia, arthralgia, iridocyclitis, facial paresis and meningism.

*Jaundice* is often observed. Histologically, signs of non-specific *reactive hepatitis* with spotty liver cell necrosis are generally detectable. (87−90)

### 3.6 Listeriosis

Listeria monocytogenes is most common in animals. **Transmission** to humans is effected through the secretions of infected animals or contaminated food (e. g. milk and dairy products, raw meat). An increased proneness to listeriosis is found in drug-related immunosuppression, pregnancy, liver cirrhosis, diabetes mellitus

and AIDS. In connatal (diaplacental) transmission *( = granulomatosis infantiseptica)*, listeriosis generally leads to an abortion or premature delivery with meningoencephalitis and multiple organ abscesses, so that the neonate dies within a few days. • The **disease course** varies from uncharacteristic "flu-like" manifestations to (*1.*) septic, (*2.*) central nervous, (*3.*) glandular or cutaneous, and (*4.*) chronic septic forms with isolated organic affection. • **Treatment:** ampicillin and amoxicillin at high dosage are the remedies of choice.

Liver involvement is reflected in moderately elevated transaminases, histologically detected monohistiocytic *granulomas* and miliary microabscesses (frequently with gram-positive rods) as well as occasional evidence of *non-specific reactive hepatitis.* (91, 93) (s. fig. 24.13)

*Fig. 24.13:* Dense, granulocytic infiltration in the environment of fresh hepatocellular necrosis (right lower half of the picture). Clinical diagnosis: listeriosis (HE)

### 3.7 Brucellosis

Brucellae are gram-negative, aerobic, non-motile, rod-shaped bacteria, with a natural **reservoir** in some mammals: B. abortus in cattle (Bang's disease), B. melitensis (in goats and sheep, the "Malta fever" is a special form), B. suis (especially in pigs, the natural host of the Brucellae), B. ovis (in sheep) and B. canis (in dogs). The pathogens enter the host via skin lesions or mucosa (conjunctiva, respiratory tract, gastrointestinal tract).

Brucellosis is the generic term for diseases induced by the various Brucella species in animals and humans. Following an incubation period of approximately 14 days, headaches, pronounced fatigue, myalgia, arthralgia, swollen lymph nodes and especially undulant fever occur. Frequently, organ manifestations (cholecystitis, endocarditis, meningoencephalitis, nephritis, prostatitis, pneumonia, etc.) are in evidence. • Hepatosplenomegaly and moderate increases in transaminases and in alkaline phosphatase are found. Histologically, histiocytic *granulomas* are present (in 90−95% of cases), often with central necrosis, portal and peripheral infiltration and hyperplasia of the Kupffer cells. (100, 105) Up to now, about 30 cases of *hepatic brucelloma* have been reported in the literature. (101, 103) They result from the caseation of a granulomatous reaction by persistent brucellae in macrophages. The imaging methods show central calcification and peripheral necrotic areas, which imitate

malignant tumours or pyogenic liver abscesses. In many patients, fatty infiltration of liver cells, lipofuscinosis and siderosis are found. Extensive focal necrosis may occur in infections with B. melitensis and B. suis. Severe courses, possibly with acute liver failure, are rarely observed. Occasionally, ascites appears. Hepatic *abscesses* are seldom. Fewer than 50 cases have been described in the literature. (101, 104) • The *diagnosis* is confirmed by serological tests, culture of pathogens or animal experiments. As *treatment*, the combination of rifampicin (900 mg/day) + doxycycline (200 mg/day) for 3 months or doxycycline + gentamycin, possibly also tetracycline + streptomycin, has proved effective. In chronic brucellosis, treatment with tetracycline must be repeated.

## 3.8 Rickettsiosis

Rickettsiae are gram-negative pathogens living as cellular parasites in the gastrointestinal tract of arthropods (especially lice, fleas, ticks and mites). They may be transmitted to human beings and cause endemic and epidemic rickettsioses, generally showing a typhoid-like clinical picture. Major rickettsioses include *classic spotted fever* (R. prowazeki), *Rocky Mountain spotted fever* (R. rickettsii), *Q fever* (R. burneti), *Boutonneuse fever* (R. conori) and *murine endemic spotted fever* (R. typhi). Following infection, the pathogens may spread haematogenously to all organs and colonize the endothelial cells of the small arteries and capillaries, so that partial or complete vascular obstruction ensues.

**Fig. 24.14:** Two intraparenchymal granulomas, one of which has the appearance of a lipogranuloma (→). Clinical diagnosis: Q fever

Each of the 10 Rickettsia species pathogenic to humans may cause *concomitant hepatitis*. Clinical findings include hepatomegaly with an increase in transaminases as well as (occasionally) in alkaline phosphatase and bilirubin. Histology reveals *granulomas* of round cells, granulocytes, proliferated stellate cells and polynuclear giant cells as well as spotty infiltrations with single-cell necrosis and portal infiltrates. (s. fig. 24.14) Chronic Q-fever hepatitis has been reported. Fatty granulomas typical of Q fever are frequently found in the liver lobules or in the portal tracts. *Treatment* consists of doxycycline, chloramphenicol or tetracycline. (106−113)

## 3.9 Tularaemia

This clinical picture was observed for the first time in Tulare, California in 1911 (G.W. McCoy). The causative pathogen was identified as Bacterium tularense by G.W. McCoy et al. (1912) and W.B. Wheery et al. (1914). The gram-negative, aerobic and non-motile **Francisella tularense** is transmitted to humans by arthropods infected by sick rodents, directly by the rodents themselves or through contaminated water.

After a short incubation period (1 to 3 days), a clinical picture develops comprising high fever, chills, lymphadenitis and local ulceration, occasionally also meningitis, pneumonia or pulmonary abscesses and mediastinitis. • In the course of this severe disease, *liver granulomas* up to 2 mm in diameter may occur with central necrosis, epithelioid cells and giant cells. The portal fields show inflammatory infiltration. *Liver abscesses* and the clinical picture of *cholangitis* or obstructive jaundice have also been observed; ascites is rarely seen. There is evidence of hepatomegaly together with the corresponding pathological laboratory parameters. *Diagnosis* is confirmed by serology or skin tests. *Treatment* consists of antibiotics (e.g. tetracycline, streptomycin, gentamycin, ampicillin). (114, 115)

## 3.10 Psittacosis

Chlamydia psittaci is the causative pathogen of **ornithosis** (psittacosis or parrot disease). It is transmitted to humans by birds via their droppings. The incubation period is 4 to 28 days. In the course of the occasionally severe pneumonia, *concomitant hepatitis* may be in evidence. (116, 118, 119) The *Fitz-Hugh-Curtis syndrome* rarely develops. (117, 120) (s. fig. 24.2) Clinical findings generally include hepatomegaly and slightly increased transaminases. *Diagnosis* of this infectious disease is confirmed by CFR. The *treatment* regimen consists of tetracycline.

## 3.11 Clostridium welchii

In the course of the rare systemic gas gangrene caused by Clostridium perfringens (gram-positive, anaerobic bacterium), severe *clostridial hepatitis* may ensue. Necrotic foci, abscesses and aerogenesis develop. The pathogens can be cultivated from biopsy material. A major harmful factor is the respective exotoxin, which sometimes causes pronounced haemolytic icterus. (121)

## 3.12 Tropheryma whippeli

Whipple's disease (G.H. Whipple, 1907) with feverish, sprue-like symptoms is generally accompanied by polyadenopathy, arthritis, polyserositis and endocarditis or pericarditis. • Liver involvement occurs in the form of *granulomas*, in which macrophages loaded with bacteria are present. The gram-positive bacterium Tropheryma whippeli has been identified as the causative pathogen. It is assigned to the group of Actinomyces. (122, 123)

## 3.13 Campylobacter colitis

The intestinal disease with fever and arthralgia caused by Campylobacter colitis may show findings corresponding to *non-specific reactive hepatitis* in terms of laboratory parameters and histology. (124, 125)

## 3.14 Rochalimaea

The Rochalimaea species (R. quintana, R. henselae, R. vinsonii, R. bacilliformis) are responsible for **four clinical syndromes:** (*1.*) cat-scratch disease, (*2.*) bacterial angiomatosis, (*3.*) bacterial peliosis hepatis, and (*4.*) relapsing fever with bacteriaemia (so-called trench fever). • The *cat-scratch disease* (R. DEBRÉ et al., 1950) was first attributed to a new pathogen, named Afipia felis; more recent studies point to a species of Rochalimaea (Bartonella henselae) as the causative pathogen. The incubation period ranges from 3 to 20 days. Thereafter, feverish lymphadenitis with a morbilliform rash appears. Painful hepatomegaly is experienced. Transaminases are elevated. Diagnosis involves specific serological tests, PCR or liver biopsy. • Liver involvement is manifested by *granulomas* with occasional central star-shaped microabscesses, in which pathogens can be demonstrated, and by *focal infiltrates*, possibly also with *single-cell necrosis*. (126−130)

## 3.15 Actinomycosis

The abdominal form of the so-called ray-fungus disease (actinomycosis) is a non-contagious, mostly chronic infectious disease induced through the gram-positive, anaerobic rod-shaped bacterium **Actinomyces israelii.** It is a pseudomycosis. Under favourable conditions, this human saprophyte can cause enterocolitis.

Pronounced formation of *granulomas* or *microabscesses* and major (hyperdense) liver abscesses with cauliflower-like *druses* may be due to haematogenous spread of the pathogen to the liver (portal vein, systemic circulation) or, occasionally, to direct encroachment on the liver. The abscess pus contains the typical so-called sulphur granules. *Treatment* consists of penicillin G (e. g. $2 \times 10$ million U/day i.v. for approximately 4 weeks), ampicillin, tetracycline, clindamycin or metronidazole. (131−141)

## 3.16 Burkholderia pseudomallei

Melioidosis, which is caused by pathogens, is endemic in the different subtropical and tropical countries. Patients with diabetes mellitus are particularly susceptible to infection. Acute melioidosis displays large numbers of both localized and disseminated necrotic foci, which produce confluent abscesses, sometimes with a diameter of 2−3 mm. The presence of pathogens can be confirmed using Giemsa staining. Chronic melioidosis is characterized by epithelioid cell granuloma with giant cells and central necrosis. Pathogens (previously known as pseudomonas) are only rarely found in the foci themselves. (142)

# Clinical Aspects of Liver Diseases

## 25 Parasitic infections and the liver

# 25 Parasitic infections and the liver

A number of parasitic diseases result in a **coexisting liver reaction** or even lead to **coexisting liver disease.** However, most of these parasitoses are rarely encountered in the temperate zones, and if at all, they occur only sporadically in the wake of immigration and tourist travel to endemic regions.

▶ During the past 15 years, an enormous number of people, totalling 9−10 million, have immigrated to Europe from the Near East and from African and Asian countries. At the same time, hundreds of thousands of people travel every year to the most remote regions of the earth in search of adventure and new experiences, usually living in unhygienic conditions such as those common to backpacking and trekking. In addition, some parasitic diseases that are barely known today have to be constantly considered for differential diagnosis when unresolved symptoms of disease are present.

**Tab. 25.1:** Major parasitic diseases caused by protozoiases and helminthiases which may lead to liver involvement or concomitant liver disease. The **obligation for notification** in Germany is given in cases of suspected disease (S), disease (D), exitus (E) or perinatal infection (P). This can, however, vary from country to country. *If in doubt:* contact the Public Health Department

Generally, the clinical manifestations of the respective parasitosis predominate, and the involvement of the liver may even go unnoticed, especially in the early stages. In individual cases, the laboratory parameters indicative of liver damage are only slightly changed. The various parasites mainly affect either the biliary tract or the liver cells. Consequently, inflammatory infiltration, liver cell necrosis, granulomas, abscesses, fibrosis, vascular occlusion and biliary obstruction as well as the deposition of eggs or larvae in the liver may be observed. There are hence multiform morphological findings. Parasitoses with potential liver involvement belong to the group of protozoiases and helminthiases. (s. tab. 25.1)

## 1 Protozoiases

**Protozoa** are unicellular organisms with a well-defined cell nucleus. Some species are capable of sexual reproduction, while others reproduce asexually. In addition to their vegetative (usually motile) forms, most protozoa also develop cysts as a permanent state under unfavourable external conditions. They move with the aid of flagella or cilia, by amoeboid locomotion, or in a winding, gliding manner.

### 1.1 Amoebiasis

#### 1.1.1 Definition

Amoebiasis is defined as the invasion of the human body by the protozoal organism Entamoeba histolytica, with or without ensuing symptoms of disease or clinical manifestations.

#### 1.1.2 Epidemiology and pathogens

*Entamoeba histolytica* is an obligate pathogen. It has worldwide distribution and is the third most common parasitic pathogen, with a prevalence of 20−90% among the populations of tropical and subtropical countries. However, given unfavourable hygiene conditions, Ent. histolytica can also be encountered in the temperate zones, particularly when imported by individuals after a stay in the tropics. The frequency of infection is less than 1% in Germany and other European countries, whereby the disease/infection ratio ranges between 1:300 and 4:10. Homosexual males showed a higher incidence of amoebic abscesses. (8)

**Cysts:** The resistant quadrinucleate (in the immature stage mono- or binuclear) cysts are the permanent forms of Ent. histolytica. The organisms, 10−16 μm in diameter, are round with a monoplastic cytoplasm, in which chromidium bodies may be

embedded. They develop from the vegetative minuta form in the lower intestine as a result of increasing dehydration in this area. Both the cysts and the vegetative minuta forms are excreted in semi-solid stools. The minuta form is rapidly destroyed in the external environment. *For this reason, it is the cysts which are the mode of transmission of Ent. histolytica.*

**Minuta form:** Following oral ingestion of the cyst, 4 trophozoites (= minuta form) are generated from each cyst in the intestine. This form, which inhabits the intestinal lumen, has an asymmetric structure, 12−20 μm in diameter, and displays 1 or 2 nuclei in its cytoplasm, occasionally with ingested bacteria in the vacuoles. It is capable of amoeboid movement. The minuta form is probably a primarily non-pathogenic amoeba, i. e. *it is sometimes the cause of mild dysenteric symptoms.*

**Magna form:** The minuta form reaches the intestinal wall and is converted into the magna form. This is an asymmetric organism, 20−30 (−60) μm in size, with delicate, honeycomb-like cytoplasm and phagocytized erythrocytes (= haematophagous trophozoites), which produce proteolytic enzymes. *Detection of the magna form is the only reliable criterion of manifest (invasive) intestinal amoebiasis.* Magna forms are excreted from intestinal ulcers or transported to the liver in the portal blood. Very rarely, they can also be directly transmitted through small skin or mucosal lesions.

The minuta and magna forms excreted in the faeces in intestinal amoebiasis are usually not infectious, as they perish rapidly in the stools once they have been excreted. Today, differentiation can be made between the two forms using molecular biology techniques. • Only the **cysts** are responsible for transmission, but they are not present in the stool in the acute phase: infection from the cysts is transmitted by the faecal-oral route and hence only in the symptom-free, chronic stage of the disease. An exact incubation period has not been defined. The latent period may last for several years.

### 1.1.3 Courses of disease

**Intestinal amoebiasis:** Initially, clinical differentiation must be made between diffuse colonic amoebiasis and the (rare) circumscribed involvement of the colon. *Diffuse amoebiasis* of the colon may take different courses: (*1*.) asymptomatic, (*2*.) symptomatic, and (*3*.) symptomatic, but non-dysenteric. (18)

1. **Asymptomatic intestinal amoebiasis** may be witnessed both with and without excretion of cysts or the minuta form of the pathogen. It is, however, possible that the tissue is invaded without the appearance of symptoms, so that patients with extraintestinal amoebiasis do not complain of diarrhoea, either at the time of consultation or in the anamnesis. This is obviously of clinical and therapeutic relevance.

2. **Symptomatic intestinal amoebiasis** may, in rare instances, follow a *fulminant course*, whereby the entire colon is affected with clinical symptoms resembling severe shigellosis. Usually, the symptomatic intestinal form is either *acute* or *chronic recurrent*. The cardinal symptoms are: diarrhoea of gradual, sometimes also sudden onset (evacuation frequency 6−8 [−20]/day), small stools of semi-solid or watery consistency with bloody raspberry jelly-like mucous contents as well as lower abdominal spasms, tender abdominal walls and an episodic course of disease. Laboratory tests reveal changes in the blood count (anaemia, leucocytosis, eosinophilia) and inflammation-related parameters. Endoscopic examination of the rectum, sigmoid and colon reveals mucosal ulceration resembling ulcerative colitis or Crohn's disease. The diagnosis can only be confirmed by the identification of the magna forms (mucosal smear, smear preparation of fresh stool specimens, mucosal biopsy or culture method).

3. **Symptomatic, non-dysenteric courses** of disease elicit minor symptoms in the form of loss of appetite, nausea, meteorism, rectal tenesmus, slight diarrhoea alternating with constipation, and diffuse abdominal pain of varying intensity. In patients whose physical defence response is weakened, exacerbation may occur at any moment. • In most cases, amoebic dysentery affects only isolated colonic sections, leaving intermediate regions largely free from lesions. • In the rare instance of **circumscribed intestinal amoebiasis,** the rectum and coecum or sigmoid are primarily and predominantly affected. **Amoebic appendicitis** and **perianal cutaneous amoebiasis** are seen as particular manifestation forms. • Focal inflammatory infiltration of the abscessed intestinal wall is called **amoeboma.** This consists of granulation tissue with a bleeding tendency. It is mainly localized in the coecum and rectosigmoid. In the case of amoeboma, it can be rather difficult to set up a differential diagnosis to distinguish it from carcinoma, especially in the presence of a symptom complex of stenosis.

**Complications:** Potential complications include the perforation of the intestinal wall (covered or open), stenosis and stricture as well as intussusception or haemorrhage.

**Extraintestinal amoebiasis:** In the event of an imbalance between the pathogen and the host organism due to various factors (s. tab. 26.1), the minuta form becomes pathogenic. Although it normally inhabits the intestinal mucosa, the minuta form infiltrates the intestinal wall with the aid of a cytolytic enzyme and is converted into the magna form. These magna forms then pass via the portal vein to the *liver*, where they are partially destroyed. Moreover, the liver may now become involved in the amoebiasis. • Extraintestinal dissemination of amoebiasis is effected haematogenically; after passing the hepatic sinusoids, it reaches the lung and brain, rarely also the spleen and kidney. Intestinal amoebiasis may encroach on the neighbouring areas (e. g. peritoneum, pericardium, pleura, female pelvic organs) through direct contact (per continuitatem).

### 1.1.4 Hepatic amoebiasis

1. **Non-specific mesenchymal reactions:** The reaction to acute intestinal affection from Ent. histolytica consists of moderate diffuse swelling and multiplication of the stellate cells. Other morphological lesions are generally not detectable. The liver may be enlarged and sensitive to pressure.

2. **Liver amoebiasis:** The propagation of amoebae in the liver leads to focal liver cell necrosis, which regresses spontaneously. Further episodes of focal necrosis may follow. Occasionally, *granulomas* are formed as well. The liver is generally enlarged and sensitive to pressure. The transaminases are slightly elevated. This involvement is called *non-suppurative amoebiasis of the liver*. Liver amoebiasis does not lead to cirrhosis. • (There is no evidence of "hepatitis", "chronic non-suppurative hepatitis" or "chronic amoebic hepatitis".)

**3. Liver abscess:** In 5−10% of patients with acute invasive intestinal amoebiasis, liver abscesses are formed, which are either solitary (50−70%) or multiple (30−50%). The right lobe of liver is affected five times as often as the left lobe (80−90%). Strictly speaking, the term "abscess" is not correct in this context, since there is actually no leucocytic abscess formation but a pathogen-free cytolytic necrosis. This consists of a viscous, creamy, yellowish-green to chocolate-brown mass, which does not contain any amoebae. Trophozoites are only found in the viable, cell-infiltrated tissues of marginal areas. Secondary infections of the amoebic abscesses are possible. • *Clinical observations* include fever (occasionally with chills), tachycardia, sweats, pain in the right epigastrium radiating to the right shoulder and back, an enlarged liver that is sensitive to pressure, a right costal arch that is sensitive to percussion and a tickling sensation in the throat. Men are affected significantly more often by an abscess than women. • *Laboratory findings* reveal severe bacterial inflammation, a slight increase in transaminases and a distinct rise in alkaline phosphatase. (15) Hyperbilirubinaemia is a rare occurrence. IgM antibodies against Ent. histolytica can be detected in 90−100% of patients. These antibody titres persist for months or even years. Apart from ELISA, the highly sensitive EIA test and the indirect haemagglutination test are available. Evidence of amoebae is rarely obtained (< 10% of cases) by stool examination. • *Imaging techniques* facilitate the diagnosis. In ultrasonography, an amoebic liver abscess appears as a vaguely delineated, hypoechoic (yet not echo-free) space-occupying lesion. (s. fig. 25.1) CT yields the same information. With scintigraphy, "cold" areas are visible. (s. fig. 9.2) Radiological evaluation often shows an elevation or restricted movement of the right diaphragm, atelectasis or infiltration in the right lower area of the lung as well as a marginal angular effusion. Diagnostic puncture is not necessary as a rule; however, PCR may provide proof of Ent. histolytica DNA in the abscess content.

**Fig. 25.1:** Ultrasonographic visualization of an amoebic abscess in the right lobe of liver (s. fig. 9.2)

**Complications:** One of the major complications is the confluence of abscesses with subsequent necrosis of large areas of the liver. Furthermore, there is a risk of a covered perforation or rupture into the free abdominal cavity or the adjacent organs, e. g. pleura, pericardium (possibly with the formation of a hepatobronchial fistula) (3), stomach, lung, intestine, gall bladder, bile ducts. Rupture occurs more frequently (20−25%) than in pyogenic liver abscess. Moreover, thrombosis of the inferior vena cava (9) or the portal vein as well as obstructive jaundice may be observed. Arrosion of blood vessels may lead to considerable bleeding. Metastatic spread (e. g. brain) has been witnessed. (2, 4−8, 10−14, 16, 17, 19−21) • With early diagnosis and appropriate treatment, **lethality** is well below 1%, yet ranges between 6.2% (thorax) and 29.6% (pericardium) in cases of abscess perforation. (16)

### 1.1.5 Therapy

Treatment consists of metronidazole (4 × 500 or 3 × 750 mg/day, orally) for about 10 to 14 days. As an alternative approach, tinidazole (3 × 800 mg/day, orally) for 7 to 10 days or ornidazole (2 × 0.5−1.0 g/day) for 10 to 12 days may be administered. Additional administration of chloroquine (600 mg) for 2 days followed by 300 mg for approx. 2 weeks may be advisable. For decontamination of the intestinal lumen, this regimen should be combined with diloxanide fuorate (3 × 500 mg) for 10 to 12 days or paromomycin (3 × 500 mg) for approx. 1 week or iodoquinol (3 × 650 mg) for approx. 3 weeks. Therapeutic success is monitored by ultrasound (possibly also by CT). If therapy is not entirely successful, the course of treatment is prolonged. • Regression following medication may take several months (probably even > 6). With large abscesses (> 6 cm in diameter), impending rupture or lack of impact of the treatment within 5 to 7 days, the abscess should be emptied by means of puncture or drainage. Surgical procedures are only necessary in very severe and/or therapy-resistant cases, especially in necrosis of the left lobe of liver. (2, 16)

### 1.2 Lambliasis

A pear-shaped, 10−20 μm sized parasite of the small intestine, **Lamblia intestinalis** (or Giardia lamblia), is the causative pathogen of lambliasis (or giardiasis). (23) This semipathogenic organism shows a high prevalence in tropical and subtropical regions, but is also repeatedly found in Central European countries − particularly following a stay in the tropics by travellers. • It causes an **infection of the small intestine**. The lambliae attach themselves to the cryptic epithelium of the small intestinal mucosa with the aid of sucking disks. Here, they can form such an extensive and dense lamblia covering that steatorrhoea may result from the disrupted absorption.

Liver involvement can occasionally be recognized by the occurrence of *granulomas*. Laboratory findings reveal a slight increase in γ-GT and AP, pointing to the involvement of the small bile ducts, possibly in the form of *lamblia-induced cholangiopathy*. (24) After parasitization of the gall bladder, *cholecystitis* may occur. • Evidence of highly motile lambliae is readily obtained by examin-

ing A, B or C bile procured with the help of a nasoduo-denal tube, secretion taken from the small intestine, or suspended and centrifuged stool specimens. In the meantime, tests for the detection of giardia antigens in the stool are available as well. • *Treatment* is effected with ornidazole, tinidazole (1.5 g) or metronidazole (2 × 250 mg) for 5 to 10 days. (22)

## 1.3 Cryptosporidiosis

Cryptosporidiosis is classed as traveller's diarrhoea, particularly endemic on the Caribbean islands. The pathogen, an opportunistic protozoon (2−4 μm), is transmitted through contaminated water or food. Clinical findings include watery faeces (5−22 days) with subsequent exsiccation and acetonaemia, headaches and limb pain, vomiting and severe general malaise. The disease persists for up to 6 weeks. • This infection is also observed in AIDS patients (in 6% of all patients and in 21% of patients with diarrhoea). • The biliary system and the gall bladder are especially affected: epigastric pain and anicteric cholestasis are present. Sonography and CT show dilated bile ducts with mural thickening. ERC may reveal findings similar to those found in primary sclerosing *cholangitis*, while papillary stenosis is also observed on occasions. Frequently, a coexisting cytomegalovirus infection has been found. (25−27)

## 1.4 Leishmaniasis

▶ Leishmania (W. B. LEISHMAN, 1900) is a parasite with host exchange between humans and female sandflies (Phlebotomus sp.). Leishmaniasis occurs as a zoonosis, usually found in dogs and rodents. Of essential pathological relevance to humans is **Leishmania donovani** (India, East Africa), an oval, gram-negative, basophilic organism, 3 μm in length. It is the causative pathogen of *visceral leishmaniasis* (kala-azar = black fever, dumdum fever, tropical splenomegaly). These organisms multiply in the RES and macrophages (spleen, liver, small intestine, lymph nodes). L. infantum (Mediterranean region) and L. chagasi (South America) are less frequently found. • **Evidence** is based on cultural or microscopic examination of biopsy specimens (liver, spleen, sternum, tibia or lymph node) and on immunological methods (ELISA, indirect fluorescence test). The leishmaniae penetrate the skin and multiply there, causing an ulcer at the site of entry. • The **infection** may be self-limiting (the pathogens are eliminated in the skin or the liver), or it may become systemic in patients with a weakened immune system and develop into visceral leishmaniasis. The incubation period lasts 2−3 weeks, and even up to 8 months.

The disease runs a course similar to that of an insidious infection with remittent fever (often with a dromedary curve during the day), tickling of the throat, diarrhoea and lymphadenopathy. Hepatosplenomegaly develops as a result of affected sinus endothelia and the subsequent neoformation and multiplication of these cells (a process which is also found in the lymph nodes). A blackish hyperpigmentation (face, hands, feet and abdomen) is a characteristic symptom of visceral leishmaniasis. • *Laboratory tests* reveal a marked increase in IgM and γ-globulins as well as anaemia, leucopenia, throm-

**Fig. 25.2:** Amastigotes of Leishmania donovani in swollen Kupffer cells (→)

bopenia and slightly elevated transaminases. Leucosis is a common tentative, albeit incorrect, diagnosis. • The *liver* is enlarged, the hepatocytes are free of pathogens. The Kupffer cells are severely affected; the basophilic Leishman bodies (2−5 μm in length) can be detected in their interior. (s. fig. 25.2) Non-specific reactive *hepatitis* is present: the portal tracts show dense, small and round-cell infiltrations; lobular peripheral single-cell necrosis and centrolobular fatty degeneration of the liver cells are found. (29) Occasionally, *granulomas* (30) and periportal *fibrosis* develop, in some cases with portal hypertension. (28) • *Treatment* consists of sodium stibogluconate (10−20 mg/kg BW for approx. 20 days) and meglumine antimoniate. Recurrence is possible (even after several years). Combined treatment with γ-interferon or aminosidin is thought to be promising. As alternative regimens, amphotericin B and pentamidine may also be used. With the new drug miltefosin, oral therapy has proved very successful and represents a true breakthrough in the treatment of visceral leishmaniasis. (31) If untreated, the disease is fatal in over 80% of cases as a result of cachexia and/or superinfection. (32)

## 1.5 Malaria

With 300−500 million new infections annually, malaria is one of the most common infectious diseases in the world. The mortality rate is about 2 million/year. • In Germany, approximately 1,000 cases are reported each year, and the tendency is rising. About half of them are due to tropical malaria.

### 1.5.1 Pathogens

*Quartan malaria* is caused by Plasmodium malariae (incubation period of 18−40 days), *tertian malaria* by Plasmodium vivax and Plasmodium ovale (incubation period of 10 to 18 days), and *tropical malaria* by Plasmodium falciparum (incubation period of 7 to 14 days);

administering malaria drugs can extend the incubation period by up to 6 weeks.

## 1.5.2 Malarial cycle

The **sexual cycle** (sporogony) takes place in the female anopheline mosquito, while the **asexual cycle** (schizogony) takes place in humans.

Following the bite of an infected female mosquito, the *sporozoites* injected from her salivary gland are rapidly conducted through the bloodstream to the liver cells, where either the pre-erythrocytic or exoerythrocytic phase commences. The sporozoites turn into *schizonts*, which rupture and release massive numbers of *merozoites* into the blood (after 6 to 16 days of maturation), invading the erythrocytes within 20−30 seconds. The erythrocytic phase produces trophozoites and schizonts (which, in turn, discharge large amounts of merozoites into the blood) as well as male and female *gametocytes*, which also reach the blood, possibly to be ingested by another Anopheles mosquito while biting. Sporozoites are formed in intermediary stages in the mosquito stomach, completing the malarial infection cycle. • A certain number of Pl. vivax and Pl. ovale may persist in the liver cells (perhaps even for several years) and provoke late relapses of tertian or tropical malaria. • **Evidence of plasmodias** is obtained in the peripheral blood using the "thin-film method" or the "thick-film method" with the help of Giemsa stain. A **quick test** is now available. Such tests are helpful, but are not considered to be an alternative to stained blood smears.

## 1.5.3 Clinical findings

The typical bouts of fever (in tertian malaria, every 3 days with a tendency to recur for up to 1 year; in quartan malaria, every 4 days with relapses over a period of up to 4 years; in tropical malaria, at irregular intervals without late relapses) and chills are caused by the release of merozoites from the erythrocytes. Interestingly, "influenza" is the most common incorrect diagnosis in malaria. Symptoms include headaches and limb pain, severe malaise and hepatosplenomegaly. A reduced HDL cholesterol level is a reliable (and early) indicator of malarial infection. The generally mild jaundice is mainly caused by haemolysis − which correlates with the increased LDH. (39) A moderate rise in transaminases, possibly also in alkaline phosphatase, and a marked increase in IgG and IgM with a reduction in cholinesterase are only witnessed in some cases, particularly when the course of disease is severe. (37) Leucocytosis suggests a poor prognosis. Especially with Pl. vivax, marked splenomegaly is present (= hyperreactive malaria splenomegaly syndrome) with a danger of splenic rupture. This can also lead to a lymphoproliferative disease. (35) In severe cases and with high pathogen counts, consumption coagulopathy may develop from microthrombi. • The so-called *airport malaria* is clinically significant. In the vicinity of European airports, anopheles mosquitoes brought inadvertently into the country in summer can result in unexpected cases of malaria. • During pregnancy, this infection may be passed on to the child by transplacental or perinatal transmission, resulting in initially unexplained fever. • *Liver* histology shows isolated hepatocytes with phago-

cytized erythrocytes and finely grained siderin. The generally distended sinusoidal cells contain large amounts of haemozoin: small brownish-black balls, 1−2 µm in diameter, of an iron-porphyrin-protein complex, exhibiting a characteristic double refraction under the polarizing microscope. This *malarial pigment* is abundant in quartan malaria. (34, 36, 40, 42) (s. fig. 25.3)

***Fig. 25.3:*** *Malarial pigment:* marked haemozoin deposition in the hepatic macrophages (HE)

With the augmented deposition of haemozoin, the grey discolouration of the malaria liver develops. In the acute stage, single-cell necrosis may also be detected; chronic malaria generally shows blocks of malarial pigment in the portal field, lobular central sclerosis and occasionally non-specific *granulomas* consisting of histiocytes. Findings of non-specific reactive hepatitis or centroacinar liver cell necrosis might be due to a disrupted microcirculation or hypoxia. Cirrhosis does not occur as a sequela of malaria. • The *lethality* of severe malaria tropica is still >10% despite intensive medical care.

## 1.5.4 Prophylactic measures

Prevention of malaria comprises exposure prophylaxis and chemoprophylaxis.

1. **Exposure prophylaxis,** i.e. avoiding mosquito bites, may considerably reduce the risk of malaria when carried out systematically. This means applying mosquito repellants to uncovered skin areas, wearing sufficient clothing to protect as much of the skin surface as possible, staying in rooms free of mosquitoes (air-conditioning, insect screens) and using insecticide-impregnated mosquito nets. The additional use of insecticides (spray, aerosol) in rooms and vaporizers or smoke spirals outdoors (e.g. on the patio) may be very effective. Preventing exposure is imperative particularly at dawn and dusk and during the night, since these are the times when Anopheles mosquitoes are active.

2. **Chemoprophylactic measures** have, in recent years, become extremely complex and more difficult to apply as a result of increasing resistance. Varying degrees of resistance to virtually every **antimalarial agent** can be expected, depending on the geographic region. Multiresistance is also on the rise. According to a WHO classification, the malaria areas are defined as **zone A** (areas without chloroquine resistance or without Pl. falciparum), **zone B**

(areas with resistance to chloroquine) and **zone C** (areas with extreme resistance to chloroquine or multiresistance). In the light of this zone definition, chemoprophylaxis by means of *chloroquine* (300−450 mg/week), *proguanil* (200 mg/day) or *mefloquine* (250 mg/week) is recommended. *Tafenoquine* (250 mg/day for 3 days) may in future be a new drug for the prevention of malaria; the prophylactic effect is given as being 7 weeks. • *Preventive inoculation* is still in the experimental stage.

### 1.5.5 Therapy

In the case of suspected malaria, *self-treatment* with halofantrine (3 × 500 mg = 3 × 2 tablets at intervals of 6 hours) on day 1 and day 8 should commence if immediate diagnosis and treatment are not possible. Alternatively, mefloquine can also be given (1,000 mg = 4 tablets or 15 mg/kg BW as a single dose; with a body weight of > 60 kg, another 250 mg may have to be given after 6 hours and 12 hours). • In non-immune patients, malaria tropica should always be treated in a hospital as an emergency. Treatment consists of quinine (3 × daily, approx. 10 mg/kg BW, orally) for a period of 8 days, and in complicated cases as i.v. infusion, possibly with simultaneous administration of doxycycline. Further alternative regimens include mefloquine or halofantrine. • In the case of tertian and quartan malaria, chloroquine, mefloquine or halofantine are used. Additionally, primaquine (15 mg = 1 tablet for 14 days) is imperative for the elimination of persistent (proerythrocytic) hypnozoites; with inadequate efficacy, the treatment should be repeated with a maximum total dosage of 280−420 mg. (41) • New drug combinations for combating tropical malaria are proguanil plus atovaquone (38) and arthemether plus lumefantrin. In cerebral malaria, artemisinin has been used with good therapeutic success. (33)

## 1.6 Toxoplasmosis

Toxoplasmosis is caused by **Toxoplasma gondii** (2−7 μm in size). There is a secondary exchange of hosts with a developmental cycle (coccidian cycle) in cats (and possibly other Felidae) as specific hosts with excretion of oocysts in the faeces. Such an acyclic development is found in all mammals and various birds (= non-specific hosts) as well as in humans. The **infection** is transmitted through exposure to cat faeces, by consumption of raw meat infected with oocysts, in the breast milk or via the placenta. The exact incubation period is not known. • Toxoplasma is one of the most widespread parasites, especially in humid and warm climates. The frequency of toxoplasma infection in the population is therefore extremely high, although there are considerable regional and individual differences. As a rule, both the acute and the chronic stages of disease are asymptomatic. Consequently, toxoplasmosis presents a mild pathological picture, since the virulence of the pathogen is balanced by the undisturbed immunological response of the organism; in this case, an infection with Toxoplasma gondii is of no consequence. Occasionally observed concomitant symptoms (fatigue, basophilia in the blood, lymphadenopathy, etc.) are signs of an immunization process. Swollen lymph nodes may therefore persist for some months before the condition regresses spontaneously. • Toxoplasmosis will only lead to a serious clinical picture in the presence of an **impaired immune response.** Most cysts are then found in the CNS and myocardium as well as in the liver, where the parasite can multiply longest. In these tissues, late sensi-

tization leads to the destruction of the parasite with simultaneous development of varying degress of tissue necrosis.

### 1.6.1 Congenital toxoplasmosis

Toxoplasma infections occurring before pregnancy have no effect on the child: the parasite is not transmitted to the foetus. • During pregnancy, the infection is transmitted in approx. 50% of cases; the later the maternal infection is acquired, the greater the frequency (approx. 15% in the 1st, approx. 25% in the 2nd and approx. 65% in the 3rd trimenon). Massive parasitization leads to stillbirth or premature delivery, usually with severe defects. Besides generalized invasion, the parasites are mainly localized in the CNS, whereby chorioretinitis is also in evidence. • From the hepatological viewpoint, marked jaundice and hepatosplenomegaly as well as anasarca and ascites are worth mentioning. The endothelial cells of the liver are distended, and this is where the slightly falcate pathogens are also detectable. Only isolated cases present liver cell degeneration and necrosis as well as microcalcification.

### 1.6.2 Acquired toxoplasmosis

In early infancy, liver involvement manifests as *giant-cell hepatitis* (s. fig. 22.5) or non-specific reactive hepatitis. (s. fig. 21.1) Furthermore, granulomas (s. p. 398) may develop, sometimes with marked density. Transaminases are elevated; cholestasis is also frequently detectable. (43, 44, 46, 48)

***Fig. 25.4:*** Granuloma close to a portal field. Clinical diagnosis: Toxoplasmosis

In children and adults, signs of *non-specific reactive hepatitis* have also been observed. (42, 47) Acidophilic liver cell necrosis occasionally develops, depending on the type of red corpuscles. The endothelial cells are distended, the portal zones show inflammatory infiltration and *granulomas* or retothelial nodules are frequently found. (s. fig. 25.4) The pathogens can be demonstrated in the liver. *Cirrhosis* may develop, especially after the destruction of the lobular architecture as a sequela of extensive parenchymal necrosis. • There are various *serological tests* available, including the Sabin-Feldmann

dye test, the indirect immunofluorescence test (IFT), the indirect haemagglutination test (IHA) and the ELISA test. Evidence of IgM antibodies is obtained as early as 5 days after infection. Direct identification of the pathogen is achieved by means of the PCR technique. (45)

### 1.6.3 Therapy

Asymptomatic or uncomplicated primary infection requires no treatment. Severe courses of disease are treated with pyrimethamine (50 mg/day for approx. 2 weeks, followed by 25 mg/day for approx. 2 weeks) or sulphamethoxydiazine (50 mg for day 1, 25 mg as from day 2 or 3) + pyrimethamine (100 mg/kg BW/day) or clindamycin + pyrimethamine. As an alternative approach (e. g. in the first trimester of pregnancy), spiramycin may be given. In order to reduce the myelotoxicity of pyrimethamine, the administration of folic acid (10−15 mg/day) is recommended.

## 1.7 Trypanosomiasis

**Trypanosomes** belong to the genus of flagellates with a spindle-shaped thin body, large central nucleus, small kinetoplasts and a highly motile flagellum. The cycle of development requires both vertebrate and insect hosts. • **Diagnosis** of the blood parasite is obtained by dark-field and phase-contrast microscopy, Giemsa stain, culture and tissue biopsy. Serological evidence is based on the FTA test as well as on CFR and IgM antibodies in the liquor. • **Treatment** in early stages (also as a preventive measure) consists of suraminum natricum or pentamidine; in the tertiary stage, tryparsamide or melarsoprol are recommended.

The **transmission** of **Tryp. gambiense** and **Tryp. rhodesiense** *("African sleeping sickness")* is caused by tsetse flies. Outside the body, these pathogens only survive for a brief period of time. Multiplication takes place in the peripheral blood, possibly also in the lymph nodes, CSF and bone marrow. The incubation period is between 1 and 3 weeks (= primary stage with headaches, limb pain and fever). Pathogenic invasion of the blood and lymph vessels (= secondary stage) causes swelling of the lymph nodes, splenomegaly and bouts of fever. When the CNS is affected, a serious clinical picture appears, which generally culminates in death after a few weeks or months if untreated. • The *liver* shows centroacinar cell necrosis and inflammatory infiltration, especially in the portal fields.

The **transmission** of **Tryp. cruzi** is caused by reduviid bugs, which excrete infectious trypanosomes in their faeces. These enter the body through small skin or mucosal lesions. They cause the "South American sleeping sickness", also called *Chagas' disease* (C. CHAGAS, 1908). • In the *liver* only portal round-cell infiltrates are found.

# 2 Helminthiases

Infections caused by helminths often lead to liver involvement. The parasites or their immature forms may reach the **liver** (*1.*) via the *portal vein* (e. g. eggs of schistosomes), (*2.*) via the *hepatic artery* (e. g. scolices of echinococci), (*3.*) transperitoneally through *Glisson's capsule* (e. g. larvae of Fasciola hepatica), and (*4.*) ascending through the *bile ducts* (e. g. larvae of the Clonorchis sinensis). • *Histological signs* of the parasitization of the

liver often include granuloma formation, fibroblast activation and an eosinophilic cellular reaction. • *Laboratory parameters* frequently reveal eosinophilia and an increase in IgE. • Under certain circumstances, three different **helminth species** come in question: (*1.*) nematodes (roundworms or eelworms), (*2.*) trematodes (flukes), and (*3.*) cestodes (tapeworms). (s. tab. 25.1)

## 2.1 Nematodes

### 2.1.1 Ascaris lumbricoides

Ascariasis is one of the most common parasitoses: approx. 800 million people are infected. The **ascarid** is cream-coloured, mostly 4−6 mm in diameter and 15−25 cm (males) or 20−40 cm (females) in length, the latter showing an involuted posterior part. The worm lives mainly in the jejunum. The female lays nearly 200,000 eggs daily during her life span of about one year, so that faecal evidence is relatively easy to obtain. • The compact oval **ascaris eggs** (up to 60 μm in diameter) show a peculiarly structured surface, yellowish-brown in colour. (s. fig. 25.5) After fertilization, the larvae in the eggs mature in about 2 (−8) weeks at the appropriate temperature (= **larval stages 1 and 2**). The route of infection is faecal-oral. After oral ingestion, the eggs reach the small intestine, where the **larvae** shed the egg membrane. They penetrate the intestinal mucosa and enter the lymph vessels and bloodstream and migrate to the liver (= **larval stage 3**), where a major part of the larvae is destroyed. The rest travel to the lung, where they leave the capillaries and reach the alveoli (= **larval stage 4**). The larvae are transported via the bronchial tract to the trachea and larynx. The pulmonary larval migration may be accompanied by transitory, often multiple eosinophilic lung infiltrates, sometimes with asthmatic symptoms for the individual and, in the case of secondary infection, by bronchopneumonia. When swallowed, the larvae reach the small intestine a second time (= **larval stage 5**). Here, in roughly 3 months, they mature to become ascarids of separate sexes. Their life span as intestinal parasites is about 12 to 18 months.

*Fig. 25.5:* Egg of Ascaris lumbricoides in bile fluid (obtained by means of a nasogastroduodenal probe)

**Diagnosis:** The diagnosis is confirmed by the presence of Ascaris eggs in the stool or bile. (s. fig. 25.5) With the help of X-ray examination, the ascarids are generally shown to form a recess in the contrast medium in the bowl (s. figs. 25.6, 25.7); alternatively, they are detectable one day later due to their intestinal resorption of the

**Fig. 25.6:** X-ray with contrast medium showing 2 ascarids in the duodenum

**Fig. 25.8:** Sonographic visualization of an Ascaris lumbricoides in the common bile duct (longitudinal/transverse imaging). Clinical findings: colicky pain, cholestasis and slight jaundice

**Fig. 25.7:** Passage of the ascaris pair and 3 young ascarids (not shown by the X-ray above) through the intestine following anti-helminthic treatment

CM. Occasionally, the ascarids travel to the common bile duct, so that the parasite can also be confirmed by ultrasound (50, 52, 57, 60) (s. fig. 25.8) and/or by endoscopic retrograde cholangiography (ERC). (56, 61)

The **clinical picture** may be characterized by a variety of symptoms; in some cases, the ascarid leads to diffuse abdominal pain of varying severity. By entering the bile ducts, it causes recurrent biliary colics and fever, sometimes also haemobilia, and the symptom complex of obstructive cholestasis, cholangitis or cholecystitis. (51, 54, 56, 59) Residues of a dead ascarid in the bile duct may calcify or trigger the formation of bile concrement. The abdominal complaints are not relieved by spasmolytics, especially since the parasite can now penetrate even further into the bile ducts. (s. fig. 25.8) • The ascarids may migrate from the biliary system to the liver parenchyma and even reach below Glisson's capsule. This may entail vascular thrombosis and abscesses, mainly in the left lobe of liver. In the liver, the coloniza-

tion by larvae or eggs provokes granulomas with giant cells and eosinophilic margins as well as portal infiltration. (53, 58)

The following **complications** have been reported: pneumonia, asthmatic attacks *(= asthma verminosum)*, parasitization of the biliary tract (= cholangitis) (49, 59, 62), liver (= hepatic lesions), pancreatic duct (= pancreatitis) and appendix (= appendicitis), or entanglement of worms (= ileus).

**Therapy:** The treatment regimen consists of levamisole (1 × 150 mg) or albendazole (400−800 mg), flubendazole (1 × 200 mg), pyrantel pamoate (1 × 10 mg/kg BW), piperazine (1 × 75 mg/kg BW, up to a maximum total dosage of 4 g) as well as mebendazole (2 × 100 mg/day for 3 days). Endoscopic measures for the removal of an ascarid from the common bile duct, possibly after sphincterotomy, are sometimes necessary. (49, 55, 56, 62, 63)

### 2.1.2 Capillaria hepatica

Capillaria hepatica is encountered in the livers of vertebrates such as rats, squirrels, dogs, beavers and pigs. The worm measures 35−50 (−60) mm in length. Humans are infected through the ingestion of worm eggs excreted in the faeces of these host animals, occasionally also through the consumption of the liver of infected animals. The worm eggs are transported to the coecum, where the larvae hatch. They penetrate the coecal wall and reach the liver via the portal system. This is where the maturation of the adult worms takes place. The females die after some weeks, and a large number of eggs are released into the liver. The infection with Capillaria hepatica may be mild or asymptomatic or lead to weight loss, general malaise, fever, oedema and eosinophilia as well as hepatomegaly, with an increase in transaminases and alkaline phosphatase. Histiocytic granulomas develop in the liver, with an

abundance of eosinophilic granulocytes. Their identification by liver biopsy yields the diagnosis. • No *treatment* for this worm disease is yet known.

### 2.1.3 Pentastomum denticulatum

Pentastomum denticulatum is the final larva of the nasal worm Linguatula serrata. The adult parasites (4−5 mm long) live in the nasal cavities and respiratory tracts of carnivorous animals and snakes. Infection is transmitted through oral ingestion of the eggs with subsequent development of the larvae in the small intestine. They travel via the portal vein to the *liver*, where they encyst and form hard, yellow nodules of ca. 3 mm in diameter. Histology reveals fibrous alterations as well as granulomatous infiltrates; fine calcifications can occasionally be detected. • No *therapy* is known.

### 2.1.4 Strongyloides stercoralis

The **dwarf threadworm** has two separate developmental phases: a *strongyloid type* with a parthenogenetic, parasitic cycle and a free-living *saprozoic type* of both sexes. The filariform larvae penetrate the skin and reach the lungs via the bloodstream; from the lungs, they migrate through the trachea to the oesophagus, where they are swallowed, and subsequently make their way to the upper section of the small intestine. Here, the mature female parasites develop and lay eggs. The larvae hatch and are either excreted in the stool or re-enter the body through the bloodstream after penetrating the intestinal wall (endoautoinvasion) or the perianal skin (exoautoinvasion), so that a new developmental phase begins via the lung. The two types of autoinfection and the additional free-living cycle account for the extreme obstinacy of strongyloidosis. In some cases, major gastrointestinal disorders with bloody diarrhoea or pulmonary infiltrates as well as asthma verminosum may occur.

In the *liver*, the larvae cause portal infiltration and granulomas. The parasites can also invade the bile ducts and give rise to cholestasis or cholangitis, even obstructive jaundice or cholecystitis. • The *diagnosis* is based on the finding of motile larvae (ca. 300 µm) in the stool or duodenal juice (if necessary, after enrichment) and by an indirect immunofluorescence test or ELISA. • *Treatment* consists of thiabendazole (2 × 25 mg/kg BW for about 5 days), mebendazole (2 × 200 mg for 3 days) or albendazole (400−800 mg for 3 days). • In Germany, the infection is accepted as an *occupational disease* among miners and tunnel workers with obligation for notification. (s. p. 567)

### 2.1.5 Toxocariasis

Toxocariasis is transmitted to humans by dogs (T. canis) and more rarely by cats (T. cati) through oral infection with eggs. The adult worms measure 4−12 cm in length. The larvae mature in the eggs and after hatching in the intestinal tract, pass into various organs, including the liver and lungs. (65)

In the *liver*, the larvae cause local inflammatory infiltrates, eosinophilic portal infiltration, small abscesses and granulomas. On occasions, the granulomas may become confluent and form conglomerates. A large proportion of the larvae die in the liver, the rest encyst in granulomas. (67) Fibrous alterations may occur. This liver infestation is also known as *visceral larva migrans disease*. (66) • The *diagnosis* is obtained by means of ELISA and liver biopsy. (64, 67) Clinically, there is evidence of fever, nausea, eosinophilia, hepato(spleno)megaly, bronchopulmonary disorders and an increase in γ-globulins. Migration of the larvae to the eyes (chorioretinitis, iridocyclitis), the lungs and the myocardium may lead to severe complications. • The disease is mostly self-limiting, no *therapy* being required. In severe cases, treatment consists of diethylcarbamazine (9 mg/kg BW/day), given in 3 single doses per day for 3 weeks. As an alternative regimen, thiabendazole (50 mg/kg BW/day) may be administered, possibly combined with steroids, mebendazole or ivermectine. (54)

### 2.1.6 Trichinella spiralis

Infection with *Trichinella spiralis* is caused by consumption of raw meat from pigs or wild boars containing encysted larvae. The larvae are released in the stomach or duodenum and grow within 5−7 days to sexually mature parasites. Following fertilization, the female trichinae burrow into the intestinal wall and discharge living larvae into the bloodstream and lymph vessels. They are deposited as trichina cysts in muscles, with involuted trichinae. The diagnosis is established by antibody detection (unfortunately, not until the 3$^{rd}$ or 4$^{th}$ week). It may also be possible to establish the presence of nucleinic acids using PCR.

The trichinae also reach the *liver*, where they invade the sinusoids and may cause an inflammatory mesenchymal reaction. There is likewise an abundance of liver granulomas. (69, 70) • *Treatment* for trichinosis during the motile phase consists of mebendazole and possibly thiabendazole (in gradually increasing dosage, with additional administration of glucocorticoids, if necessary).

## 2.2 Trematodes

### 2.2.1 Clonorchis sinensis

The **Chinese liver fluke** measures 1.0−2.5 cm in length. It is most common in China, Japan and South East Asia. Transmission is via consumption of raw or undercooked freshwater fish. The main hosts are pigs, dogs, cats and humans. The yellowish-brown eggs are approx. 30 µm in size and have an "operculum". (s. fig. 25.9)

***Fig. 25.9:*** Egg of Clonorchis sinensis in bile fluid (obtained by a nasogastroduodenal probe)

They are excreted in the faeces. The eggs, which contain a miracidium, are eaten by water snails. The latter excrete cercarias, which penetrate fish as metacercarias and encyst in their muscles. After these fish have been ingested, the cercarias are released in the duodenum and migrate to the bile ducts, where they mature into parasitic worms within the space of one month. The worms can live in the bile ducts for several years. (s. fig. 25.10)

***Fig. 25.10:*** Chinese liver fluke (Clonorchis sinensis)

The *clinical picture* is characterized by epigastric pain and fever, sometimes with chills, diarrhoea, weight loss, hepatomegaly, eosinophilia, slight jaundice and an increase in enzymatic markers of cholestasis. These blood-sucking liver flukes cause proliferation and adenoma-like growth with periductal fibrosis in the area of the affected *bile ducts*. Potential late sequelae of chronic cholangitis are miliary liver abscesses, intrahepatic gallstones and biliary cirrhosis. Cholangiocarcinoma and carcinoma of the gall bladder may also develop. (71−76, 78, 79) • The *diagnosis* is confirmed by the presence of eggs in stool specimens, but more reliably in the bile after nasoduodenal probing (especially in the so-called B bile after choleretic stimulation). Sonographically, widened bile ducts with inhomogeneous reflexes are generally detectable. (73, 77) ERC shows filling defects and mural irregularities of the bile ducts. • *Treatment* is with praziquantel (3 × 25 mg/kg BW/day) for about 2 days.

### 2.2.2 Dicrocoelium dentriciticum

The **small liver fluke** (5−12 mm long) evolves in two intermediate hosts. A special snail species excreting metacercarias is necessary as the first host. These are ingested by cattle and sheep. Human infection is rare. • The cercarias travel through the duodenum to the bile ducts, where they grow into mature liver flukes. Dicrocoeliasis is characterized by biliary ailments and respective findings.

### 2.2.3 Fasciola hepatica

The **large liver fluke** (length: 2−3 cm, diameter: 0.8−1.5 cm) is a leaf-shaped biliary parasite. It is found worldwide, its main natural reservoirs being in sheep and cattle. Human infection is accidental. (81) The eggs are excreted in the faeces. The larvae (miracidia) emerge from the eggs and penetrate freshwater snails (Lymnaea species), which, in turn, release cercarias. As metacercarias, they attach themselves to water plants, especially watercress. (100) When infected plants are ingested, the metacercarias are released in the upper intestinal tract. They penetrate the intestinal wall, reach the free abdominal cavity and invade other organs, particularly the liver parenchyma via Glisson's capsule. It takes them several weeks to reach the biliary system, where the parasite then develops in a hermaphroditic fashion. (s. fig. 25.11)

***Fig. 25.11:*** Fasciola hepatica (large liver fluke), $2.9 \times 1.1$ cm ($\times 3$). • Ovum of Fasciola hepatica, approx. $0.13 \times 0.07$ mm, in bile fluid (obtained by means of a nasogastroduodenal probe) ($\times 400$)

During their migration through the *liver parenchyma*, the young parasites cause major lesions, cell necroses, haemorrhages and inflammatory infiltration. (83, 91, 97, 100) The eggs deposited in the liver tissue lead to the formation of granulomas. The bile ducts display epithelial proliferation, budding processes and proliferation of the connective tissue with the associated circumscribed inflammatory narrowing of the affected bile ducts. Cholangitis can occur, possibly with abscess formation. (97, 99) The bile ducts may be obstructed by the liver flukes and their eggs. • *Clinical symptoms and signs* during the liver invasion and migration phase (approximately 5 or 6 days after ingestion) feature pain in the right epigastrium, hepato(spleno)megaly, fever, vomiting, diarrhoea, loss of appetite, urticaria, meteorism as well as leucocytosis, eosinophilia, increased ESR, slight jaundice and elevated liver enzymes. Over a period of years, chronic cholangitis and biliary cirrhosis may develop. (83, 88) • *Diagnosis* is based on the presence of eggs ($0.14 \times 0.08$ mm in size) in the stool or bile fluid. (s. fig. 25.11) Serological tests are also available. Nodular changes (4−10 mm), small liver abscesses and bile-duct irregularities may be identified by ultrasound (80, 82, 86, 89), CT (82, 83, 89, 93, 94, 98) (s. tab. 8.2) or cholangi-

ography. (85, 95) • *Treatment* is based on bithionol (30−50 mg/kg BW, in 3 single doses, every second day for 2−3 weeks), or alternatively triclabendazole (1−2 × 10 mg/kg BW) and nitazoxanide (90), possibly also with (the less potent) praziquantel. (96) If oral therapy has proved unsuccessful, an endoscopic rinsing of the biliary system using a povidone-iodine solution is recommended. (86) Invasive methods (sphincterotomy, insertion of endoprostheses) and surgical intervention may be necessary in individual cases. (83, 87)

### 2.2.4 Fasciolopsis buski

This **large intestinal fluke** is a common parasite in East Asia. It is the largest trematode (5−7 cm by 1.2−1.5 cm) to infect humans. (s. fig. 25.12) Infection occurs through consumption of freshwater plants, especially raw water-nuts, infected with metacercarias. Water snails serve as intermediate hosts. • Infection leads to fever, weight loss, vomiting, abdominal pain, bloody diarrhoea (later greyish-yellow stool), anaemia and ascites as well as cholangitis and liver abscesses, with corresponding laboratory findings.

**Fig. 25.12:** Large intestinal fluke (Fasciolopsis buski)

### 2.2.5 Opisthorchis felineus

**Opisthorchis felineus:** This fluke, also called *Siberian liver fluke,* is found mainly in Asia, but to an increasing extent in Europe as well. It measures 0.7−1.2 cm in length by 2−3 mm in diameter and is of a light reddish colour. The pale brown eggs, with a length of 20−30 μm and a diameter of 10−14 μm, are somewhat smaller than the eggs of Clonorchis sinensis; they also have an "operculum". (s. fig. 25.9) Their developmental process corresponds to that of the Chinese liver fluke. • This fluke infection of the *biliary tract* likewise leads to severe reactive cholangitis with proliferation, adenoma-like growth and fibrosis as well as chronic cholangitis, liver abscesses, haemobilia and cholelithiasis. Biliary cirrhosis and cholangiolar carcinoma may develop. (101, 102, 104) • *Treatment* is with praziquantel (40−75 mg/kg BW in 3 doses).

**Opisthorchis viverrini:** This fluke is also encountered in East Asia, mainly in Thailand, Laos and Cambodia,

and has the same course of development as Clonorchis sinensis. It causes similar alterations in the biliary tract and liver. (103, 104)

### 2.2.6 Schistosomiasis

▶ Approximately 200−250 million people in over 70 countries are suffering from schistosomiasis (bilharziosis). This parasitosis is found in large areas of Africa, South America, Asia and Puerto Rico. • The eggs (approx. 150 μm long with a **characteristic side "thorn"**) reach the water in the environment with the stools and are ingested by freshwater snails; subsequently, cercarians develop in these intermediate hosts. Humans are exposed to **infection** when coming into contact with contaminated water; the larvae penetrate the skin by way of borer glands or, alternatively, infection occurs via mucous membranes. During this process, the larvae discard their tails before making their way through the venous system into the right heart and the pulmonary capillaries, subsequently passing through the left heart into the arterial circulation and hence to the **liver.** Here, within a space of 4−6 weeks, the larvae develop into worms, 10−20 mm in length and 1−2 mm in diameter, each with 2 sucking disks on the head and another 2 on the posterior part of the body. The worms migrate hepatofugally in pairs into the **portal system,** mainly into the superior mesenteric vein (and through anastomoses also into the pelvic veins). The worms can reside here for years, living either in sexual segregation or as pairs, the females laying up to 350 eggs daily. Some eggs are excreted in the stool, others reach the liver via the portal system and embolize into the perisinusoidal venoles. (107, 108, 114, 115)

Four of the five species infecting humans may cause liver disease: *S. mansoni. S. japonicum, S. intercalatum* and *S. mekongi.* The disease sets in after an incubation period of 4−6 weeks. It manifests as fever ("Katayama fever"), chills, headaches, arthralgia, pain in the right epigastrium, blood-flocked mucous diarrhoea, loss of weight, lymphadenopathy and urticarial skin reactions. The liver and the spleen are moderately enlarged, especially in the case of S. japonicum and S. mansoni (= hepatolienal bilharziosis). Chronic schistosomiasis develops (in about 10% of infected persons) after years or even decades. Laboratory values reveal eosinophilia, thrombopenia (as a predictor of portal hypertension) (112) and anaemia, markedly increased inflammatory parameters (e. g. ESR, α- and γ-globulins, CRP) as well as a moderate rise in transaminases, γ-GT and alkaline phosphatase. Jaundice is rare. (108, 114, 116, 118, 119, 121)

During the early stages of larval and worm migration and at the outset of egg-laying, the *liver* often shows signs of non-specific reactive *hepatitis.* The Kupffer cells frequently contain an iron-free pigment. The deposited eggs lead to the formation of *granulomas* with lamellar wall structures and perigranulomatous inflammatory reactions. (109, 114, 115, 121, 125) (s. fig. 25.13) • The eggs are detectable inside the granulomas and may occasionally calcify. Especially in cases of infection (e.g. Staphylococcus pyogenes aureus, Streptococcus intermedius) (124), conglomerates of bacteria in the form of granules can develop. Because of their grape-like shape, they are termed bothryomycosis (but they are not fungi!). They form eosinophilic antigen-antibody precipitates, which surround fungal foci, parasites or abscesses. They

appear as radiating eosinophilic spokes or thick eosinophilic rings. This condition is known as the **Splendore-Hoeppli phenomenon**. (s. p. 397) • There is subsequent formation of marked portal and perilobular *fibrosis*, which is most pronounced with S. mansoni and S. japonicum. (s. fig. 25.14) Especially in the case of S. mansoni, white *clay pipe-stem fibrosis* is characteristically present (W. S. C. SYMMERS, 1904). The lobular structure is retained. The portal branches reveal a thickening of the walls, with clot formation and rarefaction, resulting in the picture of *endophlebitis obliterans*. • Portal hypertension occurs as a sequela of presinusoidal block formation. (s. p. 219) As a result of compression of the small liver veins by granulomas, postsinusoidal block formation can arise as an additional feature. Splenic infarcts with perisplenitis are frequently detectable. Isolated bilharzia eggs can also be found in the spleen. Even in the early stage of the disease, oesophageal and fundus varices are formed as a result of *portal hypertension* and are in danger of bleeding. (111, 123) Oedemas and ascites are often observed. Hepatic encephalopathy need not be feared owing to the intact liver function; nor does cirrhosis occur. In the course of time, however, the liver (especially the left lobe) shows signs of shrinkage.

**Fig. 25.13:** *Schistosomiasis:* cicatricial granulomas with lamellar walls; perifocal lymphohistiocytic inflammatory rim (HE)

**Fig. 25.14:** *Schistosomiasis:* portal fibrosis (so-called clay pipe-stem fibrosis) (HE)

► Schistosomiasis is frequently accompanied by an additional *HBV* or *HCV infection*, corresponding to the respective regional infection rate. As a result, the course of disease is generally more severe, portal hypertension becomes progressive more rapidly, and there is a greater disposition towards hepatocellular carcinoma. (122)

The *diagnosis* can be established by identification of eggs in the stool as well as by rectal and/or sigmoidal mucosa biopsy or liver biopsy. Serological tests (e. g. ELISA) may be useful. The PCR technique can likewise be applied. Imaging techniques (ultrasound, CT) are of diagnostic value. (105, 108, 113, 115, 117−121, 125) Early oesophagogastroscopy and follow-ups are necessary. In advanced stages, the laboratory parameters usually show only moderate cholestasis and γ-globulinaemia.

The *treatment* for all forms of schistosomiasis consists of praziquantel (30−45 mg/kg BW as a single dose). In severe courses of the disease or with an S. japonicum infection, 60 mg/kg BW daily, in 3 single doses, should be administered. A 6-day course of therapy with 30 mg/kg BW/day is likewise recommended. S. mansoni is also effectively treated with oxamniquine (20 mg/kg BW/day for 3 days). (110, 114, 115, 121)

## 2.3 Cestodes

Infections with Taenia, a genus belonging to the family of tapeworms, is of no consequence for the human liver and bile ducts. • In contrast, **echinococcosis** is a helminthic infection of major clinical significance.

► Hepatic hydatids were reported for the first time by F. RUYSCH in 1691. • The pathogens responsible for echinococcosis are found worldwide and comprise four different species: (*1*.) **Echinococcus cysticus** (E. granulosus, E. hydatidosus), (*2*.) **Echinococcus alveolaris** (E. multilocularis), (*3*.) **Echinococcus oligarthrus**, and (*4*.) **Echinococcus vogeli.** All forms of echinococcosis differ greatly with respect to epidemiology, pathomorphology and clinical findings. • E. oligarthrus and E. vogeli have been identified in isolated cases in Africa and South America. So far, only a few instances of parasite diseases have been reported in humans. E. vogeli is the cause of polycystic echinococcosis.

### 2.3.1 Echinococcus cysticus

With a frequency rate of over 90%, E. cysticus (E. granulosus) is the major causative pathogen of echinococcosis and is encountered frequently in countries where intensive cattle breeding is common. (137, 147, 163) • The *principal hosts* (final hosts) of the dog tapeworm are various canine species such as dogs, wolves, jackals and hyenas. Sheep, pigs, cattle, horses and deer serve as *intermediate hosts.* Humans infected by the principal host serve as *false intermediate hosts* (secondary host), since the developmental process of the dog tapeworm

cannot be brought to an end in humans. • Echinococcus cysticus is 3−6 mm long and is generally made up of 3 (−7) proglottids. The eggs are discharged into the intestinal lumen in each case from the last proglottid. The head (scolex) is equipped with 4 suckers and a double-hooked crown. Humans are infected by oral ingestion of Echinococcus eggs (embryophores), 30−40 μm in diameter, which are present in the stool and sputum of infected dogs. The larvae (oncospheres) are released in the intestine, where they penetrate the intestinal wall and gain access to the portal system. Within 3−4 hours, they reach the liver. Approximately 70% stay in the liver, while the remaining 30% are transported into the lungs and via the arterial circulation into the brain, spleen, bone, kidney and other organs. • The larvae encyst and form fluid-filled cysts or **hydatids** (cysticercus) with a three-layered wall. The outer, milky-white lamellar layer, about 1 mm thick, is a PAS-positive chitin membrane; the middle layer is a hyaline membrane, and the inner wall constitutes the germinal layer, 10−15 μm thick, where internal brood capsules are formed, initially without, but later with scolices. These capsules may rupture and release protoscolices as "hydatid sand" into the hydatids. Other brood capsules are formed which grow outwards through the hydatid wall and subsequently become "free" daughter cysts. (s. figs. 25.15) Through hydatid rupture (e. g. surgery, puncture), the partly free-floating scolices are disseminated, resulting in the formation of secondary cysts (E. multicysticus). The release of allergenic hydatid fluid may cause a strong anaphylactic reaction. • The hydatids grow ca. 0.5−1.0 (−5.0) cm/year and only lead to clinical symptoms after a number of years. In 7−10% of cases, the cysts may disappear spontaneously or remain unchanged. The secondary cysts frequently perish in human beings, remaining only in a sterile and calcified form. (s. fig. 25.19) • If the main hosts ingest organs containing hydatids with mature head structures, the developmental course will be completed, i. e. tapeworms are again formed in the intestine of the final host, and eggs are excreted. (157)

*Fig. 25.15:* Morphology of a hydatid cyst (E. cysticus) in the liver

**Clinical symptoms** appear after 3−5 years at the earliest, the peak of their manifestation being in the 3rd decade. The patients occasionally complain of fatigue, food intolerance, pruritus, loss of weight and episodes of fever. Further symptoms depend on the localization, size and growth of the hydatids. The liver is nearly always affected, most frequently the right lobe. With increasing hydatid growth, the right epigastrium or costal arch may show protrusion; in cranial localization, the right diaphragm is elevated. When the left lobe is affected, the increase in hydatid size leads to epigastric protrusion. Depending on the mechanical situation, a sensation of pressure and repletion as well as pain is felt by the patient. With the exception of eosinophilia (30−40% of cases) and an occasional increase in γ-GT and transaminases, laboratory parameters are not particularly striking. When the bile ducts are compressed, there is an increase in the enzymatic markers of cholestasis, and mild jaundice may be witnessed. (131, 163)

**Diagnosis** is based on sonography, possibly with 4 or 6-stage classification. (s. figs. 6.11, 25.16) (137, 157, 163, 170) (s. p. 174) Additional information may be yielded by CT (s. fig. 25.17), MRT (140, 154, 159, 161) (s. p. 156) and by routine X-ray of the chest and abdomen (elevated right diaphragm, reduced respiration-related movement of the diaphragm, pleural effusion, pulmonary foci, evidence of calcification). (s. fig. 25.18) Hydatids can be identified in the large bile ducts by ERC. Angiography (only indicated in individual cases) shows a poorly vascularized area with a discolouration of the capsule.

*Fig. 25.16:* Echinoccus cysticus (stage II B): bizarre conglomerate with peripheral daughter cysts

Laparoscopically, (134), the cyst appears on the liver surface with an irregularly thickened capsule and moderately diffuse vascular irritation (no vascular breaks). Slight fibrinous exudates may be seen at the adjacent peritoneum. (s. fig. 25.19) Palpation with the palpatory rod reveals a distended elastic consistency. Although puncture is considered to be dangerous, it is nonetheless

frequently performed for diagnostic and therapeutic reasons (166, 170); it is less dangerous when carried out under laparoscopic surveillance.

*Fig. 25.17:* CT showing Echinococcus cysticus in the liver

*Fig. 25.18:* Calcified Echinococcus cysticus in the liver

*Fig. 25.19:* Laparoscopic view of a large Echinococcus cysticus hydatid in the right lobe of liver: irregularly thickened hypervascular capsule. Fibrin deposition at the adjacent peritoneum. Distended elastic consistency

Serological tests (Em-2-ELISA, indirect haemagglutination, indirect immunofluorescence) are positive in some 85%−95% of cases. All tests may yield false-positive or false-negative results. The tests are negative if the hydatid shows no leak or contains no or only dead scolices. Differentiation of the species is effected successfully by Western blot. (147)

**Complications** in the form of a rupture into the free abdominal cavity (with anaphylactic shock) (155, 156, 159), bile ducts (174), duodenum, large intestine, pleura and lungs have been reported, as has the Budd-Chiari syndrome after rupture into the liver veins and bronchobiliary fistulas. (162, 168) Secondary infection may appear following damage to the cystic wall, presenting the clinical picture of a liver abscess. Rare manifestations comprise formation of gallstones in the cysts, obstructive jaundice (148), obstruction of the inferior vena cava (153) or glomerulonephritis as an immunological reaction. Complications may also occur as a result of localization and growth in other organs (brain, lung, kidney, bones or spleen). (s. fig. 25.20) (135, 152, 171, 177, 178)

*Fig. 25.20:* Hydatid cyst of Echinococcus cysticus in the spleen

**Treatment** of choice is surgical removal of the hydatid cyst (pericystectomy) following systemic pretreatment with albendazole, possibly with concurrent partial liver resection. Surgical deroofing is easy to perform and, in contrast to other minor surgical interventions, universally applicable. (127, 130, 136, 141, 142, 151, 160, 163, 167, 169, 176) For intraoperative destruction of the scolices, the cyst may, before resection, be injected with a 10−30% common salt solution, a highly concentrated glucose solution, hydrogen peroxide, alcohol (90%), PVD iodine (10%), cetrimide (0.5%) or even mebendazole. • Percutaneous aspiration or drainage treatment was reported to be successful. (126, 129, 132, 143, 146, 150, 163, 166, 167, 169, 175) The PAIR procedure (**p**uncture/**a**spiration/**i**njection/**r**easpiration) (M. Gargouri et al., 1990) has proved generally effective when using a sodium chloride solution (20%, 10 min) and ethanol (95%, 10 min). The two solutions can also be administered successively. These therapeutic measures can be performed with a higher degree of reliability under laparoscopic control (M. Ertem et al., 1998). • Medicamentous treatment consists of mebendazole (40−100 mg/kg BW daily in 3 single doses) together with meals of a high fat

content, initially for a period of 4−6 months, but in most cases for life. It is essential to have a guaranteed serum level of >10 ng/ml or a plasma level of >200 mmol/l for approx. 4 hours after the morning intake; a higher plasma level is attained by additional administration of cimetidine. The dose is adjusted daily in accordance with the control values in the serum. Albendazole (2 × 400 mg/day for 4 weeks, followed by a therapy-free period of 2 weeks and a new treatment cycle) and fenbendazole as well as a combination chemotherapy with albendazole and praziquantel (50 mg/kg BW) have also proved effective. (127, 128, 138, 139, 144, 145, 149, 150, 158, 163−165, 167, 173)

## 2.3.2 Echinococcus alveolaris

The *principal host* of E. alveolaris (E. multilocularis) is the fox; more rarely, the dog and the cat are infected as well. *Intermediate hosts* include the common field mouse and other wild animals. Humans can also be infected as intermediate hosts. (137, 147) • This tapeworm inhabiting the small intestine has a length of 1.0−3.5 mm and possesses five proglottids. *Infection* with eggs results from consuming contaminated food (wild berries, windfall fruit, vegetables) and from contact with fox pelts. E. alveolaris can be found worldwide, particularly in the various endemic areas. Apart from these endemic areas, there are "hyperendemic" regions, where the prevalence is 1:1000. • The *development cycle* is identical to that of E. cysticus. In 90% of cases, only the liver is affected. The cysticercus, however, grows in an infiltrative, destructive manner from organ to organ, i.e. the growth pattern shows tumour-like aggression. Metastatic spread is systemic (especially lungs, brain, bones) and lymphogenic. Many daughter cysts, up to the size of a hazelnut and coarse in structure, are formed on the surface of the generally small primary cyst, producing a crunching noise when cut. These cystoid proliferations have no proper capsules. Their interiors display necrotic cavities and colloidal, jelly-like contents. (s. figs. 25.21, 25.22)

**Fig. 25.21:** Laparoscopic view of multiple Echinococcus alveolaris hydatids in the right lobe of liver

**Fig. 25.22:** Echinococcus alveolaris hydatid: pseudocyst surrounded by a rim of radially arranged histiocytes. Markedly damaged adjacent liver parenchyma. Small parasitic membranes in the bright lumen of the pseudocyst (arrow) (HE)

**Macroscopy:** In terms of macroscopy, alveolar echinococcosis presents in two different forms, whereby the latter is more common:

(*1.*) *pseudometastatic multinodular form* (= generally isolated, white, hard nodules on the liver surface without central retractions such as are found in metastases)

(*2.*) *confluent form* (= irregular, yellowish-white plaques on the liver surface)

**Diagnosis:** Alveolar echinococcosis is a rare, but severe disease. Diagnostics and therapy resemble that of carcinoma. The incubation period is unknown. The latency period before clinical symptoms appear is 5−15 years. As with E. cysticus, an early diagnosis is not possible. However, uncharacteristic ailments can occur earlier and with greater intensity. From the clinical viewpoint, there is a discrepancy between the good general state of health of the patient and the increasingly severe organic destruction. The outbreak of disease possibly depends upon the individual immunogenetic predisposition or resistance. • Over the years, hepatomegaly develops. Fever, growing malaise and epigastric pain with occasional radiation to the right shoulder are in evidence. In some cases, right-side pleural effusion, transitory erythema, tingling in the nose and sweats are observed. Tuberous resistance, as hard as cartilage, may be palpable in the area of the liver. • Laboratory examinations reveal eosinophilia in ca. 40% of cases; inflammatory parameters (ESR, CRP, leucocytes, α- and γ-globulins) and enzymatic activities (GPT, GOT, γGT, AP) are generally elevated. Slight jaundice is sometimes detectable. The diagnosis is obtained by confirmation of specific antibodies (e.g. by means of Em1-/Em2-antigen). Thus a differentiation can be made between the cystic and the alveolar type of echinococcus. Direct identification of the pathogen is achieved by means of PCR. • In ultrasonography, E. alveolaris is seen as irregularly delineated, with an echogenic and hypoechoic, inhomogeneous

internal structure, so that it is often indistinguishable from a malignant tumour. (140) (s. p. 120) In angiography, E. alveolaris also resembles a malignant tumour, showing a constricting, stretching or corkscrew-shaped arrangement, irregularities in the walls and convolutions of the arteries. CT and MRT provide a better basis for differential diagnosis. MRT shows the areas of necrosis and the periportal or perihepatic spread on $T_1$. (s. p. 156) • In laparoscopy, white or grey, hard nodular proliferations up to the size of a hazelnut are visible on the surface. Sufficient material can be obtained by forceps biopsy (there is no danger of anaphylactic shock).

**Complications:** The following complications have been reported: (*1.*) cholangitis, (*2.*) obstructive jaundice, (*3.*) intrahepatic cholelithiasis, (*4.*) sepsis, (*5.*) portal hypertension (oesophageal varices, portal vein thrombosis, chronic Budd-Chiari syndrome, etc.), (*6.*) thrombosis of the inferior vena cava, (*7.*) amyloidosis, (*8.*) immune complex-associated glomerulonephritis, (*9.*) metastases, (*10.*) "acute on chronic" liver insufficiency or acute liver failure, and (*11.*) bronchobiliary fistula.

**Treatment:** Treatment of E. alveolaris has no influence on the generally poor prognosis. In isolated cases with an early diagnosis, some improvement has been attained by extensive surgical procedures (e. g. en bloc resection of the liver with lymphadenectomy). At best, this method is applicable in 20−40% of patients. As a rule, however, no successful surgical intervention is possible because of the advanced hepatic infiltration. • Orthotopic liver transplantation, already reported in more than 40 incurable cases, would, therefore, seem to be the last resort. An indication is given if the lesions are inaccessible and thus cannot be removed by partial resection of the liver, in cases of chronic Budd-Chiari syndrome or in secondary biliary cirrhosis, and if no metastases are present. The survival rate after liver transplantation is about 65% after 5 years. Late mortality may be attributed to relapses in the transplant or the formation of metastases. (133) • Medicamentous therapy (mebendazole) starts some 4 weeks before surgery and is continued until the normalization of serologic parameters, if necessary in adequate dosage lifelong. • The 10-year survival rate of inoperable patients could be improved with the aid of consistent and continuous chemotherapy (mebendazole, albendazole) by up to 85% (as compared to 10% without this therapy). (126, 137, 141, 147)

## 26  Mycotic infections and the liver

# 26 Mycotic infections and the liver

▶ *The clinical diagnosis of any mycosis requires proof of the pathogenic fungus and, as far as possible, additional differentiation by fungal culture.* • **Endogenous mycosis** is a fungal infection caused by saprophytic fungi − normal inhabitants of the gastrointestinal tract − especially as secondary mycosis following other immunocompromising diseases. • **Exogenous mycosis** is caused by primary pathogenic fungi: it may be localized or generalized, and it may show a preference for certain tissues or systems. • **Systemic mycosis** shows widespread dissemination, predominantly affecting particular organs and tissues; it may originate from endogenous or exogenous mycosis. • *Thus, a mycotic disease of the liver and biliary tract is always systemic.*

## 1 Predisposing factors

Hepatic or biliary mycosis is only likely to occur with a deficiency of the endogenic defence response. However, in isolated cases, discussion has also centred on locally impaired defence mechanisms (e.g. after ERCP (17), choledocholithiasis, papillotomy) which cause or exacerbate an existing mycotic focus. There have been several cases without any noticeable immunosuppression (e.g. aspergillosis and candidosis). The occurrence of systemic and organ mycosis is causally related to many factors or events leading to a reduced immune response, especially the clearance function of the hepatic RES. Saprophytic fungi thus become opportunistic pathogens, which, like exogenous primary pathogenic fungi, gain the upper hand over the body's defence system. (s. tab. 26.1)

## 2 Pathogens

Hepatobiliary organ mycosis may be caused by several fungal species, whereby the Candida species by far outnumber the others. With the exception of Candida sp. and Mucor sp., all hepatotoxic fungi have an airborne route of infection. (s. tab. 26.2)

## 3 Diagnosis

Even though hepatobiliary mycosis is a rare occurrence in terms of numbers, the possibility of mycotic infection should always be considered in the presence of predisposing factors or respective events. • Signs of such a complication include additional **complaints** (e.g. loss of appetite, increasing malaise, tenderness in the right epigastrium) or **clinical symptoms** (e.g. fever of unknown origin − especially in non-response to antibiotics − hepato(spleno)megaly) and **laboratory parameters** (e.g. increase in transaminases, alkaline phosphatase, serum bilirubin, ESR, CRP, decrease in ChE). (s. tab. 27.4)

1. Medicaments
   − immunosuppressants
   − glucocorticoids
   − cytostatics
   − antibiotics
2. Immunological diseases
   − e.g. AIDS, collagenosis
3. Haematological diseases
   − e.g. leukaemia, aplastic anaemia
4. Malignant diseases
5. Organ transplantation
6. Severe hepatic dysfunction
7. Serious acute diseases
   − e.g. pancreatitis, endocarditis, peritonitis
8. Chronic renal diseases
   − e.g. glomerulonephritis, dialysis
9. Intensive care
   − e.g. artificial respiration, parenteral feeding
10. Infectious diseases
    − e.g. salmonellosis, tuberculosis
11. Diabetes mellitus
12. Burns
13. Major surgery
14. Prepartal and postpartal complications
15. Chronic alcoholism
16. Malnutrition
17. Ileus
18. Tooth extraction
19. ERCP, papillotomy

***Tab. 26.1:*** Predisposing factors for organ mycosis, including the liver and biliary tract

**Ultrasound** and **CT** only reveal hepato(spleno)megaly or suggest multiple foci similar to small abscesses, possibly in the form of a "snowstorm" − and occasionally biliary congestion as a result of obstruction due to fungal masses. (1, 2, 13, 15, 25, 26, 28, 29) • **MRI** is a better diagnostic tool (85−100%) − equally reliable information was also obtained with MRI when monitoring the treatment and follow-up of hepatolienal mycoses. (7)

These hints of hepatolienal mycosis can be confirmed by **liver biopsy** or **fine needle biopsy.** (9, 18, 20, 51, 52) In this respect, however, only a small area is examined by the puncture technique, with the result that negative histological findings are not always representative of the liver as a whole. Diagnostic reliability is, of course, increased by taking 2 or 3 biopsy samples from the two lobes of liver during laparoscopy. (s. pp 157, 161) • Conclusive proof of **mycosis** is obtained by (*1.*) microscopic examination, (*2.*) serological tests or immunoassays, and (*3.*) fungal culture.

1. Candida species
   - C. albicans, C. glabrata (22), C. krusei
     C. parapsilosis, C. tropicalis
2. Aspergillus species
   - A. flavus, A. fumigatus, A. niger
3. Blastomyces species
   - B. brasiliensis, B. dermatitidis
4. Trichosporon species
   - T. beigelii, T. capitatum
5. Cryptococcus neoformans
6. Coccidioides immitis
   Paracoccidioides brasiliensis
7. Histoplasma capsulatum
8. Torulopsis glabrata
9. Mucor indicus
10. Prototheca wickerhamii
    Prototheca zopfii
11. Coniothyrium fuckelii

**Tab. 26.2:** Fungal species causing hepatobiliary organ mycosis in the presence of predisposing factors

# 4 Morphological findings

Systemic organ mycosis is characterized by different manifestations in the area of the liver or biliary tract. The manifestations vary depending on the type of mycosis, and indeed some of them have only been seen in certain mycosis forms. The following morphological findings have been reported:

1. Granulomas
   Granulomatous suppurative or caseating foci
2. Microabscesses and small abscesses
3. Cholangitis
4. Hepatitis
   - portal, often eosinophilic cellular infiltration
   - focal inflammatory lesions
   - single-cell necrosis
5. Mesenchymal reactions
6. Splendore-Hoeppli phenomenon (s. p. 397, 497)
7. Biliary obstruction by fungal conglomerates

# 5 Hepatobiliary organ mycoses

## 5.1 Candidosis

▶ Some of the facultative pathogenic Candida species are extremely common pathogens responsible for mycosis of the hepatobiliary system. (s. tab. 26.2) This candida mycosis, also called thrush or moniliasis, is a typical **opportunistic mycosis,** generally known about more than 140 years ago as the *"disease of the sick"*. The human intestinal tract serves as a reservoir for pathogens in the body. As a rule, thrush initially manifests in the area of the oral and pharyngeal mucosa. Depending on the degree of impairment of the body's own defence mechanisms, the candida infection can disseminate further into the tracheobronchial system and gastrointestinal tract, where it penetrates the intestinal wall and, via the vascular system, affects other organs (liver, lungs, spleen, bone marrow, eyes, CNS, endocardium)

as well; it may also spread systematically, possibly as septicaemic candidosis. (11)

In most cases, the liver and spleen are concurrently and similarly affected, especially in the form of microabscesses (= *hepatolienal candidosis*). A greater risk of candidosis exists for patients with severe hepatic dysfunction, in particular cirrhosis or acute liver failure (5, 19, 32), after marrow or liver transplantation (3, 6, 8) and with leukaemia or carcinoma. (1, 4, 31) Fever of unknown origin and non-response to antibiotics are suggestive of systemic candidosis. Alkaline phosphatase is always elevated. (14, 21, 24, 25) • *Morphological findings* include granulomas (12, 20, 21, 30), hepatitis-like lesions (18), microabscesses (1, 2, 4, 28), cholangitis (16), biliary obstruction by fungal conglomerates (10, 22, 23) and perihepatic adhesions. (12) • *Sonography* shows multiple small abscesses (> 5 mm in diameter), which are usually detectable as hypoechoic areas and target zones; however, aetiological clarification is not possible. "Wheels within wheels" is considered to be more characteristic: a round, hypoechoic (fibrosis-related) focus shows an inner hyperechoic (inflammation-related) zone, which, in turn, exhibits an inner hypoechoic (caseation-related) area. (26) Sonographic clues to candidosis of the (generally enlarged) liver and spleen (9, 13, 15, 24−28) are further underpinned by *computer tomography* and *MRI*, using gadolinium as a contrast medium. Cytological or histological clarification and cultural or serological tests as well as DNA analysis (PCR) are now indicated. Lethality is 40−50%.

## 5.2 Aspergillosis

▶ **Environmental reservoirs** for the Aspergillus species (s. tab. 26.2) include damp cellars and old stone walls, soil in flowerpots (thus possibly in hospital rooms!) and mouldy food. The aflatoxins of the mould Aspergillus flavus (e. g. in mouldy nuts) are deemed to have a high *carcinogenic potential*.

The aspergillus spores enter the body through *airborne transmission*, nearly always via the respiratory tract. Under normal conditions (good defence response, no excessively high germ count), aspergillus is eliminated. In cases of reduced body-own defence (s. tab. 26.1), the mucosa is affected more severely, and after vascular invasion, generalized aspergillosis also occurs. The lungs are mainly affected in the form of bronchopulmonary aspergillosis, aspergilloma or aspergillus pneumonia. Generalization may likewise affect other organs, such as the *liver* and *spleen*. Focal lesions can be detected by imaging techniques. (35, 37) Disseminated aspergillosis has also been reported in acute liver failure. (36, 38) Following liver transplantation, aspergillosis is a feared and relatively frequent complication (6−10% of cases). (3, 8, 33, 34, 37)

## 5.3 Blastomycosis

Blastomyces species cause South American (B. brasiliensis) and North American (B. dermatitidis) blasto-

mycosis (s. tab. 26.2), the budding forms of which are also found in body tissue. The pathogens are mainly transmitted via the respiratory tract, which explains why bronchopulmonary infections clearly predominate. Yet, multiple organ involvement, particularly with Blastomyces dermatitidis, is also known.

A case report of blastomycosis of the *hepatobiliary system* describes the following conditions: (39) development of chronic cholangitis in the area of the left hepatic duct with encroachment of the mycotic inflammation to the left lobe of liver in cases of predisposing and/or pre-existing choledocholithiasis; histological evidence of liver granulomas and periportal fibrosis; marked increase in alkaline phosphatase and γ-GT. (40)

### 5.4 Trichosporosis

Systemic infection induced by the Trichosporon species (s. tab. 26.2) may lead to sepsis and, in the liver, to marked hepatitis-like findings, granulomas and micro-abscesses. Laboratory tests revealed an increase in transaminases, alkaline phosphatase and bilirubin. Diagnosis was confirmed by liver biopsy and fungal culture. (41, 42)

### 5.5 Cryptococcosis

Mycosis caused by *Cryptococcus neoformans*, also termed European blastomycosis, is airborne and reaches the organism via the respiratory tract. The source of infection is mostly bird excrement, especially pigeon droppings. The pathogen consists of large round yeast cells, 10 μm in diameter, surrounded by gelatinous capsules. It can be selectively demonstrated by mucicarmine staining or Chinese ink.

In generalized cryptococcosis, hepatitis-like findings, simulating a surgical emergency (47) or causing peritonitis (44) and cholangitis (43), were reported; in a further case, the clinical picture of primary sclerosing cholangitis was imitated. (45) Cryptococcosis is mainly found in AIDS patients. Both acute liver failure and liver cirrhosis have also been provoked by cryptococcosis. (46, 48) Proof is obtained by histological and microscopic examination as well as by fungal culture, and, if necessary, by serological tests.

### 5.6 Coccidioidomycosis

The mycelial fungus *Coccidioides immitis*, affecting both humans and animals, is rarely encountered in Europe, whereas endemic areas are known in America. • In this context, coccidioidomycosis *(Paracoccidioides brasiliensis)* should also be mentioned.

In disseminated coccidioidomycosis (A. Posada, 1894), lung involvement is predominant; however, in 45−60% of cases, autopsy findings showed the *liver* to be affected as well. The principal manifestations are granulomas

and small abscess-like foci. Clinical findings generally include fever, hepatomegaly and eosinophilia as well as an increase in transaminases and occasionally in serum bilirubin. Liver biopsy provided the diagnosis in almost all cases. (49−54)

### 5.7 Histoplasmosis

▶ Disseminated infection with *Histoplasma capsulatum* is a form of mycosis frequently found in North and South America, but rarely in Europe. It affects both animals and humans. Henhouses and caves inhabited by bats are ideal breeding grounds. Infection is usually by inhalation of dust, which is why the lungs are primarily affected. In body tissue, the pathogen is demonstrable as yeast cells, 3−5 μm in diameter, mainly localized intracellularly. As a rule, pulmonary infection runs a mild course with a good healing tendency.

Lymphogenous dissemination from the primary pulmonary focus, however, leads to serious generalized disease in the form of chronic, slowly progressive reticuloendotheliosis with fever, lymphadenopathy and splenomegaly. With *liver* involvement (organ mycosis), there is evidence of hepatomegaly with many epithelioid cell granulomas, some with central necrosis. These granulomas may subsequently become fibrous and even calcify. The fungus can be demonstrated in the RES cells and in the granulomas by PAS staining or silver impregnation. Histoplasmosis can remain latent in the body for decades before being reactivated. (55−58)

### 5.8 Torulopsosis

Of the approximately 36 Torulopsis species known so far, *T. glabrata*, also classified as a Candida species, is a human pathogen. Dissemination leads to colonization of the fungus in many organs and the development of liver abscesses. Severe hepatobiliary torulopsosis was also diagnosed in one patient with diabetes and bile duct stricture, secondary to chronic pancreatitis. (59)

### 5.9 Mucormycosis

Mucormycosis of the liver is a rare condition. In one reported case, widespread dissemination of *Mucor indicus*, resulting from isolated ileocoecal mucormycosis with markedly reduced body-own defence, led to liver infection with multiple abscesses. A serious clinical picture with fever, hepatomegaly and icterus developed. The multiple abscesses could be identified by CT and the fungal infection confirmed by microscopic examination or cultures of biopsy specimens. (60−62)

### 5.10 Protothecosis

Of the many Prototheca species, only *P. wickerhamii* and *P. zopfii* cause disease in humans. Infection only occurs when the body's defence system is seriously impaired. Liver involvement is rare. In one noteworthy case, a

severe feverish hepatobiliary disease simulating sclerosing cholangitis, as demonstrated by ERC, was reported. Liver biopsy showed portal infiltration with eosinophilic cells and granulomas as well as fibrosis. (63, 64)

## 5.11 Coniothyrium mycosis

Liver infection with *Coniothyrium fuckelii* in a female patient with leukaemia was reported for the first time in 1987. (65) The acute clinical picture consisting of fever, arthralgia and myalgia, nightly sweats, increased inflammatory parameters and enhanced alkaline phosphatase could be identified, after extensive examination, as a fungal infection of the liver. Histology revealed focal, partly granulomatous inflammatory lesions, from which C. fuckelii was demonstrated by culture.

# 6 Therapy

The fungistatic therapy, which has been used so far, includes (liposomal) amphotericin B, also in combination with 5-fluorocytosine, fluconazole, ketoconazole and itraconazole.

The possibility of **mycosis** should be considered in all those patients with liver disease and reduced body-own defence who are experiencing growing malaise and fever!

# Clinical Aspects of Liver Diseases

## 27 Liver abscess

# 27 Liver abscess

## 1 Definition

The term liver abscess describes a circumscribed, often encapsulated, purulent inflammation with necrosis of the local parenchyma caused by a multitude of pathogens (bacteria, protozoa, helminths) and fungi. Liver abscesses can be detected as a solitary or multiple occurrence. Microabscesses are also witnessed, diffusely affecting the entire liver, sometimes as the outcome of purulent, suppurative cholangitis.

## 2 Pathogenesis

Infection can develop in five different ways, whereby a weakening of the body's defence system enormously heightens susceptibility. (13, 42, 91) (s. tab. 27.1)

1. **haematogenic:** via the *proper hepatic artery* in severe septic processes (e. g. furunculosis, osteomyelitis) as a metastatic-pyaemic liver abscess, or via the *portal vein* as a pylephlebitic liver abscess (such as in appendicitis, colitis, diverticulitis), and occasionally via the *umbilical vein* as omphalophlebitis
2. **biliary:** via the bile ducts, arising from cholecystitis or cholangitis as well as from the invasion of parasites or foreign bodies
3. **per continuitatem:** spread of inflammatory processes to the adjacent areas (e. g. gall-bladder empyema, subphrenic or perinephritic abscess)
4. **posttraumatic:** following injuries to the liver or as a result of intrahepatic haematoma
5. **postoperative**

*Tab. 27.1:* Access routes leading to the development of liver abscesses

## 3 Pathogens

Fundamental differentiation may be made between four types of liver abscess, depending on the **aetiology:**

| | |
|---|---|
| 1. bacterial abscess | 3. helminthic abscess |
| 2. protozoal abscess | 4. fungal abscess |

The causative **pathogen** can be detected directly from the abscess or by cultures set up from the blood or bile, sometimes even from the urine or stool. It can also be detected microscopically (e. g. evidence of parasites or their eggs and larvae) and sometimes serologically or sonographically (e. g. Ascaris lumbricoides, s. figs.

25.5−25.8). In order to reach a diagnosis, it is necessary to select the examination method which is most suitable for the detection of the respective pathogen. When applying suitable bacteriological techniques, anaerobes can be found in 30−40% of cases. Solitary liver abscesses (63%) displayed a polymicrobial pathogenic spectrum in twice as many cases as did multiple abscesses (30%). (13) Streptococcus milleri is a very common cause. (72) It can be cultured in a carbon dioxide-enriched medium. (s. tab. 27.2)

**Bacteria** (12, 21, 24, 27, 32, 36, 39, 70, 87, 91, 97)

**Gram-negative aerobes**
Acinetobacter
Brucella species (86, 107)
Campylobacter jejuni (14)
Citrobacter freundii
Edwardsiella tarda (116)
Eikenella corrodens
Escherichia coli
Klebsiella species (19)
Proteus species
Pseudomonas species (108)
Salmonella species (35, 95)
Yersinia species (1, 6, 26, 49, 58, 105)

**Gram-positive aerobes**
Listeria monocytogenes (63, 84)
Mycobacterium tuberculosis (18, 43)
Pediococcus acidilactici (93)
Staphylococcus (38, 109)
Streptococcus pneumoniae (61)
Streptococcus species (64, 72)

**Gram-negative anaerobes**
Aeromonas hydrophilia (96)
Bacteroides species
Fusobacterium nucleatum (90)

**Gram-positive anaerobes**
Actinomyces (9, 69)
Clostridium species
Diphtheria species
Lactobacillus (11)
Peptostreptococcus
Streptococcus anaerobius

**Protozoa**
Amoebiasis

**Helminths**
Ascaris lumbricoides
Fasciola hepatica

**Fungi**
Aspergillosis
Candida species (92)
Mucormycosis
Torulopsis glabrata
Trichosporon species

*Tab. 27.2:* Main pathogens (bacteria, protozoa, helminths, fungi) of liver abscesses and microabscesses (with some references) *(see chapters 24, 25 and 26)*

# 4 Causes

The frequency of **cryptogenic liver abscesses** (at one time $30-40\%$) has now been reduced to $10-15\%$ as a result of modern contrast-medium imaging procedures and improved or more advanced serological, bacteriological and parasitological methods. Improved diagnostic clarification of the clinical picture in terms of respective pathogens and other causes has contributed to better treatment results and a clear drop in mortality. (91, 113)

<div style="border:1px solid">

1. Biliary diseases
   − cholecystitis
   − cholangitis
   − cholelithiasis, choledocholithiasis (5, 31)

   − pancreatic carcinoma (114)
   − pancreatic surgery
5. Trauma, abdominal injuries
6. Abscesses of adjacent organs
   − perinephritic abscess
   − subphrenic abscess
   − retrocaecal abscess
   − gall-bladder empyema
   − gall-bladder carcinoma (114)
7. Parasitoses
   − amoebiasis
   − Fasciola hepatica
   − Ascaris lumbricoides
8. Thrombophlebitis
   − portal vein (pylephlebitis)
   − umbilical vein (omphalophlebitis)
9. Alcohol injections for HCC (28, 44, 75, 94)
10. Leukaemia
11. Chronic granulomatosis (37, 41)
12. Arterial embolization (88)
13. Ligature of the hepatic artery (46, 101)
14. Haemosiderosis and yersiniosis (6, 105)
15. Haemorrhoidectomy (76)
16. Infected liver cysts and echinococcus cysts
17. Passage of a swallowed toothpick (2, 47) or fish bone through the stomach into the liver
18. Cryptogenic diseases

</div>

**Tab. 27.3:** Underlying diseases causing the development of liver abscesses (with some references)

The **spectrum** of causative diseases in the development of a liver abscess has changed significantly over the past 10 years, as have the respective frequency rates. The perityphlitic abscess, once predominant in appendicitis, is now relatively rare; in contrast, traumatic injuries to the liver or adjacent organs as a result of accidents have increased in frequency (some 10%); the biliary infection route has acquired much greater significance ($35-40\%$). Of note is the rising number of liver abscesses caused by the Yersinia species in patients suffering from haemosiderosis or haemochromatosis, or following long-term substitution of iron, since the metabolism of the Yersiniae is iron-dependent. • With regard to all these causative factors, a *weakening of the body's own defence system* (s. tab. 26.1), such as in diabetes mellitus and alcoholism or during a course of treatment with immunosuppressants, glucocorticoids and chemotherapeutic agents, increases the risk of infection. (13, 15, 25, 57, 71, 90) The causes of abscesses hitherto reported have been numerous and diverse. (48) (s. tab. 27.3)

# 5 Clinical picture and diagnosis

## 5.1 Clinical findings

In **clinical** terms, continuous or intermittent *fever* predominates. (54) In children with fever of unknown aetiology, a liver abscess should always be considered when setting up the differential diagnosis. Additional signs of febrile infection include bursts of perspiration, night sweats, lack of appetite, loss of weight, nausea, weakness and a general malaise. *Local symptoms* are abdominal pain in the right upper quadrant, radiation of pain to the right shoulder, occasional respiratory pain on the right side and irritable (dry) cough. The liver is often enlarged and tender on pressure; guarding of abdominal muscles is usually in evidence. (54) The clinical course can proceed gradually, yet may also show dramatic symptoms (e. g. shivers, sepsis, jaundice, shock), especially in the case of purulent cholangitis.

## 5.2 Imaging procedures

**Sonography** is the method of choice for identifying a liver abscess (sensitivity $71-92\%$ for foci $>1.5$ cm). Frequently, especially with small and multiple foci, the liver structure is initially inhomogeneous; clearly definable focal lesions only develop during the further course of disease. As a rule, sonographic morphology shows circular foci which are hypoechoic to anechoic. The echogenic focus usually appears as fluid-filled with several internal echoes. Sometimes, however, a fluid level can actually be detected. Multiple small abscesses aggregate, suggesting the beginning of coalescence into a single larger abscess ($=$ *cluster sign*). (45) Should no gas be present in the abscess, a dorsal reduction in sound waves ($=$ *comet tail*) is observed. Splenomegaly is frequently

witnessed. In addition, particularly with mycotic abscesses, an anechoic focus is visible with a centre that is rich in echoes (= *target phenomenon*); such an abscess occasionally presents an anechoic centre inside the echo-rich area (= *double wheel structure*). (15, 17, 18, 33, 40, 58, 109) (s. p. 132) (s. figs. 6.11; 25.1!)

**Computer tomography,** besides establishing the diagnosis (in 86−93% of cases with foci >0.5 cm), also makes it possible to locate the abscess exactly. (s. fig. 27.1) When enhanced with a contrast medium, CT can differentiate an abscess from an intrahepatic metastasis. Pyogenic and mycotic abscesses are visible as hypodense areas both in their natural state as well as after administration of a contrast medium; occasionally, the contrast medium is visible as a ring-shaped enhancement. A small amount of ascites may be detectable. With the help of ultrasonography and computer tomography, it is possible to carry out guided aspiration or drainage of an abscess reliably. (15, 58, 71) (s. p. 175)

*Fig. 27.1:* CT scan shows multiple pyogenic liver abscesses in segment 4 (a and b) following perforation in diverticulitis (E. coli). Full recovery

**X-ray examination** of the chest and abdomen is still imperative, despite the paramount importance of ultrasonography. These standardized routine techniques are usually applied prior to computer tomography because of the wide spectrum of findings acquired as well as the considerably lower costs involved. (13, 36, 80) • In the case of liver abscess, the following findings can be detected in the area of the *thorax*: (*1.*) lack of diaphragmatic motion or right-sided diaphragmatic elevation (40−65%), (*2.*) masking of the right-sided phrenicocostal angle, (*3.*) pleural effusion on the right (40−50%), (*4.*) hypoventilation and atelectasis of the right lower pulmonary lobe, (*5.*) subdiaphragmatic air-fluid level, (*6.*) free air in the subdiaphragmatic area, and (*7.*) infiltration of the lungs. • In the *abdominal area*, the

following findings are occasionally observed: (*1.*) evidence of intrahepatic air, (*2.*) intrahepatic air-fluid level, (*3.*) free air in the biliary tract, and (*4.*) foreign bodies.

**Cholangiography:** In the event that a biliary cause is suspected, cholangiography (i.v., ERC, PTC) may be indicated. With PTC, multiple abscesses mimic the picture of sclerosing cholangitis. (55, 98)

**Angiography** is deemed indispensable during the course of preoperative preparations for an extensive partial resection of the liver in order to demonstrate atypical arteries. It can also be helpful in detecting multiple small abscesses, where vessels as well as hypervascular zones surrounding small avascular areas are typically pushed aside or displaced.

**Scintigraphy,** preferably using $^{99m}$Tc sulphur colloid or $^{67}$Ga-citrate, detects a focal lesion with an abscess of >1.5−2 cm in approximately 80% of cases. (s. fig. 9.2) However, the rate of false-negative findings is quite high, and differentiation cannot be made between abscess, tumour, cyst or haemangioma. For this reason, scintigraphy is of no clinical relevance for diagnosing an abscess.

**Magnetic resonance imaging** produces different elevations of the signal intensity in the $T_2$-weighted image in 70−75% and hypointensity in the $T_1$-weighted image in approx. 60% of cases. A perifocal oedema (pointing to an inflammatory process), which receded rapidly after good response to therapy, was detected in 30−40% of cases. After administration of a contrast medium, over 80% of cases displayed wheelspoke-like enhancement. (67)

## 5.3 Laboratory parameters

Laboratory investigation reveals signs of infection as well as liver disease depending on the degree of severity, the course of disease and the extent of involvement of the bile ducts. (10, 13, 24, 36, 40, 48, 50, 66, 74, 80, 91, 97, 113) (s. tab. 27.4)

1. *Signs of infection*
   - changes in the blood count (leucocytosis, left shift, anaemia)
   - BSR ↑, CRP reaction +
   - fibrinogen, LDH ↑
   - serum iron ↓
   - changes in electrophoresis ($\alpha_2$- and $\gamma$-globulins ↑, albumin ↓)

2. *Signs of liver disease*
   - GPT, GOT, GDH ↑
   - $\gamma$-GT, alkaline phosphatase ↑
   - serum bilirubin ↑
   - cholinesterase, Quick's value ↓
   - bile acids ↑

*Tab. 27.4:* Laboratory parameters in liver abscess(es) depending on the respective degree of severity and course of disease and on the involvement of the biliary tract

## 5.4 Aspiration material

Diagnosis is reached by means of needle aspiration of the abscess guided by ultrasonography or computer tomography and subsequent examination of the abscess

contents. In pyogenic abscesses, it is possible to detect one or several pathogens in 62−95% of cases. (quot. 70; 85) Gram-negative aerobic bacteria are found in approx. 60% and gram-positive aerobic pathogens in 15−20% of cases. In order to detect anaerobic bacteria (approx. 20% of cases), utmost care is required when collecting the anaerobic cultures; so-called sterile cultures are often due to mistakes made during the process of collection or are attributable to preceding antibiotic therapy. The aspiration material should also be tested by selective culture, since mixed infections resulting from both bacteria and fungi may be present. In individual cases, microscopic examination can make it possible to differentiate between tumorous and mycotic material. The respective results determine therapy requirements; with the help of targeted treatment, greater efficacy can be achieved.

## 6 Localization

The right lobe of liver, especially the dorsal segments, is most frequently involved (60−70%). In 20−30% of cases, both lobes are affected. Solitary abscesses are localized in the right lobe of liver in 80−90% of cases. Multiple abscesses can be observed in approx. 40% of patients. Subhepatic localization of an abscess was observed following the perforation of a gastric ulcer (11) and conventional cholecystectomy. (111)

## 7 Complications

With pyogenic abscesses, the most frequent complication is septicaemia and its deleterious sequelae. The abscess can, however, also penetrate the biliary tract or the intrahepatic vascular system (59), or rupture into the abdominal cavity and subphrenic space. (22) Sometimes, thrombosis of the portal vein develops. Penetration through the diaphragm into the pleural cavity and the pulmonary parenchyma is likewise to be feared. Pyogenic or mycotic sepsis can also give rise to endophthalmitis, particularly in patients suffering from diabetes mellitus. (23, 100) Initial signs of eye symptoms in the presence of a liver abscess call for immediate examination by the ophthalmologist and, if necessary, appropriate treatment. • *Gas-forming pyogenic abscess:* Numerous pathogens are capable of gas formation, especially klebsiella pneumoniae. Such gas reveales four major constituents: nitrogen, oxygen, carbon dioxide and hydrogen. This composition implicates mixed acid fermentation of glucose as the mechanism of gas formation.

## 8 Therapy

### 8.1 Conservative treatment

1. Multiple, small and minute abscesses are not accessible to invasive or surgical treatment. Hence it is import-

ant to sanitize any focus of infection to prevent it from spreading and to combat the infectious toxic process by suitable therapeutic measures. A bacteriological analysis must be obtained as early as possible by aspiration of the abscess area using a thin needle. Until the pathogenic result is available, a combination of antibiotics should be administered which covers the aerobic as well as the anaerobic spectrum of the most frequent pathogens (e. g. E. coli, Proteus, Klebsiella, Bacteroides fragilis, aerobic and anaerobic streptococci, staphylococci). A suitable combination is cephalosporin + metronidazole + aminoglycoside. The combination of aminoglycoside + clindamycin has also proved helpful. (48) Once the bacteriological result is available, the antibiotic combination is altered in line with the antibiogram, possibly supplemented in the individual case by a fungistatic agent. The duration of parenteral administration is 10−14 (−21) days with subsequent oral treatment for about 3 to 4 weeks. Prior to cessation of the antibiotic therapy, a check-up should be carried out by ultrasonography and/or computer tomography. In the case of successful treatment, the abscess is either obliterated or at least significantly reduced. (36, 48)

2. It is probable that antibiotics will reach the interior of those abscesses which are still relatively small and have only existed for a short period of time. In these cases, too, the spectrum of aerobic and anaerobic bacteria should initially be covered non-specifically by the above-mentioned combination of antibiotics. At the same time, the presence of an amoebic abscess or echinococcosis should be ruled out serologically (as quickly as possible) and aspirated material collected for bacterial and mycotic testing. Depending on the results, the respective antibiotic (and possibly fungistatic) therapy is effected. After 2−3 (−4) days, the efficacy of this targeted treatment is reviewed clinically and biochemically as well as ultrasonographically. If the treatment is considered to have been effective, it is continued until obliteration of the abscess foci is achieved. (12, 29, 53, 60, 64, 74, 91, 97, 113)

### 8.2 Aspiration treatment

1. Should initial antibiotic therapy fail to show any success within the limited period of 2−4 days (persistence of fever, leucocytosis, bacteriaemia), percutaneous aspiration of the abscess contents, if necessary repeated several times during the next few days, usually proves successful. Antibiotic therapy is continued during the course of percutaneous aspiration treatment.

2. In an extremely large abscess, percutaneous aspiration of the focus with evacuation of the pus is carried out as an initial measure. Generally, several punctures have to be performed with respective aspiration of the focal contents until the abscess cavity is gradually obliterated under the impact of specific antibiotics. The outcome of

this form of treatment is considered to be more favourable and the concomitant complications (e. g. intraperitoneal contamination, bleeding) are less numerous than with percutaneous drainage. (4, 12, 13, 24, 35, 40, 42, 53, 81, 85, 92, 97, 99, 113, 115)

## 8.3 Percutaneous drainage

▶ Percutaneous drainage was initially attempted by A. F. S MacFadzen et al. in 1953. It was later introduced into clinical routine by J. R. Haaga et al. (1976) (s. tab. 7.2) using the CT-guided method. An improved technique was applied by S. G. Gerzof et al. (1981) and proved very successful in the treatment of liver abscesses.

**Puncture** is effected using a teflon-coated 18 (or 20) gauge needle. After aspiration of the contents, a pigtail catheter (7 or 8 Charrière scale) is placed in the cavity of the abscess by means of a guidewire. Subsequently, the **position of the catheter** and the abscess cavity itself are checked by computer tomography to ensure that there is no septation and that the abscess cavity is completely drained. Once the catheter has been placed in an optimal position, the pus is totally evacuated and the cavity rinsed clean with a physiological NaCl solution. The original catheter may be replaced later, if necessary, by one with a wider lumen (14−16 Charrière scale). • Simultaneous **antibiotic therapy** is readjusted according to the bacteriological results and the antibiogram. Additional injection of antibiotics into the abscess cavity can further improve the efficacy of the parenteral and subsequent oral antibiotic treatment.

The drainage can be removed if ultrasonography or computer tomography show the abscess cavity to be completely (or extensively) obliterated, if no more fluid can be detected and if the white blood cell count has dropped to below 10,000/mm$^3$. This method of treatment of liver abscesses has proved its worth; success rates are of 70−90%. (8, 24, 25, 30, 34, 40, 42, 53, 54, 56, 66, 72, 77, 81, 83, 85, 99, 111, 112, 113)

## 8.4 Surgical drainage

Percutaneous drainage may be limited by antelocated intestinal loops or by abscesses that are difficult to reach. Similarly, surgery is indicated following unsuccessful percutaneous drainage, in extensive cavernous or multifocal abscesses, tissue sequestration, formation of enteral fistula and viscous abscess contents as well as local recurrences. • With abscess perforation or the existence of other purulent foci in the abdomen, surgical intervention is called for immediately.

The **surgical approach** depends on the location of the abscess, any abdominal investigation that may be required, and possible sanitization of a focus. • The respective **access routes** are: (*1.*) transperitoneal, (*2.*) extraperitoneal, (*3.*) in special cases also retroperitoneal or infrapleural, and (*4.*) transpleural as well as transdia-

phragmatic. Evidence of biliary genesis calls for operative or endoscopic sanitization of the biliary tracts and safeguarding of the biliary flow, possibly via a T drain in the choledochus. (8, 24, 42, 53, 54, 72, 78, 85, 99, 113)

**Laparoscopic drainage:** An alternative to the open surgical drainage of abscesses can be found in laparoscopic drainage. This method is deemed to be safe and successful. In a group of 20 patients, there were no intraoperative or postoperative complications. (103) Consequently, before deciding on open surgery, the possibility of laparoscopic abscess drainage should be considered.

## 8.5 Liver resection

Liver resection as treatment of a liver abscess is still reserved for exceptional circumstances. Nevertheless, the **advantages** are definitive sanitization of the abscess, an insignificant degree or indeed absence of peritoneal contamination, short-term postoperative antibiotic therapy and the possibility of histological clarification in the event of suspected superinfected malignant tumours. Moreover, the quality of life is nowhere near as limited as with the various operative drainage procedures, nor is the treatment as drawn-out and burdensome. A prerequisite for resection is the fundamental operability of the patient and a residual liver parenchyma that is still intact. • The **indications** concerning liver resection are as follows: large abscess cavities without any tendency to regression but possibly with rigid walls and septation, multifocal abscess systems, abscesses of unresolved status of benignancy/malignancy as well as necrotized and superinfected malignant tumours. Usually, low-complication postoperative courses without mortality have been reported. (51, 78, 80) In some cases, the liver parenchyma completely regenerates along the edge of the abscission scar. (80)

# 9 Prognosis

Prior to the introduction of liver scintigraphy, a mere 20% of liver abscesses were diagnosed antemortem; the mortality rate was correspondingly 80−100%. Following the introduction of scintigraphy in 1965, approx. 80% of all liver abscesses could be diagnosed, so that the mortality rate dropped to 28%. • Early diagnosis and the correct choice of aspiration or drainage treatment procedures have further reduced the mortality rate to below 20%; the rate for solitary abscesses is now below 10%, sometimes even as low as 3%. • **Risk factors** include: advanced age, impairment of the body's defence system, sepsis, considerable prior liver damage, increasing hepatic and renal insufficiency, multiple and/or cavernous abscesses, biliary causes of infection, gas-forming abscesses − all depending on the situation in the respective case. (20, 32, 48, 91, 113) • *For this reason, each liver abscess calls for individual therapy planning discussed at an interdisciplinary level!*

# Clinical Aspects of Liver Diseases

## 28 Alcohol-induced liver damage

# 28 Alcohol-induced liver damage

## 1 The "alcohol" factor

### 1.1 Use of alcohol

*We do not know when and where drinkable grape-juice was originally pressed from wild vines, nor when and where wine was produced and enjoyed for the first time following fermentation and purification.* • The oldest find is probably a grape-squeezer containing grape seeds found in the region south of Damascus, dating back to the time around 6000 BC. • Wine consumption and drunkenness are described in the Epic of Gilgamesh, which goes back to 4000−3000 BC. God told Noah, who is called Utnapishtim in the epic, to grow grapevines following the Flood (around 4000 BC). This he did: *"And he drank of the wine, and was drunken"* (Genesis, 9.21). • About 2700 BC, Chinese writings mention the benefits as well as the dangers of consuming wine. • Many descriptions pertaining to the consumption of wine (and also beer) as well as to drunkenness can be found in the rock tombs at El Kab in Upper Egypt (around 2500 BC), in the Eber´s Papyrus (around 1550 BC) and in various other discoveries. • A Babylonian clay tablet from the year 2230 BC shows a prescription written by a Sumerian physician regarding the use of wine for medical purposes. The Talmud defines the correct way to drink wine and praises its medical applications. However, in the Old Testament, Isaiah (5.11) expresses his anger saying: *"Woe unto them that rise up early in the morning, that they may follow strong drink; that continue until night, till wine inflame them!"* Homer was aware of the early onset of drunkenness due to a rapid intake of alcohol and complained: *"Often times did you wet my garment, infront, at my bosom, spilling wine from your mouth, in clumsy childishness"* (s. p. 60), *"The wine must have been doing you a mischief, as it does with all those who drink immoderately"* (Odyssey, 21.293). Ovid also admonished: *"When drinking, I will set you a limit: Head and feet must never fail."* The wild drunken orgies of the unleashed bacchantes, priestesses of Dionysus, were dreaded events. Plutarch, however, wrote on the moderate consumption of wine: *"The most exquisite amongst all beverages, the most pleasant amongst all foodstuffs, the most appetizing amongst all remedies."* • In the 11th century, pure alcohol was made from strong old wine for the first time in Southern Italy. From ca. 1250, this new substance was offered in Italian chemist's shops as a panacea and acclaimed as **aqua vitae** ("water of life"), aqua ardens ("burning water"), spiritus vini ("spirit of wine") or quinta essentia ("fifth essence" = filling the space between the cosmic bodies). The term **"alcohol"** was most probably introduced by Paracelsus about 1530, from the Arabic word al-kuhl, meaning "the finest part of something".

As far as is known, the time around 6000 BC marks the beginning of a development in which man became more and more familiar with the manifold **use and effect** of wine or other alcoholic beverages, e. g. as roborant, tonic, sedative, narcotic, appetizer, aphrodisiac, disinfectant or an externally applied antiphlogistic. Apart from that, alcohol was an essential part of festive banquets or religious rituals, but was also identified as a cause of drunkenness, physical dysfunction, disease and liver damage when consumed to excess.

### 1.2 Abuse of alcohol

▶ Alcohol abuse is defined as overindulgence, i.e. **abnormal** or **pathological drinking behaviour** (according to quantity and modality). However, there are no generally accepted threshold values regarding this definition, since intake and metabolism of alcohol are influenced by many factors varying from individual to individual. Apart from that, alcohol metabolism and tolerance mainly depend on whether the intake is a *singular, intermittent* or *continuous event.* (s. p. 61) **Lethal alcohol poisoning** generally occurs at blood alcohol concentrations ranging between 3.1 and 5.6‰ (2.0−3.5 g/kg BW). (85) However, there have been reports of isolated cases in which considerably higher concentrations did not lead to death. In this context, reduced tolerance (e. g. caused by coexistent hepatic disease, organopathies, hypothermia, age, drinking speed, drinking habits and type of drink) plays an important role. (4, 69) (s. p. 61) • Excessive alcohol intake to the point of abuse (with the alcohol dose varying from person to person) is characterized by the occurrence of **somatic damage.** • Alcohol abuse bears a certain relationship to the average intake per capita (in litres). In Germany, **annual consumption** increased from 3.1 l (1950) to 12.5 l (1980) and has remained at a level of about 12 l ever since. These statistics, however, do not take into account the large amounts of home-made cider or spirits, which cannot be recorded. Other countries, such as Denmark, Spain, Italy, France and Portugal, also sadly feature in this "top group" with 12−13 l per capita and year. At 7−8 l, consumption is, however, considerably lower in the Netherlands and the U.K., and lowest of all in Norway at 4 l. Worldwide, alcohol consumption has almost tripled since 1970. (67) • Alcohol abuse is found in **all social strata,** with people drinking at social occasions and parties, due to worry or poverty, when doing business and because of stress as well as success. • *Any of these circumstances can pave the way to abuse.* (s. tab. 28.1)

### 1.3 Addiction to alcohol

▶ A kind of (low-dose) dependence may also develop when alcohol is consumed daily, albeit in minor quantities. *As a rule of thumb, alcohol always makes people dependent when consumed on a regular basis − no matter what the dose may be.* • Alcohol addiction comprises (*1.*) **physical dependence** including increased tolerance as well as the withdrawal syndrome and (*2.*) **psychological dependence** with an uncontrollable desire for permanent or intermittent alcohol consumption, reduced self-control as well as changes in behaviour. (s. tab. 28.1) Alcohol abuse includes addiction without actually being identical to it. • Neither the **brain's reward system** (A. Herz et al., 1989) nor the **addiction memory** (J. Böning, 1992) are stimulated by *occasional alcohol consumption.* Another explanation for this

phenomenon could be that there are no alcohol-specific receptors in the brain and that the effects of alcohol are initiated "on loan" mainly via the GABAergic and glutamergic systems.

---

**Alpha alcoholism**
- Conflict- or relief-related drinking,
  no loss of control
- Certain degree of psychological dependence

**Beta alcoholism**
- Periodic and occasional drinking
- No psychological dependence

**Gamma alcoholism**
- Drinking in association with psychological dependence,
  including loss of control
- Later also signs of physical dependence

**Delta alcoholism**
- Habitual drinker (continued drinking: with abstinence of
  more than 24 hours being impossible), no loss of control
- Physical dependence

**Epsilon alcoholism**
- Episodic excessive heavy drinking with respective episodic
  loss of control ("quarterly drinker")

*Tab. 28.1:* Types of alcoholism (E. M. JELLINEK)

---

The term **alcoholism** (M. HUSS, 1852) should only be used when there are signs of dependence. In Germany, the concept of alcoholism as a disease (C. TROTTER, 1780; E. M. JELLINEK, 1960) was given official recognition as early as 1968.

## 1.4 Alcohol as a cause of disease

▶ An individual's **susceptibility to disease** as well as the average **duration of disease** are significantly increased by alcohol abuse. • A central feature here is alcohol-induced *liver damage.* • In the area of the *upper intestinal tract*, alcohol abuse is assumed to have various sequelae: stomatitis, carcinoma of the oral cavity and oesophagus, parotitis, reflux oesophagitis and gastritis. *Pancreatic diseases* occur about 20 times more frequently in alcoholics than in the rest of the population. In 30−50% of chronic alcoholics, *dilatative cardiomyopathy* can be observed. In addition, *essential hypertension* and *cerebral infarct* seem to be associated with alcohol abuse. *Bronchopulmonary diseases* occur more frequently. In the course of chronic alcohol abuse, *cerebral damage,* psychic disorders and polyneuropathy are observed. As a result, any therapeutic approach is limited or proves unsuccessful, since alcoholics displaying such cerebral damage are no longer willing to understand their condition and take an active part in the course of treatment. Damage to the *immune system* is accompanied by endogenous immune deficiency. Alcoholism is often considered to be a cause of *malnutrition* or *undernourishment.* Moreover, *obesity, gout, latent or manifest diabetes, hyperlipidaemia, endocrinological disorders* as well as *myopathy* and *osteoporosis* may also be anticipated. • Chronic alcohol abuse shortens **life expectancy** by 10 to 12 years, i.e. 9−12% in men and 13−15% in women, compared to the normal population. Every year, 30,000−40,000 people in Germany die as a result of **alcohol consumption.** These may be grouped as follows: (*1.*) direct cause of death (acute alcohol poisoning, alcohol withdrawal syndrome (M. VICTOR et al., 1953), (*2.*) typical fatal sequelae (hepatic, pancreatic, and heart diseases), (*3.*) frequently fatal sequelae (hypertension, cerebral complications, pneumonia, hypoglycaemia, carcinoma, tuberculosis), and (*4.*) fatal incidents (accidents, suicide). (67)

## 1.5 Costs for the economy

It is impossible to approximate the economic and social costs arising from alcohol abuse, as these are said to be "inestimable" or "enormous." They may, however, be grouped in (*1.*) quantifiable, material costs and (*2.*) nonquantifiable, non-material costs, which vary in form and degree in the individual case. • **Quantifiable costs** comprise (*1.*) *social costs* pertaining to disease and therapy (i.e. about 10−11 million days of hospitalization/year, with each $4^{th}-5^{th}$ bed occupied due to alcohol sequelae), rehabilitation measures, costs associated with loss of working hours including any additional costs (e.g. about 25% of wages), 3.5 times as many industrial accidents, about 16 times higher absentee rate, causing losses to employers of ca. 1.6 billion US dollars, costs due to accidents (workplace, traffic, leisure time, skiing, fights, etc.), costs arising from criminal offences (estimated figure 30−50%), legal costs, general living costs, administrative expenses and (*2.*) *private costs* pertaining to individual persons and/or their family. • Today, there are an estimated 2.0−2.5 million alcoholics in Germany − while some 4 million people are believed to be suffering extensively from the consequences of alcohol abuse, and about 10 million more are thought to be at risk. Each and every alcoholic is legally entitled to rehabilitation measures. However, no more than 30,000 people are treated as inpatients per year; for this small figure alone, the costs already amount to ca. 250 million US dollars. If the claims for inpatient rehabilitation measures were calculated for the total number of 2 million alcoholics (assuming this was at all possible in terms of bed and personnel capacity), the costs would amount to ca. 22.5 billion US dollars − a sum that would overtax any state or society. In the outpatient sector, costs are estimated at ca. 1,000 US dollars annually for each alcoholic. A person retiring early at the age of 45 due to alcoholism costs the state ca. 200,000 US dollars. The total average costs for an alcoholic amount to ca. 30,000 US dollars per year. In the time from early invalidity retirement to a usually premature death, the overall costs for the 2 million alcoholics amount to ca. 400 billion US dollars. All in all, the aggregate quantifiable material costs arising from alcoholism and alcohol abuse range between 24−26 billion US dollars per year, including all measures for inpatient treatment. (67) • In Germany, ca. 17.5 billion US dollars are spent annually on alcoholic drinks, resulting in a "mere" 3.3−3.5 billion US dollars revenue from taxation. • Realistic prevention programmes have been repeatedly suggested from all sides. Apart from that, recommendations have also been made on how to cope (at least partially) with the enormous secondary costs caused by alcoholism, such as appropriating the tax revenue from alcohol sales with a simultaneous increase in duty on alcohol, particularly the duty on wine and beer, as well as introducing a law requiring the (considerable!) private production of alcohol to be declared. (67) • *All the above mentioned figures for Germany apply equally to most other comparable societies.*

---

▶ Although alcohol is considered to be the **number one civilisation drug,** it is also an integral part of human existence, unless its use is prohibited by strict religious laws or a fundamental attitude to life. A moderate and careful approach towards alcohol is thus called for. • As a **rule of thumb** for the use of alcohol, one could say: *"Drink moderately, but not on a daily basis."* During abstinence, the liver enjoys the possibility of full recovery; daily alcohol intake inhibits protein synthesis in the liver cells as well as cell recovery. Furthermore, any risk of addiction is avoided if alcohol is only consumed in an irregular manner (= interposed days of abstention).

# 2 Biochemical effects of alcohol

As soon as alcohol reaches the liver cells, alcohol catabolism is initiated immediately and swiftly. Some 90% of the alcohol are metabolized by **ADH** and **MEOS**, whereby the intermediary metabolism of the liver cell is changed markedly. This is true for both the cytosolic and mitochondrial redox systems. • Alcohol breakdown via the MEOS involves the consumption of oxygen and NADPH. In contrast, its catabolism by ADH results in the production of NADH and formation of ATP, which, particularly because of the rise in the **NADH/NAD ratio**, affects numerous redox reactions in the liver cell. Of special importance in this context is a reduced activity of the citric acid cycle as well as of both pyruvate and fatty acid oxidation. • Some 75% (up to 85%) of the oxygen intake into the liver cell are used for alcohol oxidation, i.e. the cellular metabolic reactions which depend on sufficient $O_2$ supply are compromised during alcohol catabolism by **cellular hypoxia,** particularly in the perivenous areas. If this process is a singular one, of short duration or intermittent, the hepatocellular reactions will quickly normalize. However, due to its high $O_2$ consumption, **continued alcohol catabolism** will result in all NAD-dependent redox systems being compromised, so that subsequent disorders in the liver cell metabolism can be observed. (s. p. 63) • Research has shown that vitamins and hormones as well as trace elements play both a regulatory and a dysregulatory role in cellular metabolic processes in a far more varied manner than previously assumed. This may serve as an explanation for the persistent effects of alcohol-induced disturbances on numerous hepatocellular biochemical reactions with regard to the metabolic processes of vitamins, hormones and trace elements. (15, 18, 26, 36, 40, 54, 60, 71, 73, 77, 124, 136) *(see chapter 3.14)*

A rise in the NADH/NAD ratio and the associated increase in the redox potential as well as the formation of acetaldehyde result in a variety of **metabolic disturbances** in the hepatocellular oxidation processes, so that pathophysiological consequences can be observed. • This large variety of alcohol-induced metabolic disturbances is responsible for many situations of clinical importance, and thus acute and chronic alcohol abuse will eventually result in additional **metabolic complications.** (s. tab. 28.2)

## 2.1 Alcoholic hypoglycaemia

In $10-20\%$ of cases, hypoglycaemia is the cause of sudden, unexpected death following alcohol intoxication. When the person has been fasting before alcohol intake, the mortality rate is significantly higher. • Careful **monitoring of the blood sugar values** in patients with alcohol intoxication is required in order to treat them in time with i.v. glucose infusions. (s. tab. 28.2)

## 2.2 Alcoholic hyperglycaemia

In patients with a normal nutritional status, alcohol often results in hyperglycaemia. Apart from an alcohol-induced increase in catecholamines and cortisol (or ACTH), the reason for this also seems to be a reduced sensitivity of insulin receptors (e.g. due to zinc deficiency) (s. p. 50) and/or a lower glucose tolerance factor. (s. p. 51) (s. tab. 28.2)

## 2.3 Alcoholic hyperlipidaemia

Hypertriglyceridaemia is predominant in about 80% of all cases, whereby this condition is aggravated and potentiated by the simul-

taneous intake of dietary fat. • **Beware of the often recommended postprandial "small brandy" allegedly for better digestion after a fatty meal!** • The various metabolic disturbances (s. tab. 28.2, no. 13) ultimately lead to alcoholic fatty liver. • Alcohol-induced hyperlipidaemia and fatty liver thus have **four causes:** (*1*.) increased lipid transport due to nutrition and lipolysis, (*2*.) hypertriglyceridaemia, (*3*.) reduction in fatty acid oxidation, and (*4*.) limited removal of fat from the liver cell. (26) (s. tab. 28.2)

1. **Disturbances in hormone metabolism** (s. p. 45)
   - Hypogonadism
     (gonadotropins ↓, testosterone ↓, oestrogen ↑, zinc ↓)
   - Disturbance in $T_3$-$T_4$ conversion, TSH ↓
     5-deiodase ↓ (hyperthyroid state of liver)
   - ACTH ↑, cortisol ↑
   - Renin ↑, aldosterone ↑
   - Catecholamines ↑
2. **Disturbances in vitamin metabolism** (s. p. 47)
   - Folic acid, $B_1$, $B_2$, $B_6$, $B_{12}$, C ↓
   - A, D, E, K, F ↓
   - Conversion disorders of retinol
   - Occurrence of toxic retinol intermediary products
3. **Disturbances in trace elements** (s. p. 49)
   - Zinc, selenium, copper ↓
   - Manganese ↓ later manganese ↑
4. **Loss of electrolytes**
   - Potassium ↓, magnesium ↓
5. **Disturbances in cellular energy metabolism** (s. p. 43)
   - Hyperthyroid state of hepatocytes (see above)
   - Uncoupling of the respiratory chain due to stimulation of the sodium/potassium ATPase
   - Microsomal hypermetabolism
     ($O_2$ consumption ↑, basal metabolism ↑, thermogenesis ↑)
6. **Increase in lipid peroxidation** (s. p. 68)
   - Glutathione ↓
   - Zinc, selenium, transferrin, ceruloplasmine/copper, cysteine, methionine, vitamins C, A, E ↓
   - Malondialdehyde equivalents ↑
7. **Alcoholic sympatheticotonia**
   - Catecholamines ↑
     (lipolysis ↑, glycogenolysis ↑, vascular reactions ↑)
8. **Alcoholic hypoglycaemia**
   - Glycogen reserves in liver cells ↓ (s. p. 40)
   - Gluconeogenesis ↓ (s. p. 41)
     (inhibition of the citric acid cycle with a decrease in oxalacetate, alanine deficiency)
9. **Alcoholic hyperglycaemia**
   - Release of catecholamine ↑
   - Release of cortisol ↑
   - Inadequate insulin secretion
10. **Alcoholic hyperuricaemia**
    - Breakdown of purine nucleotides ↑
    - Acidosis/ketoacidosis
11. **Inhibition of pyruvate oxidation**
    - Hyperlactataemia → acidosis
    - Fatty acid synthesis ↓
12. **Increase in ketogenesis** (s. p. 42)
    - Ketoacidosis
13. **Disturbances in lipid metabolism** (s. p. 42)
    - Sympathicotonic lipolysis ↑ → fatty acids ↑
    - VLDL production ↑ → triglycerides ↑
      (pre-β-lipoproteins ↓)
    - α-glycerophosphate ↑ → triglycerides ↑
    - LCAT activity ↓ → cholesterol ↑
    - Pyruvate ↓ → fatty acid synthesis ↑

- Cholinphospholipids ↓
- Fatty acid oxidation ↓

**14. Disturbances in collagen metabolism**
- Acetaldehyde ↑ → collagen synthesis ↑
- Proliferation of myoblasts, fibromyoblasts, monocytes, lymphocytes ↑ → collagen synthesis ↑
- Hyperlactataemia → collagen synthesis ↑
- Proline oxidase ↓ → proline ↑
- Collagenase ↓ → collagen degradation ↓

**15. Disturbances in amino acid metabolism** (s. p. 38)
- Consumption of cysteine ↑
- Consumption of methionine ↑ → α-aminobutyrate ↑
- Consumption of glutathione ↑
- Glutamic acid ↑ → α-aminobutyrate ↑
- Glutamic acid ↑ → proline synthesis ↑
- Reduction in BCAA

**16. Disturbances in protein metabolism** (s. p. 40)
- Albumin synthesis ↓
- Carrier proteins ↓ (e.g. transferrin)
- Protein accumulation in the liver ↑

**17. Disturbances in porphyrin metabolism** (s. p. 34)
- δ-aminolaevulinic acid synthetase ↑
- δ-aminolaevulinic acid dehydratase ↓
- Coproporphyrinogen oxidase ↓
- Ferrochelatase ↓
- Uroporphyrinogen synthase ↑
- Uroporphyrin decarboxilase ↓

**18. Disturbances in neurotransmitter metabolism**
- Disturbances in decarboxylation of biogenic amines

**19. Formation of addictive substances**
- Salsolinol, tetrahydropapaveroline, β-carbolines

*Tab. 28.2:* Significant alcohol-induced metabolic disturbances and changes in biochemical reactions in the liver

## 2.4 Alcoholic hyperuricaemia

An increase in uric acid values up to an acute gout attack can only be attributed to a minor extent to diminished uric acid excretion from the kidneys, since decreased uricosuria due to hyperlactacidaemia is generally not observed unless the lactate value is >2 mmol. Excessive production of uric acid caused by increased catabolism of preformed purine nucleotides is considered to be an essential cause. This is also supported by the observation that the purine nucleotide content in liver cells is diminished after prolonged alcohol consumption. (36) (s. tab. 28.2)

## 2.5 Alcoholic porphyria

Alcohol may cause hepatic porphyria. This is true of both porphyria cutanea tarda, including latent phases of chronic hepatic porphyria, and the acute form. Given a genetic predisposition, alcohol inhibits uroporphyrin decarboxylase and induces δ-aminolaevulinic acid synthetase. This gives rise to an increase in uroporphyrinogen, which is discharged to a greater extent in the urine. • Thus, in cases of porphyria cutanea tarda, it is not only imperative to avoid sunlight, but also alcohol. (s. p. 35) (s. figs. 4.13; 7.10)

## 2.6 Haematological disturbances

Alcohol has a dose-related toxic effect on erythropoiesis. In this context, vacuolization of the nuclei and plasma of the proerythroblasts (so-called *McCurdy cells*) can mostly be observed. The mean corpuscular volume of erythrocytes (MCV) increases with rising alcohol consumption in 50−60% of patients, particularly when consuming high-proof alcoholic drinks. Megaloblastic anaemia

may occur due to vitamin deficiency (folic acid, B₁, B₂, B₆, B₁₂). Haemolytic anaemia can be found with or without Zieve's syndrome. Sideroblastic anaemia may be present when the iron metabolism is disturbed (as happens in 30−40% of cases). In 15−20% of cases, thrombopenia may be witnessed, and in 10−20% leucopenia can arise. The reason for an additional dysfunction in the leucocytes seems to be an increase in intracellular cyclic adenosine monophosphate, since alcohol activates the membrane-bound adenyl cyclase. (s. tab. 28.2)

## 2.7 Formation of addictive substances

Acetaldehyde, which is about 15 times more toxic than alcohol, enters into so-called condensation reactions with endogenous biogenic amines to form **opioid peptides.** Acetaldehyde together with dopamine leads to the formation of *salsolinol* as well as *tetrahydropapaveroline* and *β-carbolines*. The development of these (and similar) substances may explain why addiction results from alcohol abuse. • However, alcoholic drinks also contain **methanol** in different quantities, e. g. beer <7mg/l, whisky 100−300 mg/l, spirits made from fruit juice 1,000−5,000 mg/l. (!) Its metabolite is a toxic agent called formaldehyde. Methanol (or the toxic substance formaldehyde) probably plays a much more crucial role in the pathophysiology of alcoholic liver damage and in the development of alcoholism than does ethanol. Moreover, formaldehyde is considered to be a more suitable partner for the synthesis of habit-forming substances than acetaldehyde. (115, 126, 128) Thus the (high or low) methanol content in alcoholic drinks might also be of importance in the development of liver damage or alcohol addiction of varying intensities (E. V. DUNN et al., 1985).

## 2.8 Effects of disulfiram

Competitive inhibitors of acetaldehyde dehydrogenase block the breakdown of acetaldehyde. Especially **disulfiram** acts as an inhibitor, which is why the simultaneous intake of alcohol and disulfiram leads to increased acetaldehyde levels in the blood. This results in a *flush syndrome*, including perspiration, tachycardia, nausea, vomiting and even severe circulatory failure. • The effect of *medicaments* such as chloramphenicol, metronidazole, tolbutamide, chlorpropamide, griseofulvin, tolazoline, nitrofurantoin and quinacrine is **similar to that of disulfiram.** The simultaneous intake of alcohol and inhaled *nitrogen*, e. g. from fertilizers, which has a disulfiram-like effect, is also of toxicological relevance. The combination of alcohol and a mushroom called *Coprinus atramentarius* (which is usually well-tolerated) may also cause a severe reaction resembling that of disulfiram. Such effects occur as a result of contact with *chemical agents* at the workplace (e. g. carbon disulphide, calcium cyanamide, dimethylformamide, butylaldoxim).

## 2.9 Alcohol-related interactions

Interactions between alcohol and various xenobiotics, particularly medicaments, are of considerable clinical importance. (41) However, this depends upon the question of whether alcohol consumption is acute or chronic and whether these interactions are caused by gastric or hepatic ADH, MEOS or aldehyde dehydrogenase. The causes of such interactions are manifold. (s. tab. 28.3) • Gastric **ADH,** for example, is inhibited by pyrazole, cimetidine and ranitidine (but not by omeprazole or famotidine), which results in an increase in the blood alcohol concentration. A gastric isoenzyme of ADH (δ-ADH) causes the detoxification of a procarcinogen called nitrobenzaldehyde, occasionally found in foodstuffs. Similar ADH isoenzymes, which are equally capable of detoxifying procarcinogens, are also found in the colonic and rectal mucosa. Moreover, ADH is inhibited by agents such as chloralhydrate and metamizole. (40, 120, 124) The **MEOS** depends on the cytochrome P 450 (2E1, 4A1). (35) • **Acute alcohol consumption** leads to an

**inhibition** of microsomal metabolization and thus a prolongation of the half-life of xenobiotics, e. g. pentobarbital, lorazepam, tolbutamide, phenytoin, diazepam, warfarin, paracetamol, caffeine, methadone (considerable increase in concentration in the liver and brain!) as well as the procarcinogen dimethylnitrosamine. • **Chronic alcohol consumption** causes an **induction** of the alcohol-specific cytochrome P 450 (2E1, 4A1). Thus numerous xenobiotics or pharmacons are metabolized much more rapidly, i. e. their half-life is clearly shorter; this is especially true in situations where no alcohol is found in the organism at the time of drug intake. This rapid breakdown of a medicinal preparations may either shorten the period of therapeutic effect or result in intermediary products of a higher or even toxic concentration (e. g. isoniazid, paracetamol, vinyl chloride, dimethylnitrosamine, carbon tetrachloride, acetone, cocaine, halothane and butanol). Usually, this (primarily) metabolic drug tolerance then leads to higher redosing due to diminished, or a lack of, therapeutic effects. This may result in the intermediary products being present in dangerously toxic quantities. The induction of the alcohol-specific cytochrome continues for several weeks, even if no more alcohol is consumed. Furthermore, the original situation is re-established as soon as alcohol is consumed again. • Inhibition of **ALDH** may also be caused by numerous xenobiotics, which is why a *disulfiram effect* (see above) may be expected. (44) (s. p. 64)

---

1. **Effects on enteral resorption**
2. **Changes in gastric or intestinal mucosal metabolism**
3. **Additive or supra-additive effects on receptors**
4. **Effects on microsomal enzyme systems**
5. **Effects on non-microsomal cellular metabolic processes**
6. **Effects of disulfiram**

---

***Tab. 28.3:*** Causes of interaction between alcohol and xenobiotics, particularly medicinal preparations

## 2.10 Lipid peroxidation

Molecular oxygen is not always completely reduced in the metabolism of xenobiotics, so that partially decreased oxygen intermediates may be formed, such as $H_2O_2$, $O_2^-$ and $OH^-$, which are highly reactive. Due to its extreme chemical reactivity, $OH^-$ is capable of attacking every macromolecule. (s. p. 68) Consumption of alcohol causes on the one hand an enhanced formation of toxic oxygen intermediates which are catalyzed by iron and on the other hand an antioxidant deficiency (e. g. zinc, selenium, glutathione, cysteine, and vitamins A, C, E). This creates an oxidative stress situation for the liver cells, with damage to the biomembranes (s. p. 401) and stimulation of the collagen-gene expression (= alcoholic hepatic fibrosis). Furthermore, lipid peroxidations are responsible for the inactivation of enzymes and the oxidative modification of lipoproteins, proteins, free amino acids and nucleic acids. (51, 98, 136, 139, 145) (s. fig. 21.12)

## 2.11 Immune reactions

From an immunological viewpoint, an alcoholic fatty liver is considered as indifferent, while pronounced alcohol-induced cirrhosis mainly shows immunological hyporeactivity. By contrast, alcoholic hepatitis displays obvious immunological activity. It was possible to show the existence of lymphocytes with cytotoxic activity as well as antibodies against cytokeratin filaments, nucleic components and cell membranes. Occasionally, the **IgA value** in the serum is elevated and IgA deposits can also be observed along the sinusoids. The cell-mediated immunity may be impaired, so that intracutaneous tests as well as vaccinations (e. g. against HBV) show negative results (so-called alcohol-related non-responders). Following alcohol intake, endotoxins and other agents are also transported from the intestinal tract to the liver, a process which

leads to the **release of cytokines** (e. g. interleukins, tumour necrosis factor), since endotoxins are potent cytokine stimulators. Among other things, cytokines are thought to cause the stimulation of fibrogenesis, just as they are held responsible for various clinical symptoms (e. g. fever, catabolism, hypermetabolism, hypoalbuminaemia). LSP and protein aldehyde adducts are considered to be target antigens for the formation of antibodies. Verification of a **histon 2B antibody** (anti-H2B) is of particular clinical importance. (s. p. 121) (s. tabs. 5.19, 5.20; 33.1) • It is not certain whether we are dealing with epiphenomena in individual cases or whether these findings are of pathogenic relevance. (11, 59, 68, 140, 144)

# 3 Morphological effects of alcohol

Both acute alcohol consumption (in high doses and with toxic effects) and chronic alcohol intake result in manifold biochemical changes to the liver metabolism, which can be of varying intensity in the individual case in line with the respective influencing factors. (s. tab. 28.2) • Apart from these alcohol-induced changes to the hepatic metabolism, morphological modifications can also be observed at the subcellular and cellular levels, depending on the quantity and duration of alcohol consumption. This leads to an aggravation of liver damage and ultimately to extensive transformation processes. Structural changes in the organelles can be seen as an expression of an adaptation process triggered by pronounced acute or chronic strain on liver cells, but they may also constitute alcohol-induced damage.

---

There is a fluid transition between adaptation and alteration, with complete reversibility being possible if the damage does not exceed a certain limit.

---

## 3.1 Adaptation

As far as laboratory findings are concerned, the adaptation of metabolically active cell organelles or microsomal enzyme systems is generally reflected by an increase in **γ-GT activity** following a certain period of alcohol intake. In this context, an increase in γ-GT alone is an adaptive, physiological phenomenon as well as a sign that γ-GT has been released from its membrane binding. (s. pp 55, 97)

Adaptation to an alcohol intake of sufficient duration and quantity becomes morphologically visible when **proliferation** of the smooth endoplasmic reticulum as well as the Golgi complex is observed. This kind of induction can, for a certain period of time, only be detected with the aid of an electron microscope, but subsequently becomes visible under a light microscope as well. (s. pp 394, 544) (s. fig. 21.2)

## 3.2 Types of damage

With dose- and time-dependent alcohol intake, signs of morphological damage can be seen in important cellular

components, irrespective of the catabolic path of the alcohol, when for example: (*1.*) the cholesterol content of biomembranes increases, which results in a rise in membrane fluidity and permeability, (*2.*) storage of lipids and proteins in the cytosol causes an enlargement of liver cells, (*3.*) mitochondria show a swelling and structural change in their cristae, (*4.*) the Golgi complex undergoes hyperplasia, (*5.*) ribosomes are released and diminish in number, (*6.*) multivesicular lysosomes can be seen, and (*7.*) cytoskeletal structures are damaged. In general, the morphological changes, which are mainly caused by hypoxia, originate in the lobular centre (zone 3), from where they gradually progress to the periphery. (5, 24, 32, 50, 55, 64, 99)

> An early (and specific) biochemical sign of hepatocellular damage is an increase in **GPT activity.** (87) It can be demonstrated once the damage rate is >1 g hepatocytes (>170 million liver cells). (s. pp 93−96) • In pronounced vitamin B$_6$ deficiency due to alcohol abuse, GPT formation may be inhibited, so that GPT activities appear misleadingly low.

**Liver cell hydrops:** Liver cell hydrops is characterized by swollen hepatocytes, which contain a lot of liquid, but are generally free of fat. Hydropic liver cells may be 2 to 4 and even 10 times the size of normal hepatocytes. Cell hydrops is completely reversible when abstention is maintained. These cells usually die when alcohol intake is continued and are subsequently removed by macrophages and leucocytes. This leads to an alteration in the cytoskeleton. Hydropically degenerated liver cells and hyaline liberated from Mallory bodies produce a leucocytic inflammatory reaction. Unless it is compensated by regenerative processes, this cellular deficit results in defective healing by fine-fibred, cell-poor fibrils.

**Alcoholic hyalin:** Alcoholic hyalin is considered to be a characteristic maldevelopment during cellular protein synthesis and can often be found in enlarged and bloated hepatocytes. Although these cells may recover, they are often subject to cytolysis and are removed by leucocytes. Alcoholic hyalin, which contains a cellular stress protein called *ubiquitine*, is (more appropriately) referred to as a **Mallory body** (F. B. Mallory, 1911), as it can also be found in liver diseases not related to alcohol. Mallory bodies present as string-like or lumpy, sometimes granular-branched, light-refracting and acidophilic structures, which take on a bright red colour when they come into contact with aniline blue or Masson stain. They consist of an abnormal accumulation of microfilaments. Ubiquitination of damaged intermediary filaments already occurs at a very early stage of alcoholic hepatocellular damage before any Mallory bodies can be observed. Thus, moderate and early forms of hepatocellular damage due to alcohol can be detected by way of *ubiquitin-specific antibodies* displaying high sensitivity and specificity (J. Lowe et al., 1988). (33) (s. figs. 28.1, 28.2)

**Granular swelling:** Granular swelling is due to a general swelling and multiplication of mitochondria as well as the formation of **giant mitochondria.** (s. fig. 28.3) (s. pp 395, 545) These are eosinophilic, homogeneous, well-defined protein droplets of 10−20 μm in size within the cytoplasm of the generally enlarged granular liver cells. (22)

**Protein storage:** Protein storage in the cytoplasm of the liver cell is caused by antisecretory action, probably in the area of the microtubular system and the Golgi complex. This results in a **ballooning** of the hepatocytes. (s. p. 395) • Alcohol-induced *hepatomegaly* is therefore due to the concurrence of hepatocellular protein and lipid storage and liver cell hydropsy; this can lead to a

50−100% weight increase (without cellular multiplication) of the liver, i. e. up to 3,000−4,000 g (or more). (s. fig. 28.5)

**Single-cell necrosis:** Single-cell necrosis (s. pp 400, 545) becomes manifest as the destruction of fatty liver cells and as hyaline necrosis. The latter is either drained haematogenically or removed by stellate cells, which may generate stellate cell nodules. When disposing of fatty liver cells, the stellate cells take in lipoid from the necrotic epithelium and become foam-like. This may result in the formation of **lipophagic granulomas.** (s. p. 398) However, leucocytes also participate, sometimes even exclusively, in the removal of fatty hepatocytes.

***Fig. 28.1:*** Mallory bodies: immunohistochemical reaction with an antibody against ubiquitin (arrow)

***Fig. 28.2:*** Hydropic-degenerated hepatocyte with Mallory body (→) (HE)

***Fig. 28.3:*** Hepatocyte with megamitochondria (→) in alcoholic fatty liver

**Cholestasis:** Cholestasis is often identifiable by way of laboratory findings (*see chapter 13*) and becomes manifest in a pericanalicular arrangement of the rough endoplasmic reticulum. The final result is the impaired intracellular secretion of bile with yellowish guttate cell occlusions as well as excretory disorders with the formation of biliary casts. (99) (s. pp 395, 546) (s. figs. 13.2, 13.4; 28.15, 28.16)

**Siderosis:** Siderosis, especially in the form of granular *stellate cell siderosis*, can often be observed in cases of alcohol abuse and is caused by enhanced phagocytosis of erythrocytes. For this reason, it is particularly prevalent in cases of Zieve's syndrome, which means that granular stellate cell siderosis may be a hint of past stages of this syndrome or of its "formes frustes". General activation of stellate cells does not fit into the histological picture of alcoholic liver damage. • By contrast, *liver cell siderosis* mainly becomes manifest in the periphery of the hepatic lobules and is most likely to appear due to both an increase in iron supply or resorption and parenchymal lesions. (s. fig. 28.4)

**Fig. 28.4:** Siderogranular deposits ( ↑ ) in hepatocytes (siderosis) in chronic alcohol abuse (HE)

## 3.3 Steatosis hepatis and fatty liver

**Steatosis of hepatocytes** is considered to be the most common form of alcohol-induced liver damage and constitutes a complex hepatocellular metabolic disorder. (s. tab. 28.2, no. 13) There is an imbalance between the storage of fat in the liver cell and its removal. (13, 30) (s. tab. 31.1) • **Peripheral** fatty changes in liver cells are mainly caused by infectious or toxic damage which directly and haematogenically affects those peripheral areas more involved in lipid metabolism. (s. fig. 31.4) **Centroacinar** fatty changes in liver cells are mostly found in oxygen deficiency, nutritional damage, diabetes mellitus and alcohol abuse; in general, this is considered to be the more serious form of damage. (s. fig. 31.5) **Zonal** fatty changes in liver cells occur when only certain areas of a lobule are affected. Finally, a **diffuse** fatty change of the whole lobule can be witnessed. (s. fig. 31.3) • A further increase in size of the stored lipid droplets will ultimately fill the liver cell completely, enlarge it and press the cytoplasm as well as the pitted nucleus towards the cell membrane. This impairs or even stops the division of the nucleus. At the same time, the liver cell undergoes glycogen depletion. Removal of the nucleic glycogen, so-called **glycogen vacuolation of the nu-**

clei develops (s. fig. 31.1). This may be present in various diseases, particularly in the area of the portal zones. The large-droplet fatty changes result in so-called **fat cysts** of various sizes due to the cell membrane being torn. (s. fig. 31.2) • Fatty changes in liver cells are considered to constitute a **fatty liver** when *more than 50%* of the liver cells show the form of *medium* and *large fatty droplets*, and when *diffuse dissemination* occurs. (s. tab. 31.2) (s. fig. 31.3) A fatty liver may regress without any consequences. Occasionally, however, it may occur in an excessive form (up to 100% fatty liver cell changes have been observed) with a high fatality rate, e. g. in cases of acute alcohol intoxication. (s. fig. 28.5)

**Fig. 28.5:** Massive fatty liver (4,750 g hepatic wet weight) after acute alcohol intoxication ("brandy drinking bet"); exitus 4 days later

## 3.4 Hepatic fibrosis

**Fibrogenesis,** a complex biochemical process (s. p. 403) occurring in the course of alcohol-induced toxic liver disease, is of decisive clinical as well as prognostic importance. The increase in fibres is not dependent on the degree and duration of the fatty changes. Hepatic fibrosis can be observed in some 40% of all patients suffering from a fatty liver. *Determination of P-III-P* and *apolipoprotein I* is a reliable **biochemical indicator** of progressive fibrosis. (63, 78, 84, 93, 97, 101, 118)

▶ In alcohol-induced liver disease, the growth in fibres originates in the central veins. In this process, the delicate reticular fibres of collagen III are transformed into dense double-refracting collagen I. Moreover, elastic fibres can also be found in increasing numbers. This **centrilobular perivenular fibrosis** (s. fig. 21.14) consists of a coat of collagenous fibres running mainly in a longitudinal direction around the central vein (H. A. EDMONDSON et al., 1967) and is considered a precursory stage of alcoholic liver cirrhosis (C. S. LIEBER, 1979). At the same time, collagenation of Disse's space occurs, in general at the centre of the lobules, with the sinusoids being coated in a basal membrane-like manner and the sinusendothelium fenestration (= *capillarization of sinusoids*) being neutralized (H. ORREGO et al., 1979). (26, 55) (s. p. 406) This results in **perisinusoidal fibrosis.** (63, 84, 118, 146) • **Sclerosing hyaline fibrosis** can be witnessed when larger centrilobular cell groups, which had been loaded with alcoholic hyalin, perish and are replaced by scarred, cell-poor, fine-fibred fibrils (H. A. EDMONDSON et al., 1963). In cases of persistent alcohol abuse, this kind of fibrosis may quickly lead

to portal hypertension due to sinusoidal blockage. In most cases, it swiftly initiates transformation processes in the liver. (s. pp 247, 405) • Peripheral sclerosis proceeds from the portal tracts and continues towards the centre in the form of **periportal fibrosis** in a periacinar and intraacinar direction. (s. figs. 21.14; 28.6) In this process, single liver cells or small cell groups are drawn in from all sides and detached from their neighbouring structures. This spider-like fibrotic network continues to infiltrate the lobules until it connects with the central fibrosis. This results in a picture resembling more and more what is called **chicken-wire fibrosis** (W. WEPLER et al., 1968). (s. fig. 21.15) • It is by way of **proliferation of the ductules** that portal-periportal fibrosis assumes its characteristic features. Round-celled leucocytic infiltrates as well as periductular fibres may develop during this process, mimicking the picture of chronic cholangitis. • In up to 80% of all patients suffering from hepatic fibrosis associated with a fatty liver, alcoholic hepatitis develops when alcohol consumption is continued.

***Fig. 28.6:*** Alcohol-induced periportal and centrilobular fibrosis, partially spider leg-like (Sirius red) (s. fig. 21.14)

***Fig. 28.7:*** Septate liver fibrosis without cirrhotic transformation in alcohol abuse (misinterpreted as cirrhosis in sonography)

### 3.5  Liver cirrhosis

▶ *From a morphological perspective, any kind of alcohol-induced fatty liver or alcoholic hepatitis has the potential to develop into cirrhosis.* • The fibrous ramifications of the various portal fields make contact with one another as well as with other centrilobular fibre formations. This ultimately causes pronounced fibrosis of the liver, which leads to a cirrhotic transformation if alcohol consumption continues. (s. fig. 28.7)

In general, cirrhosis occurs as an insidious process characterized by permanent liver cell necrosis and fibrillogenetic stimulation. Pseudoacini and vascular shunts with impaired microcirculation develop, as do fibre paths, which show increasing signs of capillarization in the lobular structures. In the end, alcoholic cirrhosis presents as a uniform, micronodular condition. (s. figs. 28.7, 28.13, 28.14) • Histologically, it is often difficult to distinguish micronodular, postnecrotic alcoholic cirrhosis from posthepatitic/postnecrotic cirrhosis (although this is generally possible by laparoscopy). Alcoholic cirrhosis may even present macroscopically as almost "smooth cirrhosis", which is rich in interstitial fibres, but has a poor capacity to regenerate. (s. fig. 14.3) (s. p. 408)

## 4  Pathogenesis

The various metabolic, morphological and clinical aspects of alcoholic liver disease can only be explained by the concurrence of a variety of exogenous and endogenous factors typical for the individual. Acetaldehyde, reactive $O_2$ species and free radicals as well as endotoxins are particularly important in *pathogenesis.* Consequently, there is evidence of GSH depletion, lipid peroxidation and antigen-antibody reactions. Alcohol consumption supports the growth of endotoxin-forming, gram-negative bacteria in the small intestine. The endotoxins stimulate especially the Kupffer cells, whereby principally cytokines (IL 1, 6 and 8, $TNF_\alpha$) are produced. As a result, the microcirculation is impeded, T lymphocytes are stimulated and leucocytic inflammation can occur. Such pathogenesis is complex and differs in the individual case; this explains the various degrees of severity as well as the phenomenon of progression despite alcohol abstinence. (5, 39, 45, 48, 59, 61, 66, 69, 75, 76, 106, 139) (s. tab. 28.4)

***Tab. 28.4:*** Pathogenetic factors responsible for alcoholic liver disease

### 4.1  Genetic predisposition

Evidence of ethnic differences and family frequency, studies concerning twins and adoptive children as well as

animal experiments (U. Haberlein et al., 1997) suggest a genetic disposition *towards* − as well as protection *against*! − alcoholism and a higher (or lower) incidence of alcoholic liver diseases. This is also seen in the different distribution of *ADH* and *ALDH subtypes* (e. g. $ADH_2$, $ADH_3$, $ALDH_2$) in various races and populations. • Even though findings concerning an *HLA association* have not yet been substantiated, the increases in frequency reported to date reveal interesting aspects, e. g. B8 (United Kingdom), BW40 (Scandinavia), B13 (Chile), B28 (Australia), A2, DR3 and DR2. • Apart from that, there is also genetic polymorphism of *cytochrome P450* (e. g. 2E1, 2D6, 4A1). (2, 8, 14, 44, 80) (s. pp 53, 63)

## 4.2 Gender

Liver disease progresses more rapidly in women, with the incidence of cirrhosis being 2 or 3 times higher than in men. Gender-specific differences in the gastric and hepatic alcohol metabolism are thought to be the factors responsible for this.

## 4.3 Age

ADH is not present before the age of three; alcohol should therefore not be given to infants. • With advancing age, the capacity to catabolize alcohol decreases, the prevalence of alcohol-induced liver and CNS disease rises, and blood alcohol concentrations are higher because the distribution volume is smaller in older people. Gastric δ-ADH diminishes in older men, so that there is no longer a difference between men and women in later life as far as gastric ADH is concerned. Moreover, the function of the smooth endoplasmic reticulum deteriorates with advancing age, a fact which is of particular importance when older people consume medicaments and alcohol at the same time! The decrease in the antioxidant glutathione in older people is also crucial. With advancing age, concentrations of the toxic agent acetaldehyde rise.

## 4.4 Previous liver damage

**Previous liver damage** resulting in limited hepatic function and/or accompanied by considerable loss of tissue affects hepatic alcohol catabolism in a negative way. **Coexistent diseases** may then prove to be extremely detrimental if they compromise the cellular reactions of alcohol catabolism. Generally, this applies to obesity, hyperlipidaemia, diabetes mellitus, gout, endocrinopathies, etc. **Immunopathies** may cause further immunological disturbances due to alcohol-induced immune responses. A striking feature in this context is the frequent presence of **HCV** antibodies as well as their close connection to portal and/or lobular inflammations. (17, 19, 38, 105, 116, 121, 134)

## 4.5 Alcohol consumption

The **daily quantity** of alcohol consumed is the decisive factor in the development of alcoholic liver disease.

Following the intake of about 300 g alcohol, severe fatty infiltration of hepatocytes occurs within 2 to 4 days, whereas ingestion of 150 g alcohol leads to steatosis hepatis after about 21 days. The critical amount for the development of liver cirrhosis is a daily alcohol intake of $>60−70$ g for men and $>20−30$ g for women over a period of 5 years. • Another important factor for alcohol-induced liver disease is the **duration of alcohol intake.** In this context, a single alcohol dose of $>400$ g, particularly as a result of *rapid drinking* ("drinking bet"!), will usually have fatal consequences. (s. fig. 28.4) The alcohol quantity and the duration of alcohol intake are thus closely related to the manifestation of liver damage. • The **regularity** of alcohol consumption is also important, namely whether alcohol consumption is continuous or irregular, i. e. 3 or 4 days of abstention between alcohol intake. During such abstention, the liver usually has enough time for metabolic and morphological restitution. (s. p. 536) With irregular ("sporadic") drinking, there is practically no chance for biochemical *addiction potential* to develop. (4, 13, 70, 100, 107)

Single postprandial doses of 28 g or 71 g of alcohol resulted in blocked albumin synthesis or albumin and fibrinogen synthesis respectively. (142)

## 4.6 Chemical additives in alcoholic drinks

► Little is known about the content of additives in alcoholic beverages (either in *"standardized" industrial production* or in *"individual" home production*!) or their respective metabolism in the liver and potential toxicity. On the other hand, reliable information is available regarding the greatly varying amounts of *methanol* (ca. $5−5,000$ mg/l!) and its metabolic effects (or those of its metabolite formaldehyde). The present level of knowledge regarding methanol is remarkable, but more research is required. (115, 126, 128) (s. p. 523) Apart from methanol, *butanol* and *propanol* or their derivatives are found in alcoholic beverages, likewise in varying quantities. Further chemical *constituents*, which are only mentioned in very general terms, include: fusel oil, ester, acids, aromatic compounds, essential oils, sulphur, phenols, histamine-like substances, artificial colouring, preservatives and so-called stabilizers − possibly also residues of insecticides. Moreover, too little is known about different components of wooden barrels in which various alcoholic beverages are stored for longer periods. • By contrast, certain additives (such as flavonoids) are thought to have an antioxidant effect.

Considering our (still) insufficient knowledge of *chemical constituents* in individual alcoholic drinks, it is problematic *merely* to take the known ethanol content as a basic value for measurement and comparison or as a basic factor for prognosis. A critical approach is called for as long as the data are incomplete!

## 4.7 Coexistent hepatotoxic agents

It is with good reason that alcohol should be avoided when taking **medication** at the same time − however, this rule of thumb should always be complied with and not only heeded in specific cases or in advanced age. Predictions as to whether, when and what kind of biotoxometabolites will form due to biotransformatory interactions are difficult to make. (s. pp 55, 523) (s. fig. 3.11) With an estimated number of 400,000 to 500,000 persons addicted to pharmacons in Germany, this factor is of considerable importance in all statements concerning epidemiologic statistics. *(see chapter 29)* • **Chemical agents** encountered at work, at home, during leisure time and in connection with do-it-yourself activities may have a hepatotoxic effect and cause additive or even potentiated toxicity, given the individual peculiarities of ethanol metabolism. The main reason for this is alcohol-induced glutathione deficiency. *(see chapter 30)*

## 4.8 Malnutrition and undernourishment

Both malnutrition and undernourishment can be a cause or the result of alcoholic liver disease; indeed, the well-founded assumption of a vicious circle seems most likely. There is often evidence of secondary malnutrition as a result of alcohol-related disturbances affecting the intermediary metabolism. Malnutrition is brought about by the fact that each gram of alcohol supplies 7.1 kcal, so that the organism's basic need for calories can be satisfied predominantly by *"empty" alcohol calories*; on the other hand, alcohol-induced pancreatic insufficiency or damaged mucosa in the small intestine might result in maldigestion or malabsorption of various nutrients. Chronic alcoholics are able to satisfy more than half their daily calorie requirement with alcohol. A bottle of wine contains about 700 alcohol calories. Usually, a *deficiency in lipotropic substances* is observed (e. g. choline, methionine); therapeutic administration in cases of alcoholic liver disease has, however, proved unsuccessful. In addition, there is a deficiency in cysteine and glutathione, vitamins, electrolytes and trace elements. (s. tab. 28.2, nos. 2−4) • Alcohol causes a *deficiency in phospholipids* and *phosphatidylcholine* in the cellular biomembranes, particularly in the membrane of the mitochondria. This can be corrected by substitution. Both substances also proved to be successful in the prevention of alcohol-induced fibroses. For this reason, "essential" phospholipids as well as S-adenosylmethionine can be used in therapy as "supernutrients". (1, 61, 74−76, 95, 137, 142)

Alcohol abuse may be considered as the biggest mass experiment for developing liver disease voluntarily carried out by mankind to date. About 50−60% of all liver diseases in Germany are caused by alcohol.

# 5 Clinical features of alcoholic liver damage

## 5.1 Types of disease

The total range of alcoholic liver diseases can be divided into three basic forms: (*1.*) fatty liver, (*2.*) alcoholic hepatitis, and (*3.*) cirrhosis. (7) With continued alcohol consumption, the forms may indeed develop in this given sequence; the transitions are smooth, and particular courses can be observed in individual cases. • Alcoholic fatty liver, for example, may regress completely or develop into fatty liver hepatitis, or it may take the form of liver fibrosis and remain in this state of partial recovery, or progress into cirrhosis if alcohol consumption is not brought to a halt. Any acute, severe alcohol intoxication will usually be fatal within a few (1−3) days. (85) (s. fig. 28.5) Acute alcoholic hepatitis can (in about 40% of all cases) turn into a chronic form and finally into cirrhosis; in 10−20% of cases, it is accompanied by cholestasis and heals completely albeit with certain tissue defects (in about 50% of patients). Unfortunately, a lethal outcome must be anticipated in 10 to 15% of cases, and in fulminant courses even in about 90%. Occasionally, alcoholic hepatitis develops in addition to the existing alcoholic cirrhosis. • *Exact differentiation is only possible morphologically. In this respect, the most reliable tool is laparoscopy, since a biopsy sample can only be taken from the strictly limited area of the right hepatic lobe using percutaneous biopsy.* (s. fig. 7.8) *However, the biopsy specimen might not be sufficiently representative of the liver as a whole in advanced forms, e. g. chronic inflammation or fibrosis.* (s. fig. 28.8)

### 5.1.1 Alcoholic fatty liver

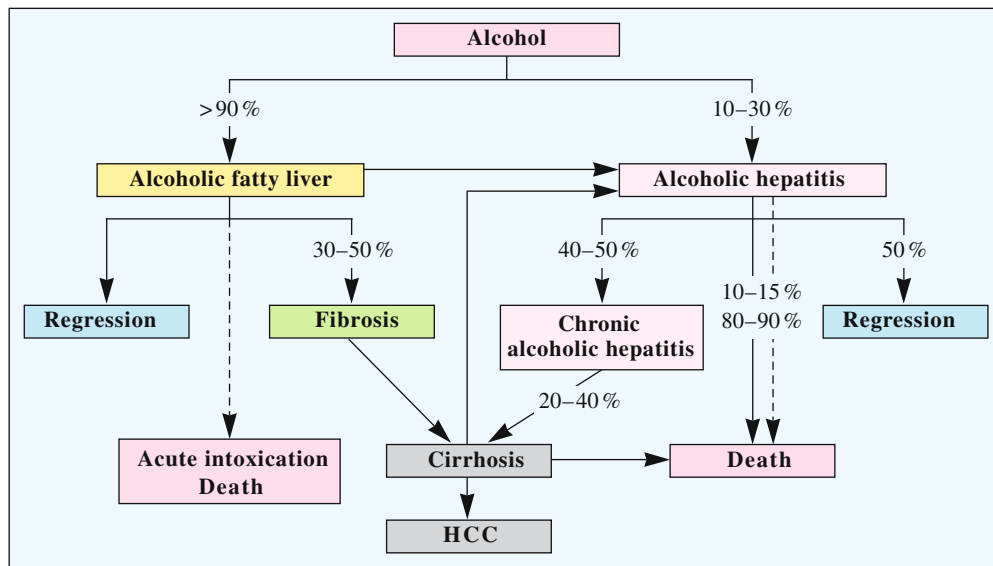
Fatty infiltrations of liver cells or fatty liver (s. pp 526, 579) are the most common morphological findings (up to 90% of all cases) in alcohol abuse. Both may develop within a short period of time (3 or 4 weeks), but may also regress completely within a few weeks or months, depending on the degree of severity. (5, 13, 30, 34) • **Subjective complaints** are often absent, or there is unspecific or dyspeptic discomfort such as bloating, meteorism, flatulence, inappetence, fatigue, drop in performance, intolerance of food and drink, impotence and a sensation of pressure in the right upper abdomen (= hepatomegaly). These complaints are reported in 30−50% of cases. • **Clinical findings** are consistent with severity and duration. The most common symptom is *hepatomegaly* (60−80%) caused by infiltration of fat, water and protein as well as by proliferation of the SER. An enlarged liver has a blunt edge generally tender on pressure and weighs 2.0−2.5 kg or more. Liver weight can be as much as 6 kg. The various skin stigmata of liver diseases (s. pp 81−86) can be observed with varying frequency (10−30%). Jaundice or scleral icterus are rare. • **Laboratory parameters** generally show an increase in γ-GT (s.


*Fig. 28.8:* Spectrum and course of alcoholic liver diseases (– – –▶ fulminant course)

p. 97) and, in more severe cases of fatty liver, an elevation of cholinesterase (60−70%). Transaminases (GPT, GOT) are slightly elevated and GPT synthesis is often reduced owing to alcohol-induced $B_6$ deficiency, while the alcohol-induced release of GOT from the extrahepatic tissues is enhanced, with the result that GOT activity is occasionally higher than that of GPT. In several cases, GDH is likewise moderately elevated. An increase in alkaline phosphatase is a sign of a cholestatic form. Impaired liver function can easily be determined, particularly by means of i.v. galactose elimination capacity and the indocyanine green test. (s. p. 108) • **Sonography** shows a typical "large, white liver" with diffusely pronounced echogenicity; single reflexes are coarsened, and sound transmission is reduced. In contrast, milder forms of fatty infiltration of liver cells are not, or only unreliably, identifiable. (s. p. 129) • The degree of steatosis hepatis can only be demonstrated by **histology.** (s. figs. 31.1−31.5) In this way, it is also possible to detect inflammatory reactions and activities resulting in fibrosis, both of which are relevant for prognosis. In steatosis hepatis, the result of percutaneous biopsy is considered to be representative of the liver as a whole. • **CT** shows a reduction in density in relation to the degree of severity of the fatty liver. The vessels and bile ducts appear "brighter" (so-called reversal of contrast). More pronounced regional or segmental areas of fatty infiltration can be detected in individual cases. (s. figs. 8.2−8.4)

**Alcoholic foamy degeneration** is considered to be a variant of alcoholic fatty liver (T. Uchida et al., 1983). There is evidence of microvesicular steatosis, giant mitochondria, focal cell necrosis (with elevation of GPT, GOT and GDH) and cholestasis (with increase of AP and sometimes of bilirubin), whereas inflammatory alterations are rare and Mallory bodies totally absent. Likewise, there is no sign of fever or leucocytosis. (133)

### 5.1.2 Alcoholic hepatitis

**Morphologically,** this form is characterized by fatty infiltration (especially perivenular), liver cell damage to the point of necrosis, presence of inflammatory reactions with polymorphonuclear leucocytes (occasionally also macrophages and lymphocytes) as well as formation of fibrosis (perivenular and pericellular). (s. figs. 21.15, 21.16) The hepatocytes are swollen (= ballooned degeneration). Mallory bodies (s. figs. 28.1, 28.2) and giant mitochondria (s. fig. 28.3) can be found. There is proliferation of the bile ducts. Kupffer cells are activated. The cytokeratic skeleton of hepatocytes is damaged or destroyed. (s. fig. 28.9)

*Fig. 28.9:* Alcoholic steatohepatitis. Satellitosis of neutrophilic granulocytes surrounding hydropic-degenerated hepatocytes with Mallory hyalin (→)

*Laparoscopy* shows a brick-red liver surface, reticulated fibrosis, enhanced vascularization of the capsule with perivascular fibrosis, reddish speckles as well as an irregular liver surface with scattered light reflection. (s. fig. 28.10) • The **clinical spectrum** of alcoholic hepatitis covers various forms: (*1.*) asymptomatic, (*2.*) chronic

| | | | | | |
|---|---|---|---|---|---|

| Triglycerides | ↑ – ↑↑↑ | | Zinc | N – ↓ | |

*Tab. 28.5:* Laboratory parameters in chronic alcohol-induced liver disease (N = normal)

persistent, (*3.*) chronic aggressive, and (*4.*) fulminant. These forms include anicteric, icteric and cholestatic courses. (s. fig. 28.8) • A variant of alcoholic hepatitis is **alcoholic steatohepatitis** with fat deposition in the hepatocytes and inflammatory changes. Necroses are rare. This course is much more common than alcoholic hepatitis, where cell necroses and inflammations are predominant (see above).

**Symptoms** include nausea, vomiting, inappetence, meteorism, fever, weight loss and a sensation of pressure in the right upper abdomen. The symptoms may vary in intensity and frequency depending upon severity and the respective alcohol consumption (30−80%). • **Clinical findings** present in the form of hepatomegaly and mild splenomegaly, possibly with icterus, skin stigmata of liver diseases, or oedema/ascites (30−60%), or hepatic encephalopathy. As in cases of severe fatty liver, symptoms of latent hepatic encephalopathy are also found in alcoholic hepatitis. Gastric colonization by *Helicobacter pylori*, which reduces gastric ADH activity, is considered to be a risk factor (47). (s. pp 56, 266) • **Laboratory findings** are characterized by the different types of course and their severity. In general, *GDH* is greatly increased. *Leucocytosis* (often considerable), reduced *albumin synthesis* and *fever* are presumably caused by endotoxinaemia. The laboratory parameters may be changed to varying degrees − depending upon the clinical forms described above. (5, 9, 11, 73, 81, 86, 87, 117, 123) (s. tab. 28.5) • The *Maddrey risk index* is a useful tool for assessing the degree of severity in acute alcoholic hepatitis. It is based on the *formula*: serum bilirubin value (mg/dl) plus (extension of prothrombin time in sec. × 4.6). A value of >90 indicates a severe course, a value of 30−90 a moderate course and <30 a mild course. (82) • **Sonographically**, there is occasionally evidence of a dilation of the hepatic artery (so-called *pseudoparallel channel sign*). (49, 132) • **Morphological findings** are decisive for diagnostic classification and prognostic evaluation. Thus liver biopsy is indispensable − and most reliable in the form of a specific biopsy during laparoscopy (including simultaneous photographic documentation). (s. figs. 28.7, 28.10, 28.13, 28.15, 28.16) After all, it was (unexpectedly) possible to find evidence of non-alcoholic liver disease in 20% of alcoholics with the aid of morphological findings. • Explorative laparotomy is contraindi-

cated due to high mortality following surgical intervention (about 50%). (27, 50, 64, 77)

**Continued alcohol abuse** which results in chronic alcoholic hepatitis in 60−70% of cases, can have a course of several years and may finally pass into cirrhosis. (s. figs.

*Fig. 28.10:* Chronic alcohol-induced fatty liver hepatitis: scattered light reflection due to irregular surface; brick-red colour with reddish-speckled pattern; reticular fibrosing process with enhanced vascularization of the capsule

*Fig. 28.11:* Chronic moderate periportal and portal inflammatory reaction with septal fibrosis and centrilobular steatosis in chronic alcoholic liver damage (DD: mild chronic viral hepatitis C!) (van Gieson)

28.13, 28.14) This final stage of cirrhosis will develop rapidly and in a relatively short period of time in about 40% of all cases. A healing process cannot be expected. • In acute alcoholic hepatitis, the mortality rate is about 10%. A fulminant form is generally observed after acute alcohol excess, with a fatal outcome in 90−100% of cases. (11, 24, 34, 47, 82, 86, 90, 104, 145) (s. fig. 28.5!)

**Total abstinence** from alcohol renders the prognosis considerably more favourable: some 30% of patients enjoy a return to full health; a further 50−60% develop a chronic course lasting several years, whereby approx. half of this latter group ultimately experience complete recovery. Cirrhosis is found in some 20% of all patients.

**Treatment** can be tried with pentoxifylline (3, 83) or, under strict indications, together with prednisolone. (12, 20, 25, 57, 83, 112) • A combination of steroids with infliximab cannot be recommended. (127)

The **healing process** is based on regression of the inflammatory and degenerative reactions, and lasts several months. The state of fibrosis present in the individual case remains as diffuse organ damage. This fibrosis may recede to a certain extent. • Despite total abstinence, the disease may worsen due to **self-perpetuation** until the stage of cirrhosis is reached. Immunological phenomena (possibly antigen-antibody reactions, such as antihistone 2B) (s. tabs. 5.20; 33.1) may be responsible for this deterioration.

### 5.1.3 Alcoholic cirrhosis

There is a close relationship between alcohol consumption and the development of cirrhosis. Nevertheless, only 20−30% of all chronic alcoholics actually reach this final stage. It should, however, be mentioned that in up to 40% of cases, the presence of cirrhosis was only discovered at autopsy. The reason for this is that alcoholic cirrhosis is characterized by a wide clinical spectrum, ranging from mostly symptom-free forms through to severe disease, sometimes with high rates of mortality (s. fig. 28.8). In Europe, alcohol is considered to be the most common cause of cirrhosis (50−70%). (5, 13, 70, 75, 90, 100−102, 107, 108, 123) (s. pp 406, 719)

To a large extent, *subjective complaints, clinical findings* and *laboratory values* correspond to those present in more severe forms of chronic alcoholic hepatitis. • It is often the respective *complications* which point to the full picture of cirrhosis: portal hypertension, splenomegaly, oedema and ascites, coagulopathies, bleeding tendency, hepatic encephalopathy, jaundice, more pronounced skin stigmata of liver diseases, feminization, VOD and oesophageal varices. Spontaneous bacterial peritonitis and the hepatorenal syndrome seem to be frequent in patients suffering from alcoholic cirrhosis. (10, 16, 34, 46, 50, 64, 71, 77, 81, 101, 109)

*Sonographic scanning* and other *imaging techniques* can be helpful in further substantiating the existing form of alcoholic liver cirrhosis and in differentiating it more closely as far as portal hypertension or ascites formation are concerned. (s. fig. 28.12)

***Fig. 28.12:*** Alcoholic cirrhosis with portal hypertension: stenosis of the portal vein (see arrow) with stagnation of blood flow in the portal vein (VP) and portal flow reversal (blue = hepatofugal) as well as enhanced arterial flow (red). Arterial signals are visible in the flow profile. Inhomogeneous liver structure

***Fig. 28.13:*** Micronodular alcohol-induced liver cirrhosis

***Fig. 28.14:*** Alcoholic cirrhosis with parenchymal steatosis and slight cholestasis (Sirius red)

The final morphological diagnosis is reached by means of *laparoscopy* with photographic documentation (s. figs. 28.7, 28.13) as well as targeted biopsies. (s. fig. 28.14) Laparoscopy is strongly indicated when hepatocellular carcinoma is suspected due to an increase in the $\alpha_1$-foetoprotein value and/or sonographic peculiarities.

# 6 Complications

## 6.1 Alcoholic ketoacidosis

Alcohol-induced ketoacidosis must be differentiated from a similar metabolic complication in diabetes mellitus (E.S. Dillon et al., 1940; D.W. Jenkins et al., 1971). With chronic alcohol consumption and concurrent malnutrition, metabolic acidosis is caused by a still unclear multifaceted pathogenesis (hypoinsulinaemia, lipolysis, extreme increase in free fatty acids, rise in ketone bodies). The clinical picture shows nausea, vomiting, dehydration, hyperventilation, fruity odour on breath, acetonuria and acetonaemia as well as a moderate form of hyperglycaemia. This syndrome probably occurs more often than has been hitherto assumed. (54)

## 6.2 Zieve's syndrome

The syndrome described by L. Zieve (1958) (148) consists of the **triad** (*1.*) *jaundice*, (*2.*) *hyperlipidaemia* and (*3.*) *haemolysis*. Hyperlipidaemia involves all fractions. The rapidly developing anaemia results in reticulocytosis, and is at the same time responsible for enhanced erythropoiesis and an increase in lipid-storing reticular cells (so-called *foam cells*) in the bone marrow. This syndrome may, in principle, occur in all forms of alcoholic liver disease. It nearly always affects men, mostly around the age of forty. Abortive forms only rudimentarily show this triad of symptoms at a subthreshold level, or any one of the other symptoms is missing altogether. The syndrome, generally in evidence after acute alcohol consumption, becomes manifest in the form of lack of appetite, nausea, vomiting, diarrhoea, and often severe colic-like abdominal pain, possibly mimicking an acute abdomen (explorative laparotomy is absolutely contraindicated!). The pathogenesis is still unresolved. This syndrome is usually reversible within a few weeks of abstaining from alcohol.

## 6.3 Cholestasis

In 15−25% of all patients with alcoholic liver disease, **cholestasis** can be detected both histologically and in laboratory findings. There is a correlation between malnutrition and cholestasis. (*see chapter 13*)

Histological analysis reveals deposits of bile pigments in the hepatic cells and bile casts. With increasing severity,

the laparoscopic picture of the liver becomes more and more striking. (s. fig. 28.15)

***Fig. 28.15:*** Alcohol-induced cholestasis

A severe **cholestatic syndrome** (H. Ballard et al., 1961) can be observed in patients suffering from alcoholic fatty liver. (s. fig. 28.16) The clinical picture may correspond to that of obstructive jaundice and cause great problems in differential diagnosis, particularly because such patients may not have been known before to be suffering from alcohol-induced liver disease. Extremely severe forms to the point of acute liver failure have been observed.

***Fig. 28.16:*** Severe alcohol-induced cholestasis syndrome

## 6.4 Fat embolism

In cases of severe fatty liver, there is indeed a risk of fat embolism occurring in the lungs, brain and kidneys. In view of the considerable fat masses stored in the hepatic parenchyma due to this condition, R. VIRCHOW suspected the manifestation of fat embolism as early as 1886. (s. tab. 31.9) Blunt traumatism of the (enlarged) liver with subsequent mobilization of fat is thought to be the cause of this condition. It is not clear at present whether this so-called *inundation theory* offers sufficient explanation or whether it needs to be amended or even replaced by the so-called *segregation theory* (high lipaemia, de-emulsification of blood fats, etc.). While hepatic fat embolism may be rare, it is nevertheless clinically relevant.

## 6.5 Portal hypertension

Portal hypertension may occasionally develop in the course of severe fatty liver, since the sinusoids and hepatic veins are compressed by massive fat deposits. Even oesophageal varices, including bleeding, have been observed. Fibrosing processes have not (yet) occurred in the liver, so that portal hypertension is completely reversible once the fatty liver has been cured. (s. pp 247, 586)

## 6.6 Primary liver cell carcinoma

Hepatocellular carcinoma (HCC) is found more often in alcoholics predominantly suffering from irregular, mixed nodular cirrhosis. The incidence is reported as being between 10−20% (3−4/100,000 inhabitants). In patients with alcoholic cirrhosis, HCC is found two to six times more often than in cirrhosis of a different genesis. Additional deterioration of the individual's general state, loss of weight, pain in the right upper abdomen, slight fever or (pronounced) jaundice can point to the development of HCC in alcoholic cirrhosis. There is a substantial increase in α-fetoprotein (slightly elevated and mainly constant values can also be found as a result of regenerative processes in the liver or in cholestasis). Alpha fetoprotein is a valuable marker in the follow-up of a cirrhosis. • Neoangiogenesis is another important factor in the development of HCC. The major mediators are VEGF, b-FGF, a-FGF, EGF, angiogenin etc. (130) • With the help of sonography, it is usually possible to detect HCC in alcoholic cirrhosis if the diameter is > 1 cm; in cases of suspicion, CT is recommended. Alcohol itself is not carcinogenic, but is considered to be a cofactor. A case of spontaneous regression of histologically proven HCC in a patient suffering from cirrhosis following total abstinence attracted great attention (E. B. GOTTFEIER et al., 1982). • Apart from hepatic hyperregeneration, other factors feature prominently in the pathogenesis of HCC, such as alcohol-induced changes in membrane properties with respect to the cellular ab-sorption of carcinogenic agents, disturbances in the biotransformation and enhanced activities of carcinogenic agents due to alcohol, etc. There is a close connection between HCC and HBV or HCV infection. (135) (s. pp 433, 444, 775) *(see chapter 37)*

# 7 Diagnostic alcohol markers

► Special questionnaires and laboratory tests have been developed for the early diagnosis or differential diagnosis of alcohol-induced liver disease, but also with respect to an assessment of therapeutic success and thus prognosis.

## 7.1 Questionnaire

The Michigan Alcoholism Screening Test **(MAST)** (M. L. SELZER, 1971), which is probably more common than any other test, has been simplified as brief MAST (BMAST) (A. D. POKORNY et al., 1972) and short MAST (SMAST) (M. L. SELZER, 1975). • The Munich Alcoholism Test **(MALT)** (W. FEUERLEIN et al., 1977) has also proved successful. • A test which is often used and easy to carry out is the **CAGE Test** (D. MAYFIELD et al., 1974). (89) It consists of no more than *four brief questions*: (*1.*) Have you ever had the feeling you should cut down on your alcohol consumption? (= **C**ut down); (*2.*) Have you ever felt annoyed when your drinking behaviour was criticized? (= **A**nnoyed about criticism); (*3.*) Have you ever felt guilty about your drinking habits? (= **G**uilty feelings); (*4.*) Have you ever needed an "eye-opener" in the morning? (= **E**ye-opener). If you answer 1 or 2 of these questions in the affirmative, you have a serious alcohol problem.

## 7.2 Laboratory findings as markers

The markers currently available still do not fulfil the criteria of an ideal marker, particularly with respect to sensitivity and specificity. However, when several tests are combined, it is possible to gain some useful knowledge. • The most simple and most specific test is, of course, the detection of **ethanol,** e. g. in the blood, which means that acute alcohol intake can be determined in a "non-alcoholic". In chronic alcohol consumption, however, the problem arises that an "alcoholic" possesses a higher catabolic rate, i. e. alcohol is more rapidly broken down. • The use of **two biological marker types** would be of considerable clinical importance: a kind of marker that reacts to alcohol consumption over a few days only (e. g. in order to recognize relapses) and another kind of marker which only reacts to long-lasting alcohol abuse (e. g. for long-term control). However, these require-

ments have not been met yet. (9, 21, 29, 30, 37, 87, 110, 115, 117, 122, 123, 143) (s. tab. 28.6)

| *I. Chronic consumption* | *II. Acute consumption* |
|---|---|
| 1. γ-GT ↑ | 1. Blood alcohol ↑ |
| 2. MCV ↑ | 2. Blood sugar ↓ |
| 3. CDT ↑ | 3. Triglycerides ↑ |
| 4. mGOT ↑ | 4. Potassium ↓ |
| 5. GOT/GPT ↑ | 5. Magnesium ↓ |
| 6. GDH ↑ | 6. Methanol ↑ |
| 7. IgA ↑ | 7. Serum acetate ↑ |

**Tab. 28.6:** Suggestion as to how to record chronic or acute alcohol consumption by means of laboratory markers and how to determine important values in emergency situations typical of alcohol-induced disease

► **Gamma-GT** is the most commonly used biological alcohol marker, but this enzyme is not alcohol-specific. It is found in increased concentrations in numerous hepatobiliary diseases as well as in many extrahepatic conditions. Figures regarding γ-GT positivity in alcoholic patients thus range from 30−90%. In general, positivity can only be observed in *regular* and *considerable* alcohol consumption; the γ-GT value usually remains normal in long-term, low-level alcohol intake. Intermittent alcohol consumption (with several days of abstention in between) does not result in an increase in γ-GT. Even an epsilon drinker (s. tab. 28.1) has normal γ-GT values. Alcohol-induced cholestasis results in enhanced neosynthesis of γ-GT and is also responsible for the rise in the serum value. Sensitivity is ca. 55%, specificity ca. 85%. The half-life of the positivity is 26 days. (58, 96) (s. p. 97)

► **Carbohydrate-deficient transferrin** (CDT) is among the best markers of alcohol abuse. The carbohydrate content of this protein was found to be abnormal in alcoholics (H. STIBLER et al., 1978), due to a deficiency in sialic acid, neutral galactose and N-acetylglucosamine. Sensitivity ranges between 69 and 91%, while specificity reaches almost 100%. These values are considerably lower in women. A reaction occurs with an alcohol dose of 50−80 g/day over a period of at least seven days. A positive result is obtained at >26 U/l in women and >20 U/l in men. It is only primary biliary cholangitis/cirrhosis which gives false-positive results, while false-negative values occur in alcoholics suffering from liver insufficiency. The half-life of increased CDT is about 2 weeks. (31, 43, 96, 129) • The *CDT/total transferrin quotient* becomes elevated to >1.3% (sensitivity 81%, specificity 97%) (L. M. FLETCHER et al., 1991).

► An increase in **mitochondrial GOT** displays relatively good specificity and sensitivity. It can be detected in the serum by immunological methods (B. NALPAS et al., 1986). The positive prognostic value of the increased mGOT/cGOT ratio was around 90%. (6)

► The **GOT/GPT ratio** increases in many cases to >1.5. A rise to >2 is considered to be a reliable indicator of alcohol-induced liver disease. (s. p. 95)

► A rise in **GDH** may be interpreted as an alcohol marker since, as an intramitochondrial enzyme, it is mainly localized in the perivenous area of the acinus. It is here that most of the alcohol-induced liver cell damage occurs. GDH is of minor importance as a marker on its own and is only of relevance in combination with other marker values. (94) (s. p. 96)

► A connection between macrocytosis and alcoholism was discovered in 1938 (A. BIANCO et al.). The **mean corpuscular volume** of erythrocytes (MCV value) has been used as a marker of alcohol since 1974 (K. W. UNGER et al.). The pathogenesis of alcohol-induced macrocytosis is still unresolved (potentially toxic effect of alcohol,

folic acid deficiency). However, an elevated MCV value (>95 fl) is a clear sign of heavy drinking, in particular the consumption of high-proof spirits. Due to the longevity of erythrocytes of about 120 days, elevated MCV values take several months to fall in the course of abstention. Determination of MCV is part of modern blood analysis and this value is therefore regarded as a routine test. Sensitivity ranges between 65−73%, specificity between 90−95%.

**Immunoglobulin A** is often increased in alcoholics. The IgA/IgG ratio can also be helpful in differential diagnosis. However, IgA is not elevated directly by alcohol, but by the underlying alcoholic liver disease. (140, 144)

**HDL cholesterol** rises at an alcohol intake of >75 g/day over a period of 5 weeks; however, the underlying mechanism remains uncertain. This value may also be influenced by medication or smoking, for example, just as a decrease in HDL cholesterol may be caused by alcohol-induced liver damage. • The rise in **apolipoprotein A II** (based on >60 g alcohol/day over 3 weeks) seems to be more specific in this context. This value, however, normalizes very quickly during abstention.

Detection of **β-hexosaminidase** in the blood and urine is sensitive enough (69−86%) and indeed suitable for routine testing. The result is, however, greatly influenced by extrahepatic and hepatic factors or diseases. (56)

An increase in urinary **dolichol** proved to be promisingly sensitive, particularly because a positive value was already observed after just 1 to 3 days of alcohol intake, with a half-life of only 3 days; however, positive values may also be observed under numerous other conditions, and thus the specificity is reduced considerably. (114)

Progressive fibrosis under continued alcohol consumption can, if necessary, be evaluated by determination of **P III P** (s. p. 112) (78, 97, 138) or **apolipoprotein I.**

Previous experience has shown that some markers are important, while others are only of minor value. Sensitivity may be improved to over 80% with certain combinations of single tests, in particular when the principle of discriminant functional analysis is applied (D. M. CHALMERS el al., 1981). • In order to examine **chronic alcohol consumption,** a triple test combination would be of advantage, which, in the individual case, could be supported by additional values derived from the set of four tests. (s. tab. 28.6) • When determining and differentiating **acute alcohol consumption,** the values of the triple test combination can be upgraded by additional tests for better clinical reliability. This would also help to determine important, so-called alcohol-typical emergency situations, including Zieve's syndrome. (s. tab. 28.6)

# 8 Prognosis

The following factors are decisive in achieving a favourable prognosis for all forms of alcoholic liver disease: (*1.*) total *abstention from alcohol*, (*2.*) extent of irreversible *loss of liver parenchyma*, (*3.*) exclusion of other *risk factors* (e. g. obesity, diabetes mellitus, malnutrition), (*4.*) additional effects of *hepatotoxic substances* (e. g. medication, chemical agents), and (*5.*) coexistence of further alcohol-induced *organ damage*. (5, 23, 37, 80, 81, 86, 99, 102, 108)

| Risk factors |
|---|
| 1. Non-compliance with alcohol abstinence |
| 2. Severity of existing liver damage |
| 3. Existing metabolic disorders |
| 4. Additional toxic substances |
| 5. Further alcohol-induced organ damage |

The prognosis for *alcoholic fatty liver* is good when abstention is uncompromisingly maintained, and complete reversibility can be expected within a few weeks or months. • In contrast, *alcoholic hepatitis* has a fatal outcome in $10-20\%$ of cases. When alcohol consumption is continued, about 40% of patients develop cirrhosis, while some 60% persist for several years. However, when alcohol abstention is maintained, only $15-20\%$ of cases develop cirrhosis, some $50-60\%$ persist for up to 3 years, and $20-30\%$ recover completely. Half of the persistent cases normalize again. There is a five-year survival rate in $50-70\%$ of patients (depending on severity), with the mortality rate remaining almost constant after the third year. • In *alcoholic cirrhosis*, the two-year mortality rate can reach 85% with continued alcohol consumption, but falls to 10% with strict abstention. (2)

# 9 Therapy

## 9.1 Alcohol abstinence

Complete and life-long abstention is an absolute necessity − this is the decisive factor for any prognosis. • The initiation and stabilization of abstinence from alcohol is made easier by a new antiethylic substance called **acamprosat,** which is water-soluble and permeates the blood-brain barrier. Above all, it has almost no side-effects. • *Optimally, an addict must aim at constant abstinence, i. e. "remaining dry", which happens in $35-50\%$ of cases. He/she relapses on renewed consumption of alcohol.*

## 9.2 Nutrition

Nutrition should provide a balance between carbohydrates, proteins and fats. Preference should be given to lactovegetarian proteins $(0.9-1.1 \ [-1.3] $ g/kg BW). Lipid intake should contain a certain percentage of unsaturated fatty acids; however, in digestive insufficiency for example, the administration of medium-chain triglycerides is required. Great importance should be attached to ensuring a sufficient supply of vitamins and trace elements. • Calorie intake needs to be adjusted to the patient's nutritional status. Obesity should be reduced. Enteral feeding is better than parenteral feeding. Malnutrition requires parenteral feeding, as do severe courses of disease. In a catabolic state, as is often found in chronic alcoholics, it is important to achieve a positive nitrogen balance, which is obtainable by amino acid infusions, in particular branched-chain amino acids (0.3 g/kg BW). • Nutrition should be in accordance with the individual state of the patients and their metabolic condition. Three normal meals and two additional snacks are recommended. (5, 61, 65, 91, 119, 125, 131) (s. pp 741, 850)

## 9.3 Substitution

Among other things, chronic alcohol intake results in **vitamin deficiency,** particularly of $B_1$, $B_6$ and folic acid as well as vitamins A and E. (92, 136) The reasons for this include (*1.*) insufficient food intake, (*2.*) reduced intestinal resorption, or (*3.*) intrahepatic disorder of the vitamin metabolism. Apart from that, (*4.*) intestinal vitamin resorption becomes diminished in later life. As a result, the necessary amount and diversity of vitamins cannot be obtained through normal nutrition. Apart from a diet "rich in vitamins", a daily dose of multivitamin preparations is advisable. Here, too, resorption losses need to be taken into account. When parenteral feeding is necessary, multivitamins are also added. • Alcoholics often suffer from a considerable $B_1$ deficiency, with the risk of developing polyneuropathy and Wernicke's encephalopathy. Administration of the fat-soluble $B_1$ prodrug **benfotiamine** is therefore recommended. • With chronic alcohol intake, **zinc** and **selenium** deficiency is often in evidence. (136, 147) Owing to their important biological functions, especially as antioxidants, daily substitution (i.v. if necessary) is advisable. Zinc can also be administered intravenously. (s. pp 50, 51, 857)

## 9.4 Physical exercise

In severe forms of alcoholic liver disease, **bed rest,** either in strict or semistrict form, is called for. • Once the disease has reached a phase in which **muscular activity** seems to be desirable, non-strenuous sport, gymnastics or swimming might be helpful. Physical exercises that can easily be carried out at home have proved successful in such cases (and also in latent HE): 2 or 3 times a day 10 to15 slow knee-bends, 10 to 15 toe-stands, 10 to 15 arm-bends, and 10 to 15 back-bends, so that some 60% of the musculature are regularly used. (s. pp 650, 732)

## 9.5 Drug therapy

When treating alcoholic liver diseases, it should be taken into account that one is generally dealing with chronic alcoholics. Therefore, one should be aware of the fact that a **withrawal syndrome** might occur, possibly requiring the application of clomethiazole, haloperidol or clonidine. • In this complicated phase, the administration of *zinc* is likewise recommended. (138)

▶ **Reviewing treatment strategies** in alcoholic liver diseases is difficult. On the one hand, individual (exogenous and endogenous) peculiarities in the alcoholic play an important role and are not easy to assess, and on the other hand, it is difficult to determine the respective

severity or the current stage of the disease. (s. tab. 28.4) (s. fig. 28.8) In all treatment groups, numerous uncertainties remain. This may be the reason for the frequently controversial results which arise even in well-designed clinical studies. (5, 48, 72, 74, 81, 83) (s. pp 56, 764)

**Antioxidants:** Combined application of the antioxidants zinc, selenium and tocopherol yielded better treatment results and a reduced mortality rate in alcoholic hepatitis. (75, 139) Alcohol-induced liver diseases are considered to be diseases associated with "free radicals": oxidative stress is thought to be a contributory factor of disease. (51, 145)

**Silymarin:** Its main active ingredient silibinin, well proven in the treatment of amanita poisoning, has been tested in almost 100 experimental and more than 120 clinical studies. Its essential *effects* are: (*1.*) protection of biological membranes against noxious agents, (*2.*) antioxidant effect (so-called radical scavenger), (*3.*) inhibition of fibrosis, and (*4.*) stimulation of protein synthesis. Recommended *dosage*: 300−500 mg/day in 2 or 3 single doses. (s. p. 867)

**EPL:** The substance known as "essential" phospholipid is the highly purified fraction of phosphatidylcholine with polyunsaturated fatty acids in positions $C_1$ and $C_2$ (= PPC), whereby 1,2 dilinoleylphosphatidylcholine is the main active ingredient. This exact biochemical definition is important, since *similar substances* do not display the effects of EPL as far as cell protection against toxic substances and inhibition of fibrosis are concerned − as was shown in many experimental and clinical studies. Recommended *dosage*: 3 × 300 mg/day over a longer period of time. (72, 74) (s. p. 865)

**Glucocorticoids:** In florid alcoholic hepatitis, particularly in acute intermittent attacks, administration of glucocorticoids in the form of prednisolone has beneficial effects, especially with respect to reducing early mortality. Diagnosis of acute alcoholic hepatitis should be made with the help of liver biopsy prior to commencement of prednisolone therapy. Treatment was given over a period of 4 to 6 weeks, with subsequent step-by-step dose reduction. A long-term course of treatment is not recommended. In cases of alcoholic cirrhosis, the prognosis is more likely to worsen. (12, 20, 25, 57, 112)

**Colchicine:** Since its first administration by M. ROJKIND et al. in 1973, the good results could not be repeated. Today colchicine is no longer recommended. (28)

**Pentoxifylline:** Increasing levels of tumour necrosis factor are associated with an increase in the mortality rate in severe acute alcoholic hepatitis. (11) Recently, it was reported that pentoxifylline (an inhibitor of TNF) can improve short-term survival due to a decrease in the risk of developing the hepatorenal syndrome. Dosage was 3 × 400 mg orally/day.

**Anabolic steroids:** In order to improve anabolism and to stimulate hepatic regeneration, application of *oxandrolone* (80 mg/day over 4 or 5 weeks) may be considered. Good results have been achieved in alcoholic hepatitis following initial treatment.

**Propylthiouracil:** The therapeutic aim is the inhibition of a hypermetabolic status and the prevention of pericentral necrotizing processes. Dosage: 300 mg/day. So far, no efficacy could be proved.

**S-adenosylmethionine:** In animal experiments, SAMe protected the liver against alcohol-induced damage. SAMe is an important donor of methyl groups. The alcohol-related lack of glutathione in the liver and the erythrocytes can be compensated with SAMe. Good results could also be achieved in alcoholic cirrhosis. SAMe is without side effects and relatively inexpensive. It can be administered orally or intravenously. (88) The effectiveness of this substance is seen in its alleged capacity to stabilize the biological membranes. (s. p. 864)

**Anti-TNF**$_\alpha$ (infliximab at 5 mg/kg BW) proved effective in alcoholic hepatitis. (53, 127)

## 9.6 Liver support system

**MARS:** A new therapy option is the use of a macromolecular adsorbed recirculating system. (52, 62) (s. p. 385)

## 9.7 Liver transplantation

Patients suffering from alcoholic liver cirrhosis in the Child-Pugh C stage may well have a chance of liver transplantation. However, **prerequisites** are: (*1.*) a minimum period of 6 months and (predictable) continued abstention, (*2.*) emotional stability, (*3.*) stable socio-economic situation, (*4.*) no other alcohol-induced organ damage, and (*5.*) subsequent psychotherapeutic support. • *Treatment results* are no worse than in non-alcoholic patients: the five-year survival rate is about 70% in both groups, the alcohol relapse rate is about 10%. • Without liver transplantation, the survival rate with continued alcohol consumption was 40% after 5 years, and when abstention was maintained, it was 63%. (42, 79, 103, 111, 113, 141)

# Clinical Aspects of Liver Diseases

## 29  Drug-induced liver damage

# 29 Drug-induced liver damage

## 1 Drugs as foreign substances

**Xenobiotics:** Xenobiotics are defined as exogenously administered or endogenously produced foreign substances that impair and ultimately damage the ecology and homoeostasis of cellular systems. This definition also includes medicinal preparations. (s. p. 52)

All orally or parenterally administered drugs enter the liver and from here, after passing through **biotransformation systems,** are released into the cardiovascular system in an unconverted or a metabolically converted state. In addition, systemic effects have to be anticipated in cases of topical administration (cutaneous, inhalant). • Metabolic processes generate **metabolites,** more specifically *catabolites* (= degradation products) and *anabolites* (= synthesis products). These biochemical processes are catalyzed or controlled inside and outside the cell by enzymes, hormones and the neurovegetative system. • Exogenous substances may also be metabolized and excreted without enzymatic processing by spontaneous chemical conversion (= **metabonates**).

▶ Of the many different xenobiotics, only a small fraction are sufficiently water-soluble to be excreted in an unchanged state via the kidneys or the bile. These are strongly polar groups such as penicillin, cephalosporin, tetracycline, thiazide, amiloride and cromoglycic acid; so far, no metabolites of these substances have been found. The phase-I reaction comprises non-synthetic processes such as the oxidation, reduction or hydrolysis of medicinal products. This largely takes place in the endoplasmic reticulum via the cytochrome P-450 isoenzyme system. For the metabolism of foreign substances, CYP 3 A 4 is quantitatively important. • The mainly lipophilic foreign substances can only be eliminated by **biotransformation,** i. e. by the metabolic production of water-soluble compounds. Phase-II reactions also occur due to specific transferases. The medicinal preparation as well as its metabolites are conjugated by various substances; this mainly takes place in the cytosol of the hepatocytes. These conjugation processes develop slowly during the first weeks of life. The metabolization of drugs via the kidneys, intestinal mucosa, muscles, lungs and skin is of minor importance in this context. (s. pp 52−55) **Biotoxometabolites** (or biotoxometabonates) may occur as a result of faulty biochemical reactions. (s. fig. 3.11) • The metabolization of medicaments also involves *antioxidants* (s. p. 67) as well as some functions of the *hepatic RES.* (s. pp 64−66) • The biochemical mechanisms related to the metabolism of xenobiotics may be affected by **non-variable factors** such as genetics, gender and age, or by **variable factors**. In individual cases, such factors may be of crucial importance. (s. tab. 3.18) (s. fig. 3.11) • The pharmacokinetic characteristics of a certain drug may be largely determined by the *pharmacogenetics* of the single patient. The enzymes responsible for biotransformation are also influenced by *genetics*; this affects largely the phase-II reactions (and occasionally the oxidation process in phase I). *Genetic polymorphism* prevails if a certain enzyme variant is found in ≥1% of the population. (9, 29, 65, 96)

Medicaments that have a hepatic clearance of >60% when passing through the liver (bioavailability = 30−40%) are termed "high clearance substances". This rate of clearance depends on the hepatic circulation. • Medicaments with a hepatic clearance rate of <30% (bioavailability = 70−80%) are termed "low clearance substances". The clearance process itself largely depends on the metabolic function of the liver. • With increasing age and/or with the existence of liver disease, hepatic clearance and the biotransformation of medicaments decline, whereby phase I is predominantly affected. Thus medicinal products that are mainly metabolized during phase II are not impaired. *(see chapter 3.12)*.

The recognition that a system which metabolizes drug products can also produce highly reactive **toxic metabolites** has proved crucial. As the liver has the highest number of enzyme biotransformation systems, it is the main site of production of such reactive metabolites and is thus more susceptible to damage. • Medicaments must therefore be regarded as **potentially hepatotoxic substances.** Basically, they can trigger a vast range of functional and morphological changes in the liver. The resulting hepatic damage can mimic almost any acute or chronic liver disease. *This means that in terms of function, morphology and clinical presentation, it is virtually impossible to differentiate between drug-induced liver diseases and the non-iatrogenic liver diseases they mimic.*

Drugs always have to be considered in the differential diagnosis of any case of liver disease lacking unequivocal clarification. The diagnosis of a pharmacon-related liver disease depends on the reliable exclusion of other potential causes of the existing disease as well as on the so-called withdrawal trial.

## 2 Frequency

**Quantification:** With regard to their frequency, adverse side effects are classified as (*1.*) *frequent* (>10%), (*2.*) *occasional* (1−10%), (*3.*) *rare* (<1%), (*4.*) *very rare* (<0.1%), and (*5.*) *isolated cases* (not yet quantifiable).

Surprisingly − but also understandably, given the great difficulties related to any reliable quantification − very little information is available regarding the **frequency** of adverse side effects in patients taking medication. A total of 2.3% or 1.9−6.2%, sometimes even up to 20%, of all hospitalizations has been attributed to drug-related diseases; 2−5% of all hospitalized types of jaundice and 25% of all patients with acute necrotizing hepatitis have been diagnosed as medication-induced toxicosis. • A ten-year study carried out in Sweden between 1966 and 1975 listed 274 deaths due to pharmaceutical preparations, 23 (9%) of them with toxic liver damage. (11) In Denmark, the incidence of drug-induced side effects doubled within the space of ten years (1978−1987). (32) In Japan, there was an 11-

fold rise in such side effects during a period of 30 years. One French study gives the incidence of drug-induced liver damage as 13.9%. (105) • Various types of liver damage have been identified as resulting from some 1,000 medicinal preparations produced worldwide. Acute liver failure may be caused by approximately 40 medicaments. The fatality rate was reported at 11.9%, whereby the risk of death did not differ significantly between hepatocellular and cholestatic patterns. (49) Over the past fifteen years, the incidence of drug-induced chronic hepatitis or cirrhosis has dropped to < 10% due to the fact that "dubious drugs" are not administered so frequently and that there is greater care and prudence in drug usage. This also applies to certain other forms of damage, e. g. malignancy, VOD, adenoma, FNH. (11, 69, 73, 84, 132)

▶ A comprehensive **survey** carried out in 1988 in a total of 2,008 medical practices in Germany found drug toxicity in 12.4% of the 7,095 patients suffering from liver disease (60): on average, the patients had been taking medication for approximately four years, with a maximum period of regular intake of up to 30 years (!). In 32.4% of patients, the liver had been exposed to a "double burden" as a result of the concomitant and regular daily ingestion of alcohol. The combination of two or more hepatotoxic drugs increased the risk considerably! This finding is of remarkable practical relevance. • In 1989 we conducted a renewed **survey** in an additional 2,990 medical practices (2,650 in Germany and 340 in Austria) and found that 17.7% of cases of acute liver disease in Germany and 14.3% of cases in Austria had been caused by drug toxicity, while 25.1% of cases of chronic hepatic disease in Germany and 22.1% of cases in Austria were attributable to the intake of medicaments. (61)

# 3 Pathogenesis

The pathogenesis of drug-induced liver damage is an individual, albeit multifactorial process. The main **mechanisms** known to date include:

(1) *Lipid peroxidation:* Free radicals induce peroxidation of the unsaturated fatty acids of the ER. As a result, there is fatty degeneration of the liver, whereby the mitochondria and biomembranes are damaged (possibly leading even to cell death).

(2) *Oxidative stress:* This process causes a depletion of glutathione in the hepatocytes with subsequent damage to (and even death of) liver cells.

(3) *Inhibition of β-oxidation:* The enhanced formation of mitochondrial oxygen radicals in the presence of fatty degeneration of the liver causes lipid peroxidation, which can lead to steatohepatitis and fibrosis or cirrhosis.

(4) *Inhibition of protein synthesis:* Some substances can inhibit RNA polymerase II and III (s. fig. 3.5). This in turn impairs the synthesis of enzymes, structural proteins and apolipoproteins. The result is fatty degeneration of the liver and cell necrosis.

(5) *Disorder of haem synthesis:* Inhibition of hepatic coproporphyrinogen-oxidase and uroporphyrinogen-decarboxylase can give rise to secondary copro- and uroporphyrinuria or porphyria cutanea tarda.

(6) *Inhibition of bile acid transport:* More than 100 medicaments can cause intrahepatic cholestasis. In this case, the canalicular transport mechanisms are impaired. The retained bile acids damage the cells.

(7) *Immunoallergenic reactions:* Chemically generated neoantigens trigger a cytotoxic immune response to those hepatocytes that have such neoantigens on their surface.

(8) *Carcinogenesis:* Highly active or metabolically activated foreign substances may form DNA adducts, which culminate in mutations, above all in the p 53 gene.

Drug metabolism in the liver is subject to numerous endogenic and exogenic **influences**. They interfere with various biotransformational reactions, alter the sensitivity of the liver to drug products and determine the pattern of damage (see above).

(1) *Non-variable factors* are genetics, gender and age.
(2) *Variable factors* are coexisting diseases (diabetes, liver or renal disease, endocrinopathies), overweight, malnutrition (e. g. lack of protein), alcohol, additional medication, tobacco smoke particles, heavy metals and pregnancy as well as drug-related overdose, long-term intake or application form, etc. (s. tab. 3.18)

Foreign substances, including medicinal products, are classified as *obligate* (directly effective) or as *facultative* (indirectly effective) hepatotoxins, depending on their degree of hepatic toxicity. Hepatotoxins are therefore grouped as either directly toxic or indirectly toxic according to the pathogenetic mechanisms of liver damage. Indirect hepatotoxins may, however, also cause an idiosyncratic type of liver impairment through immunological or metabolic mechanisms. (54, 65, 66, 69, 73, 88, 96, 115, 132) (s. tab. 29.1) (s. fig. 29.1)

## 3.1 Obligate hepatotoxins

Direct hepatotoxins cause liver damage in all exposed persons (i. e. it is always predictable). They cause **toxic damage.** This direct toxic response occurs either because the hepatotoxic foreign substance cannot be detoxified at all or because detoxification by biotransformation does not proceed rapidly enough. Following a relatively short and usually stable latent period, the hepatotoxin directly effects the destruction of cellular structures, e. g. by inactivating enzymes of the intermediary metabolism, by denaturation of cellular proteins or by lipid peroxidation. (s. fig. 21.12) This leads to *fatty infiltration* or *necrosis* of the liver cells. Obligate hepatotoxic medicaments are rarely clinically tested, since their hepatic toxicity is normally recognized at an early stage in animal testing. However, negative results from tests carried out on animals cannot guarantee absolute safety. This has been demonstrated in the case of the preparations benoxaprofen and ticrynafen, in which the respective hepatic toxicity was only recognized after they had been administered to "thousands of patients". (66) Obligate hepatotoxic pharmacons are only likely to be tested

clinically if their therapeutic benefit substantially outweighs their hepatic toxicity (e. g. as an effective cytostatic agent). • Some medicinal preparations that were shown initially to be non-hepatotoxic may, however, become obligate (directly) hepatotoxic substances in overdoses (= intoxification), as is the case with isoniazid, mercaptopurine, methotrexate, paracetamol, tetracycline, etc.

### 3.2 Facultative hepatotoxins

In contrast, indirect hepatotoxins only cause liver damage in a small number of exposed persons (i. e. it is not predictable). There is an individual, situation-related propensity towards the biotransformational production of indirect hepatotoxins or a manifestation of individual hypersensitivity (= idiosyncrasy). • **Indirect toxic hepatic damage** results from the interference of foreign substance metabolites (which are, strictly speaking, biotoxometabolites) with specific reactions of the intermediary metabolism. Such primary metabolic disorders include, for example, the alkylation or acylation of proteins, a lack of ATP or UTP, the blocking of receptors as well as of SH groups, or the binding to nucleoproteins. Only at a subsequent stage do these disorders result in structural damage: *steatosis* or *necrosis* of liver cells, *cholestasis* and also *tumour formation*. This type of impairment displays the features of facultative hepatotoxins. • **Idiosyncratic liver damage** is caused by facultative hepatotoxins. It only occurs in persons with a specific hypersensitivity to the ingested foreign substance or to one of its metabolites. Idiosyncratic liver damage may take an immunological or a metabolic course.

In the **immunological type** of hepatotoxicity, the foreign substance or one of its metabolites is bound to a liver cell protein. This leads to the production of a hapten (antigen), which in turn triggers a humoral or cell-mediated immune reaction and helps to detect autoantibodies, especially LKM-2 and LKM-3. Immunology-related liver damage is often accompanied by allergic symptoms (e. g. fever, exanthema, pruritus, arthralgia, eosinophilia) and by correspondingly identifiable histological findings (granulomas, eosinophilic infiltrations). • The **metabolic type** is reflected in an abnormal metabolic reaction, which occurs in a small number of exposed persons who are highly sensitive to the xenobiotic or to one of its metabolites. In general, this abnormal type of metabolism is primarily a genetic disorder. It results in the production of biotoxometabolites. This mechanism is thought to come into play with isoniazid and iproniazid, to name two examples. Symptoms of cholestasis are present, and AMA-$M_6$ positivity is frequently observed. (46) Idiosyncratic damage is also characterized by *steatosis* or *necrosis* of the liver cells as well as by a *hepatitic reaction*. (s. fig. 29.1)

However, these two types of damage resulting from facultative hepatotoxins do not explain all pathological metabolic effects, such as the occasional occurrence of allergens, mutagens, procarcinogens, antivitamins and "new" toxins. (s. fig. 3.11) • In this context, **two hypotheses** are conceivable: on the one hand, these pathological "end products" may develop in combined toxic/idiosyncratic liver impairment and on the other hand, the "end products" may develop as a result of biotoxometabolites binding to specific cellular proteins, sometimes to "altered" cellular proteins after the occurrence of toxic liver damage.

## 4 Morphological reactions

### 4.1 Adaptive changes

The xenobiotic-related induction of the biotransformation system usually leads to an initial adaptive response: **hyperplasia of the SER** (= smooth endoplasmic reticulum) occurs. (s. pp 55, 394, 524) (s. fig. 21.2) The cytoplasm takes on the turbid appearance of opalescent glass. These **ground glass hepatocytes** (s. pp 114, 396, 424) (s. figs. 5.7; 22.8) are not produced by all foreign substances,

| Criteria | Hepatotoxic xenobiotics | |
|---|---|---|
| | • obligate (= direct) | • facultative (= indirect) |

| 4. Reproducibility | + | ∅ |
| 5. Evidence from animal experiments | + | ∅ |

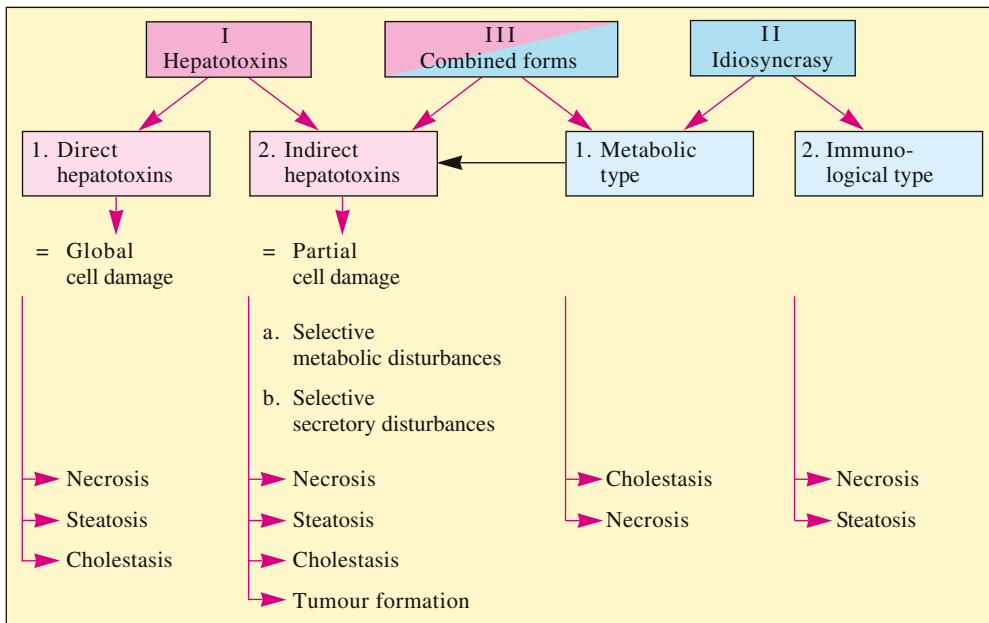
***Tab. 29.1:*** Pathogenetic criteria of hepatotoxic xenobiotics and the basic types of liver damage induced by foreign substances


*Fig. 29.1:* Diagram illustrating potential pathogenetic mechanisms related to drug-induced toxic liver damage

but they may be evident as an unspecific finding in chronic hepatitis B. The cytoplasm is fine-grained or fine-alveolate and looks pallidly eosinophilic. The nucleus, as well as the rough endoplasmic reticulum, move to the clearly contoured cell membrane. Anisokaryosis and binuclear liver cells point to an **accelerated cell metabolism.** In addition, **giant mitochondria** are sometimes present. (s. fig. 28.3) (s. pp 395, 525)

If a sufficient level of adaptation cannot be achieved, **regressive alterations** occur; homogeneous cytoplasm droplets are produced, which are then transformed into pigment granules of the lipofuscin type. It is a characteristic of *lipofuscinosis* that, after the xenobiotically induced adaptation of the smooth reticulum (s. p. 395), it appears in enlarged, hypertrophied liver cells − unlike lipofuscinosis in brown atrophy. (s. fig. 21.3) • There is no sharp distinction between adaptive and alterative hepatic changes. **Single-cell necrosis** may already be present in this border area, possibly activating the local stellate cell system. • There may be a vast range of morphological changes, depending on the individual manifestation, the pathogenetic mechanisms and the administered dosage of a drug as well as the duration of its intake.

## 4.2 Morphological changes

Alterations in the liver parenchyma as a result of foreign substances are characterized by several parenchymal, mesenchymal and vascular basic reactions as well as by benign or malignant neoplasia. It seems reasonable to classify the morphological findings in accordance with the acuteness and chronicity of their occurrence − bearing in mind all fundamental and individual reservations with regard to their systematization. (s. tab. 29.2).

### 4.2.1 Steatosis

**Microvesicular steatosis** (s. p. 582) presents as deposits of tiny lipid particles in the cisterns of the endoplasmic reticulum. The lipid particles are thus surrounded by a membrane. The nucleus remains at the centre of the cell. • **Macrovesicular steatosis** (s. p. 580) often develops further into necrosis if the intake of a foreign substance is continued. (s. tab. 29.10) • **Phospholipidosis** is regarded as a special type of steatosis. The hepatocytes are enlarged and display a foamy cytoplasm resulting from a marked increase in phospholip-

ids. Electron microscopy shows crystalline inclusions. This idiosyncratic hepatic lesion of the metabolic type has been observed for example during the administration of amiodarone. This substance has a long half-life and therefore remains in the liver for several months. Potentially fatal cirrhosis may occur. (s. p. 582)

### 4.2.2 Necrosis

Hepatocellular necrosis usually presents as coagulation necrosis. It is an aetiologically unspecific event that can have various causes, but it constitutes the most significant type of xenobiotic-induced hepatic damage. Cellular necrosis may affect either single cells or cell groups. (s. p. 400) A relatively characteristic feature of drug-induced toxicity are group necroses that are usually perivenously

localized, sometimes sector-like and accentuated, always clearly demarcated and often confluent. Idiosyncratic liver damage induced by *halothane* leads to necrosis affecting the entire liver lobule in a diffuse way. (s. fig. 29.2) • Cellular necrosis is often preceded by **cell ballooning** (s. p. 395) (s. fig. 21.4), which may appear as (*1.*) *toxic swelling of cells* or (*2.*) *cellular hydrops*. The hydropic cells are enlarged; they do not store any glycogen and look pallid. Cytoplasmic basophilia is reduced. The cisterns of the smooth endoplasmic reticulum are greatly enlarged as a result of fluid storage. The hyperchromatic nucleus perishes due to karyolysis; cell death follows. (s. tab. 29.10)

**Fig. 29.2:** Necroinflammatoric ("toxic") hepatitis after halothane intoxication (HE) (s. tab. 29.10)

### 4.2.3 Cholestasis

Xenobiotic-induced cholestasis is detected in three morphological types: (*1.*) intercellular in the form of **biliary thrombi,** which are found in the dilated canaliculi, with adjacent hepatic cells usually displaying pericanalicular condensation of the rough endoplasmic reticulum as well as frequent manifestation of cellular hydrops; (*2.*) intracellular in the form of **bile droplets,** which can be demonstrated as bile deposits of varying sizes or as small bile-imbibed protein particles − this type points to severe cell damage; (*3.*) mixed form of **intercellular** and **intracellular cholestasis.** (s. p. 229) (s. figs. 13.2, 13.5; 29.3, 29.4) Disturbed bile acid excretion is often accompanied by **feathery degeneration** of hepatic cells. (s. figs. 13.4; 22.4) (40, 63, 67, 73, 84, 91, 115) (s. tab. 29.10)

Occasionally, **ductopenia** (= vanishing bile duct syndrome) is observed. This condition is given when more than half of the portal fields in a large biopsy specimen fail to feature a bile duct. The irregular distribution of the lesions can make it very difficult to form a diagnosis based on just one biopsy specimen. The safest way is to carry out several biopsies (e. g. with the help of laparoscopy) and to make an assessment based on more than 20 portal areas. (8, 31, 93, 118, 128) (s. tabs. 29.3; 29.10)

**Jaundice:** Hyperbilirubinaemia may be caused by drug-induced haemolysis. This disorder is regarded as an undesired drug action rather than liver damage brought about by foreign substances, since the bilirubin metabolism of the hepatic cells is not affected. Differential diagnosis must first rule out this haemolytic aetiology. Jaundice (icterus) may be ascribed to various causes. (s. p. 218) Laboratory examinations and light microscopy have shown that several medicaments can (initially) cause a specific *jaundice type*, which continues in this same form until it disappears completely. If the effect of the substance and the course of the jaundice persist, this drug-induced disorder can lead to cholestasis and morphological changes. (24, 42, 47, 134)

| | |
|---|---|
| Ajmaline | Flucloxacillin |
| Amitryptyline | Gold salts |
| Amoxycillin | Haloperidol |
| Ampicillin | Imipramine |
| Azathioprine | Methyltestosterone |
| Barbiturates | Norandrostenolone |
| Carbamazepin | Perchlorperazin |
| Carbutamide | Phenytoin |
| Chlorothiazide | Promethazine |
| Chlorpromazine | Tenoxicam |
| Cimetidine | Tetrazycline |
| Clindamycin | Tiabendazole |
| Cyclohexylproprionat | Tiopronin |
| Cyproheptadin | Tolbutamide |
| Erythromycin | Trimethoprim |
| Estradiol | Trioleandomycin |

**Tab. 29.3:** Some medicaments that may provoke ductopenia (= vanishing-bile duct syndrome) in isolated cases. (s. tab. 29.10)

**Fig. 29.3:** Mixed (intracellular and canalicular) cholestasis following the use of dextropropoxyphene hydrochloride (s. tab. 29.10)

▶ *In a study of our own, we were able to demonstrate thiamazole-induced jaundice (maximum serum bilirubin 8.2 mg/dl with constantly normal values of AP, LAP and transaminases) over a period of more than five months. (s. fig. 29.4)*

**Fig. 29.4:** Pronounced bilirubinostasis and cholate stasis as well as Kupffer cell cholestasis (see arrow) following administration of thiamazole (HE) (s. tab. 29.10)

### 4.2.4 Inflammatory reactions

The pattern of damage is as follows: steatosis, necrosis and cholestasis. They occur either as defined individual phenomena or (more frequently) in combination. Depending on the severity and extent of these morphological findings, *two forms* of inflammatory reaction are possible: (*1.*) mesenchymal reaction and (*2.*) cellular infiltration.

**Mesenchymal reaction** shows an activation of the stellate cell system; the stellate cells and the mononuclear phagocytosis system proliferate. (s. p. 397) *Stellate cell nodules* form. (s. fig. 22.3) This process spreads from the sinusoids at the site of the lesion to include neighbouring parenchymal cells. The reticular lattice fibre is damaged and sometimes even destroyed. • In a more massive lesion, the inflammatory process spreads to the portal zone; histiocytes, lymphocytes and eosinophilic leucocytes lead to *portal zone cellulations* with oedematous dilations, in some cases subsequent to *portal fibrosis* (s. fig. 21.14), or to *cholangitis* of the PBC type (s. fig. 29.5) as well as of the PSC type.

***Fig. 29.5:*** Slightly florid, destructive cholangitis (see arrow) resulting from an ACE inhibitor (HE) (s. tab. 29.10)

► The hepatic mesenchyma may also respond with the formation of *granulomas*. (12, 57) (s. p. 398) This may well be the only morphological reaction provoked by foreign substances, although the formation of granulomas can sometimes be accompanied by the phenomena of steatosis, necrosis or cholestasis. From the pathogenetic perspective, granulomas can be caused by direct toxic as well as idiosyncratic lesions. The formation of granulomas has been observed during the administration of numerous pharmacons, e. g. sulphonyl urea. (s. fig. 29.6) • *Collidon* (polyvinylpyrrolidon) is used in plasma substitutes. It is stored in Kupffer cells if the molecular weight is > 80,000. The substance has a yellowish-brown colour, which with HE staining presents as greyish-blue, coarse-grained pigment. Collidon is PAS-positive. Generally, it can only be detected six months after administration. (s. fig. 29.7)

***Fig. 29.6:*** Epithelioid cell granuloma resulting from sulphonyl urea therapy (HE) (s. tab. 29.10)

***Fig. 29.7:*** Collidon storage: resorptive reaction of Kupffer cells and multinuclear macrophages to collidon deposits ten months after administration of plasma expander volume. *Insert:* Collidon granuloma

**Cellular infiltration** may vary in its degree, depending on the extent of the parenchymal lesion as well as on the type and duration of the toxic effect. A more severe inflammatory reaction corresponds to *non-specific reactive hepatitis*. (s. p. 392) (s. figs. 21.1; 29.8)

***Fig. 29.8:*** Hepatic impairment with monocellular infiltration following administration of carbamazepine (s. tab. 29.10)

In this context, cell infiltrates consisting of leucocytes and lymphocytes can be found within the acinus and/or in the portal field; in contrast, in immunological-allergic impairment mechanisms, it is primarily lymphocytic and eosinophilic-leucocytic infiltrations that become manifest. This cellular reaction is also reversible.

### 4.2.5 Vascular reactions

Medicinal agents (such as contraceptives) may result in proliferations of the intima in the hepatic artery and its branches. In some cases, these **arterial alterations** were associated with thrombosis in the hepatic veins. • Pharmacons can trigger three different forms of damage to the sinusoids: (*1.*) **dilation of the sinusoids** (e. g. by contraceptives), (*2.*) **perisinusoidal fibrosis** (e. g. by azathioprine, vitamin A and cytostatic agents), and (*3.*) **peliosis hepatis** (e. g. by contraceptives, anabolic and androgenic steroids, azathioprine, chenodesoxycholic acid). (13, 28, 130) (s. p. 398) (s. fig. 21.8)

The hepatic veins may be affected by xenobiotic-induced occlusion resulting from thrombosis or from proliferation starting in the intima and subsequently producing (secondary) thrombosis. An occlusion of the large hepatic veins is known as the **Budd-Chiari syndrome.** There are two distinct types, the truncular and the radicular form, the latter corresponding to veno-occlusive disease. (s. p. 249) Contraceptives (J. A. Ecker et al., 1966) and cytostatic agents are held responsible. Women develop this type of hepatic disease more than twice as often as men. (s. fig. 29.9)

**Fig. 29.9:** Budd-Chiari syndrome with obliterated radicular vein (see arrow) after administration of contraceptives (van Gieson) (s. tab. 29.10)

Occlusion of the small hepatic veins is called **veno-occlusive disease** (VOD) (G. Bras et al., 1954; K. L. Stuart et al., 1957). It is identical to the radicular type of the Budd-Chiari syndrome. (s. p. 249) Cytostatics and azathioprine are among the alleged causal agents. (121, 130) Diagnosis is based on imaging techniques (ultrasound, CEDS, CT), and sometimes on liver biopsy. (s. fig. 29.10) *(see chapter 39)*

**Fig. 29.10:** Intima proliferation and thrombosis of a (radicular) hepatic vein resulting from Senecio alkaloids (HE) (s. tab. 29.10)

### 4.2.6 Liver tumours

**Benign tumours**
As regards the neoformation of benign tumours, distinction is made between nodular adenoma and focal nodular hyperplasia (FNH). Because there are several transitional types between these two forms, they are generally regarded as variants of the same basic type of tumour (H.-W. Altmann, 1980). Both types may be multiple. (s. tab. 29.10)

**Diagnosis:** Benign hepatic tumours triggered by medicaments are generally diagnosed at a late stage or coincidentally during abdominal sonography. The tumour develops asymptomatically over an extended period of time. • **Symptoms** only appear when the tumour has grown to a certain size: upper abdominal pressure and occasional pain radiating to the back or to the right shoulder. This may point to tumoural bleeding, the formation of subcapsular haematoma or impending rupture. A rupture is accompanied by the obvious signs of acute abdomen and the symptoms of haemorrhagic shock (possibly with simultaneous abdominal trauma, straining or retching). • Diagnosis is possible by **ultrasound** and other **imaging techniques** (if necessary, with contrast medium). **Laparoscopy** also provides a reliable diagnosis. If at all, biopsy is only indicated by laparoscopy and using a fine needle or Robbers forceps (there is a possible danger of bleeding due to the high degree of vascularization). • Values beyond the normal **laboratory parameters** (bilirubin, AP, LAP, GPT, cholinesterase, etc.) are only evident once the tumour has reached a certain size. We have found *subnormal* or *very low GGT values* in almost all women taking oestrogen. Increased γ-GT values were accompanied by the onset of cholestasis. *(see chapter 36)*

**Adenoma:** The potential association of hepatic adenoma with the long-term use of oral contraceptives was first suggested by I. K. Baum et al. in 1973. Although the detection of adenoma was extremely rare before 1954, more than 400 cases were published by 1985. This figure has probably risen even further, but such findings have sel-

dom been published since that time, as the diagnosis was often deemed not worth reporting. Thanks to the ultrasound technique, which is now used on a routine basis, hepatocellular adenomas rarely escape detection today. Most of them are located close to the surface. (77) *(We have data on 8 unpublished cases)* (s. fig. 29.11)

*Fig. 29.11:* Adenoma (approximately 5 cm in diameter) following long-term use of oral contraceptives (s. tab. 29.10)

**Focal nodular hyperplasia:** FNH is the most common benign hepatic neoplasia. As with adenoma, it may develop after the patient has taken oestrogens for a longer period (usually more than 4 or 5 years). In some cases, the lesion develops within 6 to 12 months after intake begins. (13, 125) When the oral contraceptives are discontinued, the tumour regresses or disappears (completely). The rate of both oestrogen-induced hepatocellular adenoma and FNH was considerably reduced after the introduction of low-dose oral contraceptives.

*Fig. 29.12:* Focal nodular hyperplasia in the left liver lobe following 7 years' use of oestrogen (same patient as in fig. 29.12)

*Fig. 29.13:* Focal nodular hyperplasia with parenchymal nodules between fibrotic areas resembling portal zones (same patient as in fig. 29.11)

A genetic predisposition is assumed on the basis of frequency within families. The liver-damaging effect seems to be closely connected to the $C_{18}$ and $C_{19}$ steroid ring and alkylation in the 17α-position. Even the simultaneous occurrence of an adenoma and FNH under oestrogen administration has been described.

While there is a clear connection between adenoma formation and the intake of oestrogens, the association between FNH and oestrogens, albeit plausible, still lacks confirmation. *However, our own observations strongly suggest a causal relationship.* (s. figs. 29.12, 29.13) FNH may also be caused by azathioprine, clofibrate and nitrofurantoin.

**Malignant tumours**
Evidence that *focal nodular hyperplasia* tends to degenerate into malignant tumours is still lacking. • *Hepatocellular adenomas* pose the (rare) risk of developing into hepatocellular carcinoma (M. DAVIS et al., 1975). Several cases have been published in recent years. (44, 86, 119) We can add our own observation here. (s. fig. 29.14)

*Fig. 29.14:* Liver cell adenoma after 21 years' use of oestrogens, with subcapsular focal bleedings and malignant degeneration (hepatocellular carcinoma) (s. tab. 29.10)

▶ *A 60-year-old female patient was referred to us for differential diagnosis of cholestasis after having taken oestrogen for about 21 years (substitution following bilateral removal of polycystic ovaries): AP 206 U/l, LAP 52 U/l, γ-GT 7 U/l (!), GPT 42 U/l, GOT 32 U/l, GDH 12 U/l, copper 192 µg/dl, cholinesterase 2,150 U/l. Repeated measurements consistently provided normal values for $\alpha_1$-foetoprotein; haemogram, LDH, iron, etc. were normal; demonstration of adenoma by ultrasound and CT, but with additional "unclear structures." Laparoscopy confirmed the adenoma, together with several subcapsular bleeding foci and hepatocellular carcinoma (identified by forceps biopsy).*

In contrast to primary hepatocellular carcinoma, the $\alpha_1$-*foetoprotein values* are normal (G. KLATSKIN, 1977), which is also true of the case we presented above. In opposition to this, a rapid increase and significant rise in AFP values have been reported. *Metastasis* formation is rare and always relatively late. • It has been observed that *hepatocellular carcinoma* can follow the intake of hormone-based contraceptives as well as long-term administration (several years) of 17α-alkylated androgenic, anabolic steroids and methotrexate. *Cholangiocarcinoma* may also be caused by the long-term intake (several years) of hormone-based contraceptives, androgenic agents and α-methyldopa. The formation of *angiosarcoma* has likewise been attributed to the long-term use of oral contraceptives, oestrogens, androgenic and anabolic drugs. (s. tab. 29.10)

**Diagnosis:** Malignant tumour formation is accompanied by inappetence and weight loss, pain in the upper right abdominal quadrant, fever, specific laboratory findings and paraneoplastic symptoms. *(see chapter 37)*

### 4.2.7 Fulminant liver failure

Fulminant or protracted liver failure is caused by medicaments in $10-15\%$ of cases. A reduction in the functional liver mass to $< 20-35\%$ is deemed to be a critical stage. However, the death of the patient may already occur due to secondary metabolic disorders (so-called exogenous hepatic coma) before the extent of the parenchymal loss has fallen below the critical threshold (so-called endogenous hepatocellular disintegration coma). (s. tab. 29.10)

**Three forms** of drug-induced liver failure are distinguished: (*1.*) obligate, dose-dependent toxicity (e. g. *paracetamol*, (s. fig. 20.3), (*2.*) unpredictable, idiosyncratic liver insufficiency (e. g. *isoniazid*), and (*3.*) immunoallergic idiosyncrasy (e. g. *halothane*) (s. fig. 29.2).

Initially, unspecific **complaints** frequently include nausea, inappetence and fatigue. • In some patients, idiosyncratic hepatocellular damage may be accompanied by **hypersensitive reactions** (e. g. fever, exanthema, eosinophilia, lymphocytosis, arthralgia).

Obligate, dose-dependent drug-induced toxicity need not be feared, since substances which predictably cause severe toxicity are not usually applied as medical remedies. It is only in cases where the therapeutic effect clearly outweighs the known type of damage that an obligate toxic substance is administered as a therapeutic agent − but in accordance with strict criteria!

It should be mentioned that almost all cases of fulminant or protracted liver failure caused by a certain substance are isolated occurrences that cannot be foreseen. They develop as a result of individual idiosyncrasy despite correct dosage and observation of all possible interactions. (s. tab. 29.4)

| | |
|---|---|
| Acarbose | Labetalol |
| Allopurinol | Leflunomide |
| Amiodarone | Lisinopril |
| Amphotericin B | MAO inhibitor |
| Antirheumatics | Methotrexate |
| Benoxaprofen | Methyldopa |
| Bromfenac (48, 83) | Minocycline |
| Carbamazepine | Nefadozone |
| Clozapine (71) | Nibutamid |
| Cotrimoxazole | Nimesulide (74) |
| Cyproterone | Niperotidine |
| Cytostatics | Ofloxacin |
| Diapsone | Omeprazole |

| Isoniazid | Valproic acid |
| Ketoconazole | Zoxazolamine |

**Tab. 29.4:** Some medicaments that may provoke idiosyncratic fulminant or protracted liver failure in isolated cases (with some references) (s. tab. 29.10)

The **mortality rate** depends on the cause of disease, the patient's age as well as the intensity and duration of encephalopathy. Since the introduction of liver transplantation and temporary liver-supporting systems, the mortality rate in acute liver failure has been reduced markedly. (48)

The initial **diagnosis** is based mainly on the determination of *laboratory values*, which can be used as starting

point for assessing the further course of disease. • The same applies to *sonography* as regards the determination of liver size and echo structure. Liver size can also be determined exactly by means of *CT*. (s. tab. 29.5)

▶ **GC protein** (group-specific component) is an $\alpha_2$-globulin which is synthesized in the liver and which binds actin released due to hepatocyte decay. Decreased GC-protein values in the plasma are thus attributable both to its reduced synthesis in acute liver failure and its increased binding to actin as a result of hepatocellular disintegration. A value of < 34 μg/ml was associated with a lethal outcome in some 70% of cases.

| Basic diagnostics | Coagulation |
|---|---|
| haemogram | Quick's value |

*Tab. 29.5:* Diagnostic measures in suspected fulminant liver failure

# 5  Clinical aspects

Liver damage caused by drug-induced toxicity, more specifically the intrahepatic obstructive type of jaundice resulting from the intake of arsphenamine, was first described by F. M. Hanger et al. in 1940. (42)

## 5.1  Clinical courses

Toxic liver damage does not produce a characteristic clinical picture. It is determined by the underlying lesion pattern. Clinical courses range from asymptomatic to symptomatic and from acute to chronic. (1, 9, 27, 49, 54, 64, 70, 73, 82, 84, 85, 103, 115, 132)

- asymptomatic
- symptomatic

| 1. | acute | → | normalized |
|---|---|---|---|
| 2. | acute | → | chronic |
| 3. | chronic | → | chronic |
| 4. | chronic | → | normalized |
| | | → | healed with residual fibrosis |

Drug-related hepatic damage can mimic almost any liver disease and must, therefore, always be included in the **differential diagnosis.** (s. tab. 29.6)

1. **Jaundice type**
   − bilirubin ↑
2. **Cholestasis type**
   − AP, LAP, γ-GT ↑
3. **Jaundice-cholestasis type**
   − bilirubin, AP, LAP, γ-GT ↑
4. **Fatty liver type**
   − γ-GT ↑, perhaps GPT, ChE ↑
5. **Hepatitis type**
   − GPT, GOT, GDH, γ-GT ↑
   DeRitis quotient < 1
6. **Cholestatic hepatitis type**
   − GPT, GOT, GDH, γ-GT, AP ↑
7. **Necrosis type**
   − GPT, GOT, GDH ↑
   DeRitis quotient > 1
   generally bilirubin, AP, γ-GT ↑; ChE, Quick ↓
8. **Cholangitis type**
   − GPT, GOT, GDH, γ-GT, AP ↑
   possibly bilirubin ↑, ChE ↓
   possibly autoantibodies +
9. **Chronic hepatitis type**
10. **Cirrhosis type**
11. **Fibrosis type**
12. **Vascular type**
13. **Tumour type**

14. **Combined forms**

*Tab. 29.6:* Morphological reactions or laboratory findings resulting from hepatic damage caused by drug-induced toxicity (s. tab. 29.10)

Thus a pure *jaundice type* can occur with unconjugated hyperbilirubinaemia, or a *cholestasis type* is witnessed, which may or may not be accompanied by simultaneous jaundice. (s. figs. 29.3, 29.4) The *fatty liver type* often starts out uneventfully with no abnormal laboratory values until increased levels of γ-GT and, in several cases, an additional rise in GPT and ChE occur. The *hepatitis type* with greatly varying laboratory values also produces a clinical picture with multiple interpretations: it may present as acute hepatitis, protracted or persistent hepatitis, non-specific reactive hepatitis or "granulomatous" hepatitis. The liver damage may progress as a *cholestatic hepatitis type, necrotic type* (s. fig. 29.2) or *cholangitis type* (s. fig. 29.5), with the corresponding indicative laboratory findings. • Chronic courses include *chronic active hepatitis type, cirrhosis type* and *fibrosis* as well as *vascular* or *tumour type*. • *Combined forms of damage* are also frequent. Their diagnostic categorization presents considerable difficulties. (s. tab. 29.6)

## 5.2  Anamnesis

Sometimes, there are no complaints at all. Mostly, however, patients have atypical complaints, which are possibly suggestive of toxic liver damage:

| common cold | fever | nausea |
|---|---|---|
| diarrhoea | lack of appetite | pruritus |
| | lacrimation | |

## 5.3 Clinical findings

The following clinical findings can be considered as additional symptoms for the detection of liver damage caused by drug-induced toxicity:

| | |
|---|---|
| abdominal pain | leucocytosis/leucopenia |
| arthralgia | lymphadenopathy |
| conjunctivitis | myalgia |
| eosinophilia | rhinitis |
| exanthema | scratching |

## 5.4 Laboratory findings

The focus is on determining γ-GT as an indicator of long-term (several weeks) intensive activation of the biotransformation system as a result of drug intake − once other causes of elevated γ-GT have been excluded. (s. p. 97) Generally, the γ-GT level remains normal during the intake of oral contraceptives or long-term contact with halothane (values are even subnormal in patients taking oestrogen). • A rise in **GPT** (usually also in GOT) suggests the development of drug-induced hepatocellular damage. Generally, a so-called inflammatory type (DeRitis quotient <1) can be identified. (s. p. 95) In this context, γ-GT is regarded as the screening enzyme for drug-related activation of the biotransformation system, and GPT is seen as the screening enzyme for the resulting liver damage. • Decreased levels of **cholinesterase** point to a reduction in ChE synthesis in the area of the rough endoplasmic reticulum due to drug-related toxicity. Intake of hormone-based contraceptives likewise leads to diminished ChE activity. (s. p. 103) • The increase in **AP** suggests a toxic hepatic lesion of the cholestasis type (with or without jaundice), possibly with simultaneously augmented or normal GPT (and GOT). (s. p. 101) • This so-called **threefold pattern** (γ-GT, GPT, ChE) is regarded as an efficient and rational test to demonstrate hepatic damage with a sensitivity of approx. 95%. Cholestasis is detected by the **fourfold pattern** (γ-GT, GPT, ChE, AP) with a sensitivity of approx. 96%. (s. p. 103) (s. tab. 5.11) Additional diagnostic findings can be generated from the **enzyme ratios.** (s. p. 95) (s. tabs. 5.6, 5.7; 29.5, 29.6)

Evidence of **autoantibodies,** such as *ANA, AMA* and *SMA,* points to the immuno-allergic pathogenesis of drug-induced liver damage. These autoantibodies can be detected both singly and in a combined form. Usually, they occur in low titres. As a rule, they have been found with clometazine, fenofibrate, oxyphenisatin, papaverine, etc. *Anti-LKM 2* was detected after the administration of ticrynafene, and *anti-LM* after dihydralazine. (The subgroup *AMA anti-$M_6$* was identified as a specific antibody following the intake of iproniazid (46); it has not been found since iproniazid was taken off the market). However, autoantibodies are of no diagnostic value in medication-induced liver damage.

## 5.5 Search for causes

In most cases, the search for the causal toxin must be carried out with detective-like meticulousness. However, neither in the physician's practice nor in the hospital can this search be conducted with the required precision, since the time available is not sufficient to establish the individual medication history in depth, or the patient is generally agitated and cannot answer detailed and direct questions satisfactorily. Drug- and/or chemical-related anamneses are often incomplete or unreliable, because the patient was not given sufficient time at the doctor's surgery and was not able to take a close look at the medicines kept at home in order to provide more precise answers. • For these reasons, our **check-list**, which is given to the patient in the form of a *questionnaire*, has proved to be of great assistance over many years. (s. tab. 29.7)

| Intake via | |
|---|---|
| ○ mouth | ○ skin |
| ○ inhalation | ○ blood vessels |
| **Since when?** | **Until when?** |
| **How much?** | **How often?** |

1. **Medication?**
2. **Hormones?** (oral contraceptive, etc.)
3. **Chemicals?** (job, hobby, home, garden, environment)
4. **Alcohol?**
5. **Drug abuse?**
6. **Cosmetics?** (after-shave, personal hygiene products)
7. **Tonics?**
8. **Aphrodisiacs?** (potency drugs)
9. **Premixed herbal teas?**
10. **Food preservatives? Special foodstuffs?**
11. **Body contact with chemicals? Synthetics?**
12. **Journeys abroad?**

*Tab. 29.7:* Check-list for the detection of possible hepatotoxic xenobiotics

Very few terms in this questionnaire require further explanation, and we also include some brief instructions about how to answer the questions. The patient has sufficient time to think about the individual questions either at home or in the hospital, is able to consult family members and may even take several days to complete the questionnaire. While discussing the responses with the doctor, further information can be added. This may require repeated and sometimes outright *"inquisitory questioning"*, as the patient (*1.*) may have forgotten to

mention certain medicaments or may not consider them as such (e. g. laxatives), (*2.*) may be ashamed to admit taking or abusing certain agents (e. g. aphrodisiacs − sometimes of rather obscure composition), (*3.*) may fear detection or may not wish anyone to know (e. g. abuse of drugs, alcohol, analgesics or soporifics), or (*4.*) may also consciously (or subconsciously) repress the problems connected with toxic liver damage in line with a generally increasing tendency towards self-medication and a firm belief in tablets.

However, it must be considered that it is often only the **combined intake** of medicaments, alcohol and other chemical substances that gives rise to such biotoxometabolites, which do not form when the respective substance is taken on its own. (60, 61)

▶ **Discrepancies** between pathologically altered laboratory parameters and minor or uncharacteristic histological changes, or even normal findings in the biopsy specimen, are regarded as almost typical for liver damage resulting from drug-induced toxicity. • In individual cases, however, the histological findings can be attributed to a specific chemical substance once the toxin has been identified. • As a rule, laboratory and morphological findings are all the more distinctive when the hepatic detoxification mechanisms have been constantly used and are ultimately exhausted.

## 5.6 Herbal remedies

Remedies prepared from herbal extracts have been used by all peoples since ancient times. • In recent years, herbal remedies have enjoyed growing popularity in modern societies. This trend can be explained by the following factors: (*1.*) ecological movements in industrialized states call for a return to natural products, (*2.*) there is a widespread naive opinion that a natural product cannot be anything else but a good product, and (*3.*) it is commonly believed that unlike chemical preparations, herbal remedies are free of side effects.

Apart from the therapeutic effect, the special active agent can at the same time act as a facultative hepatotoxin in individual cases. • Furthermore, the production of herbal remedies may involve certain errors and risks which can be crucial factors in the development of liver damage. (s. tab. 29.8)

1. Misidentification of the medicinal plant
2. Contamination of the plant
   − e. g. chemicals, heavy metals, microorganisms
3. Use of unsuitable or wrong parts of the plant
4. Variations in the formation of active plant substances due to different conditions of growth
5. Adulteration of active agents during conditioning
6. Mislabelling of the end product

**Tab. 29.8:** Certain errors or risks involved in the preparation of herbal remedies

It is difficult to clarify the hepatotoxicity of herbal remedies, especially if they are comprised of a mixture of several plants or various components of the plant. Moreover, herbal remedies are often applied as automedication, and patients withhold the information that they have used them. (s. tab. 29.9) (s. fig. 29.15)

**Plants containing pyrrolizidine alkaloids**
− Crotalaria
− Heliotropium
− Senecio
− Symphytum officinale
• *These alkaloids are the main cause of VOD*

| Reported hepatotoxicity | Hepatitis | Necrosis | ALF |
|---|---|---|---|
| Atractylis gummifera | + | + | (R) |
| Callilepsis laureola | + | + | (R) |
| Cassia angustifolia (Senna) | + | | |
| Chinese herbs | + | + | (R) |
| Larrea tridentata (Chaparral) (35, 56, 106) | + | (R) | |
| Lycopodium serratum (Jin Bu Huan) (89) | + | | |
| Pennyroyal (Hedeoma pulegioides) (Mentha pulegium) | + | | (R) |
| Piper methysticum (Kava) (99, 116) | + | + | (R) |
| Teucrium chamaedrys (Germander) (26, 91) | + | | (R) |

| Suspected hepatotoxicity | |
|---|---|
| Azadirachza indica | Teucrium polium |
| Berberis vulgaris | Valeriana officinalis |
| Scutellaria lacteriflora | *etc.* |

**Tab. 29.9:** Medicinal plants with reported or suspected facultative hepatotoxicity (ALF = acute liver failure, R = rare) (with some references)

**Fig. 29.15:** Chronic toxic hepatitis after 10 months chaparral ("creosote bush") automedication. • Laparoscopy: marked acinar structure, irregular chagreen-like surface (splintered light reflex) and extremely fine fibrosis; histology: single cell necrosis, slight inflammatory infiltrations and moderate steatosis

Information about the effectiveness or safety of herbal remedies is based on experience transmitted over centuries rather than on controlled trials or toxicity studies. Numerous medicinal plants have been reported to possess facultative hepatotoxicity, or there is suspicion thereof. (53, 72, 76, 90, 108, 109)

Kava extracts can, if overdosed (> 60−120 mg kavapyrones/day) and/or taken over a longer period (> 3 months), cause hepatotoxicity in the form of hepatic reactions and liver cell necrosis; in rare cases, they may even cause cholestasis and acute liver failure (possibly leading to liver transplantation). Risk factors include the concomitant intake of medicaments and alcohol as well as a genetically based deficiency of cytochrome P 450 2 D6. (99, 116)

## 5.7 Test procedures

### 5.7.1 Withdrawal trial

The elimination of the causal noxa leads to an improvement in the pathological laboratory values, which represents an important diagnostic finding. This procedure constitutes the most significant therapeutic measure. • If various medicaments or substances are suspected to have caused the damage, one noxa after the other should be discontinued, and the effect of discontinuation on laboratory parameters should be tested after four to six weeks. The causal noxa normally "reveals itself" during this test. The drugs shown to be non-toxic can then be administered again, although laboratory parameters should be tested continuously to rule out any "false diagnosis". If a false diagnosis is established, the procedure (i.e. diagnostic and therapeutic withdrawal trial) will have to be repeated. • When hepatotoxicity due to home- or workplace-related exposure is suspected, laboratory parameters should be tested just *before* the patient goes on holiday as well as *immediately* after his/her return. This is of special significance if the patient is absent from work and/or home for at least 2 or 3 weeks. • Alcohol intake, in any form or quantity, must be prohibited during the withdrawal trial. This also applies to holiday trips that are intended to be used for such a test. • *Reliable results can only be achieved if the patient complies fully with the stringent requirements of a withdrawal trial and cooperates well!*

### 5.7.2 Re-exposure trial

▶ Re-exposure trials are regarded as *unacceptable* because dangerous exacerbations may occur. In addition, negative re-exposure trial results would not suffice to rule out drug-related liver damage completely.

At present, there are no biochemical methods that facilitate early and reliable identification of the drug-induced toxicity which causes the liver damage.

# 6 Prognosis

Patients with liver damage resulting from medicament-induced toxicity generally have a good prognosis. Changes regress completely after discontinuation of the implicated drug. However, it may take several weeks or months for the laboratory values and morphological findings to normalize. • Changes in the connective tissue remain (unless there is spontaneous reversal). These alterations appear histologically as fine periportal or periacinous fibroses (13), and laparoscopically as delicate, partly reticular fibroses, perivascular connective tissue or as a finely pimpled hepatic surface. (s. figs. 28.7, 28.10) • Vessels affected by thrombosis generally remain closed unless spontaneous thrombolysis or recanalization occurs. • The mortality is high for acute necrosing types of damage (e. g. 30−50% of halothane-induced cases). The prognosis may also be poor when various toxins take effect at the same time. The disease can progress, even though the causal toxin has been eliminated. An autoimmune process may have been triggered, or another chemical substance may have taken over the function of the eliminated causal noxa.

# 7 Therapy

▶ Liver damage may not only be caused by a certain substance, but also by an interaction of a combination of substances (e.g. multi-drug therapy, numerous constituents in plants) − moreover, this can happen in different individual ways.

The treatment of drug-induced liver damage comprises a wide range of measures. • (*1.*) *Discontinuation* of the implicated noxa is regarded as the most effective therapy. • (*2.*) In cases of acute intoxication, *elimination* of the noxa from the body is essential (e.g. gastrointestinal lavage, forced diuresis) (s. p. 572!) • (*3.*) In certain intoxications, the application of an *antidote* is required (e.g. N-acetylcystein, silibinin, deferoxamine) (s. pp 383, 571, 625). • (*4.*) In the case of lipid peroxidations, it is not known precisely to what extent a therapeutic effect is achieved by adjuvant treatment with *antioxidants*. (s. p. 67) • (*5.*) This also applies to adjuvant efforts to treat drug-induced *cholestasis* by reducing toxic-hydrophobis bile acids (e.g. lithocholic acid) with the help of ursodeoxycholic acid. The use of S-adenosyl-L-methionine has been considered in this context. (s. p. 241) • (*6.*) In rare cases, the use of *glucocorticoids* may be indicated. • (*7.*) *Symptomatic measures* may be undertaken in individual cases. They include increased intake of fluids and vitamins as well as electrolytes (if required). • (*8.*) In patients with severe courses and also in the Budd-Chiari syndrome, the therapeutic measures are the same as in acute liver failure. (s. pp 382 ff.)

# Clinical Aspects of Liver Diseases

## 30 Liver damage due to toxic substances

# 30 Liver damage due to toxic substances

► The *"chemicalization"* of the environment in the course of the last 100 years has proceeded virtually without restraint, partly as a result of ever-advancing technologies and partly because of the continuously rising demands of society and increased industrial productivity. • The liver, however, which is at the centre of the detoxification mechanisms (s. pp 52−56), is not able to adapt to new demands on the detoxification process within three to four generations. Adaptations of this kind by an organ or an organism to harmful or life-threatening influences can only take place over a much longer period of time, if at all (as has been shown in the animal and plant kingdoms).

► The *"Chemicalization"* of the workplace can be kept almost completely under control by compliance with industrial hygiene regulations. In this way, it is generally possible to avoid toxic liver damage. Specific **exposure** can, however, be expected in *occupational medicine* in the following situations: (*1.*) inadequate protective measures at work, (*2.*) the appearance of new, hitherto unforeseen or (as yet) unknown toxic compounds following a particular incident or due to a change in working techniques, and (*3.*) the combined impact of various toxic substances, especially in conjunction with alcohol and/or drugs. • In *agriculture*, the increasing use of fertilizers, animal feed additives, preservatives and pesticides has become a considerable problem. The occurrence of disulfiram-like effects has also been observed. • Far too little attention is generally paid to the risks of toxic liver damage encountered in *hobbies* or *do-it-yourself activities*. Handling chemical substances − often in small, poorly ventilated rooms over lengthy periods of time − can quite easily increase the danger of liver damage, although under normal circumstances there is nothing to fear if the manufacturer's instructions are strictly adhered to. The risk of damaging one's health is − often unconsciously − suppressed or indeed goes unnoticed.

For every liver disease that cannot be clarified with certainty, each differential diagnosis should always include toxic substances in food, at work, in the house or garden and in those places where people pursue leisure activities. It is extremely difficult to identify the causal noxa. In the individual case, however, identification can be of considerable importance for general assessment purposes and possibly when an expertise is required.

## 1 Historical review

In the 19th century, cases were observed of workers in the match industry who suffered liver damage due to **phosphorus** contamination leading to acute hepatic dystrophy. • *Since then, the relationship between exogenous noxae and liver disease has been considered unequivocal.*

► **Arsenic:** Liver damage due to arsenic was first described in 1774 by F. L. Bang. In 1888 E. Ziegler et al. reported on damage caused by arsenic to the hepatocytes and sinusoids with subsequent scarring. The occurrence of melanosis, hyperkeratosis and liver fibrosis or cirrhosis was described as *"Reichenstein's disease"* (L. Geyer, 1898). It was observed in Reichenstein (Silesia) and Freiberg (Saxony) and traced back to chronic arsenic poisoning caused by contaminated drinking water (containing up to 25 mg arsenic per litre). Toxic liver damage, even culminating in cirrhosis, due to the presence of arsenic in beer was observed in 1900. Over the following years, there were further reports of arsenic poisoning from drinking water, e. g. in Argentina (A. Ayerza, 1918), Mexico and Taiwan. In 1974 a comprehensive study was published on chronic arsenic poisoning caused by contamination of the river Tononce in Antofagasta (Chile): several hundred people became ill between 1955 and 1972; arsenic was even found in fruit juice, beer and cola as well as in milk and food. (76) • Arsenic was officially introduced as a pesticide in viniculture in 1925 (after it had already been used for this purpose for some time). Since 1942 its use as a pesticide has been banned. Consumption of the so-called *wine-grower's house drink* led to severe liver damage, liver fibrosis with portal hypertension and even oesophageal varix bleeding, carcinoma and haemangioendothelioma of the liver. This homemade wine, which was produced by watering down the wine obtained from a second pressing of the grape skins and which had a low alcohol (3−5 vol. %) but high arsenic content, was consumed in large quantities (3−5 litres per day). • The severe arsenic poisoning of an aircraft pilot who had been spraying arsenic calcium carbonate dust as a pesticide was reported in 1930. • Extensive liver damage was also observed during the long-term treatment of psoriasis with Fowler's solution. • Occurrences of well-water poisoning due to arsenic pesticides were registered as late as 1984 in the USA (2) (s. p. 569) and again in 1998 to an incredible extent in Bangladesh.

► **Thorotrast:** Thorotrast was introduced into radiology by K. Frik et al. in 1928 on the grounds of its excellent opaque properties and good tolerance. As early as 1933, the carcinogenic effect of $ThO_2$ was pointed out by C. Oberling et al. The occurrence of an angiosarcoma 12 years after the administration of thorotrast was reported by H. E. McMahon et al. in 1947. Production was stopped in 1950, but thorotrast was still occasionally used up to 1958. All in all, about 1 million patients using thorotrast between 1928 and 1958 were examined. $^{232}ThO_2$ is a 90% α-emitter with a half-life of approximately 400 years. It is never excreted from the body. Most of it (70−75 %) is stored in the liver, although the highest relative concentration per gram tissue is found in the spleen. In total, more than 125 thorotrast-induced cases of malignancy have been reported in the literature − even 36, 39 and 44 years after administration. (23, 71) (s. figs. 30.2, 30.3) (s. p. 569)

► **Thioacetamide:** In 1942 thioacetamide was introduced in the USA as a citrus fruit preservative. Shortly after ingestion of this fruit, liver damage (cell necrosis, steatosis) and cirrhosis occurred. There were even reports of fatalities. • Animal experiments showed

that the liver damage was caused with such rapidity and reliability by thioacetamide that this substance came to be used as the most potent poison (apart from CCl$_4$) for producing liver damage in animal experiments.

▶ **Vinyl chloride:** Hepatolienal diseases caused by vinyl chloride were first reported in Russia in 1949 (S.L. Tribukh et al.). Severe changes to the liver were observed by J.M. Cordier et al. in France in 1960 and by J. Suciu et al. in Romania in 1963. The carcinogenic effect of vinyl chloride (VC) was demonstrated by P.L. Viola in animal experiments in 1970. Vinyl chloride can induce two different types of liver tumour: haemangiosarcoma and hepatocellular carcinoma (C. Maltoni et al., 1974). J.B. Block reported on haemangiosarcoma in more detail in 1974, and in 1976 J.M. Gokel et al. described hepatocellular carcinoma in persons exposed to VC. The two forms of carcinoma may also occur simultaneously. (s. p. 568)

▶ **Hexachlorobenzene:** Between 1955 and 1959, more than 3,000 people in Turkey contracted porphyria cutanea tarda after hexachlorobenzene had been used as a preservative for cereals. (52)

▶ **Aflatoxin:** Fatal liver necrosis was reported in about 100,000 turkeys and ducks in England by A.J. Stevens et al. in 1960. The causative agent was found to be aflatoxin from mouldy peanut meal in animal feed. (s. p. 571)

▶ **Methylene dianiline:** In 1965 at least 84 people in the English town of Epping contracted toxic hepatitis with jaundice and cholestasis (= **Epping disease**) after eating bread which contained flour that had been contaminated by a hardening agent for synthetic resin: methylene dianiline (4.4′-diaminodiphenyl methane). Histologically, portal infiltrations, manifestations of cholangitis and centrilobular cholestasis were found. Pronounced hepatomegaly was also reported. (33, 34, 48) (s. p. 569)

▶ **Polybrominated diphenylene:** In 1973 in the USA, about 30,000 cattle and some 1.6 million chickens died or had to be slaughtered (so-called "Michigan catastrophe") after being given feed to which a flame retardant containing polybrominated diphenylene had been mistakenly added in place of a fattening additive. However, none of the exposed persons showed any signs of poisoning. (1)

▶ **Dioxin:** The first (8-fold chlorinated) dioxin was prepared as early as 1872 by the German chemists Merz and Weith. Tetrachlorodiphenyl-p-dioxin ("dioxin") was synthesized in 1957 (W. Sandermann et al.). The first large-scale case of intoxication was reported in Virginia/USA in 1949. Following the accident at the BASF chemical plant in Germany in 1953, 6 of the affected 53 persons developed liver damage. In the period leading up to the chemical disaster in Seveso/Italy on 10th July in 1976, there had been 21(!) such incidents reported in various countries, 6 of them in Germany (B. Holmstedt, 1980). Following Seveso, some 27 years after the first chemical accident with dioxin in 1949, the irresponsible underestimation and ignorance of "chloracne" poisoning − known for nearly 3 decades − finally became public knowledge. (s. p. 568) Only then was it evident that dioxin was *"the most toxic carcinogenic and teratogenic chemical substance ever made by man"*.

▶ **Salad-oil:** Since 1981 more than 24,000 persons have become ill (with 357 fatalities up to 1985) in Spain due to the consumption of salad-oil. The suspected cause was poisoning by oil which had been adulterated by being mixed with cheap industrial oil containing, among other things, aniline, acetanilide and quinoline. The patients showed generalized damage to the capillaries, including those of the liver. (64, 72)

## 2 Detoxification of toxic substances

Like medicaments, toxic substances can also enter the body by the oral, percutaneous, parenteral and respiratory routes. The detoxification and elimination of toxic substances essentially takes place via the same **biotransformation** mechanisms that are responsible for the metabolism of drugs. (s. p. 544) Overall, the capacity of the liver to eliminate foreign substances is dependent both on microsomal enzyme activity (which is affected by a number of factors) and on the blood flow through the liver. (s. tab. 3.18) Biotransformation can, however, lead to the production of **biotoxometabolites** (or biotoxometabonates), which are sometimes considerably more toxic than the original substance taken up by the body or which (by reacting with cellular proteins) can lead to the development of new hazardous substances such as mutagens, carcinogens or antigens. (s. pp 52−56) (s. fig. 3.11) For the elimination of various toxic substances including cadmium, manganese, lead, etc., the **functions of the RES** are also utilized. (s. p. 65) In addition, the **antioxidant systems** may be necessary for the elimination of other toxic substances. (s. p. 67)

## 3 Pathophysiology

While medicaments (with few exceptions) can be regarded as facultative (indirect) hepatotoxins, almost all toxic chemicals act as obligate (direct) hepatotoxins. (s. tab. 29.1; s. fig. 29.1) • The extent and type of hepatic damage caused by toxic substances is determined by a number of influencing **factors.** (s. tab. 30.1)

| |
|---|
| 1. Amount of noxious substance |
| 2. Concentration |
| 3. Duration of action |
| 4. Method of uptake |
| 5. Extent of protein binding |
| 6. Degree of distribution or accumulation of the noxa within the liver or other organs |
| 7. Radioactivity of the substance |
| 8. Excretability of the noxa |
| 9. Previous liver damage or coexisting liver disease |
| 10. Coexistent strain caused by alcohol and drugs |
| 11. Age, gender |
| 12. Nutritional status |

*Tab. 30.1:* Factors influencing the extent and type of liver damage caused by toxic substances

A variety of cellular sites of attack, sometimes very difficult to differentiate and often in combination with one another, have to be considered with regard to the **pathomechanisms** of liver damage. (s. tab. 30.2)

| |
|---|
| 1. Direct toxic damage to membranes and organelles |
| 2. Occurrence of biotoxometabolites |
| 3. Formation of free radicals |
| 4. Interactions with DNA |
| 5. Interference with bilirubin metabolism |
| 6. Interference with bile acid metabolism |
| 7. Inhibition of protein synthesis |
| 8. Inhibition of lipoprotein synthesis |

*Tab. 30.2:* Pathogenic and pathophysiological mechanisms of liver damage caused by toxic substances

Liver damage caused by toxic substances sometimes only appears and is hence first recognizable after a latent period of several years. This applies particularly to radioactive substances (e.g. thorotrast, which has a latent period of up to 40 years). Exogenous factors (alcohol, medicaments and chemicals) can substantially impair the course and prognosis of intoxication. This may be due to (*1*.) acute multiple intoxication by simultaneous exposure to various toxic substances or (*2*.) the fact that the noxa is administered during the "deficiency period" of a biotransformative induction, since toxic substances cause greater hepatic lesions in this phase.

In the individual case, the personal reaction to exposure to toxic substances can vary greatly. Long-term exposure to toxins, even in low concentrations, often leads to liver damage. (65)

# 4 Morphology

Upon the intake of direct toxic noxae, the detoxification systems of the liver are only able to react with adaptive processes in isolated cases. The "force of the respective toxicity" leads to cell damage so rapidly that there is generally no chance for time-consuming adaptation to take place.

Morphological changes due to toxic substances are characterized by **four parenchymal alterations,** which also occur in alcohol-mediated or drug-induced liver damage: (*1*.) enlargement of cells, (*2*.) steatosis, (*3*.) cholestasis, and (*4*.) necrosis. These changes are not specific to particular noxae, even though a certain pattern of damage may predominate. There are frequent reports concerning fulminant liver failure. • In addition to these parenchymal changes, there may also be **mesenchymal reactions** with stellate cell activation, portal infiltration, reticular fibre sclerosis, fibrosis and vascular changes. Parenchymal and mesenchymal alterations of varying degrees often occur in combination with each other. • After **long-term exposure,** the occurrence of liver fibrosis, cirrhosis or even malignant tumours can be expected. (s. pp 361, 495)

# 5 Toxic substances

*Toxically relevant substances* have been recognized as such either as a result of animal experiments or casuistic observations. Here, too, it has been seen that findings from animal experiments can only be applied to humans to a certain extent. The dosage and duration of exposure are extremely relevant: the lesion pattern after acute, high exposure (e.g. in an accident or attempted suicide) can differ considerably from that after chronic exposure (to both high and low quantities). • A clear differentiation must be made from *naturally occurring liver noxae and carcinogens.* These can be present in plants, particularly in fungi (e.g. 3.4′-benzpyrene) and in bacteria (e.g. ethionine, endotoxins, 3.4′-benzpyrene). As a result, beverages and foodstuffs sometimes contain toxic substances, which were present naturally in the original raw material, derive from intentionally added pesticides, preservatives and animal feed, or have been inadvertently introduced into the final product in some way. (s. tab. 30.3)

► In 1988 we carried out a **survey** in 2,008 doctor's practices (37): liver damage was ascertained in 7,095 patients and confirmed morphologically in one third of cases. Long-term exposure to commercially available chemicals was found in 9.3% of those questioned, whereby the liver damage was ascribed to such chemical noxae in 7.4% of cases. Regular simultaneous alcohol consumption was confirmed by 34.1% of these patients. The following (in order of frequency) were found to be long-term contact noxae probably responsible for liver damage: hydrocarbons, carbon tetrachloride, lead, phenols, trichloroethylene, methyl alcohol, aniline, vinyl chloride, chloroform, heavy metals, pesticides and herbicides, lyes, carbides, glue, nitrosamines, inorganic acids and dioxins. (s. tab. 30.3)

► In a further **survey** in 2,650 doctor's practices in Germany (G) and 340 in Austria (A) carried out by us in 1989, the following statistics were obtained (38): existing *acute liver disease* was ascribed to household chemicals in 11.2% (G) and 9.3% (A) of patients. The most common cause of existing *chronic liver disease* was thought to be job-related noxae in 23.4% (G) and 21.8% (A) of cases; household chemicals were held to be responsible in 8.3% (G) and 7.2% (A) of patients. Sectors associated with the development of job-related toxic liver damage were found to be as follows: painting and varnishing trades in 46% (G) and 41.8% (A), mineral oil processing industries (including the production of solvents, dyes and adhesives) in 35% (G) and 30.8% (A), dry cleaning in 28.4% (G) and 38.8% (A), pesticide production in 27.6% (G) and 24.8% (A), and food preservation in 2.5% (G) and 3.3% (A) of cases. • Genuine proof that the respective noxa is the real and sole cause of the disease can naturally only be provided in a small number of cases. However, the high patient figures in Austria and former West Germany considerably increase the validity of these findings. (s. tab. 30.3)

## 5.1 Regulations governing occupational diseases

In the current German regulations on *occupational diseases due to industrial toxins*, the respective substances are divided into six classes and assigned specific numbers. *Occupational disease* is a legal term defined under German accident insurance law; *occupation-related disease* is a medical diagnosis. In individual cases, diseases can be recognized as occupation-related and appropri-

ate compensation awarded, provided that they meet the pertinent legal requirements based on the most recent level of medical knowledge (so-called *opening clause*). The following are of importance in hepatology:

> Arsenic and its compounds
> Benzene and its homologues
> Dimethylformamide
> Halogenated alkyl, aryl or alkylaryl oxides
> Halogenated hydrocarbons
> Methyl alcohol (methanol)
> Nitrobenzene or amino-benzene compounds (with their homologues or derivatives)
> Phosphorus and its inorganic compounds

▶ When there are *good reasons for suspecting* the existence of an *occupation-related disease*, this must be reported immediately to the regional medical officer responsible for workplace health and safety, the respective governmental department for industrial medicine or directly to the appropriate industrial accident insurance provider. • Notification is mandatory for every registered doctor and dentist. No declaration of consent by the insured person is necessary, nor is there any right of objection. Notification does not constitute a breach of doctor-patient confidentiality. Insured persons or the employer can also report a suspected occupation-related disease themselves. In 1995 a total of 86,705 suspected cases were reported in Germany, of which about one fifth were accepted as occupational diseases.

▶ The doctor's obligation to report cases or suspected cases of poisoning is laid down in the German regulations on notification concerning toxic substances. This notification must be made in accordance with the *German chemicals law* using an appropriate form.

▶ *Food poisoning* does not have to be reported to the authorities unless it involves a disease covered by the German Epidemic Control Act. It is, however, strongly advisable to inform the appropriate authorities when food poisoning occurs or is suspected (see, for example, regulations relating to aflatoxin).

As regards **clarification by a medical expert,** four points are of great importance: (*1.*) gathering information for compiling a comprehensive job-history (specific job characteristics, exposure pattern, materials used, presence of additional chemical substances at the workplace), (*2.*) objectifying and quantifying the suspected liver noxa in the air (i.e. maximum allowable concentration) and in the biological material used for the job, (*3.*) assessment of the hepatotoxic potency of the working materials on humans, and (*4.*) exclusion of other possible causal factors (previous or present liver disease, alcohol, metabolic diseases, medicaments). In individual cases, discussion will focus on the extent or deterioration of already existing damage. Possible interference from potentially injurious factors must be taken into account. • **Assessment of a reduction in earning capacity** is made in accordance with the usual criteria for evalu-

ating liver diseases: (*1.*) fatty liver (20−40%), (*2.*) toxic hepatitis (20−40%), (*3.*) chronic hepatitis (40−60%), (*4.*) liver cirrhosis (40−100%), (*5.*) acute intoxication (100%), and (*6.*) malignant tumours (100%). The **measures for combating** such occupation-related diseases are based on the principles of the respective employers' liability insurance association:

> 1. **Prophylactic medical measures**
>    − recruitment criteria
>    − monitoring criteria
> 2. **Technical measures**
>    − informing staff members
>    − ventilation, monitoring the air in rooms (industrial threshold limit values), protective clothing, masks
>    − technical modifications
> 3. **Medical and social measures**
>    − acceptance as an occupational disease
>       *etc.*

## 5.2 Industrial toxins

A tabular compilation of all important known toxins can be useful for recording suspected cases of liver damage by toxic agents. (s. tab. 30.3) • Some substances are described separately below. (3, 7, 13, 14, 22, 24, 28, 39, 40, 47, 55−58, 62, 63, 65−67, 70) • The following substances may cause **cirrhosis** or **liver fibrosis:**

> Arsenic                     Iron
> Cadmium                     Phosphorus
> Carbon tetrachloride        Tetrachloroethane
> Chloronaphthalene           Tetranitromethylaniline
> Copper                      Thioacetamide
> Dichlorobenzene             Trinitrotoluene
> Dimethylnitrosamine         Vinyl chloride
> Dinitrotoluene

Some toxic substances can induce the formation of **malignant tumours.** This has been demonstrated in humans for some substances, whereas for others it has so far only been confirmed in animal experiments. Protein deficiency appears to increase the frequency of carcinoma considerably. Such substances include:

> Acrylonitrile               Tetrachlorodiphenyl-p-dioxin
> Arsenic                     Thioacetamide
> Butter yellow               Thorium dioxide
> Carbon tetrachloride        Vinyl chloride
> Dimethylnitrosamine

### 5.2.1 Halogenated hydrocarbons

Aliphatic and aromatic halogenated hydrocarbons are widely used as industrial reagents, cleaning agents and solvents. The toxicity of the individual substances is very varied, e.g. relative to trichloroethane (nominal toxicity = 1), trichloroethylene, chloroform and carbon tetrachloride have a toxicity of 8, 60 and 190, respectively. (s. tab. 30.3)

Chlorinated halogenated hydrocarbons can be taken up via the respiratory tract and via the skin (even perorally in suicide attempts). In addition, they are also dangerous in their solid form. The so-called **perna disease** is named after an insulating material mainly consisting of "**per**chloro**na**phthalene". This substance, which is commonly used in the electrical industry, produces toxic vapour during soldering; that may cause severe liver cell necrosis and acute liver dystrophy.

*Acute* and high-dosage intoxication by **trichloroethylene** leads to severe symptoms associated with the central nervous system, but **not** to (noteworthy) liver damage.

▶ *We were able to confirm this condition in a 29-year-old female patient with severe acute trichloroethylene poisoning after taking 80−90 ml trichloroethylene perorally with suicidal intent. Despite a 6-day comatose state, intensive care produced a complete recovery. Throughout the 3-week period of treatment, all of the liver enzymes remained normal, and percutaneous liver biopsy yielded normal histology.* (36)

In contrast, *chronic exposure to trichloroethylene* may lead to severe liver damage or even cirrhosis. (68)

**Dichlorodiphenyl trichloroethane** (DDT) was introduced as an insecticide in 1941. Its use in Germany has been prohibited since 1971. Toxic liver damage (steatosis, necrosis) and fatalities following liver dystrophy have been described. The strongly lipophilic properties of DDT, its accumulation in fatty tissue over many years and its resistance to all forms of inactivation or degradation are indicative of its long-term toxic potential. It can also be detected in high concentrations in breast milk. DDT considerably increased induction of the cytochrome P-450 system: Japanese workers in the plastics industry were found to have reduced bilirubin values as a result of continuous and strong enzyme induction with subsequent accelerated coupling of glucuronic acid and increased excretion of bilirubin. Peroral intake of 3−6 g DDT (e.g. with suicidal intent) causes fatal poisoning.

**Carbon tetrachloride:** Chronic intoxication due to year-long inhalation of even small quantities of hydrocarbons, including carbon tetrachloride, can lead to the development of cirrhosis. An already existing fatty liver promotes the toxicity of $CCl_4$ through the elevated affinity of the adipose tissue. The presence of trichloroethylene, vitamin A and alcohol likewise increases the hepatotoxicity of even small quantities of $CCl_4$. When there is a decrease in the activity of $CCl_4$-metabolizing enzymes (e.g. in cases of protein deficiency), a decrease in the toxicity of $CCl_4$ can also be expected. $CCl_4$ itself is atoxic; the high toxicity is produced by hepatic formation of the toxic radicals $CCl_3$, $Cl$ and $CHCl_3$ due to CYP 2E1, CYP 2B1 and CYP 2B2. (s. p. 400) Severe impairment of the membranes of the liver cells and their organelles produces massive and diffuse liver damage with steatosis and necrosis, which finally results in the collapse of liver functions, particularly haemostasis. The degree of damage to the liver and kidneys by $CCl_4$ can apparently be reduced by high intravenous doses of acetylcysteine. (4, 27, 59, 61, 75)

**Vinyl chloride:** The gaseous, pleasantly sweet smelling vinyl chloride (VC), which also has a slight anaesthetic effect, was formerly used in the production of polyvinyl chloride (PVC). Hepatolienal damage by VC was recognized in 1949 and 1960. (s. p. 565) As far as such cases could be recorded, a total of 109 fatalities occurred worldwide up to 1985. Symptoms included elevations of GPT, GOT, GDH, γ-GT and AP together with a decrease in ChE (60−70%), splenomegaly (40−50%), portal hypertension with oesophageal varices sometimes with bleeding (10−15%), as well as liver fibrosis and malignant tumours (haemangiosarcoma and/or hepatocellular carcinoma). (s. fig. 30.1) Laparoscopy shows strik-ing Glisson's capsule fibrosis (initially linear like a *"star-filled sky"*). Histology reveals severe pre-/intrasinusoidal fibrosis, often with cavernoma-like enlarged sinusoids. It was found that it is not the inhaled VC that is toxic, but rather the highly reactive epoxide chloroethylene oxide produced by biotransformation. Considerably improved regulations for protection have in the meantime prevented any new cases of the disease occurring, as far as we know. However, in view of the long latency period of about 20 years, further manifestations of the disease must be expected. (10−12, 43−45, 69)

*Fig. 30.1:* Haemangiosarcoma in a case of disease induced by vinyl chloride. Tumorous endothelial proliferation with blood cavities and vascular fissures containing erythrocytes (HE)

**Dioxin:** Of the approximately 200 isomers of dioxin, tetrachlorodiphenyl-p-dioxin (TCDD) is regarded as the most toxic: its half-life in the soil is about 10 years, whereas in humans and animals, the half-life is up to 1 year (as a result of its lipophilic properties). In the region of the liver, dioxin causes steatosis, cell necrosis, haemofuscin deposits and fibrosis with portal hypertension and oesophageal varices. In Missouri/USA in 1971, for instance, marked fibrosis was observed in poisoned animals following contact with contaminated oil. (s. p. 565) The long-term damage caused by this highly carcinogenic substance is particularly serious; this effect may be exacerbated by the simultaneous action of other chlorinated hydrocarbons, dibenzofurans or hexachlorocyclohexane. Following the use of dioxin as a defoliant in the Vietnam war ("agent orange"), a four-fold increase in the frequency of liver cancer was recorded. The number of malformations as a result of VC-induced foetotoxicity was described as enormous.

### 5.2.2 Hydrocarbon derivatives

**Pentachlorophenol:** Because of its good fungicidal, pesticidal and preservative properties, pentachlorophenol (PCP) is frequently used for industrial and domestic purposes. Numerous cases of intoxication, even via bath water, with considerable liver damage are known. Infant fatalities have been reported after nappies were washed with PCP. (77)

**Polychlorinated biphenyls** are still used in large quantities in electrical and condenser technology. One of the main members of this group of substances is perchlorobiphenyl (PCB). In fires involving polychlorinated biphenyls, toxic dioxins can be released. Biphenyls lead to powerful induction of the cytochrome P-450 system. Following exposure, biphenyls can be detected in adipose tissue and breast milk. Severe cases of liver damage, including fatalities, have been reported.

**Hexachlorocyclohexane:** During the production of this substance from chlorine and benzene under the influence of light, various isomers are also formed, particularly the toxic substance lindane.

Isomers of hexachlorocyclohexane (HCH) are found in air, soil, water, food and even breast milk. Lindane is used in large quantities in agriculture and forestry as a wood preservative as well as in veterinary medicine. Provided that the required safety measures are adhered to, no liver damage occurs during the production of lindane. On the other hand, liver cell necrosis was observed in animal experiments after HCH isomers were added to the feed; a carcinogenic effect was seen after long-term administration. An increased toxic potential is to be expected when there is simultaneous exposure to DDT, PCB, contraceptives, etc.

**Paints and varnishes:** On the basis of our experience (37, 38) and data in the literature (13, 41), working as a *painter, spray-varnisher* or *floor layer* must be regarded as more hazardous in comparison to non-exposed groups with respect to toxic liver damage. Even though dispersion pigments are mainly (i. e. not exclusively) used, paints and sprays nevertheless contain a broad range of organic solvents and substances, including fungicides and pesticides. Despite observance of the specified industrial threshold limit values, so-called combination effects can never be totally ruled out. The risk of illness is hence elevated in single cases, and it may be further aggravated by additional individual factors. Elevated transaminases are found, while steatosis and focal necrosis have been demonstrated histologically.

▶ It is always open to question as to what extent the risk threshold for chemical noxae may be exceeded due to altered technical working procedures and individual conditions despite compliance with the legal regulations. *The recruitment and monitoring criteria prescribed by the employers' liability insurance association are of great importance in this respect.*

### 5.2.3 Aromatic amines

**Methylene dianiline** (4,4-diaminodiphenylmethane) is used as a liquid hardening agent for epoxy resins. Its high hepatotoxicity was clearly seen in **Epping disease** in 1965. (s. p. 565) In the following decades (1974, 1985), severe toxic liver damage with liver cell necrosis, cholestasis and hepatomegaly was also found in workers who had been poisoned by percutaneous uptake of this substance (through carelessness). (33, 34, 48) • Other aromatic amines or nitrocompounds (e. g. dinitrobenzene: dye and paint industry; dinitrotoluene: explosives; dimethyl nitrosamine: anticorrosive agents) can likewise lead to steatosis and cell necrosis after sufficient exposure. (s. tab. 30.3)

### 5.2.4 Inorganic substances

**Phosphorus:** Poisoning by phosphorus and its inorganic compounds is rare. While insoluble red phosphorus is only slightly toxic, yellow and (above all) white forms of phosphorus show considerable hepatotoxicity. Occasional instances of toxicosis occur through rat poison containing phosphorus. Phosphorus poisoning causes a loss of glycogen in the liver cells, subsequently leading to marked steatosis and cell necrosis with portal infiltration. Jaundice appears at an early stage. Transaminases are greatly elevated, whereas ChE and Quick's value fall. Signs of increasing liver insufficiency and azotaemia are prognostically unfavourable symptoms. Postnecrotic cirrhosis (or scarred liver) can develop in survivors. (18)

**Arsenic:** Arsenic poisoning is of great medicohistorical interest. (s. p. 564) Chronic arsenic intoxication can be caused by inhalation or, more often, by oral uptake. Steatosis and cell necrosis occur in the liver; fibrosis or cirrhosis with portal hypertension and oesophageal varices develop. The presence of liver adenoma and VOD as well as liver carcinoma or haemangioendothelioma has been described. (16, 42, 50, 53, 60, 76)

**Lead:** Lead poisoning (= *saturnism*) results in mild, rapidly regressive toxic hepatitis in about 30% of cases. Occasionally, eosinophilic, acid-resistant inclusions are found in the nuclei of the liver cells (so-called lead protein complexes). Steatosis and liver-cell necrosis have also been witnessed. Although there is a correlation between exposure to lead and severity of damage, individual sensitivity to lead can nevertheless vary. In addition, lead intoxication causes an inhibition of erythrocyte δ-aminolaevulinic acid dehydratase and an induction of δ-aminolaevulinic acid synthase. This brings about the manifestation of acute intermittent porphyria. (8)

### 5.2.5 Thorotrast

▶ The introduction of thorotrast into radiological diagnostics (1928) despite foreseeable radiation damage is not exactly a glorious chapter in the annals of 20th century medicine. Thirty years passed before the administration of thorotrast was stopped (after numerous reports of severe organ damage and the development of malignancies). (s. p. 564) • The term **thorotrastosis** subsumed (*1.*) aplastic anaemia, leukaemia and osteomyelofibrosis, (*2.*) atrophy of lymphatic organs with scarring obliteration, (*3.*) fibrosis of the liver and spleen with the occurrence of scarred areas (= *dystrophia lenta*, H. F. BRUNNER, 1955), (*4.*) development of scarred areas in the form of granulomas around thorotrast extravasations (H. F. BRUNNER, 1960), and (*5.*) occurrence of malignancies. (30, 32, 49)

*Fig. 30.2:* Thorotrast liver: dark brown colouring of the liver surface with reticular bright white fibrosis

*Fig. 30.3:* Thorotrast liver: deposits of thorotrast in portal and perisinusoidal macrophages; periportal fibrosis and inflammation

The development of FNH due to thoratrast was reported for the first time in 1998. (6) In the liver, thorotrast is initially stored in the Kupffer cells; after their destruction, it is deposited in the periportal areas. From here, periportal and periacinar fibrosis as well as Glisson's capsule fibrosis develop. (s. figs. 30.2, 30.3)

## 5.3 Mycotoxins

▶ The following hepatotoxic mycotoxins are worthy of note: *aflatoxin* (Aspergillus flavus), *griseofulvin* (Penicillium griseofulvum), *ochratoxin A* (Aspergillus ochraceus), *maltrozyne* (from the fermentation of rice wine) and *luteoskyrin* (Penicillium islandicum). Their toxicity is increased by protein deficiency in the organism.

A disease of epidemic proportions affected more than 1,000 persons in India in 1974. The patients suffered from jaundice and ascites. Histological examination revealed centroacinar necrosis, inflammatory mesenchymal reactions and bile-duct proliferation; fibrosis and septal formation, sometimes ultimately cirrhosis, were determined. Mortality was 10%. The cause was thought to be the additive effect of several unidentified mycotoxins (B. N. Tandon et al., 1977).

**Aflatoxins:** So far, 13 types of aflatoxin (B, G, M) have been identified in various Aspergillus fungi. Their great toxicity is due to their alkylating effect with blocking of the DNA-dependent RNA polymerase. The highest toxicity to date has been ascribed to aflatoxin $B_1$. Under warm and humid conditions, certain agricultural products (rice, soybeans, peanuts, almonds, pistachios, hazelnuts, cereals, etc.) are attacked by Aspergillus fungi. (s. p. 565) Aflatoxins may be present in peanuts in vending machines. Some types (B, M) have also been detected in dairy products. Aflatoxins can be neither seen, smelt nor tasted. • Acute poisoning leads to jaundice, steatosis and liver cell necrosis; ascites and fulminant liver failure have likewise been observed. In cases of chronic intoxication, it is possible that cholestasis, bile-duct proliferation, fibrosis and the clinical picture of biliary cirrhosis will occur. Since 1968, aflatoxin has been regarded as the most potent hepatocarcinogenic substance; it can act alone as a carcinogen or, in the case of HBV infection, as a co-carcinogen. (15, 35, 46, 51) (s. p. 507)

## 5.4 Phytotoxins

The plant kingdom contains numerous phytotoxins. Their number is, however, far greater than has been realized so far. They are also of great significance as direct hepatotoxins. • The most important phytotoxins are considered to be the *fungal poisons* (e. g. amanitin, phalloidin, gyromitrin), *pyrrolizidine alkaloids, cycasin* from the sago palm, *safrol* from the gassafras tree, *tannins* and *3.4'-benzpyrene*.

| Carcinogenic phytotoxins | |
|---|---|
| Cycasin | Pyrrolizidine alkaloids |
| Luteoskyrin | Safrol |
| Maltrozyn | Tannins |
| Ochratoxin A | |

There have been repeated reports of intoxication by still largely unknown phytotoxins: liver cell necrosis and cholestasis following the consumption of herbal medicine made from *mulberry tree bark* (S. Tozuka et al., 1983), liver cell necrosis (even fatal) following the intake of a root extract from the *distaff thistle* (G. Lemaigre et al., 1975), poisoning by a decoction from *Callilepsis laureola* (J. Wainwright et al., 1977) and due to *mint oil* (J. B. Sullivan et al., 1979).

### 5.4.1 3.4'-benzpyrene

This polycyclic, aromatic hydrocarbon is produced continuously by almost all plants, irrespective of their habitat, and remains qualitatively and quantitatively constant. The normal content of the carcinogenic 3.4'-benzpyrene equals 1 µg/100 g dried plant material. (The assumed quantity of carcinogenic polycyclic hydrocarbons ingested daily with food and drinking water is calculated at 10 µg/day.) Food of animal origin, even in roasted, smoked or grilled form, contains substantially less benzpyrene than plants do.

### 5.4.2 Pyrrolizidine alkaloids

Pyrrolizidine alkaloids are found in > 200 crotalaria, senecio and heliotrope plants, but only about 100 types are toxic. Even honey may contain such pyrrolizidine alkaloids collected in pollen by bees from these plants. These alkaloids were held responsible for **veno-occlusive disease** simultaneously in South Africa (K. B. Mokhobo) and Jamaica (K. R. Hill) in 1951. As early as 1920, however, F. C. Willmot et al. had reported on the development of cirrhosis due to senecio poisoning. Generally, intake was in the form of "bush tea", such as an Indian herbal tea for psoriasis (P. S. Gupta et al., 1963), a dubious form of maté tea (J. D. McGee et al., 1976), an antirheumatic tea (C. L. Lyford et al., 1976) and a Mexican antitussive tea (A. E. Stillman et al., 1977). Likewise in Europe, various types of herbal tea may contain senecio alkaloids. • Liver damage manifests as hepatomegaly, epigastric pain, a rise in liver enzymes and an occasional ascites. Hepatomegaly is due to the 10−20 fold enlargement of hepatocytes, which is a result of the anti-mitotic effect of pyrrolizidine alkaloids. Centrolobular necrosis, steatosis and obliterative hepatic endophlebitis as well as an acute or chronic **Budd-Chiari syndrome** may appear. Diagnosis is established with the aid of imaging techniques. In cases of acute poisoning, death often occurs within a few days. About half the affected persons survive. Chronic intoxications sometimes lead to the development of cirrhosis and possibly malignant liver tumours. (s. p. 830)

### 5.4.3  Amanita phalloides

The highly poisonous Amanita phalloides is easily confused with the field mushroom and yellow knight fungus. About 15−25% of all fungal poisonings and 50−60% of all fatalities are due to the ingestion of Amanita phalloides. Four **Amanita species** can be distinguished: (*1.*) *Amanita phalloides* (green type), (*2.*) *Amanita virosa* (white type), (*3.*) *Amanita citrina mappa* (yellowish type), and (*4.*) *Amanita verna* (spring amanita mushroom). The fungal toxins *α-amanitin* and *phalloidin* are not destroyed by drying or heating. Some 25 g of fungus contain about 4.0−4.5 mg α-amanitin, i.e. one mushroom (approx. 50 g) is sufficient for the fatal poisoning of 1−2 persons. • The maximum serum value is reached within 3 hours of ingesting the fungal poison. As a result of the enterohepatic circulation, the serum concentration remains virtually constant for about 18 hours before beginning to fall steadily. The latency period (5−24 h) is asymptomatic. In the gastrointestinal phase (24−48 h), vomiting, gastric spasms, diarrhoea and dehydration occur, with loss of electrolytes and zinc. Metabolic alkalosis can abruptly change into metabolic acidosis. This phase is caused by the rapid onset of phallotoxic action. The hepatorenal phase sets in from about the third day onwards, with hepatic encephalopathy, cerebral oedema, a rise in transaminases, jaundice, a drop in the clotting factors, and hypoglycaemia. Death due to haemorrhagic diathesis in coma and/or uraemia occurs within 5 days; later deaths are unknown (or very rare).

> ▶ **Wieland test:** The section plane of the fungus, which is cut open, is rubbed on a newspaper. One drop of 6 NHCl is then added to the dried sap, which takes on a blue colouring in the presence of amanitin.

*Therapy* consists of gastric lavage, nasogastral intestinal lavage, for example with 100 g lactulose + active charcoal + Ringer's solution and a high cleansing enema; haemoperfusion or forced diuresis can be carried out if necessary. • Silibinin (30 mg/kg BW in 500 ml glucose solution, four times daily) as well as penicillin G (1 mega/kg BW, i.v.) have proved their therapeutic value. N-acetylcysteine, fresh plasma, glucose, AT III and vitamins can be administered as supportive measures. The therapeutic success achieved with silibinin is good; it should be administered as soon as there is suspicion of amanita poisoning without waiting for the mushroom to be identified in the urine (RIA, HPCL). It is important to keep samples of the fungi, stomach contents, blood, urine, etc. (5, 9, 17, 19, 20, 31, 54) (s. pp 378, 383)

▶ *Our own experience with the immediate use of silibinin in three validated cases of poisoning showed almost reaction-free survival*.

### 5.4.4  Helvella esculenta

The toxins in Helvella esculenta (Gyromitra esculenta) can be completely removed by boiling, but this boiled water must not be re-used as it contains the fungal poison. The toxin was found to be *gyromitrin*, a hydrazine derivative. Liver damage manifests as extensive cell necrosis. With a rapid rise in the transaminases and serum bilirubin, the illness progresses to liver insufficiency followed by hepatic coma and death. • No *antidote* is known. • *Therapy* hence consists of thorough gastrointestinal lavage with the addition of active charcoal and, where applicable, haemoperfusion. It is also advisable to use supportive measures (see above), as well as − where appropriate − thioctic acid (5 × 200 mg i.v.), zinc and selenium.

## 5.5  Endotoxins

Endotoxins are fragments of long-chain lipopolysaccharides. They pass from the cell membrane − mainly from gram-negative bacteria in the intestine − into the circulation and, as potential hepatotoxins, subsequently lead to liver damage. In the liver cells, they bring about a decrease in the activity of tryptophan pyrrolase as well as an increase in the activity of tyrosine-α-ketoglutarate transaminase. It is therefore understandable that a continuous flow of intestinal endotoxins via the portal vein may well exacerbate an existing liver disease, in particular liver cirrhosis. At the same time, these endotoxins cause fever, leucopenia, blood clotting disorders and kinin activation. The burden on the RES leads to a rise in γ-globulins with a simultaneous depressor effect on albumin synthesis.

## 5.6  Drugs

Elevated transaminases are found in more than 60% of anicteric drug addicts. It is, however, difficult to relate the respective liver damage to a particular drug as there is usually abuse of several addictive substances, including alcohol (= polytoxicomania). It is likewise extremely difficult to obtain an accurate medical history from drug addicts. Examinations by liver biopsy have presented a picture of chronic non-specific, chronic persistent or active chronic hepatitis. • Recently, there have been increasing reports of Ecstasy intoxications (and even acute liver failure requiring liver transplantation) as well as the development of liver fibrosis following Ecstasy abuse. (21, 25, 26, 29, 74)

## 6  Diagnosis

### 6.1  Chronic intoxication

The diagnosis of liver damage due to toxic substances is based on a detailed **medical history.** In addition to

general anamnesis, precise information on alcohol intake and medication is of primary importance. Alcohol and medication are regarded as substantial uncertainty factors in the differential diagnosis and assessment of liver damage due to chemical toxins. Knowledge of existing metabolic diseases and special aspects in the person's lifestyle is also important. Even though subjective symptoms are generally uncharacteristic, observations concerning the commencement of the illness, its intensity and, of course, any striking factors can nevertheless simplify diagnostic clarification. The attempt to compile a comprehensive occupational history can then begin. A certain flair for detective work may sometimes be necessary in this connection. • *It is important to obtain documentation of certain workplace-related chemicals and working materials!*

Objective **clinical findings** are obtained by *physical examination*, determination of *laboratory parameters* (γ-GT, GPT, GOT, GDH, AP, ChE) and *sonography.* Clarification of hepatitis serology is necessary. Additional laboratory parameters for differential diagnosis or long-term monitoring (e. g. immunoglobulins, P-III-P, electrophoresis) may be recommended in individual cases. Although these findings mainly serve to determine the hepatological status, the possibility or even probability of toxically induced liver damage can generally be assessed as well. In the individual case, the constellation of *histological changes* also facilitates an aetiological assessment. • Definitive elucidation can only be achieved once the respective occupational physician and industrial toxicologist have clarified the relevant conditions at the workplace. When there is any suspicion that the working environment has caused liver damage, it is necessary to notify the authorities, who will then instigate all requisite diagnostic measures and draw up expertises.

► **Objectification and quantification** of the suspected liver noxa(e) at the workplace and in the respective industrial materials are carried out in accordance with the current state of knowledge concerning toxicology in occupational medicine. *Even when the chemically induced liver damage is not obviously related to the patient's place of work, it is nevertheless recommended to seek advice and help from institutions for occupational medicine and toxicology.*

### 6.2 Acute poisoning

In cases of acute poisoning (e. g. after suicide attempts or industrial accidents), it is generally straightforward to connect the poisoning to a particular chemical noxa. Numerous **poison information centres** are accessible − round the clock (!) − for rapid toxicological and therapeutic consultation. The prognosis for poisoning depends decisively on the early commencement of therapeutic measures. • For the initial care of cases of acute poisoning, the **five-finger rule** should be observed: (*1.*) removal of the toxin, (*2.*) antidote therapy (if possible), (*3.*) elementary assistance (respiration, circulation), (*4.*) transport to the hospital, and (*5.*) collecting evidence of the intoxication (toxic substances, etc.). • Medical confidentiality also applies in cases of acute intoxication.

## 7 Therapeutic aspects

► **Acute poisoning** is the result of **three parameters:** *toxin + toxin uptake + toxin action*. **Three corresponding therapeutic equivalents** should be applied: *antidote therapy + detoxification + first-aid treatment*. Detoxification and first-aid treatment are generally at the fore until an antidote (provided one exists) can be used (information obtainable from special **emergency centres for poisons** or from an antidote list). Depending upon the type of toxin involved, detoxification can be effected by gastrointestinal lavage, diuretic therapy, blood exchange, peritoneal dialysis, haemodialysis, ultrafiltration or haemoperfusion. • In cases of severe intoxication with acute liver failure, liver transplantation is indicated. (20, 25, 66) In this context, a report has recently been published about the successful treatment of acute potassium dichromate poisoning by means of liver transplantation. (66)

► In **chronic intoxication,** the therapeutic objective is removal of the patient from the site of exposure and elimination of the noxa from the body (e. g. detoxification measures, infusions of calcium-disodium EDTA in cases of lead poisoning, etc.). There is no justification whatsoever for therapeutic nihilism. With the aid of dietetic measures (if necessary) and adjuvant therapy (N-acetylcysteine, antioxidants, ursodeoxycholic acid, S-adenosyl-methionine, etc.), the clinical course and hence the prognosis can be favourably influenced. • Insufficient regression or inadequate normalization of laboratory parameters and histological changes despite removal of the patient from the area of exposure must arouse suspicion of a *further, still existing noxa* (alcohol, medicaments, other chemicals).

Despite the presence of numerous potential hepatotoxic substances at the workplace, the frequency of industrial toxic liver damage is nevertheless low. This is no doubt due to the success of screening programmes in occupational medicine, tolerance limits for toxic substances at the workplace as laid down by law and careful compliance with all preventive measures. • However, experience has shown that one must always reckon with new, potentially hepatotoxic substances. In fact, far more attention must be paid to those chemicals belonging to the category of "recreational and hobby noxae", which are often handled with an irresponsible disregard of all risks.

# 8 Industrial hepatotoxic agents

1. **Aliphatic halogenated hydrocarbons**
   +Chloroform (= trichloromethane)
   Chloroprene (= 2-chloro-1,3-butadiene)
   +1,1-dichloroethane, 1,2-dichloroethane
   1,1-dichloroethene, 1,2-dichloroethene
   Dichloromethane
   Fluorchloromethane
   Methyl bromide (= monobromomethane)
   Methyl chloride (= monochloromethane)
   Methylene chloride (= dichloromethane)
   Methyliodide (= monoiodomethane)
   +Pentachloroethane
   Propylene dichloride (= dichloropropane)
   +Tetrachloroethane
   Tetrachloroethene (PER)
   +Tetrachloromethane (= carbon tetrachloride)
   1,1,1-trichloroethane, 1,1,2-trichloroethane
   +Trichloroethen (TRI)
   Vinyl chloride

2. **Aromatic halogenated hydrocarbons**
   Benzyl chloride (= monochlorobenzene)
   Chlorinated benzene derivatives
   Chlorinated naphthalenes
   +Chlorobiphenyl
   Dichlorodiphenyltrichloro-ethane (DDT)
   +Perchlorobiphenyl (PCB)

3. **Aliphatic hydrocarbons and cycloalcans**
   Cyclohexane
   Cyclopropane
   N-heptane
   N-hexane

4. **Aromatic hydrocarbons**
   Benzene
   Diphenyl
   +Naphthalene
   Styrene (= ethyl benzene)
   Toluene (= methyl benzene)
   Xylene (= dimethyl benzene)

5. **Aliphatic amines**
   2-acetylaminofluorene
   Ethanolamine (= aminoethanole)
   Ethylenediamine (= 1,2-diaminoethane)

6. **Aromatic amines**
   4,4-diaminodiphenyl methane
   3,3-dichlorobenzidine and its salts
   4-dimethylamino-azobenzene (= "butter yellow")
   4,4-methylene-bis(2-chloroaniline)

7. **Nitro compounds**
   +Dinitrobenzene
   4,6-dinitro-o-cresol (DNOC)
   +Dinitrophenole
   2,4-dinitrotoluene
   Nitrobenzenel
   Nitroparaffins (nitroalkanes)
   Nitrophenol
   Nitropropane
   N,N-dimethylnitrosamine
   +Picric acid (= 2,4,6-trinitrophenol)
   Tetryl (= nitramine)
   +Toluene diamine (= neutral red)
   +2,4,6-trinitrotoluene (TNT)

8. **Nitriles**
   Acetonitrile
   Acrylonitrile

9. **Acetates and silicates**
   Amyl, N-butyl, ethyl, isopropyl, methyl and N-propyl acetates
   Ethyl silicate

10. **Halogens and halogenides**
    Bromine
    Bromide
    Hydrobromic acid

11. **Ethers and epoxides**
    Diethyl ether
    +Dioxane (= 1,4-dioxane)
    Epichlorohydrin
    Ethylene oxide
    Ethylglycol ether and derivatives

12. **Alcohols and derivatives**
    Allyl alcohol
    Dichloropropanol (= 1,3-dichloro-2-propanol)
    Ethanol (= ethyl alcohol)
    Ethylene chlorhydrin (= 2-chloroethanol)
    Methanol (= methyl alcohol)

13. **Carboxylic acids and anhydrides**
    Phthalic acid anhydride

14. **Phenols and derivatives**
    Cresol (= methyl phenol)
    Pentachlorophenol (PCP)
    Phenol

15. **Cyanides and Cyanates**
    Cyanhydric acid (= prussic acid)
    +Isocyanate

16. **Pesticides**
    Dipyridyl (= 2,2-bipyridine)
    +Paraquat (= paraquat dichloride)
    +Thallium sulphate

17. **Other organic compounds**
    Aldehydes
    Betapropiolactone
    Carbon disulfide
    Dimethyl sulphate
    +Hydrazine and derivatives
    Mercaptans
    N,N-dimethylacetamide
    +N,N-dimethylformamide
    N-nitrosodimethylamine
    Pyridine
    Tetrachlorodiphenyl-p-dioxin (TCDD)
    Tetramethylthiuram disulphide (= thiram)
    Turpentine

18. **Metal and inorganic compounds**
    +Arsenic
    +Arsines
    Beryllium
    Bismuth and bismuth compounds
    Boron and boron compounds
    Cadmium and cadmium compounds
    Carbonyl
    Chromium and chromium compounds
    Germanium
    Iron
    Copper
    Lead
    Manganese
    Mercury and mercury compounds
    Nickel and nickel compounds
    Phosphine (= hydrogen phosphide)
    +Phosphorus and phosphorus compounds
    Selenium and selenium compounds
    Stibium (= antimony hydrogen)
    +Thallium and thallium compounds
    Thorium dioxide
    Tin and tin compounds
    Uranium and uranium compounds

**Tab. 30.3:** Table of important, mainly industrially used, toxic substances (selection). (+ = causes very severe liver damage, severe toxic hepatitis and acute liver failure) • *We would appreciate any corrections, supplements or additions.*

# Clinical Aspects of Liver Diseases

## 31 Metabolic disorders and storage diseases

# 31 Metabolic disorders and storage diseases

## 1 Definition

> **Primary** metabolic disorders and storage diseases are caused by endogenous factors, usually a gene mutation. Since the congenital defect is predominantly or exclusively located in the liver, the resulting diseases also become manifest in this organ.
>
> **Secondary** metabolic disorders and storage diseases are present in almost all liver diseases and occur with more or less pronounced intensity. • They are, however, also caused by faulty nutrition as well as by many exogenous factors or noxae − just as latent metabolic disorders may generally become manifest due to such factors.

> **Thesaurismoses** are storage diseases caused by the accumulation of metabolic products or substances in body fluids, organs or cells as a result of metabolic disorders.

## 2 Pathogenesis

▶ The pathogenic processes leading to the development of **primary** metabolic disorders or storage diseases are essentially caused by *two mechanisms*: (*1.*) formation of atypical macromolecules and (*2.*) extensive or complete blockage of a metabolic pathway. • These pathologically formed macromolecules cannot be broken down or secreted, with the result that they accumulate in the cells, including hepatocytes, or in the extracellular spaces. • Blockage of a metabolic pathway leads to (*1.*) insufficient production of certain metabolites, (*2.*) metabolite accumulation at the point of blockage, or (*3.*) formation of abnormal metabolites. This gives rise to the respective primary metabolic disorder or storage disease. It is, however, largely unclear what kind of mechanisms are actually responsible for liver cell damage.

▶ The pathogenesis of **secondary** metabolic disorders or storage diseases depends on the specific metabolic influence resulting from the character of the existing liver disease as well as other individual factors (e. g. malnutrition, alcohol abuse, chemicals, toxins). • Either a severe deficiency or an excessive supply of nutrients can cause persistent disorders in the hepatic metabolism and possibly result in morphological changes. This may also trigger a latent metabolic disorder which leads to further hepatocellular damage. This is especially true when the hepatic metabolism is compromised by a combination of stress factors, such as are present with diabetes mellitus, obesity, alcoholism or hyperlipidaemia.

▶ In primary or secondary metabolic disorders or storage diseases, almost all **metabolic functions** of the liver may be affected.

| Bilirubin metabolism (= jaundice) Bile acid metabolism (= cholestasis) | |
| --- | --- |
| Amino acid metabolism Carbohydrate metabolism Copper metabolism Glycolipid metabolism Iron metabolism | Lipid metabolism Lipoprotein metabolism Mucopolysaccharide metabolism Porphyrin metabolism Protein metabolism |

*Genetically induced disorders* of **bilirubin metabolism** affect (*1.*) bilirubin conjugation or (*2.*) bilirubin excretion through the canalicular membrane. This results in *functional hyperbilirubinaemia*. (s. tabs. 12.1, 12.4) (*see chapter 12*)

*Genetically induced disorders* of **bile acid metabolism** cause non-obstructive intrahepatic *cholestasis*. Cholestasis due to primary storage diseases also belongs to this group of disorders. (s. tab. 13.4) (*see chapter 13*)

## 3 Non-alcoholic fatty liver disease

### 3.1 Physiological aspects

Usually, the liver contains $0.8-1.5\%$ of its wet weight in the form of extractable, finely dispersed structural fats, which cannot be detected by normal histological techniques. Under the light microscope, the liver fat, which is mainly made up of small droplets of triglycerides, only becomes visible when an increase to $>2-3\%$ occurs. Above this value, hepatocytes "register" this event as a pathological process per se.

**Triglycerides:** Triglycerides are formed by the esterification of fatty acids with glycerophosphate being produced by glycolysis. • Short- and medium-chain fatty acids from foodstuffs as well as fatty acids derived from lipolysis within adipose tissue are bound to albumin and transported to the liver cells through the portal vein. Long-chain fatty acids from foodstuffs become inserted as triglycerides in the chylomicrons within the mucosal cells of the small intestine. After having been broken down by endothelial lipoprotein lipase, the chylomicrons reach the hepatocytes in the form of remnants together with fatty acids. There, the fatty acids are beta-oxidized (to acetate and ketone bodies) in order to release energy or to synthesize phospholipids, cholesterol ester and triglycerides. The liver cell is also capable of de-novo synthesis of fatty acids from acetyl coenzyme A. Triglycerides are synthesized rapidly, particularly when there is a sufficient supply of α-glycerophosphate and acetyl coenzyme A. This also explains the influence of glucose and insulin on the regulation of hepatocellular metabolism. High carbohydrate (and alcohol) levels increase the esterification of fatty acids to form glycerides. Partial conjugation of lipids and apoproteins takes place at the contact surfaces (i. e. membranes) of the smooth and rough endoplasmic reticulum, while the carbohydrate

component is subsequently added within the Golgi complex, so that a complete VLDL particle is formed. It is only in this form, and together with cellular membrane lipids, that triglycerides can be actively exported from the liver cell by way of exocytosis. Otherwise, both retention and thus storage occur in the liver cell. • VLDL particles secreted from the hepatocyte are once more broken down in the capillaries by lipoprotein lipase to form LDL and fatty acids. In this way, the fatty acids can be reused as an energy source, stored in fat depots or remetabolized in the hepatocytes. • The lipids stored in fat depots are likewise broken down by triglyceride lipase into fatty acids (and glycerin) and reach the liver cells again via the blood stream, where the same possibilities of metabolization exist. • The liver cell is capable of either synthesizing or metabolizing lipid substances separately within itself, both in terms of time and place. *These metabolic processes may occur parallel to and independently of each other.* (s. p. 43) (s. fig. 3.8)

## 3.2 Definition

**Liver steatosis** is defined as a condition when there are small or medium-sized fat droplets in singular, disseminated liver cells and when the fat content is $3-10\%$ of liver wet weight. • **Fatty liver** is defined as a condition when the fat storage is $>10\%$ of liver wet weight, when $>50\%$ of the hepatocytes contain fat droplets in different sizes (small to large) and when fat deposition shows a diffuse pattern in the parenchyma. • *Storage of fat in the liver cell is the most common form of morphological hepatocellular damage.*

▶ **Symptom:** Low-grade fat storage in liver cells, ranging from the deposition of tiny to medium-sized droplets, is deemed to be a mere symptom (or "metabolic siding") and therefore a harmless phenomenon. • Such a finding can be seen as a "dynamic" (short-term) liver steatosis after a high-fat meal, particularly together with alcohol.

▶ **Disease:** A diffuse fatty liver showing medium and large-sized droplets is regarded as a disease when the severity increases to a point where $>50\%$ of hepatocytes are involved (= *"from symptom to disease"*). Occasionally, excessive fat storage occurs (up to 100% of hepatocytes involved) with a high mortality rate, e.g. in acute alcohol intoxication (s. fig. 28.5) and acute poisoning due to chemicals or toxins. A maximum fat storage rate of 24% of liver wet weight has been observed.

## 3.3 Pathogenesis

When the hepatocytes are continuously inundated by fatty acids, from either the intestines or fat depots, their oxidative degradation or synthesis capacity may be reduced and triglyceride binding to lipoproteins can be depleted. This is most likely to happen whenever apoprotein synthesis or lipoprotein formation is compromised by noxae (e.g. alcohol). • Fat storage in hepatocytes is a *question of equilibrium* since accelerated or increased formation of triglycerides in the liver cell is *not* compensated by sufficient synthesis of lipoproteins and adequate secretion of VLDL from the liver cell. • Therefore, both exogenous and endogenous pathogenic

factors may be responsible for the development of liver steatosis. In this process, additive as well as potentiating metabolic disorders sometimes occur, resulting in a biochemical/morphological vicious circle. (s. tab. 31.1)

**Exogenous**
1. **Increase in lipid uptake from the intestine**
2. **Enhanced supply of glyceride precursors**
   (glucose, fructose, galactose)

**Endogenous**
1. **Increase in peripheral lipid mobilization**
   • Lipolysis ↑ (= triglyceride lipase activity ↑ )
     (by ACTH, cortisol, catecholamines, prostaglandins, caffeine, alcohol, nicotine)
2. **Inhibition of lipid utilization in hepatocytes**
   • β-oxidation ↓
   • Fatty acid-binding protein ↓
3. **Increase in lipid synthesis in hepatocytes**
   • Formation of fatty acids ↑
   • Formation of triglycerides ↑
4. **Reduction in lipid export**
   • Secretion of VLDL ↓
   • Synthesis of apoproteins B, $C_1-C_3$, E ↓
   • Disturbance in gluconeogenesis

**Tab. 31.1:** Pathogenesis of liver steatosis and fatty liver

## 3.4 Morphology

▶ The earliest histological criteria of **fatty liver** were described by W. Bowman in 1842. • As early as 1861, F. T. Frerichs demonstrated the development of hepatic steatosis and its reversibility in dogs. He gave a detailed description of minute fat droplets in liver cells and their continuous growth. Even at that time, he differentiated between **fatty infiltration** and **fatty degeneration.** Indeed, he considered fatty degeneration to be more "pernicious" than fatty infiltration. (1861, volume I, pp $285-324$; figs. 41, 42) • (see below: W. S. Hartroft et al., 1968)

### 3.4.1 Fatty infiltration

**Fat storage** in liver cells starts with tiny droplets being deposited inside the endoplasmic reticulum and cytoplasm. This fatty deposition in the form of **small droplets** without a surrounding membrane is also called *fatty infiltration* (type A) (W. S. Hartroft et al., 1968). (14) Initially, only a few hepatocytes are affected by small-droplet deposits, whereas later on whole clusters are grouped together, mainly at the periphery of the lobules or in the centroacinar area. • Slowly but steadily, the droplets become larger, resulting in **medium-droplet steatosis.** The stored fatty droplets increase further in size and eventually fill the hepatocytes completely (= *macrovesicular steatosis*). (20, 24, 40, 49) (s. tab. 31.2)

As a result of **large-droplet steatosis,** the hepatocytes become enlarged, the fine cytoplasmatic structures are destroyed and the nucleus is pushed towards the cellular membrane. The functions of the nucleus are impaired or even halted. This also results in a strong tendency of the fatty cells to develop necrosis even under mildly

**Formation of fat droplets**

**Fig. 31.1:** Glycogenated nuclei (so-called glycogen vacuolations of the nuclei) in diabetes mellitus. *Insert:* nucleus strongly laden with glycogen ( ↑ ) (PAS) (s. pp 396, 526, 589, 596, 611, 620)

**Fig. 31.2:** Large-droplet (coarse-vacuolar) fatty liver in diabetes mellitus (preliminary stage of fat cyst formation) (HE)

**Fig. 31.3:** Pronounced mixed-droplet fatty liver (Sudan red)

toxic conditions. At the same time, the hepatocyte loses more and more glycogen. **Glycogen vacuolations of the nuclei** form when nuclear glycogen is removed. (s. fig. 31.1) They can be observed in various diseases, most frequently in diabetes mellitus, predominantly in the area of the portal fields. • So-called **fat cysts** of various sizes are the result of large-droplet steatosis due to the cellular membrane being torn apart. (s. fig. 31.2) This fat-storing process results ultimately in a diffuse **mixed-droplet** fatty liver. (s. fig. 31.3) • **Peripheral** fat deposits (zone 1) are mainly caused by infectious or toxic damage directly affecting the periphery, where the liver cells are more involved in lipid metabolism via the blood stream. (s. fig. 31.4) • **Centroacinar** steatosis (zone 3) is mostly found in O$_2$ deficiency, nutrition-related damage, diabetes mellitus and alcohol abuse. It is basically considered to be the more severe form of damage. (s. fig. 31.5) • **Zonal** steatosis occurs when only certain zones or areas of a lobule are affected. • This eventually results in **diffuse** steatosis of the whole lobule. (s. fig. 31.3) In general, the left lobe shows less homogeneous steatosis than the right lobe. Regionally more pronounced fatty changes − which were formerly known laparoscopically as "yellow spots" (s. fig. 31.6), can be clearly detected as **focal** (s. fig. 8.3) or **segmental** fatty infiltration (s. fig. 8.4) by means of CT. (8, 13, 17, 26, 40)

***Fig. 31.6:*** Fatty liver with pronounced, regional, thumb-sized fatty changes at the periphery of the left liver lobe (so-called "yellow spot")

### 3.4.2 Fatty degeneration

This form of microvesicular fat storage in hepatocytes, which is also termed type B (W. S. Hartroft et al., 1968) (14), is a rare but prognostically serious condition. The cytoplasm is filled with small non-confluent fat particles

which are surrounded by a delicate membrane. This may give the hepatocytes a foamy appearance. The nucleus remains largely unmodified in the centre of the cell. Such *microvesicular degeneration* can be found in various thesaurismoses, different liver conditions and numerous drug-induced diseases. (15) (s. tab. 31.3)

### 3.4.3 Phospholipidosis

Enhanced lysosomal storage of phospholipids due to the inhibition of phospholipases is another special form of hepatic steatosis. The hepatocytes are enlarged and exhibit a distinctive foamy lucency of the cytoplasm. Crystalline inclusions and an agglomeration of myelin structures are visible in the lysosomes by electron microscopy. Mallory bodies may also be found. This idiosyncratic metabolic liver damage may even develop into cirrhosis. (s. p. 545) (s. tab. 31.4)

## 3.5 Causes

Causes of fatty liver are manifold, and combinations of causes quite common. **Acquired causes** are by far the most frequent, but there are also rare causes, e. g. coeliac disease (9, 25), parenteral nutrition. (28, 29) • **Congenital metabolic disorders** can also lead to the development of a fatty liver, as in the case of a rare thesaurismosis. • It is of considerable therapeutic and prognostic importance to differentiate between an alcoholic fatty liver (AFL) and alcoholic steatohepatitis (ASH) (s. pp 529, 531) as well as between non-alcoholic fatty liver (NAFLD) and non-alcoholic steatohepatitis (NASH). (2, 20, 24, 36) (s. tabs. 31.5−31.7)

1. **Nutritional causes**

**Tab. 31.6:** Congenital causes of liver steatosis or fatty liver (so-called thesaurismoses)

The frequency of NAFLD in the general population is given as 3−58%, whereby the great variability is due to socio-economic differences (average value 20−23%). The development of NAFLD is more closely correlated with obesity than with alcohol abuse. In the case of combined obesity and alcohol abuse, the frequency of fatty liver is estimated to be 50−60%. About one third of overweight patients suffer from type II diabetes, which in turn is responsible for the development of an NAFLD or it can lead to the formation of ASH and NASH. Consequently, if several causal factors of

NAFLD coincide, the frequency and severity of fatty liver increases. (18)

## 3.6 Non-alcoholic steatohepatitis

▶ In 1980 the term non-alcoholic steatohepatitis (NASH) was introduced by J. Ludwig et al. to denote chronic liver disease with increased enzymatic activity and the histological picture of alcohol-induced hepatitis. (60) • The histological feature itself was described by H. Thaler as early as 1962 in his paper "Fatty liver and its relationship to cirrhosis". (76) • Over the following years, transition from a diabetic fatty liver into cirrhosis was reported (S. Itoh et al., 1979) as well as from an obesity-induced fatty liver into cirrhosis (M. Adler et al., 1979).

### 3.6.1 Definition

Histologically, non-alcoholic steatohepatitis shows moderate to high-grade, mainly macrovesicular fatty degeneration of the liver cells with inflammatory infiltrates and formation of fibrosis. Cirrhosis frequently develops. • Despite the morphological similarity to alcohol-induced fatty liver hepatitis, there is no (noteworthy) alcohol consumption involved in NASH. Viral or autoimmune hepatitis are not detectable either. • There are no or only moderate subjective complaints. The transaminases are normal or slightly increased. NASH is mostly associated with obesity and/or type II diabetes, thus *NASH is regarded as the hepatic manifestation of a metabolic syndrome.*

### 3.6.2 Epidemiology

Once alcohol consumption, viral hepatitis or autoimmune hepatitis have been ruled out, NASH is deemed the most common cause of a long-term increase in

transaminases. • The information available on prevalence and general frequency is not yet sufficient. In 2−6% of the US population, however, an increase in GPT (ALT) was detected without chronic liver disease being diagnosed. (55) Based on liver biopsies, a prevalence of 1.2−9.0% was determined. (70) NASH is frequently associated with obesity (ca. 40%), non-insulin-dependent diabetes mellitus (ca. 20%) and hyperlipidaemia (ca. 20%). Women (particularly in middle age) are more often affected than men. (51, 55, 77, 78) • NASH may indeed also be found in children. (61, 67, 73). In this context, it was associated with obesity in 83% and with a disorder of the lipid metabolism in 50% of cases, while diabetes mellitus could only be detected in 5% of patients (but with increasing frequency during the further course of life as was shown in the follow-up). (67)

### 3.6.3 Pathogenesis

The development of **liver steatosis** is attributable to various exogenous and endogenous mechanisms, which may combine with and/or potentiate each other. (s. tab. 31.1) Numerous causal factors must be considered in the pathogenesis of fatty liver. (s. tabs. 31.5, 31.7)

With the increasing storage of fat, the liver cells also become more and more vulnerable to **noxae.** Thus oxidative stress may cause augmented oxidation of free fatty acids in the peroxisomes as well as enhanced activity of cytochrome P450 2E1. The biotoxometabolites (e. g. malonyldialdehyde, 4-hydroxynonenal) arising during this process provoke inflammatory infiltrations and fibrosis.

**Second-hit hypothesis:** This hypothesis has been proposed as a plausible explanation for the occurrence of NASH. (48, 70) • The first hit is considered to be the development of *fatty liver*, particularly due to hyperalimentation and obesity resulting in insulin resistance. As *second hit* follows the mobilization of free fatty acids from fat depots and their transport to the liver cells. This leads to a massive increase of free radicals due to oxidative stress with lipid peroxidation and induction of cytokines (TNFα, TGFβ, IL6, IL8). As a result, there is a reactive formation of uncoupling protein (UCP2) with a subsequent decrease in hepatocyte ATP and a disturbance of macrophage function with higher sensitivity to endotoxin. This leads to an inflammatory reaction, cell death and the formation of fibrosis. (44, 50, 65)

A *genetic basis* seems to be necessary as a predisposition of NASH; however, such mechanisms are still unknown. It is discussed that genes can influence the degree of oxidative stress, the severity of steatosis, the regulation of immune reactions and apoptosis.

▶ The pathogenesis of NASH is multifactorial, i.e. in the presence of steatosis, it is attributed to the additional (even combined) influence of different noxae (e. g. oxygen deficiency, endotoxins, medicaments, chemicals, iron, biotoxometabolites). • There should be no laboratory findings pointing to alcohol abuse; chronic hepatitis B and C as well as autoimmune hepatitis (75) must also be ruled out.

▶ From present knowledge, it can be assumed that numerous cases of cryptogenic chronic hepatitis or cryptogenic cirrhosis are attributable to the presence of NASH in terms of aetiopathogenesis.

### 3.6.4 Morphology

The diagnosis of NASH as well as the assessment of its prognosis is most reliably derived from liver histology. • In the lobule, *steatosis* is distributed mainly in a macrovesicular and diffuse manner, but sometimes it is also concentrated microvesicularly and perivenously. Glycogenated nuclei are commonly present. • The *inflammatory reaction* consists of granulocytic and lymphocytic infiltrates, which are more frequently found in the portal and perivenous area than intralobular, with or without focal necrosis. Cell ballooning, Mallory's hyaline and ubiquitin are generally present, while occasionally megamitochondria are also found. Steatosis and mild lobular chronic inflammation alone are insufficient for the diagnosis of NASH. • First of all, *fibrosis* appears within the perisinusoidal area, then additionally within the portal field; subsequently, it develops as bridging fibrosis giving rise to architectural remodelling, and eventually results in *cirrhosis* with portal hypertension. The histological picture of NASH can be mistaken for chronic hepatitis C, steroid-treated autoimmune hepatitis, drug-induced hepatitis or the early stage of Wilson's disease. It is even more difficult for the pathologist to differentiate between a cirrhosis as a result of NASH, chronic hepatitis C and autoimmune hepatitis. Often a diagnosis of cryptogenic cirrhosis has to be made. (11, 40, 42, 43, 44, 52, 54, 58, 61, 66, 70, 71, 73) (s. fig. 31.7)

**Fig. 31.7:** Non-alcoholic steatohepatitis (NASH): Hydropic degenerated hepatocytes with Mallory's hyaline (←); lymphocytic and granulocytic infiltration as well as activated Kupffer cells (HE)

▶ There are no morphological differences between alcoholic steatohepatitis and NASH. • In some 30(−50)% of patients with NASH, predominantly micronodular cirrhosis develops within 5 years.

## 3.7 Diagnosis

**Clinical findings:** Steatosis does not cause any subjective complaints or clinical symptoms; it remains undetected or is discovered incidentally when diagnostic screening is being carried out for another disease. In this context, the presence of *risk factors* (overweight, diabetes, gout, hyperlipidaemia, medication, malnutrition, etc.) is of considerable diagnostic importance. • *Subjective complaints* may include fatigue, repletion, malaise or loss of appetite. In hepatomegaly, right upper quadrant abdominal discomfort may occur, especially when stooping or lying on the right side. In obesity, which is present in most cases, hepatomegaly is often not palpable, so that the actual size of the liver may only be demonstrated by sonography (or CT). *Hepatomegaly* correlates with the severity of the fatty liver, allowing determination of the course. *Splenomegaly* is found in 20−25% of patients. (37) • In advanced cases, *skin stigmata* of liver disease as well as signs pointing to portal hypertension might be in evidence. (s. tab. 31.8)

**Laboratory diagnostics:** With increasing severity of a fatty liver or NASH, some laboratory parameters are pathological in 80−90% of cases, i. e. 10−20% of patients show normal values. There is an initial rise in *γ-GT*, and subsequently in *GPT* and *GOT*. As a rule, the mildly to moderately increased values are detected purely by chance during a medical check-up. The DeRitis quotient is < 1 (cf. alcoholic hepatitis with > 1). While this constellation in itself is a useful hint of liver cell damage induced by toxins or metabolic processes, an increase in *cholinesterase* actually suggests the presence of disturbed lipid metabolism or a fatty liver. Decreased functioning of the liver, detectable at an early stage, can be determined by measuring the *galactose elimination capacity* (s. p. 95) or by applying the *indocyanine green test* (s. p. 96); these tests may also be used in long-term follow-up. • Other important laboratory parameters include alkaline phosphatase, bilirubin, electrophoresis, ferritin, leptin (46, 68), thioredoxin (74) and parameters connected with lipid metabolism. Progressive and severe courses correlate well with laboratory values well outside the normal range. Sonographic signs of liver steatosis indicate screening for *diabetes mellitus*, if necessary with the help of the oral glucose tolerance test. (6, 36, 50, 52, 54, 55, 58, 72, 74) (s. tab. 31.8)

**Sonography:** Hepatomegaly can usually be confirmed by sonography (vertical diameter liver enlargement in MCL > 11−12 cm), with the liver generally showing a plump form. The echogenicity is increased as a result of the high number of water/fat boundary layers, and the single reflexes are coarsened (in contrast to the renal parenchyma). In general, the hepatic veins are difficult to visualize. In pronounced fatty liver, sonographic signs of portal hypertension may appear (= sinusoidal block). There is a positive correlation between the degree of fatty changes and the increase in echogenicity (so-called *large, white liver*). Fatty changes below 10−20% cannot

be reliably detected by sonography. (s. p. 117) • Often, it is difficult to differentiate *focal fatty changes* (circumscribed density of the echo pattern) from malignant foci, so that further clarification by means of scintigraphy (26) or CT scanning is required. *Fibrosis* shows an inhomogeneous parenchymal structure in relation to the degree of severity. (7, 8, 13, 23, 31) (s. tab. 31.8)

**CT:** In a fatty liver, CT scanning shows diffuse density reduction with a corresponding decrease in Hounsfield units (HU). (27) A fatty liver is markedly darker than the spleen (so-called *large, grey liver*). The vessels and bile ducts are hyperdense as compared to the parenchyma. There is a linear relationship between the extent of fat deposition and the reduction in density. The diagnostic reliability of a fatty liver determined by CT is 85−95%. *Focal fatty changes* or segmental fatty changes are easy to differentiate since, in contrast to metastases, they do not have any vascular branching. A 10% increase in the relative fat content results in a density reduction of 17−20 HU; i. e. in fatty changes of 80%, a density decrease to about −50 HU occurs. (s. p. 153) • Investigations have also been carried out to determine whether it is possible to quantify the fat content of the liver by **MRI.** (17, 21, 27) (s. tab. 31.8)

***Tab. 31.8:*** Diagnosis of fatty liver or NASH, involving determination of the degree of severity, differential diagnosis and course

**Liver biopsy:** Only morphology provides a definitive diagnosis of fatty changes in the liver cells or a fatty liver. Apart from revealing *fatty changes*, it is even more important histologically to detect *inflammatory reactions* and to determine whether there is any sign of *progressive fibrosis* (e. g. due to iron overload). (6) The result of grading and staging (43) is decisive for the prognosis. (s. tabs. 34.2, 34.3) • Laparoscopic evaluation of the liver surface is of considerable diagnostic importance, as is the targeted biopsy of hepatic areas which are suspected of being pathological.

## 3.8 Prognosis

▶ A fatty liver has a good prognosis, since complete reversibility can be achieved if the causes are fully eliminated. However, existing fibrotic processes generally remain. • A fatty liver should in no way be underestimated, since it involves many **dangers:** (*1.*) the manifold liver cell functions may be distinctly compromised, causing unfavourable effects on the liver or the organism as a whole; (*2.*) fatty changes in the liver cells make them susceptible to noxae or toxins, so that there is an increased tendency towards steatonecrosis and an impaired regeneration capacity; (*3.*) a fatty liver responds strongly to inflammatory processes with mesenchymal reactions; (*4.*) a severe fatty liver sometimes results in a narrowing of the intrahepatic vessels with ensuing impairment of biliary flow and haemodynamics, or it may even lead to the development of portal hypertension. Prognosis is essentially dependent on whether the causes of fatty liver as well as any additional risk factors can be eliminated. NASH develops into fibrosis or cirrhosis within 5−10 years in 10−40% of cases. Some 10−15% of these patients die within 10 years as a result of complications associated with cirrhosis. • Risk factors showing that NASH is progressing include: age > 50 years, body mass index > 30, type II diabetes, hyperlipidaemia, DeRitis quotient > 1, thrombopenia, and the presence of Mallory bodies. (16, 36, 50, 54, 58, 66, 71) • *Metastases* originating from a colorectal carcinoma are very rarely found in fatty liver.

## 3.9 Complications

The occurrence of complications points to the fact that fatty liver should not generally be regarded as a harmless disorder. A fatty liver as well as the various risk factors may give rise to complications which occasionally manifest as a separate disease. (20, 36, 58, 66) (s. tab. 31.9)

1. Development of fatty liver hepatitis progressing to fatty fibrosis (50%) or cirrhosis (15%) (e.g. via *non-alcoholic steatohepatitis*)
2. Formation of intrahepatic cholestasis with or without jaundice, possibly even similar to obstructive jaundice (3)
3. Fat embolism (R. Virchow, 1886) (32)
4. Compression and narrowing of sinusoids (33) with potentially reversible portal hypertension − but also with formation of collaterals and ascites
5. Intrahepatic narrowing of the inferior vena cava, with occurrence of leg oedema
6. Hepatic insufficiency (3%)

***Tab. 31.9:*** Possible complications of fatty liver

Such complications must be reckoned with in fatty liver if (*1.*) the cause or any additional risk factors have not been eliminated and continue to have an effect, (*2.*) the underlying cause has not been identified despite all efforts (= *cryptogenic fatty liver*) and thus no real starting point for therapeutic measures is given, and (*3.*) the specific cause of fatty liver, and the occurrence of NASH in particular, already has a tendency towards progression. • In this case, there is evidence of *liver cell necrosis* and inflammatory *infiltration*, both of which are reversible. However, in some cases, particularly with simultaneous *lipid peroxidation*, they can lead to a vicious circle with subsequent mesenchymal reactions. The outcome is increasing *fibrosis* or development of *cirrhosis.*

## 3.10 Therapy

*So far, no medicament has been found that can achieve a normalization of the disturbed hepatocellular lipid metabolism or bring about the release of the fat stored in liver cells.*

▶ Fatty liver does not require any specific therapy. Exclusion of the *cause* and elimination of additional *risk factors* − in as far as these two basic therapeutic requirements can be accomplished − usually result in complete regression of steatosis. • Should these measures fail to bring about a regression within a period of 3−6 months, it can be assumed that *either* exclusion of the cause and elimination of risk factors have not been successful *or* the real underlying cause was not identified, so that no effective treatment measures were actually applied. • A lack of regression thus necessitates (*1.*) renewed investigation of the cause and risk factors as well as (*2.*) consistent implementation of the therapy that results from this!

Strict *alcohol abstinence* is called for − even in those cases where alcohol is not the cause of fatty liver. The same applies to the exact adjustment of the *blood-sugar levels* in diabetes mellitus or the *uric acid values* in gout. *Hyperlipidaemia* may likewise necessitate a specific drug therapy depending on the respective type and course. • In *obesity* due to overnutrition, it is absolutely imperative to reduce weight (gradually!) by means of a low caloric diet, based on the principles of the physiology of nutrition. Proteins and water-soluble vitamins should be administered at a higher daily dosage than is normally required. The effect of dietary measures can be supported by *orlistat*. Regression of a fatty liver may be achieved by weight reduction. • Given a normal body weight, reducing the intake of fat in the diet (below the level that is usually needed) does not influence the regression of hepatic steatosis. (12, 27)

Although the therapeutical principles described above are generally accepted knowledge, pharmacological possibilities for facilitating the release of fat from the liver cells by administering **specific medication** have been repeatedly sought in the past. This has still not been achieved − *but nevertheless remains a visionary idea for the future.*

**Adjuvant therapy:** In view of the fact that it has hitherto proved impossible to restore a fatty liver by means of medication, attention has focused on the possibility of averting the pathomorphological forms of damage described above (and thus the development of a complicative progression) with the help of medicaments as an adjuvant therapy.

Prevention of fibrosis is of particular importance. Three substances have already proved their worth in the **inhibition of fibrosis:** *essential phospholipids* (EPL or PPC), *silymarin* and *UDCA*. • The antifibrogenic effect of EPL has been demonstrated repeatedly in experiments; it is based upon the stimulation of collagenase. (s. fig. 40.3) • The antifibrogenic efficacy of silymarin is attributed to the proven inhibition and transformation of Ito cells as well as the reduction in gene expression of ECM and TGF-β. (s. tab. 40.13) • Recently, an antifibrogenic effect of UDCA in alcoholic liver disease was also reported.

The occurrence of **lipid peroxidation** normally results in inflammatory tissue reactions and progression of the morphological process. Under experimental conditions, elimination of the free radicals responsible for lipid peroxidation has proved useful in therapy. The administration of antioxidants may thus be advisable as adjuvant therapy. The three most effective active agents are *essential phospholipids* (s. fig. 40.3), *N-acetylcysteine* and *silymarin*. In the case of silymarin, stimulation of superoxide dismutase, inhibition of lipoxygenase, reduction in malonyl dialdehyde and decreased consumption of glutathione have been demonstrated. (s. tab. 40.13) Administration of *vitamins C and E* as antioxidants led to the regression of fibrosis. (53) Likewise, *probucol*, an agent with antioxidant properties, caused a significant decrease in GPT and GOT.

The use of **lipotropic substances** has always been of special interest. They show a particular affinity to fats and have counteracted hepatic steatosis in animal experiments. • In a 12-month course of therapy involving patients with fatty liver, especially due to NASH, *PPC* led to a significant and lasting improvement and even to normalization of the increased transaminases and γGT within 4 weeks. (64) • *Choline* is substantially involved in the mobilization of triglycerides from the liver cell, because it uses these neutral fats to form transportable phospholipids. However, choline needs *betaine* for demethylation. Thus betaine has an important function in transmethylation processes of lipid metabolism. Resynthesis of methionine likewise requires the assistance of betaine. A dosage of 20 g/day (over 1 year) led to a reduction of transaminases, liver steatosis and inflammatory activity. (41) • *Clofibrat* proved ineffective in patients with NASH. *Gemfibrozil* (600 mg/day), which reduces the mobilization of free fatty acids from the fat depots, brought about a decrease in transaminases. • By contrast, the use of *rosiglitazone*, a peroxi-

some proliferator-activated receptor (PPAR), led to an improvement in the histological findings. This could imply that insulin resistance is significant in the pathogenesis of NASH. (63) *Atorvastatin* (10 mg/day) was effective in patients with hyperlipidaemia. *Metformin* had only little efficacy.

The use of *ursodeoxycholic* acid is advisable in cases involving a cholestatic course of NAFLD or NASH. With a dosage of 13−15 mg/kg BW/day, it was possible to achieve an improvement in the transaminase values and the fat content of the liver. An increase in dosage to 20−25 mg/kg BW/day might be advisable. (57)

A *phlebotomy* reduces transaminase levels and increases iron parameters in patients with NASH. This is understandable, since intrahepatic iron storage correlates with the severity of fibrosis.

*Liver transplantation* may be indicated in patients with considerable cirrhosis-related complications. However, NASH can also reoccur in the transplanted liver. (45, 63) This observation points to a systemic disorder of the lipid metabolism.

# 4 Faulty nutrition

A **healthy liver** is capable over a longer period of time of tolerating considerable changes in the pattern of food intake (irregular meals) or with respect to the quantity and quality of the food itself. • However, even a healthy liver reacts with functional disturbances or morphological changes to long-term **malnutrition.** During a state of hunger or a period of low protein intake, for example, almost all toxic substances have more severe effects, while the ability of the immune system to fight infections is likewise compromised. • General **hyperalimentation** results in surplus calorie supply. The excess in carbohydrates and fat usually goes together with simultaneous protein deficiency. In this context, both the kind of fat or carbohydrate and any imbalance between lipogenic and lipotropic substances are extremely important.

▶ Animal experiments have shown that **faulty nutrition,** i. e. > 90% fat, < 10% protein and < 2 mg choline per day, leads to pronounced fatty liver and even fatty cirrhosis within a few weeks. The same changes could be observed when the protein intake remained more or less normal, while extremely little methionine and choline was offered. • With a **partial surplus** of certain foodstuffs, the special nature of the excessive nutritional components is also of considerable importance. • The term **partial malnutrition** may, for example, be associated with a pronounced protein deficiency (and thus possibly inadequate production of lipoproteins) or a lack of lipotropic substances (such as methionine, choline, cystine, glycocollbetaine, pyridoxine, casein and various N- or S-methylated substances). *Protein deficiency has particularly severe consequences when toxic substances are absorbed at the same time or when the organism has to fight bacterial or parasitic infections.* • A **diseased liver** reacts to both a serious deficiency in and an excessive supply of different nutrients (e. g. proteins, certain kinds of amino acids, various lipids, trace elements) with unfavourable or even complicative developments during the course of disease.

## 4.1 Malnutrition

Functional disturbances and morphological cell damage of the liver can be observed after prolonged general

malnutrition. They are fully reversible using nutritional therapy. In *anorexia nervosa*, there may also be an increase in transaminases or a pathological tendency shown in liver function tests.

**Lipofuscin:** The presence of lipofuscin is without pathological relevance and can be witnessed when medication is taken (e. g. phenacetin, chlorpromazine) (s. p. 395) (s. fig. 21.3), with advancing age and during prolonged malnutrition. The yellowish-brown pigment granules, some 1 μ in size, are PAS-positive, orcein-negative and acid-proof. They are produced from cell-own material and stored in the centroacinar hepatocytes, i. e. between the nucleus and bile canaliculi (so-called *centroaxial pigment pathways*).

**Ceroid:** The presence of ceroid is occasionally observed in both malnutrition and in acute viral hepatitis. It is PAS-positive, orcein-positive and, like lipofuscin, acid-proof. This orange-brown granular pigment is mainly stored centroacinarly. (s. p. 397) (s. fig. 21.6)

**Brown atrophy:** In malnutrition, the liver shows a decrease in cell and nucleus size, glycogen depletion, pigment deposits, occasional siderosis as well as proliferation of Kupffer cells. The liver as a whole becomes smaller (by as much as two thirds of its normal weight). Due to its pigment deposits, particularly siderin, the liver takes on a brown colour. These changes have been subsumed under the term brown atrophy (H. POPPER, 1948).

## 4.2 Kwashiorkor

*Kwashiorkor* (meaning in the Ghanaian language "a disease which develops in a baby when it is replaced by a new baby and is weaned from the breast onto starch paps") was first described by C. WILLIAMS in 1933. This disease is caused by at diet which is extremely poor in protein, particularly animal protein, while at the same time the supply of carbohydrates and fat calories is too high. Two new hypotheses of aetiology have recently emerged suggesting that the disease stems from (*1*.) the action of excess free radicals (M.N.H. GOLDEN et al., 1987) or (*2*.) the action of dietary toxins, e. g. cyanogens, aflatoxins (R.G. HENDRICKSE, 1991; R.P. KAMALU, 1993). Generally, manifestation is attributable to intercurrent intestinal infections. In both children and adults, the symptoms include dermatosis, muscle atrophy, oedema due to hypoalbuminaemia, diarrhoea and growth retardation. The hair shows typical depigmentation (red hair), at the same time becoming straight, thin and soft. (s. p. 80) There is severe fatty liver (predominantly in zone 1), often with enormous hepatomegaly. Striking dark red skin patches appear, mainly in the periumbilical and/or inguinal areas as well as in the nuchal region. This skin discoloration as well as the red hair gave the illness the name "red boy". When animal protein is supplied, particularly in the form of skimmed milk, complete restitution can be achieved. • Kwashiorkor as such does not result in liver fibrosis or cirrhosis. However, lymphocytic infiltration of the portal fields and progressive periportal/perilobular fibrosis (as well as pancreatic fibrosis and endocardial sclerosis) can often be observed; there is also evidence of necrosis and collapse areas as well as signs of cirrhosis. Such changes are attributable to the great susceptibility of kwashiorkor patients to infections and toxic effects (e. g. aflatoxin). (30, 38)

## 4.3 Tropical juvenile cirrhosis

This clinical picture is also caused by animal protein deficiency. However, it was common practice in the affected regions to use beaver oil as a laxative, and this is known to be extremely toxic to the liver. Fatty liver, hepatomegaly and jaundice were observed; ultimately, cirrhosis of a more biliary type developed.

## 4.4 Infantile sclerosis

This disease has mainly been encountered in Jamaica. Severe fatty liver with hepatomegaly developed together with early ascites (but no jaundice) and an increasing deterioration in liver synthesis performance. Death occurs in liver coma. Morphologically, there was evidence of fibrosis as well as veno-occlusive disease, features which suggested a combination of protein-deficient nutrition and phytotoxins.

## 4.5 Obesity

In 30−50% of cases of obesity, *fatty liver* is detected. A statistical evaluation of available data (1996) revealed that 15−17% of the German population displayed a **body mass index** of > 30 (BMI = body weight [in kg] ÷ body size [in m²]). Another 40% are overweight, with a BMI of 25−30. (4) Thus the German population occupies a leading position in the world with regard to the percentage of persons who are considerably overweight. The degree of obesity correlates with the severity of fatty liver. Adipose people suffering from android distribution of fat (i. e. bulk of the fat in the abdominal area) also develop more pronounced fatty liver. (19) Steatosis is predominantly macrovesicular and localized in zone 3. The increased release of fatty acids is responsible for diminished glucose utilization, whereby blood sugar rises and insulin secretion is stimulated, with simultaneous insulin resistance. Apart from that, any excessive carbohydrates are used for liponeogenesis. The outcome is a *metabolic disorder similar to diabetes* with increasing fatty changes in the liver; this condition is further aggravated by an enhanced production of endogenous cortisol due to adiposity, with the result that a vicious circle is established. (1, 2, 5, 10, 34, 51, 61, 77, 78)

*Leptin*, an anti-obesity hormone, can prevent "lipotoxicity" from damaging hepatocytes by limiting triglyceride accumulation. A deficiency of leptin could be a risk factor for NASH. (68) Hyperleptinaemia correlates with the severity of fatty liver, but not with inflammation or fibrosis. • *Thioredoxin* is a stress-inducible, thiol-containing protein. It is elevated in NASH compared to patients with simple fatty liver. There is a correlation with increasing iron accumulation in the liver cells. Therefore, the pathogenesis of NASH may be associated with iron-related oxidative stress.

### 4.5.1 Diabetes mellitus

In type II diabetes, *fatty liver* is detectable with a frequency of 30−40%, principally due to adiposity and insulin resistance. The course is generally more aggressive with rapid progression to cirrhosis; mortality is also higher. (39) In diabetics, fatty acid oxidation in the liver cell remains undisturbed as far as coenzyme A acetate; glucose deficiency then stops any further oxidation within the citric-acid cycle. The additional energy required has to be supplied through increased degradation of fatty acids in the fat depots (= lipolysis) or reduced storage (= lipogenesis). This inevitably results in *hyperlipidaemia*, fatty liver and ketosis. Often, so-called *glycogen vacuolization of the nuclei* is found, mainly in the vicinity of the portal fields. Ketoacidosis increases lipolysis, causing steatosis to progress. • In a type I diabetes, however, fatty liver is less common and is indeed only to be expected in a ketotic metabolic situation, e.g. if the diabetes is not well-regulated. The course is more favourable; the mortality rate is not influenced. (2, 22, 34, 39, 64, 78) (s. fig. 31.1)

### 4.5.2 Hyperlipidaemia

Disorders of lipid metabolism, particularly type IV (endogenous hypertriglyceridaemia), cause fatty liver to develop. Hyperlipidaemia is present in ca. 50% of patients with sonographically determined fatty liver. (2, 56) • Likewise, patients suffering from **gout** are very often found to have fatty liver. Both these metabolic disorders frequently appear in combination with obesity.

# 5 Reye's syndrome

> ► This syndrome was described by W. R. Brain et al. in 1929. (81) In 1963 it was differentiated as a clinical pathological entity by R. D. K. Reye et al. and defined as a feverish disease of unclear aetiology in infancy. Almost half the children died of cerebral manifestations including brain oedema. (91)

## 5.1 Causes

Causes, which are generally linked to a genetic disposition, include viral infection (e.g. influenza viruses, varicella) and the administration of salicylates (involved in some 95% of cases). (90) • In the USA, as many as 2,900 cases were reported in 1973 alone, with more than 800 fatalities; a further 1,207 cases were reported between 1980 and 1997. (80) About 98% of these patients were younger than 20 years of age. The frequency peak was 1978 to 1980; the disease appeared predominantly in December to April, i.e. during the so-called influenza peak. It only occurs rarely nowadays: from 1994 to 1997 only two cases were observed. (79, 80, 82, 85, 87, 90) (s. p. 271)

## 5.2 Clinical picture

The onset of the disease is an influenza-like, feverish syndrome. Uncontrollable vomiting results in severe hypoglycaemia. Progressive CNS disturbances develop along with convulsions, clouding of consciousness and brain oedema. Laboratory values show a pronounced increase in the transaminases, distinct hyperammonaemia and moderate cholestasis (without jaundice). Striking features are elevated serum levels of alanine, glutamine and lysine. There are severe blood coagulation disorders. • The tumour-necrosis factor is increased. Hepatomegaly and microvesicular fatty changes in the liver cells predominate. The hepatocytes are swollen and depleted of glycogen. Cell necrosis is found at the periphery of the lobules. The smooth endoplasmic reticulum and peroxisomes are clearly increased, while the mitochondria are swollen and deformed; no signs of inflammation are present. (s. fig. 31.8) Development of chronic liver disease has not been observed as yet. The mortality rate is 30−50%. (82, 83, 84, 86−89, 92)

***Fig. 31.8:*** Reye's syndrome (newborn): fine-droplet fatty changes of hepatocytes as well as glycogen depletion; no signs of inflammation (PAS)

# 6 Acute fatty liver of pregnancy

> ► The first descriptions of acute fatty liver of pregnancy were given by H. J. Stander et al. (1934) (109); H. L. Sheehan (1940) later defined this disease as a separate syndrome. (107)

## 6.1 Clinical picture

This severe clinical picture occurs more often than has previously been assumed; nowadays, however, the survival rate is higher. Incidence is about 1 in 13,000 births. (97, 104, 105, 114) • The cause is still unknown. Up to now, a correlation with high-dosage intravenous tetracycline has been assumed. (98) An analogy to Reye's syndrome is also under discussion, as this clinical picture is considered to be part of the spectrum of pre-eclampsia. Primigravidas and multigravidas are equally affected. There is evidence of an already existing genetic enzyme defect (3-hydroxyacyl-CoA dehydrogenase?). (102, 111) Acute fatty liver of pregnancy occurs in the third trimester, particularly in the 34<sup>th</sup>−36<sup>th</sup> week. The disease

begins in a state of complete well-being and a hitherto uncomplicated pregnancy. It comprises nausea and vomiting (often coffee-ground-like), polydipsia, right-sided abdominal pain, headaches and jaundice. Pruritus is rare. Sometimes, gastrointestinal bleeding, oedema and ascites occur. Encephalopathy develops with neurological symptoms similar to eclampsia. Hypertension, tachycardia, proteinuria and oliguria as well as signs of acute pancreatitis are frequently observed. The whole clinical picture of the disease is characterized by multiple organ insufficiency with haemorrhagic diathesis and fulminant hepatic failure. However, relatively asymptomatic and moderate courses with jaundice have also been witnessed.

**Laboratory values** show progressive hyperbilirubinaemia up to about 15 mg/dl, an increase in alkaline phosphatase (3 to 5 times above the normal range) and triglycerides as well as a rise in the transaminases up to about 500 U/l. Usually, $\gamma$-GT is normal. Uric acid, which is elevated in most cases, is considered to be an early laboratory marker of the disease. Severe hypoglycaemias are evident. A striking feature is pronounced leucocytosis ($> 50,000/\mu l$), with neutrophils predominating. The differential blood count shows giant thrombocytes, target cells and normoblasts. There is a tendency towards bleeding due to thrombopenia as well as to a decrease in Quick's value, fibrinogen and AT III; disseminated intravascular coagulopathy is usually present. (96, 99, 105, 106)

**Computer tomography** provides evidence of massive fatty deposits in the liver. (88, 112) • *Sonography*, however, does not generally demonstrate such steatosis. There is pronounced hepatomegaly. (94)

**Liver biopsy** may be required for diagnosis − unless there are any contraindications. (s. tab. 7.4) In order to detect the characteristic microvesicular (mainly centroacinar) fatty changes, fixation without alcohol and examination of the biopsy material in the form of a frozen section are necessary. (108) The hepatocytes are swollen and resemble so-called foam cells. The nucleus is pyknotic. The mitochondria are deformed. (s. fig. 31.9)

***Fig. 31.9:*** Microvesicular fatty changes of liver cells in acute fatty liver of pregnancy (Sudan red)

Additional **complications** were observed during the course of disease, including pronounced cholestasis (113), portal hypertension (95) and liver rupture (101).

## 6.2 Prognosis

The prognosis depends on early diagnosis and subsequent early (even premature) delivery. When a pregnant woman in the third trimester suddenly suffers from complaints and/or when the laboratory liver values are pathological, acute fatty liver of pregnancy should be suspected and other hepatobiliary diseases excluded as soon as possible. • The previous mortality rates for mother (ca. 90%) and child (ca. 70%) have been reduced to $10-35\%$ and $7-50\%$, respectively. The duration of the disease up to the death of the mother was on average 11 days (3 days up to 6 weeks), and in cases of survival from 2 to 8 weeks. (97, 104, 105, 106, 110) • After acute fatty liver of pregnancy has been overcome, the liver values normalize within a few days. There is no danger of chronic liver damage. In subsequent pregnancies, there is mostly no tendency to relapse, and there are no contraindications against further pregnancies. (93, 114) However, a certain risk remains, so that the women affected should be given the relevant information. Usually, the patient prefers not to risk a further pregnancy.

## 6.3 Treatment

Immediate delivery (per section or vaginally) is the most important treatment. Further therapy consists of intensive medical care. (96, 106, 113) In individual cases, liver transplantation may be indicated. (103)

# 7 Mauriac's syndrome

This clinical picture was described by P. MAURIAC in 1930. Pathogenesis is attributed to pluriglandular dysregulation. In combination with difficult-to-control infantile or juvenile diabetes mellitus, secondary glycogenosis may develop due to large deposits of glycogen and fat in the hepatocytes, resulting in *hepatomegaly*. • In addition to considerable fluctuations between hyperglycaemia and hypoglycaemia, there is evidence of hypercholesterolaemia, hyperlipidaemia and acetonuria. The clinical picture is characterized by repeated abdominal colic, meteorism, venectasias of the abdominal wall, buffalo obesity, moon face, retarded growth and osteoporosis. Careful monitoring and stabilization of diabetes mellitus are the most essential aspects of the treatment. (115)

# 8 Protein storage diseases

Numerous proteins are produced in the liver. *Genetically induced disorders* of protein metabolism may cause pro-

teins to be stored in the hepatocytes or even deposited in the intestinal tract. Primary storage diseases in this context include: (*1*.) $\alpha_1$-antitrypsin deficiency, (*2*.) amyloidosis, and (*3*.) $\alpha_1$-antichymotrypsin deficiency.

# 8.1 $\alpha_1$-antitrypsin deficiency

▶ The association between lung emphysema and $\alpha_1$-antitrypsin ($\alpha_1$AT) deficiency was recognized by C. B. LAURELL et al. in 1963. The development of liver cirrhosis due to $\alpha_1$AT deficiency was first observed in children by E. FREIER et al. in 1968 and in adults by N. O. BERG et al. in 1972.

This disease is biochemically more correctly termed **$\alpha_1$-protease inhibition deficiency** since the protein acts against trypsin and numerous serine proteases, in particular chymotrypsin and leucocyte elastase. In the pulmonary alveoli, for example, elastase inhibits the breakdown of elastin. • Serum $\alpha_1$AT is a glycoprotein with 394 amino acids and 3 carbohydrate chains. It is generally synthesized in the Golgi apparatus of the hepatocytes, although small amounts are also formed in the gastrointestinal tract and in macrophages. Due to gene mutation, the transport of $\alpha_1$AT from the endoplasmic reticulum (high-mannose type) to the Golgi apparatus is inhibited, so that the "secretion-competent complex" cannot be produced (= *$\alpha_1$AT deficiency*). (125) Thus $\alpha_1$AT is not transferred to the blood by way of exocytosis, but remains stored in the endoplasmic reticulum in the form of **globular deposits** and is subsequently broken down. • The $\alpha_1$AT gene is localized on chromosome 14 q 31−32 and possesses about 75 allelic variants, which are named according to the **Pi nomenclature** (= **p**rotease **i**nhibitor). In homozygosity, *normal allele PiM* regulates the formation of the normal phenotype PiMM, which is present in >90% of the population. • Alpha$_1$-antitrypsin deficiency is caused by an autosomal recessive mutation of two alleles. • **Homozygous defective alleles** are: PiZZ, PiSS, PiZnull, PiPP, PiWW, Pinull, PiMmalton. They show plasma concentrations between 0% and 15% of the normal $\alpha_1$-AT value. *These homozygous combinations of defective alleles are accompanied by a high risk of pulmonary emphysema, newborn cholestasis, infantile hepatitis, cirrhosis and hepatocellular carcinoma.* • PiMS, PiMZ, PiSZ, PiFZ and PiMnull are deemed to be **heterozygous defective alleles.** In Europe, the allele type PiMZ is found in 3%, PiMS in 7%, and PiSZ as well as PiZZ in 1% of the population. Plasma values range between 42% and 60% of the normal $\alpha_1$AT value. Heterozygosity thus causes only moderate and/or intermediary $\alpha_1$-AT deficiency, but is nevertheless considered to be a *predisposing factor of liver disease.* (117, 118, 120, 126−128, 132)

## 8.1.1 Clinical picture

The great variability of this clinical picture depends upon allele type, age at initial manifestation and individual progression. • About 0.02−0.06% (1 : 1,500−3,500) of all newborns are *homozygous carriers* of defective alleles. In 10−12% of these, conjugated hyperbilirubinaemia with intrahepatic cholestasis and pruritus develops within the first months of life. A lethal course is possible; in most cases, the cholestasis present in the newborn disappears by the age of six or seven years. Hepatosplenomegaly generally persists. In 10−15% of the patients, cirrhosis is most likely to develop. Additional genetic or exogenous factors are held responsible for manifestation and progression. An $\alpha_1$-antitrypsin deficiency of the PiZZ type caused *cirrhosis* in 45−50% (as shown after autopsy) and *liver carcinoma* in 25−30% of adults. In some 50% of

homozygous patients, nothing more than an increase in the transaminases was observed. Uninhibited neutrophilic elastase results in a loss of elasticity in the lung, so that emphysema and obstructive pulmonary disease develop. However, a combined hepatopulmonary disease is rarely witnessed. Extrahepatic manifestations include pancreas fibrosis, panniculitis, glomerulonephritis and arterial aneurysm. • *Heterozygous* $\alpha_1$-antitrypsin deficiency does not cause any manifest hepatic or pulmonary diseases as a rule, but it is considered to be a predisposing factor. Heterozygotes of type PiZ have an increased risk of HCC both in a non-cirrhotic liver and in the absence of liver disease. Heterozygous carriers are in any case overrepresented in patients suffering from cryptogenic or viral chronic hepatitis and cirrhosis. A higher prevalence of PiMZ was found in idiopathic haemochromatosis; greater frequency was likewise observed in pregnancies and twin births. There was a higher prevalence of PiZ in polyarthritis rheumatica. (116, 120, 122, 124, 126, 127, 129, 134, 135)

## 8.1.2 Diagnosis and treatment

Evidence of conjugated jaundice in neonates as well as frequent bronchopulmonary infections in infants arouse suspicion of $\alpha_1$-antitrypsin deficiency. In later life, this genetic cause needs to be ruled out in cases of cryptogenic chronic hepatitis or cirrhosis. • Reduction in the $\alpha_1$-globulin fraction in electrophoresis to <2 rel.% is an important indicator of $\alpha_1$-antitrypsin deficiency, because $\alpha_1$AT is the main component of $\alpha_1$-globulins (90%). Diagnosis is confirmed by determination of $\alpha_1$AT in the serum. *Normal values* range between 190−330 mg/dl or 80−147 IU/ml. The half-life is approx. 5 days. Values <20% of the normal level suggest a homozygous type, while a 40−70% reduction below normal points to a heterozygous type. Identification of the phenotype of $\alpha_1$AT is possible. Alpha$_1$-AT is normally also found in tears, rhinal secretion, saliva, duodenal juice, bronchial secretion, cerebrospinal fluid and breast milk. • *Liver histology* points to cholestasis or changes in the biliary ductules. PAS-positive, diastasis-resistent, 1−40 μm sized globular deposits of $\alpha_1$AT in the hepatocytes are typical features, mainly found in the periportal area (zone 1), but only in homozygosity. (119, 120, 126, 133) (s. fig. 31.10) Inflammatory and fibrotic reactions are detectable in the vicinity, although $\alpha_1$AT is not considered to be a toxic agent. Copper content in the liver is increased. In progressive fibrosis, there is generally a rise in P-III-P in the serum. The prognosis for $\alpha_1$-antitrypsin cirrhosis is much poorer than for other types of cirrhosis; the mean survival rate is reported to be 2 years after a diagnosis has been established. In 10−30% of cases, hepatic carcinoma can be expected. (127, 131, 136)

**Causal treatment** is not yet possible, but *gene therapy* may prove feasible, i. e. integration of a normal allele M into the genome of the patient's somatic cells. *Substitu-*

*tion* with $\alpha_1$AT (e.g. infusion or aerosol inhalation of $\alpha_1$AT) is less promising. An increase in $\alpha_1$AT synthesis has been attempted by means of androgens and oestrogen antagonists (e. g. tamoxifen). • In progressive cirrhosis and imminent liver failure, *liver transplantation* is indicated. (123, 127, 130) The five-year survival rate in children was 83%. (121) Transplantation allows a phenotypical healing to take place.

**Fig. 31.10:** Serologically confirmed $\alpha_1$-antitrypsin deficiency type PiZ in a juvenile patient (homozygosity). Globular $\alpha_1$-antitrypsin deposits in the hepatocytes ( ↑ ); PiZ immunohistochemistry with PiZ antibody ATZ11

## 8.2 Amyloidosis

Amyloid is an insoluble protein-polysaccharide complex consisting of fibrillary protein, AP component and glycosaminoglycan; this AP protein is identical with the regular serum amyloid P (= SAP). Amyloid is mainly stored in the extracellular spaces. The substance shows a strong affinity to iodine (R. Virchow, 1854: "amyloid" = "starch-like") and Congo red (H. Puchtler et al., 1962). Under a polarizing microscope, amyloid shows a green staining with double refraction. Electron microscopy reveals a fibrillary structure with $7-10$ μm fibres. Various amyloid types can be distinguished, depending on the different kinds of protein in the fibrils. Secondary amyloidosis is the most common form. • Autosomal dominant hereditary amyloidosis is transmitted by means of structurally altered transthyretin (TTR). Meanwhile, more than 60 mutations of TTR have been detected. The gene responsible is located on chromosome 18; a gene test is already available. (138, 141)

**AA amyloid** appears in a generalized form and is mainly stored perireticularly in the kidney, spleen and liver. This kind of amyloidosis occurs as (*1.*) a **congenital** form in cases of familial Mediterranean fever, (*2.*) an **idiopathic** (= primary) form without any associated basic disease, and (*3.*) a **reactive** (= secondary) form in chronic inflammations or tumours (e.g. Hodgkin's disease) as well as in drug abuse and AIDS.

**AL amyloid** (AIg) possesses fibrils composed of fragments from Ig light chains of the *kappa* or *lambda* type. This amyloid is stored pericollagenically both in a generalized and organ-localized form. Deposits in organs, including the liver, may take the form of nod-

ules (so-called amyloid tumour or paramyloid). AL amyloidosis may be: (*1.*) **idiopathic** (= primary) without any associated basic disease or (*2.*) **reactive** (= secondary) in cases of multiple myeloma, Waldenström's syndrome, Bence-Jones plasmocytoma and various type B cell tumours.

Further differentiation distinguishes between **AF amyloid** (ATTR) (amyloid types in familial amyloidosis), endocrine **EA amyloid** and **AS amyloid** (occasionally detected in old age in its isolated form in the heart as well as in the brain) and **AB amyloid** (A$\beta_2$m) (often observed in the osseous system during long-term dialysis).

### 8.2.1 Clinical picture and diagnosis

Clinically, pronounced *hepatomegaly* predominates; later on, splenomegaly also develops in most cases. An increase in *alkaline phosphatase* is observed at a relatively early stage. Severe courses of intrahepatic cholestasis have been observed. (137, 144, 146, 147, 151, 154, 155) In most cases, these involve obstructive cholestasis due to deposits of fibrils between the sinusoidal wall and hepatocytes, so that the canaliculi and the ductules are compressed. Hepatic enzymes and liver function tests are normal or deviate only slightly from normal values. *Jaundice*, which appears only in the late phases, is indicative of a poor prognosis. A decrease in *cholinesterase* is considered to be a sign of increasing amyloid deposition with subsequent compromising of de novo synthesis. Factor X is often decreased. • In *CT scanning*, a reduced contrast medium enhancement in the area of amyloid storage may be detected. *Scintigraphy* by means of $^{99m}$Tc-sulphocolloid shows markedly decreased uptake in the spleen as compared to the liver, and also metastasis-like storage defects. (156) • The tracers $^{123}$I-SAP or $^{99m}$Tc-SAP show abnormal uptake into amyloid deposits. (143) In individual cases, *involvement of other organs* (kidney (137, 140), heart, spleen (150, 152, 155), intestines, CNS, carpal tunnel syndrome) suggests the existence of amyloidosis. Often, there is reddish-brown dyschromia. (141) • Rectum biopsy, when carried out expertly, provides diagnostic accuracy in $80-85\%$ of cases. Aspiration biopsy from bone marrow or subcutaneous abdominal fat tissue only has an accuracy of $40-50\%$. (s. fig. 31.11)

**Fig. 31.11:** Liver amyloidosis: Perisinusoidal amyloidosis with atrophic hepatocyte trabeculae (HE)

**Morphology:** Amyloid is also stored in the small portal vein branches of the liver. Depending on the guiding fibres used by amyloid, it is possible to differentiate between perireticular and pericollagenous amyloidosis. The vascular amyloid involvement together with the solidity and fragility of the liver are the cause of occasional excessive *haemorrhagic tendency* (142); this condition is also given after liver biopsy. Therefore, **percutaneous liver biopsy** must be considered as a *contraindication.* (s. tab. 7.4) If liver histology is required, the sample should be obtained by **laparoscopic liver biopsy,** so that targeted treatment measures can be applied "with visual control" should complicative bleeding occur. (s. pp 157, 158) The biopsy specimen is pale pink. The liver surface appears pale and wax-like with coarse reddish marbling. (s. fig. 31.11)

### 8.2.2 Prognosis and treatment

The **prognosis** for amyloidosis is poor. In AL amyloidosis, fewer than 20% of patients had a five-year survival rate. A course of $1-2$ years is regarded as a mean survival period. The outcome depends mainly upon renal and cardiac amyloidosis; the prognosis regarding the liver is determined by the development of portal hypertension or acute liver failure. (139) Cytostatics are recommended for the **treatment** of benign or malignant B cell tumours in type AL amyloidosis, while melphalan and prednisolone are used for concomitant amyloidosis. However, therapeutic measures are generally limited. The mobilization of amyloid deposits may be attempted by administering dimethyl sulphoxide ($1.5-10.0$ g/day). • In secondary amyloidosis, treatment of the underlying disease is the main issue; individual cases have been reported in which amyloidosis disappeared due to successful therapy. • In hereditary amyloidosis, the indication for *liver transplantation* is given, since the liver is indeed the main site of transthyretin synthesis. Mutant transthyretin is no longer detectable in the serum after transplantation. (145, 148, 153, 155) Regression of extrahepatic amyloid deposits has been reported following transplantation.

### 8.3 $\alpha_1$-antichymotrypsin deficiency

In genetically (autosomal dominant) induced $\alpha_1$-antichymotrypsin deficiency, this inhibitor of serine proteases is not secreted in sufficient quantities from the hepatocytes or alveolar macrophages. Therefore $\alpha_1$-antichymotrypsin is stored in these cells. The deposits can be detected as cellular inclusions by light microscopy. Patients suffering from this condition may develop chronic hepatitis and cirrhosis. ($157-159$)

# 9 Amino acid storage diseases

## 9.1 Hereditary tyrosinaemia

▶ This clinical picture was described for the first time by M. D. BABER in 1956; it was identified as an enzyme deficiency by B. LINDBLAD et al. in 1977.

**Tyrosinaemia type I** is very rare (incidence 1 : 100,000 births). It is caused by an autosomal recessive defect of fumarylacetoacetate hydrolase (localized on chromosome 15 q $23-25$), which impairs tyrosine degradation. Tyrosine metabolites accumulate at the point where the metabolic process is compromised. This results in either an **acute** clinical course initiated immediately after birth and usually leading to a quick death or a **chronic** course in which patients reach adult age. (160, 161, 163, 164)

**Tyrosinaemia type II** is caused by reduced activity of tyrosine aminotransferase, resulting in a greater concentration of tyrosine in the serum. This may develop into an independent **congenital-hereditary** clinical picture or physiological hypertyrosinaemia, which occurs in about 10% of newborns as a **neonatal-transitory** event.

### 9.1.1 Clinical picture

The gene mutation inhibits hydrolytic cleavage of fumarylacetoacetate into fumarate and acetoacetate. Consequently, the toxic precursors maleylacetoacetate and fumarylacetoacetate accumulate in the liver and kidneys. They possess a reactive double bond and can therefore react with macromolecules to assume the properties of alkylating substances. In addition, intracellular glutathione deficiency develops due to the stable complex formation with glutathione, favouring *lipid peroxidations*. Enhanced formation of δ-aminolaevulinic acid can also be observed during occasional attacks of acute intermittent porphyria (G. MITCHEL et al., 1990).

The **acute course** in newborns is characterized by vomiting and diarrhoea as well as growth disturbances. Hepatosplenomegaly, hypoalbuminaemia, hypercholesterinaemia and hypoglycaemia as well as oedema/ascites and coagulopathy develop very rapidly. A striking feature is the early and marked rise in the $\alpha_1$-foetoprotein value in the serum. Excretion of succinylacetone ($> 50$ nmol/l) and delta-aminolaevulinic acid in the urine is noticeably increased. Methionine, phenylalanine and tyrosine are clearly elevated in the serum. A slight rise in transaminases and serum bilirubin occurs. Death is due to acute liver failure. • There is histologic evidence of extensive necrosis, fatty infiltration, cholestasis and regenerative nodes in the liver. • Should the newborn survive the first few months, the proximal renal tubule suffers complex damage, resulting in the clinical picture of **Fanconi's syndrome**: glucosuria, aminoaciduria, phosphaturia including osteomalacia, and renal tubular acidosis with polyuria.

The **chronic course** is characterized by a milder form. The general symptoms are less pronounced, and often they do not appear before the patient reaches school age. Hepatosplenomegaly is present. Laboratory findings include hypoalbuminaemia, coagulopathy and markedly elevated serum values of $\alpha_1$-foetoprotein, methionine, tyrosine and phenylalanine. Activity of the fumarylacetoacetate hydrolase in leucocytes, fibroblasts and hepatocytes is increased. • The *liver* is granular and firm with a yellowish colour. Histologically, the picture is similar to that of galactosaemia (fatty changes, tubular

transformation, cholestasis, periportal fibrosis, central sclerosis). Within a few months, micronodular cirrhosis is detectable with early multifocal liver cell carcinoma. (160, 163, 166) • *Fanconi's syndrome* (see above) also develops in the chronic course. Occasionally, there are symptoms of peripheral neuropathy.

### 9.1.2 Treatment

The **prognosis** is determined by the early onset of acute liver failure in the newborn and, in the following months or years, by the development of hepatocellular carcinoma. (163, 167) • A **liver transplantation** is thus recommended as from the second or third year of life. (162) Dietary measures (avoidance of methionine, tyrosine and phenylalanine as nutritional components) have not proved particularly successful. • Good therapeutic results were achieved when 2-(2-nitro-4-trifluoromethyl-benzoyl)-1-3-cyclohexanedione) (NTBC) was applied. This substance is an inhibitor of 4-hydroxyphenylpyruvate dioxygenase, which prevents the accumulation of succinylacetone. (165) Even the risk of HCC development was reduced by this substance.

## 9.2 Disturbances of the urea cycle

**Six enzymes** are involved in the urea cycle: (*1.*) carbamoylphosphate synthetase (CPS), (*2.*) ornithine transcarbamylase (OTC), (*3.*) argininosuccinate synthetase, (*4.*) argininosuccinate lyase, (*5.*) arginase, and (*6.*) N-acetyl glutamate synthetase − as well as enzymes involved in supply reactions. They may be compromised by a genetic defect. Up to now, 6 congenital disorders of the urea cycle are known. The cumulative frequency is estimated at 1 : 8,000. • The genetic disorder is autosomal recessive; only the ornithine transcarbamylase disorder (= OTC deficiency) shows a dominant chromosomal pattern of transmission (chromosome p 21.1). This is the most frequently detected intramitochondrial defect to date (1 : 14,000). (172) • Following preliminary detoxification of ammonia at the site of formation by reaction with glutamate (whereby glutamine is formed), definitive detoxification takes place in the urea cycle and by hepatic glutamine synthesis. • The **urea cycle** has two other functions: (*1.*) de-novo synthesis of arginine and (*2.*) regulation of the acid-base balance by consumption of bicarbonate. (s. pp 57, 58) (s. figs. 3.12, 3.15)

The **clinical symptomatology,** which is almost the same in all enzymatic disturbances of the urea cycle, is caused by hyperammonaemia. An *arginase defect* results in enhanced excretion of lysine, ornithine and cystine. Neurological symptoms such as hyperreactivity and athetosis followed by paresis and tetraplegia predominate.

In neonatal manifestation of *OTC deficiency*, lethargy, vomiting, refusal to take food, hyperventilation and hypothermia develop quickly. Death ensues in coma within a few days. Manifestation in infants or adolescents is based upon the residual activity of the defective enzyme. This course is also characterized by vomiting and lethargy. The clinical picture is aggravated by a protein-rich diet, whereas protein reduction improves the clinical situation. Without treatment, death occurs in a hepatic coma.

**Diagnosis** is based upon hyperammonaemia, which is detectable either spontaneously or after the oral intake of proteins − or, most obviously, following intravenous infusion of amino acids. The respective amino acids are increased in the serum prior to the disturbed metabolic reaction. Argininosuccinate is only detectable in the urine. A striking feature in these patients is their thin, brittle hair. With defective ornithine transcarbamylase, there is an increase in orotic acid, uridine and uric acid in the urine, while the respective citrulline concentration is decreased. The determination of OTC activity in liver tissue verifies the diagnosis and facilitates a genomic analysis. (172) The allopurinol test can be applied for the identification of heterozygosity (or the mild form of OTC deficiency). The liver shows steatosis, portal inflammation and portal fibrosis.

A defect in *argininosuccinate synthetase* coincides with markedly elevated citrulline values in the blood. Neither citrullinaemia nor a carbamylphosphate synthetase defect cause liver damage. By contrast, an argininosuccinase defect leads to microvesicular steatosis and megamitochondria with dilatation of the ER.

**Treatment** involves a low-protein diet (0.5−0.7 g/kg BW/day) with a sufficient supply of calories. Substitution of essential amino acids (in about the same quantity) is required. • The administration of benzoate (0.1−0.25 g/kg BW/day), arginine hydrochloride (1 mmol/kg BW/day) or sodium phenylacetate (0.3−0.5 g/kg BW/day) (phenylbutyrate tends to be more effective) facilitates nitrogen excretion via other metabolic pathways. (168−170) • With an enhanced excretion of orotate or other metabolites of pyrimidine synthesis, the administration of allopurinol leads to an increase in the excretion of nitrogen via metabolites from pyrimidine synthesis. Ammonia and urea precursors are eliminated by haemodialysis. In individual cases, liver transplantation is indicated. (171)

## 9.3 Cystinosis

Autosomal recessive cystinosis is caused by an enzyme-induced blockage of cystine degradation, particularly in the RES lysosomes of the bone marrow, liver, spleen and kidneys. Especially in the stellate cells of the spleen and to a lesser extent of the hepatic lobule centres, hexagonal and rectangular cystine crystals are found, pointing at an early stage to cystinosis. There is evidence of hepatosplenomegaly and microvesicular steatosis. The clinical picture of the infantile type presents as a *Fanconi syndrome*. (s. pp 593, 597) The children affected die in the first five years of life.

## 9.4 Homocystinuria

This rare disease has an autosomal recessive inheritance pattern. It is based on a deficiency of cystathion-β syn-

thase, so that homocystein and other metabolites (e.g. methionine) accumulate and are eliminated in increased quantities in the urine. There is evidence of disturbed mental development and a marked tendency to thrombosis in the arterial system. Liver steatosis (mainly in zone 1) and hepatomegaly with subsequent portal fibrosis can be seen.

# 10 Carbohydrate storage diseases

Carbohydrate storage diseases include: (*1.*) glycogenoses, (*2.*) galactosaemia, (*3.*) hereditary fructose intolerance, and (*4.*) fructose-1,6-biphosphatase deficiency.

## 10.1 Glycogenoses

Glycogenoses are congenital metabolic diseases with enzyme defects in which glycogen cannot be broken down to glucose. This results in normal or structurally changed glycogen being stored in the organs in ever-increasing quantities. To date, **ten types** (types I–X) have been defined. Types VIII–X are very rare and partly present as subgroups of the other types. • The **incidence** of types I–VII ranges between 1 : 20,000 and 1 : 40,000 births with geographic differences. A relative frequency was determined from 1,192 cases: type I (23%), type II (15%), type III (21%), type IV (2.5%), type V (6%), type VI (30%) and type VII (2.5%). • Transmission is **autosomal recessive.** With regard to the extent of the enzymatic disturbance or the involvement of regulatory enzymes, pronounced heterogeneity can be observed within the individual types. • **Liver disease** only develops in types I, III, IV and VI. *Hepatomegaly* is also found in type II and in the rare types IX and X. • Differential diagnosis of glycogenoses and their subtypes is not possible simply using liver histology. However, it can be achieved by means of additional *histochemistry*, quantitative determination of *glycogen* and *enzyme analysis*. (174, 178, 186, 187)

### Gierke's disease (type I)

▶ **Hepatorenal glycogenosis** was described for the first time by S. Van Creveld in 1928 and resolved in terms of pathological morphology by E. O. E. von Gierke in 1929. This genetic defect (localized on chromosome 17) causes the complete or partial absence of **glucose-6-phosphatase** activity **(subtype Ia)**. (179) • Enzymatic activity is only detectable after the application of detergents. There is a defect in the translocase of glucose-6-phosphatase at the endoplasmic reticulum membrane. This defect is also found in adults **(subtype Ib)**. • Disturbance of this microsomal phosphate/pyrophosphate translocase may occur **(subtype Ic)**. • Glucose-6-phosphatase is necessary for the discharge of glucose from the liver when glucose-1-phosphate is supplied by glycogenolysis. This results in an accumulation of **glucose-1-phosphate,** which in turn stimulates the neosynthesis of glycogen. However, glucose-1-phosphate is also broken down by glycolysis, with an increased formation of lactate, acetyl-coenzyme A and glycerol-3-phosphate. The last two are basic products for the hepatic synthesis of fatty acids and triglycerides.

The **clinical picture** is characterized by hepatomegaly due to deposits of glycogen and triglycerides and by marked kidney enlargement (no splenomegaly as occurs in lipoidosis or cirrhosis). • Severe metabolic disorders such as hypoglycaemia and hyperlipidaemia (triglycerides, free fatty acids, cholesterol) as well as increased

VLDL and LDL values are found, leading to the development of skin and tendon xanthomas, lactate acidosis, a slight increase in transaminases, a tendency towards infection (due to leucopenia related to abnormal glucose-6-phosphatase transport), weakened skeletal muscles, bleeding tendency (due to abnormal platelet function), hyperuricaemia (with possible manifestations of gout, nephrocalcinosis, kidney stones) and osteoporosis. Hyposomia with fat pads, particularly in the buccal area, is often witnessed. Diagnosis is additionally confirmed by a glucagon test (no or inadequate rise in the blood sugar level) as well as fructose or galactose tests and liver biopsy. (s. fig. 31.12) • The occurrence of adenoma or HCC is associated with an increase in fatty acid synthesis. Subtype I b is characterized above all by susceptibility to infection with leucopenia. Recurrent oral ulcers are often a cardinal symptom. The *liver* shows evidence of enlarged, polygonal hepatocytes with bright cytoplasm and centrally located small nuclei as a result of glycogen storage. Occasionally, Mallory bodies and glycogen vacuolation of the nuclei can be found. The hepatocytes have a pronounced (phytocell-like) cellular membrane. (175–177, 179–184)

***Fig. 31.12:*** Gierke's disease: phytocyte-like hepatocytes surrounded by a delicate network of fibrosis

**Treatment** consists of prevention or elimination of hypoglycaemia. In newborns and infants, this can be achieved by the continuous application of formula diets, if required via nasogastric tube feeding. The administration of allopurinol may also be advisable. A starch diet (e.g. uncooked corn starch) is then used to ensure that glucose is released and resorbed slowly in the intestinal tract. (173, 177) After puberty, the course of disease is usually less pronounced. In the long term, especially in adenoma-related complications, liver transplantation may be indicated. (185)

### Pompe's disease (type II)

Generalized glycogenosis type II, also called Pompe's disease (J. C. Pompe, 1932), is caused by a deficiency of lysosomal acidic **α1,4 glucosidase.** This enzyme is responsible for the degradation of glycogen and maltose within the lysosomes. Glycogen is accumulated in all organs, particularly in the heart, but also in the liver. The disease may occur in the newborn (death due to heart failure, often within the first 12 months of life), but may also become manifest in infants and adults. • **Clinical symptoms** include weakened skeletal

muscles, hyperlipidaemia, increased values of the muscle enzymes aldolase and CK, macroglossia as well as pronounced cardiomegaly and *moderate hepatomegaly.* Mental development is not impaired. The glucagon test is normal; hypoglycaemia does not occur. Diagnosis is confirmed by the detection of reduced enzyme activity in biopsy material obtained from the liver or muscle. Vacuoles can be demonstrated in the liver cells. • No specific **treatment** is known. The genetical engineering of acid glucosidase (rhGAA) could become a new form of therapy in future. In the later stages of life, the prognosis quoad vitam is determined by heart failure, pneumonia and respiratory insufficiency.

### Cori's disease (type III)

**Hepatomuscular glycogenosis** (G. B. Forbes, 1952; G. H. Hers, 1959) is caused by a deficiency of **amylo-1,6-glucosidase** (debranching enzyme). Consequently, degradation of the glycogenic branched chains is impaired, yielding an abnormal residual molecule (limit dextrinosis). Gluconeogenesis from lactate is possible. In **Forbes subtype,** deposits of the markedly branched glycogen (with short external chains) are observed in the heart, liver and musculature; in **Forbes-Hers subtype,** they are found in the hepatocytes only. Further subtypes (up to III F) have been described.

**Clinical symptoms** include hepatomegaly, increased transaminases, hypoglycaemia (glucose may be released from glycogen when the terminal glucose fragments split off), hyperlipidaemia and moderate lactate acidosis. The glucagon tolerance test is positive (= no increase in blood sugar); the galactose test and the fructose test are normal. Histologically, the liver shows numerous *glycogen vacuolizations of the nuclei* (s. fig. 31.1), slight steatosis and periportal fibrosis (also transition to cirrhosis). Adenomas frequently appear. • The **treatment** consists of frequent small meals rich in carbohydrates and proteins plus additional dietary corn starch preparations.

### Andersen's disease (type IV)

Liver-cirrhotic, reticulo-endothelial glycogenosis type IV (D. A. Andersen, 1956) is a defect of the branching enzyme **amylo-1,4-1,6-transglucosidase.** There is a disturbance in the formation of glycogen side-chains, which results in the production of a low-branched glycogen with long side-chains (amylopectinosis). This abnormal structure causes low solubility, resulting in the **deposition** of the malstructured glycogen in the hepatocytes at the periphery of the lobule in the form of eosinophilic or colourless, granular, PAS-positive substances. This abnormal glycogen has a cellulotoxic effect. It is also deposited in the spleen, lymph nodes and RES.

**Clinical symptoms** include hepatosplenomegaly and increased transaminases as well as an occasional rise in cholestasis-indicating enzymes. Histologically, the liver specimen shows a number of giant cells, cell necrosis and cholestasis. The abnormal glycogen stored in the hepatocytes can to a certain extent be removed by diastasis digestion, and it takes on a violet stain when in contact with iodine (in contrast to the usual reddish-brown colour); PAS staining is positive. Diagnosis can also be reached using rectal biopsy: macrophages with globular inclusions containing amylopectin are found. The further course is determined by portal hypertension with the formation of ascites and a haemorrhagic tendency. In addition, diminished reflexes, muscular atro-

phy and motor dysfunctions as well as dilative cardiomyopathy may be observed. The disease can also take a protracted course, so that the patient even reaches adolescence. • There is no specific course of **treatment**. Liver transplantation is indicated, whereby a surprisingly positive effect on extrahepatic complications and growth retardation can be expected. (185)

### Hers' disease (type VI)

**Hepatic glycogenosis** (type VI) (G. H. Hers, 1959) is due to hepatic phosphorylase deficiency. Subtype VIa is caused by a lack of **phosphorylase-B kinase,** and it is transmitted by the x-chromosomal recessive route. Subtype VIb shows a deficiency in **glycogen phosphorylase,** and its transmission is autosomal recessive. In the musculature, the analogous enzyme is, however, intact. Nevertheless, there is pronounced genetic and phenotypical heterogeneity.

The **clinical picture** shows moderate hepatomegaly. The normal glycogen is stored in focal form at the periphery of the lobules. There is a mixed pattern of small and large hepatocytes, giving the picture of an irregular mosaic. Hypoglycaemia occurs only during fasting. No other biochemical deviations are observed. The prognosis is relatively good when dietary instructions are adhered to. Mental functions are normal.

### Type IX and type X

These benign glycogenoses are due to a defect in hepatic phosphorylase kinase or cAMP-dependent phosphorylase kinase. Glycogen is deposited unevenly in the hepatocytes; there is evidence of hepatomegaly with fine-droplet steatosis and occasional fibrosis. Hyperlipidaemia and elevated GPT values are present. In the course of time, the patient is able to catch up on physical growth, and hepatomegaly recedes.

## 10.2 Galactosaemia

Hereditary galactose intolerance (A. v. Reuss, 1908; F. Göppert, 1917) is caused by an autosomal recessive disorder in galactose metabolism. • Type II is characterized by an enzyme defect in **galactose-1-phosphate uridyltransferase.** (Type I, caused by a defect of galactokinase, only affects the eyes and is therefore not discussed here.) Transferase deficiency affects several organs, particularly the liver, and results in severe damage. Galactonate and galactite develop as **toxic metabolites,** which are deposited in the tissues; galactite is also detectable in the urine. (188, 191)

The **prevalence** of the disease is about 1:35,000 to 1:70,000 births. With the help of neonate screening, the defect can be discovered and treated at an early stage. • The enzyme coding for transferase is on **chromosome 9 p 13**; there are various mutations and pronounced polymorphisms. Accordingly, several **variants** displaying different kinds of enzymatic activities have been described in many different places (the Duarre, Rennes, Los Angeles and Chicago variants as well as the Caucasian and Negroid variants). Usually, the defect can only be detected by means of the **galactose tolerance test.** A healthy person oxidizes $30-50\%$ of orally administered galactose to $CO_2$ in 5 hours, whereas in transferase deficiency, only $0-8\%$ is oxidized. • Galactonate causes syn-

thesis disorders of glycoproteins and glycolipids in the liver cell by the consumption of UDP. Due to the accumulation of **galactose-1-phosphate,** the consumption of phosphate is increased with a subsequent decrease in ATP and gluconeogenesis. • The deposits of galactose-1-phosphate in the proximal renal tubular cells lead to the development of *Fanconi's syndrome* (glucosuria, aminoaciduria, phosphaturia, acidosis) (s. pp 593, 594).

The **clinical picture** sets in immediately after birth, as soon as milk (including breast milk) is given. The symptoms are vomiting, diarrhoea, no weight gain and galactosuria. As early as the second week, pronounced hepatomegaly (or hepatosplenomegaly) is observed, often accompanied by jaundice and cholestasis. The findings correspond to those in haemolysis. Transaminases are elevated, liver functions are increasingly compromised, and metabolic acidosis is generally in evidence. Cataracts develop. • The diagnosis is confirmed by galactosuria and a rise in galactose and galactose-1-phosphate concentrations in the blood as well as reduced transferase activity in the erythrocytes. • Histologically, the *liver* shows mixed-droplet fatty changes, cholestasis with ductular proliferations, liver cell necrosis, collapse of reticular fibre structures as well as pseudoglandular and/or tubular transformation processes of the liver cell plates around the canaliculi. Within a period of 3−6 months, micronodular cirrhosis develops, followed by ascites and increasing liver insufficiency. (189, 190, 192)

**Treatment** is successful when the disease is recognized early enough and when nutrition is free of galactose and lactose, so that the prognosis is generally considered to be favourable. Organ damage can be halted or indeed prevented completely; occasionally, there is (partial) recession. The UDP galactose required for cell metabolism is supplied from UDP glucose. (192)

## 10.3 Hereditary fructose intolerance

Hereditary fructose intolerance is caused by an autosomal recessive hereditary defect of the enzyme **fructose-1-phosphate aldolase**. Whenever fructose is supplied, severe hypoglycaemia and functional disorders occur in the liver, kidneys and CNS. • The **prevalence** is estimated at 1:20,000 births. As with galactose intolerance, the gene which codes aldolase B is also localized on **chromosome 9.** This enzyme defect causes fructose-1-phosphate to accumulate in the liver and tissue. The cleavage of fructose-1,6-biphosphate is only slightly compromised since the enzymes aldolase A and C are available for this process. • The consumption of phosphate and ATP in the tissue results in various **functional disorders:** (*1.*) inhibition of gluconeogenesis in the liver and kidneys, (*2.*) increase in lactate in the serum with metabolic acidosis, (*3.*) decrease in protein synthesis in the liver, and (*4.*) functional disorders of the proximal tubular cells with development of **Fanconi's syndrome**. (s. pp 593, 594) (193, 194, 196, 198)

The **clinical picture** is characterized by nausea, vomiting, diarrhoea, abdominal pain, dizziness and hypoglycaemia, not only following the intake of fructose (oral, intravenous), but also after sorbitol infusions (sorbitol is converted to fructose in the organism). Growth failure

is observed in babies and infants. • During adolescence and in adults, a chronic course may develop, characterized by hepatomegaly, hypophosphataemia, hypoglycaemia, blood coagulation disorders and an increase in transaminases as well as jaundice and moderate cholestasis. Phosphaturia results in osteomalacia. Hypermagnesaemia is a striking feature. • *Histological findings* include a fatty liver with liver cell necrosis and increasing fibrosis; the liver cell plates show tubular transformation. Giant cells are often found. At a later stage, cirrhosis develops. (193, 195−197) • When the intake of fructose (or sorbitol) is avoided, even patients with a homozygous genotype are symptom-free. The diagnosis is based upon the determination of liver aldolase B or on the *fructose tolerance test*:

> **Method:** Oral administration of 200 mg/kg BW fructose in a 20% solution over a period of 30 minutes. After establishing the initial values, both glucose and phosphate are determined every 10 minutes; after 1 hour, the intervals are extended to 30 minutes. The test findings are pathological when serum glucose decreases to <40 mg/dl and phosphate to <1.5 mg/dl. Hypoglycaemia requires an immediate i.v. glucose infusion.

**Treatment** consists of completely avoiding fructose and commercially available cane sugar as well as excluding sorbitol from i.v. infusions. When this regime is strictly adhered to, prognosis is good and life expectancy unaffected.

## 10.4 Fructose-1,6-biphosphatase deficiency

Due to the autosomal recessively inherited reduction in fructose-1,6-biphosphatase activity in the liver, the gluconeogenesis of lactate, glycerine and glucogenic amino acids is inhibited. If fructose or glycerine are supplied, phosphate and bicarbonate are consumed in higher quantities and lactate production is increased. This results in metabolic acidosis.

The **clinical picture** is much less pronounced than in hereditary fructose intolerance (type aldolase B). When fructose is supplied or when infections develop, the affected children may suffer from metabolic disorders, such as hypoglycaemia, nausea, vomiting, diarrhoea, hyperventilation, convulsions, lactate acidosis and ketosis. The glucagon tolerance test is pathological (= no increase in blood sugar). • Histology shows a fatty liver. Diagnosis can be confirmed by measuring the fructose-1,6-biphosphatase activity in the liver tissue.

**Treatment** consists of completely avoiding fructose and, if necessary, in correcting metabolic acidosis, electrolytes and blood sugar values.

# 11 Lipid storage diseases

## 11.1 Wolman's disease

**Xanthomatosis,** an autosomal recessive inherited disorder, was described by A. ABRAMOV, S. SCHORR and M. WOLMAN in 1956. Probably, this rare clinical picture (about 40 cases have been reported to

597

date) was already published by H. Dienst and H. Hamperl as early as 1927. Some cases may indeed have been attributed erroneously to Niemann-Pick disease. • Wolman's disease is caused by a considerable reduction or complete absence of **intra-lysosomal lipase activity.** In acid pH, the lipase catalyzes the hydrolytic cleavage of cholesterol esters and triglycerides in the lysosomes. This enzyme defect results in an excessive storage of cholesterol esters and triglycerides in the abdominal organs, skin and nervous system. The mutant gene for isoenzyme A of acidic lysosomal lipase is located on **chromosome 10.** In homozygotes, lipase activity in the liver is reduced to less than 10% of the normal value, in heterozygotes to around 50%. • The **enzyme defect** is responsible for (*1.*) storage of cholesterol esters and triglycerides in the hepatocytes, Kupffer cells and macrophages as well as in various other body cells, and (*2.*) disturbance of cholesterol homoeostasis in the blood, since the lysosomes release an insufficient quantity of free cholesterol into the cytosol. For this reason, the regulation of cholesterol metabolism in the cytosol is considerably impaired: (*1.*) inadequate or no inhibition of the synthesis of cholesterol and the LDL receptor, and (*2.*) inadequate or no stimulation of cholesterol esterification with saturated fatty acids.

The **clinical picture,** which is already manifested in early infancy, comprises vomiting, diarrhoea, growth failure and meteorism. Hepatosplenomegaly and anaemia develop rapidly. Multiple xanthomas of the skin appear. CT scanning shows enlarged adrenal glands (due to xanthomatous redifferentiation), often with finely spotted calcifications. Deposits of cholesterol esters, triglycerides and, to a certain extent, phospholipids are found in the spleen, liver, small intestine, lymph nodes, lungs, skin and nervous system. The foam cells detectable in the bone marrow differ from Pick cells in that they lack sphingomyelin. Transaminases are increased; liver function is markedly compromised. Death usually ensues within the first year of life. (199−201)

## 11.2 Cholesterol ester storage disease

Cholesterol ester storage disease (CESD) was first described by D. S. Fredrickson in 1966. No more than 20 cases of this **very rare disease** have been reported to date, with twice as many girls being affected as boys. • Just like *Wolman's disease*, it is transmitted as an autosomal recessive mutation with the gene localization on **chromosome 10.** Due to this defect, degradation of cholesterol esters and triglycerides in the lysosomes is inhibited. Therefore, these lipids are stored in the hepatocytes, Kupffer cells and macrophages as well as in other somatic cells. Although CESD displays the same biochemical and metabolic disorders as Wolman's disease, it is less severe. It does not become evident until adulthood.

▶ *It was possible for us to describe this clinical picture in detail from our own observations of a 13-year-old girl. We detected a very high content of cholesterol ester in the biopsy sample and a deficiency of lysosomal α-naphthylacetate esterase in the fibroblast culture. (205) (s. figs. 21.5; 31.13, 31.14)*

Initially, the **clinical picture** is largely asymptomatic. The average age of the patients reported to date was 6.5 years at the time of diagnosis. Striking features are hepatomegaly and, occasionally, splenomegaly. (206) The cholesterol ester content of the liver can be up to 10% of the liver wet weight, while the total lipid content

**Fig. 31.13:** Cholesterol ester storage disease. Fine-droplet fatty changes in the hepatocytes. Widely extensive small and larger lipid vacuoles in the liver cells and foam cells of the portal field (Sudan black) (s. fig. 21.5). Same patient as in fig. 31.14

**Fig. 31.14:** Light yellowish-red, smooth surface in fatty liver due to cholesterol ester storage (13-year-old girl). Same patient as in fig. 31.13

of the liver ranges between 22% and 28%. • *Laboratory findings* show a slight increase in transaminases and bile acids as well as reduced liver function. In most cases, jaundice is observed. Markedly augmented concentrations of cholesterol, triglycerides and LDH are characteristic. (204) Foam cells can be found in the bone marrow. Diagnosis is confirmed by determination of lysosomal acidic lipase in the leucocytes and skin fibroblasts. • Corresponding to the high lipid content, the *liver surface* has an orange-yellowish colour, as does the liver specimen. (205) The lipid drops found in the hepatocytes and Kupffer cells are surrounded by a lysosomal membrane; they replace the cytoplasm and nucleus. In polarized light, the hepatocellular lipids show birefringence of the Maltese cross type. The hepatocytes contain finely floccular, PAS-positive glycogen deposits. In all, the prevalent picture is that of mixed-droplet fatty changes. (205) In the further course, hepatic fibrosis or micronodular cirrhosis develop. Both the course and prognosis depend on whether cirrhosis develops and what its concomitant complications are. (202, 203, 265)

## 11.3 Cerebrotendinous xanthomatosis

This disease is caused by an autosomal recessive gene mutation (localization on chromosome 2) and leads to an enzyme defect in mitochondrial **steroid-27 hydroxylase.** The enzyme itself is responsible for the breakdown of cholesterol side-chains in bile acid synthesis. Such a defect results in the formation of **cholestanol,** a reduction product of cholesterol. It is deposited in various organs, particularly in the tendons and in the nervous system, because the substance cannot be broken down adequately. **Deposition** takes place conjointly with cholesterol. (209, 210)

The **clinical picture** is characterized by xanthomas, particularly on the tendons (especially the Achilles tendon). Xanthomas consist of cholesterol and cholestanol. The enzyme defect also results in disturbed vitamin D metabolism. Osteoporosis is thus observed quite often, with a tendency towards spontaneous fractures. (208) Striking clinical features are cerebral functional disorders (from deviant behaviour to severe dementia, motor disturbances and convulsions) as well as peripheral neurological symptoms caused by cholestanol deposits. (211) High concentrations of apolipoprotein B and cholestanol are found in the CSF. (213) • **Treatment** is based on the administration of chenodeoxycholic acid (750 mg/day). Effectiveness is improved if HMG-CoA reductase inhibitors (e. g. pravastatin) are used concomitantly. (207, 212)

## 11.4 Abetalipoproteinaemia

In this autosomal recessive disease, the disorder does not involve the gene on chromosome 2, which is responsible for apoprotein assembly, but the **MTP gene** (microsomal triglyceride transfer protein), which is localized on chromosome 4 q 22−24. In the endoplasmic reticulum, MTP transfers cholesterol esters, triglycerides and phospholipids to the nascent apoprotein B. This process is a prerequisite for the transport of the complete **lipoproteins** (e. g. chylomicrons, VLDL) to the Golgi complex and their secretion into the blood via subsequent exocytosis. In the case of MTP deficiency, lipoprotein particles are not secreted, with the result that any superfluous **apoprotein B** is broken down in the endoplasmic reticulum. (214, 216, 219, 220)

Even in infants fed with high-fat milk, the **clinical picture** is characterized by malabsorption leading to fatty stools and diarrhoea. This results in a deficiency of fat-soluble vitamins with all the respective complications. • Reduced elimination of lipids from the *liver* leads to hepatomegaly with large-droplet fatty changes, possibly causing the formation of fat cysts and larger fat pools. (s. fig. 31.2) Splenomegaly often occurs due to fat storage in the macrophages of the spleen as well as to portal hypertension, which may be caused by an increased resistance in the sinusoids in cases of fatty liver. (215, 217) Development of cirrhosis has also been reported. • As far as *laboratory findings* are concerned, a marked decrease in cholesterol (usually < 40 mg/dl) and triglycerides (usually < 10 mg/dl) is relevant for the diagnosis; VLDL (= pre-beta lipoproteins) are not found. The haemogram shows deformed (e. g. crenated) erythrocytes due to their altered membrane lipids. (218) • **Treatment** is based on the administration of triglycerides with medium-chain fatty acids (MTC diet) with strict avoidance of other fats. Fat-soluble vitamins have to be substituted (if necessary, orally in high doses).

## 11.5 Hypoalphalipoproteinaemia

▶ In 1961 D. S. Fredrickson et al. described an autosomal recessive disease called hypo- or analphalipoproteinaemia. This lipid storage disease is also known as **Tangier disease** − named after the small Tangier Island in Chesapeake Bay/Maryland − where it was first observed in two siblings. The cause is probably a genetic **synthesis defect** in the apoproteins of $\alpha_1$-lipoproteins.

The most important **clinical feature** is the storage of cholesterol esters in the lymph nodes, tonsils, spleen and liver. (221) The noticeably enlarged tonsils are of a distinctive yellowish or orange colour. There is evidence of lymphadenopathy and hepatosplenomegaly as well as polyneuropathy. PAS-positive foam cells or foamy Kupffer cells are found in the bone marrow, lymph nodes and liver. • *Laboratory findings* show an increase in triglyceride and cholesterol values, $\alpha_1$-lipoprotein deficiency and moderate jaundice; occasionally, thrombopenia and leucopenia are observed. • The **prognosis** is generally good. Therefore, the disease is often diagnosed for the first time in adulthood. (222, 223)

## 11.6 Debré's syndrome

This metabolic disorder with simultaneous storage of fat and glycogen in the liver was described by A. R. Debré et al. in 1934. Within a few weeks of birth, infants suffer from considerable hepatomegaly (without splenomegaly). There is evidence of hyperlipidaemia with hypercholesterolaemia, a tendency towards fasting hypoglycaemia, and disturbed glucose mobilization following exposure to insulin or adrenaline. • *It should be noted, however, that this form of glycolipidosis has still not been reliably classified.*

# 12 Sphingolipid storage diseases

The biochemical group of sphingolipids comprises: sphingomyelin, cerebroside, sulphatide, gangliosides, ceramide trihexosides, etc. Depending on the substance stored, differentiation is made between (*1.*) glucosyl ceramidoses (e. g. gangliosidoses, ceramide trihexosidosis, cerebrosidoses, sulphatidosis), (*2.*) phosphoryl ceramidoses (e. g. sphingomyelinosis), and (*3.*) mucopolysaccharidoses.

## 12.1 Gaucher's disease

▶ This form of glucosyl ceramidosis is the longest known lipid storage disease. It was described by P. C. E. Gaucher as early as 1882 and recognized as a separate entity with systemic character by F. Schlagenhaufer in 1907.

The condition is an autosomal recessive disease with reduced activity of the lysosomal **β-glucocerebrosidase.** (Instead of an enzyme defect, the cause may be the absence of cofactor **saposin C.**) The

relevant gene is localized on **chromosome 1.** There is considerable genetic **heterogeneity.** While some gene mutations are responsible for more frequent neurologic and severe courses, others have been recognized, particularly in older patients, as causing a late onset and more moderate course of disease. The gene mutations are detectable with varying frequency in different ethnic groups. Due to the enzyme defect, sphingolipids are only broken down to the level of the glucocerebroside, whereby this glycolipid is subsequently stored. **Prevalence** is $1 : 30,000 - 1 : 50,000$

**Glucocerebroside** is stored predominantly in the RES cells, but also in the spleen, hepatocytes, bone marrow and lymph nodes; rod-like tubules (20−40 nm) develop. • The storage of glucocerebroside leads to the formation of so-called **Gaucher cells.** These oval or polygonal cells are characterized by their light, striated ("crumpled") cytoplasm and a swollen cell body with a decentralized nucleus; occasionally, there are two or more hyperchromatic nuclei at the periphery. Apart from glucocerebroside, Gaucher cells also contain lysosomal acidic phosphatase. They are PAS-positive, 20−100 μm in size and grouped together within the hepatic lobule; in some areas, the cells fill the sinusoids and are likewise found in the portal fields, where they originate from histiocytes.

**Type I** *(chronic visceral type):* This is the most common course and may manifest at any time in life; most often, however, it occurs between the ages of 20 and 40. The patients are able to lead relatively normal lives. Clinical features include pronounced *hepatosplenomegaly, ostealgia* with spontaneous fractures, backache and pain in the extremities, fever and *haematopoetic disorders* (microcytic anaemia, leucopenia, thrombopenia with haemorrhagic diathesis). The transaminases and the liver function values are usually normal; alkaline phosphatase is increased. Portal hypertension and ascites may occur due to obstruction or compression of the sinusoidal pathway. (233) After a course of several years, yellowish brown, patchy pigmentations (containing melanin) appear in the face, particularly at the root of the nose, and on the legs. Yellowish grey pingueculae may be present around the eyes (nasal or bilateral). Diagnosis is confirmed by the detection of acidic phosphatase in the cells and a reduced activity of glucocerebrosidase in leucocyte suspensions or fibroblast cultures. Meanwhile, the various types of Gaucher's disease can be identified by PCR. There are no neurologic symptoms. The cholesterol level is normal. (229, 231, 232, 235) • Prognosis is determined by haematological complications, an increased susceptibility to infections and a higher rate of lymphoproliferative diseases. Transition to cirrhosis has often been observed, as have bleeding oesophageal varices. (224, 233, 237, 239, 241)

▶ *We were able to observe a family with 6 children, 4 of whom (3 boys and 1 girl) suffered from Gaucher's disease. I examined one of the children laparoscopically. All 4 children showed pronounced hepatosplenomegaly with symptoms of abdominal organ displacement; splenectomy was carried out in good time. (240) (s. fig. 31.15)*

*Fig. 31.15:* Gaucher's disease. Gaucher cells (sphingolipid-storing macrophages) within the liver parenchyma (arrow), shown here as pale-blue cells with an internal structure similar to cigarette paper (PAS)

For a successful course of **treatment,** *β-glucocerebrosidase* gained from the placenta or recombinant imiglucerase can be used as an intravenous infusion every second week. (225−227, 230, 234, 236) • A novel form of oral treatment with N-butyldeoxynojirimycin over a period of up to 12 months produced good results. Further trials with this substance, which inhibits the synthesis of glucocerebrosides, are justified. Diarrhoea was a frequent side effect (79%). (228) • Following *liver transplantation,* there was a regression in glucosylceramide deposition in the extrahepatic organs − the metabolic defect was not corrected however. (244) Long-term follow-up showed good results after *bone-marrow transplantation.* (238)

**Type II** *(acute infantile neurological type):* Type II becomes manifest within the first few months of life. Splenomegaly followed by hepatomegaly can be observed at a very early stage. A striking feature is the cerebral and neurological symptomatology. The affected child usually dies within the first year of life due to bronchopulmonary infection.

**Type III** *(chronic juvenile neurological type):* At the onset of the disease, splenomegaly and, subsequently, hepatomegaly are observed. Gaucher cells are found in the bone marrow at an early stage. There are severe cerebral and neurological disorders.

## 12.2  Fabry's disease

The enzymatic defect in glycoprotein and lipid metabolism in this disease, which is based on X-chromosomal transmission, is most likely to be **α-galactosidase-A deficiency.** Storage products consist of sphingolipids, mainly GL-3. They are principally stored in the kidneys, vascular walls and smooth musculature, but also in the **liver** (stellate cells, portal macrophages, vascular endothelium). These affected cells take on a yellowish-brown colour. The hepatocytes are finely vacuolated; the Kupffer cells and macrophages are hypertrophic and contain cholesterol and lipofuscin. • The clinical picture, which usually begins with swelling of and burning pains in the limbs as well as skin changes and corneal opacity, was simultaneously described by J. Fabry and by W. Anderson in 1898. • *Treatment* with recombinant agalsidase beta has proved successful.

## 12.3  Gangliosidosis

Among other things, gangliosidosis may also affect the liver. The deposition of gangliosides (particularly of the $G_{M1}$ and $G_{M2}$ type) in the liver causes hepatomegaly to develop. In 1964 B. H. Landing et al. described *familial neurovisceral lipidosis* as a disease in its own right, although this entity had probably been observed by J. Caffey as early as 1951. The type of metabolic disorder was defined by J. S. O'Brien et al. in 1965. It is in fact an autosomal recessive **$G_{M1}$ gangliosidosis** of the infantile generalized type I. The disease is caused by **β-galactosidase A, B and C deficiency**, so that the cleavage of the terminal galactose of both the ganglioside $G_{M1}$ and the mucopolysaccharides is inhibited. These abnormal products are then stored. Foam cells with PAS-positive substances develop, which in turn involves the total RES and hence the stellate cells and portal histiocytes as well. Progressive hepatomegaly is present. Familial neurovisceral lipidosis causes the death of the child in the first or second year of life. (Type II $G_{M1}$ gangliosidosis is considered to be a juvenile type without visceral involvement.)

**$G_{M2}$ gangliosidosis** is caused by a deficiency of **hexosamidase A and B**. It was described for the first time by K. Sandhoff et al. as *Sandhoff's disease* in 1968. This biochemical variant (type II) largely corresponds to Tay-Sachs disease, which is also autosomal recessive. Renal globoside (ceramide trihexoside) is stored in the visceral organs, particularly in the liver and spleen. Hepatomegaly is present, occasionally with splenomegaly. The lysosomes within the hepatocytes become considerably larger until they are as big as the nucleus and show lamellar structures.

## 12.4  Niemann-Pick disease

▶ In 1914 A. Niemann described a type of storage disease which, however, he did not recognize. In 1926 L. Pick differentiated this clinical picture from Gaucher's disease and called it "lipid cellular splenomegaly". The substance predominantly stored was identified as sphingomyelin by E. Klenk in 1934. Thus, this condition is a kind of phosphoryl ceramidosis.

The disease is based upon a deficiency of the lysosomal enzyme **sphingomyelinase,** mainly in the RES cells. This autosomal recessive enzyme defect results in **sphingomyelin** being stored in the liver (hepatocytes, Kupffer cells, portal macrophages), spleen, bone marrow and lungs. These pale storage cells, the so-called **Pick cells** (20−40 µm) display a mulberry-like, alveolate structure, and, in addition to sphingomyelin, contain cholesterol and triglycerides as well as pigment ceroid (s. fig. 21.6). The cell inclusions are granular and double-refractory. Due to vacuolation, the Pick cells look like foam cells. • Meanwhile, five biochemical and **clinical types** have been differentiated (types A−E); type A is equivalent to the classical Niemann-Pick disease observed in infants. To date, some 200 cases have been reported.

**Type A** is already present in infancy. The following symptoms rapidly develop: anorexia, vomiting, weight loss, growth retardation, hepatosplenomegaly, lymphadenopathy, profuse sweating, a brownish-yellow waxy complexion and a pronounced cerebral and neurological symptomatology (muscular hypotonia, areflexia, deafness, loss of sight). In about 5 % of cases, cherry-red spots with yellowish prominence can be found on the fundus of the eye. Liver cell damage and cell necro-

sis as well as cholestasis develop. The affected child dies before reaching the age of 2 years. (244, 248)

**Type B** is often characterized by neonatal cholestasis, which disappears in the later course of disease. The condition becomes manifest in childhood and progresses slowly. Hepatosplenomegaly develops, as does cirrhosis with portal hypertension. (245) The lungs occasionally display a miliary picture due to the interstitial storage of sphingomyelin; chronic bronchitis is often observed. No neurological or cerebral symptoms are in evidence. The haemogram shows anaemia and thrombopenia. • *Treatment* with allogeneic bone marrow transplantation has been reported. (246)

**Type C** is characterized by a slow course with neurological symptoms and gradual mental deterioration. A rare event is the development of neonatal cholestasis (243) or an HCC (242).

**Type E** is also known as the **sea-blue histiocytes syndrome** and is considered to be a special form of Niemann-Pick disease found in adults. The stored, ceroid-like, acid-proof and PAS-positive pigment shows a sea-blue colour on Giemsa staining. Hepatosplenomegaly is present; thrombopenia is likewise in evidence due to bone marrow involvement. Cirrhosis may develop. The prognosis is considered to be good. (243)

## 12.5  Mucopolysaccharidoses

These are congenital disturbances in the enzymatic degradation of acidic mucopolysaccharides (MPS) by the lysosomes. *Four types of mucopolysaccharides* (glycosaminoglycam, dermatan sulfate, heparan sulfate, chondroitin-6 sulfate) are stored, ultimately compromising all organs and tissues. In addition, ganglioside is stored in the CNS. Depending on the respective disease, varying distribution patterns can be found, with storage forms occurring individually or in combination. To date, **ten individual forms** have been identified; others, however, have remained unclassified. In all forms, there is increased elimination of the above-mentioned MPS in the urine. • Six out of a total of ten forms are accompanied by **liver involvement** *(storage in the hepatocytes, Kupffer cells and portal macrophages as well as vacuolization of the cytoplasm)* and **hepatomegaly**. The liver is firm and has a bluish-yellow or greyish-yellow colour. The stored mucopolysaccharides are PAS-positive, but not diastasis-resistant. During a longer course, *fibrosis* develops and *cirrhosis* may occur.

**Pfaundler-Hurler syndrome** *(type I-H):* This syndrome is caused by an α-L-iduronidase deficiency (M. v. Pfaundler, 1920; G. Hurler, 1920). It is autosomal recessive and panethnic, with an incidence of approx. 1: 100,000 live births. A major cause of morbidity and mortality is respiratory insufficiency together with cardiac compromise (valvular dysfunction).

**Ullrich-Scheie's syndrome** *(type V):* This is also characterized by an α-L-iduronidase deficiency, but it does not appear before school

age (O. ULLRICH et al., 1943; H. G. SCHEIE et al., 1962). Further symptoms are above-normal growth and head size, chronic otitis, chronic rhinitis, hepatosplenomegaly, corneal clouding, ankylosis and mental retardation.

▶ These forms overlap in symptomatology and cannot be distinguished by enzyme or urinary assays. • A **new therapy** for α-L-iduronidase deficiency using enzyme replacement (= *laronidase*) as i.v. infusion has proved safe and efficacious (J. WRAITH et al., 2004).

**Hunter's syndrome** *(type II):* Initially, this disease was erroneously classified as type I-H. Its nosological independence and X-chromosomal recessive transmission were recognized in 1964 (A. NJA). The disease is based on a deficiency of L-iduron-sulphate sulphatase and sulphoiduronate sulphatase. The syndrome may appear in a moderate or severe form.

**Sanfilippo's syndrome** *(type III):* This syndrome exhibits a similar clinical picture as described above with at least two different enzyme defects: heparan-sulphamidase deficiency (type A) and N-acetyl-α-D-glucosamidase deficiency (type B) and possibly types C or D as well (S. J. SANFILIPPO et al., 1963).

**Morquio's syndrome** *(type IV):* This syndrome is a result of a galactosamine-6-sulphatase deficiency (type A) or a beta-galactosidase deficiency (type B) (L. MORQUIO, 1929; J. F. BRAILSFORD, 1929).

**Maroteaux-Lamy syndrome** *(type VI):* This syndrome is due to an arylsulphatase B deficiency. It appears in a severe or moderate form (P. MAROTEAUX et al., 1965).

## 12.6 Mucolipidoses

Mucolipidoses are characterized by a **combined metabolic disorder** of mucopolysaccharides, lipids, and glycoproteins. Lysosomal storage and foamy swollen Kupffer cells with hepatomegaly may be seen. In some of the numerous types, the underlying enzymatic defects have not yet been detected. • Type II is also called **Leroy syndrome** (J. G. LEROY et al., 1967). Due to distinctive cytoplasmic inclusions in fibroblast cultures, this disorder is also known as **"inclusion cell disease"** (J. G. LEROY et al., 1971). Foamy altered stellate cells, macrophages and also epithelioid foam cell granulomas are found.

**Fucosidosis,** being a so-called mucolipidosis, can be grouped among the mucopolysaccharidoses. It is due to α-fucosidase deficiency (localized on chromosome 1p 34). The storage products are deposited in the form of granular or lamellar inclusions in the lysosomes. This autosomal recessive disorder was first observed by P. DURAND et al. in 1967 and clarified by F. VAN HOOF et al. in 1968. Besides hepatomegaly, splenomegaly may also sometimes occur.

**Mannosidosis,** first observed by P.-A. ÖCKERMAN in 1967, is caused by α-mannosidase deficiency. The gene defect (autosomal recessive) is localized on chromosome 19p, 13, 2-q12. Hepatosplenomegaly, steatosis and perisinusoidal fibrosis are in evidence. PAS-positive vacuoles, consisting of lysosomally stored substances, are found in the cytoplasm of the hepatocytes.

**Mucosulphatidosis** is caused by arylsulphatase deficiency (types A, B and C). Metachromatic granules are found mostly in portal macrophages and less frequently in hepatocytes or Kupffer cells.

**Lafora's disease** (H. UNVERRICHT et al., 1891) is regarded as an autosomal recessive enzyme defect. A striking feature are the severe CNS disorders. The myocardium, liver and musculature are also involved. The affected hepatocytes are similar to so-called *ground glass cells* and mostly found at the periphery of the lobules. The coarse granular and lamellar cytoplasmic inclusions are PAS-positive glycoprotein-mucopolysaccharide particles, also known as *Lafora bodies* (C. R. LAFORA, 1911). Liver biopsy shows signs of unspecific reactive hepatitis and fibrosis. Death occurs in infancy.

## 13 Mucoviscidosis

Mucoviscidosis or **cystic fibrosis (CF)** is indeed one of the most common autosomal recessive diseases. It is characterized by the production of a viscous secretion in the excretory glands. Accordingly, pancreatic cystic fibrosis can be observed in the pancreatic area and cylindrical bronchiectases in the pulmonary area. The inspissation of bile and mucus leads to obstruction of the bile canaliculi and subsequently to cholestasis. The gene product is characterized as cystic fibrosis transmembrane regulator (CFTR). (252) The gene defect, which is located on chromosome 7, causes a disorder of the intracellular transport of chloride ions (probably also of chloride ion secretion) and thus triggers the occurrence of CF. The incidence of mucoviscidosis is about 1:2,000−4,500.

In protracted disease, the **liver** becomes involved in 20−25% of cases. Rarely, a symptomatic hepatobiliary disease, mostly in the form of fatty liver but also as focal biliary cirrhosis, occurs in the first few weeks of life. Proliferation of the ductuli and dilatation of the intralobular bile ducts can be detected. As a result of this, crumbly products are deposited and the lumina are completely sealed off. These retained crumbly products have not yet been differentiated more specifically; they are, however, PAS-positive and mucin-negative and consist mainly of precipitated protein. Hepatomegaly is due to macrovesicular steatosis. Inflammatory changes in the bile canaliculi and the small bile ducts with cholestasis and infiltration of the portal fields can be observed. (250, 254) With progressive proliferation of the ductules and liver fibrosis, there is a rise in γ-GT, AP and 5' NU. In the further course, a slight increase in transaminases as a sign of hepatocellular damage is detectable. A score can be used for the sonographic diagnosis of liver involvement in CF. (258) Scintigraphy may be applied for the quantification of impaired secretion. (256) Liver function is assessed by means of ChE, Quick's value, GEC (s. p. 108) and ICG tests (s. p. 108). Gene mutation can easily be confirmed by direct genetic screening with allele-specific oligonucleotides. The inflammatory and reactive-fibrosing processes may ultimately result in necrotizing cholangitis and multilobular biliary cirrhosis, possibly with bleeding oesophageal varices; the frequency is reported to be 5−20%. (250, 254, 255) • The only effective **therapy** is gene replacement. (253, 259) Symptomatically, liver damage and cholestasis can be reduced by UDCA. (249) It is also advisable to use essential phospholipids as long-term therapy. (257) In severe cases, there may be an indication for liver transplantation or indeed combined liver-lung transplantation. (251)

# 14 Zellweger's syndrome

This **cerebro-hepatorenal syndrome** was described by P. Bowen, C. S. Lee, H. Zellweger and R. Lindenberg in 1964 on the basis of observations originally made by Zellweger. (260) It is an autosomal recessive disease, with a lack of peroxisomes due to a mutation of the mRNA peroxisome-assembly factor 1. In this complex syndrome, there are various malformations with *disturbances in the amino-acid balance and β-oxidation of long chain fatty acids as well as iron metabolism resulting from a disorder of bile acid synthesis* at the side chain. (261, 262) The blood shows hypersiderinaemia, and there are increases of different intensity regarding alanine, lysine, isoleucine, methionine, phenylalanine and serine. Signs of substantial cholestatic liver damage, siderosis, portal inflammation, fibrosis and the potential development of cirrhosis are evident. (263–265) (s. p. 234)

# 15 Porphyrias

## 15.1 Definition

Porphyrias are metabolic disorders caused by hereditary enzyme defects or acquired disorders of haem synthesis. These result in the increased formation of porphyrins and porphyrinogens and their precursors, which are either stored in the tissue or excreted in the urine or faeces. The term porphyria is derived from the Greek "porphuros", which means purple and describes the purple-red crystalline porphyrins. • Depending on the underlying enzyme defect or the respective aetiopathogenesis, porphyrias become clinically manifest with neurological, photocutaneous, cerebral, cardiovascular, abdominal or hepatic symptomatology.

## 15.2 Classification

▶ **Primary porphyrias** are caused by hereditary enzyme defects in haem synthesis. They can be differentiated clinically into **acute** and **chronic** porphyrias as well as pathogenetically into **hepatic** and **erythropoietic** porphyrias. **Secondary porphyrias** are symptomatic porphyrias present in various diseases or caused by poisoning or chemical substances, particularly alcohol. • Depending on the preferred **manifestation site** of the enzyme defect, either in the hepatocytes or erythrocytes (bone marrow), the porphyrias are subdivided into hepatic, erythropoietic and hepatoerythropoietic forms. However, this classification is not always strictly applicable. • Based on the **course of disease,** acute and chronic forms may be differentiated in primary hepatic porphyrias. The acute form is characterized by a congenital reg-

ulatory disturbance of porphyrin and haem synthesis together with the induction of ALA synthase within the hepatocyte. The acute forms are less frequent, but are associated with a higher risk. Only acute hepatic porphyrias show convulsive gastrointestinal and neuropsychiatric symptoms. Chronic hepatic porphyrias are due to congenital or acquired enzyme defects; they are the most frequent forms and always involve liver damage. • Only the erythropoietic forms are accompanied by acute phototoxic reactions. Skin changes are found in two forms of hepatic porphyrias: variegate porphyria and porphyria cutanea tarda. (s. tab. 31.10)

**Primary porphyrias** may arise from a *hereditary defect* in any of the **eight enzymes** involved in haem synthesis: (*1.*) δ-aminolaevulinic acid synthase (which causes a sideroblastic anaemia), (*2.*) porphobilinogen synthase, (*3.*) porphobilinogen deaminase, (*4.*) uroporphyrinogen III synthase, (*5.*) uroporphyrinogen decarboxylase, (*6.*) coproporphyrinogen oxidase, (*7.*) protoporphyrinogen oxidase, and (*8.*) ferrochelatase. • An important **branching point** in haem synthesis is the transformation of porphobilinogen (by PBG deaminase) into pre-uroporphyrinogen. The latter is transformed by uroporphyrinogen III synthase into uroporphyrinogen III; in the case of reduced enzyme activity, uroporphyrinogen I is spontaneously formed and subsequently eliminated in the urine. (309) (s. fig. 3.2)

▶ **Secondary porphyrias** are symptomatic and hepatic porphyrias. (309) They are coproporphyrinurias with simultaneously increased protoporphyrin concentrations in blood plasma. For prophylactic, prognostic and therapeutic reasons, it is important to differentiate between primary (hereditary) porphyria and secondary (symptomatic) coproporphyrinuria. • Only in coproporphyrinuria caused by lead intoxication and in tyrosinaemia can δ-aminolaevulinaciduria be found at the same time. The alcohol-liver-porphyrinuria syndrome is the most important form of secondary porphyrinuria. In chronic alcohol abuse, secondary coproporphyrinuria may develop into chronic hepatic porphyria. (281) • *Some 30% of patients suffering from chronic liver disease develop pathological coproporphyrinuria during the further course.* (s. tab. 31.11)

## 15.3 Biochemistry

**Glycine** and **succinyl coenzyme A** are the *initial substrates* for porphyrin synthesis, from which δ-aminolaevulinic acid (ALA) is formed with the help of ALA synthase. This is the first biosynthetic step and takes place in the mitochondria. Porphobilinogen (PBG) develops in the cellular cytosol due to the connection of 2 mol ALA. Uroporphyrinogen is then formed from 4 mol PBG; this is subsequently decarboxylated, thus producing coproporphyrinogen. Further decarboxylation takes place within the mitochondria, leading to the production of protoporphyrin. Due to its lipophilic qualities, the latter is not filtered by the kidneys and is therefore subject to enterohepatic circulation. With the help of ferrochelatase, iron is stored and haem is formed. • **Haem** is the *final product* of porphyrin synthesis, which may take place in all cells. It is required as a prosthetic group by enzymes or pigments (catalase, cytochrome, haemoglobin, myoglobin, etc.). By way of feedback, haem regulates the limiting enzyme *ALA synthase* and thus the whole porphyrin synthesis. The activity of ALA synthase is increased by various drugs (s. tab. 31.13), chemical agents and endogenous metabolic products. • Induction of

| Primary porphyrias | International abbreviations | Enzyme defect | Hereditary transmission |
|---|---|---|---|

| • Porphyria cutanea tarda | PCT | Uroporphyrinogen III decarboxylase | autosomal dominant |
| • Hepatoerythropoietic porphyria | HEP | Uroporphyrinogen III decarboxylase | autosomal recessive |

**Tab. 31.10:** Primary (erythropoietic, hepatic, hepatoerythropoietic) porphyrias

ALA synthase can be suppressed by glucose. Due to the short half-life of ALA synthase of $70-80$ minutes, inhibition or induction of this enzyme very quickly affects haem synthesis. Haem deficiency due to an enzyme defect causes an increase in δ-aminolaevulinic acid. Free haem is either integrated into various apoproteins or it intervenes as a haem repressor with the nuclear gene chain, which leads to the formation of specific mRNA for ALA synthase. • Synthesis and consumption of haem are synchronized precisely. The organism produces some 300 mg haem per day, with only 1% being excreted unused in the urine or faeces. (271, 273, 300, 309) (s. p. 34) (s. tab. 3.3)

▶ The colourless porphyrinogens easily convert to coloured *red-fluorescent uroporphyrins* at 366 nm when there is a sufficient amount of oxygen. This causes a red colour in the urine, which becomes darker (burgundy red) when left in contact with air. • The *red-fluorescent specimen* obtained by liver biopsy in chronic hepatic porphyria is impressive. (s. pp 145, 158) (s. fig. 7.10)

## 15.4 Genetics

Primary porphyrias are genetically determined, whereby their expression varies in intensity, i.e. there is either a reduction in or instability of the enzyme affected by gene mutation. A total loss of enzyme activity or a lack of enzyme protein is inconsistent with the viability of the organism. Transmission is autosomal dominant in five forms of porphyrias, but autosomal recessive in congenital erythropoietic porphyria (CEP), hepatoerythropoietic porphyria (HEP) and the so-called Doss porphyria. (s. tab. 31.10) • Any type of porphyria may be caused by various gene mutations, which results in pronounced genetic heterogeneity. Two different types of porphyria may even become manifest within one family. The penetrance of the relevant gene mutation is low, so that about 80% of the persons involved are without clinical or laboratory findings. The probability of the enzyme defect being passed on to a child is about 50%. (274, 278, 284, 290, 308, 309)

▶ However, not only genetic factors figure prominently in the manifestation of porphyria, but also endogenous and exogenous causes such as alcohol (281), medicaments, stress situations, fasting, intoxication, metabolic products, effects of light and chemical agents (e. g. polyhalogenized biphenyls, dioxin). • In Turkey, about 4,000 people contracted hepatocutaneous porphyria after eating wheat contaminated with the fungicide hexachlorobenzene. (s. p. 565)

## 15.5 Clinical aspects

In cases of suspected hepatic porphyria, **instant orientation** is gained by examining the urine for evidence of δ-

aminolaevulinic acid (ALA) and porphobilinogen (PBG) − using the *Watson-Schwartz test* (C. J. WATSON et al., 1941) or *Hoesch test* (K. HOESCH, 1947) − as well as for the presence of porphyrins. (HOESCH test: 2 ml Ehrlich's reagent + 3 drops of urine = pinkish-red discoloration after shaking, revealing positive evidence of porphobilinogen.) • Further **differentiation** of porphyrins excreted in the urine and faeces or present in plasma and erythrocytes as well as of the distribution pattern of porphyrin metabolites is necessary; for this purpose, thin-layer chromatography, ion-exchange chromatography and HPLC are available. • Identification of asymptomatic **gene carriers,** which is of particular importance for preventive measures, can be achieved by determining the enzymes involved in porphyrin synthesis.

The **symptomatology** of porphyrias is of such complexity and variability that there is always a danger of misinterpretation. Wrongly indicated laparotomy due to suspected acute abdomen entails a high risk. The initiation of incorrect treatment measures may also have grave consequences. Owing to the extremely complex interdisciplinary symptomatology, an emergency due to porphyria must be interpreted in terms of surgery, internal medicine or neurology, and depending on the results obtained, the patient is referred to the corresponding department. • *Porphyria can imitate numerous diseases.*

## 15.6  Erythropoietic porphyrias

The enzymatic metabolic defect is mainly restricted to the erythrocytes or bone marrow. Two distinct clinical pictures can be differentiated: *congenital erythropoietic porphyria (CEP)* and *erythropoietic protoporphyria (EPP)* (W. KOSENOW et al., 1953; I. A. MAGNUS et al., 1961). From a hepatological point of view, only EPP is important. (s. tab. 31.12)

*Tab. 31.12:* Constellation of findings in erythropoietic porphyrias (v = variable, N = normal)

### 15.6.1  Congenital erythropoietic porphyria (CEP)

This clinical picture is also termed *Günther's disease* (H. GÜNTHER, 1911). About 200 cases have been described so far. An autosomal recessive deficiency of uroporphyrinogen III synthase (chromosome 10q25) results in augmented accumulation of porphyrin isomers of type I, which cannot be used biologically. In particular, this causes an increase in uroporphyrin with the occurrence of fluorocytes (most of all erythrocytes, but occasionally also hepatocytes). A red discolouration of urine is already observed in infants. Exposure to the sun leads to severe burns with the formation of blisters (the content of which may fluoresce) and necroses. Pronounced mutilations on the face and hands develop in the course of time. The teeth are discoloured reddish-brown due to the deposition of porphyrins in dentine. Haemolytic anaemia with splenomegaly may develop. • *CEP causes neither neurologic disorders nor (substantial) liver damage.*

### 15.6.2  Erythropoietic protoporphyria (EPP)

An autosomal dominant ferrochelatase deficiency causes enhanced accumulation of protoporphyrin within the erythrocytes. The gene for ferrochelatase has been detected on chromosome 18q21. EPP is considered to be the third most frequent porphyria (1 : 100,000). (315) Red-fluorescing erythrocytes form as a result of the high porphyrin content. EPP becomes manifest already in childhood, but the course of disease may be latent for a long time. Exposure to the sun causes strong skin reactions, such as painful erubescence, oedema and blisters. After long-term insolation, permanent skin infiltrations are observed. The prognosis is generally good. • The liver is damaged considerably by increasing deposits of porphyrins. Cholestasis as well as liver fibrosis and cirrhosis may become manifest. Pigment gallstones can occur. Acute liver failure with a fatal outcome has also been reported. (272, 293, 307) • **Treatment** consists of the administration of β-carotene and vitamin E in order to capture the oxygen radicals which are present in greatly increased numbers in the skin following exposure to sunlight and thus to prevent the triggering of phototoxic reactions. Administration of chenodeoxycholic acid, cholestyramine and glucose (> 300 g/day) is likewise recommended. Liver transplantation may be indicated. (270, 274, 277, 278, 280, 291, 296, 298, 303, 304, 306, 309, 317, 319)

## 15.7  Hepatic porphyrias

Hepatic porphyrias show the following *characteristics:* (*1.*) intermittent course, (*2.*) increased ALA synthase activity, and (*3.*) acute attacks induced or manifesting during the latency period due to numerous causes such as alcohol (281), hunger, carbohydrate deficiency, hormones, stress, intoxication, metabolic products and medicaments. (s. tab. 31.13) • The *diagnosis* is based upon the clinical symptomatology and the excretion pattern of the porphyrins or their precursors in the urine and faeces as well as their concentrations in the erythrocytes and plasma. (s. tab. 31.14)

***Tab. 31.14:*** Porphyrin and porphyrin precursor content in urine and faeces for the differentiation of hepatic porphyrias (v = variable, N = normal) (s. tab. 31.10)

▶ Patients suffering from hepatic porphyria receive a **porphyria pass** as well as all important **information** referring to the disease; in particular, they must be well informed about risk factors leading to manifestation (e.g. avoidance of porphyria-inducing drugs [s. tab.

31.13] and xenobiotics, alcohol abstinence). A diet rich in carbohydrates is important as a preventive measure, because this reduces ALA activity in the liver. • It is essential to examine other **family members** in order to recognize any potential genetic carriers or to identify a relative afflicted by porphyria which is still in the latency phase. Such persons are likewise informed about the disease, particularly with respect to potential manifestation factors, and they also receive a porphyria pass.

### Acute hepatic porphyrias

There are pathophysiological and clinical transitions between all forms of acute hepatic porphyrias. Due to the complex clinical symptomatology, including abdominal, neurological and cardiovascular findings, misinterpretations are possible, and often the diagnosis is made too late. Skin symptoms are observed when porphyrins have accumulated in the tissue, causing reactive oxygen intermediates to form following exposure to sunlight. *In all acute hepatic porphyrias, the excretion of δ-aminolaevulinic acid, porphobilinogen and porphyrins is increased in the urine.* However, no augmentation in the excretion of PBG is observed in defective PBG synthase. Even genetically identified acute hepatic porphyrias may remain latent for a considerable period of time. Their frequency is given at about 5:100,000, with remarkable geographic variations. There are four (or five) different forms of acute hepatic porphyria. (309, 312) (s. tab. 31.10)

### 15.7.1 Acute intermittent porphyria (AIP)

This disease, considered to be the second most frequent form of porphyria, occurs 3−4 times more often in women than in men. The peak rate is between the ages of 20 and 40 years. This autosomal dominant form is responsible for a deficiency in porphobilinogen deaminase (uroporphyrinogen I synthase). The genetic defect of this enzyme is localized on chromosome 11q24. Several genetic variants (>4) exist. The frequency of gene defects shows geographic variations. **Manifestation** of AIP is also caused by numerous exogenous or endogenous factors (see above). In women, the first clinical manifestation is often associated with the premenstrual phase. Some women suffer from cycle-related episodes of the disease. The overall frequency of AIP is 5−10: 100,000. • There are **five cardinal symptoms,** which may appear with widely differing intensity: (*1.*) cardiovascular findings such as tachycardia, hypertension and changes in the ECG, (*2.*) intermittent and diffuse abdominal pain, often localized in the lower abdomen, which may take the form of colic, including vomiting and ileus-like features, (*3.*) severe obstipation, largely unresponsive to treatment (onset mostly during puberty), (*4.*) peripheral neurological and muscular disorders, which may result in pareses or paralyses, and (*5.*) neurotic or psychotic behaviour (confusion, depression, anxiety, hallucinations, delirium and coma). In cases of hyponatraemia (insufficient ADH secretion), encepha-

lopathy may become manifest (B. DIXON, 1997). If cardiovascular and psychiatric symptoms coincide, the picture may be misinterpreted as a thyrotoxic crisis, particularly because the serum values of $T_3$ and $T_4$ are increased in approximately 20% of patients suffering from AIP. The causes of the clinical symptoms are thought to be abnormal biochemical stimuli, triggering dysregulations in peripheral and autonomic innervation. However, there are no skin changes in AIP, and there is no photosensitivity. (268)

Occasionally, the **liver** is also involved: slight increases in the transaminases and bilirubin, and possibly impaired excretory functions as well. Initially the hepatocytes reveal ultrastructural changes, and later slight steatosis and siderosis. The liver bioptate shows no signs of red fluorescence. In AIP, there is a high risk of *cirrhosis* and *liver cell carcinoma* developing. (266, 269, 294) In some patients suffering from such conditions, liver transplantation has proved successful.

▶ **Acute attacks** often coincide with oliguria and hyponatraemia. It is relatively simple to demonstrate the enhanced excretion of porbholbilinogen in the urine by means of the Watson-Schwartz test or Hoesch test. Urinary excretion of ALA is increased. In about 60% of cases, the urine takes on a burgundy-red colour as a result of uro- and coproporphyrin when allowed to stand (due to the action of light and $O_2$). For evaluating prognosis and preventive measures, it is important to consider the different **AIP disease phases:** (*1.*) enzymatic defect, (*2.*) compensated latency period with moderate excretion of porphyrins, (*3.*) decompensated latency period with stronger excretion of porphyrins and discrete clinical symptomatology, and (*4.*) resultant clinical period with acute porphyria syndrome. When PBG is discharged in small amounts during remission, no acute episodes need to be feared as a rule. • **Misdiagnoses** may include: acute abdomen, ileus, pancreatitis and peritonitis (= beware of laparotomy!) as well as poliomyelitis, psychosis, hysteria, hypertonic crisis, thyrotoxic crisis, heart attack, etc. • A **prognosis** is difficult to make regarding an acute attack, which may be life-threatening. An acute sporadic attack has to be treated immediately. Morphological damage to nerves and also demyelination can develop after a long period of paralysis following an acute attack. The regression of these forms of damage often takes many months. Residual defects may remain, mostly in the hands and feet. If corresponding preventive measures are carried out to curtail the factors triggering the disease, the prognosis is quite favourable.

**Treatment** consists of i.v. glucose infusions (2 × 2,000 ml, 20% per day) plus administration of **haem arginate** (3 mg/kg BW/day on four consecutive days and at varying sites of injection) (s. p. 846), possibly with simultaneous administration of metalloporphyrin (for the inhibition of haemoxygenase) (276, 301) as well as intensive care measures and administration of cimetidine (292) or iron. In cases with peripheral or CNS symptoms, prednisolone (100 mg/day) may be administered in addition. (267, 289, 295, 296, 312, 313, 318)

### 15.7.2 Variegate porphyria (VP)

Porphyria variegata is caused by protoporphyrinogen oxidase deficiency. Transmission is autosomal dominant (chromosome 1 q 23). The frequency is 1 : 100,000. • The **clinical picture** is characterized by skin changes similar to PCT (men > women), abdominal pain

and internal as well as neurological symptoms similar to AIP (women > men). Therefore, VP is also called "mixed porphyria". Skin symptoms (increased photosensitivity, vulnerability, formation of blisters, pigmentation, hypertrichosis) are observed in 85% of patients, beginning mostly between the ages of 20 and 30 years. Constipation, vomiting and hypertension are even more common in PV than in AIP. Growth is retarded. • **Laboratory findings** show relatively high increases in total porphyrins, porphobilinogen and ALA, particularly in acute attacks. Enhanced excretion of coproporphyrin in the urine and faeces is observed, even in the preclinical period. The following are considered to be characteristic features of VP: (*1.*) increased excretion of porphyrin-peptide (x-porphyrin) in faeces and (*2.*) maximum absorption of porphyrins in the plasma at 626 nm, while the maximum is 619 nm in all other porphyrias. • The liver biopsy sample shows no red fluorescence. No significant or even characteristic histological liver changes are in evidence. • Factors triggering an acute attack correspond to those found in AIP. The prognosis is quite good when these noxae are avoided. (279, 297)

### 15.7.3 Hereditary coproporphyria (HC)

This is an autosomal dominant coproporphyrinogen oxidase deficiency (chromosome 3 q 12). The frequency is 1 : 100,000. An increase in porphyrins, coproporphyrin and porphobilinogen is found in the urine. This form of acute hepatic porphyria is very rare. Its clinical course is largely identical to that of AIP, whereby acute gastrointestinal and neuropsychiatric symptoms predominate. However, they are less pronounced and cannot be detected with the same frequency as in AIP and VP. Skin symptoms (in about 30% of cases) include photosensitivity, pigmentation and hypertrichosis. The liver displays red fluorescence due to the accumulation of porphyrin (s. fig. 7.10), but no morphological damage. Coexistence with PCT has been described. (282)

### 15.7.4 Doss porphyria (DP)

This rare, autosomal recessive form of porphyria is based on 5'-aminolaevulinic acid dehydratase deficiency (chromosome 9q34). A symptomatic disease only occurs in homozygotes or double heterozygotes. No more than seven cases have been described to date. Urinary excretion of ALA and coproporphyrin is increased; greater amounts of protoporphyrin accumulate in the erythrocytes. Neuropathy develops, as in AIP. Repeated severe neurological crises may necessitate liver transplantation. Heterozygotes are considerably endangered by lead, because lead inhibits ALA and thus triggers the manifestation of porphyria (= plumboporphyria).

### 15.7.5 Porphobilinogen synthase defect

This rare form shows a very varied symptomatology. The disease may become manifest during puberty with severe pain or it may present later in life (beyond the 5th decade) with the clinical picture of moderate polyneuritis. ALA as well as uroporphyrins and coproporphyrins are augmented in the urine, whereas no abnormalities are evident in faeces or plasma.

### Chronic hepatic porphyrias

Chronic hepatic porphyrias appear in two variants: (*1.*) porphyria cutanea tarda and (*2.*) hepatoerythropoietic porphyria. Chronic hepatic porphyria develops in about 10% of patients suffering from chronic liver disease. (s. tabs. 31.10, 31.11)

### 15.7.6 Porphyria cutanea tarda (PCT)

This is the most common form of porphyria (prevalence 20−50 : 100,000). The primary enzyme defect is a *uro-*

*porphyrinogen III decarboxylase* deficiency. The coded gene for the enzyme defect is on chromosome 1q34. PCT is characterized by pronounced genetic heterogeneity. • As far as its transmission is concerned, two forms can be differentiated: (*1.*) **familial form** (type 2), which is characterized by an autosomal dominant transmission route with heterozygote enzyme deficiency (about 50% enzyme activity) in all tissues (e. g. erythrocytes, liver, fibroblasts) − other family members are frequently affected as well; (*2.*) **acquired form** (type 1), which is also autosomal dominant, displays a uroporphyrinogen decarboxylase deficiency, but only in the liver (normal enzymatic activity in erythrocytes). This "sporadic" type occurs about six times as often as the familial form. Probably, there is also a third form of PCT, namely another familial form, in which, however, the inheritance is not confirmed. The URO-D in the hepatocytes is normal (100%) in these patients. The enzyme defect seems to be limited to the liver. (284) It is (not yet) possible to differentiate clinically between these forms.

▶ As is the case with all hepatic porphyrias except HEP, additional **realization factors** such as (*1.*) alcohol, (*2.*) oestrogens, and (*3.*) haemodialysis (together with a genetically induced enzyme defect) are required for the clinical manifestation of PCT. Alcohol may cause the manifestation of PCT due to the induction of MEOS and an alcohol-related increase in iron in the liver. However, (*4.*) pharmacons (particularly lipophilic medicaments) may also be responsible for PCT, e. g. barbiturates, diazepam, hydantoin, rifampicin, antipyrin, cyclophosphamide (299), hexachlorobenzene. (s. p. 565) These substances also trigger induction of the cytochrome P 450 system, but no regulatory disorder of haem synthesis, so there is no compensatory increase in ALA synthase. A rise in PBG and ALA is therefore not detectable in the urine; this means that no neuropsychiatric symptoms appear in PCT. • Apart from that, there are substances which act as **provocation factors**, e. g. xenobiotics, steroids, lead, iron and mercury. Iron interferes with porphyrin metabolism by inhibiting uroporphyrinogen decarboxylase and probably the subsequent ferrochelatase as well, so that PCT becomes manifest. While these factors trigger an acute life-threatening porphyric process in acute hepatic porphyrias, they are generally well tolerated in PCT (e. g. all drugs), at least for a short period of time. (285, 309)

While PCT was formerly observed with greater **frequency** in men (peak rate between the third and fifth decade), the ratio between the sexes nowadays is assumed to be 1:1, with women occasionally being even more prone to the disease. This situation is possibly attributable to oestrogen intake (e. g. contraceptives) and increased alcohol consumption among women. Obviously, hepatic siderosis is a prerequisite for the expression of the "sporadic" form. The frequency of PCT is estimated to be 1% of the population in the age groups 30−70 years.

**Predisposition:** The additional liver damage caused by the accumulation of urocarboxyporphyrins (UCP) and heptacarboxyporphyrins (HCP) in hepatic tissue is a prerequisite for clinically manifest PCT. Several forms of **liver disease** increase susceptibility to PCT, e. g. viral hepatitis B, and more particularly type C (286, 287, 302, 309), fibrosis, siderosis, cirrhosis, alcohol-induced liver disease and liver cell carcinoma. Chronic liver disease is found in 30−40% of patients with PCT. (285, 305)

The **pathogenesis** of PCT is thus caused by a combination of *four factors:*

1. Defective uroporphyrinogen decarboxylase
2. Realization and provocation factors
3. Accumulation of UCP and HCP in the liver
4. Liver disease

**Clinical picture:** The clinical picture is characterized by skin lesions and liver damage. • The **skin changes** usually begin between the ages of 40 and 70 years. Photosensitivity is due to porphyrin deposits in the skin, where their distribution pattern resembles that in the urine and serum. The lesions are so typical that there are hardly any misinterpretations. They are found at locations exposed to light such as the dorsal surface of the hands and fingers, face, neck, auricle and hairless areas of the head. The following forms are evident: (*1.*) vesiculated erosive blisters of 2 mm to 3 cm in size, which "migrate" when subjected to pressure (= *Nikolsky's phenomenon*), (*2.*) bloody scabs after the blisters have ruptured, with a poor tendency to heal, but only a slight inclination to secondary bacterial infection, (*3.*) healed vesiculated erosive blisters with atrophic scar formation and blotchy hyper- or depigmentation as well as whitish epithelial cysts, the size of a pinhead, filled with pearly bodies, (*4.*) hypertrichosis and facial cyanosis as well as melanotic hyperpigmentation, (*5.*) chronic actinic skin changes (premature skin ageing, cutis rhomboidalis, elastosis), and (*6.*) pseudosclerodermia on skin areas exposed to sunlight. (s. figs. 4.13; 31.16)

***Fig. 31.16:*** Skin changes (face, front part of the neck) in porphyria cutanea tarda (s. fig. 4.13)

**Liver damage** is clinically recognizable as hepatomegaly. There is an increase in transaminases, GDH, γ-GT, serum iron (increased saturation of transferrin) with secondary polycythaemia, and occasionally alkaline phosphatase. Reduced liver function is evident due to decreased cholinesterase. • Depending on the duration and progression of PCT, changes in the *liver surface* range from a faded lobular pattern on a reddish-brown coloured liver to finely granulated areas with fine whitish fibrosis on a diffuse blue-grey surface colour (due to porphyrin deposits) and brownish speckled areas as well as flat tuberous surfaces with scar formation. (s. fig. 31.17)

*Fig. 31.17:* Chronic active hepatitis in porphyria cutanea tarda. Dispersed light reflection, capsular fibrosis with pronounced net-like fibrosis. Spider-like subcapsular neovascularization

*Histology* shows deposits of needle-like porphyrins and large-droplet fatty changes in the hepatocytes, moderate iron deposits in the hepatocytes and Kupffer cells as well as signs of non-specific reactive hepatitis. (s. fig. 31.18)

*Fig. 31.18:* Chronic porphyria: uncharacteristic lobular hepatitis histomorphologically correlating to increased liver enzyme levels (HE)

In the bluish-grey areas, the porphyrin content is three to four times higher than in the lighter liver sections. In

*UV examinations* (366 nm), to which every liver bioptate should be subjected, the red fluorescence has different intensities, facilitating classification into *PCT groups A−D:* types A and B (no clinical symptoms) show dot-like fluorescence, type C (latent PCT) has mostly reticular fluorescence, and type D (manifest PCT) is characterized by homogeneous red fluorescence. (s. fig. 7.10!) (s. pp 145, 158) • In the further course, scar tissue or micronodular cirrhosis develop. There is a greater risk of hepatocellular carcinoma (15−25%) (due to concomitant HBV or HCV infection as well as haemochromatosis?). (305, 309−311)

**Diagnosis** of PCT is based upon *skin changes* with characteristic anamnesis and *detection of porphyrins* in the urine and faeces. (s. tab. 31.14) There is evidence of increased uroporphyrins, particularly heptacarboxyporphyrin and coproporphyrin in the urine as well as elevated uroporphyrin in the faeces and plasma. Dark red discolouration of the urine resulting from enhanced release of porphyrin (>15 μmol/day) has frequently been observed. Subclinical forms can be detected three times more frequently using targeted diagnostics! • In most cases, *HLA-A3* and *HLA-B7* (as in haemochromatosis) are present in the serum. *Serum iron* is elevated. The undoubtedly important role of **iron** in the pathogenesis of PCT has still not been clarified. Mutations of the HFE gene in haemochromatosis (C 282 Y, H 63 D) are also much more numerous in PCT. Probably, these (and other?) mutations cause an enhanced resorption of iron from the intestine. (284, 310) • There is a close coincidence of PCT and **HCV** infection (mainly genotype I b). A considerable geographical variation in frequency has been reported, from which an average of HCV positivity in PCT patients of about 45% can be determined. Interactions between the two diseases have not been clarified as yet; however, it is striking that both conditions generally show siderosis as well as being influenced to a particularly unfavourable degree by alcohol. (284, 287, 288, 302)

**Sonography:** Even at an early stage of porphyria, ring-shaped foci with marginal hyperechoic ring and central hypoechoic reflexes can be detected. (s. fig. 31.19)

*Fig. 31.19:* Chronic hepatic porphyria: Sonographically, multiple, ring-shaped foci with marginal hyperechoic ring and central hypoechoic reflexes. (Completely reversible after alcohol abstinence)

These foci result from porphyrin deposition and are often only discovered by chance since there is no evidence of a chronic porphyria. They can be mistaken for tumours or metastases; neither the foci nor their neighbouring parenchyma are hypervascularized. Following abstinence of alcohol and avoidance of oestrogens, they are completely reversible. • In a chronic porphyria, there is frequently a uniform increase in density due to diffuse porphyrin storage.

**Treatment** comprises avoidance of *trigger factors* (alcohol, oestrogens, sunlight, etc.) and application of sunblocks. • *Venesection* with its withdrawal of iron results in inhibition of ALA synthetase, while uroporphyrinogen III decarboxylase activity is increased. This bloodletting therapy is based on 500 ml per week, after $4-6$ weeks at monthly intervals. As an alternative, plasmapheresis has also been applied. • *Chloroquine* (2 x 50 mg/day) is administered every second day for $6-12$ months; it combines biochemically with porphyrins in the hepatocytes, thus improving the elimination of porphyrins from the liver. Venesection and chloroquine therapy may be carried out jointly. • *Alkalization* of the renal metabolism enhances the elimination of porphyrins via the kidneys. (296)

## 15.8 Hepatoerythropoietic porphyria (HEP)

This is a very rare form of chronic hepatic porphyria. As with PCT, the enzymatic defect is a deficiency of uroporphyrinogen decarboxylase. However, the genetic defect is homozygous. It may also be caused by exogenous factors. HEP manifests in early childhood with high photosensitivity, sclerodermia, hypertrichosis and anaemia. • The *liver* shows red fluorescence. Histologically, siderosis and non-specific hepatitis are found. Development of cirrhosis is possible. • No effective *therapy* is known. (314, 316)

# 16 Wilson's disease

▶ The first clinical and morphological description of the disease was published by S. A. K. WILSON in 1912. (394) This article did not mention the previous reports by K. F. O. WESTPHAL (1883) and A. VON STRÜMPELL (1898); they distinguished between the neuropsychiatric picture of the disease, assigning to it the rather unfortunate term *"pseudosclerosis"*, derived from multiple sclerosis, which was already clearly defined at that time. • In 1921 H. C. HALL maintained that Wilson's disease and pseudosclerosis were actually one and the same thing and that it was even hereditary; he coined the term *"hepatolenticular degeneration"*. • The *storage of copper* in the liver and brain was postulated by A. RUMPEL in 1913 and confirmed by F. HAUROWITZ in 1930. The brown-green colour of the corneal ring described by B. KAYSER (1902) (347) and B. FLEISCHER (1902) (337, 338) is due to copper deposits, as was confirmed by W. GERLACH in 1934. J. N. CUMINGS (1948) identified copper as the cause of disease. *Hypercupriuria* was first described by B. M. MANTELBROTE et al. (1948) and *hypocupraemia* by A. G. BEARN et al. (1952). This abnormality in copper metabolism was clarified by the detection of *hypoceruloplasminaemia* (I. H. SCHEINBERG et al., 1952). In 1960 A. G. BEARN demonstrated the recessive autosomal transmission.

The first therapeutic attempts to eliminate the increased copper content of the tissue by way of chelating agents go back to J. N. CUMINGS (1948) and D. DENNY-BROWN et al. (1951). For this purpose, *dimercaprol* and *ethylene-diaminetetraacetic acid* (EDTA) were used. Treatment with *potassium sulphide* was recommended by M. M. WINTROBE et al. in 1954. The final breakthrough came with examinations carried out by J. M. WALSHE (1956), who recognized the copper-binding properties of *β,β-dimethylcysteine* (penicillamine). Another copper-chelating substance, *trientin-dihydrochloride*, was introduced by J. M. WALSHE in 1969. (389) The therapeutic effectiveness of zinc in patients suffering from Wilson's disease had been reported as early as 1961 (G. SCHOUWINK), while the therapeutic principle itself was described at a later date by T. U. HOOGENRAAD et al. (1978). (343)

## 16.1 Definition

Wilson's disease is a genetically determined, autosomal recessive copper storage disease with a reduced discharge of copper into the bile. Due to pathological copper deposits in the liver and brain as well as various other organs, sequelae develop above all in the liver and CNS. The other affected organs are generally involved in the disease as late manifestation. The chromosomal defect is still not fully clarified.

## 16.2 Frequency

The incidence rate is 1:100,000 inhabitants/year. The prevalence of this disease in patients with manifestation is estimated at 1:30,000 and in heterozygote symptom carriers at 1:100 to 1:200 of the population, i. e. $5-30$ patients/1 million inhabitants. • Wilson's disease appears in childhood, adolescence and early adulthood. Initial occurrence before the 5th or after the 35th year of life is considered to be an exception. However, mild courses of disease have also been diagnosed beyond the age of 50. (321, 323) Most patients develop the first clinical symptoms around the age of 15. Geographical or race-related differences in frequency have not been reported. However, a higher incidence is found in regions with strong consanguinity (e. g. Sardinia, Israel).

## 16.3 Pathogenesis

The metabolic defect in Wilson's disease is located in the liver on chromosome 13 close to the esterase-D locus (ATP 7B). (325, 346, 359) Apparently, this is a genetically determined disturbance of **hepatobiliary copper** discharge due to a *defect in lysosomal copper-transporting ATPase*, which is localized in the trans-Golgi network. As a result, apoceruloplasmin cannot be loaded with copper, and is therefore degraded. The reduced secretion of ceruloplasmin explains the low

copper level in the serum. So far, more than 250 different mutations of Wilson's gene have been described. (327, 358) This disorder may be located (*1.*) in the area of the sinusoidal membrane (transfer into the blood via ceruloplasmin) or (*2.*) in the area of the canalicular membrane (transfer into the bile via copper-binding ATPase). About 80% of the copper absorbed enterally is excreted via the bile, while in Wilson's disease, the biliary excretion is reduced to 10−20%. Neither reabsorption of copper excreted via the bile nor intestinal copper resorption are increased. (332, 370, 385, 395)

In the first 3−4 months of life, the **newborn** usually shows findings concerning copper metabolism which correspond to those found in Wilson's disease. It is therefore assumed that the conversion of foetal copper metabolism to that normally found later on in life is effected by a control gene. From birth onwards, 10−20 mg copper are accumulated every year. It usually takes 6−15 years before clinical symptoms become apparent as a result of the cumulative copper deposition. • In **siblings,** there may be considerable differences regarding clinical and laboratory findings. It can therefore be concluded that *exogenous* or *endogenous factors* modify the genetically determined process or alter the gene expression within the families involved. There is *genetic heterogeneity.*

**Copper:** The daily intake from food is 0.8−2.0 mg; it is released into the portal vein via copper-transporting ATPase. The transport of copper, which is toxic in its free form, is effected by the binding to ceruloplasmin, albumin and transcuprin. • Copper is bound to reduced glutathione and metallothionein in the hepatocytes and distributed to various organelles or incorporated into enzymes. The biological effects of copper are manifold and essential for some cellular functions. (s. p. 50) Copper is toxic not only in its free form, but also in cases of overload (e. g. cirrhosis in childhood due to the consumption of water from copper pipes). Copper homoeostasis is regulated via biliary excretion (normal value: about 1.2−2.0 mg/day), so that the **normal value** in serum is 75−130 µg/dl. (321, 323, 370, 383, 386) (s. p. 102)

**Ceruloplasmin** binds eight copper atoms per molecule and is of an intense blue colour. The coding gene is localized on chromosome 3. (396) Ceruloplasmin is the most important transport protein for copper in circulating blood (about 75−95% binding capacity). Another important function of this protein is the catalysis of oxidative metabolic reactions; it also possesses antioxidative features for the elimination of reactive oxygen intermediates. (s. tab. 3.25) The **normal value** in serum is 20−35 mg/dl.

The **reduction** in the serum value of ceruloplasmin led to the assumption that a primary synthesis disturbance was of particular pathogenic importance. There are several observations which contradict this hypothesis, suggesting that the *disturbance in ceruloplasmin synthesis* is probably a secondary consequence of the underlying metabolic defect. The introduction of copper into ceruloplasmin is possibly inhibited as a result of a dysfunctional apoprotein of ceruloplasmin.

**Transcuprin** is another transport protein for copper in circulating blood (about 7% binding capacity). • Apart from being bound to glutathione and metallothionein,

copper may also be bound intracellularly to *another protein* that has only recently been detected.

## 16.4 Pathophysiology

The **toxicity of copper** is due to (*1.*) its binding to SH groups of cysteine, which is converted into an irreversible form by oxidation, and (*2.*) the fact that it is responsible for the formation of reactive oxygen intermediates (e. g. hydroxyl radicals), resulting in lipid peroxidation, which, in turn, is responsible for functional and structural disturbances of biomembranes. (342) In addition, a reduction in vitamin E likewise encourages the occurrence of lipid peroxidations. • Initially, copper is diffusely distributed in the cytosol and then stored in the hepatocellular lysosomes. At this point, it can also be demonstrated histochemically. Rapid transfer from the cytosol to the lysosomes may lead to increased lipid peroxidation with cell necrosis. (370, 383) • *Abrupt discharge of copper from the lysosomes into the bloodstream results in intravasal haemolysis and widespread liver cell necroses with fulminant hepatitis.*

## 16.5 Morphological changes

### 16.5.1 Hepatic manifestation

**Electron-microscopically,** the *mitochondria* − an essential target of toxic copper − show swelling and altered morphology, separation of external and internal membranes, greater density of the matrix, and granular or vacuolic inclusions. The *peroxisomes* are characterized by their increase in size and altered form as well as a granular matrix. Secretion of lipids is reduced. These structural changes result in discernible steatosis of the hepatocytes. • The *lysosomes* grow in number and size; finally, they decay and release lysosomal enzymes. (350) Apart from that, structural changes in the endoplasmic *reticulum* and *cytoskeleton* can be observed (= **stage I**).

**Histologically,** fine-droplet, ultimately also large-droplet, fatty changes of the hepatocytes in the peripheral lobules and the occasional formation of Mallory bodies can be found. There are no signs of fat cysts. Steatosis subsides with increasing duration of disease. The lysosomes, meanwhile overloaded with copper, are deposited mainly at the bile pole of the hepatocytes and resemble lipofuscin-like pigment bodies. Degenerative changes in the hepatocytes, hypertrophy of Kupffer cells and an accumulation of glycogen in the nuclei with formation of *glycogen vacuolations* can be observed. (s. fig. 31.1) • Rapid intracellular redistribution of copper causes extensive cell necrosis. In this intermediate stage (= **stage II**), inflammatory reactions (very probably of an autoimmune nature) and proliferations of the bile ducts are evident. The histological picture − as well as the laparoscopic image of the liver surface − may at this point correspond to that of chronic hepatitis. (s. fig. 31.20) The late stage shows increased fibrogenesis with variable fibre contents, and micronodular cirrhosis develops (= **stage III**). (s. figs. 31.21, 31.22)

*Fig. 31.20:* Chronic hepatitis in Wilson's disease. Pronounced "simian cleft" with barely recognizable hepar succenturatum (s. p. 15)

*Fig. 31.21:* Explanted liver with micronodular cirrhosis in Wilson's disease (18-year-old woman presenting with acute liver failure) (Sirius)

*Fig. 31.22:* Cirrhosis in Wilson's disease. Numerous copper deposits in periportal liver epithelia (Rhodanine)

The *distribution of copper* in the liver is concentrated in the peripheral lobules, but its pattern is nevertheless irregular (even in advanced stages): there may be areas with very high copper concentrations adjacent to regions which are almost copper-free; this can give rise to false-negative findings during histochemical exami-

nation of the liver bioptate. The *detection of copper* is possible by means of (unreliable) rhodanine staining, while the copper bound to metallothionein in the lysosomes is demonstrable by orcein staining (likewise not reliable). The copper content of the liver (normal 15–55 µg/g dry weight) may indeed rise to 3,000 µg/g. If untreated, Wilson's disease shows rapid progression, also in the liver. (339, 349, 355, 378, 382) With an effective therapeutic reversal of copper deposition, the copper balance can be restored. The patient returns to an asymptomatic course of Wilson's disease. However, the organ damage that has hitherto occurred is irreversible (= **stage IV**).

The **morphological spectrum** may therefore range from steatosis, acute hepatitis, fulminant course, chronic hepatitis, aggressive episodes in chronic hepatitis and liver fibrosis through to micronodular cirrhosis. Complete cirrhosis can already exist in children aged 4–5 years. • The development of *hepatocellular carcinoma* is extremely rare (360); it is assumed that copper has a protective effect against malignant transformation. (391, 393)

### 16.5.2 Extrahepatic manifestations

After complete saturation of the copper-binding capacity of the liver, the copper absorbed from food can no longer be taken up by the liver. This means that copper is stored in the brain, skeletal system, heart, cornea and kidneys – as is also the case when copper stored in the hepatocytes is released into the circulation on a large scale due to extensive liver cell necrosis. (339)

**CNS:** Copper deposits affect the whole CNS. Degeneration and tissue loss as well as atrophy of the lenticular nucleus prevail. Occasionally, there are also small necrotic foci with a diffuse spot-like distribution. Microcavernous lesions occur due to the destruction of nerve cells. Myelinized fibres and oligodendrocytes are present, but there is also cellular hyperplasia and hypertrophy of astrocytes rich in protoplasm. The cerebral changes detectable in CT scanning do not correlate with the degree of severity of the functional disturbances (320, 335); however, there is a close correlation between the lesions detected by MRI and certain neurological findings. (350, 366, 376, 388) (s. p. 615)

**Eyes:** Copper is deposited in the form of a copper-sulphur complex in Descemet's membrane on the back of the cornea. Fine copper granules are observed, first as moderate colour changes at the upper limbus, then also at the lower limbus, with the ultimate development of a complete brown-green ring, 1–3 mm in width. (337, 338, 347) The **Kayser-Fleischer corneal ring** is nearly always found in adults with principally neurological and psychological problems, whereas it is generally not present in juveniles with a hepatic course. The best way to detect this ring is by slit-lamp examination. (s. fig. 4.17) The existence of such a ring is not in itself proof of Wilson's disease, as it is also found in CDNC-induced cirrhosis

and primary sclerosing cholangitis; its absence does not, however, exclude Wilson's disease. • Occasionally (10−20%), a **sunflower cataract** is observed on the lens (E. SIEMERLING et al., 1922): a central gold-brown copper deposit in the frontal lens capsule with radial emanation into the posterior capsule areas. (328) Visual acuity is not compromised by these changes. Successful treatment leads to the regression of both ocular findings, making it possible to evaluate the course of disease (as well as to monitor inadequate treatment).

**Kidneys:** Dysfunction of the proximal tubule may occur as a late manifestation of Wilson's disease. Epithelial flattening, a loss of the brush-border membrane, mitochondrial anomalies and fatty cellular changes can be observed. These findings are, in turn, responsible for *proteinuria* with a predominance of *hyperaminoaciduria* (L. UZMAN et al., 1948). Enhanced *calciuria* and *phosphaturia* may cause osteomalacia as well as hypoparathyroidism. (329, 344) Glucosuria and uricosuria, if present, are without clinical relevance. Due to decreased bicarbonate resorption, *tubular acidosis* may occur, with a tendency towards osteomalacia as well as the development of nephrocalcinosis and renal stones (in some 15% of cases). (344, 356, 392) The intensity of the copper deposits in the kidneys correlates closely with the cellular changes and functional disorders. • The glomerular function is not compromised, with the result that substances normally excreted in the urine are not retained.

**Skeleton:** Renal phosphate diabetes associated with hypercalciuria may lead to osteomalacia or osteoporosis. Likewise, inflammatory or degenerative arthrosis is thought to be a late manifestation of Wilson's disease. (354) Often, these developments are combined with intra-articular calcium deposits and chondromalacia, in particular *patellar chondromalacia*. Bone fractures are frequently observed even with minor traumas. Calcification may occur in articular cartilage, capsule and tendinous insertions, and deposits of calcium pyrophosphate dihydrate can appear in the intervertebral disks.

**Myocardium:** Copper deposits in the myocardium causes interstitial fibrosis, the sclerosing of small vessels and focal inflammatory or degenerative lesions. This results in cardiac arrhythmia and cardiomyopathy.

**Bone marrow:** Leucopenia and thrombopenia may be a result of bone-marrow damage caused by copper deposits, although this can also be due to splenomegaly.

**Skin and muscles:** Acute *rhabdomyolysis* (362) as well as *dermatomyositis* are considered to be rare manifestations of Wilson's disease. • Occasionally, there is evidence of *hyperpigmentation* as well as *acanthosis nigricans.* Bluish, lunular discolorations of the nails, so-called *azure lunulae,* are rare. (322) (s. p. 84)

## 16.6  Clinical picture

The **symptoms** of Wilson's disease can hardly ever be recognized before the age of six. In most cases, the patients show symptoms between the 6th and 20th year of life − occasionally, however, as late as the 4th decade. About half the patients develop the disease before the age of 15. Sometimes, above-average growth in height is observed. Based on the prevailing symptoms, **three clinical forms** can be differentiated: (*1.*) *hepatic*, (*2.*) *neurological*, and (*3.*) *mixed courses*. The hepatic form is observed almost exclusively in children between the ages of 6 and 15, while the neurological form predominates in adults. • **Asymptomatic courses** are usually diagnosed only by chance. (326, 330, 339, 341, 364, 370, 377, 379, 381)

**Early diagnosis** is essential. This is true both for the recognition of *heterozygous carriers* and for the diagnosis of asymptomatic *homozygous carriers* − often, the two groups can only be differentiated by using complicated methods (e. g. specific DNA markers, gene linkage analysis, $^{64}$Cu kinetics). (345, 351)

▶ Once the diagnosis of Wilson's disease has been confirmed beyond doubt, all other **family members** have to be examined as well. During this process, occasional cases of a presymptomatic course of disease are detected. A reduction of ceruloplasmin in serum may even be present in carriers of heterozygous features. Genetic analysis can provide a diagnosis in some 95% of cases, even prenatally.

**Liver diseases**

Hepatic disorders are a prominent feature of Wilson's disease in childhood and adolescence. In the early stages, a **fatty liver** is often observed, the aetiology of which is at first unclear. • A slight increase in the transaminases may be the first biochemical sign, before any other symptoms appear. • In **acute hepatitis** of varying degrees of severity, Wilson's disease must always be ruled out. • In the natural course of disease, **chronic active hepatitis** may be found in the initial phase. In terms of clinical and laboratory examination, it can only be distinguished from other forms of chronic active hepatitis by way of aetiology-specific findings. (s. fig. 31.20) • **Fulminant hepatitis,** which is observed quite often, shows rapid progression with the development of pronounced jaundice; there is evidence of increased copper values in the serum and urine, while ceruloplasmin in the blood is decreased or normal. Ascites and growing liver insufficiency are evident. (335) Transaminases are only slightly elevated. A marked reduction in alkaline phosphatase is considered to be a characteristic feature. (374) At the same time, haemolysis is often present due to an abrupt discharge of cytosolic copper into the bloodstream. Fulminant hepatitis in Wilson's disease is usually fatal if there is no chance of liver transplantation. (333, 334, 339, 340, 353, 358, 368, 375, 380) • **Liver cirrhosis** develops slowly. (s. figs. 31.21, 31.22) Non-specific general complaints and skin stigmata of liver disease (s. fig. 4.21), which are typical in chronic forms, as well as the symptoms and sequelae of portal hypertension are

evident. In association with thrombopenia, cutaneous and mucosal bleeding may occur due to synthesis disorders of the coagulation factors. Occasionally, recurrent bouts of jaundice (generally due to haemolysis) are observed. An acute necrotizing episode may have a fatal outcome.

### Neurological and psychiatric disorders

*Neurological symptoms* are not observed before an advanced stage of disease is reached, particularly in older juveniles or adults. In their case history, half of these patients have not shown any signs of haemolytic anaemia or hepatic symptoms which could have pointed to Wilson's disease. However, a very discrete symptomatology at the onset progresses continuously and ultimately characterizes the clinical picture of untreated Wilson's disease. (320, 371, 381, 397) • *Psychiatric symptoms* (personality changes, behavioural disorders, neuroses, psychoses) are detected in 55−65% of cases. • A drop in *performance at school* may be one of the first signs of Wilson's disease. • The following symptoms are found in varying degrees of intensity and in different combinations (although some of the late features are no longer observed nowadays due to effective treatment techniques which are generally initiated at an early stage):

- unsteady gait, balance disturbance, uncoordinated movements, grimacing
- dysarthria, scanning speech, palilalia
- dysphagia, salivation, raising and retracting of the upper lip
- dysgraphia, micrographia
- seizures
- tremor, athetosis, resting and intention tremor, nystagmus, rigor, flexion contractures, spasticity
- personality changes, behavioural disorders, neurotic or psychotic symptoms (including forgetfulness, irritability, emotional lability, inability to keep a distance)
- hypomimia and amimia, mask-like face

### Haemolysis

In about 15% of patients suffering from Wilson's disease, haemolysis with corresponding jaundice can be observed, sometimes as a relapse and occasionally as a haemolytic crisis. (s. tab. 12.3) The release of large amounts of copper from necrotized liver cells causes copper-induced damage to erythrocytes with subsequent haemolysis (due to enzyme deficiency). Haemolysis may even constitute the first manifestation of Wilson's disease (333, 334, 365) and precede the hepatic findings by several years. Usually, it is transitory and self-limiting. In severe cases, this non-spherocytic, Coombs-negative, intravascular haemoloysis may be combined with haemoglobinuria. • Chronic haemolysis can lead to the formation of *pigment gallstones*.

## 16.7 Laboratory findings

When there are clinical signs suggesting the presence of Wilson's disease or corresponding differential diagnostic considerations, diagnosis (or diagnosis by exclusion) is established by laboratory parameters. AP is normal or slightly increased. The GPT/GOT quotient is generally > 4. (330, 339−341, 357, 381, 390, 397) (s. tab. 31.15)

| | | |
|---|---|---|
| Ceruloplasmin in the serum | ↓ | (< 20 mg/dl) |
| Copper content of the liver | ↑ | (> 250 µg/g) |
| Copper in the urine | ↑ | (> 70 µg/day) |
| Free copper in the serum | ↑ | (> 25 µg/dl) |
| Penicillamine test (600 mg) | + | (> 300 µg/6h) |
| Total copper in the serum | ↓ | (< 70 µg/dl) |

***Tab. 31.15:*** Decisive laboratory criteria for the diagnosis and follow-up of Wilson's disease

**Ceruloplasmin:** Usually, the serum value of ceruloplasmin is below 20 mg/dl in homozygous Wilson's disease; however, in about 15% of such symptomatic patients, the values are found in the lower normal range (20−30 mg/dl). In about 15% of heterozygous patients without manifestation of the disease, a slight decrease in the ceruloplasmin value is also observed. When the value is > 30 mg/dl, Wilson's disease can usually be ruled out. Nevertheless, in strongly compromised liver function, the ceruloplasmin value increases due to hyperoestrogenism, which develops subsequently and stimulates ceruloplasmin synthesis in the liver. A decrease to < 20 mg/dl is not confirmation of Wilson's disease. **Decreased values** are also found in nephrosis, Menkes' disease, aceruloplasminaemia (J.D. GITLIN, 1998), malabsorption syndrome, etc. **Increased values** are observed in cholestasis, during pregnancy, with oral contraceptives, in malignant and inflammatory processes, etc.

**Cupruria:** In pronounced liver cell decay, there is not only a rise in the copper value in serum, but more particularly in the amount of copper excretion in the urine. Cupruria of < 50 µg/day rules out the presence of Wilson's disease (differential diagnosis: e. g. kidney disease). • The **penicillamine test** has proved successful: after administration of 600 mg penicillamine, copper excretion increases to > 300 µg/6 hr (> 600 µg/24 hr). However, it should be noted that this test may show similar positive results in cholestatic liver diseases.

**Copper content of the liver:** The diagnosis of Wilson's disease is confirmed by determination of the liver copper content (normal: 20−50 µg/g dry weight) using atomic absorption spectrometry. First of all, the puncture instruments and glass vessels have to be free of copper (cleaned with a 0.1 EDTA solution). An inhomogenous distribution of copper in the liver, particularly in cases of cirrhosis, has to be taken into account. • In addition, an increased hepatic copper content can also be detected in other liver diseases, e. g. bile-duct atresia, primary biliary or primary sclerosing cholangitis, bile-duct obstruction, chronic hepatitis, neoplasm, $\alpha_1$-antitrypsin deficiency, Gilbert's disease, Dubin-Johnson syndrome.

## 16.8 Diagnostic measures

▶ *Suspicion:* Detection of acute or chronic liver disease of unclear aetiology (in particular fatty liver) and/or haemolysis, and/or neurological or psychological peculiarities in children above the age of 6, in juveniles and in

adults up to the age of 40 suggest the suspected presence of Wilson's disease *("give it thought")*.

▶ *Hints:* Detection of a Kayser-Fleischer corneal ring (in the early phase by slit-lamp examination) is considered to be the most important clinical finding of manifest Wilson's disease. (s. fig. 4.17)

▶ *Confirmation:* The diagnosis is verified by laboratory parameters (determination of the serum values of copper and ceruloplasmin as well as of copper excretion in the urine, if necessary also by means of the penicillamine test) and by demonstration of the copper content of the liver, with simultaneous differentiation of existing liver damage.

▶ *Organ involvement:* The type and extent of organ involvement is determined by a broad spectrum of examinations. To a certain degree, these examinations are also important for monitoring progress and therapy. (s. tab. 31.16)

---

1. **Liver**
   laboratory parameters
   liver biopsy/laparoscopy
   copper content of the liver
2. **CNS**
   EEG, ENG, EMG (CT), MRI
3. **Eyes**
   slit-lamp examination
4. **Kidneys**
   calciuria, phosphaturia, glucosuria,
   aminoaciduria, tubular acidosis
5. **Sonography**
   liver status, portal hypertension,
   kidney stones, nephrocalcinosis,
   gallstones
6. **Skeleton**
   osteomalacia, osteoporosis,
   chondrocalcinosis, arthropathy
7. **Blood**
   thrombocytes, leucocytes,
   coagulation factors,
   signs of haemolysis (s. tab. 12.3)
8. **Heart**
   ECG
   echocardiography

---

**Tab. 31.16:** Diagnostic measures for detecting the type and extent of organ involvement in Wilson's disease

At an advanced stage, *sonography* yields a metastasis-like picture: fatty degeneration together with areas of fibrosis (= echogenic) and normal parenchyma (= hypoechoic).

An *MRI brain scan* may demonstrate typical changes such as atrophy and densification in the basal ganglia and the lenticular nucleus (i.e. in the putamen and the globus pallidus). The cause of the particular sensitivity of these regions is unknown.

## 16.9 Prognosis

The prognosis depends essentially on **early diagnosis** and consistent treatment. (357, 370) If untreated, Wilson's disease is fatal. When treatment is initiated too late, irreversible, chronic damage is inevitable and the prognosis is poor. However, when **early treatment** is applied at an initial stage, the prognosis for Wilson's disease is relatively good; remissions over a period of 7 years have even been reported. *(One of our own patients has now been in remission for more than 20 years.)* The prognosis is particularly favourable if copper excretion therapy is already started in the preclinical phase. Compared to the normal population, the life expectancy of the patients is not compromised if the therapy is successful. After recovery, the patient's general condition and physical performance is usually unimpaired.

## 16.10 Treatment

**Early diagnosis** and thus **early treatment** form the basis for (*1.*) establishing copper homoeostasis which is as stable as possible, (*2.*) avoiding chronic or irreversible organ damage, (*3.*) supporting the regression of still reversible lesions, and (*4.*) improving (perhaps even normalizing) functional disorders. Therapy must be continued lifelong, since copper reaccumulates, with the result that Wilson's disease becomes manifest, and there is a danger of acute liver failure. (326, 339, 340, 371, 381, 390)

### 16.10.1 Dietary measures

Nutrition should be *low in copper*. Patients must avoid foodstuffs and beverages containing copper, e. g. edible offal, nuts, cocoa products, mushrooms, potato crisps, rye flour, oat flakes, beans, dried figs, certain types of cheese, meat and fish, pineapple, mineral water (see relevant *lists* as to the composition of foodstuffs and copper content in food). Vegetarian food, from which copper cannot be easily mobilized, is therefore recommended. • Cooking utensils containing copper should not be used. • *Alcohol* is strictly forbidden.

### 16.10.2 Drug therapy

**D-penicillamine:** The first-choice medication is D-penicillamine (J. M. Walshe, 1956). By forming copper chelate, it not only causes a reversal of copper deposition and cupruria (see penicillamine test), but also induces metallothionein synthesis, whereby the toxicity of the remaining copper is reduced, even though the copper content in the liver does not sink. Penicillamine reduces the activity of lysil oxidase, thus diminishing the deposition of collagen. As a result, however, the skin unfortunately becomes fragile and wounds heal more slowly. • The *initial dose* is adapted to the individual and ranges from 900−1,200 (−1,800) mg/day. The medication is given in 3 (−4) single doses per day, which have to be taken half an hour before meals. Therapeutic success is to be

expected after 6 months at the earliest: there is a considerable and continuous improvement with regard to abdominal complaints, neurological and psychological disorders, opthalmic findings and laboratory parameters. Occasionally, an initial worsening of the neurological symptoms is observed (most likely due to excessive copper mobilization), which, however, ultimately results in a constant improvement in the neurological status if treatment is carried on consistently. Whether or not the treatment has actually been successful can only be determined after about 2 years. • The removal of copper deposits is reflected in a normalization of copper excretion in the urine (after 2 days without medication) and serum parameters regarding copper metabolism. At this stage, a *maintenance dose* of 600−900 mg/day can be administered. Any interruption of treatment should not exceed a period of several weeks, since this would definitely result in a renewed overload of the organism with copper and possibly lead to acute and dangerous relapses. Treatment with penicillamine is continued even during pregnancy; breastfeeding is, however, not recommended.

In 20−25% of cases, **side effects** are observed, depending mainly on the dose (hypersensitivity reactions, aphthous lesions, arthralgia, nausea, fever). All in all, treatment of Wilson's disease with penicillamine is considered to be successful and safe. If penicillamine is not well tolerated or if serious side effects are observed (e. g. kidney or bone-marrow damage, polyneuropathy, pemphigus), treatment must be discontinued. • Penicillamine usually causes **pyridoxin deficiency**, so that substitution (25−40 mg/day) is recommended, particularly as chronic liver damage also leads to vitamin $B_6$ deficiency. • If necessary, **electrolytes** and **trace elements** also have to be substituted.

**Zinc:** Treatment with zinc is considered to be an alternative therapy for mobilizing copper deposits (T. U. Hoogenraad et al., 1978). (343) *Zinc causes inhibition of intestinal copper resorption and stimulates the synthesis of metallothionein in the liver and intestinal mucosa.* The recommended dosage is 3 (−4) × 50 mg/day, one hour before meals. The duration of administration and the dose are adjusted in line with therapeutic success. Zinc can also be used in long-term treatment (i. e. maintenance of copper homoeostasis) following the initial release of copper deposits by means of penicillamine. Side effects have been reported in the form of gastrointestinal complaints. There is an increase in AP as well as amylase and lipase. (367, 387)

**Potassium sulphide:** A decrease in intestinal copper resorption can also be achieved by the administration of potassium sulphide (3 × 20 mg/day) (M. M. Wintrobe et al., 1954). However, this therapy is not readily accepted by patients because the substance has a bad taste and very unpleasant smell.

**Triethylene tetramine:** The copper-chelating agent triethylene tetramine (trientine) can be considered as an alternative therapy to penicillamine (J. M. Walshe, 1982). (389) The initial dose is 3−4 × 600 mg/day; the recommended maintenance dose is 2 × 600 mg/day, administered about one hour before meals. The side effects are similar to those observed with penicillamine, but efficacy is lower. Iron-deficiency anaemia can occur. The substance is commercially available in the USA. (369) • *Further chelating agents being tested include 2,3,2-tetramine, APD and tetrathiomolybdate.*

### 16.10.3 Peritoneal dialysis

In acute copper toxicosis (378), peritoneal dialysis has also been successfully implemented with simultaneous administration of penicillamine. In order to bridge the time until liver transplantation can be carried out, plasmapheresis and haemofiltrations are recommended.

### 16.10.4 Liver transplantation

In a fulminant course of Wilson's disease or an advanced stage of cirrhosis with complications or in cases where medication is not feasible, the only remaining alternative is liver transplantation. After successful transplantation, all clinical findings and laboratory parameters improve, and even neurological disorders become reversible. Transplantation is a causal therapy, which confirms that the primary metabolic defect of Wilson's disease is located in the liver. (348) This means that no copper-releasing medication is required following transplantation. (324, 352, 361, 363, 372, 375, 384)

## 16.11  Indian childhood cirrhosis

This condition, which is confined to India, leads to the development of childhood cirrhosis; it is fatal in almost all cases. Its aetiology is unknown. The condition affects children of both sexes between the ages of 1−3 years. Its familial occurrence points to genetic factors. There is increased copper ingestion through food and milk as well as from household utensils. Alkaloids may also be involved in aetiopathogenesis. • Initially, the symptoms include increased appetite, restlessness, sleep disturbances, bright and sticky stools as well as hepatomegaly. Kayser-Fleischer rings are not present. Serum ceruloplasmin is normal. The further course is characterized by jaundice, oedema and ascites, bouts of fever and liver atrophy. • The histological picture is similar to acute alcoholic hepatitis, but without fatty degeneration. Mallory's hyaline, which is surrounded by polymorphonuclear leucocytes, is detectable in 80−90% of hepatocytes. The liver shows the highest content of copper so far verified in humans; it is located in the cytoplasm. As a result of low-grade liver cell regeneration, only small nodules are formed in the extensive, dense connective tissue, so that micronodular cirrhosis results. • *Therapy* is based on a strict reduction in copper intake and the administration of D-penicillamine. (399)

**Non-Indian childhood cirrhosis:** This similar condition, found in other countries, is indistinguishable from Indian childhood cirrhosis. Therefore, it is also called *copper-related liver disease*. A genetic defect is probably involved. Any correlation with increased copper ingestion is unlikely. (398)

# 17 Haemochromatosis

▶ The first observation of haemochromatosis was made by Th. Bonnet (1679). The first clinical case was described by A. Trousseau (1865) with the *three main symptoms* of iron storage diseases: diabetes mellitus, bronze pigmentation of the skin and cirrhosis. In 1871 C. E. Troisier termed this condition "la cirrhose pigmentaire dans le diabète sucré". In 1877 H. Quincke detected iron deposits in the liver parenchyma of these patients and called this clinical picture "siderosis". For the same condition, V. Hanot and A. M. Chauffard (1892) coined the term "cirrhose hypertrophique pigmentaire dans le diabète sucré". In 1895 P. Marie also described this illness as "diabète bronzé". The term "haemochromatosis" was suggested by F. D. v. Recklinghausen in 1889. (469) Since 1935, haemochromatosis has been regarded as a genetically determined entity in itself and hypogonadism was added as a fourth cardinal symptom by J. H. Sheldon.

## 17.1 Definition

**Haemochromatosis (HC)** is a hereditary disease (autosomal recessive) affecting the iron metabolism. It refers to pronounced iron deposition, predominantly in the liver (> 50% of the total iron in the body), but also in other organs, such as pancreas, spleen, heart, endocrinium, bone marrow, lymph nodes, salivary glands, basal skin layers and gastrointestinal epithelia. • In addition to these *hereditary* (HFE-related) or idiopathic (non-HFE-related) primary forms, there are numerous *acquired* secondary forms of HC. At first, the cells of the RES become laden with iron. Only when the capacity of the RES is exceeded is there iron deposition in the parenchymal cells; this leads to damage of the respective organs. (s. tab 31.17)

**Haemosiderosis (HS)** denotes iron storage in the organism, whereby iron deposition in the liver is < 0.5 g/100 g liver WW. Iron deposition occurs almost exclusively in the RES; parenchymal cells are rarely affected. Haemosiderosis exists in two forms: (*1*.) *absolute HS* resulting in generalized iron deposition in the body as a whole, or (*2*.) *relative HS* localized in a certain organ with the rest of the body showing normal iron distribution. Haemosiderosis does not cause haemochromatosis. (s. tab. 31.17)

## 17.2 Classification

Hereditary haemochromatosis (HC) can be differentiated in one HFE-related and three non-HFE-related types as well as in a few other forms. (s. tab. 31.17)

### 17.2.1 HFE-related haemochromatosis

**Type 1** is the classic **HFE-related form** of HC. It has an autosomal recessive inheritance pattern. The gene mutation is localized on chromosome 6, directly next to the A-locus of the HLA system. (426, 427) It was originally

---

**Hereditary (primary) haemochromatosis**

*HFE-related haemochromatosis*

**type 1**   Hereditary haemochromatosis

*Non-HFE-related haemochromatosis*

**type 2**   Juvenile haemochromatosis
**type 3**   Italian variant
**type 4**   Autosomal dominant form

*Aceruloplasminaemia*

*Atransferrinaemia*

*Neonatal haemochromatosis (inherited/acquired?)*

---

**Acquired (secondary) haemochromatosis**
(iron content of the liver > 0.5 g/100 g liver WW)

- extreme iron intake due to dietary habits
  e. g. Bantu disease or African iron overload (together with genetic basis), dietary iron overload
- extreme iron intake due to therapy
  e. g. frequent blood transfusions, chronic haemodialysis
- haemolytically induced
  e. g. thalassaemia
- metabolically induced
  e. g. tyrosinaemia, porphyria cutanea tarda, Zellweger's syndrome, glycogenoses, lipidoses, paraneoplastic ferritin production
  (such as in bronchiolar carcinoma)

---

*Haemosiderosis*

- liver siderosis
  (iron content of the liver < 0.5 g/100 g liver WW)
  e. g. chronic alcohol damage, portocaval anastomoses, hepatitis C, cirrhosis
- pulmonary haemosiderosis
- renal siderosis
  e. g. paroxysmal haemoglobinuria
- cerebral siderosis
  e. g. Alzheimer's disease, Huntington's chorea, Pick's atrophy

***Tab. 31.17:*** Classification of haemochromatosis and haemosiderosis (WW = wet weight)

---

termed HLA-H gene and later on called HFE gene (J. N. Feder et al., 1996). The exact interpretation of the letters HFE is unknown (human ferritin?). In about 90% of patients with haemochromatosis, a homozygote point mutation (Cys 282 Tyr) in the HFE gene is evident. A further point mutation (His 63 Asp) is found in 5−10% of HC patients. Its role in iron metabolism is still not clarified. This mutation is often observed in HC together with a heterozygote status for Cys 282 Tyr mutation (so-called compound heterozygosity). For these two point mutations the terms C 282 Y and H 63 D have been used. • The phenotype of HC in northern Europe and the USA comprises the genotypes: (*1*.) C

282 Y / C 282 Y (85−95%), (2.) wildtype / wildtype (5−8%), (3.) C 282 Y / H 63 D (= compound heterozygosity) (<5%), (4.) C 282 Y / wildtype (<2%), (5.) H 63 D / wildtype (<2%), and (6.) H 63 D / H 63 D (<1%). In southern European populations, the frequency of C 282 Y homozygosity is lower (ca. 65%). • The localization of the HFE gene on chromosome 6 has no close association to the receptor protein synthesis of ferritin (chromosomes 11 and 19), transferrin (chromosome 3) or the iron-regulating factor (chromosome 9). (403, 429, 448, 459, 468) (s. tab. 31.17)

### 17.2.2 Non-HFE-related haemochromatosis

**Type 2** is the **juvenile haemochromatosis**. This rare form of iron storage can be differentiated from type 1 by an earlier onset of clinical symptoms. It becomes manifest prior to the age of 30. Both sexes are affected equally. The gene defect is localized on chromosome 1q (A. ROETTO et al., 1999). Compared to type 1, cardiomyopathy and hypogonadism are more frequent, the course of disease is more severe and cardiac-induced death is more common. HFE mutations are absent, and there is no association with the HLA system. This form of HC has an autosomal recessive inheritance. (s. tab. 31.17)

**Type 3** is the **Italian variant** of haemochromatosis. The gene defect is localized on chromosome 7 q 22 and affects transferring receptor 2 (D. GIRELLI et al., 2001). This form of HC probably has an autosomal recessive inheritance. The histomorphological and clinical findings are similar to those of type 1. (466) (s. tab 31.17)

**Type 4** is an **autosomal dominant variant** of HC. It has only been observed in Italy. The gene defect is located on chromosome 2 q 32 and affects the iron export protein ferroportin (O. T. NJAJOU et al., 2001). In contrast to types 1 and 3, there is early iron storage in the macrophages. A characteristic feature are the markedly increased values of ferritin together with a slight elevation of transferrin saturation. (s. p. 98) (s. tab. 31.17)

### 17.2.3 Aceruloplasminaemia

Aceruloplasminaemia is a very rare, autosomal recessive disease with diffuse iron overload. It is caused by a mutation of the ceruloplasmin gene. This leads to excessive iron storage, mainly in the brain, liver and pancreas. The principal symptoms are increased serum ferritin, decreased serum iron and transferrin saturation as well as extrapyramidal disturbances, retinal degeneration, cerebellar ataxia and diabetes mellitus. (486−488) (s. tab. 31.17)

### 17.2.4 Atransferrinaemia

Atransferrinaemia is likewise a very rare inherited syndrome. The first and only case involving a seven-year-old girl was described in 1961 (L. HEILMEYER et al.). Clinic-ally, there was a serious iron deficiency in serum together with marked iron storage in the tissue. (s. tab. 31.17)

### 17.2.5 Neonatal haemochromatosis

Neonatal haemochromatosis was first described by H. COTTIER in 1957. This fatal form of HC starts in utero and must be differentiated from the above-mentioned genetically induced types; it does not represent a variant of HC. Genetic markers are not known and the basic underlying defect is still unclarified (inherited/acquired?). "Sporadic" cases have also been observed. Both sexes are affected with the same frequency. Even at birth, newborns have pronounced ferritin values, jaundice, cholestasis, coagulopathy, oedemas and ascites as well as cirrhosis with iron storage. The babies affected die generally within the first few days or weeks. Pathogenetically, irregular transport of iron through the placenta or dysregulated iron metabolism in the foetal liver cells is assumed to be responsible. The following therapy can be recommended: acetylcysteine (100 mg/kg BW/day i.v. for 7 days), $\alpha$-tocopherol (25 U/kg BW/day orally), desferrioxamine (30 mg/kg BW/day i.v. infusion over 8 hours until the serum ferritin is <500 µg/l), selenium (3 µg/kg BW i.v. by continuous infusion) and prostaglandin $E_1$ (0.4 µg/kg BW i.v.). Liver transplantation, if successful, is curative. (411, 439, 447, 456) (s. tab. 31.17)

## 17.3 Hereditary haemochromatosis

HFE-related haemochromatosis, which is synonymous with type 1, is the most frequent and most important form of HC. The following chapter refers to this clinical feature.

### 17.3.1 Frequency

Hereditary haemochromatosis (HC) has an incidence of 0.25−0.5% in the Caucasian population. After Gilbert's disease, HC is the most common hereditary liver disease. Men are affected 5−10 times more frequently than women. The gene mutation on chromosome 6 occurs with a frequency of 1:10 to 1:20 for the heterozygous type and of 1:200 up to 1:400 for the homozygous type, as far as this can be detected by current methods. The number of those affected with manifest HC is strongly influenced by racial as well as exogenous factors (e. g. diet, alcohol, personal habits), which is an explanation for the variations in frequency between 1:500 to 1:4,000. Prevalence of the HC gene in the normal population is estimated as being 6−7%. If both parents are heterozygous carriers, the probability of the children being homozygous is 1:4 and heterozygous 1:2. (403, 407, 410, 428, 452, 483)

About 1:500 persons in Germany are carriers of homozygous HC. However, the number of clinically detected cases of HC only corresponds to a ratio of 1:5,000. A considerable number of homozygous carriers are diagnosed and treated far too late. • In 1% of patients with newly detected diabetes mellitus and in 3−15% of cirrhotic patients, the respective disease is aetiologically attributable to HC.

## 17.3.2 Pathogenesis

▶ **Iron storage** is about 0.07 g per year in heterozygous carriers. In homozygous men, however, it is about ten times higher (0.6 g), whereas the rate in homozygous women is only 0.16 g due to loss of iron during menstruation, pregnancy and breastfeeding. Generally, men have stored a total of 20−30 g iron by the age of 50. As from 5−8 g, progredient organ damage begins. (434, 460, 468, 477) (s. fig. 31.23)

A defect in the HFE gene leads to overenhanced (undesired) intestinal iron absorption. Thus the enteral absorption of iron is at a higher level in HC (2 to 4-fold) because of this dysregulation, although the iron content of the organism is increased. After being above average for several years, iron uptake returns to normal, even in HC patients. However, following venesection, the iron absorption in HC increases again. This disorder is primarily caused by the *HFE mutation* present in the crypts of the small intestine cells, where iron uptake usually occurs. • Iron absorption is regulated by the iron-responsive-elements-binding-protein. This *IRE-BP* shows a normal function in HC, since its gene is not localized on chromosome 6. In contrast, there is a disturbance of the association between C 282 Y mutation of HFE and the *ß-microglobulin*, so that the normal function of HFE is reduced. In addition, the defect HFE gene does not interact with the transferrin receptor 1, with the result that iron is more easily absorbed in the cell. Both the transmembranous protein *Nramp 2* and the iron reductase (Dcyt = duodenal cytochrome B) are considered as apical iron transporters. • Intestinal uptake of iron is still influenced by the basolateral iron transporter *ferroportin 1*, whose gene defect causes type 4 HC. Iron is also transported by the multi-copper-iron-oxidase *hephaistin*, which creates the connection between iron and copper transport. • Transferrin receptor 2 is also involved in the regulation of intestinal iron transport; in the case of a gene defect, it is responsible for the development of type 3 HC. The modes of action behind iron absorption and iron transport based on the above-mentioned (and other?) proteins have only been partially clarified. (414, 418, 453, 454, 464, 477)

**Iron metabolism:** Iron is the sixth most abundant element in the universe; it has two oxidation states: Fe(II) and Fe(III). Normal **diet** accounts for 10−30 mg iron/day, with about 1.5 mg/day of this amount being stored mainly in the bone marrow, skeletal musculature and liver (hepatocytes, Kupffer cells, endothelial cells); in

HC, however, the amount is 3−5 mg/day. Thus HC produces an annual iron surplus of 500−1,000 mg. • **Resorption** of bivalent iron takes place in the mucosal cells of the duodenum and proximal jejunum. There, it is oxidized by ferroxidases into trivalent iron and bound (by means of apoferritin) reversibly to water-soluble **ferritin** (molecular weight 460,000, 50 Å in diameter, iron content about 20%). A single molecule of ferritin may contain up to 4,500 atoms of iron. The synthesis of ferritin, which enters the cell via ferritin receptors, is stimulated by iron; the site of synthesis is the RES. Ferritin is also formed on the polysomes of the hepatocytes and broken down in the lysosomes. The plasma ferritin value correlates with the total amount of iron stored in the body. Enteral iron resorption is controlled by the intracellular ferritin concentration: there is a negative correlation between these two quantities. In HC, ferritin is considerably decreased in or absent from the mucosal cells; there may be disturbed regulation of ferritin gene expression, i.e. ferritin-determined dysregulation is observed. (414, 426) • A second (but labile) intracellular storage form of iron is **haemosiderin,** a water-insoluble pigment of Fe(III) hydroxide (ca. 37%), protein, carbohydrate, lipids, copper and calcium. Haemosiderin is formed during the lysosomal breakdown of ferritin, a process by which released iron can be stored in the lysosomes. It is mainly stored in the peripheral area of the lobules and in the portal fields. In contrast to ferritin, haemosiderin shows a *positive Berlin-blue reaction.* (s. figs. 31.25, 31.26) • Intracellular iron is, to a certain extent, bound to **transferrin,** which is mainly produced in the hepatocytes. It is considered to be a carrier molecule for extracellular iron. Only one third of the total *iron-binding capacity* of transferrin (normal 250−370 µg/dl) is iron-saturated. The saturation capacity beyond this normal degree of transferrin saturation is called *free (latent) iron-binding capacity.* There is a negative correlation between the amount of iron in the organism and the transferrin synthesis rate. The absorption of transferrin into the target cells occurs by means of a specific receptor. (418, 434, 448, 453, 454, 464) (s. pp 49, 98)

An **additional pathogenetic factor** (apart from excessive iron supply or alcohol abuse) is *vitamin C*, which has different effects: on the one hand, it enhances intestinal iron resorption as well as iron excretion from the RES, but on the other hand, it is broken down due to an iron overload, which results in subsequent vitamin C deficiency. • *Alcoholic beverages* may support the development of haemochromatosis when the respective iron content is considerably increased (depending on the iron content of the soil or of the drinking water used in their production). Furthermore, alcohol-induced folate deficiency may cause ineffective erythropoiesis with enhanced endogenous iron storage. • A genetic association also exists between HC and *α₁-antitrypsin deficiency syndrome* as well as *porphyria cutanea tarda*, which leads to a more rapid development of cirrhosis. • Any rise in iron storage is due to a **disturbed iron balance:** if the daily supply continues to be higher than the daily loss, the individual organs will absorb iron in line with their respective storage capacity.

## 17.3.3 Iron toxicity

It was O. WARBURG (1928) who first observed the toxic effects of "free" (ionized) iron on cell metabolism. Increased acid phosphatase, decreased glucose-6-phosphatase, disturbances in oxidative cell metabolism as well as augmented glycolytic breakdown processes in the liver and cardiac muscle cells have since been reported. • There are **three molecular mechanisms** which are important for the toxic effects of free iron on cell metabolism: (*1.*) increased formation of *reactive oxygen intermediates* (with release of lysosomal enzymes and indirect stimulation of fibrogenesis) (s. p. 67), (*2.*) direct *stimulation of collagen synthesis* (with enhanced fibrogenesis) (s. p. 403), and (*3.*) changes in or damage to *DNA* (with the possible induction of carcinogenesis). (s. fig. 31.23)

### 17.3.4 Morphology

After being transported in increased quantities to the liver, iron is mostly stored as haemosiderin and ferritin in the hepatocytes of the lobular periphery. Initially, this *liver cell siderosis* does not impair the function of hepatocytes, as iron is absorbed by lysosomes. Iron storage commences in lobular zone 1 and progresses to zone 3. Gradually, the cells of the whole lobule become involved in iron deposition, mainly in the form of centroaxial pigment pathways, with enhanced iron deposition in the periportal area (haemosiderin granules). (422, 442)

When the storage capacity of the lysosomes has been exhausted (usually with a liver iron content of $> 4,000$ µg/g wet weight), there are unspecific inflammatory reactions in the portal field and lobular periphery, including single-cell necrosis as well as activation of fibroblasts and macrophages. Siderin, released from necrotized hepatocytes, is absorbed by Kupffer cells, which are usually increased in number and arranged in a nodular form. Coarse, grained siderosis of stellate cells likewise points to the extent of liver cell necrosis (= sideronecrosis). This phase may be called *acute siderophile hepatitis.* (421) Occasionally, there is formation of giant siderosomes and *glycogen vacuolations of the nuclei* in the hepatocytes of the peripheral lobules. (s. fig. 31.1) • Some excess iron is transported into the *bile ducts* and stored in their epithelial cells. The fainter and more finely granulated pigmentation (compared to hepatocytes) is important for the morphological diagnosis of HC.

The inflammatory mesenchymal reactions in the portal field and lobular periphery induce extremely low-cell perilobular and tylotic fibrosis. (425, 442) Slowly, star-shaped **portal fibrosis,** so-called *holly-leaf fibrosis*, develops. This morphological picture, similar to that of chronic hepatitis, was termed *chronic siderophile hepatitis* by H. KALK (1962). • The hepatic lobules are gradually grouped into islet-like structures. Within the tylotic connective tissue, very fine epithelial tubuli, also known as pseudo bile ducts, are found; they are more strongly loaded with iron pigments than are the preformed bile ducts. These pseudo bile ducts are seen as minimal and ineffective attempts to regenerate the parenchyma, although the constant iron supply prevents epithelial substitution. This leads to the development of almost uniform, micronodular (later on mixed-nodular) and very coarse **pigment cirrhosis,** which is rich in fibres and poor in regeneration. (s. figs. 31.24−31.26)

*Fig. 31.24:* Haemochromatotic cirrhosis: micronodular, slate-grey to brownish discolouration, rich in septate fibrosis, marked neovascularization

► The morphological damage in other **iron-storing organs** (particularly the pancreas, heart and endocrinium) follows pathological mechanisms similar to those in the liver. These organs also show brown tissue changes with increasing fibrosis. HFE is expressed in all tissues involved in HC. • In HC, zinc is also stored in the liver at up to eight times the normal levels.
*Fig. 31.25:* Micronodular cirrhosis due to hereditary (HFE-related) haemochromatosis (Berlin blue)

*Fig. 31.26:* Cirrhosis in hereditary haemochromatosis. Massive siderosis in hepatocytes and in epithelia of preformed bile ducts (arrows) (Berlin blue)

### 17.3.5 Early diagnosis

For successful treatment and thus also for prognosis, it is of the utmost importance to detect HC in its early phase. At this stage, however, neither subjective complaints nor clinical findings are apparent. The development of symptoms is slow and gradual − in men, not before the age of 30; in women, usually not before the menopause. • It is only by chance that an *increase in serum iron* ($>160$ µg/dl), *ferritin* ($>200$ µg/dl) or *transferrin saturation* ($>45\%$) occasionally becomes evident. The combined determination of ferritin and transferrin saturation has a sensitivity of $90−95\%$, although specificity is lower. (s. tab. 31.18) These purely accidental findings, which initially appear as moderate deviations from normal values, are by no means conclusive, but they are nevertheless suggestive of HC. • However, *hepatic siderosis* can likewise be detected incidentally in liver biopsy, sometimes with an iron content of $>1.7$ mg/g dry weight, allowing the additional option of determining the hepatic iron index. (406, 408, 410, 417, 458)

For the early diagnosis of HC, it has proved very useful to determine the **hepatic iron index:** iron content of the liver (in µmol/g dry weight) divided by age (given in years) (M. L. Bassett et al., 1984). A ratio of $>2.0$ suggests HC, while a ratio of $<1.5$ points to heterozygous HC or chronic alcoholic liver disease. (472, 478) Depending on the results obtained, subsequent determination of the *phenotype* or even of the *genotype*, if necessary, will follow (analogous to preventive diagnosis).

▶ In the future, non-invasive **liver-iron quantification** (measuring the magnetic susceptibility as in "magnetic biopsy") by way of SQUID biosusceptimeter (BTi ferritometer) as a quick and sensitive method will open up new possibilities of early detection and therapy control.

### 17.3.6 Preventive diagnosis

The detection of HC requires targeted preventive diagnosis of family members (including siblings) and close relatives. First of all, **HFE genotyping** is carried out by determining the *C 282 Y mutation*. Determination of the C 282 Y mutation shows a similarly high diagnostic sensitivity as a liver biopsy; HFE genotyping is therefore of the utmost importance for family screening. In heterozygosity, however, liver biopsy should be performed as a diagnostic marker instead of HFE genotyping. (403, 407−410, 417, 429, 434, 451, 458, 467, 468, 471, 473) • The **phenotype** varies considerably and is influenced by a number of factors (alcohol abuse, oestrogens, dietary iron intake, loss of iron, etc.). Elucidation of the phenotype focuses on the determination of *transferrin saturation* and *ferritin* concentration in the blood. With increased values, liver biopsy is indicated: an iron content of $>1.7$ mg/g dry weight points to HC, while a value of $>4.5$ mg/g or an iron index of $>2.0$ confirms the presence of HC and is also an indication for therapy.

**HLA system:** This system may have one of *three constellations*: (*1.*) when two alleles (A3 and B14 or B7) of the relative are identical to those of the patient, there is a high risk of HC occurring (= annual check-ups are required); (*2.*) with only one HLA allele of the relative being identical to that of the diseased person, there is merely a minor risk of manifestation (= check-ups every $4−5$ years are sufficient); (*3.*) if neither allele of the relative is identical to those of the patient, there is no risk that the disease will become manifest (= no further check-ups are required). (427, 443) • It should be noted, however, that the formerly recommended determination of the HLA types (A3, B7, B14) is no longer common.

### 17.3.7 Manifestation

#### Subjective complaints

When the organism is constantly overloaded with iron, subjective complaints gradually develop (in $5−40\%$ of cases). These present a variety of uncharacteristic features, varying from individual to individual.

| Fatigue | (40−60%) | Impaired potency | (10−20%) |
|---|---|---|---|
| Abdominal pain | (30−40%) | Nausea | (10−20%) |
| Stress dyspnoea | (20−30%) | Diarrhoea | (5−10%) |
| Weight loss | (15−25%) | Meteorism | (5−10%) |
| Heart problems | (15−25%) | Dysmenorrhoea | (5−10%) |
| Arthralgia | (15−25%) | Proneness to infection | (5−10%) |
| Thirst | (10−20%) | | |

## Clinical findings

During the development of the disease, clinical findings appear which can be attributed to those organs primarily involved in iron storage and to their respective damaging mechanisms. (402, 407, 417, 429, 452, 458, 467)

| 1. Liver involvement | (> 90%) |
|---|---|
| 2. Cutaneous pigmentation | (60−80%) |
| 3. Diabetes mellitus | (60−80%) |
| 4. Cardiomyopathy | (20−50%) |
| 5. Arthropathy | (20−50%) |
| 6. Endocrinopathy | (20−50%) |

**1. Liver involvement:** The liver is enlarged and of firm consistency. Skin stigmata of liver disease occur with varying degrees of intensity. (s. p. 80) Portal hypertension with splenomegaly (30−50%), oesophageal varices and ascites develop. • Laboratory findings may include a slight increase in transaminases, P-III-P and IgG values as well as borderline pathological ICG and galactose tests. (s. p. 108) Occasionally, CA 19-9 levels are moderately increased. Vitamin E is reduced. (440) A striking feature is the detection of normal parameters despite the presence of manifest cirrhosis. The existence of cirrhosis with a ferritin value of < 1,000 μg/l is unlikely. • Determination of $\alpha_1$-foetoprotein is recommended at long intervals.

**2. Cutaneous pigmentation:** "Bronze diabetes" (s. p. 616) is rare. The colour of the skin is usually grey-brown, particularly in areas exposed to light, but also in axillae and conjunctivae as well as in the genital area and oral cavity. The dirty grey discolouration is due to increased melanin and enhanced iron storage, particularly in the sweat glands. Pigmentation is most striking along the lines of the palms. (s. fig. 4.12!) (s. p. 84)

**3. Diabetes mellitus:** A glucose tolerance disorder is detectable at an early stage. Subsequently, 60−70% of the patients develop the distinct clinical picture of diabetes, including diabetic complications (retinopathy, polyneuropathy, nephropathy, arteriopathy). The β-cells show iron deposition and fibrosis, in contrast to the α-cells (so that glucagon secretion is still normal). It remains unclear whether an additional genetic defect is present in the β-cells. Usually, there is peripheral insulin resistance, which often becomes reversible as a result of successful treatment. With progressive destruction of the β-cells, insulin-dependent diabetes mellitus develops.

**4. Cardiomyopathy:** Iron deposition in the myocardium and/or the conduction system causes the walls of the heart, particularly of the ventricles, to thicken; apart from that, necrosis of the cardiac muscle cells with subsequent fibrosis can be observed. Dilatative cardiomyopathy is accompanied by tachyarrhythmias. Cases of sudden death have been described. Considerable improvement is generally achieved by the release of iron deposits. The aetiology of cardiomyopathy can be clarified by myocardial biopsy. (416, 462, 470, 482)

**5. Arthropathy:** Initially, the small joints (finger, toe and wrist) are affected. Subsequently, the large joints (knee, shoulder and hip) also become involved in the clinical picture of arthrosis. The patients complain at an early stage (in 30−50% of cases) of arthralgia located in the areas described above, but there seems to be no correlation with the degree of iron overload. X-ray scanning shows subchondral cysts and sclerotic changes, narrowing of the articular space, hypertrophic bone proliferations, chondrocalcinosis, and osteoporosis (particularly when hypogonadism is present). This kind of damage in the joints, cartilaginous parts and adjacent bones is caused by the formation of calcium phosphate crystals within the synovial cells, mainly due to iron-induced pyrophosphatase inhibition. Venesection treatment has little effect on arthropathy. (404, 474)

**6. Endocrinopathy:** Pronounced iron deposition can be found in the thyroid and parathyroid glands, the anterior lobe of the hypophysis and the adrenal cortex. Testicular atrophy is caused by insufficiency of the anterior lobe of the hypophysis, particularly since only a small (perivascular) amount of iron, or no iron at all, is deposited in the testes. Hypogonadism (loss of libido, menstrual disorders, impotency) may regress after the removal of iron deposits. In addition, signs of hypothyroidism, hypoparathyroidism and slight insufficiency of the adrenal cortex are found. Biochemical evidence showing decreased serum values of the relevant hormones (gonadotropins, testosterone, oestrogens, aldosterone, thyroid hormones) may provide an overview of the underlying endocrinopathy. Gynaecomastia has not been observed. (419, 445)

## Laboratory findings

There are many reasons why laboratory parameters of iron metabolism may deviate from normal values; they should always be checked to facilitate the differential diagnosis of HC or of acquired haemochromatosis and haemosiderosis. • In cases of HC, there are various deviations from normal values. (406, 410, 417, 458, 467) (s. tab. 31.18)

The determination of **serum iron concentration** often shows normal values over a long period of manifest HC. In suspected HC, repeated examinations may be necessary due to daily fluctuations and circadian rhythms in the serum iron concentration as well as in factors influencing laboratory procedures. It is only in the later course of HC that serum iron is constantly and signifi-

cantly increased. In 1953 H. KALK described **hyper-siderinaemia** as the typical fifth cardinal symptom of HC. • When serum iron continues to fall, liver carcinoma can be suspected.

The determination of **transferrin saturation** (after 12 hours of fasting) supports a strong suspicion of manifest HC when the value is > 55%, while a saturation of > 75% is almost diagnostic proof of homozygosity. This method is also considered to be a reliable screening test. A value of > 55% shows a specificity and sensitivity of 92% for HC. With a value of > 50% in women and > 60% in men, the ferritin level should be checked as well. An increased saturation value calls for liver biopsy, whereas a normal value requires a follow-up after 1−2 years.

The **total iron-binding capacity** (TIBC) of transferrin can be calculated from the transferrin concentration in μg/dl or μmol/l: transferrin x 1.41 or transferrin x 25.2. This gives a normal value for men of 268−436 μg/dl or 48−78 μmol/l and for women of 257−402 μg/dl or 46−72 μmol/l. • The difference between TIBC and the amount of iron found before $Fe^{3+}$ and magnesium carbonate are added is called **free iron-binding capacity.** This is the FIBC which is possible beyond the normal saturation capacity of about one third of the transferrin. • The **transferrin saturation** (in %) can be calculated as follows: serum iron (μg/dl) x 100 divided by transferrin (mg/dl) x 1.25. • *A free IBC of ≤ 50 μg/dl, i.e. transferrin saturation of > 62%, suggests the presence of HC.*

The **ferritin value** corresponds well to the total value of body iron, whereby 1 μg/l ferritin is equivalent to about 7.5 mg body iron. The sensitivity of the ferritin value in HC is 85% and the specificity is 95%. A value of > 700 μg/l points both to the presence of HC and to the development of liver fibrosis or cirrhosis. In contrast, a normal ferritin value and normal transferrin saturation rule out HC in about 95% of cases. (s. tab. 31.18)

| Normal values | | Haemochromatosis |
|---|---|---|
| 1. **Serum iron** | | |
| Men | 59−158 μg/dl | |
| | 10.6−28.3 mol/l | > 180 μg/dl |
| Women | 37−145 μg/dl | > 32 μmol/l |
| | 6.6−26.0 μmol/l | |
| 2. **Ferritin** | | |
| Men | 35−217 μg/l | > 300 μg/l |
| Women | 23−110 μg/l | |
| 3. **Transferrin** | | |
| Men | 210−340 mg/dl | > 500 mg/dl |
| Women | 200−310 mg/dl | |
| Saturation | 16−45% | |
| Heterozygotes | | > 55% |
| Homozygotes | | > 70% |
| 4. **Hepatic iron index** | | |
| $\frac{\text{iron content of the liver (μmol/g)}}{\text{age (years)}} =$ | | > 2.0 |
| 5. **Deferoxamine test** | | |
| 500 mg i.m./iron excretion rate | | > 4 mg/6 hr |

*Tab. 31.18:* Biochemical findings in hereditary haemochromatosis

**Hypochromic anaemia** with *poikilocytosis* may point to disturbed erythropoiesis as a result of iron overload. • Transferrin deficiency may, however, also be causally related to this disease.

While the **deferoxamine test** (s. p. 99) is often considered obsolete, it can nevertheless serve as another stone in the mosaic and prove helpful in the diagnostics or follow-up of HC, since it is an iron chelation test that is easy to apply, free of side effects and inexpensive. In healthy persons, this test reveals a urinary iron excretion of < 1−2 mg; in haemosiderosis, the excreted amount is < 4 mg, and in HC > 4 mg. (461)

A **gastric mucosa biopsy** may facilitate differentiation between HC and secondary haemochromatosis, yet this examination is also regarded as obsolete today. (Iron in macrophages with HC = ∅, with secondary HC = ↑↑.)

### Imaging techniques

**CT** determination of increased liver density due to iron overload in haemochromatosis yields values of 80−140 Hounsfield units (= white liver). The deposition of 1 g iron causes an increase in density of 1 HU. CT densitometry makes it possible to monitor the course of the blood-letting therapy. (463) (s. p. 173) • In **MRI,** a haemochromatotic liver appears dark grey to black (= dark liver) due to signal loss depending on the iron content. (s. fig. 8.8) With an iron concentration of 1 mg/g liver tissue, accuracy is 95−100%. (405, 415, 436, 438, 450) (s. p. 177) • Both examination techniques are of great importance in detecting liver cell carcinoma. • By using the newly developed **SQUID biosusceptimeter** (BTi ferritometer), even more reliable quantification of liver iron is expected.

### Liver biopsy and laparoscopy

Laparoscopically, a dark brown liver surface with augmented fibrosis can be seen. (s. fig. 31.23) • Quantitative measuring of iron in the liver bioptate is the most reliable technique for diagnosing haemochromatosis. If possible, this kind of biopsy should be carried out under laparoscopic guidance, and *two biopsy punches* should be taken. The first sample is designed to serve as a histological specimen as well as to detect iron and iron localization, while the second sample is used for quantitative iron determination. • At the same time, the *hepatic iron index* is calculated arithmetically. This index also facilitates the differential diagnosis of chronic alcoholic disease, which is not always an easy task, particularly at the cirrhotic stage (index < 1.4, in HC > 2.0). (449, 481)

### 17.3.8 Prognosis

The following *three factors* are of decisive importance for course and prognosis:

1. early diagnosis
2. consistent long-term treatment
3. close (life-long) cooperation between patient and physician

▶ Therapeutic results will be better if the morphological damage is less severe and the other organs have not been seriously affected. • It is necessary to regard HC treatment as a life-long procedure requiring the joint therapeutic involvement of the patient and the general practitioner or specialist. (457)

**Untreated HC** has a slow course and follows certain patterns in its progression; spontaneous regressions are not to be expected. The 5-year survival rate after establishing the diagnosis is only 18%. The mean survival rate was about 1.5 years in 1935, about 4.4 years after the introduction of insulin treatment, and 8.2 years with consistent venesection therapy. (484)

However, with early diagnosis and consistent treatment, **HC** has a good prognosis. In a comparison of treated versus untreated patients with HC, 5-year survival rates of 89% (vs. 33%) or 92%, with an overall 10-year survival rate of 76% were observed. When cirrhosis was already manifest, the survival rate was only 62% after 10 years, whereas it was 93% in non-cirrhotic patients. • We believe that normal life expectancy is indeed a realistic perspective. *One of our patients died after 19 years of consistent treatment of causes apparently unrelated to HC.*

The greater the effectiveness of iron depletion, the more likely it is that morphological liver changes or even fibrosis and hepatic transformation processes will be reversed. • Portal hypertension and oesophageal varices may regress in the same way, and a decisive improvement in diabetic metabolism is often observed. *One of our patients with diabetes mellitus showed a normal diurnal blood sugar profile after 8 years of consistent treatment, while the glucose tolerance test (monitored over longer periods of time) only produced a moderately pathological result.* • In contrast, arthropathy appears to be unresponsive to treatment and may cause considerable suffering.

The main **causes of death** in HC are the following developments which aggravate the clinical picture (particularly when alcohol consumption is continued):

1. complicative diabetes mellitus
2. cardiac insufficiency
3. primary liver cell carcinoma
4. hepatic coma, liver failure
5. bleeding oesophageal varices
6. intercurrent infections
7. acute abdomen

▶ The correlation between **hepatocellular carcinoma** and haemochromatosis was described by M.J. STEWART in 1922. Primary liver cell carcinoma is thought to be the most common cause of death in haemochromatosis. Its frequency is reported to range between 6−42% or 7.3−18.9% (mean value approx. 14%), i.e. the risk of

developing liver cell carcinoma in HC is about 200 times higher than in the normal population. Nevertheless, carcinogenicity is not necessarily related to the presence of cirrhosis, nor to appropriate therapy or non-treatment (cf. potential cocarcinogens, alcohol or hepatitis viruses). HCC development is mainly multilocular. Manifestation of a sarcoma has only rarely been observed. The latency period is reported to be 20−30 years. Follow-up with sonography and AFP determination at six-month intervals is indicated. HCC can also develop some years after complete iron depletion. Long-term iron overload acts as a cocarcinogen, apparently by way of DNA impairment. (412, 413, 423, 430, 432, 435, 441, 446, 455, 479)

▶ In HC, the frequency of **extrahepatic carcinoma** may also be increased: in one Italian study, the figure was 3.7%. This correlation, which has also been assumed by other authors, raises the question as to whether there are additional cocarcinogenic factors, such as alcohol or hepatitis viruses. (475) • It is a striking feature that **alcoholism** is much more frequently observed in patients with HC than in people suffering from liver cirrhosis or from hepatic carcinoma of different genesis. • It is also remarkable that prevalence of **HBsAg** and **anti-HCV** is two and three times higher respectively in HC patients than in the normal population. Presumably, the function of the immune system is blocked by iron. This would help to explain the high carcinoma rate in patients with HC, due to the procarcinogenicity of HBV and HCV on the one hand and of iron on the other hand. • In cases of iron overload, **yersiniosis** should also be considered as a typical concomitant infection, possibly with the development of liver abscesses: iron is of exceptional importance for the metabolism of yersinia and to a considerable extent conducive to their growth. (401, 480) (s. p. 476)

### 17.3.9 Treatment

*The paramount aim of treatment is to reach a negative iron balance.* This must be achieved before complications due to the chronic iron overload have their effect on the predisposed organs. • *The extreme uncontrolled increase in iron absorption is treatable by adjuvant measures, albeit with limited success.*

**Venesection treatment**

*Venesection treatment (W. D. DAVIS et al., 1950) is the method of choice; it is the most effective therapy.* Blood-letting of about 500 ml blood frees the body of some 250 mg iron. With an average accumulation of >25 g iron, *weekly venesection* should be considered over a period of at least 2 years. • In patients with haemochromatosis (without simultaneous anaemia), blood-letting of 500 ml is carried out once a week until the serum ferritin value has normalized. Experience shows that the de-ironing of the body using this technique takes about

18 months. Blood-letting is well-tolerated, and the patient's physical capacity is usually not affected. In general, the haemoglobin value does not fall below 12g/dl. • By the time the respective *blood values* (ferritin level and transferrin saturation) normalize, a considerable quantity of iron has been discharged. At this stage, blood-letting can be reduced to 2−3 times per 3 months, provided the ferritin value and transferrin saturation continue to remain within the normal range. Subsequently, 3−4 venesections per year usually suffice in order to maintain the iron balance. • *Plasmapheresis* is not required, since the plasmaproteins removed by blood-letting are easily replaced by the organism. Nevertheless, in isolated cases, plasmapheresis may become necessary due to a cirrhosis-induced decrease in protein synthesis. The haemoglobin content should not (or only for a short period of time) fall below 11.5−12.0 g/dl, and the protein concentration should not fall below 6.0 g/dl. (406, 417, 420, 429, 445, 452, 458, 467) *The number of venesections per year required to maintain the iron balance must be adhered to lifelong. Blood-letting therapy must never be discontinued!*

### Deferoxamine

This specific iron-chelating agent is obtained from actinomyces cultures. In a dose of 1.5 g, it is capable of mobilizing about 25 mg iron, i.e. the same amount as during a 500 ml venesection. • An indication may be given, even if only temporarily, when blood-letting cannot be carried out (e.g. anaemia, cardiac insufficiency). Deferoxamine binds iron in the tissue and in the serum; excretion occurs via the urine and faeces. However, the biological half-life of about 10 minutes is quite short, i.e. after this time only half the pharmacon is still effective, but with decreasing intensity. Oral administration is ineffective. For this reason, subcutaneous injection is required as a slow infusion of 12 hours (using a portable infusion pump). With a daily dose of 25−50 mg/kg BW, removal of iron deposits will probably be successful. • Local irritations have been observed as *side effects*. Oculotoxicity (initial visual loss) may be evident, depending on the dose. Neurotoxic disturbances usually only occur when the dose is higher than 2−3 g/day (>90 mg/kg BW). This type of treatment is more complicated, less effective and much more expensive − it is intended as an alternative only when there is no possibility of venesection treatment. • In the foreseeable future, we can expect the development of other **iron-chelating agents** which will meet the ideal standards: oral administration, higher efficiency, lower costs and fewer side effects.

### Adjuvant treatment measures

(*1*.) **Low-iron nutrition** is a fundamental requirement (there is practically no iron-free form of nutrition). However, intake of foodstuffs rich in iron is contraindicated when the iron balance has to be maintained. The iron balance is not influenced to any great extent by this

measure, but it nevertheless has a certain effect: low-iron nutrition corresponds to 2−3 venesections per year! • *Every kind of adjuvant therapy should be used as a matter of principle − nothing can be said against such measures.*

(*2*.) This is also true of the daily consumption of **black tea** (1 cup with 5 g tea in the morning and at lunchtime). Tea is deemed to be an iron-chelating agent (iron tannate), which significantly reduces the resorption of iron, particularly in a low-iron diet − with or without ascorbic acid or milk added. (424, 444) • *We have always made sure that these adjuvant measures are strictly adhered to.*

(*3*.) **Deferoxamine** can also be used as an adjuvant agent in the initial treatment phase to reinforce venesection therapy. This is administered as an i.m. injection of 500 mg/week, usually by the family doctor, about 2−3 days before blood-letting is carried out.

(*4*.) **Abstention from alcohol** is absolutely essential and must be strictly adhered to. This is not only because of the minor amounts of iron usually found in alcoholic beverages, but also in order to avoid additional alcohol-induced lipid peroxidation and further stimulation of fibrosis already caused by iron.

(*5*.) The use of **antioxidants** is plausible from a pharmacological point of view, since lipid peroxidation due to iron intake may indeed lead to further tissue damage. (460) Silymarin (e.g. 2 x 140−170 mg), vitamin E (e.g. 100−200 mg) or β-carotene are good choices due to their lack of side effects and plausibility of efficacy.

(*6*.) HC patients who are **HBV-negative** should be actively immunized against hepatitis B. • As far as possible, patients should avoid any risk of HCV infection.

Normalization of the respective serum parameters, stabilization of the body's iron content at 3−5 g and improvement in the organ damage are to be expected in quite a short period of time when blood-letting therapy (if necessary, with deferoxamine as an option in long-term treatment) and adjuvant treatment measures (which may serve to support or speed up the successful outcome) are carried out consistently. The fact that better results can be achieved if the above-mentioned measures are applied has been shown by several impressive and carefully conducted studies. Therapeutic removal of iron overload is in any case not bound to a time factor! Generally, the faster and more constant the iron removal process is, the better. • Hypogonadism and arthropathies are less susceptible to treatment. Given the basic possibility of fibrosis regression, a certain optimism in this respect is definitely justified.

### Simultaneous treatment

At the same time, consideration has to be given to the treatment of complaints or sequelae of organic mani-

festations, such as careful regulation of diabetes, management of cardiac insufficiency or dysrhythmia, hormone substitution, pain therapy in arthropathy, etc.

### Liver transplantation

In principle, the indication for liver transplantation is limited to individual cases suitable for surgery (i. e. only in cases of early diagnosis and appropriate treatment). Unlike in Wilson's disease, the genetic defect is *not* removed by transplantation, and the transplanted liver may store iron again. • Consequently, a genuine indication is only given in acute liver failure and in an operable carcinoma restricted to the liver. The final stages of cirrhosis certainly continue to justify a transplantation, although the indication in this case is not based on HC, but on the fact that the diagnosis was established too late and/or that treatment was inadequate or not carried out at all. In young men with severe iron overload, a swift liver transplantation is always indicated. (433, 465)

A number of grave **mistakes** may occur in the treatment of HC. These include:

1. delay in reaching a precise diagnosis (including quantitative determination of iron in the liver bioptate)
2. blood-letting therapy carried out too hesitantly or inadequately
3. failure to carry out a family examination (preventive diagnosis)
4. merely monitoring family members who (still) show no signs of manifest disease instead of treating them properly

# 18 Acquired haemochromatosis/ haemosiderosis

Acquired ("secondary") haemochromatosis is caused by other diseases/conditions characterized by iron overload resulting from excessive iron storage in the organism (e.g. due to diet, medical treatment or haemolysis). The term acquired haemochromatosis should not be used unless the iron content of the liver is $>0.5$ g/100g wet weight. The causes are manifold. • In these patients, there is occasionally an HLA constellation which is identical to that of HC or a family history of iron storage. Therefore, it is postulated that these patients might be heterozygous HC carriers or that there might be another hitherto undetected triggering factor or a genetic defect in addition. (s. tab. 31.17)

## 18.1 Alcohol abuse

The most common cause (about 30% of cases) of hepatic siderosis is alcohol-induced liver disease. Its aetiology is unknown. With this form of acquired iron

deposition, the more pronounced courses are characterized by stronger brownish cutaneous pigmentation, hypogonadism, glucose intolerance and hepatomegaly together with increased iron and ferritin values in the serum. This results in a similar symptomatology to that found in HC, only with a hepatic iron index clearly below 2.0. Blood-letting therapy is successful and reliable within a relatively short period of time. Iron deposition occurs mainly in the Kupffer cells, while the hepatocytes and the septa are largely free of iron.

## 18.2 Porphyria cutanea tarda

In porphyria cutanea tarda, iron deposition in the liver is generally low to moderate, predominantly in the hepatocytes of the acinar periphery. The cause is thought to be reduced activity of uroporphyrinogen decarboxylase resulting in decreased synthesis of porphyrin and haem. However, this variant of hepatic siderosis only becomes manifest as a result of various triggering factors. Treatment is also based on venesection.

## 18.3 Blood transfusion

Transfusional haemosiderosis (R. M. KARK, 1937) can occur following numerous blood transfusions. There are $200-250$ mg iron in 500 ml ($=$ 1 unit) blood. Thus numerous units (more than $50-60$) must be transfused before siderin is clinically recognizable. It is initially deposited in the RES of the bone marrow, spleen and liver, ultimately in the hepatocytes as well.

## 18.4 Haemolytic anaemia

In all haemolytic anaemias, especially the genetically related forms, siderin is firstly deposited in Kupffer cells. The extent of siderosis depends on the duration and severity of the haemolysis. (s. fig. 31.27) In long-term haemolysis, iron is also stored increasingly in hepatocytes. In such cases, the morphological and clinical picture of haemochromatosis can develop.

***Fig. 31.27:*** Siderosis of Kupffer cells in haemolytic anaemia (Berlin blue)

## 18.5 Chronic liver disease

Haemosiderosis can be found in several chronic liver diseases, such as chronic hepatitis (especially HVC leading to a reduced response rate to α-interferon), late-stage cirrhosis, spontaneous or surgical portal-systemic shunts, and non-alcoholic steatohepatitis.

## 18.6 African iron overload

In rural sub-Saharan Africa, there is a kind of beer which is traditionally brewed in iron vats. The daily iron overload can amount to as much as 200 mg with markedly increased iron absorption (T. H. BOTHWELL et al., 1965). • Such a condition is also observed in South Africa among the black population. Their diet consists of porridge fermented in iron pots with an acid pH value (V. R. GORDEUK et al., 1986). • In both conditions, absorption of iron is facilitated by various factors, e. g. protein or vitamin C deficiency, alcohol abuse, acidic diet. It has been suggested that such iron overload is triggered by genetic factors. (437)

# Clinical Aspects of Liver Diseases

## 32 Cholangitis and cholangiodysplasia

# 32 Cholangitis

## 1 Definition

The term cholangitis subsumes localized or diffuse inflammatory changes of diverse aetiology, i.e. between the canal of Hering and the ampulla of Vater, affecting the intrahepatic and extrahepatic bile ducts. Cholangitis can be acute or chronic; it may originate as a primary disease in the bile ducts or develop as secondary concomitant cholangitis in the course of another underlying disease. Forms of cholangitis which exclusively affect the intrahepatic bile ducts generally give rise to the clinical picture of liver disease.

## 2 Systematics and aetiology

▶ *The bile is sterile under physiological conditions.* • Pathophysiological events can cause **asymptomatic bacteriocholia,** which is of no clinical importance. Microorganisms are verifiable in bile in 75−100% of patients with obstruction of the large bile ducts − whereas this applies only to 0−10% of patients with obstruction due to pancreatic carcinoma. Diagnostic or therapeutic endoscopic interventions in the bile ducts are often followed by **bacterial cholangitis**, attributable to the importation of microorganisms, particularly as a result of a (usually temporary) hindrance of bile flow. • *Cholangitis caused by infection is not a separate entity.*

Initially, **ascending cholangitis** has to be considered on account of its pathogenetic development. This condition originates in the gall bladder, duodenum or pancreas. Moreover, the bile ducts are liable to infection by bacteria or parasites as a consequence of cholestasis and/or achylia. • **Descending cholangitis** is considered to be less frequent, with the infection descending from a chronically infected gall bladder or from a primary infection of the liver, for example in the case of salmonellosis. • An infection of the bile ducts may cause **pyogenic cholangitis,** which can take an acute, relapsing or chronic course, the latter mainly being caused by a hindrance of bile flow. • Depending on the time taken for an obstruction to develop, **obstructive cholangitis** manifests as either acute or chronic disease. In the case of obstruction, the increase in intraductal pressure ($>15-20$ cm $H_2O$) causes a cholangiovenous or cholangiolymphatic *reflux* of bacteria or endotoxins into the blood circulation. As a result, signs of systemic and, in severe cases, septic disease appear. • **Toxic cholangitis** may be triggered by chemicals, medicaments or toxins. • Further-

more, there is also the clinical picture of **immunological cholangitis.** This form includes (*1.*) *primary biliary cholangitis*, (*2.*) *primary sclerosing cholangitis*, (*3.*) *autoimmune cholangitis*, and (*4.*) *overlap syndromes.* (s. tab. 32.1)

| 1. **Aetiology** |
|---|
| • **Infections** |
|   − bacteria        − parasites |
|   − mycoses       − viruses |
| • **Obstruction** |
|   − benign stenoses (stenosis of the papilla of Vater, Mirizzi's syndrome, postoperative strictures, chronic pancreatitis, juxtapapillary diverticula, *etc.*) |
|   − blood clots |
|   − mycoses |
|   − gallstones |
|   − malignant stenoses (histiocytosis X, Hodgkin's disease, CCC, *etc.*) |
|   − oriental cholangitis |
|   − parasites |
|   − suture material, clips, sponges |
|   − highly viscous mucus (e.g. mucoviscidosis) |
| • **Immunological causes** |
|   − primary biliary cholangitis |
|   − primary sclerosing cholangitis |
|   − autoimmune cholangitis |
|   − graft-versus-host disease |
|   − rejection reaction |
|   − sarcoidosis |
|   − pharmacons |
| • **Toxic causes** |
|   − burn injury |
|   − cytostatics |
|   − pharmacons |
| • **Caroli's disease** |

| 2. **Clinical forms** |
|---|
| • acute           • non-suppurative |
| • chronic        • suppurative |
| • relapsing |
|              ▶ asymptomatic |
|              ▶ symptomatic |

| 3. **Pathogenesis** |
|---|
| • **primary development** |
|   − genetic/congenital |
|   − immunological |
|   − toxic |
| • **secondary development** |
|   − ascending      − periductular lymphogenic |
|   − descending    − septicaemic via hepatic artery |

*Tab. 32.1:* Classification, causes and pathogenesis of cholangitis

# 3 Cholangitis

## 3.1 Infectious cholangitis

### 3.1.1 Bacterial cholangitis

Based on the number of reported cases, bacterial cholangitis is by far the most frequent type. It can take an acute, relapsing or chronic course, and it may have a purulent (pyogenic, suppurative) or non-suppurative form. • There are **four routes** for bacteria, and hence infection, to spread: (*1.*) ascending, (*2.*) descending, (*3.*) periductular lymphogenetic, and (*4.*) in the case of sepsis, via the hepatic artery. The condition following Billroth's anastomosis II exposes patients to a particular risk, because the duodenal stump serves as a bacterial reservoir. Biliodigestive anastomoses are also regarded as risk factors. Older people are more frequently affected by cholangitis. In general, bacteriocholia only results in cholangitis in the case of disrupted bile flow. (s. tab. 32.1)

In bacterial cholangitis, bile culture is positive in 90−100% of cases, whereby several species of microorganisms are verifiable in 45−60%. Escherichia coli, Klebsiella pneumoniae, Aeromonas (11), Streptococcus faecalis and Pseudomonas are found most frequently. In up to 10% of cases, anaerobes may be the causative agents of cholangitis. Yersinia enterocolitica (42), Salmonella and tuberculosis bacilli are seen as rare causal pathogens. • Under normal circumstances, bacteria from the intestinal tract sometimes enter the portal blood. Migration of microorganisms into the bile is prevented by different defence mechanisms (e. g. intactness of tight junctions, normal phagocytic function of RES cells). Development of cholangitis is likewise impossible in the case of normal biliary flow and normal secretion of IgA into the bile. (7, 11, 14, 20, 33, 36, 49, 52) *(see chapter 24)*

### 3.1.2 Parasitic cholangitis

Ascaris lumbricoides, Clonorchis sinensis, Lamblia intestinalis, Fasciola hepatica, Opisthorchis felineus and viverrini, Lymnaea trunculata, Cryptosporidium, etc. have been identified as parasitic causes of cholangitis. The development of cholangitis is mainly due to a hindrance of bile drainage. Parasites induce inflammation and fibrosis of the bile ducts with partial or intermittent obstruction. During their migration into the biliary tree, parasites may physically introduce bacteria into the bile ducts, which often leads to secondary bacterial cholangitis. Cholangitis induced by Opisthorchis and Clonorchis predisposes to cholangiocarcinoma and liver cell carcinoma. Echinococcus cysts may break in the bile ducts. (7, 15, 17, 51) (s. tab. 32.1) *(see chapter 25)*

### 3.1.3 Mycotic cholangitis

Various fungi have also been found to cause (obstructive) cholangitis, e. g. Cryptococcus neoformans (3), Candida (9), Microsporidium (40), Blastomyces. (43) (s. tab. 32.1) *(see chapter 26)*

### 3.1.4 Viral cholangitis

Viral cholangitis is rare. It can be caused by primary hepatotropic viruses, such as HCV or HBV, and may also occur in systemic viral diseases. (4) Both immunocompetent and immunocompromised patients are affected. The effect on the bile ducts depends mainly on the status of the host immune system. Generally, bile ducts of 50−70 μm diameter are targeted. The cholangitic lesions can be divided in *four types*: granulomatous, lymphoid, fibrous and pleomorphic (J. LUDWIG et al., 1984). It is postulated that damage to the bile duct leads to an increase in alkaline phosphatase. • In adults, cytomegaly is the sole cause of viral cholangitis, especially in the case of HIV infections (= *HIV-associated cholangiopathy*) and in patients who have undergone liver transplantation. In the course of AIDS, biliary infections are frequently caused by opportunistic microorganisms, e. g. cryptosporidiosis, microsporidiosis (2, 10, 16, 27, 40, 51) and sclerosing cholangitis. (17, 45) • ERCP is very important in the diagnosis of HIV-associated cholangiopathy. In acute viral hepatitis, HCV is more frequently associated with cholangitis (20−30%) than is HBV. There is mostly evidence of lymphocytic cholangitis, which is, as a rule, reversible and does not adversely influence the course of disease or response to therapy. The intraepithelial lymphocytes are of the T-cell type. • During the foetal period, viral cholangitis due to reoviruses (type 3) can cause bile-duct atresia, which may also be the result of rotaviruses (types A and C) and RS viruses. *(see chapter 23)*

## 3.2 Obstructive cholangitis

An obstruction in the bile ducts does not always result in cholangitis; however, a disorder of bile drainage is considered to be a prerequisite for the manifestation of cholangitis. In this case, the defence system is of particular importance with regard to bacterial infections. Further risk factors include advanced age and alcohol abuse. The causes of obstruction are manifold, with cholangiolithiasis being the most frequent. • An impaction of a gallstone in the cystic duct or neck of the gall bladder can narrow the choledochus, a condition known as *Mirizzi's syndrome* (P. L. MIRIZZI, 1948), with subsequent development of obstructive cholangitis or cholecystobiliary fistula. (13) (s. fig. 32.1)

During cholecystectomy, choledocholithiasis was found in 12−24% of cases. A stone-free gall bladder does not exclude cholangiolithiasis. About 80% of the bile-duct stones are found in the choledochus, 15% in the common hepatic duct and 5% in the intrahepatic bile ducts. In obstructive cholangitis, the recognition and removal

***Fig. 32.1:*** Cholesterol-calcium-pigment stone: a rare specimen showing a striking coloured/chemical development (here: a so-called *tiger-eye stone*) (at our disposal). Diagnosis: obstructive cholangitis due to *Mirizzi's syndrome*

of the obstruction constitutes causal therapy and is decisive for prognosis. (9, 15, 21, 25, 34, 35, 39, 50, 56)

**Oriental cholangiohepatitis:** This particular type of cholangitis was first described by K. DIGBY in 1930. It develops from the formation of calcium bilirubinate stones, especially with intrahepatic localization. It is mainly found in China, Japan, Malaysia and Taiwan. A nutritional cause together with a deficiency of glucaro-1,4-lactone is assumed, so that deglucuronidated bilirubin precipitates. Migration of parasites, especially Ascaris lumbricoides, into the bile ducts is probably an initiating event. (s. fig. 25.8!) Suppurative cholangitis develops. ERCP and MRCP are excellent diagnostic tools for depicting and examining the biliary tree. • *Treatment* consists of endoscopic stone removal, which often has to be repeated. The insertion of an expandable metallic stent has not proved effective in the long term. Surgical procedures include sphincteroplasty, biliointestinal bypass or hepatic resections. (6, 32, 47) • So-called *recurrent pyogenic cholangitis* is thought to be identical to oriental cholangiohepatitis. (12, 22, 26, 48, 55, 56)

## 3.3 Toxic cholangitis

Toxic (especially sclerosing) cholangitis (5, 8, 17−19, 24, 38, 39, 44−46) has been attributed to the effects of *aromatic amines*. Likewise, this condition can be caused by *lithocholic acid*. It may also be triggered by various *medicaments* acting as facultative toxins, e. g. allopurinol, antibiotics, carbamazepine, phenylbutazone, tolbutamide. (s. tab. 29.6) • Such a type sometimes occurs after intra-arterial administration of *cytostatics* (18, 19, 24, 38) and as a result of burn injuries. (44) (s. p. 651) (s. tab. 32.4)

## 3.4 Clinical aspects

**Acute cholangitis:** The acute course is initially diagnosed clinically. It is characterized by **Charcot's triad:** (*1.*) sudden onset of pain (epigastric, right-sided), (*2.*) fever (also with shivers), and (*3.*) jaundice (J. M. CHARCOT, 1877: "intermittent gall fever"). This triad was expanded by B. M. REYNOLDS et al. (1959) to a **pentad,** which points to septic cholangitis: (*4.*) confusion, and (*5.*) coagulation disorder, occasionally with the development of disseminated intravascular coagulopathy (DIC). The course can be intermittent, or it may rapidly progress to sepsis with septic shock (in about 5%). However, a severe course of disease does not necessarily confirm the existence of suppurative cholangitis. In younger people, Charcot's triad is more clearly marked than in older patients, in whom jaundice is absent in 20−30% of cases. The liver is enlarged and tender upon pressure; splenomegaly is occasionally found. (33, 36, 52)

**Suppurative cholangitis:** Pyogenic (suppurative) cholangitis has the most severe course with a very poor prognosis. In general, there is complete bile obstruction with expanded pus-filled bile ducts (= bile-duct empyema). Clinically, *Reynold's pentad* is present in most cases. Hepatosplenomegaly, pronounced leucocytosis and hyperbilirubinaemia (in general >9 mg/dl) are found. Suspected severe or suppurative cholangitis requires instant diagnostic measures and, on confirmation of diagnosis, immediate therapeutic endoscopic (occasionally also surgical) intervention. (11, 14, 21, 30, 31) • *Severe or suppurative cholangitis is always an emergency!*

**Chronic cholangitis:** The symptomatology is bland − particularly in older people. Younger people mostly suffer from a chronic relapsing course. Clinical symptoms include pain in the right upper abdomen, possibly also inappetence and nausea as well as occasionally verifiable hepatomegaly. Laboratory tests provide evidence of cholestasis with or without slight jaundice. Symptom-free intervals and exacerbations with fever and jaundice can alternate. • Both acute and chronic cholangitis have a variable clinical picture with a wide spectrum of severity, including *cholangitis lenta.*

## 3.5 Morphology

**Acute cholangitis:** Thickened bile-duct walls with inflammatory infiltration as well as focal ulcerations are found histologically. The portal fields are expanded by oedema and reveal pericholangiolar and intracholangiolar infiltrations from leucocytes. Ductal tortuosity reflects increased pressure in the biliary ducts. Periductular abscesses can develop during the course of cholangitis. (s. fig. 32.2)

**Chronic cholangitis:** This disease shows dilated, proliferated, peripherally located ductules, which contain concentrated bile with degenerative epithelial changes. Large numbers of polymorphonuclear leucocytes are verifiable in the lumen and in the bile-duct wall; leucocytic infiltrations spread to the neighbouring parenchyma. Increasing (lamellar) periductular fibrosis and

biliary strictures develop. (s. fig. 32.3) • *Laparoscopically*, progressive portal and portoportal fibrosis with cholestasis is characteristic of the macroscopic picture of chronic cholangitis. (s. fig. 32.4)

**Fig. 32.2:** Ascending, suppurative, destructive, relapsing cholangitis with abscess formation; the loose periportal fibre cuff (arrow) points to previous cholangitic episodes (HE)

**Fig. 32.3:** Periductal, portoportal slight fibrosis. Clinically: history of previous bile-duct inflammation (Sirius red)

**Fig. 32.4:** Chronic cholangitis. Periportal fibrosis; dark red/brownish discolouration of the liver with greenish patches: finely nodular surface (= scattered light reflection)

If it is not possible to remove the obstruction and achieve defect healing (i. e. with fibrous residues) of the chronic (relapsing) cholangitis, the inflammatory destruction of periportal liver parenchyma will result in portoportal bridge formations and thus isolation of hepatic lobules by means of connective tissue. • Monolobular, mostly micronodular *biliary cirrhosis* develops. (41, 54) (s. fig. 32.5)

**Fig. 32.5:** Biliary cirrhosis following chronic relapsing and abscessforming cholangitis; green and grey "dirty" colouration of the deformed micronodular surface. (Chronic cholecystitis with formation of a shrunken gall bladder)

### 3.6  Diagnostics

The diagnosis is initially based on detailed *anamnesis* focusing on the biliary system (preceding hepatobiliary diseases, endoscopic examinations, operative interventions). Previous examination results and surgical reports (if applicable) should be obtained. • With regard to *clinical findings*, the liver can be enlarged and/or tender on pressure, and jaundice may also be present. • *Laboratory investigations* reveal leucocytosis with inflammation criteria in the differential blood count, increased values for the erythrocyte sedimentation rate and CRP, elevated $\gamma$-GT, AP, LAP and bile acids, hyperbilirubinaemia, augmented $\alpha_2$- and $\gamma$-globulins and IgM as well as increased GPT, GOT and GDH (pointing to involvement of the lobular periphery in the form of cholangiohepatitis). Occasionally, the amylase value and the tumour marker CEA $19-9$ (due to cholestasis) are elevated. • *Bacteriaemia* is verifiable in $20-40\%$ of patients during a fever episode, with the result that an antibiogram guarantees a more targeted therapy in these cases. • *Sonography* shows dilated bile ducts; normal bile ducts, however, do not exclude cholangitis! As a rule, the type and localization of an obstruction are verifiable and gas can occasionally be detected in the portal veins. Abscess foci are easily recognizable. (16, 30) • *Computer tomography* provides valuable evidence in difficult cases, for example in malignant obstruction. (1, 12) More recently, good results have been obtained by means of MRC. (26, 53) (s. p. 183)

► **Direct cholangiography** by means of *ERCP* (s. p. 183) and *PTC* (s. p. 185) is a decisive examination with very high diagnostic reliability. However, these techniques should be carried out under antibiotic prophylaxis, the duration of which depends on the clinical picture. The important factor here is the well contrasted and complete visualization of the bile ducts. Using these two methods, it is possible to implement simultaneous therapeutic procedures, such as decompression of bile ducts, flushing with antibiotics, papillotomy with stone extraction, nasobiliary or bilioduodenal drainage, stent implantation, etc. • If there is no suspicion of suppurative cholangitis (which calls for immediate invasive or surgical intervention!), antibiotic therapy for 1 (or 2) day(s) is carried out prior to ERCP and the result awaited, because ERCP can trigger complicative cholangitis in rare cases. • An inconspicuous cholangiogram now requires further diagnostic efforts to find the still unresolved cause of cholangitis, such as serological examination for viruses or bacteria, evidence of parasitic larvae or eggs in the bile or stool, autoantibodies (e. g. AMA, pANCA), toxins and colour-encoded Doppler sonography of the portal system.

**Aerobilia** may have various causes, e. g. biliodigestive anastomosis or fistula, ERCP, cholangitis due to gas-forming bacteria. In aerobilia, there are sonographically echogenic, strand-like gas bubbles in the respective bile ducts. (s. fig. 32.6)

*Fig. 32.6:* Aerobilia: Sonography shows echogenic, strand-like gas bubbles in the respective bile ducts

This diagnostic programme, which has proved its worth in the case of cholangitis, can be incorporated into a **flow diagram** for the clarification of cholestasis or jaundice. (s. fig. 13.7) The individual characteristics of each case always have to be considered!

## 3.7 Complications and prognosis

The mild form of cholangitis frequently subsides spontaneously, mostly with antibiotic therapy, and can even be cured without morphological residues. • Severe and progressive courses have a poor prognosis due to the development of **complications:** (*1.*) suppurative cholangitis, (*2.*) sepsis, possibly with septic shock, (*3.*) DIC, (*4.*) infected portal thrombosis, (*5.*) acute renal failure (so-called *biliorenal syndrome*), and (*6.*) liver abscesses or metastatic abscess formation. • However, complications also have to be feared when using ERCP and PTC, since the inherent risks of these invasive techniques are greatly increased by bacterial infection of the bile duct (e. g. phlegmon, retroperitoneal or subphrenic abscess, pleural infection). There is a particular risk involved in the application of contrast medium under pressure (!) into the bile ducts, which may even result in death. • The **prognosis** is based on establishing whether (*1.*) the causal obstruction can be removed, (*2.*) decompression of the bile ducts can be achieved, (*3.*) effective drainage is guaranteed, and (*4.*) antibiotic therapy is effective.

## 3.8 Therapy

1. **Standard therapy:** Intensive care treatment and monitoring is accepted as standard therapy; complications may appear unexpectedly and rapidly. In about 75% of patients with mild cholangitis, therapeutic success can be achieved by the substitution of fluid, electrolytes and zinc as well as vitamins, glucose (possibly also amino acids) and the (indispensable) administration of antibiotics. Analgesics and spasmolytics are generally necessary. • In addition, the administration of *fresh plasma* is recommended to stabilize haemostasis.

As long as there is no positive bacteriological result from the bile (or blood), **antibiotics** are administered on empirical and plausible principles. In this case, *mezlocillin* or *piperacillin* is initially recommended, 3 x 2 (−4 or −5) g/day, i.v. (55) These antibiotics are effective against virtually all bacteria in acute cholangitis, since they can reach high biliary concentrations. Once the course of disease has entered a more severe stage, an additional dose of *tobramycin*, for example, is indicated (e. g. 3 x 80 mg/day, i.v.). A septic clinical picture requires a course of *triple therapy* with ureidopenicillin + aminoglycoside (see above) + metronidazole (3 x 500 mg/day, i.v.).

2. **Invasive therapy:** If clinical improvement and defervescence do not occur within 12 (to 36) hours, **decompression** of the bile ducts becomes necessary. Decompression is carried out endoscopically by means of papillotomy. Providing there are no reasons against doing so, **bile drainage** should also be carried out at the same time via a nasobiliary tube or bilioduodenal endoprosthesis. Early decompression is recommended with a thrombocyte count of < 100,000/mm$^3$ and an albumin value of < 3.0 g/dl. (23, 29, 31, 47, 56) Under these circumstances, we regard the simultaneous administration of *fresh plasma* as a necessity. • If the bile ducts cannot be reached by retrograde endoscopy, **PTC** is available as an

ideal alternative for decompression and drainage (and, occasionally, antibiotic instillation). Nevertheless, because of the bacterial (suppurative) situation, a higher complication rate also has to be expected. (23, 37, 47) • **Surgical measures** carry a substantially higher risk than endoscopic papillotomy + drainage, which is why they are restricted to particular situations in special cases (e. g. Caroli's syndrome, liver abscess). (23, 28, 48)

# 4 Primary biliary cholangitis (PBC)

> ► In 1826 P.F. RAYER reported on the peculiar appearance of xanthelasmas and xanthomas in middle-aged women. • In 1851 T. ADDISON et al. assumed a correlation between skin changes and liver disease. (58) In 1857 R. VIRCHOW pointed to a connection between these skin changes and cholestasis and cirrhosis. V. HANOT (1876) described the clinical picture of hypertrophic cirrhosis with chronic jaundice. (134) S.G. THANNHAUSER et al. (1938) postulated the combination of xanthomas and biliary cirrhosis as a separate entity. (271) In 1949 H.E. MACMAHON et al. used the term "xanthomatous biliary cirrhosis". (193) • A detailed description of this disease was presented by J.A. DAUPHINEE et al. (1949) (98) and E.H. AHRENS jr. et al. (1950), who coined the term **"primary biliary cirrhosis"**. (60) • In 1965 the group of H. POPPER introduced the expression **"chronic non-suppurative destructive cholangitis" (CNDC)**. (247)

## 4.1 Definition

Primary biliary cholangitis (PBC) is characterized by chronic, non-suppurative, destructive cholangitis (CNDC) of the small and medium-sized bile ducts (ductule, interlobular and septal). The cause is not yet known. • PBC proceeds slowly and does not cause any clinical symptoms for a long period of time. However, antimitochondrial antibodies (AMA) already appear at the preclinical stage, which allows a very early diagnosis to be made. During the further course of disease, the symptoms are those of chronic cholestasis. The final stage is characterized by the total destruction of the bile ducts. • In the case of a progressive (or unsuccessfully treated) course, primary biliary cholangitis gradually develops into *biliary cirrhosis* − as is also the case with primary and secondary sclerosing cholangitis.

## 4.2 Epidemiology

PBC is found in all races and social classes, although it is virtually unknown in Africa. Its *prevalence* ranges between 25−40/100,000 inhabitants (with regional differences). The *incidence* is 2.7−3.5 cases per 100,000 inhabitants/year. The disease predominantly affects women (in about 90% of cases); the prevalence among women between the ages of 35 and 60 is >90/100,000. PBC is nearly always witnessed in adults; it is a very rare event in children. (97) Close relatives have a prevalence of 4−6%. Patients with ulcerative colitis are affected thirty times more frequently than the general population. (108, 148, 188, 190, 204)

## 4.3 Aetiology

The aetiology of PBC is still unknown. Possible causal factors include genetic susceptibility, infections, environmental influences and immunological reactions. • *Probably, there is an individual concurrence of endogenous and exogenous factors.*

### 4.3.1 Genetic susceptibility

Isolated instances of **familial aggregation** of PBC involving siblings, twins, mother and daughter or father and daughter have been reported. The occurrence of AMA as well as an increase in IgM and γ-GT, or deficiency of IgA has been observed in relatives of PBC patients (genetics? close physical contact?). It is not a hereditary disease, however. (59, 66, 83, 85, 87, 89, 90, 117, 127, 144, 148, 163, 275)

There is a certain **association with HLA,** such as HLA-DR8, -DR3, -DR4, -DPB1, -B8 or -DQB1, as well as with the formation of isohaemagglutinins − but not with the AB0 blood-group system or the Rhesus groups. The HLA-A class 2 antigen is significant in reducing susceptibility to and affording protection against PBC. HLA-DR8 is deemed to be a risk factor, particularly in the combination DR8/C4B2 and DR8/C4AQ0. (270, 278)

### 4.3.2 Hormone theory

► The so-called **hormone theory** (J. AHLQVIST, 1980) is based on the impact of hyperoestrogenaemia on the biliary/canalicular system and bile acid metabolism. The question of sequential causality remains open. (quot. 75)

### 4.3.3 Mycotoxin theory

► The so-called **mycotoxin theory** (E. KUNTZ, 1984) emerged from our examinations of stools for the presence of fungi in 54 female patients. (170, 171) • Normally, the lumen of the bile capillaries is surrounded by a network of actin-like filaments which radiate into the microvilli. The bile flow is essentially steered by this network. The mycotoxin cytochalasin B (possibly also other mycotoxins) causes loss of microvilli and dilatation of the canaliculi (M.J. PHILLIPS et al., 1975) − and as a result, probably also retention of leukotrienes. (see 4.3.5) Mycotoxins can penetrate the intestinal mucosa and reach the liver cells through the portal vein. The frequent evidence of antiactin antibodies in PBC patients may be attributable to this. A (myco)toxic canalicular impairment as an "initiator" may result in self-perpetuation in connection with (secondary) hyperoestrogenaemia due to a (tertiary) defect in the immunoregulatory mechanism. The formation of mitochondrial antibodies can be induced by a mycotoxic (?) (possibly bacterial?) antigen, which culminates in the formation of AMA with subsequent T-cell infiltration into the small bile ducts. Yet, the question remained unanswered for us as to whether this applies to (*1.*) markedly increased fungal colonization of the intestinal tract in individual cases, (*2.*) specific fungal species, (*3.*) increased perviousness of the (predamaged?) intestinal mucosa with regard to mycotoxins, or (*4.*) insufficient clearance function of the hepatic RES. • We were subsequently able to confirm this marked associ-

ation on the basis of numerous mycological stool examinations – however, no further evidence could be obtained to substantiate our mycotoxic hypothesis at that time. • It is of interest that AMA also react with PDH-E2 contained in mycoses.

### 4.3.4 Bacterial or viral theory

▶ The group of U. Hopf also examined the question of an **infectious toxic factor**, since there is a great similarity between bacterial and mitochondrial membranes. (75, 139, 254, 261, 267, 293) Evidence of so-called *R forms of E. coli* could be found in all PBC patients in the stool (with no relation to the severity of cholestasis), and A lipid could be detected very frequently in hepatocytes and Kupffer cells. Mitochondrial antigens were present in the bacterial wall of Enterobacteriaceae. • Evidence of AMA in *tuberculosis patients* is of interest (R. Klein et al, 1993). *Urinary tract infections* with E. coli may also play a role in the development of anti-$M_2$ (A.K. Burroughs et al., 1984). • Anti-$M_2$ has also been observed after *infections* with EBV, cytomegalovirus, Salmonella sp., toxoplasma, Chlamidia sp. (57), etc. Hepatitis viruses may also be "initiators". Propionibacterium acnes could be detected in granulomas. • PBC is possibly caused by a coated retrovirus. This as yet unnamed virus has been detected in the epithelia of small bile ducts. It contains neither human nor viral DNA. Therefore, it is deemed to be an exogenous virus. Thus antiviral treatment of patients with PBC may be considered a new therapy option. (198)

### 4.3.5 Elevation of leukotrienes

Leukotrienes can form in hepatocytes, Kupffer cells and mastocytes. Their release, induced by endotoxins for example, correlates with the increase in AP, LAP and γ-GT. Leukotrienes have a marked inflammatory effect. Enhanced production together with reduced secretion of leukotrienes into the bile can result in severe lesions of the bile ducts. (203)

### 4.3.6 Increase in Mn-SOD

In PBC patients, manganese superoxide dismutase levels in the serum were found to be increased; it is secreted in greater quantities from damaged bile-duct epithelia. Free radicals were therefore assumed to play an aetiopathogenetic role regarding immunologically induced lipid peroxidations. (229)

### 4.3.7 Immunologic factors

**1. Antimitochondrial antibodies (AMA):** D.C. Gajdusek (1957) and J.R. Mackay (1958) were able to determine different antibodies in the serum of patients suffering from PBC by means of a complement fixation test (CFT). (s. p. 120) • In 1965 J.G. Walker et al. reported the occurrence of antimitochondrial antibodies in PBC patients. (282) These were directed against the antigens of the inner mitochondrial membrane. The antigen specific to PBC and sensitive to trypsin was termed *AMA-$M_2$*. The target antigen is an enzyme complex containing pyruvate dehydrogenase, keto acid dehydrogenase and branched chain keto dehydrogenase. In about 95% of cases, patients with PBC show a positive result. Four determinants (I–IV) are attributed to $M_2$: $E_2$, X, $E_1$, $E_3$. (70, 74, 112, 137, 215, 264, 295) • The group of P.A. Berg identified an *anti-$M_9$* (1984) in PBC patients as well as a trypsin-resistant *anti-$M_4$* and a trypsin-sensitive *anti-$M_8$* (1985). Anti-$M_9$ was found almost exclusively in the early stage, often in family members who did not have an anti-$M_2$ – as well as in female laboratory assistants in frequent contact with AMA-positive serum. Anti-$M_9$ is verifiable in 10–15% of the population. (77, 285) (s. tab. 5.21) (s. p. 120) (s. fig. 5.14) It is still not clear whether AMA-positivity is a sequela or a pathogenetic factor of PBC. • Further *AMA subgroups* have been verified: anti-$M_1$ against syphilis (D.J. Wright et al., 1970), anti-$M_3$ against pseudolupus (T.J. Sayers et al., 1981), anti-$M_5$ against collagenosis, anti-$M_6$ against iproniacid (M.T. Labro et al.,

1982) and anti-$M_7$ against cardiomyopathies (R. Klein et al., 1984). • The typical antibodies for PBC ($M_2$, $M_4$, $M_8$, $M_9$) can be combined into **four constellation types** (A–D), which are probably of clinical importance. The sensitivity of detection ranges between 66–96%. • However, AMA are neither species nor organ-specific. (76, 130, 152, 163–165, 199, 236, 263) (s. tab. 5.21)

**2. Other antibodies:** Antinuclear antibodies (ANA) in PBC are verifiable in 10–40% of cases. Antibodies to hepatocyte membranes (LMA) are present in about 40% of PBC patients. Furthermore, antibodies to microfilaments, intermediary filaments and microtubuli as well as to antiactin have been detected. In approx. 100% of PBC patients, antibodies against parietal cells can be identified (H.P. Wirth et al., 1994). In 25% of cases, antibodies to thyreoglobulin have also been demonstrated. (96, 104, 149, 263, 265) (s. tabs. 5.19–5.21)

**3. Immunocomplexes:** It has also been suggested that complement activation with subsequent bile-duct lesions and an increased synthesis of immunoglobulins is evoked by immunocomplexes. They are even considered to be responsible for the formation of granulomas. However, they are certainly not the primary aetiological factors.

**4. Immunoglobulin M:** Virtually all PBC patients show increased serum IgM values. This IgM differs remarkably from the IgM of healthy persons. Elevated monomeric IgM was also detected in the skin, in hepatocytes and in the intestinal mucosa. Enhanced IgM serum values were likewise determined in relatives of PBC patients. (see 4.3.1) However, there was no correlation between IgM serum values and the tissue level values, cholestasis or morphological changes. Progressive PBC courses result in augmented IgG as well.

**5. Cellular immunoreactions:** Increased IgM values are a characteristic sign of enhanced B-lymphocyte activity, namely of an IgM-secreting subgroup, as well as a restriction in the normal transfer from type IgM to type IgG. Infiltrations are found in the hepatic tissue and consist mainly of T lymphocytes (activated, cytotoxic CD8+ as well as CD4+ helper cells). The portal field infiltrations predominantly show CD4 T lymphocytes, while the ductuli are surrounded by CD8 T lymphocytes. It is still not known which mechanisms are responsible for the bile-duct lesions brought about by the T lymphocytes, mainly of the CD8 type. The latter are assumed to react with $M_2$ antigens, which are expressed from the ductulus cells. • So-called MHC antigens are found on the surface of the bile-duct epithelia of PBC patients, i.e. they act as antigen-presenting (target) cells. This leads to the stimulation and proliferation of CD4 lymphocytes. These emit cytokines, which cause a proliferation of CD8 lymphocytes in the direct neighbourhood of the small bile ducts. However, the bile-duct epithelial cells are also target cells of the CD8 lymphocytes; the latter adhere to the bile-duct epithelia due to the expression of MHC antigens and adhesion molecules (ICAM), and enter the cells. Their cytotoxic impact destroys the small bile ducts and evokes an immunological inflammatory process with further secretion of cytokines, which are conducive to inflammation. However, with regard to cytokine production and response in PBC, the findings are still contradictory. Nor is it clear why these processes take place almost exclusively in the small bile ducts. (182, 215)

**6. Selenium deficiency:** The trace element selenium is also obligatory for the normal functioning of the immunological system. Selenium deficiency has been proposed as one of the aetiological factors in PBC – although this has not yet been verified.

## 4.4 Pathogenesis

In the pathogenesis of PBC, cellular immunoreactions, particularly the formation of autoantibodies, are probably of greater importance than humoral reactions. *Due to disturbed immunoregulation, the immune response is ineffective against both cell and humorally*

*mediated cytotoxicity. On the one hand, therefore, causality is not eliminated and on the other hand, the initial damage still has an effect, so that the autoimmunological inflammatory reactions continue to target the organ in a self-perpetuating process.* • The frequent association with other autoimmunological diseases, infiltrations of activated CD4 and CD8 T lymphocytes in the portal fields and around the intralobular bile ducts as well as the expression of antigens of the MHC class II and ICAM class I on bile-duct cells point to the importance of autoimmunological reactions in the pathogenesis of PBC. • The involvement of $M_2$ antibodies in the pathogenesis of PBC has been discussed, but seems rather unlikely. A possible aspect would be the pathogenetic significance of AMA through antibody-transmitted cytotoxicity and the incorporation of complement factors. (100, 125, 144, 150)

### Aetiopathogenetic hypothesis

The primary provocation of immunological phenomena by **toxins,** such as mycotoxins (E. KUNTZ, 1984) (170, 171), **bacteria** (U. HOPF et al., 1989) (139, 261) and **viral infection** (H.I. MASON et al., 1998) (198) − probably accompanied by hormone-induced bile-duct lesions (J. AHLQVIST, 1980) − can therefore be interpreted in terms of subsequent **self-perpetuation.** The expression of relevant mitochondrial epitopes in the small bile ducts caused by an external antigen through **molecular mimicry** (M.E. GERSHWIN, 1991, 1997) (120, 267) may support the chronic inflammatory process by way of autoaggression. Immunologically induced lipid peroxidations may be significant here. (229) Already in the year 1979, it could be demonstrated by means of electron microscopy that mitochondria multiply in the epithelial cells of the canaliculi of PBC patients; this finally leads to obliteration of the affected canaliculi. The longitudinal consolidations of intercellular gaps point like fingers to the obliterated lumen (G. SCHWALBACH, 1979). • These results concurred with our concept at that time (171) which was based on the assumption that a *primary mycotoxic factor* (or *molecular mimicry*) *constitutes an "initiator".* (s. p. 643)

## 4.5 Morphology

▶ The morphological changes in *"primary biliary cirrhosis"* (PBC) (60) were described as *"chronic non-suppurative destructive cholangitis"* (CNDC) by the study group of H. POPPER if the stage of cirrhosis had not been reached. (247) • The morphological classification of PBC, first proposed by P.J. SCHEUER in 1967 (252), was modified in 1980. It differentiates **four stages,** which show fluid transition: ductal phase (I), ductular phase (II), fibrosing-cicatrizing (precirrhotic) stage (III), and cirrhotic stage (IV). (252) • Applying this classification, H. POPPER et al. (1970) described stage I as a cholangitic phase and stage II as a phase of ductular proliferation − they retained the original terms for stages III and IV. • A modified classification was proposed by J. LUDWIG et al. in 1978. (191) They used the terms: portal hepatitis (I), periportal hepatitis (II), septal necrosis/fibrosis (III), and cirrhosis (IV).

**Electron microscopy:** Focal destruction of the numerically diminished microvilli is evident. Spreading of the

peribiliary canalicular ectoplasm is attributed to an increase in filamentous structures. The mitochondria within the epithelial cells of the bile ducts multiply. Finally, the affected bile canaliculi are completely obliterated. • *Thus it would seem that the primary damage, which results in CNDC, actually originates from the canaliculi* (G. SCHWALBACH, 1979; K. TOBE, 1982). (213, 215, 294)

**Stage I:** *Laparoscopically*, the liver is of normal size and consistency. The surface colour is reddish-brown, possibly with yellowish spots; it may even have a "tiger skin-like" colouring. • *Histologically*, there is evidence of ductular lesions similar to cholangitis as well as portal and pericanalicular infiltrations (lymphocytes, histiocytes, plasma cells, eosinophilic leucocytes and, more rarely, polymorphonuclear granulocytes). The portal fields are affected regionally to different degrees and to a variably severe extent − sometimes, they are not affected at all. Mononuclear cells penetrate the walls of the small bile ducts. The histiocytes can form granulomas, mostly of the sarcoid type, which may also contain Langhans' giant cells. At first, the florid, interlobular and septa bile-duct lesions with follicular elements only develop focally. The liver parenchyma is hardly affected. The lesions are distributed irregularly in the liver. There is no evidence of cholestasis. (194, 214−216) (s. fig. 32.7)

***Fig. 32.7:*** PBC stage I: Epithelioid cell granuloma (↑) related to a septal bile duct; focal inflammatory destruction of the bile-duct epithelium; granuloma-like nodule of macrophages entering the lumen

**Stage II:** *Laparoscopically*, the liver now has a firmer consistency (ascertained by pressure of the probe). With the onset of cholestasis, the surface colour gradually becomes reddish-yellow to speckled green. There are clearly more subcapsular blood vessels. The surface is finely rippled or granulated. (118, 184, 207) (s. fig. 32.8) • *Histologically*, there is a reduction in the periductular lesions, possibly with increasing proliferation of the cholangioles, and a drop in the number of portal bile ducts (= increasing appearance of arteries without concomitant bile ducts). There is often evidence of pigmentation

and PAS-positive material in the bile-duct endothelia. A dense collagenous fibre network develops. The liver cells occasionally contain Mallory bodies. Activated macrophages cause secondary cellular necroses. Proliferation of stellate cells and lymphocytic infiltrations develop within the sinusoids. The inflammatory infiltrations spread to the lobules and present as piecemeal necrosis (= interface hepatitis). (99, 110, 199, 234, 236, 251, 256)

**Fig. 32.8:** Primary biliary cholangitis: Map-like marking of the liver surface (stage I); still largely smooth surface (see light reflex), dark red/livid blue colouring; tiger skin-like pattern in the irregular reddish areas

**Stage III:** *Laparoscopically*, the liver has a markedly firmer consistency; the granular, in parts finely tuberous surface has a reddish-brown colour with greyish-green speckling. There are noticeably more subcapsular blood and lymphatic vessels. The first evidence of commencing portal hypertension is found in the ligaments. The spleen is enlarged and of a dark red colour. • *Histologically*, periportal scarring and the formation of fibrosis predominate due to persistent stimulation of fibrogenesis. The bile ducts are greatly reduced in number, and countless small arteries are apparent. The inflammatory infiltrations and bile-duct proliferations gradually become less obvious. (s. fig. 32.9) However, the different morphological stages can overlap in the same patient. Copper is increasingly deposited in the lysosomes (10−60 mg/100 g/dry weight) and subsequently in the liver, spleen and kidneys (but not in the brain). Severe lobular central cholestasis now becomes pronounced. Macrophages occasionally contain lipid and form pseudoxanthomatous cells. (s. fig. 32.9)

**Stage IV:** *Biliary cirrhosis*, also described as stage IV, is the possible morphological final stage of PBC (or CNDC), in which the remaining biliary ductules are now subject to destruction, and consequently disappear. Basically, CNDC is in itself "chronic cholangitis". • *Laparoscopically*, the liver surface shows irregular, finely rippled, micronodular (at selective sites also macronod-

ular) cirrhosis. The vessels are more numerous and more clearly marked. The colour is brownish-grey to graphite-green, in some places more distinct. There are lymph cysts and signs of portal hypertension. • *Histologically*, one can find advanced scarred septation and regenerative growth in the form of a complete cirrhosis with almost no inflammatory activity. Cholestasis is severe. There is virtually no evidence of bile ducts; granulomas are rare. (146, 234, 246) (s. fig. 32.9)

**Fig. 32.9:** Primary biliary cholangitis with cirrhotic transformation. Well-rounded parenchymal residues surrounded by collagenous fibre tissue; hardly recognizable bile ducts in the residual round cell-infiltrated portal fields (stages III−IV) (HE)

▶ Strictly speaking, the historical term primary biliary "cirrhosis" (coined in 1950) (60) cannot be retained for primary biliary cholangitis with all its well-defined stages (CNDC I−III) − because there is no sign of cirrhosis during the precirrhotic stages I−III, and CNDC does not necessarily lead to cirrhosis. As early as 1965, E. RUBIN et al. objected to the definition of PBC as "cirrhosis" on the grounds that it was a "misnomer" (247). • All forms of "chronic cholangitis" (e. g. obstructive, primary biliary, primary or secondary sclerosing and immunological) may develop into **biliary cirrhosis** − which can barely (or only unreliably) be differentiated histologically and in no way aetiologically. • It is not justified to use a pathologically incorrect term simply because it once became established in a historical context.

*Cirrhosis is never "primary", but always has a relatively long developmental phase. Consequently, there is no "primary" and hence no "primary biliary" cirrhosis!*

## 4.6 Clinical courses

In general, the three morphological stages I−III (precirrhotic) are more or less equivalent to the clinical stages I−III, although fluid transitions understandably exist in each case. Stage IV (cirrhotic) would correspond to the clinical stages IV and V. • Assignment to a particular

disease phase also yields prognostic information. From a clinical and morphological point of view, the division into a *precirrhotic* and a *cirrhotic* stage is significant (and generally adequate).

### 4.6.1 Asymptomatic stage (I)

In general, there is no evidence of PBC in this initial phase. Occasionally, some patients complain of *fatigue* (s. p. 235) and *weakness* (116, 122, 140, 240, 242) as well as minor, short-term *pruritus*. (s. p. 235) • Often, an (initially inexplicable) increase in *γ-GT and AP* is witnessed during investigations indicated for other reasons. The sulphated bile acids in the serum are elevated. • If the possibility of PBC is "taken into consideration" at this stage, evidence of *AMA*, especially of the subtype $M_2$, can provide an early diagnosis. AMA are a very early marker of PBC − often a long time before other laboratory or clinical findings become evident. (76, 77, 104, 112, 137, 149, 152, 163−165, 205, 225, 246, 260, 263, 285, 295) • However, jaundice, gastrointestinal haemorrhages, bleeding oesophageal varices, osteoporosis and ascites have also been reported as *initial symptoms*. (65, 79, 91, 124, 242, 297)

### 4.6.2 Oligosymptomatic stage (II)

Clinically, pruritus becomes more and more pronounced, particularly at night, and is mainly localized in the extremities and perianal region. Pruritus is often the reason for a dermatological examination. Subjectively, arthralgia and steatorrhoea may also occur. Hepatomegaly is verifiable in about 50% of cases. The cholestasis-indicating enzymes are elevated; this correlates with the release of leukotrienes. Occasionally, (nearly) normal values of AP are found. The metabolism of bile acids is disturbed. • *AMA* are positive (ca. 95% of cases), so that the subtype $M_2$ can now be determined. (s. tab. 5.21) (s. fig. 5.14) There is no difference in the frequency of AMA between men and women. AMA are sometimes detectable also in urine, bile and tears. About 10% of cases show no evidence of AMA. *ANA* appear in 25−50% of patients as a multiple nuclear dot type (MND-ANA) or a nuclear ring standing form. Their presence confirms an AMA-negative PBC. Furthermore, antibodies against Escherichia coli proteases are found in ca. 30% and a typical pANCA in ca 15% of patients. Antibodies against parietal cells *(anti-PCA)* are detectable in nearly all cases. Simultaneous negativity of AMA may be suggestive of an overlap syndrome. (s. p. 660) As a rule, IgM is clearly increased. Elevated cholesterol and reduced HDL are often found with an additional rise in LDL. Generally, lipoprotein X is detectable. (61, 91, 205)

### 4.6.3 Symptomatic anicteric stage (III)

Pruritus and scratch wounds are a major impairment in daily life; the patients suffer enormously. With marked pruritus, a so-called *butterfly sign* is sometimes found on the patient's back, i.e. the area which cannot be reached by scratching (T. B. REYNOLDS, 1973). (s. pp 85, 235) • Gradually, hyperpigmentation of the skin occurs due to melanin. Hepatomegaly is verifiable in 70−80% of cases, splenomegaly in 20%. Portal hypertension develops, predominantly of the intrahepatic presinusoidal type. Xanthelasmas and xanthomas form slowly, particularly on the lower and upper eyelids, on the tendons of the extensor muscles, on the elbows and heels as well as on the palms of the hands. (s. figs. 4.14−4.16) Biochemistry reveals increased values of AP, LAP, γ-GT and transaminases as well as enhanced values of cholesterol, LDL and IgM. In some patients, considerable eosinophilia occurs − in correlation with the activity of mast cells in the portal field. The galactose elimination capacity is reduced. Osteoporosis has reached an advanced stage. Up to now, no factors predicting progression from the presymptomatic to the symptomatic stage are known. (91, 98, 146, 157, 205, 209, 225, 246)

### 4.6.4 Icteric stage (IV)

Jaundice develops within 6 months in rapidly progressing forms or between 2 to 3 years after the onset of pruritus. In general, icterus suggests transition to the final stage. The bilirubin value mostly remains stable below 5.0 mg/dl for months or years, while clinical symptoms as well as hepatic erythema grow in intensity. Dark urine and acholic stool are observed. The AP, LAP and γ-GT levels are (noticeably or even markedly) elevated; transaminases remain within the range of 30−100 U/l. The parameters relating to the rate of synthesis (cholinesterase, Quick's value, albumin) decrease. The galactose elimination capacity is significantly reduced. (244) The γ-globulins and P-III-P are elevated. Serum copper is often increased, and copper secretion in urine is likewise higher.

### 4.6.5 Final stage (V)

Clinically, morphologically and biochemically, the overall picture of cirrhosis prevails (in 4 years: 30−50%); however, 20% of precirrhotic patients do not show any progression. PBC ends fatally either due to bleeding of oesophageal varices (50%) or liver insufficiency. This final stage is reached after a period of 8 to 15 years (depending on individual progression).

## 4.7 Complications

Owing to the greater sensitivity of PBC patients to pharmaceutical preparations, different pharmacons, e. g. phenothiazines, contraceptives, oestrogens and anabolic steroids, can reinforce cholestasis and the clinical symptoms, thus aggravating the course of disease. • *Gallstones* are frequently detectable (35−40%); as a rule, they are pigment gallstones. Administration of clofibrate is con-

traindicated; it gives rise to increased formation of gall-stones due to enhanced cholesterol secretion into the bile. • *Xanthomas* can lead to mechanically induced neuropathy. (272) *Malabsorption* of fat-soluble vitamins due to steatorrhoea resulting from bile acid deficiency causes corresponding deficiency symptoms. (168, 257) • *Osteopathies* occur in 20−60% (−100%) of cases; a decrease in bone density may be measurable at an early stage. Osteoporosis occurs twice as often as in the general population. The cause is multifactorial (e.g. deficiency of calcium, vitamin D and oestrogen, long duration of disease, genetic factors). Osteomalacia is less frequent. In both forms of osteopathy, excretion of hydroxyproline in urine is increased as a sign of the enhanced rate of bone absorption. (78, 105, 113, 128, 129, 133, 208, 217, 228, 232) • About 20% of patients are suffering from asymptomatic urinary tract infection. Hepatocellular carcinoma develops in about 6% of PBC cases. PBC may sometimes be accompanied by severe complications, leading to a poorer prognosis. (s. tab. 32.2)

   − ascites
   − hepatic encephalopathy
9. Renal tubular acidosis
10. Xanthomatous neuropathy (272)

**Tab. 32.2:** Complications of PBC (with some references)

## 4.8 PBC-associated immunologic diseases

Apart from complicative developments, the course of PBC is also aggravated by associated diseases, which occur almost exclusively as immunologic disorders. About 25% (−40%) of all patients with PBC contract one or more such diseases. As a result, the quality of life is considerably impaired, further complications are induced or reinforced, and the prognosis worsens. (s. tabs. 32.3, 32.6)

27. Thrombocytopenia (253)
28. Thyroiditis, hypothyroidism (96, 106)

**Tab. 32.3:** PBC-associated immunological diseases (with some references)

## 4.9 Diagnosis

First of all, the diagnosis of PBC is based on the patient's **discomfort** in the form of fatigue, decline in functional capacity and pruritus, all of which, however, are uncharacteristic symptoms. PBC is verified if the following **laboratory parameters** can be demonstrated:

---

1. γ-GT ↑, AP ↑, LAP ↑
2. IgM ↑
3. Evidence of AMA
   − with subtypes (AMA profile)

---

The diagnosis of PBC should be supplemented by **laboratory values,** such as GPT, GOT, cholinesterase, cholesterol (especially HDL fraction), LP-X and/or α-lipoprotein, the galactose test, bilirubin as well as IgG and electrophoresis, possibly also P-III-P and the MEGX test. Because of their prognostic weighting, these values (including γ-GT and AP) are considered to be the main parameters for monitoring the course of disease and success of therapy. Furthermore, they co-determine the most suitable time for liver transplantation.

In the first instance, **morphological diagnostics** is based on *laparoscopy,* and, as a general principle, this method should be used for the initial diagnosis. All essential endoscopic findings are documented photographically. Naturally, laparoscopy does not produce a diagnosis of PBC, but it facilitates classification into the respective stages I−IV. (118, 184, 207) (s. p. 645) (s. fig. 32.8) • Targeted *liver biopsy* is then carried out by laparoscopy, whereby biopsy material is taken from both the right *and* left lobes of liver. The histological diagnosis of PBC is very unreliable because of the different patterns of morphological findings and the fact that criteria of the various stages can coexist. Nevertheless, targeted liver biopsy is imperative, even if the diagnosis is based upon reliable laboratory values: it facilitates an important additional assessment of inflammatory activity. (s. figs. 32.7, 32.9) • **Ultrasound** and **CT** do not yield any further diagnostic information. Lymphadenopathy is frequently present. (103, 109, 192, 230) Hepatobiliary sequential **scintigraphy** demonstrates a 7 to 10-fold prolongation of the excretory phase in stages III and IV. (174, 224, 256) (s. fig. 13.7) • The **MRI** periportal halo sign is deemed to be highly specific for PBC. (287) • Although **ERCP** plays an essential role in differential diagnosis, it cannot produce a diagnosis of PBC in itself. In the later course of disease, the bile ducts show certain irregularities and rarefaction (as ambiguous findings). (s. fig. 32.10)

***Fig. 32.10:*** ERCP shows smooth bile ducts of normal calibre; in later stages, there is rarefaction of bile ducts, and certain irregularities appear

## 4.10  Prognosis

Life expectancy ranges from 9−15 years following the diagnosis of PBC. The patient's life span is thus shorter than in the general population. The course of asymptomatic PBC is variable and difficult to predict. Some (25−35%) will never become symptomatic and others will run a progressive downhill course. The survival time of asymptomatic patients is generally longer than that of symptomatic patients; about 45% of cases were still asymptomatic at death. (242) Approximately 26% of PBC patients developed acute liver failure; in 39% of cases, liver transplantation could be kept until the censor date. (241) An individual prognostic assessment is desirable for the initiation of therapeutic measures. Indeed, several prognostic models have become established in recent years, e. g. Mayo model for survival (E.R. DICKSON et al., 1989). (86, 125, 225, 249, 256) • *Female patients* (only a very low number of males are affected) contract PBC in middle age (between 35 and 60 years). *Pregnancy* after the onset of PBC is very rare (so far < 20 cases have been reported). (222) • An *early diagnosis* in the presymptomatic or, at the latest, in the oligosymptomatic stage offers the best prognosis. This is also true if the stage of disease is identified at a relatively early age (between 35 and 45 years). The *AMA profile* is apparently of some significance in early diagnosis (s. p. 120): in long-term follow-up over a period of up to 18 years, the poor prognosis of patients with profile C was only identifiable after 8−9 years, and with profile D after 6−7 years. In other studies, AMA profiles were not confirmed as a prognostic parameter. The profile of AMA subtypes does not change during the course of PBC. (s. tab. 5.21) • Those courses with less favourable prognoses showed a greater increase in *IgG values* as a sign of more distinct immunologic activity and correlated with increased TNF. • The presence of *SLA/LP antibodies* has a high specificity for the development of a secondary AIH overlap syndrome. (s. p. 660)

With regard to laboratory parameters, an increase in *bilirubin* to > 5−6 mg/dl is considered to be an essential prognostic factor. In such cases, the average life expectancy is now less than 2 years. A decline in the *synthesis rate* of the liver (cholinesterase, Quick's value, albumin) is usually also evident. Follow-up checks by means of the *galactose test* (244) are useful. Severe *cholestasis,* which can hardly or not at all be influenced, has to be rated just as poorly in terms of prognosis as a therapy-resistant and progressive pruritus. Increasing *portal hypertension* together with its complications, e. g. oesophageal varices, ascites and/or oedemas and hepatic encephalopathy, point to the final stage of PBC or to decompensated liver insufficiency. • Based on the pattern of these prognostic factors, important decisions can be taken with regard to drug therapy and possibly also the date of liver transplantation. • Histological findings are not suitable for the prognostic assessment of PBC.

## 4.11 Therapy

### 4.11.1 Symptomatic therapy

**Pruritus:** The relief or elimination of the unbearable itching is a top priority of any symptomatic therapy. (s. tab. 13.11) • Recommendations include: *cholestyramine* (8−30 g/day, gradually increasing dosage) or *cholestipol* (15−30 g/day), *phenobarbital* (5−20 mg/kg BW/day or 120 mg at night), *naloxone* (0.2 µg/kg BW/min i.v. infusion or 0.4−0.8 mg i.m.), *rifampicin* (10 mg/kg BW/day) (121) *prednisolone* (10−20 mg/day), *metronidazole* (3 x 250 mg/day for 1 week), *antihistamines* and *propofol* in low doses, or *ultraviolet therapy* (9−12 min/day). The success rate of rifampicin was 80%, but 10−15% of patients suffered considerable side effects, including oedema of the lower leg (L. BACHS et al., 1992). *Ursodeoxycholic acid* (10−15 mg/kg BW/day) proved valuable; the success rate in stages I−II was 80−100% and in the precirrhotic stage III 40−60%. • In persistent PBC, there can be even more intensive pruritus despite treatment with UDCA. Itching which cannot be influenced or which becomes more intense generally points to an unfavourable prognosis. • In a case with refractory pruritus, a single **MARS** treatment effectively improved itching. Repetitive procedures are necessary to sustain this effect. (212)

**Osteopathy:** Prevention or improvement in osteopathy typical in PBC can be achieved by means of UDCA. In addition, sodium fluoride (50 mg/day), calcium (1,500 mg/day), alendronate (10 mg/day orally), and vitamin D, e.g. 1.25 $(OH)_2$ $D_3$ (500−5000 units/day orally) should be administered. Calcitonin (50 units 3×/week i.m.) has also been used. (113) Substitution of oestrogens is advisable for postmenopausal women. (228) • Daily **muscular activity** is considered to be the most important measure (e. g. regular physical exercise, stretching exercises, purposeful swimming). *Every patient should engage in physical exercise as a daily "must", because this is very effective for the activation of the muscular system* (s. pp 536, 732):

> Twice a day, 10 to 15 slow knee-bends (= thigh muscles), plus 10 to 15 times standing on tiptoe (= calf muscles), plus 10 to 15 times upper arm flexing (= biceps), plus 10 to 15 times bending from the waist (= back muscles). This activates > 60% of the total musculature on a daily basis without any special effort or expense, i.e. in the home environment, "in all weathers". Such regular exercise is essential for both prevention and treatment of osteopathy.

The administration of **medium-chain triglycerides** has a positive influence on the malabsorption of fat when accompanied by an adequate intake of proteins. Pancreas enzymes may be helpful. • **Simvastatin** or **bezafibrate** can be successfully used in the treatment of hypercholesterinaemia. (154, 155, 172, 245) • The deficiency of **fat-soluble vitamins** (A, D, E, K), accompanied by malabsorption of fatty acids, is treated by i.m. administration of these vitamins as combined medication (1−2 times a month). • **Zinc deficiency** requires substitution of this trace element. • The desired continuous detoxification of the intestine can be achieved by the use of **lactulose.**

### 4.11.2 Approaches to causal therapy

Drug therapy is of little help except as a form of symptomatological or adjuvant treatment. Up to now, there is no causal or specific treatment for PBC. • Several substances, also in combination, have been used and partially tested in clinical studies over recent years. • *The therapeutic objectives in the choice of substances included prevention of an autoimmunologic inflammatory process, inhibition of fibrosis or improvement of chronic cholestasis with its unfavourable consequences.* (157)

**Azathioprine:** As early as 1967, immunosuppression was attempted in PBC by means of azathioprine, but no positive influence on clinical course, laboratory parameters or morphological findings could be achieved. (111) • Subsequent studies have sometimes yielded encouragingly good results. Side effects are rare; despite occasional leucopenia, the risk of infection is not increased. (92)

**Penicillamine:** The high copper content of the liver led to the use of this substance in PBC. No positive effect on the disease could be ascertained. (80, 102, 218) In 46% of cases, severe side effects forced the discontinuation of therapy. (102) In individual cases, however, an improvement in the survival rate could be achieved with penicillamine during the late stages of PBC. (107)

**Chlorambucil:** A favourable influence on laboratory parameters and on inflammatory changes in histology was observed, but the morphological progression of PBC was not halted. Moreover, therapeutic use of chlorambucil is unacceptable owing to the danger of bone-marrow toxicity. (138)

**Colchicine:** This substance has been used in several studies over a period of up to 4 years (0.6−2.0 mg/day). There was an improvement both in laboratory values and in the survival rate (84% vs. 69% in the placebo group) (284) as well as in the mortality rate (21% vs. 47% in the placebo group). (156) Therapeutic efficacy was good. Side effects, mainly in the form of diarrhoea, were minimal (10−15%). (81, 158, 175, 298)

**Prednisolone:** There was no effect on laboratory values, progression or survival rate following an initial dosage of 30 mg/day and a maintenance dosage of 10 mg/day. Increased demineralization with the development of osteopathy only occurred during the first few months under high prednisolone doses. (202, 210) • In some patients, however, a favourable effect on laboratory values and histological inflammatory activity could be achieved using prednisolone. • This was confirmed by our own experience. (170) It is essential to keep the prednisolone dosage as low as possible − with consistent osteopathy prophylaxis (s. p. 646). • **We should have "respect" for, but no "fear" of prednisolone.**

**Cyclosporine A:** Cyclosporine was used for the first time by G. ROUTHIER et al. (1980) and by G.J.M. ALEXANDER et al. (1984) with encouraging results, yet with nephrotoxic side effects. In subsequent studies, the clinical picture and laboratory parameters as well as histological findings also showed significant improvement. However, an impairment of renal function and the occurrence of hypertension have to be anticipated. (180, 189, 288)

**Methotrexate:** The treatment of PBC with methotrexate was attempted for the first time by M.M. KAPLAN et al. (1988): the results

were encouraging, but histology was unaffected. An initial dosage of 3 x 2.5 mg/week and a long-term dosage of 3 x 5 mg/week is recommended. Methotrexate should only be administered during the precirrhotic stages (I, II, II−III). (67) The hepatotoxicity of methotrexate, depression of bone marrow and possible development of interstitial pneumonia limit the use of this substance and may even force discontinuation of therapy. Administration of methotrexate led to better results regarding clinical symptoms, laboratory parameters and histology compared to a second group which received colchicine. (158)

**Ursodeoxycholic acid:** F. Ichida et al. (1961) and T. Nakahara et al. (1975) were the first to report on the efficacy of UDCA in patients with *chronic hepatitis*. (s. p. 705) • In 1988 our group demonstrated obvious (and lasting) effects on the clinical and laboratory course with the use of UDCA in patients with a severe form of *acute viral hepatitis B*. (s. p. 437) • The first results of treatment of *primary biliary cholangitis* were submitted by the group of U. Leuschner et al. (1985). During the following years (1986−1989), several clinically uncontrolled studies were published, all of them confirming the success of treatment in patients with PBC. The efficacy of hydrophilic UDCA is mainly based on the displacement of hydrophobic, potentially hepatotoxic bile acids. (173, 174, 296) So far, numerous clinically controlled studies regarding the use of UDCA in PBC have been carried out. The effects on clinical symptoms, laboratory parameters, AMA or IgM titres and histological findings ranged from good to very good, and a delayed formation of oesophageal varices was witnessed. Morphological lesions were shown to remain constant over a period of 6 years. (200) Progression was slowed down by UDCA, even though it was not possible to cure PBC. (176) However, contradictory results have also been submitted according to which PBC was only temporarily influenced by UDCA, and the development of cirrhosis could not be prevented. Nevertheless, UDCA proved to be significantly superior to all other substances and is now regarded as the drug of choice. The modes of action of UDCA are considered to be choleretic, hepatoprotective, immunomodulatory, membrane-stabilizing, anti-apoptic and membrane transporter-influencing. • A *dosage* of 13−15 mg/kg BW/day is recommended, divided into 3 single doses. Early commencement of therapy and lifelong application (without UDCA-free phases) are necessary! The survival rate has improved significantly (R. E. Poupon et al., 1997). Except for diarrhoea, no side effects are known. (63, 71−73, 95, 99, 114, 136, 141, 178, 186, 187, 201, 219, 227, 231, 235, 237, 238, 262, 270, 276, 280, 296) (s. p. 857)

**Tauro-ursodeoxycholic acid:** This substance (TUDCA) has a hepatoprotective effect, even against toxic hydrophobic bile acids. In a dosage of 9 mg/kg BW/day, efficacy in PBC is similar to that of UDCA.

**Mycophenolate mofetil:** Esterification of the immunosuppressive agent mycophenolic acid (MMA) leads to mycophenolate mofetil (MMF) as a prodrug with improved oral bioavailability. MMF (2 g/day) was first administered in PBC, combined with UDCA, by E. A. Jones et al. in 1999. In a later study, they were able to confirm their good results (based on selectively and reversibly inhibiting

lymphocyte function) and the safety profile of MMF in long-term administration. (151)

▶ **Lamivudine + zidovudine:** Due to the fact that viruses are believed to play an important role in pathogenesis, lamivudine and zidovudine were added to the UDCA treatment which so far had been unsuccessful. After 12 months, the majority of patients showed a normalization of the transaminases and alkaline phosphatase as well as a considerable improvement in histological findings. (198)

**UDCA + colchicine:** A combined application with colchicine was proposed in 1992 (600 mg UDCA + 1 mg colchicine/day) since the outcome of UDCA therapy had not been fully satisfactory. Good results were obtained with minor side effects. In a subsequent study, this combination therapy showed a slight advantage when the treatment was introduced in the early stages of PBC. (159, 235, 255, 281)

**UDCA + methotrexate:** It was frequently observed that not all patients with PBC responded to treatment with UDCA or that the disease even progressed. Therefore, a combination with methotrexate (1.5 mg/week) was introduced in 1993, which produced favourable results in some cases. (86) However, the side effects of methotrexate were considerable. This combination did not prove to be any more effective than UDCA alone, so that the application of methotrexate was considered to be inadvisable. (185)

**UDCA + prednisone:** In 1994 F. H. J. Wolfhagen et al. succeeded in favourably influencing the course of disease with a combination of UDCA and prednisone (10 mg/day) in those cases which had not previously been treatable in a satisfactory way. (290) • The combination of **UDCA + budesonide** has also proved successful. (64, 177) Budesonide shows a 15-times higher affinity to the glucocorticosteroid receptor as well as a distinct first-pass effect of >90%. The systemic side effects are low. • In cirrhosis, budesonide is contraindicated.

**Azathioprine + prednisolone:** As early as 1984, I reported on the good results obtained in 37 female patients (stages I−III) who had been treated with azathioprine (maintenance dose 1−2 x 50 mg/day) and prednisolone (initially 40 mg, maintenance dose 4−6 mg, intercurrently 8 mg) over a period of 2 to 13(!) years. Later on, a maintenance dose of 50 mg azathioprine every second day proved sufficient. (At that time, UDCA was not yet at our disposal.) The clinical and biochemical values during this long period of time can be described as good to very good; the histological changes likewise showed significant retrogression, and unspecific scarred residues were found. Consistent compliance with adjuvant measures (nutrition, fat-soluble vitamins, medium-chained triglycerides, muscular training) kept the side effects (osteopathy, diabetes, cataract, changes in the blood count) acceptably low. (170)

▶ **UDCA + prednisone + azathioprine:** More recent results presented by F. H. J. Wolfhagen et al. on the first implementation of this triple therapy showed an impressive improvement in clinical, biochemical and histological findings. Dosage was as follows: UDCA (usual dose), prednisone (30 mg/day, gradually reduced to 10 mg/day) and azathioprine (50 mg/day). (291)

**Prednimustine:** The use of this substance (9 mg chlorambucil + 11 mg prednisolone) led to the normalization of bilirubin, IgM and alkaline phosphatase; however, these values increased again on discontinuation of prednimustine. (183)

**Cyclosporine + prednisolone:** Good treatment results were reported following the combined use of cyloisporine (2.0−2.5 mg/kg BW/day) and prednisolone (4−8 mg/day).

**UDCA + bezafibrate:** This combination treatment also proved successful. The dose of UDCA was 600 mg/day and that of bezafibrate 400 mg/day over a period of 12 months. The administration of bezafibrate alone also produced good results. (155, 172) Recently, similar efficacy was reported in another study. (143)

**UDCA + sulindac:** The additional administration of sulindac, a non-steroidal antirheumatic agent (100−300 mg/day), showed an improvement in laboratory parameters − probably due to its choleretic effect. (179)

**Alanine:** In end-stage PBC, treatment with alanine (18 g/day) led to a remarkable improvement in jaundice, pruritus and laboratory values. (223)

**Boswellinic acids:** Leukotrienes appear to play a special role as inflammation mediators in the pathogenesis of PBC; they also correlate closely with the increase in cholestasis-indicating enzymes. Boswellinic acids are selective non-redox inhibitors of 5-lipoxygenase and therefore inhibit leukotriene biosynthesis. So far, they have not been used in PBC treatment. Based on existing pharmacological data, their application should now be considered.

### 4.11.3 Therapy concepts

The very extensive literature available on the treatment of PBC indeed provides valuable information for developing useful therapy concepts. *In this respect, the main aim is to apply a course of drug therapy which is as efficacious as possible with the fewest side effects.* • The following can be considered as evidence of **success:** (*1.*) improvement in life quality, (*2.*) tendency towards normalization of laboratory parameters (especially of bilirubin), (*3.*) regression of the inflammatory changes in histology or prevention of their progression, (*4.*) prolongation of life, and (*5.*) prolongation of the period of time prior to liver transplantation.

▶ In this respect, it must be remembered, that the **histological results** are extremely unreliable regarding both initial diagnosis and follow-up, because as a rule only one biopsy sample is taken percutaneously. The rate of error is so high in fact that the results are of little value, and thus initial diagnosis should also include targeted biopsy from both liver lobes by laparoscopy as well as photographic documentation of the liver surface.

At first, **symptomatic measures** (s. p. 648) are required in order to eliminate pruritus, prevent malnutrition, counteract osteopathy by means of regular physical exercise and eliminate the occurrence of complicative developments. This also includes careful observation with regard to any possible side effects of medicaments or metabolic disorders. • The intensity of these measures as well as the intervals between any necessary monitoring measures depend on the initial findings and the individual course of disease.

When applying the **substances** described above or their possible combinations, the efficacy spectrum of the remedy and the respective risk of side effects always have to be weighed against each other. In *long-term treatment*, a reduction in dosage may serve to lower the risk of side effects while maintaining a satisfactory level of success.

1. Irrespective of PBC stage (s. pp 643, 645) and AMA profile (s. p. 119), **UDCA** (13−15 mg/kg BW/day or 900 mg/day) is considered to be the drug of choice to be applied *as soon as possible and then continuously*!

2. At an advanced stage (II, III) with AMA profile B, the combination of **UDCA + prednisolone** (maintenance dose 4−8 mg/day in the morning) should generally be administered as first medication. • In the case of unsatisfactory therapeutic results or with AMA profiles C or D (= stages III or IV), we would recommend the additional administration of **azathioprine** as a triple therapy. A dosage of 1 x 50 mg (up to 2 x 50 mg) per day is well-tolerated and, like prednisolone at this dosage, has relatively few side effects. A maintenance dose of 50 mg every second day may be sufficient. (170) • The *immunomodulatory action of UDCA* is thus combined with the *immunosuppressive effect of azathioprine*, while the *anti-inflammatory characteristics of the steroids* are also included, i.e. *the two-substance combination is extended to a triple combination if necessary, especially in profiles C or D.*

3. **Colchicine** (0.6−2.0 mg/day) has relatively minor side effects. As far as I know, the combination of **UDCA + prednisolone + colchicine** has never been applied in PBC stages II−IV or AMA profiles C and D, although this seems plausible from a pharmalogical point of view.

In the light of current knowledge and in view of the reinforced effect, there should be no objection to using a combination of **UDCA + methotrexate + colchicine;** nevertheless, the frequency of side effects due to methotrexate must be considered.

### 4.11.4 Liver transplantation

The symptomatic measures and a suitable combination of pharmacons are primarily aimed at preventing PBC progression and improving or even normalizing the findings. If this is not successful, the secondary aim is to achieve the longest possible period of time between initial diagnosis and *liver transplantation, which is the only chance in the late stages (IV, IV−V), and hence the therapy of choice.* The **optimal date** depends on general conditions, increase in the bilirubin value up to >6 mg/dl, but <9 mg/dl, extent of osteopathy, onset of water retention (oedema, ascites) and occurrence of drug-induced side effects, all of which rule out any further medication. If the bilirubin value is in excess of 9 mg/dl, the patient should in any case consult a transplantation centre.

The **success rate** of OLT is convincing in cases of PBC. However, consistent and regular osteopathy treatment

during the postoperative phase, e. g. muscular training (s. p. 587) and drug therapy, is also of great importance. The 1-year survival rate was 93%, the 5-year survival rate was 76%, and the 8-year survival rate was 71%. About 80% of transplant patients become completely rehabilitated and are able to work again. Retransplantation is necessary in 10% of patients because of a "vanishing bile-duct syndrome". Most manifestations of PBC disappear, and even a reduction in bone changes may occur. In the first few months after LTX, osteoporosis becomes far more pronounced; the loss of bone density can be as much as 20%. There is a risk of spontaneous fractures. The rate of occurrence of PBC in the graft (granulomatous bile-duct damage, ductopenia, biliary-type fibrosis) increases with time: after 10 years, it may be observed in 30−50% of patients. The risk factors are unknown. Cirrhosis has only rarely been reported. Differentiation between PBC relapse and rejection of the transplant is very difficult, because both present a similar morphological picture. However, patients with PBC show an increased frequency of chronic transplant rejection in comparison to other liver transplantation patients. After transplantation, AMA are still verifiable in the serum. (97, 105, 131, 160−162, 181, 250, 273, 289)

# 5 Primary sclerosing cholangitis

▶ The report by K. Delbet in 1924 is considered to be the first observation of a sclerosing cholangitis. (325) In 1958 J. Seymour et al. distinguished between primary and secondary forms of the disease. (421)

## 5.1 Definition

Progressive, fibrous-stenosing and obliterating, predominantly segmental inflammation of the intrahepatic and/or extrahepatic bile ducts is described as idiopathic PSC. The aetiology and pathogenesis of this chronic cholestatic disease are still unknown. In patients with a genetic predisposition, it is actually deemed to be an autoimmune disease. The course is slowly progressive, yet very variable and unpredictable. PSC is a rare condition; it is closely associated with ulcerative colitis and less closely with Crohn's disease. • In general, PSC develops into *biliary cirrhosis* (s. p. 646) with corresponding complications.

## 5.2 Systematics

*Secondary sclerosing cholangitis* (SSC) is distinguished from "classical" *primary sclerosing cholangitis* (PSC). The secondary type shows clinical, morphological and radiological findings identical to those of PSC. Manifest SSC is irreversible. While the origin of (idiopathic) PSC has not yet been resolved, secondary sclerosing cholang-

itis can be attributed to various known causes. Until its aetiopathogenesis is clarified, PSC (like PBC) should continue to be defined as a particular form of "idiopathic" disease. (s. tab. 32.4)

## 5.3 Epidemiology

▶ PSC, which was seldom described in the past, has been identified more and more frequently since the introduction of ERCP. • The prevalence of PSC is estimated at 1−5/100,000 inhabitants. About 70% of patients are males; they are affected twice as often as females. People aged between 25 and 45 years are most often affected. (318) PSC in childhood is a rarity. However, isolated cases have been diagnosed even at the neonatal stage. (329, 334, 336, 339, 372, 413, 423, 426, 440, 446) • There is a close association with simultaneous chronic inflammatory bowel disease (60−75%, up to 100%), whereby ca. 80% of cases involve ulcerative colitis, and only 10−15% Crohn's disease. PSC without concomitant CIBD affects mostly women. (s. p. 653) Smokers contract ulcerative colitis and PSC far less frequently than non-smokers (4% vs. 70%). (381) Perinuclear anti-

neutrophilic cytoplasmic antibodies (pANCA) can also be detected in healthy members of the PSC patient's family.

## 5.4 Aetiopathogenesis

► A **genetic disposition** is assumed for the occurrence of PSC. This idea is supported by the fact that the disease has often been observed in certain races or families. (358, 366, 410)

**HLA haplotypes:** Frequent associations with special HLA haplotypes point to a specific immunological disposition in patients: HLA-B8 (60−80%), HLA-DR3 (25−70%) and HLA-DRw52a (100%) (the last-mentioned is said to be highly specific to PSC). HLA-DR2 is determined in up to 70% of HLA-B8-negative and HLA-DR3-negative patients. An association with HLA-DR4, HLA-DRb12, HLA-Drw17, HLA-Cw7, HLA-DQw2, HLA-A1 and HLA-DW has also been demonstrated. The discrepancy in findings may result from regional, individual, methodological and age differences within the patient cohorts. (315, 327, 390, 409) • A further specific feature is the aberrant expression of **blood group antigens** (A and B) on bile-duct epithelial cells and colon mucosa cells.

**Cellular immunity:** The decline in T lymphocytes resulting from a drop in the number of CD8$^+$ suppressor cells points to pre-existing cellular immunity (increase in the quotient CD4$^+$ : CD8$^+$), as does a rise in B lymphocytes (with an increase in T lymphocytes in the portal fields); an inhibition of leucocyte migration was likewise found. D. H. Adams et al. (1991) identified an elevated expression of the ICAM 1 on the bile-duct epithelia.

**Humoral immunity:** Indicators of the existence of humoral immunity are: hypergammaglobulinaemia with a predominance of IgM antibodies (321, 436); evidence of circulating immunocomplexes (>80% of cases), also in the bile; activation of the complement system. (420) • Antibodies were found with the following prevalence: SMA (<1:80) (60%), anticolon antibodies (60%) and ANA (<1:80) (35%). (386, 448) The detection of these antibodies did not correlate with disease activity.

**pANCA:** The perinuclear antineutrophilic cytoplasmic antibodies, particularly types IgG$_1$ and IgG$_3$, are important. (328, 367, 380, 388, 403, 419, 448) (s. pp 120, 654) (s. tab. 5.20)

**ARP:** An anti-ribosomal P antibody was recently reported to be present in 80% of PSC patients.

It is still unclear whether these findings constitute disorders of pathogenetic relevance or immunological epiphenomena. Yet there is every reason to believe that PSC is an autoimmunological disease, which is triggered or initiated by different agents (e.g. toxins, infections (407), viruses) in predisposed patients and in cases of reduced barrier function of the gut. • Due to increased permeability of the mucosa in CIBD, endotoxins reach the liver via the portal vein. However, it has not been confirmed that endotoxins are in any way pathogenetic. It is significant that the morphological changes are (apparently) predominantly segmental, even though immunological reactions are, in fact, systemically disturbed. • Ulcerative colitis and other inflammatory bowel diseases are of no primary pathogenetic importance. A connection with vascular components (e.g. association of PSC with periarteriitis nodosa) is unlikely. Furthermore, a disorder of copper metabolism does not play any pathogenetic role.

## 5.5 Morphology

► However important the **liver biopsy** sample may be for the characterization of PSC (or PBC), the assessment of each individual finding can be problematic: liver changes often show a focal arrangement, while portal and lobular lesions can vary in degree; the signs of damage frequently overlap, depending on the stage of disease. Furthermore, no histological picture typical of PSC exists. In 25−50% of biopsies, no findings pointing to PSC are detected at all; in 40%, histology is generally decisive, but with almost the same frequency even stages III and IV were not recognized. • **Laparoscopically,** stages I and II display a liver surface which is still smooth. To an increasing degree (stages II, II−III), finely structured fibrosis as well as greyish-green maculation can be identified. • The terminal stage is characterized by mixed-nodular *biliary cirrhosis* of a greyish-green to dirty grey colour. Liver biopsy, which is always regarded as a necessity, should be carried out as a targeted procedure during laparoscopy when establishing the initial diagnosis; in fact (as is the case with PBC), samples should be taken from *both* liver lobes in order to increase diagnostic reliability. (s. p. 646) The surface structure of the liver must be described in detail and documented by means of photographs. (s. fig. 32.11)

*Fig. 32.11:* Primary sclerosing cholangitis following cholecystectomy (due to involvement of the gall bladder); distinct periportal fibrosis with initial surface roughness

The **biliary ducts** are affected intrahepatically in 20%, intra- and extrahepatically in 70−75% and extrahepatically in 5% of cases. Differentiation between "large-duct" and "small-duct" PSC by means of ERC or MRC may also be of importance. • **Small-duct PSC** (termed *pericholangitis* by A. Wee et al., 1985) is a variant of PSC involving only the small bile ducts. Probably, it is an early stage of PSC. It cannot be demonstrated by means of ERC. Marked cholestasis is evident. Prognosis is better than in large-duct PSC. (304, 382, 383, 391)

**Stage I:** The **portal stage** is characterized by a widening of the portal field as a result of proliferations of the interlobular bile ducts, by formation of connective tissue and periductal oedema as well as by portal infiltrations (so-called portitis + cholangitis). The bile-duct ephithelia show degenerative and atrophic changes, and even cell necrosis. Occasionally, bile-duct ectasia is evident. (s. fig. 32.12) (349, 388, 405, 439)

**Fig. 32.12:** PSC: periductal fibrosis and inflammatory infiltration; aneurysmal bile-duct ectasia (HE)

**Stage II:** The **periportal stage** presents an encroachment of the inflammatory changes on the parenchyma with piecemeal necrosis; connective tissue proliferations also break into the lobule (so-called periportal hepatitis + fibrosis). Liver cell necroses are also found sporadically, whereby CD4 cells, CD56-NK cells and lymphocytes are markedly increased. In places, reduction in and fibrosis of bile ducts are already in evidence. (s. fig. 32.13) (335, 349, 384)

**Fig. 32.13:** PSC: marked concentric fibrosis around a septal bile duct as well as slight periportal inflammation (HE)

**Stage III:** The **septal stage** displays periportal and bridging necrosis as well as an increasing loss of bile ducts with a simultaneous decline in portal inflammatory infiltrations. Dense concentric fibrosis develops around

the bile ducts (so-called onion-skin appearance), and a portoportal band of connective tissue (bridging fibrosis) is subsequently formed. Occasionally, segmental PSC is found. (353) • MRI and CT often show a focal atrophy of segments 2 and 3. (335, 365, 384)

▶ **Stage IV:** In this stage, **biliary cirrhosis** exhibits a loss of interlobular and septal bile ducts and the formation of regenerative nodes as well as distinct septation and connective tissue fields. As a result of cholestasis, the liver parenchyma contains high concentrations of copper. • The *extrahepatic bile ducts* appear as string-like thickened cords with a narrowing of the lumen. The *gall bladder* may likewise be involved in a process of chronic fibrosing inflammation. (314, 356, 435) (s. fig. 32.11) • *Transitions* between the precirrhotic stages and biliary cirrhosis are found to be fluid in the *biopsy material*, and in part overlap; occasionally, even normal intralobular bile ducts alternate with inflammatory, periductal infiltrations or bile-duct scleroses. The *autoptic examination* may conflict with the result of liver biopsy. (335, 348, 364, 388, 441)

## 5.6 Clinical aspects

In the early stages, PSC can be clinically **asymptomatic** in 10−40% of cases. Initially, laboratory tests often reveal an inexplicable state of cholestasis by chance. However, cases with normal alkaline phosphatase have also been reported. (307, 351, 365, 404, 408)

The **symptomatic course** starts slowly, mostly with fatigue, loss of vitality, pruritus, occasional scleral icterus, upper abdominal pain on pressure, loss of weight and fever. Hepatomegaly is verifiable in 50−75% of cases; splenomegaly is less frequent. The type and intensity of the discomfort as well as the clinical findings vary remarkably from patient to patient. In general, these symptoms have already existed for about two years prior to initial diagnosis. (351, 375, 441) • An increase in γ-GT and alkaline phosphatase is a first and important sign of the existence of hepatobiliary disease. But even in a symptomatic course, normal values of AP have been reported. (307) This observation also confirms the importance of determining LAP in cases of an unresolved increase in γ-GT and normal AP values (AP non-response exists in 2−4% of patients with cholestasis!). IgM is rarely elevated. • In other patients, cholangitic episodes predominate in the clinical picture. • In some cases, the diagnosis is only established in a more advanced course of disease or even during the stage of cirrhosis (with portal hypertension and oesophageal varices). (317, 332, 336, 351, 355, 375, 400, 404, 418, 441, 442)

## 5.7 Diagnosis

The diagnosis of PSC is made on the basis of clinical, laboratory and morphological findings as well as by

ERCP. The **main criteria** of PSC are: (*1*.) chronic cholestasis (γ-GT, AP, LAP), (*2*.) evidence of pANCA, and (*3*.) ERCP or MRC. (323, 336, 388, 404, 418, 437, 445) (s. tab. 32.5)

<div style="border:1px solid">

**I. Suggestive factors**

1. Subjective discomfort
2. Men, 20 to 45 years old
3. Non-smoker
4. Association with chronic IBD
5. Increased transaminases
6. Hepato/splenomegaly

**II. Definite diagnosis**

1. *Chronic cholestasis*       3. *ERCP, MRC*
2. *pANCA +*                          4. *Laparoscopy, liver biopsy*

**III. Supplementary findings**

1. *Laboratory tests*
   − bilirubin ↑                     − cholinesterase ↓
   − IgM ↑                            − α-, γ-globulins ↑
   − HLA haplotypes            − CRP +, ESR ↑
   − ANA, SMA (+)               − haemoglobin ↓
   − serum copper ↑            − eosinophilia
   − cupruria
2. *Sonography, CT*

</div>

**Tab. 32.5:** Indicative, evidential and supplementary parameters for diagnosis of PSC

**1. Association with CIBD:** In 33−93% of cases (mean value 64%), PSC is associated with a chronic inflammatory bowel disease (chronic IBD). Ulcerative colitis clearly predominates in 69−100% of cases (mean value 89%) compared to Crohn's disease in 0−31% (mean value 11%); however, a reversed rate of frequency regarding these two bowel diseases with 38% vs. 56% has also been reported. • The frequency of patients suffering from PSC in chronic IBD is about 3.7% (397), in ulcerative colitis 3.3% and in Crohn's disease 2.5%. • PSC can occur before the determination of chronic IBD, after a long course of chronic IBD and occasionally after colectomy. There is no correlation between the degree of severity of chronic IBD and the course of PSC. (333, 389, 391, 401, 410, 411, 431, 447) • Proctocolectomy does not influence the course of PSC. (319)

**2. Cholestasis:** The values of γ-GT, AP and LAP are elevated (with non-response of AP in 2−4% of cases). Hyperbilirubinaemia is verifiable in about half the patients at the time of initial diagnosis. Copper values in serum and urine are elevated. (299, 345) A slight rise in transaminases is likewise observed. The first diagnostic step in determining cholestasis is sonography.

**3. Sonography:** Except in the late stage, there are generally no findings which point to PSC or explain the existing cholestasis. However, there is evidence of hepa

tomegaly and increased reflections from dilated intrahepatic bile ducts as well as a thickening of the bile duct walls; in addition, splenomegaly (385, 438) or intra-abdominal lymphadenopathy (301) are occasionally found. A nodular transformation of the liver can be detected. Tentative diagnosis by sonography now provides the indication for ERCP. • Compared to sonography, **CT** does not offer any fundamental advantages. (369, 433)

**4. ERC:** This is the decisive examination for the final diagnosis of PSC. It is carried out under periendoscopic protection with antibiotics. Cholestasis can be accelerated by ERC. Typical findings include: *pearlstring-like changes* of the bile ducts with intermittent, diffusely distributed, multiple, irregular, circular strictures of different length (0.5−2.0 cm), with normal or only insignificantly widened bile-duct segments; *diverticular sacculation* of the bile ducts with or without preceding stenosis; segmental or diffuse rarefication of the bile ducts. Serious changes of the bile ducts are invariably found in more advanced stages of PSC. (s. fig. 32.14)

**Fig. 32.14:** ERC in primary sclerosing cholangitis: irregular wall contours, variable intrahepatic and extrahepatic duct stenoses with prestenotic dilatations (subsequently demonstrated bile-duct carcinoma on the basis of existing PSC)

About 80% of patients show both intrahepatic and extrahepatic changes; in 20% of cases, only the extrahepatic bile-duct system is affected. The severest changes are found in the area of the hepatic bifurcation (differential diagnosis: Klatkin's tumour). Distal bile-

duct stenosis is frequent and almost characteristic. The gall bladder can also be involved. (369, 395, 398, 431, 437)

**5. pANCA:** In 80−87% of cases, perinuclear antineutrophilic cytoplasmic antibodies are demonstrable with simultaneous PSC and chronic IBD. In PSC, detection of pANCA is possible in only 40% of patients, but in isolated chronic IBD in 85%. Evidence of pANCA correlates not with the activity of PSC, but with chronic IBD and portal inflammation. After colectomy or liver transplantation, antibodies are still evident in the serum. • pANCA are also found in AIH, PBC, LE, rheumatoid arthritis and autoimmune glomerulonephritis; cANCA can be detected in Wegener's disease. • At the same time, further antibodies can be identified, e. g. ANA (6−35%), SMA (10−60%), anticardiolipin, antithyroid antibodies. (303, 328, 368, 380, 388, 403, 419, 448) (s. tabs. 5.19, 5.20) (s. fig. 5.15)

**6. MRC:** It is only at stages II−III, III and IV that MRC facilitates a reliable assessment of the intra- and extrahepatic bile ducts, whereby it is often even more reliable than ERC. MRC cannot replace ERC in primary diagnostics of PSC, but serves as an important supplementary examination. (306, 330, 337, 354, 395, 412)

## 5.8 PSC-associated diseases

Like PBC, PSC is not limited to the hepatobiliary area. In about 25% of cases, it occurs as an independent disease; however, in more than 70% of patients, chronic IBD exists simultaneously. • Associations with **autoimmune diseases** have been observed far less frequently in PSC than in PBC. (s. tabs. 32.3, 32.6)

| | |
|---|---|
| AIDS | Lymphadenopathy (301) |
| Coeliac disease | Myasthenia gravis |
| Collagenoses | Myelopathy |
| Diabetes mellitus (type 1) | Orbital pseudotumour |
| Folliculitis (360) | Pulmonary fibrosis (357) |
| Haemolytic anaemia (392) | Retroperitoneal fibrosis |
| Hodgkin's disease | Sarcoidosis |
| Hyperthyroidism (312) | Sjögren's syndrome |
| Lupus erythematosus (305) | Vasculitis |

*Tab. 32.6:* Autoimmunological diseases associated with PSC (with some references)

## 5.9 Complications

The volume of the gall bladder is frequently increased. (314, 435) **Cholelithiasis** occurs in 20−25% of patients with PSC; in 30−35% of all cases, cholecystectomy was already carried out prior to initial diagnosis. (s. fig. 32.1) **Choledocholithiasis** (ca. 40%) is regarded as a complication of PSC or even as the cause of SSC. The following figure shows a rare finding in the form of a staghorn calculus taken from the bifurcation of the choledochus and the two branches of the common bile duct (still at our disposal). (s. fig. 32.15)

*Fig. 32.15:* Staghorn calculus in the common bile duct and the two branches of the common hepatic duct (so-called *Mercedes-star type*) in primary sclerosing cholangitis

**Chronic pancreatitis** with typical changes in ERCP is verifiable in 10−12% of patients; exocrine pancreas insufficiency is rare.

PSC is considered to be a pronounced form of precancerosis. The occurrence of **cholangiocarcinoma** must be anticipated in 6−23% of cases (1.5% per year, i. e. 161 times higher than in healthy persons). In autopsies and explanted livers, bile-duct carcinoma has been demonstrated in 30−50% of cases. The frequency rate increases with the duration of disease and the existence of CIBD. This complicative development is suspected in cases of rapidly progressing cholestasis. The diagnosis is difficult to establish; in >80% of cases, CT may yield evidence of cholangiocarcinoma, together with findings of the late stage of PSC. If the formula *CA19-9 + (CEA* x *40)* shows a value of >400 with a sensitivity of 86% (−100%), a CCC is to be expected. (313, 318, 320, 371, 387, 414, 422, 427) • PET is a new diagnostic procedure in this respect. In PSC patients with colitis ulcerosa, the frequency of colon carcinoma is 10 times and that of pancreas carcinoma 14 times higher than in healthy persons. This requires regular coloscopy and sonography. (425) Development of spindle cell carcinoma is extremely rare.

**Osteopathy,** which is expected in chronic cholestasis and often verifiable in PBC as well, is less frequently detected in PSC. (302, 350) **Xanthelasmas,** which are prevalent in PBC, are likewise less common in PSC (19% vs. 3%). • The frequency of **cholangitic episodes,** however, is about 7 times higher in PSC than in PBC; there is a risk of liver abscess formation. • In PSC, **hyperpigmentation** can be identified in only 25% of cases (compared to >50% in PBC). • Cirrhosis-related complications are more frequent in PSC (13%) than in PBC (8%).

## 5.10 Course and prognosis

The natural course of PSC showed a survival rate of 65−70% after 6 years, 75% after 9 years and 30−70% after 5 years, depending on the respective stage of PSC at the time of diagnosis. The average survival rate was calcu-

lated to be 12.9 or 17 and even 21 years, whereby patients with a symptomatic course at initial diagnosis had a far less favourable prognosis: 40−50% (−90%) of patients who died within a 6-year period underwent a symptomatic course. In contrast, a 5-year survival period was witnessed in 78−88% (and more) of asymptomatic patients. In 22−60% of cases with an asymptomatic course of PSC, a symptomatic clinical picture developed within 5 years. Based on current knowledge, it is not possible to predict which patients should be assigned to the risk group. (308, 317, 326, 336, 351, 375, 404, 417, 442, 445)

*These greatly differing figures in the literature reflect the fact that:* (*1.*) due to the inexact definition of PSC, the stage at initial diagnosis is based on different parameters and may vary greatly; (*2.*) the earlier the initial diagnosis is established and therapy is initiated, the more favourable the influence on survival time can be (as is also true for PBC); (*3.*) monitoring and assessment of insidious PSC is inadequate despite such means as selected laboratory parameters, liver function tests, ERC and histology (the last-mentioned at long intervals). Evidence of DR4 points to rapid progression. (390) • *Pregnancy* does not influence the course of PSC, nor does PSC impair the course of pregnancy or harm the embryo or foetus. • Any statement concerning prognosis is dependent on the following **criteria:** bilirubin value in the serum, concomitant chronic inflammatory bowel disease, histological stage of the biopsy specimen (if possible by laparoscopy from both the right and left lobes), hepato/splenomegaly, duration of the symptomatic phase of disease and age.

► There is no standardized evaluation of the valency of **cholestasis parameters:** the variations in weighting the prognosis parameters in the scores clearly show the difficulty of reliable assessment, especially as these parameters are not always obtained by uniform criteria (prospectively or retrospectively). However, the claim that cholestasis parameters do not permit any prognosis to be made must be seen as controversial. In our experience, cholestasis-indicating enzymes and the bilirubin value as well as GEC and the ICG tests (e.g. under UDCA or prednisolone therapy) facilitate an **evaluation of the course of disease** and provide valuable benchmarks for the planning or postponement of invasive and surgical measures. • Knowing the "natural" history of a disease and evaluating its course under therapeutic measures with regular laboratory tests are the two (essential and different) aspects of prognostic assessment.

## 5.11 Therapy

### 5.11.1 Conservative therapy

Therapeutic measures are aimed at improving or normalizing the bile flow as well as reducing inflammatory tissue reactions in order to prevent the progression of biliary obstruction.

There is no specific or causal therapy of PSC. Reduction in or elimination of **pruritus** (341), elimination of **malabsorption** and, if necessary, replacement of fat-soluble vitamins (359), selenium (299) and zinc are the primary targets of therapy − as in PBC. (359) (s. p. 648) • Relapsing cholangitis requires the administration of **broad-spectrum antibiotics;** however, antibiotic prophylaxis is not indicated. (316, 323, 363, 376, 388, 404, 418, 443, 445)

Therapeutic trials with *D-penicillamine* (e. g. 750 mg/day for three years) did not influence the course of disease. *Cyclosporine* and *azathioprine* were also ineffective.

**Cyclosporine + prednisolone:** A combination of cyclosporine and prednisolone, however, proved to be successful. (373)

**Colchicine:** The positive results achieved with colchicine (377) could not be confirmed in a subsequent study. (399)

**Methotrexate:** The use of methotrexate (15 mg/week) led to an improvement in symptoms, cholestasis and histological findings. Application is worth considering in the early phase of PSC. (362, 370) However, occasional severe side effects have to be taken into account. (379)

**Prednisolone + colchicine:** A combination of both substances (10 mg plus 1.2 mg per day) led to an improvement in biochemical findings, but no favourable long-term effect could be demonstrated. (378)

**Ursodeoxycholic acid:** In 1985 UDCA was used for the first time in PSC by the group of U. Leuschner. (s. p. 649) Meanwhile, UDCA has proved to be the drug of choice. Clinical symptoms (322, 394) and laboratory findings (cholestasis, bilirubin) (310, 339, 380, 394, 428) as well as radiological changes and histology (310) could be favourably influenced in numerous patients. An inhibition of the expression of HLA class II antigens on hepatocytes was also verified. However, long-term therapeutic success has not been achieved so far. Administration of UDCA (15−20 mg/kg BW/day) does not cause any side effects. Due to its beneficial effect, this substance should be used in the early phase of PSC (as in PBC), and thereafter continuously. (347, 396, 401, 429, 430, 434)

**UDCA + prednisolone:** UDCA (10−15 mg/kg BW/day) combined with prednisolone (initially about 40 mg/day, declining rapidly to a maintenance dose of 4−6 mg/day) is worth considering in view of the positive therapeutic effects recently reported.

**UDCA + prednisolone + azathioprine:** A triple therapy comprising azathioprine (1.0−1.5 mg/kg BW/day), prednisolone (1 mg/kg BW/day, decreasing to 5−10 mg/day) and UDCA (500−750 mg/day) has been reported for the first time. The (biochemical, histological, cholangiographic) results following an average observation period of 41 months were promising. (416)

**UDCA + methotrexate:** The combination of UDCA (13−15 mg/kg BW/day) and methotrexate (0.25 mg/kg BW/week) was ineffective, and side effects from methotrexate occurred frequently. (379)

**UDCA + sulfasalazine:** Using this combination as treatment, an improvement was achieved in 3 children with PSC. (372)

**Budesonide, corticosteroids** (312) or **pentoxifylline** appear to be of minimal, if any, benefit in PSC.

**Boswellinic acids:** The previous proposal regarding Boswellinic acids also applies to the treatment of PSC (s. p. 652), particularly as this substance has already been used with some success in patients with ulcerative colitis.

### 5.11.2 Invasive therapy

In isolated or short-length stenoses in the extrahepatic bile ducts, palliative but nevertheless effective treatment is possible by means of **balloon dilatation** and **stent insertion.** Generally, balloon dilatation is preferred. Due to the high risk of bacterial cholangitis, the stent should not be in position for longer than two weeks. Sphincterotomy may be necessary. This should precede surgical interventions. Repeated balloon dilatation and intermittent stenting may be indicated in order to bridge the period of time prior to liver transplantation (which is not negatively influenced as a result) and is generally applied in older patients. These measures should be supplemented by simultaneous administration of antibiotics and metronidazole as well as UDCA. (300, 308, 324, 338, 346, 361, 402, 406, 415, 424, 429, 430)

### 5.11.3 Surgical measures

All reconstructive or resective interventions of the bile-duct system (as well as all abdominal operations) have the disadvantage that subsequent orthotopic liver transplantation is rendered more difficult or even impossible. (300, 352) • Intrahepatic **cholangiojejunostomy,** the influence of which on the survival rate was not confirmed, should also be mentioned in this respect. (340) There is a significantly high perioperative risk with increased mortality regarding all of these surgical interventions, particularly in the late stages of PSC. For this reason, all possibilities of endoscopic therapy should be exhausted first.

**Proctocolectomy** may be indicated in the individual case of severe ulcerative colitis, but not in PSC. This operative intervention did not lead to an improvement in PSC in any of the patients. (319) Peristomal varicosis with a risk of haemorrhage sometimes occurs. The infection risk is significantly increased in subsequent liver transplantation.

**Liver transplantation** is the therapy of choice in the late stage of PSC. According to existing publications, the survival rate was: 81% or 94% after 1 year, 71% or 92% after 2 years, 67−86% after 5 years and 70% after 10 years. It is important to determine an optimal date for transplantation. End-to-end anastomosis of bile ducts is often impossible if PSC affects the extrahepatic bile ducts, which is why choledochojejunostomy has to be carried out first in this special case. It has to be taken into consideration that PSC reoccurred in the transplanted liver in 5 out of 32 patients. (343) At first, the pANCA values decrease after LTX, but they return to pre-transplantation levels after one year. The presence of colon carcinoma should be excluded prior to transplantation. After liver transplantation, colitis can exacerbate, and there may also be biliary complications. (331, 342−344, 374, 393, 427, 432, 444)

# 6 Autoimmune cholangitis

▶ The clinical picture of *autoimmune cholangitis (AIC)* was described by G. Brunner and O. Klinge in 1987. (452) All patients were women. A genetic disposition was assumed, as all examined daughters and one granddaughter of the female patients had increased ANA and SMA titres as well (with AMA negativity). Treatment with azathioprine and prednisolone was successful.

Subsequently, this disease was also observed by others and described as *"autoimmune cholangiopathy"* (451, 453, 466) or *"autoimmune cholangitis"*. (464, 474) AIC is not regarded as identical either to PBC and small-duct PSC or to AMA-negative PBC (457, 464) and idiopathic adulthood ductopenia. It may be a variant, i. e. a transitional form between various autoimmune diseases, each of which manifests in a different way. It could also be an initial transitional stage in the early development of a classical syndrome. (454, 457) *AIC is generally considered to be an autoimmune enigma.* (460) Meanwhile, more cases of autoimmune cholangitis have been reported. (456, 461, 462, 467, 468, 470, 472, 473)

The distinction between primary biliary cholangitis and primary or secondary sclerosing cholangitis by differential diagnosis may be made substantially more difficult at times owing to special courses of disease, autoimmune hepatitis or overlap syndromes.

## 6.1 Clinical aspects

In most aspects, immune cholangitis is similar to PBC: subjective *discomfort* corresponds to that of PBC, hepatomegaly is generally present, all the patients are female, the disease usually occurs after the age of 35 and there is a genetic disposition. Coexistent ulcerative colitis is rarely found. • *Laboratory findings* are similar to those of PBC. However, the levels of cholesterol and transaminases are increased to a lesser extent; the values of AP and γGT are generally higher, whereas the IgM values are lower. AMA are negative, while ANA and SMA are verifiable (17−71%). With the more sensitive AMA-immune blot test, 43% of AIC patients showed positive results. (460) Yet, ANA could also be determined in the above-mentioned daughters (and granddaughter) who had not been recognizably ill before (as is the case with AMA in numerous cases of PBC). There is an association with HLA-B8, -DR3 and -DR4. Thus the HLA risk factors are similar to those of AIH type I and PBC, but they differ from those of PSC. Differentiation between AIC and PBC by means of anticarbonic anhydrase II (458) could not be confirmed. (450) • In *histology*, and even in *immunohistochemistry*, immune cholangitis can hardly be differentiated from PBC. (459) However, it shows more substantial hepatocellular necrosis as well as more distinct reactions of the stellate cells around the ductuli, which proliferate into the parenchyma. •

Immune cholangitis differs markedly from the early forms of PSC. In particular, the fibre coats surrounding proliferated ductuli, which are typical of PSC and which develop early, and the PAS-positive colouring of the basal membrane are absent. *Biliary cirrhosis* must be anticipated as the final stage. (454, 469, 471) (s. p. 644) • *Therapy* is with UDCA, first of all as monotherapy. With non-responders, the additional administration of azathioprine plus prednisolone is recommended. In coexistent chronic IBD, the administration of mesalazine (5' ASA) is indicated. Liver transplantation is required in the individual case. (455, 461, 463, 465)

## 6.2 Hypothesis of autoimmune cholangitis

The question arises as to whether *PBC* and *PSC* as well as *AIC* are "merely" **variations** (or subgroups) which can be subsumed under the generic clinical term **autoimmune cholangitis**

In fact, very similar subjective discomfort or clinical findings as well as virtually identical laboratory parameters are found. Genetic disposition is generally verifiable. There is gender-related frequency: PBC and immune cholangitis are witnessed almost exclusively in women, PSC (almost) exclusively in men. (449, 466)

**Immune reactions:** A further difference is found in the variety of cellular and humoral immune reactions which can occur in the neuroendocrinologically influenced system. *Four serological types* are broadly distinguishable. (456) • *Two additional serological types* may well appear as further variants of PSC. The association of PBC and PSC with numerous immunopathies should be noted. (s. tabs. 22.6, 22.7, 22.8; 32.3, 32.6)

| | |
|---|---|
| **(1.) AMA + / ANA ∅** | **(3.) AMA ∅ / ANA +** |
| **(2.) AMA + / ANA +** | **(4.) AMA ∅ / ANA ∅** |
| **(5.) pANCA + / AMA ∅** | |
| **(6.) pANCA + / AMA +** | |

**Morphology:** While cellular and humoral immunity reactions exhibit a very broad spectrum of forms of manifestation, phenomena or epiphenomena and constellation types, this is not the case with liver morphology (which reacts in a relatively "monotonous" way). Given a *genetic* or *gender-related* disposition, the lesions, which seem to be primarily located either at the canaliculi or at the bile-duct epithelia, may be triggered by particular *causal factors*. The type and intensity as well as the combination of the now developing cellular or humoral *immunity reactions* influence the histological changes at and around the bile ducts with their own particular characteristics − yet with a certain monotony peculiar to the biliary system. The result is "progressive cholangitis" with variations in the fine tissue structure in the respective morphological stages, but with the basic tendency of autoimmune cholangitis.

▶ **Liver biopsy:** The histological analysis of biopsy samples (which can sometimes be overrated!) should be regarded critically in this context. It is frequently emphasized that (*1.*) PBC or PSC are focally and segmentally pronounced to different degrees and (*2.*) different morphological stages are recognizable at the same time, in the same patient and in the same biopsy material. • In addition, (*1.*) percutaneous biopsy can only provide biopsy material from the right lobe of liver and only from a limited area (s. fig. 7.8), and (*2.*) follow-up biopsies can only reach this particular limited area of the liver, even if several biopsies are performed over a number of years. Not even initial diagnosis by means of laparoscopy and biopsy from both liver lobes can guarantee the definitive fine-tissue classification of autoimmune cholangitis. • *It should be noted that all percutaneous follow-up biopsies remain restricted to the small liver area.*

**Therapy:** The following therapeutic observations point to the independent status of AIC compared to PBC and PSC and are also suggestive of a close correlation with AIH: (*1.*) good response to corticosteroid therapy (452), (*2.*) tendency towards aggravation when the prednisolone dosage is too low (451), and (*3.*) successful administration of a prednisolone-azathioprine combination in the case of relapse after monotherapy. • Thus, depending on the respective finding, prednisolone therapy or additional administration of azathioprine is recommended right from the outset. • In cholestasis, which is generally present, *UDCA* is indicated in addition.

In view of the variety of possible immunological reactions directed towards the canaliculi or bile-duct epithelia and the difficulties involved in making a definitive histological diagnosis and classification, it would be feasible to include a so-called overlap syndrome or conversion syndrome in the hypothesis of autoimmune cholangitis.

# 7 Overlap syndrome

**Definition**

There is currently no clear definition of the overlap syndrome (OLS). It is considered to be present if thorough assessment of biochemical, serologic, immunologic and histologic findings suggests the simultaneous occurrence of two chronic diseases in one liver. This term was probably first used in connection with rheumatoid diseases as "mixed connective tissue disease" (MCTD) (H.-H. Peter, 1996). It was later introduced in hepatology by J. Woodward et al. in 2001. The single findings may differ both qualitatively and quantitatively from patient to patient. Moreover, each of the two clinical pictures may predominate alternately.

| | |
|---|---|
| **AIH (type 1)** | **+ PBC:**    7−9% (475, 476, 482, 486, 492)<br>1st variant: AMA +/histology = AIH; therefore also termed "PBC, hepatic form" (486) |
| **AIH (type 1)** | **+ PSC:**    1−6% (477−481, 483, 485, 487, 488, 490, 493)<br>Anti-ribosomal P (ARP) antibody is frequently found (ca. 80%). • Recently, further observations have been reported. |
| **AIH (type 1)** | **+ AIC:**    11% |
| **AIH (type 2)** | **+ CAH-C:** 10%<br>(HCV +, ANA +, SMA +, LKM1 +) |
| **PBC** | **+ CAH** (484, 489) |

---

The following **outlier syndromes** are diseases which cannot be classified: (*1.*) AIC : AMA-negative PBC, (*2.*) AIH : AMA-negative PBC (2nd variant of PBC), (*3.*) AIH : cryptogenic CAH.

Aetiology and pathogenesis are unknown. There is probably a genetic predisposition, whereupon OLS is caused by one or more triggers or pathogens. Subsequently, it becomes self-perpetuating. One of the two diseases of OLS is always type 1 or type 2 AIH. It is important for diagnosis that there is a constellation which consists of biochemical, serological, immunological and histological findings relating to both diseases. The prevalence of OLS in all hepatic immunopathies is 10−12%. (491, 494) • The following overlap syndromes have been confirmed:

**AIH/PBC:** This form usually develops in adults only, because children are not affected by PBC. Such an overlap syndrome can occur as two different variants:

*Variant 1:* Histology generally like AIH
           AMA $M_2$ +
           IgM ↑↑, IgG (↑)
           ANA, SMA less frequent than in AIH
           HLA factors as in AIH

*Variant 2:* Histology generally like PBC
           AMA ∅
           IgM mostly lower than in PBC
           ANA, SMA more frequent than in PBC
           HLA factors as in AIH and PBC

Variant 2 thus corresponds to AIC. There are various criteria pointing to the entity of AIC: IgM lower than in PBC, GOT is higher, HLA factors differ from those of PBC, lymphocytes in liver parenchyma express V β 5.1 Tc receptors. (472)

**AIH/PSC:** This form is frequently found in children and has been adequately described. IgG are markedly higher. ANA, SMA and pANCA correspond to those of PSC. A typical feature is the evidence of the anti-ribosomal P antibody (80%). Rarely, there is an association with CIBD. Administration of prednisolone is as a rule contraindicated due to the danger of bacterial cholangitis.

**Cryptogenic chronic hepatitis** is part of the outlier syndrome; it is serologically unclassifiable. The condition of such patients is, however, similar to AIH. They often show positive evidence of SLP.

▶ Regarding the therapeutic effects, it is per se unimportant whether the existing overlap is a coincidence, a subsequent sequela or a real overlap syndrome: *every PBC or PSC with the criteria of AIH requires immunosuppressive therapy.*

### 7.1 Conversion syndrome

Conversion syndromes are also possible: (*1.*) transition of PBC into AMA-negative PBC, then into ANA-positive autoimmune hepatitis (AIH), (*2.*) transition of AIH into primary sclerosing cholangitis (PSC).

A progressive course of disease results in **biliary cirrhosis,** which does not, however, reveal whether the original diagnosis was PBC, PSC or AIH, or even an overlap syndrome.

### 7.2 Therapy

In the presence of an overlap syndrome (or a conversion syndrome), the therapy concept depends on the respective predominant component, which as a rule is AIH. Consequently, prednisolone + UDCA or prednisolone + azathioprine + UDCA are applied.

Therapy becomes problematic when antibodies and markers of HCV infection are evident. It is imperative to complete the unambiguous identification of HCV antibodies by determination of HCV RNA. (The positivity of HCV antibodies may well be a methodologically related "false-positive" result.). If HCV RNA is detected, i.e. in florid HCV infection, interferon therapy (or a combination with ribavirin) should be considered. This antiviral therapy may be indicated despite positivity of LKM 1 following critical evaluation and close-meshed controls. There is a possibility of AIH activation under antiviral therapy. In this case, INF therapy has to be stopped as quickly as possible. It is not currently known whether this risk can be avoided by simultaneous administration of low-dose prednisolone. • The same problem arises in the (very rare) combination of AIH with coexistent florid HBV infection.

# 8 Cholangiodysplasia

## 8.1 Cholangiogenesis

The development of the liver begins with the formation of the hepatic diverticulum around the 18th day of the

embryonic growth. The initial sign of this event is a thickening of the endoplastic epithelium in the ventral wall of the foregut. (The foregut is the future duodenum.) • The hepatic diverticulum is formed in the **3rd embryonal week** (22-day embryo). It consists of a hollow structure with a biliary and a hepatic section. Endodermal cells sprout into the mesenchymal tissue of the transverse septum from the ventral and lateral walls of the foregut. The cranial population of these cells forms the extrahepatic bile ducts and the liver, while the branching canals of the omphaloenterical vein create the sinusoids. The liver grows rapidly, whereby the majority of progenitor cells differentiate into liver parenchymal cells. The second population of bipotential progenitor cells develops into biliary epithelial cells. • From the **8th embryonic week** onwards, both the hepatocytes and bile-duct epithelia develop in the vicinity of the portal vein branches, whereby the ductal epithelium is derived from hepatoblasts, i.e. hepatocytogenic origin of intrahepatic bile ducts (A. KÖLLIKER, 1867). These ductular cells form a kind of cuff around the "portal" ramifications and thus create a double-layered epithelial sleeve, the so-called **ductal plate** (J. A. HAMMAR, 1926). • As from the 12th embryonic week, remodelling of the ductal plate into the interlobular bile ducts takes place, whereby surplus bile ducts are degraded. Bile secretion commences after the 16th week. Principally, the formation of the bile ducts is completed by the **28th embryonic week.**

However, the intrahepatic bile-duct system is indeed still immature at birth, so that the final development of the smallest ramifications takes place during the first few neonatal weeks. At this stage, the intrahepatic biliary system is therefore very susceptible to noxae, which can lead to paucity or even atresia of the bile ducts.

## 8.2 Definition

Cholangiodysplasia can manifest as **atresia** of the intrahepatic or extrahepatic bile ducts ("vanishing bile-duct syndrome") as **ductopenia** (or *paucity*) due to a marked decrease in the interlobular bile ducts (which may occur both in infancy and in early adulthood) and as **hypoplasia** or **ectasia** of the bile ducts. Destructive cholangitis (or cholangiolitis) may be an intermediate stage in the development of ductopenia. **Fibropolycystic diseases** must also be regarded as cholangiodysplasia. • Generally, they do not appear as a single entity, but in various combinations; they also become manifest to a different extent.

## 8.3 Aetiopathogenesis

These diseases can arise as a result of (*1.*) genetic defects of the ductal plate during embryonic development, (*2.*)

congenital (prenatal or perinatal) disorders of the bile ducts, (*3.*) genetically determined metabolic diseases, (*4.*) acquired destruction of the bile ducts in later life caused, for example, by viral, bacterial, immunological and toxic factors, or they can arise (*5.*) in an idiopathic form. Causal factors may also combine and then act pathogenetically either at the same time or in sequence. (s. fig. 32.16)

## 8.4 Ductal plate malformation

► Remodelling of the ductal plate can be arrested as a result of a genetic defect: in this case, a cuff-shaped cavity remains, which is coated with ductal cells. The portal vessel situated in this cavity is closed and obstructed by connective tissue. • The complete absence of bile ducts constitutes **biliary atresia.** It is rarely familial. This abnormality can commence at any time during ductal plate development, in most cases caused by extraneous noxae or infections. Thus atresia results from bile-duct destruction during intrauterine development or shortly after birth, but not from embryonic malformation of the biliary system. Biliary atresia may be located extrahepatically or intrahepatically. Generally, babies with complete atresia die during the first 5 years of life.

A drastic reduction in numbers of interlobular bile ducts is termed ductopenia (or *paucity of bile ducts*). Ductopenia is considered to be present if the ratio of interlobular ducts to the number of portal tracts is < 0.5 (normal value: 0.9−1.8), i.e. in a sufficiently large biopsy specimen, no more than half of the portal fields should be without a bile duct. Ductopenia can appear as an isolated defect (non-syndromic) or in combination with other extrahepatic (syndromic) anomalies. Non-syndromic paucity constantly exhibits bile-duct dilatation with blunting of microvilli. Idiopathic neonatal hepatitis sometimes overlaps with non-syndromatic ductopenia. Children with ductopenia may survive into adulthood. (504) (s. fig. 32.16)

### 8.4.1 Caroli's disease

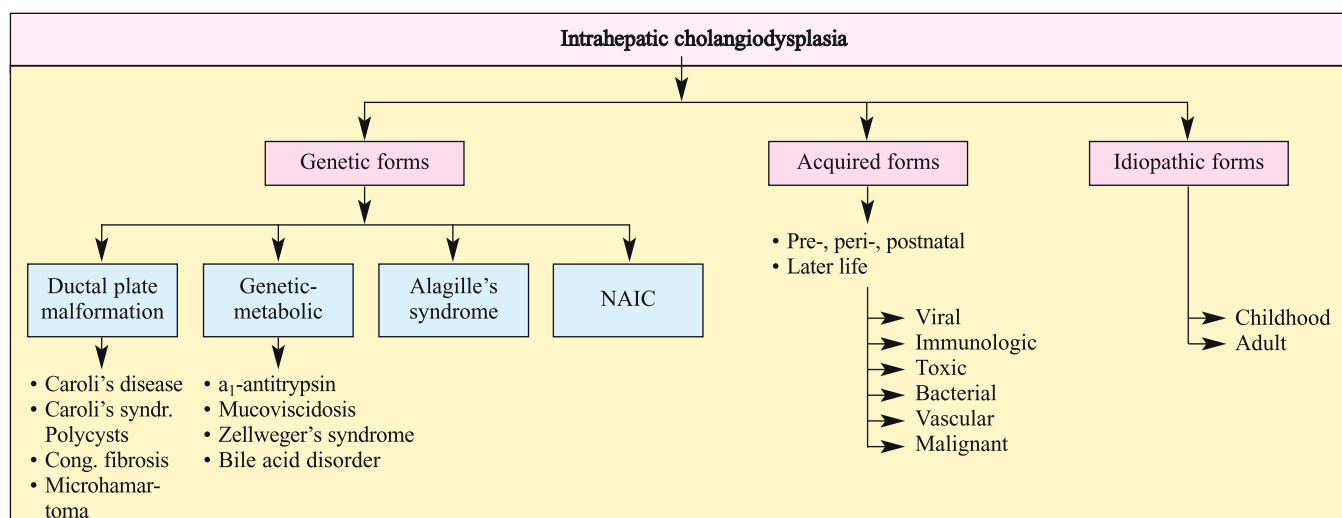
A characteristic finding of this rare disease (J. CAROLI et al., 1958, 1964) (501) are the saccular multifocal dilatations of the large interlobular bile ducts. Cyst-like dilatations communicate with the remaining bile-duct system. There are no other morphological liver alterations. The bile ducts contain stagnated bile and sludge, so that cholangitis and intrahepatic calculi develop. This disease may spread diffusely in the liver, but mostly the left lobe or only a segment of the left lobe is affected. Fibroangiomatosis of the bile ducts with cholangiolithiasis and chronic cholangitis may develop as well as portal hypertension with oesophageal varices. • Caroli's disease has an autosomal recessive origin. An association with congenital liver fibrosis and medullary sponge kidney has been described. (497) About 75% of cases are men. • Diagnosis


Fig. 32.16: Intrahepatic cholangiodysplasia − a proposed schematic classification. (NAIC = North American Indian cirrhosis in children) (506)

is confirmed by CT scanning (by means of the characteristic "central dot" sign) (502) and by ERC, MRC or PTC. Hepatomegaly, abdominal pain and jaundice (in particular during cholangitis-induced fever) may be present. (497, 499, 530, 534) The development of cholangiocarcinoma is found in about 7% of patients. • *Therapy:* Antibiotics are required in cholangitis. Intrahepatic stones may be treated with UDCA, endoscopic and surgical procedures or extracorporeal shock wave lithotripsy. (515) Occasionally, liver resection (520) or even liver transplantation is necessary. (499, 531) (s. pp 174, 762) (s. figs. 32.16; 36.13)

### 8.4.2 Congenital liver fibrosis

This is an autosomal recessive condition which can appear in a sporadic or familial form. Ductal plate malformation of interlobular bile ducts has been suggested as a pathogenetic mechanism of this disease (H. E. MAC-MAHON, 1929; R. G. F. PARKER, 1956). Histologically, congenital hepatic fibrosis is characterized by dense mature fibrous tissue of the considerably enlarged and restructured portal fields; subsequently, broad bands of connective tissue surround normal lobules and connect the portal fields with each other. These fibrous bands contain partly obliterated, partly dilated bile ducts, the latter often in the form of microcysts. (s. fig. 32.17)

Generally, the portal vein branches are hypoplastic, and the arteries are more numerous. Both the architecture and function are normal, but the liver is enlarged, smooth and firm. Serum values of AP are sometimes increased. Sonographically, the dense fibrous bands are seen as bright areas of echogenicity. CT scanning may show cystic changes, often also in the kidneys. (537) Liver biopsy is essential for diagnosis, but laparoscopy together with biopsy gives additional important information. This disease can take a latent course or may cause presinusoidal portal hypertension with splenomegaly. There are associ-

Fig. 32.17: Congenital liver fibrosis: onset of cirrhotic transformation, pathologically augmented bile-duct aggregates in portal and septal areas (Sirius red)

ations with Caroli's disease (497), choledochal cysts, polycystic liver disease or microhamartoma. The slowly progressing destructive cholangitis leads to VBDS and "cholangiodysplastic pseudocirrhosis". Generally, the kidneys are involved as renal dysplasia or renal cysts. Due to their normal liver function, such patients are excellent candidates for portacaval shunts if subsequent oesophageal varix bleeding occurs. Hepatocellular and cholangiocellular carcinoma (495) as well as adenomatous hyperplasia (496) of the liver have been reported.

### 8.4.3 Childhood fibropolycystic disease

This polycystic degeneration is an inherited autosomal recessive disorder and its occurrence can be perinatal (at birth, renal cystic changes in 90%) neonatal (after ca. 1 month, renal cysts in 60%) and infantile (3−6 months of life, renal cysts in about 25% of cases). The incidence

ranges between 1:6,000 and 1:40,000 births. Usually, there are only small liver cysts. Microscopically, enlarged portal fields due to connective tissue with ectatic bile ducts are found, which are erroneously regarded as cysts. These dilated ducts communicate with the remaining biliary system. The enlarged kidneys show cystically dilated collecting tubes. As a rule, children with a neonatal form die shortly after birth. The prognosis for the perinatal and infantile forms depends on the time of manifestation, i. e. it improves as age advances. A chronic course of disease develops into cholestasis, progressive fibrosis and portal hypertension.

### 8.4.4 Adult polycystic disease

This condition is an autosomal dominant disease. The liver cysts are mostly (50−60%) associated with (also dominantly inherited) polycystic kidneys. The prevalence of liver cysts increases with age (at <20 years = less than 1%, at >60 years = 75%). Isolated, dominantly inherited polycystic liver disease without renal involvement has been reported. (524) Liver cysts are the result of a developmental disorder of the ductal plate at about the 23-mm stage of foetal life (i. e. ca 5$^{th}$−8$^{th}$ embryonic week). There is no biliary dysfunction. Liver cysts vary in size from a pinhead to ca. 10 cm in diameter, i.e. having a capacity of about 1 litre. They contain clear fluid secreted by the bile-duct epithelium lining the cysts or, occasionally, brown-coloured fluid due to haemolyzed and altered blood. The following complicative events are to be feared: haemorrhage into a cyst, infection and rupture of cysts. • Liver function is normal; alkaline phosphatase and γ-GT may be increased. The best methods of diagnosis are sonography and CT scanning. (514) The asymptomatic course is diagnosed by chance. Symptoms are usually caused by a considerable increase in the size of the cysts (dull abdominal pain, epigastric complaints, nausea and flatulence). Prognosis is determined by renal insufficiency due to renal cysts. (514) • *Therapy:* Large cysts can be treated by instillation of minocycline, sclerotherapy with alcohol, operative or laparoscopic fenestration (510, 525) and liver resection (525, 528) as well as transplantation. (529) (s. p. 761)

### 8.4.5 Solitary non-parasitic liver cyst

This condition is probably a variant of polycystic liver disease. Aberrant bile ducts and blood vessels are noticeable in the fibrous cyst capsule. The cyst fluid is clear or brownish due to altered blood. Usually, the cyst develops in the inferior-anterior segment of the right lobe. The symptoms, which depend on the size of the cyst, include pressure effects on adjacent organs, cholestasis and obstructive jaundice.

### 8.4.6 Microhamartoma

A further disorder in ductal plate remodelling is seen in the so-called von Meyenburg complex (H. von Meyen-

burg, 1918). Microhamartomas are the residues of malformed ductal plates (from which the peripheral branches of the intrahepatic bile ducts develop). They occur as groups of rounded biliary channels, which are lined with cuboid epithelium and embedded in fibrous tissue. The interlobular and terminal bile ducts are enlarged, often with inspissated bile; they communicate with the remaining, normal biliary system. They are usually located directly in the portal tracts or nearby. The course of disease is asymptomatic; generally, the diagnosis is made by chance. Microhamartomas are occasionally associated with polycystic disease or medullary sponge kidney. Portal hypertension rarely develops. (s. figs. 32.16, 32.18) (s. p. 763)

*Fig. 32.18:* von Meyenburg complex: biliary microhamartoma with ectatic bile ducts in an enlarged fibrous portal stroma (HE)

## 8.5 Alagille's syndrome

*Arteriohepatic dysplasia* (syndromic bile-duct hypoplasia) (G. Watson et al., 1973, D. Alagille et al., 1975, 1987) derives from dysfunction of the endoplasmic reticulum and the Golgi apparatus in the biligenetic area of the hepatocyte. This disorder is a dominant autosomal defect of the JAG-1 gen localized on chromosome 20 p 12. Components essential to the bile are retained at this site and result in secondary dysplasia or subsequent reduction in the interlobular bile flow system. The incidence is approx. 1 : 100,000 neonates. • The disease can be detected in all children during the first year of life. There is evidence of the following *symptoms*: chronic cholestasis with pronounced pruritus, xanthomas, intermittent jaundice, steatorrhoea, disturbance of mental development, deformities of the fingers, shortening of the ulna and radius, butterfly-shaped vertebrae, ataxia, chronic otitis and pigment changes in the retina. There are conspicuous facial anomalies, including deep-set eyes and a flat nose, prominent forehead and slender chin; various anomalies of the cardiovascular system (particularly hypoplasia of the peripheral pulmonary artery) and several renal anomalies also play an important role. Liver fibrosis with portal hypertension and hepatosplenomegaly can develop; in some 15% of cases,

liver cirrhosis may occur. The 20-year survival rate is about 75%. Children without neonatal jaundice show a better prognosis with a longer survival rate; in these cases, liver transplantation is rarely indicated. • *Therapy* comprises UDCA, medium-chain fatty acids and fat-soluble vitamins. The possibility of liver transplantation always has to be considered. (500, 503, 509, 517, 523, 527, 532) (s. fig. 32.16) (s. tab. 40.14)

## 8.6 North American Indian cirrhosis

North American Indian cirrhosis (NAIC) in children with a rapidly evolving form of familial cholestasis was first described by A. M. WEBER et al. (1981) in aboriginal children from northwestern Quebec. Genetic investigations suggested autosomal recessive inheritance and showed that the NAIC gene is located on chromosome 16q22. There is a carrier frequency of 10% in this population. • Symptomatology consists of neonatal cholestasis with elevation of serum bile acids, alkaline phosphatase, LAP and γ-GT (ca. 70% of cases). Portal hypertension (ca. 90% of cases) develops rapidly due to early bile-duct proliferation, portal fibrosis and biliary cirrhosis. This results in variceal bleeding (ca. 50% of cases), which even occurs in children aged 10−12 months. Liver transplantation is therefore indicated. • On the basis of findings obtained from 30 patients, NAIC is regarded as a distinct entity and classified as "progressive familial cholangiopathy". (506)

## 8.7 Genetic-metabolic ductopenia

Some genetic defects can cause disturbed restructuring of the ductal plates in foetal development, so-called ductal plate malformations. (s. p. 660) • In contrast, in genetically determined metabolic disorders, secondary ductopenia (or *paucity of bile ducts*) may arise during the subsequent course of disease.

### 8.7.1 α₁-antitrypsin deficiency

The deficiency may lead to a significant accumulation of non-secretable, abnormal α₁-antitrypsin. This causes cholestasis with inflammatory reactions in the region of the small bile ducts during the further course of disease. Destruction, obstruction and atrophy of the small bile ducts can therefore develop. (s. p. 591) (s. fig. 31.10)

### 8.7.2 Mucoviscidosis

Mucoviscidosis (or cystic fibrosis) is an autosomal recessive disease which is accompanied by the pathological production of viscous secretions in the excretory glands. Diagnosis is based on the sweat test (= pilocarpine iontophoresis; positive: chloride >70 mmol/l, sodium >60 mmol/l). There is a pronounced association with HLA types A2, B7, DR2 and DQw6. Serum cholic acid and the ratio of cholic acid/chenodeoxycholic acid correlate with histological liver damage and fibrosis. The further course of disease can lead to cholestasis and periportal inflammatory processes with fibrosis, which results in increasing destruction and obliteration of the bile ducts. Macrovesicular steatosis with hepatomegaly

is often found. With advancing age, the frequency of hepatic damage (chronic cholestasis, fatty liver, fibrosis, cirrhosis) reaches 25−30% in adults. About 5% of patients develop biliary cirrhosis. Treatment with UDCA is recommended. Liver transplantation may be indicated. (s. p. 602)

### 8.7.3 Zellweger's syndrome

Peroxisomal disorders of bile acid synthesis, both in the side-chain decomposition process and at the steroid ring, can cause atrophy of the small bile ducts. This gives rise to Zellweger's syndrome with asyndromic bile-duct hypoplasia. (513) (s. pp 234, 603) (s. tabs. 13.3, 13.4)

► Bile-duct hypoplasia has also been observed in the **Aagenaes syndrome** of recurrent intrahepatic cholestasis (s. p. 233), in **Turkish non-syndromic paucity** of interlobular bile ducts (N. KOCAK et al., 1997), etc.

## 8.8 Acquired ductopenia

*Non-syndromic ductopenia* is caused by the following events: (*1.*) degeneration and necrosis of bile-duct epithelia, (*2.*) hypoperfusion of the periductular capillary plexus, and (*3.*) inflammatory processes. However, there are close interactions between these three pathomorphological changes. • Degeneration and necrosis of bile-duct epithelia can be attributed to immunologic reactions or the influence of endogenous or exogenous toxins. This results in oxidative stress and hypercalcia with subsequent cell necrosis. • The hypoperfusion of the capillary plexus as a result of atrophy or arteritis also causes oxidative stress and hypercalcia. • Inflammatory processes (e. g. due to viruses, bacteria and toxins) damage the ductular cells and stimulate fibrogenesis ("vanishing bile ducts"). (498, 533, 535)

**Immunologic reactions:** Primary biliary cholangitis, primary sclerosing cholangitis, overlap syndromes, allograft rejection, sarcoidosis, etc. are worth mentioning in this context.

**Malignant diseases:** Histiocytosis X and Hodgkin's disease (but not NHL) have been identified as causing ductopenia.

**Vascular disorders:** A decrease in the arterial blood supply, especially hypoperfusion of the periductular capillary plexus, can be caused by vasculitis, i.v. infusions of cytostatics (e. g. floxuridine) (18, 19, 24, 38) or alcohol into the hepatic artery, postoperative scarry strictures of the hepatic artery, allograft rejection, etc.

**Foreign substances:** Given an individual predisposition, chemicals or pharmacons (505) may trigger the syndrome of vanishing bile ducts. Numerous drugs can be included in this category. (s. tab. 29.3)

**Virus infections:** Viral cholangiopathy, sometimes with concomitant destruction of the intrahepatic bile ducts, has been reported to derive from several species of viruses, e. g. HIV, cytomegaly, rotaviruses, respiratory syncitial virus (RS), hepatitis C, congenital rubella and reovirus 3. • **Bacteria** may, however, also be the cause of disease, as is the case with congenital syphilis.

## 8.9 Idiopathic ductopenia

**Idiopathic adulthood ductopenia:** The rare, non-syndromic form of ductopenia was described by J. Ludwig et al. in 1988. He subsequently diagnosed this condition in almost 60 patients. (516) Further cases have also been reported in the literature. (498, 507, 518, 519, 521, 522, 535, 536) • This form of ductopenia does not reveal any congenital or acquired causes (*see subchapters 7.4–7.7*). All known causes of cholestasis must firstly be excluded and there should be no evidence of inflammatory bowel disease. The aetiology is (still) unclarified, i.e. *idiopathic*. • The onset of the disease is between the ages of 15 and 77, average 27 years, i.e. in adulthood. (516) Women are more often affected than men (1.8:1.0). • The clinical symptoms vary; relatively long asymptomatic phases may precede diagnosis. Episodes of pruritus and jaundice are the first noticeable symptoms; occasionally, right upper quadrant pain develops. Signs of cholestasis are present: increase in the serum values of bile acids, alkaline phosphatase, γ-GT and LAP. There may be concomitant jaundice. Transaminases, which are suggestive of hepatocellular damage, vary from normal to a 10-fold increase.

*Morphologically*, diagnosis is based on a loss of interlobular or septal bile ducts in at least 50% of the portal fields. Nevertheless, 20 or more portal tracts should be evaluated, i.e. several needle biopsy samples must be obtained. The collection of biopsic material is best performed by laparoscopy, whereby specimens should be taken from both liver lobes. (s. pp 157, 160) (s. fig. 7.8) The bile ducts can only be counted correctly if they are clearly distinguishable from the ductules (cholangioles). In most cases, the ductules have proliferated, i.e. bile-duct loss and ductular proliferation often coexist. At the same time, the biopsy samples should not display further findings, such as granulomas, PBC, PSC, histiocytosis, lymphoma, etc. • There may be a correlation between the cause of disease and the respective prognosis. Thus there have been reports of patients in adulthood presenting with a mild form of biliary idiopathic ductopenia. They showed no clinical findings and were largely asymptomatic. The values of γ-GT, AP and transaminases in these cases were normal or moderately increased. The prognosis was assessed as favourable. (518) However, the course of disease is usually progressive, culminating in biliary cirrhosis or acute liver failure. • *Treatment* with UDCA is recommended, although no favourable results have hitherto been reported. (508) Liver transplantation is the treatment of choice.

**Idiopathic childhood ductopenia:** The same criteria as established by J. Ludwig et al. for ductopenia in adulthood also apply to ductopenia in childhood. There is no clinical or biochemical difference between this form and the one found in infants. Chronic progressive cholestasis can occur in children as well, accompanied by pruritus, and sometimes by jaundice or xanthomas.

Electron microscopic examination of livers taken from numerous premature infants (before 90 days of age) suggests that paucity in non-syndromic patients may result from primary ductal plate insult: there are undulations and breaks in the basal lamina and lymphocytic infiltration of the duct epithelium as well as canalicular dilatations with blunting of microvilli. (511) The cause is unknown. Apparently, one and the same event is involved, yet with different manifestation forms in childhood and in adulthood as well as with varying degrees of severity. (498)

# Clinical Aspects of Liver Diseases

## 33 Autoimmune hepatitis

► A particular form of chronic liver disease prevalent among young women with an excessive increase in protein and γ-globulin was first described by S. Amberg (1942) (1) and later by J. Waldenström (1950), who used the name **"autoimmune hepatitis"**. (101). In 1951 H. G. Kunkel et al. termed this condition **"hypergammaglobulinaemic chronic hepatitis"**. (47) This type of disease was confirmed by A. G. Bearn et al. (1956) (2) and, because of a positive LE-cell phenomenon in about 10% of cases (R. A. Joske et al., 1955) (43), was given the name **"lupoid hepatitis"** by I. R. MacKay et al. (1956). (49) • During the following years, there were frequent reports of a particular form of active and necrotizing liver disease, which was assumed in many cases to be autoimmune due to the treatment success achieved with glucocorticoids and/or azathioprine. Laboratory parameters were characterized by increased transaminase values, GDH, γ-globulins and immunoglobulins as well as by distinct histological findings − *there was no possibility of obtaining immunologic evidence at that time.*

# 1  Definition

The cause of autoimmune hepatitis (AIH) is unknown. Autoimmune reactions lead to a chronic (rarely acute) inflammatory process (periportal piecemeal necrosis, infiltration of portal zones). AIH is frequently associated with autoimmune diseases of other organs. It occurs predominantly among women, particularly in younger years. Hypergammaglobulinaemia is invariably in evidence. Various autoantibodies to components of the liver parenchyma are found. The presence and specificity of these antibodies, together with the respective clinical symptoms, facilitate differentiation between the various subtypes of AIH. Diagnosis is substantiated by the response to immunosuppressive therapy. If left untreated, AIH progresses rapidly with transition to cirrhosis and/or liver failure. If treated adequately, the course taken by the disease is favourable.

# 2  Epidemiology

AIH is present worldwide. Some 15−20% of all patients with chronic hepatitis can be classified as AIH. Prevalence and incidence differ in various geographic regions. In Europe and North America, *prevalence* ranges between 3−17/100,000 inhabitants, whereby the lowest rates are found in southern countries. The *incidence* in Europe and North America is estimated to be between 0.1−1.9/100,000 inhabitants per year. Women are 4 to 5 times and children 7 to 9 times more frequently affected. AIH can occur in all age groups. (7)

# 3  Aetiology

## 3.1  Immunologic tolerance

**The aetiology of autoimmune hepatitis is (as yet) unresolved.** • The immunologic tolerance of the body's own cell structures can be disturbed as a result of (*1.*) immunogenetic abnormalities in the **MHC system** (= major histocompatibility complex, i. e. the main complex in the HLA system, classes I and II), (*2.*) **clonal deletion** (= removal of so-called "mobile" genes from plasmids) as well as suppressor defects, and (*3.*) **molecular mimicry** (= partial correspondence of the molecular structure of a foreign antigen with a certain body-own protein structure). (s. p. 643)

## 3.2  Immunogenetic susceptibility

**Genetic predisposition is paramount.** • The existence of such a genetic factor can be deduced from occasional familial occurrence (25, 37), gender and age specificity as well as a close correlation with the HLA system. (64) Women are affected in 85−90% of cases, mainly between the ages of 14−55 years (women: men = 4:1).

## 3.3  Trigger factors

**AIH must be triggered by an antigen.** • Trigger factors include environmental noxae, medication, toxins, bacteria (e. g. salmonella antigen), hepatitis viruses HAV (72, 89, 95), HBV, HCV, Epstein-Barr (63, 96), lymphochoriomeningitis virus (39) and measles viruses (77, 97) as well as the Herpes simplex virus (type 1 of which is mainly responsible for AIH type 2). (48, 74) The development of AIH has also been precipitated by interferon therapy in chronic hepatitis B (13) and C (32, 66) even in children. (78) • The *viral trigger hypothesis* has recently aroused great interest, since various viruses (e. g. HAV, measles, Epstein-Barr) are known to persist "unnoticed" for years, e. g. in lymphocytes.

# 4  Pathogenesis

## 4.1  HLA system

Immunogenetic susceptibility is substantiated by the close association between autoimmune hepatitis and the HLA system. (24, 50, 64, 81) **Ethnic differences are evident:** an association with HLA-DR4 is frequent in Japan and in the Euro-Caucasian population. In patients with HLA-DR3 positivity, manifestation occurs in younger years, there is greater activity of disease and the outcome of therapy is less favourable (higher rate of non-responders and recurrences after ceasing immunosuppressive therapy, as well as more frequent indications for liver transplantation). In contrast, HLA-DR4 positivity correlates with manifestation at a more advanced age, a milder course of disease and a good response to immunosuppressives, albeit with the considerably more frequent occurrence of extrahepatic syndromes. The HLA markers DR3 and DR4 are hence characteristic of two different courses. • Further HLA types of importance include: HLA-A1, -B8, -DR4, -Bw54, -DR3, -DR13 (Brazil), -Dw3, -DR53, -C4AQO and -DQ4. A close relationship was found between AIH and the CD 45 gene, which is considered quasi to be a *"modifier gene of human autoimmunity"*. (99)

## 4.2 Cellular immune reaction

Cellular alteration of the immune response is characterized by T lymphocytes infiltrating liver tissue. The target antigens of the T lymphocytes are deemed to be cytochrome P450 II D6, mitochondrial pyruvate dehydrogenase and asialoglycoprotein receptor proteins. (92) A loss of immune tolerance for autologous liver tissue can be attributed to the decrease in activity of T suppressor cells (with lymphocyte marker T8) and the preponderance of T helper cells (with lymphocyte marker T4) over the suppressor cells. Any existing suppressor defect in autoimmune hepatitis is eliminated by glucocorticoids − but not in cases of chronic viral hepatitis B. The suppressor T cell defect causes immunological hyperactivity against surface structures of the hepatocytes. T cells from the liver of autoimmune hepatitis patients are sensitized to asialoglycoprotein receptor proteins. (5, 53, 54, 65, 87, 93, 103)

## 4.3 Autoantibodies

▶ There are various circulating autoantibodies to nuclear, cytoplasmatic and membranous antigens; they differ in their diagnostic and clinical significance. Autoantibodies are deemed to be secondary immunological phenomena of liver cell lesions and have no pathogenetic importance. Correlation of the antibody titres with AIH activity is unreliable. The antibodies may play a part in eliminating autoantigens. Their determination is essential for the diagnosis and classification of AIH as well as its overlap syndromes. (6, 17, 20, 65, 86, 88) (s. tabs. 5.19, 5.20; 33.1)

**ANA:** Antinuclear factors were described for the first time by G. J. Friou et al. in 1957. These antibodies are mainly directed against nucleoprotein DNA histone and cycline A. They show a predominantly homogeneous or "speckled" pattern of fluorescence. ANA is not specific to the liver or to liver disease. (s. figs. 5.10, 5.11) (s. p. 118)

**SMA:** Smooth muscle antibodies were first described by G. D. Johnson et al. (1965). They mostly possess anti-actin (generally F-actin) specificity, predominantly of the IgG type. Antibodies against troponin and α-actin may also be present. There is great heterogeneity, and a mixture of different antibodies can almost always be found. Evidence of anti-actin antibodies has a high diagnostic value, particularly with a titre of > 1:640 and in the presence of an IgG type. (s. fig. 5.12) (s. p. 119)

**LKM:** *Anti-LKM 1* were detected by M. Rizzetto et al. and W. B. Storch (86) in 1973. As liver/kidney microsomes, they are directed against an antigen of the ER (cytochrome P 450 II D 6) (anti-AER) as well as against proximal kidney tubuli. • There are also *anti-LKM 2* (antigen: P 450 II C 8−II C 11 in tienilic acid-induced hepatitis) and *anti-LKM 3* (antigen: part of the UDP glucuronyltransferase in chronic hepatitis D as well as in hydralazine and carbamazepine-induced hepatitis against P 450 I A2). LKM antibodies are directed against other microsomal antigens as well and consequently may be present in viral or toxic liver diseases. They constitute a heterogeneous group. (26, 38) (s. p. 119)

**LP/SLA:** Anti-LP antibodies were described by P. A. Berg et al. in 1981. (4) They show a particularly strong reaction against soluble antigens from the liver and pancreas. The specific antigen has not been identified. In autoimmune hepatitis, anti-LP antibodies are associated with ANA and/or SMA in > 60% of cases; even when detected on their own, they are of diagnostic importance. (84) • Soluble liver-antigen antibodies (SLA) were demonstrated for the first time by M. P. Manns et al. in 1987. (51) They seem to recognize cytokeratins as antigens and identify a target antigen of activated lymphocytes. SLA are probably identical to LP and possibly even characterize the same patient group. Although they are indeed of diagnostic relevance in AIH, they are not specific. LP/SLA are detectable in AIH in 25% of cases. (s. p. 120) • The postulated main antigen of cytosol antibodies has meanwhile been cloned. (100, 104) This group of cytosol antibodies was first described by W. Storch in 1975; they are probably identical to anti-LP and anti-SLA antibodies. (86)

▶ The autoantibodies ANA, SMA, LKM 1 and LP/SLA are of diagnostic relevance in autoimmune hepatitis. Moreover, they are usually detectable at a time when no clear diagnosis can be derived from clinical, laboratory or histological findings. This is most important with regard to early immunosuppressive therapy. Other autoantibodies (such as LMA, LC1, HHPM) are indeed often associated with AIH, yet have no diagnostic relevance.

**LC:** These liver-specific antibodies (LC1 and LC2) react with a soluble cytosolic antigen in the liver cells (W. Storch, 1975, 1979). This was confirmed by E. Martini et al. in 1982. They are frequently associated with anti-LKM 1 antibodies (60−70%). The hepatocytes around the central vein of the liver lobule are left out of the otherwise homogeneous cytoplasmatic fluorescence. LC 1 antibodies are not present in chronic viral hepatitis C, and thus they are important in differentiating between (LC1-positive) AIH and (LC1-negative) chronic HCV infection. LC1 is primarily found in young patients presenting with AIH type 2. Only rarely are LC2 antibodies found in AIH; they react with periportal liver cells. (35, 45)

**LMA:** The liver membrane antibodies were first identified by W. Storch in 1973 (86) and confirmed by U. Hopf et al. in 1976. They are directed against various epitopes of the liver cell membrane, e. g. the ASGPR receptor. LMA are mostly associated with other (relevant) antibodies in AIH. (s. p. 119)

**Asialoglycoprotein receptor:** The antigen spectrum of anti-LSP antibodies is a heterogeneous group. The asialoglycoprotein receptor protein (anti-ASGPR) is a specific antigen of this LSP mixture (B. M. McFarlane et al., 1986). In AIH, 80−85% of cases displayed antibodies against this purified protein. Yet, anti-ASGPR are also

*Tab. 33.1:* Differentiation of autoimmune liver diseases and their overlap syndromes (s. tab. 5.20) (s. p. 658). • (AHA = anti-histone antibody; anti-GOR = anti-specific nuclear antigen in HCV) (see text for other abbreviations). −/(+) = no or occasional slight increase

found in primary biliary cholangitis, primary sclerosing cholangitis and viral hepatitis. (92)

# 5 Classification

Autoimmune hepatitis may be classified into three (sometimes four) types according to the different antibody specificities in conjunction with the seromarkers of viral hepatitis. Further differentiation has also been made into subtypes (1a, 1b and 2a, 2b), although this remains controversial. In the future, it may well be possible to derive therapeutic indications or prognostic indices from these subtypes; at the moment, they offer no guidance in this respect. It is, however, remarkable that ANA, SMA and LKM 1 are not primarily detectable in 20% of patients with AIH, whereas other antibodies, such as LP/SLA and ASGPR antibodies, can often be identified. (52) • In this context, a more reliable definition of overlap syndromes might therefore be useful for therapy and prognosis. (s. tab. 33.1)

## 5.1 Type 1

This is the classical (formerly lupoid) form of autoimmune hepatitis. It shows a markedly genetic predisposition. Type 1 is the most frequently occurring form of AIH (70−80% of cases) and is mainly found in young women, especially between the ages of 20 and 40 years. There is a marked increase in γ-globulins. ANA (40−70%), SMA (70−100%) (titre >1:80) and ASGPR (70−80%) are commonly present. AMA and pANCA are also occasionally detected. ANA often only appears during the course of disease. Type 1 is highly responsive to immunosuppressive therapy. That is why cirrhosis develops in "only" 40−45% of cases. HCV antibodies of groups 1a and 1b are found with the same frequency (14%). (16, 17, 36, 38, 60)

**Subtype 1a:** This subtype is ANA-positive; it can be found with or without SMA. Its course is generally subclinical, so that the initial diagnosis can only be made later. Type 1a occurs more frequently in women than in men. Its frequency is distributed bimodally, with a peak between 10 and 30 years (= association with HLA-DR3) and again after 30 years of age or following the menopause (= association with HLA-DR4); occasionally, C4AQO is detectable. Frequency is 25−30% of cases.

**Subtype 1b:** The SMA-positive subtype occurs particularly in children of all ages and of both sexes. In later life, men are more often affected. This classification is, however, still disputed.

## 5.2 Type 2

The main criterion of this type is the detection of LKM 1 (titre >1:80), which is exclusively found in AIH. ASGPR and LC 1 are sometimes also present. (26, 35, 45, 92, 107) In contrast, ANA and SMA antibodies are not detectable as a rule. Antithyroid and antiparietal cell antibodies can be frequently identified. Type 2 is 5−6 times less frequent (5−10%) than type 1. It occurs early in life (about 50% of cases involve children (34, 56) and adolescents) (68) and is often associated with extrahepatic manifestations. Type 2 usually commences like acute viral hepatitis, and genetically determined IgA defi-

ciency is occasionally evident. Hypergammaglobulin-aemia is not, however, as obvious as in type 1. Antibodies against thyroid and parietal cell antigens are frequently detectable. Type 2 is less responsive to immunosuppressive therapy than type 1. The prognosis is thus less favourable: cirrhosis develops frequently (approx. 80% of cases) and rapidly. Type 2 is associated in 10−15% of cases with the autoimmune polyendocrine syndrome type 1. (s. p. 679) • Owing to a respective HCV positivity of 20−60% or 35%, differentiation into subtypes 2a and 2b was proposed. This may, however, not always be reliable.

**Subtype 2a:** The criteria of this subtype are positivity of LKM 1 and LC 1 with negativity of anti-HCV and HCV RNA. It becomes manifest early in life, and the course of disease is severe. Women are mainly affected. HLA-DR3, -B14 and -C4AQO are present.

**Subtype 2b:** The criteria of this subtype are positivity of LKM1 and anti-HCV as well as HCV RNA. It becomes manifest at a more advanced age. Men in particular are affected. In 70% of cases, it was possible to detect antibodies to certain nuclear HCV antigens, so-called **anti-GOR.** This is a fusion protein which is derived from a cDNA clone (GOR 47-1). (55) (s. pp 121, 443)

> ► The **explanation of the term GOR** is as follows: S. Mishiro et al. were trying at that time (before the discovery of HCV) to detect a new virus which could be the cause of NANB hepatitis by immunoscreening cDNA libraries which were derived from chimpanzees infected with NANB hepatitis. One of these chimpanzees had the name "Gabriel" ("G"). Two cDNA libraries were made from Gabriel's serum: one was primed with oligo-dT primer ("GO library") and the other with random primer ("GR library"). These two libraries were mixed to a combined one, "GO" + "GR" → GOR. Subsequently, an interesting clone was identified from the 47th plate of the GOR library: this was GOR 47-1. *(Personal information from S. Mishiro)*

## 5.3  Type 3

Type 3 is characterized by the positivity of LP/SLA. These antibodies are the only type found in 25% of patients with AIH. • Sometimes, SMA, ANA and ASGPR can also be detected, but at low titre levels. The frequency is 5−10%. Women are affected five times more often than men. There is a high concentration of γ-globulin. HCV antibodies were found in 11% of patients. (37) The clinical course is similar to type 1; as a rule, it progresses rapidly. The response to immunosuppressives is good. • Cryptogenic chronic hepatitis can often be diagnosed with the help of LP/SLA. (s. tab. 33.1)

## 5.4  Drug-induced AIH

With a genetic or disease-related predisposition, the intake of medicaments and their subsequent catabolism in the biotransformatory system sometimes lead to the formation of reactive metabolites. (s. p. 55) (s. fig. 3.11) These can bind to components of the cytochrome system. After cytolysis, they may become the target antigens of antibodies. (s. p. 544) (s. fig. 29.1) This has been ascertained, for example, for carbamazepine (LMK 3),

halothane (LMK 2), hydralazine 1 (LMA, LMK 3) and ticrynafen (LKM 2) as well as for tienilic acid (LKM 2) and minocycline. (33) Other antibodies (ANA, LMA) may also be present.

## 5.5  Overlap syndrome

**Primary biliary cholangitis:** The overlap of PBC with AIH reveals positivity of AMA, ANA and ASGPR as well as lower titres of LP and SMA. In approx. 20% of cases, AMA can be found in AIH. The frequency of this overlap syndrome is 5−10% (−15%). It was first detected in a child (12-year-old girl). (34) IgG and IgM fractions are simultaneously elevated. Histological findings can comprise the criteria of both PBC and CAH. Thus two different autoimmune diseases are present, whereby prognosis is determined by the degree of severity of AIH. This provides the indication for immunosuppressive therapy. (s. tab. 33.1) (s. p. 660)

**Primary sclerosing cholangitis:** An overlap of primary sclerosing cholangitis with AIH is likewise possible; the latter also displayed pANCA in 13−16% of cases. (s. p. 657)

**Collagenosis:** An overlap of collagenosis with AIH is rare (0.2%). Confirmation requires the determination of specific antinuclear antibodies (SSA, SSB, RNP, Sm, Scl70, ACA). (s. tab. 5.19)

**Autoimmune polyendocrine syndrome:** Approximately 20% of cases of the autosomal recessive APS type 1 are accompanied by autoimmune hepatitis. A loss of autoimmune regulator activity is considered to be the underlying cause. There are autoimmune reactions in the skin, ovaries, suprarenal glands, parathyroid glands, intestinal tract, etc.; generalized candidiasis is also evident. Antibodies to LM (targeted against cytochrome P450 I A2) may be present. A combination of AIH and APS is more aggressive, with a tendency to an acute or subfulminant course, and shows a weak response to corticosteroid therapy.

**Alcohol-related liver disease:** Approximately 80% of these patients display positive anti-histone 2B antibodies. In alcoholic hepatitis, there is frequent evidence of LMA (60%) and LSP (30%) as well as ANA and/or SMA. In autoimmune hepatitis (15% of cases), high titres of IgA antibodies to histone 2B can also be detected. • This autoimmune situation in alcoholic liver disease can indeed give rise to therapeutic problems *if, despite absolute abstinence, there is self-perpetuation of the morphological findings* (as we ourselves noticed in some cases).

## 5.6  Association with HV infection

In **chronic hepatitis B,** 5−10% of cases display ANA and/or SMA. Due to the subtle differentiation achieved with HBV markers, it is possible to classify each individual case reliably. Prognosis and therapy are determined by chronic hepatitis B. Interferon therapy can trigger or exacerbate autoimmune hepatitis. (13, 66, 74, 78)

In **chronic hepatitis D,** 10−20% of cases displayed antibodies to LKM 3. The antigen is a part of UDP glucuronosyl transferase (T. PHILIPP et al. 1994).

In **chronic hepatitis C,** there is a strikingly frequent association with autoimmune hepatitis; this association, however, varies in different geographic regions. In ANA-positive AIH, HCV antibodies were detected in 40−50%, whereas in LKM-positive AIH, HCV markers were found in up to 88% of cases. Chronic hepatitis C showed ANA and/or SMA in 10−15% of patients, whereas 2−10% simultaneously displayed LKM 1 antibodies. This constellation, also classified as subtype 2b, has a relatively mild clinical course with relatively low LKM titres. Interferon therapy is indicated − yet caution is called for, since this can trigger acute inflammatory episodes of chronic hepatitis C as well as the development of AIH. (32, 66, 78) In the event of replicative HCV infection, immunosuppressive therapy is not indicated. In this case, it is assumed that this is primarily a chronic hepatitis C with concurrent autoimmunity. It is necessary to clarify the HCV infection by PCR and to differentiate the autoantibodies further. In assessing such an overlap retrospectively, consideration must be given to the fact that (*1.*) the determination of HCV antibodies has often been false owing to the still unreliable detection method, (*2.*) it has not yet been possible to verify HCV RNA by PCR, and (*3.*) hypergammaglobulinaemia produces higher false anti-HCV levels. (3, 31, 48, 55, 60, 68, 91) (s. p. 440)

## 5.7 Cryptogenic chronic hepatitis

Occasionally, forms of autoantibody-negative chronic hepatitis are found with no detectable cause. They resemble autoimmune hepatitis in every respect and respond well to corticosteroid therapy. This special group (10−15%) possibly comprises cases of autoimmune hepatitis for which no immunoserologic markers are known as yet. In numerous cases of cryptogenic chronic hepatitis, AIH type 3 can be detected due to evidence of high-titric LP/LSA.

## 6 Morphology

Autoimmune hepatitis has no distinctive histology. The picture presented resembles that of *chronic active hepatitis*: portal and periportal infiltration from some plasma cells as well as a high number of lymphocytes are in evidence. (s. figs. 33.1, 33.2) The lymphocytes are mainly of the T-cell type, whereby the ratio of subtypes CD4 : CD8 is about 1:1. The lymphocytes demonstrate *emperipolesis* (= capable of infiltrating and surrounding other cells). (s. fig. 21.11) Hepatocytes often show

hydropic swelling and ballooning (s. fig. 21.4). Inflammatory activity varies, whereby some areas are near normal. In the lobule, there are infiltrates of lymphocytes with differing density together with activated Kupffer cells. As the degree of infiltration increases, with inflammatory activity varying considerably from portal zone to portal zone, *piecemeal necroses* (= interphase hepatitis) and bridging necroses (between adjacent vascular structures) as well as *liver cell rosettes* become more and more distinctive histologically. Whereas lytic necrosis leaves a "blank" in the trabecular texture, acidophilic necrosis shows Councilman bodies as residues. Early on in this process, it may be possible to detect pronounced *fibrosis.* (s. figs. 33.3, 33.4) • Bile-duct lesions, granulomas and deposits of iron or copper are not present; their detection argues against AIH. (11, 23, 58, 83, 90) • *Non-alcoholic steatohepatitis* can resemble the picture of AIH.

***Fig. 33.1:*** Acute AIH (ANCA +) resembling acute hepatitis, with pronounced centrilobular parenchymal loss. Rapid therapy success (clinically, biochemically) with immunosuppressives (HE).

***Fig. 33.2:*** So-called *lupoid hepatitis*. The left lobe of liver shows an irregularly rippled surface (scattered light reflex) with salmon-pink and yellow colouring, patchy red marking due to highly inflammatory parenchymal zones; fine vascular multiplication and whitish scarred areas with diffuse fibrosis
**Fig. 33.3:** Autoimmune hepatitis in remission under treatment with septal fibrosis and disarranged lobular structure

**Fig. 33.4:** Liver cirrhosis due to AIH: flat-nodular liver surface, highly cicatrized furrows, local neovascularization, signs of mild inflammation

# 7 Clinical aspects

## 7.1 Clinical symptoms

Some 10−20% of patients with chronic active hepatitis can be categorized as autoimmune hepatitis cases. • Occasionally, the disease develops over a considerable period of time without being noticed subjectively. (36) This is why AIH is often not diagnosed before the stage of chronic hepatitis is reached. Non-specific *complaints* have been reported, such as fatigue, languor, inappetence, decreased performance and sometimes arthralgia as well as myalgia, frequently accompanied by slight fever. *Clinical findings* include hepato/splenomegaly, palmar erythema, facial teleangiectasia, hirsutism, amenorrhoea and spider naevi. (s. figs. 4.6, 4.7) • In 25−40% of cases, AIH can become manifest in the same manner as acute viral hepatitis, but it presents more distinct subjective and clinical symptoms. At this point, scleral icterus or jaundice is usually present − as is generally the case in active phases of a disease. (31, 41, 65, 93, 98)

## 7.2 Laboratory diagnostics

Even at the subjective, asymptomatic stage, *transaminases* are elevated to differing degrees. With the onset of symptomatic or acute hepatitis, high values can be detected for GPT, GOT and GDH (3 to 10 times, and more, above normal levels). The γ-GT value is only moderately or not at all increased; the same applies to bilirubin. Cholinesterase is often decreased. • Cholestasis-indicating enzymes (γ-GT, AP, LAP) are rarely elevated; clearly raised levels point to an overlap syndrome rather than to a (very infrequent) cholestatic form of autoimmune hepatitis. • A sharp rise in *γ-globulin* (1.5 to 2 times above normal) is a characteristic feature. This is almost solely due to an increase in the IgG fraction. IgA can be decreased. Hyperproteinaemia (> 8g/dl) ensues. The blood sedimentation rate is greatly increased. • At this point, the serology of viral hepatitis (HBV, HCV, possibly HDV) has to be clarified. *Autoantibodies* (ANA, SMA, LKM, LP) and their titres are determined. When the presence of an overlap syndrome is suspected, the determination of specific autoantibodies is required (e. g. AMA with subtypes, LP, pANCA, anti-histone 2B, antinuclear antibodies). (s. tabs. 5.19, 5.20; 33.1) HLA typing (e. g. -A1, -B8, -DR3, -DR4) should then complete the diagnosis.

## 7.3 Liver histology

Histological examination of the liver and morphological clarification of the phase of disease (i.e. grading, staging) are imperative, although this does not facilitate the diagnosis of AIH. (11, 90) However, *liver biopsy* is recommended for the initial diagnosis; it should be carried out under *laparoscopy* to provide photodocumentation of the surface structure of the liver and to obtain several specimens (including some from the left lobe of liver).

# 8 Course and prognosis

## 8.1 Course of disease

Autoimmune hepatitis displays a wide spectrum of clinical courses. Besides the subjective asymptomatic and insidious onset of the disease, acute manifestations similar to acute viral hepatitis may occur. Severe courses have also been described, including acute liver failure and extreme atrophy of the right lobe of liver. (36, 61) The course of disease is often characterized by acute intermittent phases. Other patients, however, experience uncharacteristic complaints over long periods of time as well as aetiologically unexplained increases in transaminases. The effect of pregnancy on the course of AIH varies: deterioration, unchanged status and remission have been reported. Long-lasting spontaneous remissions were observed in up to 20% of cases (e. g. in placebo groups), but there were also cases of rapid transition into cirrhosis. (9, 29, 41, 45, 93)

## 8.2 Associated diseases

A variety of immunopathies and diseases have been associated with autoimmune hepatitis (20−30%). These association factors can render it more difficult to establish a diagnosis or differential diagnosis; as a result, therapy is more problematic, and the prognosis deteriorates. (s. tab. 33.2)

| Iridocyclitis | Thyroidism |
| Lupus erythematodes | Ulcerative colitis |
| Mixed collagenoses | Vasculitis |
| Myasthenia gravis | Vitiligo |
| Myocarditis | |

**Tab. 33.2:** Diseases or immunopathies which may be associated with autoimmune hepatitis (s. tabs. 22.2, 22.7, 22.8; 32.3, 32.6)

## 8.3 Hepatocellular carcinoma

Hepatocellular carcinoma is a rare occurrence (5−7%). (67, 79, 106) It may not be due to AIH or related medication, but to concurrent HBV or HCV infection. An association of HCC with corticosteroid therapy is unusual (102); the same study group, however, reported an association of HCC with azathioprine therapy.

## 8.4 Prognosis

Prognosis depends on the time when the diagnosis is established and therapy initiated. *Risk factors* are considered to be manifestation in early years, severe hepatic inflammatory reactions with bridging necroses and the presence of HLA-DR3. Type 2 develops more rapidly into *cirrhosis* (up to 82% within 3 years). (38) If the condition is not treated, prognosis is poor; in such cases, cirrhosis inevitably develops. Approximately 50% of patients die after 3−5 years, and some 90% within 10 years; mortality is highest during the first 2 years. Obviously, prognosis is worst in those patients who have already reached the cirrhotic stage at the time of initial diagnosis. • The prognosis of the overlap syndrome is presumably determined by the stage and degree of activity of primary biliary cholangitis or primary sclerosing cholangitis. (46)

When immunosuppression is properly administered at an early stage, prognosis is good; such patients can anticipate normal life expectancy. It is even possible for liver *fibrosis* to recede. (19, 28) In general, a therapy-related *remission rate* of 80−90% can be achieved. • Relapse occurs in some two-thirds of successfully treated patients, yet this usually responds well to re-administration of the initial therapy at an adequately high dosage. So-called *non-responders* (approximately 15% of cases) should be critically reviewed in terms of detailed diagnosis, while additional exogenous or endogenous risk factors as well as patient compliance should be investigated anew. • The *survival rate* of treated patients (excluding cirrhosis and severe, well-advanced CAH at the time of initial diagnosis) is ca. 90% and 80% after 5 and 10 years, respectively. In cases of cirrhosis, despite properly administered therapy, the 10-year survival rate is reduced to <65% (relapse risk is 90%).

# 9 Therapy

Hardly any other autoimmunopathy responds so well to immunosuppressive treatment as does autoimmune hepatitis. Most patients can reckon with normal life expectancy. • However, this calls for the following *prerequisites*: (*1*.) early detailed diagnosis, (*2*.) appropriate, continuous therapy, and (*3*.) elimination and prevention of exogenous risk factors.

## 9.1 Detailed diagnosis

*The diagnosis of autoimmune disease is in itself not difficult.* • **Nevertheless**, the wide variety of autoimmunopathies and their multiple facets, their unpredictable preference for certain tissue, cellular or organ systems and the fact that they frequently overlap with a multitude of associated partners to differing degrees often give rise to problems which cannot be solved when setting up a detailed diagnosis. For this reason, depending on the respective level of knowledge, it is inevitable that "similar" immunopathies will be classified either as "identical" forms or possibly even as "entities" in their own right.

*The occurrence of an autoimmunopathy is invariably based on a genetic predisposition with an inducibility that differs in intensity from case to case.* • **However,** it is possible with great subtlety to detect the biochemical/biomolecular products of the cascade from the complement system, HLA system, antigen-antibody reactions, helper and suppressor cell functions, etc. (which in point of fact come *"at the end of the successful reaction"*). Furthermore, it is also possible to assess the respective interrelations of these products and to predict their immunopathogenetic significance. • Although the endocrine-autonomic-central nervous systems (in evidence *"at the beginning of humoral / cellular tolerance or defence"*) are generally accepted as a matter of course, they are still inadequately quantifiable.

The multiple reactions invoked *"on the biochemical pathway" (i. e. between the beginning and the end of an autoimmunopathy)* are definitely involved in the accumulation of other unknown intermediary products, which can in turn influence and manipulate a state of autoimmunopathy.

▶ see D. BITTER-SUERMANN (1983) and particularly „Immunologie und Psychoneuroendokrinium" (W.P. KASCHKA) in „Medizinische Immunologie" (H.W. BAENKLER, editor) (1996)

From their own experience, many clinicians are familiar with that often rapid and even insidious deterioration of an autoimmune disease as a result of extreme **overburdening of the endocrine or mental systems.** The cases of two patients, whose fate touched my staff and me deeply at the time, are briefly outlined below; as we experienced them, these were not merely post hoc, but propter hoc events, i. e. the one directly caused the other.

▶ *A female patient between 35 and 40 years of age with confirmed (in line with the methods of the time, including laparoscopy and biopsy) autoimmune hepatitis (ANA ++, SMA+, LMA+, LE factor+, IgG ++, γ-globulin++, GPT, GOT 80−100 U/l, GDH ca. 12 U/l, no cholestasis) had been undergoing treatment with prednisolone / azathioprine and had been in constant remission for over 3 years (maintenance dose of 4−6 mg prednisolone and 50 mg azathioprine for over 2 years). Physically and mentally stable, engaged in her profession, she had placed great confidence in us. Approximately 3 days after a sudden, severe emotional trauma with mental breakdown, the AIH deteriorated on a massive scale, and about 3 weeks later, the patient died in a coma hepaticum from acute liver failure.*

▶ *A female patient of approx. 45 years of age with autoimmune hepatitis and Sjögren's syndrome was in constant remission, having undergone treatment with prednisolone / azathioprine for more than 6 years. Physically and mentally stable, she was active at home, with her family and in her profession; compliance was excellent. The maintenance dose was 4−6 mg prednisolone and 50 mg azathioprine. A sudden, severe emotional trauma triggered an excessive and, despite all medication, progressive deterioration of her condition within a few days. A 2-year period of suffering followed with progression of CAH, confirmed by laparoscopy and two biopsies, to florid complete cirrhosis, from which the patient died.*

The methods applied today allow precise differentiation of autoimmune hepatitis, thus providing the necessary **early diagnosis.** • Besides the "classical" or "pure" forms of autoimmune hepatitis and autoimmune cholangitis (s. p. 659), HBV-positive and HCV-positive individuals and possibly PCR-confirmed carriers should be strictly excluded from types 1−3 with their respective subgroups and classified in their own overlap groups. (s. tab. 33.1) (s. p. 660)

## 9.2 Immunosuppressive therapy

*The primary target in treating autoimmune disease, especially autoimmune hepatitis, is to restore the immune balance.* • When correctly administered, immunosuppression can effect the remission of autoimmune hepatitis and improve the survival rate − and even normalize

individual life expectancy. However, this requires an early detailed diagnosis and the widest possible differentiation of the immunological and serological profiles as well as a histological investigation of the liver. (18, 53, 73, 93, 98)

### 9.2.1 Glucocorticoids

▶ Treatment of autoimmune hepatitis with glucocorticoids has been successfully carried out for about 45 years (A. R. PAGE et al., 1960). Fundamentally, prednisolone brings about remission of the condition in approx. 80% of patients. A survival rate of 10 years has been observed in over 90% of precirrhotic patients under prednisolone therapy (G. L. DAVIES et al., 1989). A course of glucocorticoid monotherapy is indicated in (*1.*) young patients, (*2.*) minimal inflammatory activity in the initial phase, (*3.*) relevant bone-marrow depression, (*4.*) cholestasis under azathioprine therapy (very rare), and (*5.*) women contemplating pregnancy, but who have to avoid using azathioprine. (15, 19, 69, 80, 85)

**Dosage:** Initial dose of approx. 1mg/kg BW/day for about 1 week (until an obvious reduction in transaminase values has been achieved), ca. 40 mg/day for 1 week, ca. 30 mg/day for a further 2 weeks and then ca. 20 mg/day, depending on the decrease in activity and onset of remission. With continued acceptance of a lower dose, a further reduction should be made in steps of 2.5−5 mg at intervals of 5−10 days until the desired maintenance dose of 4−8 mg is reached. A mean duration of treatment of 2−3 years is generally recommended. • Basically, we continued to administer the achieved maintenance dose ("only as much as required") as a *lifelong prednisolone therapy* unless, for any reason, it became necessary to stop treatment. In such cases, therapy should be phased out at a rate of 1 mg per week (!). On the principle of *"having respect for, but no fear of prednisolone"*, **osteoporosis prophylaxis** is of the utmost importance. Besides the administration of, for example, a combination of calcium and sodium fluorophosphates together with vitamin D, it is essential for the patients to exercise their muscles regularly every day. (s. p. 650) • *We also can confirm that the maintenance dose differs greatly for each individual patient − some patients remain in remission with 2−4 mg glucocorticoids.*

### 9.2.2 Glucocorticoids and azathioprine

▶ **Azathioprine** should not be used initially as monotherapy. However, remission attained with prednisolone and azathioprine can be maintained by azathioprine on its own (some 100−200 mg/day). (42, 85) • The combination of prednisolone with azathioprine (I. R. MACKAY, 1968) is just as effective as monotherapy with prednisolone. Moreover, with the above-mentioned initial dose of prednisolone (together with azathioprine), any subsequent dosage of prednisolone can be reduced more rapidly to a maintenance dose of 4−6 (−8) mg/day.

**Dosage:** An initial dose of azathioprine of 1−2 mg/kg BW/day (rounded off to the nearest 25 mg or 50 mg tablet) is recommended. A maintenance dose of 50−75 (−100) mg/day is sufficient. • We always administered the combination therapy from the outset and thereby did not observe any side effects from azathioprine − minor fluctuations in bone-marrow depression reverted to normal values spontaneously or after a short period of reduced dosage (25 mg). • With this maintenance dose, we retained a

number of female patients in remission for over 16 years (!) − see the patient group treated with prednisolone and azathioprine for primary biliary cholangitis. (s. p. 650)

As a criterion of successful therapy, the following remission figures are given in the relevant literature: 50−60% after 6 months, 70−80% after 12 months and 80−90% after 24 months. The corresponding success figures in terms of liver histology are 10%, 30−40% and 50−60%, respectively. At the end of successful therapy with a cessation of medication, ca. 50% of patients suffered a **relapse,** so that a new "initial dose" had to be applied − sometimes with less positive results, however. • Thus we consider a **lifelong maintenance dose** to be preferable. We have repeatedly noted that continued administration of the combination therapy eventually achieved a stabilized remission, even after a period of 2−3 (−4) years. *Particularly in immunopathies, patience is called for, while attention must focus on the current state of disease and on the patient "in his/her entirety".*

▶ Should *cirrhosis* be present at the time of initial diagnosis in the wake of confirmed "pure" autoimmune hepatitis (i.e. without HBV or HCV replication markers), it is advisable to implement combined immunosuppression − which is often successful in relatively low but sufficient dosage. Even if the morphological end-stage has already been reached, inflammatory activity can be repressed and clinical improvement achieved. • The question of whether (and when) a liver transplantation should be planned always has to be considered.

**Budesonide:** Initial results with the oral "topical" steroid budesonide have also proved remarkable in AIH. (21) In precirrhotic patients without collateral shunts, this substance achieves a first-pass effect in the liver of up to 90%, resulting in a satisfactory anti-inflammatory steroid impact with only minor side effects.

### 9.2.3 Ursodeoxycholic acid

If cholestasis is not present, the additional application of ursodeoxycholic acid (UDCA) is worth considering because of its pharmacological properties and lack of side effects or interactions. • Initial results on the treatment of **chronic hepatitis** with UDCA were reported by F. Ichida (1961), T. Nakahara et al. (1975) and K. Miyaji (1976). (s. p. 705) • In 1988 our study group also noted obvious and permanent effects of UDCA on the course of disease in terms of clinical and laboratory indices in severe **acute viral hepatitis B.** (s. p. 437) Such observations were confirmed by A. Jorge in 1993. • Owing to the multiple mechanisms of action of UDCA, in particular its immunomodulatory effect, adjuvant therapeutic efficacy can be anticipated in **autoimmune hepatitis,** as reported by P. Janowitz et al. in 1996. In autoimmune-associated chronic hepatitis C, UDCA proved to be a successful therapeutic agent (K. Nakamura et al., 1999).

### 9.2.4 Monitoring therapy

*GPT* is the leading parameter for regular monitoring of laboratory indices − initially at intervals of 4−8 days and subsequently every 2−4 weeks (depending on the activity status). *GDH* is a good complementary value, possibly together with GOT (for the concurrent determination of the respective quotient). (s. tabs. 5.6, 5.7) • The *γ-globulin* value is a further important parameter. With these results, it is possible to assess the course of AIH reliably and to monitor the success of therapy. (14)

### 9.2.5 Non-responders to therapy

▶ Patients in whom initial treatment was devoid of success (though a detailed diagnosis had been made) and increased dosage in a renewed course of therapy failed or in whom relapse therapy was not efficacious were administered **cyclosporin** (3−5mg/kg BW). However, there are divergent reports regarding the success rate of this treatment. (30, 40, 59, 68, 70, 82) • In individual cases, good results have been achieved with **cyclophosphamide** (100 mg and subsequently 50 mg/day). (44) • New, effective substances that have been successfully used in AIH type 1 include **tacrolimus** (94) and **mycophenolate mofetil.** (8, 76) • In the case of treatment failure (prednisolone + azathioprine), the administration of **methotrexate** (7.5 mg/week) proved successful in type 1. (10) Good therapeutic efficacy could also be achieved with **6-mercaptopurine** after failure with azathioprine. (71)

**Boswellinic acids** are seen as selective non-redox inhibitors of leukotriene biosynthesis. Leukotrienes are mediators of inflammation. Boswellic acids proved to be antiphlogistic, hepatoprotective and immunosuppressive in their impact (H. P. T. Ammon et al., 1991). • Although there has been no therapeutic application in hepatology up to now, it is likely that future discussion will focus on this pharmacologically interesting group of substances. (s. pp 652, 659)

A small percentage (5−15%) of patients can be defined at an early stage as **non-responders;** their condition and the laboratory parameters show no improvement within the first 2−4 weeks. Should histological investigation reveal bridging necroses that are already dilated as well as multilobular liver cell necroses, conservative therapy does not usually prove successful − such patients are candidates for liver transplantation.

### 9.2.6 Overlap syndrome

Present-day immunological examination techniques facilitate a detailed differential diagnosis of the presenting overlap syndrome. They also provide information which is useful for the pathogenetic, clinical and prognostic assessment of the associated diseases. Whether or not such immunological diagnostics will result in further divergent therapeutic measures cannot (as yet) be foreseen − but this is feasible in view of the anticipated development and testing of new immunosuppressive substances (such as mycophenolate mofetil, monoclonal anti-CD4 antibodies, T-cell vaccines, T-cell

receptor antibodies, HLA-blocking peptides, anti-HLA antibodies, etc.).

**UDCA:** The administration of UDCA offers the least risk due to its relative lack of side effects or interactions. It is the therapy of choice in all overlap syndromes with PBC or PSC features and also in cases with autoimmune cholangitis phenomenology. • In view of the above-mentioned positive effects on chronic and acute viral hepatitis as well as in AIH, UDCA is both pharmacologically and clinically plausible as adjuvant therapy.

**Interferon:** The occurrence of AIH during the treatment of chronic hepatitis B with interferon has already been described (13), as have manifestations and new episodes of inflammation caused by interferon in patients with AIH and chronic hepatitis C. (32, 66, 78) The indication for interferon therapy has to be considered with caution in cases of chronic viral hepatitis with concurrent AIH or autoimmune cholangitis; it should also be monitored with great care. In replicative chronic hepatitis B, B/D or C, the chronic viral hepatitis constitutes the major factor − whereas AIH is seen as a concomitant phenomenon. Immunosuppressive therapy is not indicated. • In addition, as recent studies show, there are also differences within the HCV infection itself; for example, 90% of HCV carriers in Japan and 20% of those in the USA and Germany are at the same time HGV carriers (GB-C). The GB-C and HGV hepatitis viruses are designated "defective" because they require "completion" by the helper virus HCV. (s. p. 450)

This recently acquired knowledge gives new impetus to our **suggestion** of removing all patients with replicative HBV, HBV/HDV and HCV infections from their respective groups (1a, 1b, 2b, 3); they can then be redefined and treated as separate overlap groups. • *These patients have "another immunology" − and indeed "other statistics".*

## 9.3 Liver transplantation

Liver transplantation is indicated in the terminal stage of cirrhosis, in acute liver failure and, above all, for non-responders to long-term therapy. The 5-year survival rate is 85−90%. Determining the right time for transplantation is problematical, however. *All possibilities of medication should have been exploited first.* It is remarkable that AIH reoccurs in the transplanted liver: in 7−10% of cases after 1 year and in 65−70% of cases after 5 years. In patients with HLA-DR3, there was no evidence of recurrence anymore. (13) Following transplantation, the autoantibodies may disappear from the serum. (12, 22, 27, 57, 62, 75, 80, 105)

# Clinical Aspects of Liver Diseases

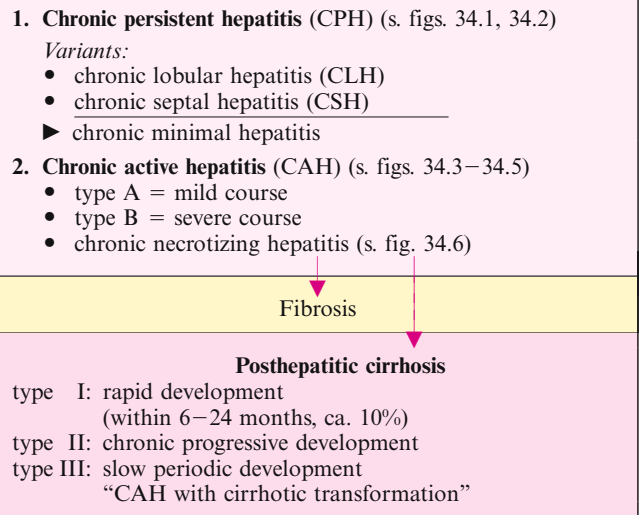
## 34 Chronic hepatitis

# 34 Chronic hepatitis

## 1 Definition

Chronic hepatitis is *not an entity*, but a heterogeneous group of diseases of varying aetiology, pathogenesis, degree of activity and stage of progression. Thus, like acute hepatitis, this condition constitutes a *syndrome*. • The joint *histological picture* comprises predominant portal inflammation and subsequent periportitis (= interface hepatitis) with different degrees of focal, periportal, zonal or confluent liver cell necrosis, and progredient fibrosis. • *Duration* is long: chronic inflammatory liver diseases persist for more than 6 months. • *Prognosis* is doubtful. This condition may progress through a common final stage to cirrhosis, HCC or liver failure, but also to defective healing, whereby stationary liver fibrosis persists.

## 2 Historical review

▶ About 70 years ago (1932), the term **latent liver damage** was coined by H. KALK, who, without any knowledge of morphological findings, was the first clinician to attempt a classification of different chronic liver diseases into clinical groups. • This interpretation was the basis for G. v. BERGMANN's definition of **latent hepatopathy** (1936) (s. p. 74); the clinical observations made by him at that time indeed correspond closely to the picture of chronic hepatitis. • Based on clinical findings in eight patients, E. POLACK observed the transition of acute epidemic hepatitis into **chronic hepatitis** as early as 1937. • *Later, in 1942, K. ROHOLM et al. reported on the histological progression of acute hepatitis to chronic hepatitis in an extensive study involving twelve patients and even monitored the further course up to the development of cirrhosis.* • In 1942 A. KORNBERG used the nomenclature **chronic latent liver damage** following jaundice; F. GEBHARDT et al. (1944) reported on **posthepatitic residual damage** and M. D. ALTSCHULE et al. (1944) on **chronic latent hepatitis** following catarrhal jaundice. The occurrence of **late posthepatitic liver damage** was substantiated by W. VOLWILER et al. (1948). (quot. 18) • From 1947 onwards, H. KALK provided more basic knowledge about **chronic hepatitis**, which he considered to be a chronic interstitial inflammation (according to R. RÖSSLE). By means of laparoscopy, H. KALK distinguished between **four stages:** (*1.*) *large red liver*, (*2.*) *large white liver*, (*3.*) *large multicoloured liver*, and (*4.*) *large multicoloured tuberous liver*. (quot. 18)


## 3 Histology

### 3.1 Classification (1968)

Based on the different histological criteria, chronic hepatitis was subdivided in 1968 into (*1.*) **chronic persistent hepatitis** (CPH) (a term coined by H. F. SMETANA as early as 1954) and (*2.*) **chronic active hepatitis** (CAH) (E. G. SAINT et al., 1953) with a *mild* (type A) and a *severe* (type B) course. (7) In this context so-called **chronic necrotizing hepatitis** can be integrated. (24) (s. fig. 34.6) (s. tab. 34.1) • This classification was further refined by the additional

differentiation into **chronic lobular hepatitis** (CLH) (H. POPPER et al., 1971) and **chronic septal hepatitis** (CSH) (M. A. GERBER et al., 1974). (10) CLH and CSH are deemed to be variants of chronic persistent hepatitis. CPH exhibits septum formation with a clear inflammatory reaction, yet without piecemeal necrosis. The prognosis for CSH is poorer than that for CLH. • **Chronic minimal hepatitis** shows sparse hyaline necrosis and slight portal cellular infiltrations. Generally, these alterations remain unchanged for years. Morphologically, this term corresponds to so-called *non-specific reactive hepatitis* (V. DESMET, 1986). These reactions are of an inflammatory nature and can be attributed to primarily extrahepatic disease or to focal intrahepatic space-occupying lesions. (s. p. 392) • Occasionally, more severe inflammatory signs can be witnessed in CPH due to increased viral replication and immune reactions. This form was described as minimally active, chronic hepatitis (L. BIANCHI, 1986). (2) Thus, even CPH can develop into CAH.

Initially, this classification, which was based on well-defined **histological criteria**, proved useful − especially since reliable serological or immunological differentiation was not possible at that time. It should be mentioned that the differentiation of CLH was, however, not generally accepted − although this condition is frequently seen in chronic hepatitis C. (12, 18, 24, 26) (s. tabs. 34.1)

---

1. **Chronic persistent hepatitis** (CPH) (s. figs. 34.1, 34.2)
   *Variants:*
   - chronic lobular hepatitis (CLH)
   - chronic septal hepatitis (CSH)
   ▶ chronic minimal hepatitis
2. **Chronic active hepatitis** (CAH) (s. figs. 34.3−34.5)
   - type A = mild course
   - type B = severe course
   - chronic necrotizing hepatitis (s. fig. 34.6)

Fibrosis

**Posthepatitic cirrhosis**
type I: rapid development
            (within 6−24 months, ca. 10%)
type II: chronic progressive development
type III: slow periodic development
            "CAH with cirrhotic transformation"

*Tab. 34.1:* Schematized morphological classification of chronic hepatitis and its potential to develop into fibrosis and cirrhosis

---

### 3.2 Histological criteria

The histological criteria of chronic hepatitis are (*1.*) liver cell damage, (*2.*) inflammatory infiltration, and (*3.*) fibrosis formation. These chronic inflammatory reactions affect firstly the portal field, then the periportal region (i.e. zone 1) and finally the liver lobule. Such reactions constitute a dynamic process, whereby the intensity of the above-mentioned criteria as well as their topographical distribution pattern in the portal, periportal and azinar area vary considerably. (14, 16)

(*1.*) **Portal inflammation:** *Portal hepatitis* reveals varying inflammatory activity. It is common to all forms of

chronic hepatitis and is composed mainly of a mixture of lymphocytes, plasma cells and macrophages. The portal inflammation may stop at the limiting plate, but can also penetrate it. In a long-term course, ductular proliferations sometimes appear at the edge of the portal field; they are accompanied by granulocytes. If the portal hepatitis shows no signs of periportal or lobular inflammation, the disease is deemed to be *inactive*. (1)

(*2.*) **Periportal inflammation:** *Periportal hepatitis* is characterized by penetration of the limiting plate. The border between the portal field and the lobule can appear irregular; sometimes it assumes the shape of a maple leaf. In this periportal zone (i. e. zone 1), piecemeal necroses may develop. They are, however, not true "necroses", but apoptoses. Today, periportal inflammation with piecemeal necrosis is termed *interface hepatitis*. This condition is not always accompanied by piecemeal necrosis; the inflammatory infiltrate can also enter the lobule without causing liver cell necroses. The composition of the inflammatory infiltrates is similar to that in the portal fields. Periportal inflammation contributes to the grading of chronic hepatitis. (1)

(*3.*) **Lobular inflammation:** Whereas lobular, diffusely distributed inflammation is more evident, in acute hepatitis portal and periportal inflammation predominates in chronic hepatitis and lobular hepatitis is less pronounced. Generally, it consists of separate small clusters of mononuclear cells. Scattered necrotic hepatocytes (= acidophilic / Councilman bodies) are found; the hepatocellular nuclei are in disarray (= anisonucleosis); there is swelling of the hepatocytes, and mitoses are present. Marked lobular hepatitis in conjunction with considerable portal and periportal inflammation is typical of "flares" of chronic viral hepatitis or autoimmune hepatitis. In addition to single-cell necroses, there are confluent necroses, which affect entire lobules. Bridging necroses link portal tracts with other portal tracts or with terminal venules. (1)

▶ *Steatosis* is uncommon in chronic hepatitis; however, in chronic hepatitis C, steatosis is found in about 70% of cases (especially in genotype 3). Generally it is mild and non-zonal. • *Cholestasis* is rare in chronic hepatitis, but more frequent in autoimmune hepatitis.

## 3.3 Problems of designation

**Various designations** have been used in the literature for the multiform clinical picture of chronic hepatitis. This illustrates that in the absence of biochemical, serological and immunological test methods, chronic liver diseases with different aetiology or pathogenesis were defined almost exclusively on the basis of histological and occasionally also laparoscopic findings as minimal chronic hepatitis, CPH, CAH, CLH or CSH. This inevitably led to widely **varying results** concerning the assessment and treatment of the different forms. • The 5-year survival rate of CPH (97%), for instance, appeared to be nearly identical to that of CAH (87%) (63), i. e. these reference groups had been classified as CPH or CAH on the basis of "representative" biopsy specimens − yet according to current classification based on statistical evaluation, they showed a largely identical composition. • The chronic inflammatory reactions are by no means stationary, but constitute a fluent process with transitions and overlaps. • *Depending on the respective aetiopathogenesis, chronic hepatitis may vary greatly in its degree of severity with regard to segmental and focal lesions.* This significant finding, which was already made some 30 years ago(!), is most certainly worth recalling (s. p. 181 and there quot.: 155) • *The situation is further complicated by the fact that only a relatively small area of the right lobe of liver is accessible for histological examination by way of percutaneous biopsy.* Therefore, a specimen from this area is not necessarily representative for other parts of the liver! (s. fig. 7.8)

## 3.4 Classification (1994)

Increasing knowledge about HCV infection revealed that histological findings frequently suggest a seemingly favourable prognosis for CPH despite the high risk that chronic hepatitis and even cirrhosis may develop. (80) With the possibility of more exact serological and immunological differentiation, the previously used classification proved increasingly artificial and problematic. It was time to assess chronic hepatitis according to aetiopathogenetic criteria. • *The current classification of chronic hepatitis is based on:* (*1.*) aetiology of the disease, (*2.*) activity of the inflammatory process (= grading), and (*3.*) degree of fibrosis (= staging). (1, 8, 13) (s. tabs. 34.2, 34.3) (s. figs. 34.1−34.6)

(*1.*) **Aetiology** is based on laboratory parameters, serology, immunology or PCR. Immunohistochemical evidence of HBsAg and HBcAg may, in individual cases, confirm HBV infection as the cause of "cryptogenic" chronic hepatitis. By evaluating the number and the relative proportions of HBs-positive and HBc-positive cells, chronic hepatitis B can also be differentiated from HBs-carrier status or (acute or prolonged) HBV infection; the presence of antibodies against HAAg and HDAg also provides verification of a specific superinfection. • The term chronic hepatitis includes several different types: (*1.*) *chronic viral hepatitis*, (*2.*) *chronic toxic hepatitis*, (*3.*) *chronic autoimmune hepatitis*, (*4.*) *chronic metabolic hepatitis*, and (*5.*) *chronic cryptogenic hepatitis*. • Apart from that, there are numerous other pathological processes which may also trigger chronic hepatitis. The coincidence of two (or three) causative factors may likewise result in such a disease. Obviously, the severity and prognosis of chronic hepatitis primarily depend on the cause(s). (s. tab. 34.4)

***Fig. 34.1:*** Chronic persistent hepatitis: smooth liver surface with spotted, brick-red coloured pattern. Clearly pronounced blood vessels with perivascular connective tissue, fine perilobular fibrosis

***Fig. 34.2:*** Chronic portal hepatitis with dense lymphocytic infiltration of enlarged portal tracts (HE)

***Fig. 34.3:*** Chronic active hepatitis: flat, undulatory liver surface ("scattered light reflection") with pronounced fibrosis, scarring and a marked rim of connective tissue in the left lobe of liver. Red spots due to highly inflammatory parenchymal areas. Isolated fine blood vessels and distinct lymphatic congestion

***Fig. 34.4:*** Chronic active hepatitis with periportal piecemeal necrosis ($\rightarrow$) and apoptosis (▶) in the lobular parenchyma

(*2.*) **Grading** *describes the necroinflammatory activity*, which is based on (*1.*) hepatocellular damage, (*2.*) liver cell death, and (*3.*) inflammatory infiltration. Previously used terms such as CPH, CLH and CAH only represented grading, but not staging. The degree of activity ranges between minimal and severe. Various forms of *necrosis* are present: (*1.*) focal necrosis, (*2.*) confluent (bridging) necrosis, or (*3.*) periportal/periseptal piecemeal necrosis. (1) • The predominantly lymphocytic infiltrations of the portal fields occasionally result in lesions of the bile ducts located in that area. The inflammatory changes then spread to the limiting plate and subsequently to the lobule. Single-cell and group necrosis as well as confluent bridging necrosis occur. • If there are no or insufficient histological results, the values of the indicator enzymes (GPT, GOT, GDH) in combination with the DeRitis ratio and increases in γ-globulin and immunoglobulin levels (e. g. in autoimmune hepatitis) may serve as substitute parameters for assessing disease activity.

(*3.*) **Staging** *reflects the degree of architectural* alterations due to (*1.*) fibrosis and (*2.*) cirrhosis. Fibrosis may be portal, periportal, bridging portoportal or bridging portocentral. Glisson's capsule is also involved in fibrogenesis. The extent of fibrosis facilitates assessment of both the stage of chronic hepatitis and its progression to cirrhosis. Fibrosis is differentiated using the scale of "none" through to "severe". • *For reasons of simplification, the abbreviations G 1-4 and S 0-3 are suggested.* (s. tabs. 34.2, 34.3) (s. figs. 34.1−34.5)

**Fibrosis:** *As a consequence of the necroinflammatory process*, fibrogenesis is activated (s. p. 403); it begins in the portal fields and leads to their fibrotic dilation. Fibrosis extends to the periportal zones and can ultimately link portal tracts to other portal tracts and to terminal hepatic venules. Reliable staging requires con-

| Grading of chronic hepatitis (= inflammatory activity) | | |
|---|---|---|
| **G 1: minimal** | = | mild portal inflammatory infiltrates, intact limiting plates, isolated necrosis |
| **G 2: low-grade** | = | mainly portal, yet also slightly lobular inflammatory infiltrates, focal liver cell necrosis |
| **G 3: moderate** | = | dense portal inflammatory infiltrates, piecemeal necrosis, single-cell and group necrosis, centro-portal bridging necrosis |
| **G 4: high-grade** | = | dense inflammatory infiltrates with periportal and septal piecemeal necrosis, confluent portocentral and portoportal bridging necrosis, sublobular and panlobular necrosis |
| **Staging of chronic hepatitis (= degree of fibrosis)** | | |
| **S 0: no fibrosis** | ∅ | |
| **S 1: low-grade** | ⟶ | slight portal and periportal fibrosis |
| **S 2: moderate** | ⟶ | portoportal fibrous septa |
| **S 3: high-grade** | ⟶ | portoportal/portocentral fibrous septa, active and passive septa |

| **Stationary fibrosis** | **Cirrhosis** |
|---|---|

**Tab. 34.2:** Grades of activity and stages of fibrosis in chronic hepatitis (with abbreviations of classification: **G** 1−4, **S** 0−3)

nective tissue stains, because with haemotoxylin and eosin stains, the true extent of the fibrosing process is often underestimated. Especially in chronic hepatitis C, fibrosis shows wide variability. Subsequently, the formation of (active and passive) fibrous septa occurs (s. p. 407); regenerative nodules appear, pointing to the development of cirrhosis.

Due to the borderline morphology, it is impossible to draw a clear distinction between CPH and CAH, particularly with regard to chronic hepatitis C. Such cases should be classified as so-called minimally active CAH (2), since they carry the risk of cirrhosis formation. The histological picture of CPH-C should therefore not be equated with continuous morphological inactivity and favourable prognosis; it is not advisable to leave such a condition untreated, as is sometimes suggested. Chronic inflammation always has to be regarded as a fluent process, which may vary toporegionally. Histological findings are of great importance, but nevertheless only temporary (and possibly local) in nature. • The findings of *"chronic hepatitis"* (= chronic inflammatory process) and *"cirrhosis"* (= structural transformation of the hepatic lobular architecture) may overlap toporegionally. This problem of nomenclature is occasionally dealt with by using the term *"cirrhosis with CAH"*. (9)

**Scoring systems** have been proposed for classifying the results of grading and staging. (1, 3, 7, 12, 17, 20−23, 26) Such semiquantitative systems seem more practicable for scientific studies than for daily practice. (1) There is one particular system which can be recommended for histological scoring with regard to chronic hepatitis; it represents a modification of proposals. (s. tabs. 34.2, 34.3)

The histological components of chronic hepatitis can be evaluated semiquantitatively and summarized in a **histological activity index** (HAI). This index combines the values for the inflammatory infiltrate, liver cell necrosis

and fibrosis in an end score. (15) • The HAI modified in 1995 considers all aspects of criticism mentioned in this context and has proved very useful for comparative observations of the course of disease. (13)

**G 1: Minimal chronic hepatitis**
− loose lymphocytic infiltrate, single-cell necroses
− slightly widened portal fields, intact limiting plate

**G 2: Mild chronic hepatitis**
− more dense lymphocytic infiltrates
− widening of portal fields
− lymphoid/pseudolymphoid follicles
− single-cell and group necroses
− damaged limiting plate (piecemeal necroses)

**G 3: Moderate chronic hepatitis**
− numerous piecemeal necroses, clearly widened portal fields
− dominant lymphocytes, liver cell rosettes
− pronounced necroses in the parenchyma
− dense inflammatory infiltrates in the lobule

**G 4: Severe chronic hepatitis**
− bridging necroses, greater number of piecemeal necroses
− street-like hepatocyte decay with lymphocytic infiltrates
− structural disorder of the liver

**S 1: Minimal fibrosis**
− mild fibrous expansion of the portal fields
− unchanged parenchyma

**S 2: Mild fibrosis**
− distinct fibrous widening of the portal fields
− periportal fibrosis with fine strands in zone 1

**S 3: Moderate fibrosis**
− complete connective-tissue septa
− portoportal and portocentral septa

**S 4: Severe fibrosis**
− pronounced formation of bridging fibrosis
− transition into cirrhosis cannot be ruled out
− nodular regeneration

**Tab. 34.3:** Chronic hepatitis: inflammatory activity (grading) (**G** 1−4) and degree of fibrosis (staging) (**S** 1−4)

At the end of the morphological development of chronic hepatitis, aetiologically defined **cirrhosis** occurs in a certain percentage of cases. In this connection, no "primary" cirrhosis exists (as with the exclusively historical term "primary" biliary cirrhosis). Even though cryptogenic cirrhosis may be in evidence, *the term "primary" is not acceptable because cirrhosis is not a "primary" occurrence!*

# 4 Aetiology and differential diagnosis

More than 600 million people are suffering from chronic hepatitis of different aetiology worldwide. Most of the diseases included in the syndrome of acute hepatitis (s. fig. 22.6) may also develop into chronic hepatitis. The latter is therefore likewise considered to be a **syndrome**, i.e. *heterogeneous group* of chronic inflammatory liver diseases. • In most cases, chronic hepatitis is caused by the hepatitis viruses B, C, B/D, possibly also C/G and GB-C. • *However, a case of chronic hepatitis due to HAV infection was reported for the first time by K. Inoue et al. in 1996.* (27) • Isolated cases of chronic hepatitis caused by bacteriae or secondary hepatotropic viruses have been reported, e.g. Q fever (P. Atienza et al., 1988), CMV (126), Epstein-Barr virus. • Chronic hepatic autoimmunopathies are more common than has hitherto been assumed (10−20%). Toxic liver damage may pose great problems in differential diagnosis. Fulminant liver failure can also develop into chronic hepatitis. Genetic and/or metabolic diseases are relatively rare, but should always be taken into account in the broad spectrum of chronic hepatitis. All of these possibilities which must be considered in the differential diagnosis require their own specific diagnostic parameters. (s. tab. 34.4)

**Cryptogenic CAH:** All chronic inflammatory liver diseases that have not yet been fully clarified as regards their aetiology are subsumed in the group of cryptogenic chronic hepatitis (15−20%). • As a result of improved biochemical, serological, immunological and histological/histochemical test procedures, this group is diminishing in terms of figures. *It can be expected that there will be further "revelations" concerning differential diagnostics in the near future and that the cryptogenic chronic hepatitis group will gradually disappear.*

**Posthepatitic CAH:** In terms of frequency, chronic hepatitis caused by hepatitis viruses (B, C, B/D) clearly predominates. (s. tab. 34.4) Because of their great epidemiological and prognostic relevance, treatment of these viral forms of chronic hepatitis has become a central issue, particularly since the use of newly-developed compounds has facilitated genuine therapeutic success for the first time. Until recently, no antiviral compounds were available − hence, a real breakthrough has now been achieved.

**Non-viral CAH:** It should be noted that the treatment of the other, non-viral causes of chronic hepatitis is discussed in separate chapters covering the respective clinical pictures. (s. tab. 34.4)

1. **Primary hepatotropic viruses** *(see chapter 22)*
   − Hepatitis (A?) (s. p. 422!)   − Hepatitis C
   − Hepatitis B, B/D   − Hepatitis C/G
2. **Secondary hepatotropic viruses** *(see chapter 23)*
   − Cytomegalovirus   − Q fever
   − Epstein-Barr virus
3. **Bacterial infection** *(see chapter 24)*
4. **Parasitic infection** *(see chapter 25)*
5. **Toxic causes**
   − Alcohol *(see chapter 28)*
   − Drugs *(see chapter 29)*
   − Chemicals *(see chapter 30)*
6. **Genetic/metabolic aetiology** *(see chapter 31)*
   − Abetalipoproteinaemia   − Galactosaemia
   − $α_1$-antitrypsin deficiency   − Haemochromatosis
   − Chronic hepatic porphyria   − Mucoviscidosis
   − Glycogen storage disease   − Wilson's disease
7. **Autoimmunopathies**
   − Primary biliary cholangitis *(see chapter 32)*
   − Primary sclerosing cholangitis *(see chapter 32)*
   − Autoimmune cholangitis *(see chapter 32)*
   − Overlap syndrome *(see chapter 32)*
   − Autoimmune hepatitis *(see chapter 33)*
8. **Chronic cardiac liver congestion**
9. **Immunological rejection following transplantation**
10. **Malignant lymphoma**
11. **Cryptogenic chronic hepatitis**

**Tab. 34.4:** Aetiology and differential diagnosis of chronic hepatitis (see respective chapter for more details)

# 5 Diagnosis

## 5.1 Clinical findings

Chronic hepatitis may take an **asymptomatic course** for several years, both subjectively and in terms of clinical findings. Frequently, it is only noticed by chance. In some cases, liver cirrhosis may be present at initial diagnosis. • **Symptomatic courses** are most commonly characterized by chronic fatigue (so-called *"pain of the liver"*), exhaustion and reduced performance; occasionally, patients suffer from malaise, loss of appetite, nausea, intolerance of certain foodstuffs and meteorism as well as myalgia and arthralgia. The complaints are often discrete and variable − but also non-specific, which easily leads to misinterpretation. (s. p. 77) • **Clinical findings**, such as hepatomegaly, skin stigmata of liver disease (s. p. 79) or urobilinogenuria, usually only become manifest after prolonged disease. Acute episodes are generally accompanied by low-grade jaundice. (12, 18, 19, 45, 47)

## 5.2 Laboratory findings

Initially, laboratory findings are ambiguous. There is a moderate increase in GPT, GOT, GDH and γ-GT. In toxic and cholestatic forms, γ-GT and AP are correspondingly elevated. Cholinesterase is generally reduced. The rise in transaminases is a sign of enzymatic activity, which usually correlates to a greater or lesser extent with histological activity. The elevation of γ-globulins and immunoglobulins is a sign of mesenchymal activity (s. p. 100); it is also an expression of the severity of fibrosis. The latter may be recognized by the rise in serum P III P and hyaluronic acid values. (111, 123) (s. p. 112) Zinc deficiency is frequently found, albeit less pronounced than in cirrhosis • However − as has been mentioned above − no exact diagnosis is possible yet. • Subsequent diagnostic procedures should include *specific parameters*. Viral serology is examined step by step and, in the case of suspicion, also the antibody profile (e. g. ANA, SMA, LKM, LP); in cholestatic forms, AMA and pANCA are likewise determined. (s. tabs. 5.20; 33.1) Metabolic liver diseases require individual laboratory tests, such as copper, ferritin, porphyrins or $α_1$-antitrypsin. (18, 50, 56, 76, 89, 108, 133)

The *4-fold enzyme pattern*, which is compiled by adding alkaline phosphatase to the 3-fold pattern, has proved useful as a general screening test. Hereby, non-responders who do not show a γ-GT increase in cholestasis (2−3%) are also detected. Liver disease is confirmed or ruled out with a probability of 96−97%. (s. tab. 5.11) • Further diagnostic clues are rapidly and easily obtained by means of *enzyme ratios*. (s. tabs. 5.6, 5.7)

## 5.3 Morphology

As far as possible, the morphological diagnosis should be established during the first investigation by targeted **liver biopsy** (right and left lobes of liver) using **laparoscopy**. The structure of the liver surface should be recorded photographically. Examination of the biopsy specimens with UV light is essential. The sensitivity of percutaneous liver biopsy in chronic hepatitis is 75−80%, but 98% for laparoscopy plus biopsy (R. ORLANDO et al., 1990) and about 100% for biopsy specimens collected from both liver lobes. (5, 6, 9, 11, 71, 110, 212) (s. fig. 7.10) (s. pp 144, 157, 627, 699)

## 5.4 Imaging techniques

Imaging techniques (with the exception of ERC, e. g. in PSC) are generally of no diagnostic value in chronic hepatitis prior to the development of cirrhosis. • *Sonography* is regarded as a basic, routine examination and is always indicated in cholestatic diseases or suspected cirrhosis. (9) There is often evidence of abdominal lymphadenopathy (especially of the hepatoduodenal ligament), which points to a more severe histological picture. (25, 33) • *CT* should be carried out in cases where $α_1$-foetoprotein, which is initially subject to regular monitoring at longer intervals, shows a continuous increase, thus arousing suspicion of the development of hepatocellular carcinoma. • In concordance with the histopathological stages, *$^1H$-MR spectroscopy* indicated the severity of fibrosis in chronic hepatitis. This imaging technique was suggested as a potential substitute for liver biopsy in staging chronic hepatitis. (4)

# 6 Course and prognosis

## 6.1 Course

The natural course and dynamics of chronic hepatitis are determined by the **underlying disease**. In line with the multiplicity of causes, the disease course is highly variable: on the one hand, there are courses, which remain virtually static for years ("chronic persistent") − i. e. chronic hepatitis shows no changes in terms of clinical, biochemical and histological findings; on the other hand, there are chronic active courses, which progress rapidly ("chronic aggressive"), as well as "necrotic" hepatitis, which may result in cirrhosis within a few months (!). In contrast, remission periods of varying duration may also be observed. • The question of *"why"* the disease shows **chronification** in individual cases or *"why"* there is sometimes evidence of **exacerbation** remains unanswered. However, there are several possible causes which are cumulative or may even potentiate each other. Thus, the course of disease and therapy success are strongly influenced by the individual genotype of HBV (42, 58, 66), lipid peroxidation (35) and microcirculatory disturbances. (39) (s. tab. 34.5)

| **Basis for initial prognosis:** |
| --- |
| 1. Early or late diagnosis |
| 2. Underlying disease |
| 3. Available therapy regimens |

**Risk factors:**
1. **Impaired immune system**
   - genetically determined
   - endogenously induced
   - exogenously induced
2. **Endogenous mechanisms of impairment**
   - hepatitis virus mutations
   - endocrine imbalance
   - toxins
3. **Exogenous factors**
   - alcohol
   - drugs
   - chemicals
   - drug addiction
   - infections
   - malnutrition
4. **Lipid peroxidation**
5. **Extrahepatic manifestations**

*Tab. 34.5:* Prognostic factors and possible causes of chronification, exacerbation or reactivation in hepatitis

The severity of *liver cell necrosis* is the focal point of the pathogenetic process; it determines both the dynamics

and variability of the course of disease. Liver cell necrosis may result from (*1.*) direct damage by the causative factor, (*2.*) free radicals and lipid peroxidation (s. fig. 21.12) (s. pp 68, 401), and (*3.*) inadequate activation of CD4+ and CD8+ T lymphocytes in viral infection. • Lymphocytic infiltrates develop together with liver cell necrosis and the activation of phagocytosis. There is an increase in fibrosis with the associated deterioration in metabolic activity and thus further liver cell necrosis. (s. p. 400) Liver cells proliferate and regeneration nodes form, leading to more distortion and rarefaction of the vascular architecture. • Persistent liver cell necrosis continues to activate the cascade of proliferation processes and cause *fibrosis*: chronic inflammatory liver disease progresses to cirrhosis. Development of cirrhosis occurs with a probable frequency of 2−3% per year, i.e. a cumulative frequency of 15−20% in 5 years. In 2,215 patients with chronic viral hepatitis, the rate of development of cirrhosis was 7.6%, 21.7% and 32.2% in the 5th, 10th and 15th year, respectively (K. IKEDA et al., 1998). Highly active CAH (type B) leads to the development of cirrhosis after 7 years in 80−85% of cases, with a mortality rate of 40−45%. (34, 41, 49, 60, 135) • Should the damaging process come to a halt with no further liver cell necrosis, *spontaneous remission* occurs in approx. 3% of cases per year, or partial recovery takes place with defective healing at the respective stage of (generally irreversible) liver fibrosis. (92, 97, 100, 109, 111, 122, 123, 171, 224, 240, 257) Depending on the severity and localization of fibrosis and on the perfusion resistance, portal hypertension can develop. (18, 37, 49, 63, 139)

## 6.2 Extrahepatic manifestations

Extrahepatic disease manifestations associated with chronic hepatitis B and C are frequent; about 40 forms, mainly autoimmune disorders, have been reported up to now. (s. tabs. 22.2, 22.7, 22.8, 32.3, 32.6, 33.2) A reliable association of these manifestations with HBV and HCV is not known, nor is a true frequency given. The most common association is found with HCV infection. Apparently, HCV has tropism for cells other than hepatocytes, particularly lymphocytes. Therefore it has been postulated that the HCV infection of lymphocytes may be the "cause" of a greater number of extrahepatic (especially autoimmune) diseases. A selection of extrahepatic manifestations shows the wide clinical spectrum of these disorders. (67, 112, 119) (s. tab. 34.6)

**Mixed cryoglobulinaemia:** The term cryoglobulinaemia was first used by A.B. LERNER et al. in 1947. Clinical manifestation consists of the *Meltzer triad*: (*1.*) weakness, (*2.*) arthralgias, and (*3.*) palpable purpura (M. MELTZER et al., 1966) as well as other clinical features, including glomerulonephritis, hepatomegaly, splenomegaly and lymphadenopathy. Morphologically, there is predominant leucocytoclastic vasculitis involving medium and small-sized arteries with deposition of immunocomplexes in the vessel walls and subsequent inflammatory reactions. An association with HBV infection was first described by Y. LEVO et al. in 1973 and with HCV infection by M. PASCUAL et al. in 1990. There are three forms of cryoglobulin-

aemia, whereby type II consists of monoclonal IgM and polyclonal IgG and type III of polyclonal IgM with RF activity. The *course* is mostly asymptomatic. The prognosis is unpredictable in the individual case. • *Therapy* of the HCV-associated form is with IFNα + ribavirin, more recently with anti-CD20 antibody rituximab (F. ZAJA et al., 1999). (107, 140, 209, 217)

| | |
|---|---|
| Antiphospholipid syndrome | Non-Hodgkin's lymphoma |
| Behcet's syndrome | Pancreatitis |

| Lupus erythematodes | Urticaria |
| Multiple myeloma | Uveitis |

**Tab. 34.6:** Selection of extrahepatic disease manifestations associated with HBV or HCV infection (with some references)

## 6.3 Hepatocellular carcinoma

It is likely that the development of hepatocellular carcinoma is predominantly due to chronic regeneration. Usually, cirrhosis precedes the development of HCC by several years. The risk of developing HCC in HBV or HCV infection with cirrhosis is about 3−5% of cases/ year. However, individual cases of HCC without cirrhosis have also been reported. • Direct carcinogenic defects are assumed for hepatitis B (32, 44, 60) and hepatitis C (60, 79) as well as for haemochromatosis and alcohol-related disease. In 2,215 patients with chronic viral hepatitis B or C, the rate of development to HCC proved to be as follows: 2.1/4.8% in the 5th year, 4.9/ 13.6% in the 10th year and 18.8/26.0% in the 15th year (K. IKEDA et. al., 1998). • Vaccination against HBV infection prevents the development of HCC. (32) Successful treatment of chronic hepatitis C by means of IFN considerably lowers the risk of HCC. Fundamentally, an increased frequency of HCC has been observed in all kinds of cirrhosis, regardless of aetiology. The period of time prior to the development of cirrhosis and the subsequent occurrence of HCC is decisively influenced by the underlying cause. • Regular, periodic monitoring of $\alpha_1$-*foetoprotein* together with *sonography* is initially indicated. A continuous increase in $\alpha_1$FP requires investigations by **CT** (and *laparoscopy*) for suspected HCC. (s. pp 433, 444, 775)

## 6.4 Prognosis

The prognosis for chronic hepatitis is unfavourable. Depending on its aetiology, the individual course varies and is therefore difficult to predict. Prognosis depends on: (*1.*) early diagnosis, (*2.*) the nature of the underlying

disease, and (*3.*) the therapeutic possibilities available. The initial prognosis may be greatly worsened by immunological, endogenous and exogenous risk factors (s. tab. 34.5), e.g. childhood (31) and advanced age, high viral load and special viral characteristics. (19, 37, 40, 42, 51, 58, 61, 139, 142)

It is noteworthy that HBV DNA may persist in the serum and liver despite the elimination of HBsAg. Contrary to early reports, carefully performed long-term studies have shown that the prognosis is essentially more favourable with exact diagnosis and appropriate long-term treatment. (53) • Coinfection with HGV and GBV-C or HCV is frequent, but it has no influence on the course and severity of chronic hepatitis C or on liver transplantation. (74)

## 6.5 Chronic HBV infection

The **frequency** of chronic hepatitis following acute HBV infection is 5—10%. The total number of patients with chronic infection B is estimated at 350—400 million worldwide, in Germany about 500,000. HBV infection in childhood leads to a higher rate of chronicity. Lethality rate is up to 1%. *(see chapter 22.4!)*

In addition to the basic risk factors (s. tab. 34.5), possible **causes** of chronicity in HBV infection also include weak or non-existent virus-specific T cell activation, reduced interferon production and the occurrence of an HBeAg-minus variant. • **Morphology** generally shows *ground glass hepatocytes* or HBc-containing liver cell nuclei, so-called *sanded nuclei.* Ground glass hepatocytes contain homogeneous, glassy, slightly eosinophilic cytoplasm, which immunohistochemically displays a positive HBsAg reaction. This condition is probably a result of an abnormal composition of the HBsAg; in this special form, it cannot be discharged by hepatocytes. (62) (s. pp 113, 424) HBsAg can be stained with *orcein* in the hepatocytes only in HBV carriers and chronic hepatitis B (but not in the acute phase). (s. fig. 5.7) Mallory bodies are encountered much more rarely than in chronic hepatitis C. • Based on quantitative determination of certain serological markers, **three stages** of chronic hepatitis B are distinguished: (*1.*) high-replication phase with excessive HBcAg expression in the liver, positivity of HBsAg, HBeAg and DNA, moderately increased transaminases (= immunotolerant), (*2.*) low-replication phase with increase of transaminases, decrease of DNA titre and positivity of anti-HBc (= immunoactive), and (*3.*) healing process. Yet, minimal replication (< $10^5$ copies/ml in PCR) may also persist with HBeAg negativity. This may cause a more severe course or even the much-feared "reinfection" of the liver transplant. (28, 55) • **Seroconversion** marks the transition from the high-replication phase to the low-replication phase: loss of HBeAg and presence of anti-HBe with transaminases simultaneously reduced or normalized. (30, 46, 53) In the spontaneous course of chronic hepatitis B, seroconversion occurs every year in 1—3% (= HBsAg

to anti-HBs) or 10—15% (= HBeAg to anti-HBe) of cases. Perinatally transmitted HBV may be spontaneously eliminated during a period of 30—40 years (K. ÖRDÖG et al., 2003). • Shortly before or during IFN-induced seroconversion, a transitory **inflammatory episode** with elevation of GPT, GOT and GDH in the serum ("flare-up") is frequently observed. With subsidence of this reaction and normalization of the transaminases, HBeAg is usually no longer detectable. Reactivation is rare, but can be triggered by various factors, such as cytostatics (64), etc. Carriers of chronic hepatitis B are quite frequent. (29, 61) Their urine may be infectious. (s. figs. 34.5, 34.6)

**Fig. 34.5:** Chronic, mildly active hepatitis B with pronounced peri-portal and septal fibrosis (as a sequela of previous inflammatory episodes)

**Fig. 34.6:** Chronic necrotizing hepatitis B: marked postnecrotic cleft formation in the area of the left lobe of liver (10 months after severe, acute necrotic hepatitis). Brownish to brick-red colouring of the liver with a flat, undulatory surface, scarry indentations and proliferation of connective tissue as well as spots of capsular fibrosis. Fine hypervascular arteries, pronounced venous contours and isolated lymph vessel congestion

The **healing process**, which is the third phase (HBsAg, HBeAg and HBV RNA negativity as well as anti-HBs and anti-HBe positivity together with normalization of GPT), is rarely spontaneous. • After HBeAg elimination with permanent remission and anti-HBe positivity, **two serological courses** may also occur: (*1.*) persistence of

chronic hepatitis B despite the presence of anti-HBe and (*2.*) transient anti-HBe positivity with recurrence of HBeAg (30% of cases) as well as exacerbation and persistence of chronic hepatitis B.

In 10−30% of cases, **cirrhosis** appears with high morbidity and mortality, 3−6%/year. A clear reduction in the development of cirrhosis was achieved by administration of colchicine (5 mg/week) for a period of 4 years. The 10-year survival rate is 89% in CPH, 74% in CAH and as low as 47% in cirrhosis. • The frequency of **HCC** in patients with cirrhosis B is about 2%/year, i. e. the risk is approx. 200 times higher than in healthy subjects. (34, 36, 44, 51, 54, 59, 65) Development of HCC is closely associated with the seromarker status: the frequency of HCC was 87% in positivity of HBsAg and HBeAg, in HBsAg alone 12%, and in negativity of both markers only a rare event (1% of cases). (65)

## 6.6 Chronic HCV infection

The number of people suffering from chronic hepatitis C is estimated at approx. 200 million worldwide; in Germany the number is 600,000−800,000 (113, 142) If an HCV infection has not been registered, there is obligation of notification for chronic hepatitis. • Genotypes 1−3 have been observed worldwide, genotypes 4−5 predominantly in the Middle East or Africa, and genotype 6 in Asia. Different genotypes may be detected in a single patient at the same time or at different stages of the disease. The prognosis of an HCV infection differs in relation to the genotype *(see chapter 22.5!)*

**Diagnosis:** The level of *HCV-IgM antibody* titres correlates with the degree of severity of chronic hepatitis C. Evidence of anti-HCV is an important clue, but it can be interpreted as (*1.*) acute infection, (*2.*) chronic infection, (*3.*) carrier status, or (*4.*) non-infectious immune status. It should be noted that a negative test does not exclude viraemia. Infection can only be detected on the basis of HCV RNA using the PCR method; this is possible just a few days after infection. • A correlation (albeit only of minor significance) between the serum titre of HCV RNA and the level of *transaminases* is controversial. Evidence of elevated transaminases requires differential diagnostic clarification, which may result in confirmation of HCV infection. Transaminases are a good marker for chronic hepatitis C (generally being 3 to 5-fold the norm); the GPT/GOT ratio may point to the development of cirrhosis. Often (about 30%), however, stages of chronic hepatitis C with normal transaminases can be found. (125) They correlate well with modest proliferation and apoptosis as well as with the development of low-degree fibrosis, particularly during simultaneous abstinence from alcohol.

In long-term follow-ups, the transaminases frequently display major fluctuations in activity (rise and fall before reaching their normal level). (48) Occasionally,

there is a remarkable elevation of *γ-GT*, which is often even higher than GPT, initially raising suspicion of alcohol-induced liver damage. (138) In patients with increased γ-GT (particularly with a rise in AP), more severe damage of the bile ductules is evident. A decrease in hepatic function and a rise in gamma globulins and P III P can only be found during the development of cirrhosis. In most cases, the course of disease is anicteric. • Frequently, a rise in serum iron, ferritin and iron-binding capacity as well as increased iron resorption can be witnessed. • *Autoantibodies* are often found: ANA and/or SMA (15−20%), LKM 1 (5−10%), AMA (1−2%); anti-GOR is detectable in 70−80% of patients. (76) (s. p. 681) Anti-GOR titres correlate with both therapeutic success and relapses. • Extrahepatic immunopathies are common and multifaceted. (67, 112, 119) (s. tab. 34.6) Cryoglobulinaemia was in evidence in 40−50% of cases. It did not influence IFN therapy. (107, 140)

**Coinfections:** HGV-C has no deleterious effect on the course or treatment of chronic hepatitis C (115) despite conflicting observations. The simultaneous detection of TT viruses in the serum or hepatocytes, particularly with type 1b and at an advanced stage of the disease, does not have an unfavourable effect (146). Coinfection with HBV leads to aggravation of the condition. Acute hepatic failure must also be anticipated, as is the case in HAV and HBV concomitance. (141) Active inoculation is therefore recommended for lack of immunity against HAV and HBV.

**Perihepatic lymphadenopathy:** This symptom was observed in chronic hepatitis in 1994 by K. LYTTKENS et al. using sonography. It is common in chronic hepatitis C (60−100% of cases) as well as B − even with normal liver values. (102) There is a correlation between lymph node volume and hepatic inflammatory activity or viraemia. A decrease in the total volume of lymph nodes is associated with a sustained virological response and an improvement in liver histology. (81, 116, 143, 147)

**Morphology:** Following routine sonographic examination, morphology is clarified by **liver biopsy**. (70, 71, 73, 91, 94, 127, 137) Because the diagnosis is mostly established after a prolonged course of disease, liver biopsy should be carried out with the help of **laparoscopy** to obtain more reliable morphological findings by taking specimens from both lobes of liver and inspecting the liver surface (with photodocumentation!). (s. figs. 7.15, 7.16; 28.7) • In addition to the chronic inflammatory changes, which are often accompanied by *bile-duct lesions* and portal follicle-like lymphocyte aggregates, there is generally *steatosis* of the liver (40−50% of cases). Together with elevated γ-GT, this raises suspicion of alcohol-induced liver damage. (99, 131, 247) Fatty degeneration of hepatocytes in different intensities (e. g. due to hypobetalipoproteinaemia) is attributable to chronic hepatitis C (directly or indirectly) as well as to various noxae, obesity, diabetes, etc. Genotype 3 is

steatogenic. *Mallory bodies* are frequently detectable, whereas they are rare in chronic hepatitis B. Chronic lobular hepatitis accompanied by sinusoidal infiltration with lymphocytes in *single-file arrangement* is often present. • *Chronic HCV infection shows findings with great toporegional variation.* CPH and CAH (and also CLH) may therefore be present in the same liver, sometimes even showing localized initial signs of transformation. Progressive fibrosis is decisive for both course and prognosis. (92, 97, 100, 109, 111, 122, 123) Lipid peroxidation products demonstrated in the liver correlate very closely with fibrosis. (72, 80, 85, 105, 110, 111, 114, 134, 142) (s. tab. 34.3) (s. fig. 34.7)

***Fig. 34.7:*** Chronic, mildly active hepatitis C with portal lymph follicle (→) (HE)

► *The morphological divergences in "chronic hepatitis" within the liver itself had already been noted by L. WAN-NAGAT in 1977 with the help of laparoscopy and segmental portography (s. p 181!) long before viral differentiation became possible.* • These divergences have now been taken into account in the new nomenclature.

**Course and prognosis:** The natural course of HCV infection varies from patient to patient; it is influenced by the specific *mode of infection* This remains unclarified (= sporadic) in 30−40% of cases. Possible routes of transmission for HCV infection include: i. v. drug abuse (85), mother-to-child infection, skin injuries, promiscuity, nosocomial infection, contaminated blood products (136, 139), etc. Pregnancy as well as breast feeding are allowed (but not in the case of a high viral load). • Some 70−80% of acute HCV infections show an asymptomatic course, of which 50−85% develop into a chronic hepatitis, i. e. HCV infection is the most frequent cause of chronic active hepatitis. • **Risk factors** are important for the course of disease. (135) Alcohol (120, 128, 129, 144), iron (83, 84, 133), obesity (97, 99, 118), insulin resistance (97, 100), smoking (96), lipid peroxidation (84) and copper overload (95) play a decisive role. • The course itself is mostly insidious with uncharacteristic complaints such as fatigue (121, 124), decreased performance and loss of appetite. The quality of life is reduced. (88) If the regulations concerning hygiene are adhered to, there is princi-

pally no impairment in the individual ability to go to work. *Neuropsychological impairment* can often be observed. (87, 98, 106) In 10−30% of cases, chronic HCV infection is only recognized at the stage of cirrhosis. A total of 20−30% of patients with chronic hepatitis C develop cirrhosis within 20 years. HCC occurs in ca. 20% of cases, i. e. 2−6%/year. (79, 103). Pretreatment fibrosis, elevated age and alcohol abuse are risk factors for development of HCC, even in SVR. About 10 (−50)% of cases develop non-Hodgkin lymphoma. (93) The development of associated lymphoproliferative diseases can be explained due to the binding of the HCV virus to the B-cell surface marker CD 81; this leads to a stimulation of B cells, resulting in lymphoproliferative disorders. (101) (s. tab. 34.6) • Some patients with anti-HCV and HCV RNA positivity did not present with pathological liver values or histological liver damage. Possibly, these cases involve a special type of HCV, or the HCV infection is not recognized by the patient's immune system. (68, 77, 82, 85, 104, 106, 114, 106, 114, 122, 145)

**Differential diagnosis:** The following conditions should be excluded: (*1.*) alcohol-induced liver disease, (*2.*) primary biliary cholangitis (86), (*3.*) porphyria cutanea tarda (108), and (*4.*) autoimmune hepatitis (89) or autoimmune cholangitis (132) associated with anti-HCV.

## 6.7 Chronic HBV/HDV infection

Chronic hepatitis D generally takes a more severe course with especially striking histological findings. Prognosis is very poor. Cirrhosis develops (particularly in superinfection with HBV replication) in 60−70% of cases − in about 15% already within 1−2 years. Serology shows anti-HDV, generally with HBsAg and HBeAg positivity. Serum HDV RNA is present, but often detectable only by PCR; the delta-antigen is also found in the liver tissue. CAH D cannot be reliably differentiated from CAH B by means of clinical and histological criteria. However, additional HDV infection with clear, lobular mesenchymal reactions must be considered in pronounced chronic hepatitis B. (148−151)

# 7 Therapy

## 7.1 General treatment

► **Physical exercise:** Excessive physical exercise should be avoided. During inflammatory episodes, which are generally accompanied by subjective complaints, it is advisable to minimize physical effort and to lie down ("bed rest") as often as possible. Otherwise, patients may pursue their normal activities, i. e. light exercise, return to work (without overstrenuous tasks) or simple housework.

► **Diet:** No dietary measures are necessary in chronic hepatitis − there is no special diet for this condition. The physiological principles of nutrition should be used as a guideline. **Overweight** should be gradually reduced. • **Alcohol** is not permitted (aggravation of cell damage, increase in fibrogenesis, early development of cirrho-

sis, HCC, etc.). **Hepatotoxic substances** and **smoking** should be avoided.

▶ **Hygiene:** In the case of potential infectiosity, all necessary hygiene measures should be observed, if necessary in consultation with the Public Health Department. This especially applies to the work environment and to the question of active vaccination of family members or close contact persons against HBV (= **prophylactic vaccination ring**). (s. pp 422, 435)

> In HAV or HBV negativity in chronic hepatitis C or in HAV negativity in chronic hepatitis B, the immunodeficiency should be compensated by corresponding active vaccination. • *Additional viral infections must be avoided!*

## 7.2 Therapy of chronic hepatitis B

Several compounds have been used in treating chronic viral hepatitis. Experimental and clinical studies have focused on **four groups of substances:** (*1*.) antiviral agents, (*2*.) immunostimulants, (*3*.) molecular biological agents, and (*4*.) adjuvant medicinal remedies. • *The rate of spontaneous seroconversion is 8−15%/year.*

### 7.2.1 Aims of treatment

An *indication for treatment* is given (*1*.) in chronic infection with considerable activity in order to avoid cirrhosis or HCC, (*2*.) in chronic infection with cirrhosis in order to avoid decompensation or HCC, and (*3*.) possibly for immunosuppressed patients or medical staff with chronic infection showing only slight activity. • The level of transaminases and HBV-DNA values are important factors regarding the indication for therapy.

The *aims of treatment* are: (*1*.) normalization of the transaminases, (*2*.) negativity of HBeAg as well as reduction of HBV-DNA to $<10^5$ copies/ml, and (*3*.) elimination of histological activity as well as avoidance of fibrosis. This leads to a better quality of life for the patient. The prognosis can be improved considerably if therapy-induced HBeAg negativity is reached. • Elimination of HBsAg by means of interferon is only achieved in $10-20\%$ of cases.

▶ For the treatment of chronic hepatitis B, a four-fold **classification** has proved useful:

(1.) **Immunotolerant phase:** positivity of HBsAg and HBeAg, increase in HBV-DNA values ($>10^6$ copies/ml), normal to 2-fold elevated transaminases. • Generally, *no therapy* is necessary (but lamivudine or adefovir can be applied).

(2.) **Immunoactive phase:** Continued positivity of HBsAg and HBeAg, significantly elevated ($>2$-fold) transaminases, lower HBV-DNA values (but still $>10^5$ copies/ml). There is medium to strong necroinflammatory activity. • *Therapy* with interferon is indicated (possibly with lamivudine or adefovir).

(3.) **HBe-minus phase:** Predominance of minus mutants which can no longer synthesize HBeAg (so-called precore mutants). HBeAg is therefore negative, transaminases are still more than twice the normal value, HBV-DNA levels are elevated ($>10^5$ copies/ml). •

This HBeAg-negative form is found worldwide; it has a high replication rate and an increased histological index. Spontaneous remissions are less common than with the HBeAg-positive form. • *Therapy* is based on lamivudine or adefovir (possibly with interferon).

(4.) **Non-replicative phase:** HBeAg is negative, transaminases are normal, HBV-DNA values are low ($<10^5$ copies/ml) or negative in a non-PCR procedure. • *No therapy* is required.

### 7.2.2 Interferon therapy

▶ Interferons (IFN) are glycoproteins which possess antiviral, antiproliferative and immunomodulatory properties. Besides the main types α, β and γ, other forms are available (lymphoblastoid IFNα, consensus IFNα). • Administration is subcutaneous. Bioavailability is about 90%. The serum peak is reached by using $IFN\alpha_{2a}$ after $6-8$ hours with a half-life period of 5 hours or by using $IFN\alpha_{2b}$ after $3-12$ hours with a half-life of 3 hours. Elimination is primarily via the kidneys. Interferons inhibit CYP1A2. There is no development of resistance. (158, 160, 182) *(see chapter 40.5.1.1)*

Some findings point to a good response regarding an *antiviral effect* of IFN (so-called "ideal patient") and other findings to a poor response. They are considered as selection criteria for IFN treatment. (s. tab. 34.7)

| **Good response ("ideal patient")** |
| --- |
| 1. High GPT ($>100$ U/l) |
| 2. Low HBV DNA titre ($<10^5$ copies/ml) |
| 3. Infection in adulthood |
| 4. Short period since infection ($<5$ years) |
| 5. Female |
| 6. No co-infection, no noxae |
| 7. Genotype A |
| **Poor response** |
| 1. Low GPT ($<100$ U/l) |
| 2. High HBV DNA titre ($>10^5$ copies/ml) |
| 3. Infection perinatally or possibly in early childhood |
| 4. Long course since infection ($>5$ years) |
| 5. Increased hepatic iron content |
| 6. Coinfection (e.g. HDV, HCV, HIV) |
| 7. Coexistent noxae (e.g. alcohol, drugs) |
| 8. Genotype C or D |

*Tab. 34.7:* Selection criteria for IFN therapy in chronic hepatitis B with indicators of good or poor response • (**1 pg/ml = ca. 300,000 copies/ml = 50−60,000 IU/ml**)

**Therapy scheme:** IFNα (or Peg IFNα) is currently the antiviral agent of choice; it is applied as monotherapy. The following dosage is considered to be the most effective scheme of therapy: *IFNα at 5−6 million U/day* or *IFNα at 9−10 million U, 3 x/week*, preferably in the evening, usually self-administered (s.c.), in each case for $4-6$ months. A seroconversion of HBeAg to anti-HBe is achieved in $35-40\%$ of cases (vs. $8-13\%$ spontaneous). In 80% of the responders, IFNα therapy leads to sustained viral response. A longer duration of therapy ($>6$ months) is no more efficacious, whereas a shorter

duration (< 4 months) produces a less successful result. Daily administration seems to be more favourable than an injection 3 x/week due to the half-life of IFNα. • Various *contraindications* should be heeded regarding the use of interferon. (s. tab. 34.8)

| |
|---|
| 1. **Decompensated cirrhosis (Child C)** |
| 2. **Depression, suicidal tendency, epilepsy** |
| 3. **Autoimmune diseases** |
| 4. **Pregnancy, lactation period** |
| 5. **Immunosuppression** |
| 6. **Addiction problems** |
| 7. **Serious extrahepatic disease** |

| | |
|---|---|
| − coronary insufficiency | − cardiac insufficiency |
| − dysthyreosis | (NYHA 3−4) |
| − tachyarrhythmia | − HCC |
| − thrombopenia (< 50,000 µl) | − leucopenia (< 2,000 µl) |
| − renal insufficiency | − bacterial infection |

*Tab. 34.8:* Contraindications to interferon therapy

*Follow-up* is firstly every two weeks, later at monthly intervals (physical status, haemogram, transaminases). After 3 and 6 months, HBeAg, anti-HBe and HBV-DNA (quantitatively) as well as thyroid parameters (TSH, TAB) and calcium are determined.

*Therapy success* can be seen in a reduction of the initial HBV-DNA titre by about 50% within 3−5 months. The transaminases show a sudden increase (*"flare-up"*) after 8−10 weeks. (176) This results from the immunological destruction of HBV-replication hepatocytes, so that replication is terminated. Because "flare-up" is a favourable criterion, the therapy is continued unchanged.

If the course of disease remains successful, there will be a transition to the *low-replication phase* with a loss of HBeAg (i. e. positivity of HBeAg = *incomplete response*) and HBV DNA as well as normalization of the transaminases after 10−14 months. It takes several years for the HBsAg to disappear completely: about 20% are HBsAg-negative after 12 months and about 65% after 6 years (i. e positivity of HBsAg = *complete response*). At this point, HBV is considered to have been eliminated. Incomplete (*partial*) responders still have moderately increased transaminases, but show HBeAg and HBV-DNA negativity. However, anti-HBe may still be detectable in these patients after some years. Careful monitoring is required due to the danger of reactivation. • Generally, genotype A or B responds better to IFNα than type D or C, with earlier spontaneous seroconversion of HBeAg. (170, 180, 185, 203)

*HBeAg-negative patients* possess precore (minus) mutants. They show an initial response rate of up to 90%; there is no sign of "flare-up". The aim of therapy is normalization of the transaminases and a loss of HBV DNA after > 12 months. After IFNα therapy has been stopped, reactivation usually occurs, even after several years. Only 15−25% of cases achieve sustained response. For this reason, an IFN therapy lasting 12−24

months is recommended. • Patients with cirrhosis tolerate IFNα therapy in the same way as patients without cirrhosis and even show the same results.

► **Early side effects** often include fever and flu-like symptoms, which are generally alleviated or eliminated by paracetamol; they are mostly temporary and of no clinical significance. • **Late side effects** depend on the individual case and dosage; they are influenced by coexistent diseases (e. g. diabetes) or psychic disposition. (201) There have been reports of numerous and different side effects. • *When they occur, a dose reduction is necessary in 3−25% of cases (depending on the dose); IFN treatment has to be discontinued in 3−5%.* (s. tab. 34.9)

| |
|---|
| 1. **Early side effects** |
| • Fever, flu-like symptoms |
| • Local inflammatory reaction |

| |
|---|
| 2. **Late side effects** |
| • *General* |
| − exhaustion, fatigue, sleep disturbances, loss of appetite, diarrhoea, loss of weight, hair loss, myalgia, arthralgia, tinnitus, anosmia, cough, headaches |
| • *Haematological* |
| − leucopenia, thrombopenia |
| • *Psychiatric* |
| − irritability, affective lability, epileptic seizures, depression, suicidal tendency, loss of libido, changes in the EEG, schizoid psychoses, stroke syndrome |
| • *Infectious* |
| − infection (e. g. urinary tract, respiratory tract) |
| • *Endocrinological* |
| − impaired thyroid function, hypocalcaemia, insulin resistance |
| • *Cardiovascular* |
| − hypertension, hypotension, arrhythmia, cardiac insufficiency |
| • *Urogenital* |
| − proteinuria, impotence, nephritis |
| • *Immunological* |
| − IFN autoantibodies, autoimmunopathies, vasculitis, pleural effusion, pericarditis, sarcoidosis |
| • *Ophthalmological* |
| − retinal haemorrhagia, disturbed vision, conjunctivitis |
| • *Cutaneous* |
| − cutaneous necrosis, exanthema, pruritus, urticaria |
| • *Intestinal* |
| − eosinophilic enteritis, coeliac disease, pancreatitis |

*Tab. 34.9:* Possible side effects of interferon therapy

**Relapse:** Reactivation is often associated with the presence of wildtype HBV (80−85%) or the occurrence of precore mutants (15−20%). This event (increase of transaminases, evidence of replication markers such as HBeAg and HBV DNA, positive IgM anti-HBC, pronounced interface hepatitis) develops in 15−20% of cases 1−3 years after IFNα therapy has been stopped. In such cases the question then arises of whether to apply lamivudine. This antiviral agent is administered in cases with an unfavourable constellation or contraindication regarding IFNα, or if the patient refuses IFN.

## 7.2.3 Lamivudine

▶ Lamivudine is a **nucleoside analogue**, which acts as a reverse transcriptase inhibitor of HBV-DNA polymerase and causes a break in the molecular chain through its competitive integration in the DNA. Lamivudine is administered orally and well resorbed. The **half-life** is 5−7 hours; it is eliminated unchanged via the kidneys. Therefore, the dose must be adjusted to the patient's creatinine clearance.

The daily dose amounts to 100 mg. Tolerance is good; no side effects have been observed up to now. HIV infection must be ruled out prior to therapy (danger of HIV resistance); a combination with ribavirin should be avoided (danger of lactat acidosis) or with trimethoprim (reduction in renal clearance of lamivudine); in HBeAg positivity, abrupt discontinuation is not allowed (danger of exacerbation or ALF). • The recommended duration of therapy is > 1 year to long-term. If HBeAg seroconversion occurs at any time, therapy should be extended by approx. 6 months in order to improve the overall effect. The most reliable predictor of a good response is a transaminase value which is at least five times higher than normal. (154, 161−163, 168, 169, 171, 172, 175, 177, 178, 182, 184, 187, 189, 190, 196, 199, 204, 207)

**HBeAg-positive patients:** Some 90% of cases reach HBV-DNA elimination after about 1 year of treatment, but only 15−20% of cases achieve sustained HBV-DNA negativity. At the same time, a normalization of the transaminases (up to 70%) and inhibition of fibrosis may be observed. (171) Subsequent to seroconversion after 12 months of therapy, administration of lamivudine should be continued for a further 6 months due to the risk of relapse.

**HBeAg-negative patients:** These cases show no sign of seroconversion; therefore therapy should be continued for a further 2 years before being stopped. Generally, it seems reasonable to carry out long-term therapy until viral resistance (= mutants) develops.

**Viral mutants:** As the duration of lamivudine therapy increases, the number of mutants rises, especially those resulting from YMDD-polymerase mutation. Viral mutants are found in about 20% of cases after 1 year, in 35−40% after 2 years and in 60−70% after 4 years. (159) Clinically, lamivudine resistance is recognizable due to an increase of transaminases and a recurrence of viraemia. Risk factors include high GPT (ALT) values, an elevated HBV-DNA level and a pathological body mass index. In the case of resistance, the use of adefovir is recommended, since this nucleoside is also efficacious against HBV mutants.

## 7.2.4 Adefovir dipivoxil

▶ Adefovir (ADV) is a **nucleoside analogue**, which causes a break in the molecular chain through its competitive integration in the newly synthesized HBV DNA. ADV dipivoxil is a prodrug, which is converted into active ADV in the intestinal tract. Its **half-life** is 7−8 hours. Elimination is via the kidneys. Therefore, the dose must be adjusted in the case of renal insufficiency! It should be noted that the risk of damage to the kidneys is increased by simultaneous administration of aminoglycosides, vancomycin and antirheumatic agents.

Dosage is 10 mg/day orally; duration of treatment is 48 weeks. The effect of ADV is not impaired by a high viral load. In HBeAg-positive patients, it results in elimination of HBV DNA in 20−25%, seroconversion in 15−20% and normalization of transaminases in 45−50% of cases. • In HBeAg-negative patients, ADV shows a loss of HBV DNA in approx. 50% and normalization of GPT (ALT) in 70−75% of cases. In addition, a considerable improvement in histology was achieved. Viral resistance (due to mutants) was observed in < 3% of cases after 3 years. ADV can also be applied in decompensated cirrhosis. Tolerance is good. As with lamivudine, abrupt discontinuation may lead to acute exacerbation (in about 25%). (167, 181, 193, 205, 206)

## 7.2.5 Treatment failure

Treatment failure or reactivation leads to progressive fibrosis or development of cirrhosis/HCC; the patient's quality of life is also impaired. Responsibility towards the patient forces the physician to use any therapeutic approach available which is (*1.*) biomolecularly and pharmacologically plausible, (*2.*) free of or low in side effects and also suitable in a long-term regimen (the significance of a long-term follow-up should not be underrated), and (*3.*) justifiable in terms of cost.

**Combination therapy:** The combination of *IFNα + lamivudine* is superior to the corresponding monotherapy and it yielded considerably better results in patients who were resistent to IFN. (164, 166, 186, 195, 196) Likewise *Peg-IFNα + lamivudine* were applied with success. (182) A combination of *lamivudine + ADV* led to a virological and biochemical improvement during treatment up to 52 weeks (191, 192). In another study, however, therapy with *IFNα + lobucavir* (2 x 200 mg/day) had only little success. A combination of *lamivudine + famciclovir* sometimes produced a certain positive effect. (198) In the same way, *IFNα + famciclovir* improved initial values in some cases. (183) A combination of *famciclovir + thymosin* activates T-cell response in the immunotolerance phase. (174) The possibility that *IFNα + acyclovir* are synergistic in HBV infection has been suggested (S.W. SCHALM et al., 1985); acyclovir as monotherapy (45 mg/kg BW/day, i.v. infusion for 28 days) showed no benefit in chronic HBV carriers with stable disease. (152)

## 7.2.6 Nucleoside analogues

Because of their structural resemblance to natural nucleosides, these substances are integrated into the newly synthesized DNA strand by the enzymes of DNA synthesis (e.g. DNA polymerase, reverse transcriptase) in place of the natural nucleosides. The outcome is chain break. Virus mutation, however, may reduce the effectiveness of nucleoside analogue. • The clinical import-

ance of these new antiviral substances, either as mono-therapy or in combination, has not been clarified. They have not yet been introduced in the treatment of chronic hepatitis B. (155, 165)

**Famciclovir** is a prodrug of penciclovir. It is administered orally; the daily dose amounts to 1,500 mg. Its effectiveness is low. (153, 179, 197, 202)

**Tenofovir** is the active agent of the prodrug tenofovir disoproxil fumarat. Up to now, tenofovir (300 mg/day) has been used with HIV/HBV coinfected patients. In such cases, it proved effective regarding HBV DNA and the normalization of transaminases.

**Emtricitabine** is a cytosine nucleoside with antiviral potency towards HBV and HIV. It is only slightly different from lamivudine. After 48 weeks of treatment (200 mg/day), it was possible to achieve HBV-DNA negativity in 60% and HBeAg negativity in 50% of cases. Tolerance is good (N. Leung et al., 2001).

**Entecavir** is a guanosine nucleoside with strong antiviral activity. It is also effective in lamivudine-resistant patients. After 48 weeks of treatment comprising a daily dose of 0.5 or 1.0 mg, there was elimination of HBV DNA in 25−30% and normalization of the transaminases in 60−70% of lamivudine-resistant patients. Tolerance is good. Entecavir-induced mutants were not detected. (173)

**L-deoxythymidine:** LdT proved to be effective and well tolerated in a dosage of 200−400 mg/day orally (C.L. Lai et al., 2001).

**Clevudine** is a pyrimidine-nucleoside analogue. It was effective in a dosage of 200 mg/day (P. Marcellin et al., 2003).

### 7.2.7 Immunostimulants

Immunostimulants activate the immune system − especially in cases of reduced immune defence. They can be (*1.*) endogenous substances, (*2.*) extracts of microorganisms, or (*3.*) substances of plant and chemical origin. • The use of **thymosin-α** has also proved promising (G.M. Mutchnick et al., 1991). It effects an improvement in the T-cell function. Promising biochemical, serological and histological results were obtained in chronic HBV infection. (156) Good tolerance was recorded for this drug. • **Interleukins** are mediators of the induction and course of the T-cell-mediated cytotoxic immune reaction and of B-cell activation (antibody production). Interleukin 2 induces the proliferation and differentiation of T lymphocytes; the simultaneous induction of IFNγ triggers the activation of macrophages. A mixture of *interleukins 2 and 6* as well as *anti-D3* may be considered as a further option in the future. • Good results have also been achieved with the **phyllanthus amarus extract**. Further studies are necessary to clarify the biological modes of action of this interesting plant. The same applies to the **bupleurum extract** as well as extracts from **glycyrrhiza** (used in chronic hepatitis C) (247), **schizandra, kurorinone** (157), etc. (s. pp 867, 868)

### 7.2.8 Adjuvant substances

**Arguments:** The following arguments justify the search for and use of adjuvant substances: (*1.*) the high number of patients with chronic viral hepatitis worldwide, (*2.*) the high morbidity and mortality associated with this

disease, (*3.*) the high cost of treatment with interferon, ribavirin, lamivudine, etc., (*4.*) the occasionally severe side effects, and (*5.*) the still unsatisfactory therapeutic results and low success rate.

**Criteria:** The therapeutic agents should meet the following criteria: (*1.*) as far as possible, they should have no side effects or interactions, (*2.*) the adjuvant effects should be proven or at least deemed plausible by biochemical and/or pharmacological studies, and (*3.*) the additional cost should be justifiable and within certain limits. • Because of their merely adjuvant modes of action, such substances must be used long-term (> 2 years) to obtain positive effects in chronic hepatitis − as is also necessary with other chronic diseases.

| | |
|---|---|
| 1. **Colchicin** | 5. **Silymarin** |
| 2. **Essential phospholipids** | 6. **Tenoxicam** |
| 3. **Iron removal** | 7. **Ursodeoxycholic acid** |
| 4. **N-acetylcystein** | 8. **Vitamin E** |

**Iron removal:** Increased iron and ferritin levels are found in approx. 30% of patients with chronic hepatitis B or C. Several studies have shown that the success rate of interferon therapy is reduced in the presence of elevated liver iron values. This is attributed to the fact that iron overload inhibits not only lymphocyte proliferation, but also the function of killer cells and B cells as well as the production of antibodies. Iron plays a role in the formation of free radicals and the occurrence of dangerous lipid peroxidations. (s. pp 68, 401) Furthermore, iron, like oxygen radicals, promotes fibrogenesis. Iron removal leads to an improvement in laboratory parameters and better response to interferon-α therapy. (217, 243) On the other hand, the iron level is reduced as a result of successful IFN therapy. • In the case of a higher serum iron status before the initiation of interferon therapy, *venesections* at one week intervals should be considered, if necessary until normal laboratory values (iron, ferritin, transferrin saturation) have been restored. During interferon therapy, a *low-iron diet* is advisable, as is the consumption of 2 x 1 cup of *black tea* (in the morning and at noon) to reduce iron absorption through chelate formation ("cheap, free of side effects and useful"). (s. p. 625) • *Silymarin* also leads to iron mobilization due to chelate formation.

**Silymarin:** The *hepatoprotective* and *hepatoregenerative* effects of silymarin have been demonstrated in numerous in-vitro and in-vivo studies. Its antioxidant properties have also been confirmed in recent years (C. Dehmlow et al., 1996), especially in rats with iron overload (A. Pietrangelo et al., 1995). The *antiperoxidative* efficacy of silymarin was found to be ten times greater than that of an equimolar concentration of α-tocopherol. This effect is attributed to biochemical interaction (chelate formation of silymarin with $Fe^{2+}$). Clinical studies also testified to the *antifibrogenetic* effect of silymarin in patients with chronic hepatitis (G. Buzzelli et al., 1993). (see E. Kuntz: footnote*, p. 867)

**Ursodeoxycholic acid (UDCA):** As early as 1961, F. Ichida et al. reported on the successful treatment of chronic hepatitis with UDCA. Similar reports were published by T. Nakahara et al. in 1975 and two further Japanese groups in 1976. Furthermore, U.

Leuschner et al. (1985) noticed surprising improvements regarding biochemical parameters in chronic hepatitis. These effects were attributed to the immunomodulatory efficacy of UDCA. In principle, UDCA satisfies all the criteria for its combined use with interferon in chronic viral hepatitis. (s. p. 857)

**EPL:** In a multicentre study, it could be demonstrated that essential phospholipids not only significantly increased the proportion of IFN responders in patients with chronic hepatitis B and C, but also reduced the relapse rate. (188) (see E. Kuntz: footnote*, p. 865)

### 7.2.9 Molecular biological methods

In experimental studies, the short sequences of the viral genome can be blocked using antisense oligodeoxynucleotides. Blocking of the 5'region of the pre-S gene causes inhibition of virus replication and gene expression. These "code blockers" might be of significance in the future for both chronic HBV and HCV infection.

## 7.3 Therapy of chronic hepatitis C

In **acute HCV infection**, which mostly develops asymptomatically, but sometimes with uncharacteristic complaints, HCV RNA is present within the first week after infection. Antibodies against HCV are detectable after 6−8 weeks in >90% of cases. *(see chapter 22.5)*

**Chronic hepatitis C** manifests in 60−80% of infected patients and becomes active in 70−80% of cases. Of the latter, 20−30% gradually develop cirrhosis and 4−5% ultimately suffer from HCC. A higher risk of cirrhosis is given in patients with a high HCV-RNA concentration, with portal or bridging fibrosis accompanied by necroinflammatory activity and with permanently increased transaminases.

> Patients with chronic hepatitis C but without antibodies against HAV and/or HBV should be vaccinated immediately against the respective seronegative hepatitis form!

### 7.3.1 Indication for therapy

The indication for antiviral treatment of chronic hepatitis C is principally based on the following criteria: (*1.*) a symptomatic course (subjective complaints, elevated transaminases, extrahepatic manifestations), (*2.*) inflammatory activity and progressive fibrosis or cirrhosis, and (*3.*) an infection risk regarding contact persons.

Even in the case of *cirrhosis* (Child A, possibly also B), antiviral therapy should be used to achieve histological improvement of the findings and to reduce the frequency of HCC.

Half the patients with *normal transaminases* sometimes show both increased values and histological activity scores. Therefore, it is necessary to recheck the indications for these patients, especially because their sustained viral response (SVR) is comparable to that of patients with elevated transaminases. (225)

### 7.3.2 Selection criteria for therapy

> Before commencing treatment of chronic hepatitis C, the genotype and HCV-RNA titre should be determined.

**Reliable diagnosis:** A definitive determination of the respective disease stage of HCV infection is often difficult regarding serological diagnostics; there are uncertain histological findings and only moderate correlation between histology and laboratory parameters. • The situation is further complicated by occasional difficulties in making a differential diagnosis based on the serological and autoimmune overlap findings. Erroneously indicated treatment with immunosuppressives or interferon may result in serious complications. • *The most important selection criterion is a reliable diagnosis!*

*Liver biopsy:* In this context, the actual nomenclature of chronic hepatitis promises better designation and classification. (s. tabs. 34.2, 34.3) Therefore, in patients with genotype 1 (and 4), liver biopsy is recommended before planning therapy, whereby in genotypes 2 and 3, liver biopsy is less important due to the good success of the therapy. • The fundamental importance of the histological findings is based on (*1.*) determination of necro-inflammatory activity and progressive fibrosis, (*2.*) assessment of the prognosis and the necessity of treatment, (*3.*) prediction for therapy success, (*4.*) comparison of initial findings with follow-ups, (*5.*) evaluation of the therapy results, and (*6.*) exclusion of a coexisting liver disease. • The problems and the disadvantages mainly include (*1.*) sample error, (*2.*) extraction of biopsy specimen from a limited puncture area of the right lobe (s. fig. 7.8), and (*3.*) interobserver and intra-observer variability. (5, 6, 11, 70, 71, 73, 95, 127, 137) • A reliable morphological diagnosis as well as the all-important assessment of the liver surface regarding fibrosis progression or perhaps even the existence of cirrhosis are best achieved with the help of *laparoscopy* (210) and 1 (−2) biopsies from both the right and left liver lobe. (s. pp 157, 160, 695) • *Chronic hepatitis is not evenly spread in the liver in every case.* (s. p. 181, 699)

**HCV genotype:** The response rate to interferon therapy depends on the prevalent genotype. Genotypes 1 and 4 (but also 5, 6) show a poorer response to IFN than genotypes 2 and 3. The genotype reveals no relationship to the RNA titre or to histology. A change of type 1 to type 3 was also noted. (s. tab. 34.10)

**Cofactors:** *Coinfections* with HAV and HBV as well as with other viruses worsen the prognosis. By contrast, coinfections with HGV, GBV-C, SENV and TTV had no influence on the course of chronic hepatitis C. (115, 146) *Alcohol* influences the cellular immune response unfavourably and leads to an aggravation of pathological liver morphology. (85, 120, 128, 129, 144) • *Age* and *gender* play a special role. Generally, older patients are

subject to a more severe course of disease. Women below the age of 40 benefitted significantly more from IFN therapy than women over 40 (75% vs. 15.6%). HCV clearance in women is better than in men (G. INOUE et al., 2000). There is also exacerbation of chronic hepatitis C due to pregnancy (H. FONTANE et al., 2000). • *HCV-RNA titres* of <2 million copies/ml (or 0.8 million I U/ml) are considered more favourable, whereas an initial high viral load shows a worse response. • In comparison (low-titre) antibodies (e. g. ANA, AMA, LKM), are found more frequently in women than in men, but they had no influence on the response to IFNα therapy.

### 7.3.3 Combination therapy

*The standard therapy for chronic hepatitis C is a combination of pegylated IFNα with ribavirin.* (252) (s. tab. 34.11)

**Interferon** was used in the treatment of chronic hepatitis NANB as early as 1986 by J.A. HOOFNAGEL et al., i. e. three years before HCV was identified. The efficacy of IFNα for chronic hepatitis C could be proven in many studies. (213, 216, 219, 227, 229, 234, 241, 242, 245, 248, 251) • The **pegylation of IFNα** (= coupling to polyethyleneglykol) leads to reduced enzymatic degradation, diminished antigenicity and delayed renal clearance; thus its half-life is prolonged. As a result, a constant efficient level is achieved with only 1 (−2) injection(s) per week. This newly developed Peg IFNα led to a further improvement in the sustained viral response. (214, 229, 231, 232)

▶ **Peg IFNα$_{2a}$** (40 kDa) has a branched structure and is available in a ready-to-use solution. The dosage amounts to 180 μg, s.c., 1 x/week. Its efficient level lasts for 160 hours; half-life is approx. 75 hours. It can also be administered in cases of renal insufficiency due to its hepatic clearance.

▶ **Peg IFNα$_{2b}$** (12 kDa) has a linear structure. The solution comes in a two-chambered syringe and is prepared by mixing the contents of both compartments directly prior to injection. The dosage amounts to 1.0−1.5 μg/kg BW, s.c. 1 x/week. Half-life is approx. 30 hours. This substance should not be applied if creatinine clearance is <50 ml/min.

**Ribavirin:** This guanosine analogue was first used experimentally by O. REICHARD et al. (1991) and in chronic hepatitis C by J. ANDERSSON et al. (1991). Ribavirin is well resorbed. Half-life in patients with chronic hepatitis C is approx. 44 hours; once a steady state has been reached, the half-life is extended by up to 12 days. Elimination is predominantly via the kidneys. Ribavirin is contraindicated in cases where creatinine clearance is <50 ml/min. As monotherapy, it only effects a decrease in transaminases and a slight improvement in histological activity during the treatment course. It inhibits the replication of RNA and DNA viruses. Dosage is 400−600 mg, 2 x/day; it depends on body weight, renal function and HCV genotype. Due to its potentially teratogenetic effect, pregnancy must be avoided before, during and for at least 6 months after therapy. This also applies to sexual partners of men treated with ribavirin.

Ribavirin is also contraindicated during the lactation period. (254)

Using a combination of *IFNα + ribavirin*, it was possible to achieve a considerable improvement in comparison to former therapy results. (208, 210, 212, 216, 218, 221, 222, 225, 231, 237) • A combination of *Peg INFα + ribavirin* led to a further enhancement of the sustained response including normalization of the transaminases and reduction of the inflammatory activity (70−75% after 1 year). Thus, the combination of Peg INFα + ribavirin is considered to be standard therapy today.

▶ *Side effects* of ribavirin can appear in the form of nausea, pruritus, insomnia, irritability, haemolysis (224) and aggravation of IFNα-induced thrombopenia or leucopenia. In combination with other nucleoside analogues, there is a risk of lactate acidosis. • Side effects of Peg INFα are similar to those of IFNα. (229, 233) The latter usually necessitates a reduction in dosage in about 20% and termination of therapy in 5−10% of cases. • Side effects of combined IFNα + ribavirin include pancreatitis (215), pulmonary toxicity (226), manifestation of sarcoidosis (220, 240) and mental disorders (235). *It should be noted that even in combination with ribavirin IFNα may show its own customary side effects.*

### 7.3.4 Therapy scheme

In summary, the "ideal patient" with good prognosis shows the following criteria (s. tab. 34.10):

| |
|---|
| 1. **Exact diagnosis** |
| 2. **No contraindications** |
| 3. **Good response** ("ideal patient")<br> − genotype 2 or 3<br> − HCV RNA <2 million copies/ml<br> − slight fibrosis and inflammation<br> − normal hepatic iron level<br> − age <50 years (women <40 years)<br> − increase in GPT of >6 months<br> − exclusion of cirrhosis<br> − sporadic HCV infection<br> − no coinfection, no alcohol, no noxae<br> − no diabetes mellitus, no overweight<br> − short duration of infection (<10 years) |

**Tab. 34.10:** Criteria of a prognostically good response

With the help of the current therapy scheme, SVR can be achieved in up to 55% of infected patients with genotype 1 or 4 and up to 80% of those with genotype 2 or 3. Even in patients with an initial high virus load, SVR is about 40% for genotype 1 and 4 and about 75% for genotype 2 and 3. If the virus load has not fallen by factor 100 (>2 log, i. e. <30,000 IU/ml), or has not gone below the absolute limit of verification after 6 months, the therapy should be stopped. Early viral response (EVR) is a decisive factor regarding the success, failure or duration of therapy. If there is no EVR, it will probably not be possible to achieve SVR, even if therapy is continued for 12 months (or longer). • With genotype 2 and 3, therapy is stopped after 24 weeks, in genotype 1 (as well as 4, 5 and 6) after 48 weeks. Finally, the HCV-RNA titre should be measured anew. • The 5-year sur-

vival rate of patients with SVR corresponds to that of the general population. After SVR has been achieved, subsequent reactivation is rare. (s. tab. 34.11)

| **Peg IFNα₂ₐ** | 180 µg, s.c. 1 x/week | genotype 1, 4 = 48 weeks<br>genotype 2, 3 = 24 weeks |
|---|---|---|
| **Ribavirin** | >75 kg = 2 x 600 mg/day<br><75 kg = 2 x 500 mg/day | |
| **Peg IFNα₂ᵦ**<br><br>**Ribavirin** | 1.0−1.5 mg/kg BW,<br>s.c., 1 x/week<br>>85 kg = 2 x 600 mg/day<br>65−85 kg = 2 x 500 mg/day<br><65 kg = 2 x 400 mg/day | genotype 1, 4 = 48 weeks<br>genotype 2, 3 = 24 weeks |

*Tab. 34.11:* Scheme of combination therapy for chronic hepatitis C with Peg IFNα and ribavirin

**Iron removal:** In the case of increased iron storage in the liver or in hypersiderinaemia, iron removal has been reported to give better therapeutic results. (217, 243)

The **follow-ups** take place at first weekly, later at 4-week intervals; they include leucocytes, thrombocytes, haemoglobin and transaminases, occasionally also calcium and TSH. At 3-month intervals, HCV-RNA, TSH, TAB, creatinine and calcium are determined.

The **aims of treatment** are primarily the negativity of HCV RNA and secondarily the normalization of transaminases, reduction of inflammatory activity and fibrosis (219, 231, 241, 245) as well as prevention of cirrhosis.

### 7.3.5 Treatment failure

**Relapse:** In the case of relapse following successful treatment, it is advisable to wait for a certain time, since the relapse can be spontaneously limited in some patients. Some 80% of patients with genotype 2 or 3 and about 40% with genotype 1 or 4 show a stable remission in the long term (up to 3 years). Long-term follow-ups revealed that the risk of late relapse is relatively low after successful treatment. (209, 216, 218)

**Non-responders:** As in the case of patients with relapse it is advisable to weigh the slow progression of the disease against the side effects and costs of repeated combination therapy (particularly regarding higher dosage). The question also arises as to whether an improvement in the quality of life can be achieved. (208, 217, 237)

**Repeat treatment:** After a repeat treatment had been decided on, increased dosage and prolonged duration of IFNα (237) or consensus IFN (160) were used. • Other possible combinations were applied, such as *IFNα + thymosin* (236), *IFNα + cyclosporin* (223, 228), *IFNα + UDCA* (230) or *IFNα + amantadine* (250). In all these studies, positive results and an improvement in quality of life quality were described for some patients. • Even *iron removal* can be used as an additional measure. (217, 243) Likewise, good results in some patients have also been achieved with *immunostimulants* or *adjuvant sub-*

*stances* (as in chronic hepatitis B), such as thymosin (156), kurorinone (157), essential phospholipids (188) or glycyrrhizin (247). Above all, adjuvant therapy using silymarin as a fibrosis inhibitor is worth mentioning.

**Amantadine:** The antiviral efficacy of amantadine was first reported by W. Davies et al. in 1964. The mode of action consists in preventing uncoating and viral maturation (inhibition of the release of the nucleic acids that have already penetrated the host cell). The active substance is almost completely absorbed following oral intake. It is eliminated unchanged via the kidneys. Half-life is about 16 hours. So far, it has been used to combat influenza virus type A. Tolerance is good. Amantadine on its own is only minimally effective against HCV; it is therefore not suitable for initial monotherapy.

▶ Amantadine was administered for the first time in 31 patients with OLT due to chronic hepatitis C, who were suffering from severe reinfection of the transplant. Initial therapeutic success was already seen after 3 months: a significant fall in transaminases, bilirubin, AP and HCV-RNA titres, with improvement in liver histology (J.A. Goss et al., 1997). • In a further study, 22 patients with chronic hepatitis C who had failed to respond to IFN therapy were treated with amantadine (2 x 100 mg). After 6 months of treatment, GPT values showed a reduction in 64% and a normalization in 27% of cases; HCV RNA was no longer detectable. This situation was verifiable by PCR even 6 months after therapy in 18% of patients. (238) • *Amantadine seems to be a well-tolerated and effective virostatic for HCV infection in combination with IFN.* (239)

**Triple combination:** In non-responders, the triple therapy of *IFN + ribavirin + amantadine* may be effective. Sustained response can be achieved in 15−20% of cases. The additional costs for amantadine are relatively low; the number of side effects relating to IFNα + ribavirin has not proved to be higher than normal; the rate of SVR in initial therapy appears to be slightly better. Therefore, the question arises whether to use initial triple therapy in principle. (208, 211, 244, 246, 249, 253)

## 7.4 Therapy of chronic hepatitis D

Treatment consists of relatively high doses of interferon (generally 3 x 9−10 million U/week, s.c.) for a period exceeding 12 months. Even though normalization of GPT and HDV-RNA negativity as well as substantial histological improvement were achieved in 50% and 70% of cases and stabilized for over 6 years, HCV-RNA negativity was only maintained in 0% and 10% (−20%) of patients, respectively. The relapse rate is higher than in chronic hepatitis B. (255, 256) • An antiviral combination of IFN with lamivudine (257) or famciclovir (258) or aciclovir and ribavirin was not efficacious. • Liver transplantation should be planned in good time.

## 7.5 Liver transplantation

*Reinfection* occurs in about 50% of transplant recipients following chronic **HBV infection**; this seems to depend on presurgical replication activity. Some 83% of patients

who were HBV RNA-positive prior to transplantation again showed viraemia and reinfection of the graft. In patients with preoperative HBeAg, HBsAg and HBV-DNA negativity, viraemia was found in only 53% of cases. The *3-year survival rate* is 45−50%. However, with presurgical IFN therapy for improving this problematical serological situation, the danger of IFN-induced liver cell necrosis developing in HBV-related cirrhosis proved to be high. Therapy with lamivudine (occasionally with HBIG) is advisable. (194) In the case of reinfection of the transplant, HBIG must be discontinued. (28, 55, 74, 90) • In **chronic hepatitis D**, the situation is generally comparable to that of chronic HBV infection. • About 30% of liver transplantations are related to **HCV infection**. In these cases, *reinfection* of the graft is a frequent occurrence (6−28% after 5 years). However, this does not pose a serious clinical problem, since the histological finding in most cases was CPH. The difficulties regarding pretransplantation IFNα therapy with associated liver cell necrosis are of little relevance here. In individual cases, reinfection of the graft may progress to cirrhosis. Angiotensin-II receptor antagonist may help to reduce the development of graft fibrosis in recurrent hepatitis C. *Posttransplantation treatment with Peg IFNα* showed a complete response in 15−20% of cases; this correlated with a low HCV-RNA concentration prior to transplantation. (154)

---

**Epilogue**

*Counselling of chronically ill patients is extremely important.* The use of pharmacologically acceptable substances with a low frequency of side effects should always be preferred. *Medical efforts must focus on the individual criteria of the respective patient.* • In "treatment failure", we have always stressed that *this* treatment, at *this* dosage and for *this* period of time was not successful in *this* particular case (for whatever reason) and that further measures would now have to be initiated. • We can recall several patients with chronic hepatitis who felt that they had been left to their own devices and who were therefore trying out obscure, perhaps dangerous "therapeutic measures" and even consulting so-called "healers". • These (understandable) considerations on the part of both doctor and patient are an essential component of every individual treatment plan.

# 35 Liver cirrhosis

▶ Aretaeus (2$^{nd}$ century AD) coined the term "skirros", because he thought that inflammation of the liver led to its **hardening (= skirros)**. • In 1543 A. Vesal described the granulation of the liver surface as being responsible for the compression of the small hepatic vessels. Even at that time, he associated these changes, which were thought to accompany a shrinking of the liver, with alcohol consumption. • When J. Posthius (1590) described ascites, he said that the changed liver was "all granulated inside". A drawing by J. Brown (1685) shows coarse nodular liver cirrhosis. G. B. Morgagni (1761) also wrote a treatise on cirrhosis, in which he described the small vessels as being compressed due to a shrinking and hardened liver. M. Baillie (1818) wrote an excellent description of the morphology of liver cirrhosis and, like A. Vesal, he also postulated a causal connection with excessive alcohol consumption. • The first accurate report on atrophic, portal cirrhosis was given by R. T. H. Laennec (1819) as an incidental inclusion in his book «Traité d'auscultation». *Because of the* **yellow colour** *of the liver* **(= kirros)**, *he coined the term* **cirrhosis**. • The first microscopic examinations were carried out by F. Kiernan (1833), R. Carswell (1838) and E. Hallmann (1839). F. Th. Frerichs differentiated between two stages of the cirrhotic course: the stage of inflammation and the stage of shrinking with formation of nodes. In 1911 F. B. Mallory defined cirrhosis as a "chronic, destructive, progressive process" with regeneration, accompanied by scarring and shrinking of the connective tissue. A. Ghon (1928) recognized the transformational processes in the liver as being an essential feature of cirrhosis. • In 1930 R. Rössle provided a morphological definition of cirrhosis by stating **three criteria:** (*1*.) destruction of liver parenchyma, (*2*.) connective tissue proliferation, and (*3*.) nodular compensatory hyperplasia together with regeneration of liver parenchyma. In the following years, a **fourth criterion** was added: (*4*.) disturbance of the intrahepatic vascular system with consecutive formation of arteriovenous and portovenous anastomoses (H. Thaler, 1952, 1957, 1968; H. Popper et al., 1958; P. P. Anthony et al., 1977; A. M. Rappaport, 1980).

▶ Localized transformation processes such as those observed in **scarred liver** (s. p. 405) are not considered to be cirrhosis. The loss of parenchyma in scarred liver is generally the result of reduced blood supply in the respective area. Deep-set scars create the picture of a **funnel-shaped liver** (s. p. 406). Similarly, pronounced **liver fibrosis** (s. p. 405) does not fulfil the criteria of cirrhosis, since the lobular architecture as well as the intrahepatic and intra-acinar vascular supply are uncompromised. While fibrosis constitutes a precirrhotic stage, it does not necessarily progress to cirrhosis itself. Fibrosis can regress! • *Thus,* **liver cirrhosis** *is characterized by the following* **five criteria:**

1. Pronounced, insufficiently repaired necroses of the parenchyma (with or without inflammatory processes)
2. Diffuse connective tissue proliferation
3. Varying degrees of nodular parenchymal regeneration

4. *Loss and transformation of the lobular structure within the liver as a whole*
5. *Impaired intrahepatic and intra-acinar vascular supply*

## 2 Classification

Definitive classification of cirrhosis is difficult. It can be categorized according to its (*1*.) aetiology, (*2*.) morphology, (*3*.) pathogenetic development, and (*4*.) clinical features.

### 2.1 Aetiological classification

Classification of cirrhosis according to its **aetiology** would be desirable, as this approach may help determine prophylactic and therapeutic measures as well as prognosis. If all diagnostic options are employed and the patient cooperates optimally, an aetiological identification of cirrhosis is possible in almost all cases today. • Due to improved detailed diagnostics, the group of so-called *cryptogenic cirrhoses* has been consistently reduced (< 10% of cases). (s. tab. 35.2)

*However, classification of cirrhosis based on aetiology is limited for several reasons:* (*1*.) the cause of cirrhosis cannot be determined in many cases, (*2*.) a certain cause gives rise to different morphological forms in individual patients, (*3*.) there may be several causes for the same form of cirrhosis, and (*4*.) various causes may frequently coincide in diverse combinations.

## 1 Definition

Cirrhosis is a gradually developing, chronic disease of the liver which always involves the organ as a whole. It is the irreversible consequence and final stage of various chronic liver diseases of different aetiology or the result of long-term exposure to various noxae. • The extent of the morphological changes depends on the cause and stage of cirrhosis. Accordingly, there is a wide spectrum of morphological findings and clinical symptoms. The variations of this disease range from symptom-free conditions, non-characteristic complaints and different laboratory findings through to life-threatening complications. Since, in most cases, no clear dividing line can be drawn between cirrhosis and the preceding liver disease, it is very difficult to determine the point where the cirrhotic stage begins; as a rule, the transition is fluent.

## 2.2 Morphological classification

Cirrhosis is an alteration which affects the whole liver. It is characterized by septa-forming fibrosis and the transformation of the lobular/acinar architecture into insular or nodular parenchyma.

Up to now, the classification of cirrhosis according to its **morphology** has met with the most approval. (10) Classification is based on: (*1.*) liver size, (*2.*) size of the regeneration nodes, (*3.*) fine-tissue structure, (*4.*) progression, and (*5.*) completion of cirrhosis. (s. tab. 35.1) (10, 179) *(see chapter 21.5.2)*

| |
|---|
| I. **Size of liver**<br>  1. Normotrophic cirrhosis<br>  2. Hypertrophic cirrhosis<br>  3. Atrophic cirrhosis (s. fig. 35.1) |
| II. **Size of regeneration**<br>  1. Fine-nodular (granular) cirrhosis (s. fig. 28.13)<br>  2. Coarse-nodular (nodular) cirrhosis (s. fig. 35.2)<br>  3. Coarse-bulbous (lobular) cirrhosis (s. fig. 35.3)<br>  4. Mixed-nodular cirrhosis (s. fig. 35.6)<br>  5. "Smooth" cirrhosis (s. fig. 14.3) |
| III. **Structure of the fine tissue**<br>  1. Multilobular (multiacinar) cirrhosis<br>  2. Monolobular (monoacinar) cirrhosis<br>  3. Mixed forms |
| IV. **Progression of cirrhosis**<br>  1. Active  (= progressive) form<br>  2. Inactive (= stationary) form |
| V. **Completion of cirrhosis**<br>  1. Complete form<br>  2. Incomplete form<br>  3. Incomplete septal cirrhosis |

**Tab. 35.1:** Criteria for the morphological classification of cirrhosis *(see chapter 21.5.2)*

### 2.2.1 Liver size

Liver size is determined by *sonography* (or *CT*). In cirrhosis, it varies from case to case and presents as *hepatomegaly, normal-sized liver* or *atrophy*. There may even be deviations due to a disproportion between the two lobes resulting in asymmetric enlargement or reduction in size. Usually, there is more functional parenchyma present in hypertrophic or normotrophic cirrhosis than in atrophic cirrhosis. *The majority of cirrhoses are assigned to the atrophic group. A progressive reduction in liver size tending towards atrophy is to be interpreted as a prognostically unfavourable sign,* particularly when the transaminase values decrease to a subnormal level. Determination of the liver size enables the course of disease to be evaluated in terms of the remaining parenchymal mass or its potential for regeneration.

**Atrophic cirrhosis** as described by R. T. H. LAENNEC (1819) was compared with **hypertrophic cirrhosis** as described by A. GUBLER (1853) and P. OLIVIER (1871); the latter condition was identified as *biliary cirrhosis* by V. HANOT (1875).

### 2.2.2 Regeneration nodes

While the **formation of nodes** is a typical finding on the liver surface (s. figs. 28.13; 35.2−35.4), in sectional preparations (s. fig. 35.5) and under the microscope (s. fig. 35.4), it is not an obligate criterion. It is hardly recognizable in many cases, such as in haemochromatotic, biliary and alcoholic cirrhosis. • **Smooth cirrhosis,** showing a smooth liver surface despite complete transformation, is likewise found; it is micronodular and poor in fibres. (s. fig. 14.3)

▶ **Proliferation** is characterized by enlarged cells with great variability in the size of the nuclei (= anisonucleosis), occurrence of hepatocytes with 2−3 nuclei and cell plates of varying thickness. The parenchyma which has remained undamaged is capable of regenerative proliferation. The vulnerability of the acinus structure is the prerequisite for the criterion *"transformation"*, and the tendency to proliferate is the criterion for *"nodes"*. • The **blood vessels** are also involved in this process: (*1.*) reduction in the distance between presinusoidal and postsinusoidal vessels, (*2.*) development of shunts, and (*3.*) formation of a perinodular plexus (E. GAUDIO et al., 1993). This plexus consisting of arterioles guarantees the arterial blood supply within the nodes. Due to the displacement effect of the nodes, arterial vessels also become compressed. This is particularly critical since the cirrhotic liver is almost exclusively supplied by arterial blood, so that some areas become increasingly hypoxic and are thus more prone to *coagulation necrosis.* This happens mainly under conditions of circulatory collapse caused, for instance, by haemorrhage or toxicosis. • In contrast, a very favourable local arterial blood supply may lead to the formation of **gigantic regeneration nodes** similar to "proliferations". (s. fig. 35.1)

**Fig. 35.1:** Atrophic liver cirrhosis with pronounced, thick capsule callosity. Gigantic regeneration node "proliferating" from the underside of the right liver lobe, displacing the (duplicated!) gall bladder

The following forms of cirrhosis are differentiated according to the **size of the regeneration nodes:** (*1.*) micronodular (granular), (*2.*) coarse-nodular (nodular), (*3.*) coarse-bulbous (lobular), and (*4.*) mixed-nodular. The classification into granular, nodular and lobular forms was proposed by A.H. BAGGENSTOSS et al. (1952). Despite complete transformation processes, cirrhosis with a smooth surface, completely or largely without intrahepatic nodes, is occasionally found. Various synonyms have been used for this kind of classification according to the type and size of the nodes. (quot. 88, 90)

**Macronodular cirrhosis:** In *multilobular cirrhosis*, the nodes develop from parts of several lobules or from larger parenchymal areas with intact lobular architecture. This group with nodes of > 0.3 cm up to the size of a walnut is also called postnecrotic cirrhosis or Nagayo type A (M. NAGAYO, 1914). The liver is predominantly atrophic. The pseudolobules contain parts derived from several acini (= multiacinar or multilobular cirrhosis). Portal fields and central venules are present, however, in an abnormal topography. (s. fig. 35.2)

***Fig. 35.2:*** Complete, coarse-nodular liver cirrhosis due to chronic viral hepatitis B

A special form is **incomplete septal cirrhosis**; it is found especially as a result of chronic hepatitis B or in Wegener's granulomatosis. (201) The thin septa, which invade the parenchyma from the portal fields, contain no or only very few inflammatory infiltrates (= passive septa). (s. p. 407) • Lobular **coarse-bulbous cirrhosis** can likewise be assigned to this group, which, as posthepatitic cirrhosis, is also called Nagayo type B or may be referred to as *Marchand's hyperplasia* (F. MARCHAND, 1895) or *potato liver* (H. KALK, 1957) in the literature. Lobular nodes can reach such a size that they are mistaken for a normal hepatic lobe. (s. fig. 35.1) Macronodular forms may follow chronic viral hepatitis, chronic autoimmune hepatitis, metabolic diseases and toxic-necrotizing processes as well as alcohol abuse. (s. fig. 35.3)

***Fig. 35.3*** Complete, coarse-bulbous cirrhosis after years of alcohol abuse and superimposed acute viral hepatitis B, showing a chronic course. Mild tendency towards cholestasis; pronounced subcapsular vascularization and vascular stasis. Occasional funnel-shaped parenchymal depressions

**Micronodular cirrhosis:** Monolobular (monoacinar) cirrhosis consists of individual hepatic lobules separated by connective tissue, with the central vein maintained in the interior. In *pseudolobular cirrhosis*, no elements of the lobular architecture and no central vein can be detected; the nodules in this type of cirrhosis are small. The monolobular and pseudolobular forms are classified as micronodular cirrhosis, or Nagayo type C (with node size < 0.3 cm). A striking feature is the uniformity of the nodules. (s. figs. 35.4, 35.5)

***Fig. 35.4:*** Complete, micronodular, progressive liver cirrhosis with formation of pseudoacini (Sirius red)

The micronodular form can develop into a macronodular form, but not vice versa. Generally, micronodular cirrhosis contains more fibrosis than parenchyma; therefore it is firmer than macronodular cirrhosis. The development of micronodular cirrhosis, e.g. in alcohol abuse, may be caused by the fact that continuous alcohol intake blocks the protein synthesis, and thus the parenchyma has no time or chance for cellular proliferation. This form of cirrhosis mainly results from alcohol abuse, but may also be found in haemochromatosis,

congestive liver, biliary cirrhosis, toxic liver damage due to pharmacons, metabolic diseases and chronic viral hepatitis. The liver is generally enlarged.

*Fig. 35.5:* Complete, micronodular to medium-nodular liver cirrhosis after chronic viral hepatitis B (section, native preparation)

**Mixed-nodular cirrhosis** is considered to be a transitional form between micronodular and macronodular cirrhosis (V. J. Desmet et al., 1990). Due to variations in the regenerative capacity of the cirrhotic liver, 50% of

*Fig. 35.6:* Complete, mixed-nodular (toxin-induced) liver cirrhosis due to years of alcohol abuse and long-term oxyphenisatin abuse

micronodular forms with a diameter of 1.5 mm develop into macronodular forms after 2−4 years, whereas after 10 years, the rate is as high as 90%. • *Atrophic cirrhosis* is the most common form with regard to size, whereas *mixed-nodular cirrhosis* is the most common form with regard to nodes. (s. tab. 35.1) (s. figs. 35.2−35.7)

### 2.2.3 Progression

The question as to the progression of cirrhosis is of crucial importance clinically and can only be answered by means of histology. **Progressive cirrhosis** shows dense, chronic inflammatory infiltration of the connective tissue; the boundary between connective tissue and parenchyma is blurred. Groups of damaged hepatocytes, liver cell necroses as well as nodules formed from the proliferation of Kupffer cells and round cells are found within the parenchyma. In places, piecemeal necroses infiltrate the parenchymal islands. A great number of cirrhoses only take a progressive course because of circulatory disturbances. • **Stationary cirrhosis** is predominantly found in macronodular forms. It frequently exhibits round, clearly defined, nodular parenchymal areas within scar tissue. The boundary between the parenchyma and connective tissue is (relatively) clear-cut. (s. fig. 35.2) The scar tissue contains a small number of chronic inflammatory infiltrates of moderate and slightly varying density. The hepatocytes are conspicuously enlarged. Fully developed stationary cirrhosis may result, which is defined morphologically as defective healing. • **Remission** of the cirrhosis is possible, provided the cause of the disease is eliminated (e. g. abstention from alcohol, iron depletion in haemochromatotic cirrhosis, removal of biliary obstruction). However, nodular transformation processes cannot be reversed − restoration of normal lobular architecture is no longer possible. • The morphological dynamics of progression or full-scale stationary cirrhosis has to be strictly differentiated from the respective clinical course. **Clinical progression** frequently, but by no means always, corresponds to morphological progression.

*Fig. 35.7:* Scheme of possibilities for hepatic transformation after parenchymal necroses: (1) formation of pseudolobuli, (2) nodes with enclosed portal field, (3) formation of parenchymal garlands, (4) development of a coarse node from several hepatic lobules which are, in part, completely intact, (5) scar formation after total lobular necrosis (H. Thaler, 1975) (179)

### 2.2.4 Completion

Another important criterion is to determine whether the nodular transformation in the liver is complete or incomplete. This morphological characteristic can be found both in progressive and stationary cirrhoses. • In **complete cirrhosis,** the parenchyma is completely partitioned by connective tissue septa. The collapse of fibres (due to portocentral bridging necroses) results in the development of portocentral septa (= *passive septa*). Due to the spreading of the inflammation to the periportal parenchyma, septa develop and branch out from the portal fields (= *active septa*). Generally, they lead to capillarization of the sinusoidal walls as well. (s. fig. 35.7) **Incomplete cirrhosis** only displays the formation of short septa (= *subsepta*), so that there are areas of incomplete (partial) subdivision of the parenchyma.

### 2.2.5 Pathogenetic development

The development of cirrhosis can easily be understood by analysing the morphological findings. Differentiation is made between: (*1.*) *regular cirrhosis* (where the cause has a constant, long-term and strong effect, e. g. in alcohol abuse, haemochromatosis, Wilson's disease), (*2.*) *irregular cirrhosis* (where the cause has an intermittent effect interposed by inaction), (*3.*) *mixed forms*, (*4.*) *biliary forms*, and (*5.*) *vascular forms*.

### 2.2.6 Postdystrophic cirrhosis

In the course of massive subacute liver necrosis (or hepatic dystrophy), large parts of the hepatic parenchyma can be destroyed within a few months. Extensive regenerative nodes form from the remaining epithelium. Within these regenerations, the lobular architecture is either still maintained or has been partially restored. Areas of parenchymal loss are converted into fibre-dense scar tissue with embedded pseudoductuli and duct proliferations as well as irregularly located residual hepatocytes. This course is extremely rare. In the literature, it is also called *incomplete postnecrotic cirrhosis*.

### 2.2.7 Necrosis, fibrogenesis, regeneration

The mechanisms leading to *cell degeneration* and *cell death* have been described in detail. *(see chapter 21.3.4)* The processes of *regeneration (see chapter 21.3.5)* and *fibrogenesis (see chapter 21.3.6)* have also been discussed in depth. These three important events − cell death, regeneration and fibrogenesis − are involved in the development of cirrhosis.

**Fibrogenesis** commences with the activation of Ito cells by cytokines such as TGFβ1, PDGF, TNFα, IGF1. This induction of Ito cells leads to quantitatively increased (up to 10 times the norm) and qualitatively altered synthesis of the extracellular matrix, which consists of collagens, glycoproteins, proteoglycans and glucosaminoglycans. • At the same time, degeneration of the matrix is reduced by a decrease in matrix metalloproteinases (MMP) with simultaneous increase in the tissue inhibitors of metalloproteinases

(TIMP). Both factors reduce further degradation of connective tissue. • The hepatocytes are now multilayered instead of normal single-layered cell plates and lose their microvilli. Fenestration of the sinusoids disappears, whereas the sinusoidal extracellular matrix increases, leading to **capillarization of the sinusoids.** (s. pp 406, 526) In this way, the distance between the hepatocytes and the blood becomes greater, and the clearance of macromolecular substances is reduced. Stronger flow resistance in the liver leads to portal hypertension. • Portoportal and portocentral bands of connective tissue form, in which portosystemic intrahepatic shunts develop.

**Regeneration** after liver resection follows a coordinated and limited course. This is not the case in cirrhosis: isolated and excessive regenerations of hepatocytes and bile ducts are formed, from which *adenomas* and *carcinomas* may develop.

### 2.2.8 Morphological diagnostics

In order to evaluate cirrhosis in terms of morphology, certain **requirements** have to be fulfilled. Occasional *diagnostic uncertainty* or *divergent classification* may arise from the fact that the biopsy material is insufficient and therefore not representative. This, in turn, is probably due to the fact that the techniques used in obtaining these inadequate samples were faulty or unsuitable. (s. pp 160, 161, 408, 726)

# 3 Epidemiology

Cirrhosis of the liver is a disease found all over the world, affecting all races, age groups and both sexes. • However, there are **geographical differences** regarding the most important causative factors: (*1.*) rate of alcohol consumption and (*2.*) frequency of viral hepatitis. Few reliable figures concerning its incidence and prevalence are available, since cirrhosis is often symptom-free. Autopsy examinations suggest a **prevalence** of 4−10%. The **incidence** is about 240/million inhabitants/year. • The number of people suffering from cirrhosis in Germany is estimated at 600,000−700,000; some 25,000 patients die of cirrhosis every year, with **mortality** being twice as high in men as in women. Thus cirrhosis ranks ninth as a cause of death, and even fifth for the age group 45−65 years. • Generally, the increasing mortality rate runs parallel to regional alcohol consumption. This correlation between alcohol consumption and mortality as well as morbidity due to cirrhosis applies equally to men and women. • The slight decrease in mortality in some countries observed during the past 10−15 years may be due to more effective prophylaxis and improved treatment options for complications. (61, 157)

# 4 Aetiology

The causes of "liver cirrhosis" are numerous; some of them are rare, appearing even in childhood (e. g. drinking water from copper pipes). Cirrhosis can be acquired

or genetically based. Aetiological clarification, particularly with early diagnosis, should always be a priority, since it may aid treatment and thus prognosis. *Cirrhosis comes in many different forms!* • There is still no unequivocal answer to the question as to why these causal factors are responsible for the development of cirrhosis over such a widely varying period or why they may not cause cirrhosis at all in some individuals. There are even cases where cirrhosis develops despite effective elimination of the causes − probably as a result of self-perpetuation due to induced immunological mechanisms. • Although there are numerous causes with varying pathogenesis, it is possible to differentiate between three forms of cirrhosis from an aetiological viewpoint: (*1.*) parenchyma-related cirrhosis, including the so-called "common" cirrhosis (H.W. ALTMANN et al., 1986) as well as metabolic cirrhosis, (*2.*) bile duct-related cirrhosis (= biliary cirrhosis), and (*3.*) vessel-related cirrhosis (= vascular cirrhosis). (s. tab. 35.2)

**Biliary cirrhosis:** Biliary cirrhosis can be detected in 5−15% of cases. (s. pp 641, 646, 655) (s. figs. 32.5; 35.8, 35.9)

**Fig. 35.8:** Biliary liver cirrhosis after long-term chronic-recurrent cholangitis

**Fig. 35.9:** Liver cirrhosis due to chronic-recurrent, ascending cholangitis

**Alcohol abuse:** Alcohol abuse is the most common cause of cirrhosis. Nevertheless, no more than 40−60% of alcoholics contract the disease. Thus genetic factors must also be involved in the development of alcoholic cirrhosis. Alcohol itself can be a facilitative factor or cofactor. Moreover, so-called "additives" contained in various alcoholic beverages in widely different quantities may also be of greater importance than has hitherto been assumed. (100, 171, 186) (s. pp 528, 532) (s. fig. 28.13, 28.14)

**Chronic autoimmune hepatitis:** If untreated, AIH (especially type 2) develops almost inevitably into cirrhosis; the condition is further aggravated by the presence of multilobular necrosis and bridging necrosis. In bridging necrosis, development of cirrhosis is more rapid between the portal fields and the central vein than between the portal fields themselves. (s. p. 683) (s. fig. 33.4)

**Chronic viral hepatitis:** Within a period of 5−6 years, cirrhosis is caused by chronic viral hepatitis B in 15−30%, chronic viral hepatitis C in 20−50% and chronic viral hepatitis B/D in up to 60% of cases. The risk of cirrhosis is 4.2 times higher in HBsAg carriers and 2.3 times higher in carriers of anti-HCV than in people without these serum markers. (68, 78, 114, 144)

**Haemochromatotic cirrhosis:** *Untreated* idiopathic haemochromatosis has an insidious course and, as a rule, leads to (micronodular) cirrhosis. Spontaneous remission has not been observed. The survival rate in haemochromatotic cirrhosis is 60−65% after 10 years. (s. pp 620, 623) (s. figs. 31.24−31.26)

▶ We do not consider the terminological demarcation of "primary" cirrhosis or the differentiation into "primary" and "secondary" cirrhosis to be acceptable because any kind of biliary cirrhosis constitutes the final stage of a preceding chronic biliary disease. (s. p. 646!)

**Cryptogenic cirrhosis:** Cirrhoses which cannot (yet) be clarified by means of current investigation techniques are subsumed under the term cryptogenic cirrhosis. (30) Earlier data regarding the frequency no longer apply. As a result of the methods of detailed diagnosis used nowadays, only a small number of cirrhoses remain truly "cryptogenic". (15) Modern hepatological detailed diagnostics yield an aetiological clarification rate of nearly 95% of all patients! (s. tab. 35.2) • In most of the remaining cases, **chemical substances,** which are still unknown or which have not yet been identified as hepatotoxins, are probably involved, so that the patient concerned remains unaware of them; furthermore, they might occur in combination with other noxae that cannot be identified. *(see chapter 30)* **Medication** may likewise cause chronic hepatitis as well as cirrhosis. This also applies to herbal remedies, e. g. wild germander. *(see chapter 29)* Knowledge in this field has been greatly improved by cooperation between clinicians, toxicologists and specialists in industrial and environmental medicine. **AIH** was the cause of cryptogenic cirrhosis in 20−25% of cases. • **Non-alcoholic steatohepatitis** is of particular aetiological importance in cryptogenic cirrhosis, especially in cases where obesity and diabetes coexist (30−35%). (15, 138, 143) *(see chapter 31.3.6)* • *Owing to modern diagnostic options (and assuming the patient co-operates!), cryptogenic cirrhoses today constitute no more than 5−10% of cases.*

1. **Alcohol** *(see chapter 28)*
2. **Infections**
   Congenital syphilis *(see chapter 24)*
   Schistosomiasis *(see chapter 25)*
   Toxoplasmosis *(see chapter 25)*
   Viral hepatitis B, C, D *(see chapter 22)*
3. **Autoimmune diseases**
   Autoimmune hepatitis *(see chapter 33)*
   Autoimmune cholangitis *(see chapter 32)*
   Primary biliary cholangitis *(see chapter 32)*
   Primary sclerosing cholangitis *(see chapter 32)*
   Wegener's granulomatosis
4. **Pharmaceuticals** *(see chapter 29)*
   Amiodarone          Methotrexate
   Dantrolene          Methyldopa
   Halothane           Nitrofurantoin
   Isoniazid           Perhexiline
   MAO inhibitors      Propylthiouracil
5. **Chemical agents** *(see chapter 30)*
   Arsenic             Phosphorus
   Carbon tetrachloride  Phytotoxins
   Copper              Trichloroethylene
   Mycotoxins
6. **Cholestatic diseases** *(see chapters 13, 32)*
   Aagenaes syndrome       Byler's syndrome
   Arteriohepatic dysplasia  Caroli's syndrome
   Bile-duct atresia         Choledochal cyst
   Bile-duct stenoses        Chronic cholangitis
7. **Venous congestion** *(see chapters 14, 39)*
   Budd-Chiari syndrome
   Constrictive pericarditis
   Right-sided heart failure
   Veno-occlusive disease
8. **Metabolic diseases** *(see chapter 31)*
   $\alpha_1$-antitrypsin deficiency
   Abetalipoproteinaemia
   Acute intermittent porphyria
   Atransferrinaemia syndrome
   Cystinosis
   Erythrohepatic protoporphyria
   Fructose intolerance
   Galactosaemia
   Gaucher's disease
   Glycogenosis (types I, III, IV)
   Haemochromatosis
   Hurler's disease
   Hypermethioninaemia
   Mucoviscidosis
   Neonatal adrenoleucodystrophia
   Nieman-Pick disease
   Non-alcoholic steatohepatitis
   Porphyria cutanea tarda
   Seip-Lawrence syndrome
   Thalassaemia
   Tyrosinosis (type I)
   Wilson's disease
   Wolman's disease
   Zellweger syndrome
9. **Intestinal bypass**
10. **Rendu-Osler-Weber disease**
11. **Indian childhood cirrhosis**

12. **Cryptogenic cirrhosis** (< 10%)

*Tab. 35.2:* Possible causes of liver cirrhosis

# 5 Clinical classification

The following stages or courses of cirrhosis can be differentiated according to clinical criteria:

1. *Latent cirrhosis*
2. *Manifest cirrhosis*
   - active form
   - inactive form

**Latent cirrhosis:** There are no subjective complaints or clinical symptoms. This stage is identified by laboratory parameters, imaging procedures or histological examination of the liver. Frequency is between 10 and 20%.

**Manifest cirrhosis:** Manifest cirrhosis is characterized by subjective complaints and clinical findings. Hepatic haemodynamics are significantly altered, and other organs and organ systems as well as hormonal and humoral functions are affected. *Liver cirrhosis orchestrates a complex array of altered biochemical and physiological processes.* • Manifest cirrhosis can present in two forms:

1. *Stage of compensation*
2. *Stage of decompensation*
   - portal decompensation
   - metabolic decompensation

Apart from **histological activity** (= progressive) or **inactivity** (= stationary), **biochemical activity** must also be defined. The latter is determined by (*1.*) *enzymatic activity,* (*2.*) *mesenchymal activity,* and (*3.*) *immunological activity.* (s. p. 121) • Compensated cirrhosis may be either active or inactive. Even decompensated cirrhosis can sometimes be kept in an inactive (stationary) stage for a limited period of time. Jaundice (> 3 mg/dl) is a typical sign of decompensation.

▶ **Portal hypertension** derives from *microcirculatory disorders,* with increasing flow resistance in the sinusoids and postsinusoids. This condition is a consequence of the narrowing, rarefaction and compression of the sinusoids or central veins due to collagen deposition, fibrosis and nodulation as well as the presence of intrahepatic arterio-portovenous shunts. Elevated endothelin levels are involved in these processes. (13) Portal hypertension is also evoked or increased by (relatively common) **portal vein thrombosis.** (7, 20, 127, 194) Nitric oxide (4, 12, 19), endotoxins (33, 35), platelet-activating factor, prostacyclin, histamine, adenosine, serotonin, bile acids, secretin, glucagons, etc. are all considered to be mediators of **hyperdynamic splanchnic circulation.** (s. p. 738) The resulting portal hypertension with splenomegaly and collateral varicosis become detectable with progressive cirrhosis of the liver. An important factor is that in alcohol-induced liver diseases, portal hypertension may be present before cirrhosis develops. *(see chapter 14)*

**Portal decompensation:** The various forms manifest as (*1.*) hypersplenism, (*2.*) increasing collateral varicosis with a simultaneous rise in the splanchnic flow due to hyperdynamic circulation and vasodilatation in the area of the splanchnic vessels, (*3.*) hepatic encephalopathy, and (*4.*) oedema and ascites. *(see chapters 14, 15 and 16)*

**Portal decompensation**

- **Hypersplenism**
- **Collateral varicosis**
- **Portal hypertensive gastropathy**
- **Hepatic encephalopathy**
- **Oedema and ascites**

▶ By fulfilling a multitude of **metabolic functions,** the liver guarantees the survival of the organism. Some 70 metabolic partial functions grouped into 12 main metabolic areas need to be constantly maintained with the help of *some 500 biochemical processes* carried out separately within the hepatocytes. (s. p. 32)

**Metabolic decompensation:** Pronounced functional decrease or dysfunction in several metabolic areas result in *partial metabolic insufficiency.* With the failure of additional metabolic functions, there is a risk of *global metabolic insufficiency.* Development of metabolic insufficiency (also known as *cellular decompensation*) is due to a significant loss of hepatocytes (e. g. mass necroses) and/or a loss of function of the hepatocytes (e. g. insufficient numbers of hepatocytes and accumulation of waste products in cirrhotic transformation with the development of shunts).

**Metabolic decompensation**

Disturbance of some or almost all *biochemical functions*, also with a *negative energy balance* (= **partial** or **global insufficiency**) *(see chapter 20)*:
- Jaundice *(see chapter 12)*
- Encephalopathy *(see chapter 15)*
- Oedema, ascites *(see chapter 16)*
- Disturbed coagulation *(see chapter 19)*
- Impaired protein metabolism
- Impaired carbohydrate metabolism
- Disturbed biotransformation
- Hormonal dysbalances
- Altered pharmacokinetics
- Bacterial and viral infections
- States of deficiency (vitamins, trace elements, electrolytes, energy carrier substances)

1. HE and hepatic coma *(see chapter 15)*
2. Ascites *(see chapter 16)*
3. Spontaneous bacterial peritonitis *(see chapter 16)*
4. Hepatorenal syndrome *(see chapter 17)*
5. Hepatopulmonary syndrome *(see chapter 18)*
6. Coagulopathy (DIC) *(see chapter 19)*
7. Acute varix bleeding *(see chapter 19)*
8. Hepatocellular carcinoma *(see chapter 37)*
9. Hepatic osteopathy
10. Cholelithiasis
11. Impaired protein, carbohydrate, lipid, vitamin and hormonal metabolism
12. Portosystemic myelopathy and neuropathy

*Tab. 35.3:* Possible complications in liver cirrhosis

**Complications:** Generally, complications can occur during the stages of compensation and decompensation. Some complications predominantly arise from a decompensated situation, whereas others do not necessarily occur at all in the natural course of cirrhosis. However, in view of the cirrhosis-induced lability of the metabolic functions, they may easily be provoked by the patient's inappropriate behaviour or by iatrogenic measures. Viruses, such as CMV or influenza A (50), may cause deterioration of the liver function or decompensation. (59, 157) (s. tab. 35.3)

# 6 Diagnosis

▶ *Liver cirrhosis is the final stage of a hepatic disease which has generally run a chronic course for several years.* • Some 60−65% of cirrhoses are alcohol-induced (long-standing alcohol abuse does not go unnoticed!). Some 25−30% of cirrhoses are thought to be posthepatitic events. Although a very small number of anicteric HBV and particularly HCV infections remain unrecognized (the exact figure is impossible to estimate), most acute and icteric courses are diagnosed. • With today's diagnostic possibilities, **chronic liver disease** is generally detected at an early stage, either due to general complaints by the patient or during medical examinations. Its course is then carefully monitored. • The point at which a chronic liver disease, particularly cirrhosis, is first detected depends on the patient's general attitude and the diagnostic interview, *which nowadays is far more effective than the standard 20−30 years ago!*

▶ Thus (subjectively and clinically symptom-free) **latent cirrhosis,** the frequency of which is 10−20% of cases, need not remain undetected. Looking back on almost 40 years of experience, we can state that cirrhosis itself constituted the *first diagnosis* in no more than 10% of cases. The first diagnosis of cirrhosis at such a complicative stage as oesophageal varix bleeding or decompensation has fortunately become a rare event. • *The course of cirrhosis (progressing, stationary, or regressing) is monitored by clinical findings, liver function tests and sonography.*

## 6.1 Anamnesis

*Targeted anamnesis* can yield valuable diagnostic information as soon as liver disease is suspected. This may require insistent and intense questioning, involving additional consultations. Such an approach is especially helpful in determining risk factors concerning viral hepatitis infection and toxic effects. (s. p. 76) (s. fig. 4.21)

## 6.2 Complaints

The subjective complaints of cirrhosis are non-characteristic and ambiguous. Even determination of the

severity of cirrhosis is only possible to a limited extent. Most often, fatigue *("pain of the liver")* (60−80%), sleep disturbance (possibly due to an impaired melatonin rhythm) (40, 173) and gastrointestinal complaints (50−60%) as well as mental disorders are mentioned by the patient. The most important subjective complaints can be noted quickly by using a **check list.** • Frequently, however, the patient does not mention any subjective complaints. (s. p. 77) (s. fig. 4.21)

## 6.3 Clinical findings

As a rule, all of the cirrhosis-typical findings occur in the late course of the disease. Occasionally, patients report striking findings such as changes in the consistency, colour or smell of *faeces*, cutaneous or mucous *bleeding* and unexplained *febrile episodes*. The senses of *taste and smell* are both impaired. (25) Eyelid retraction and eyelid lag are often increased. • The *liver* becomes harder; hepatomegaly is present in about 60% of patients, while in about 20% of cases, the liver is atrophic and therefore usually no longer palpable. Single nodes are sometimes detectable. • *Splenomegaly* is present in 50−75% of cases. Splenic infarction may occasionally be detected (e. g. laparoscopically). (s. fig. 35.10) Generally, there is development of *hypersplenism* (= reticuloendothelial hyperplasia with increased fibrosis and hyperaemia). • *Muscle cramps* (F. KONIKOFF et al., 1985) sometimes occur. Zinc deficiency or the administration of diuretics are not considered to be possible causes. These painful cramps occur mostly at night and mainly affect the gastrocnemius muscle and small muscles of the foot. They are often accompanied by increased activity of the renin system with a decrease in the effective blood volume. As a rule, they respond to BCAA supplements in the late evening (152), quinine sulphate (oral application) or i.v. albumin infusion (1 x per week). (9) Hepatic *myelopathy* with spastic paraparesis is a rare event, especially in the advanced stage of cirrhosis. Pathogenesis is not yet clarified. Liver transplantation leads to complete recovery. • Symptoms of peripheral *neuropathy* have also been observed. (16, 83, 172) There is often *meteorism ("first the wind ...")* and in many cases *ascites* develops *("... and then the rain")*. Tachycardia, hypotension and systolic murmur point to *hyperdynamic circulation*. Evidence of pronounced spider naevi is generally a sign of a significant disturbance of the systemic and pulmonary circulation. (19, 113, 115) Occasional murmurs may be perceptible in the umbilical area (Cruveilhier-Baumgarten syndrome). Men often display symptoms of feminization, while women display symptoms of hypogonadism. • Numerous **skin stigmata of liver disease**, which may be partially pathognomonic, are visible in varying intensities and combinations; they can be rapidly and clearly documented by using a **check list**. (s. tab. 4.3) (s. figs. 4.6−4.11, 4.18−4.21) (s. pp 79−86)

**Fig. 35.10:** Splenic infarction in splenomegaly due to complete liver cirrhosis. (Postpartum blood transfusion into the umbilical vein, with subsequent severe viral hepatitis B and rapid transition into early infantile cirrhosis)

## 6.4 Laboratory findings

**Enzymatic activity:** The enzymatic activity depends upon the extent of (*1.*) inflammatory or necrobiotic damage to the hepatocytes and (*2.*) residual parenchymal mass. Accordingly, subnormal, normal or differently increased values of *GPT* and *GOT*, and in some cases also of *GDH*, are found. *Enzyme quotients* may be used for establishing the diagnosis. (s. tabs. 5.6, 5.7) *Cholestasis parameters* are moderately elevated; in biliary diseases, however, the rise is significant. A progressive increase in γ-GT and AP suggests hepatocellular carcinoma and requires determination of $\alpha_1$-foetoprotein. Disproportionally elevated γ-GT values generally indicate alcoholic or chemical-toxic aetiology or even HCV infection − but sometimes also regeneration of the hepatocytes. (88, 90, 140, 169) With the progressive loss of liver parenchyma, the transaminase values fall to the normal range, and occasionally even to subnormal levels. This prognostically unfavourable sign correlates with a deterioration of the liver function test.

**Mesenchymal activity:** Mesenchymal activity is accompanied by an increase in γ-*globulins* and *immunoglobulins*. There is a broad-based, often dromedary-like humped γ-globulin peak (typically 22−35 rel.%). Albumins can be reliably determined by means of immunonephelometry. Generally, IgA is elevated in alcoholic cirrhosis, IgG in autoimmune cirrhosis and IgM in primary biliary cholangitis or CDNC-related cirrhosis. The rise in γ-globulins is due to reduced clearance of bacterial antigens in the RES, with increased antibody formation against intestinal bacteria, mainly E. coli. At the same time, elevated γ-globulins have a depressor effect on albumin synthesis and are indicators of the degree

| Coagulation factors | | Coagulation inhibitors | | Fibrinolytic system | |
|---|---|---|---|---|---|
| Fibrinogen (I) | ↓ | Antithrombin III | ↓ | Plasminogen | ↓ |
| Factors II, IX, X | ↓ | Protein C | ↓ | α₂-antiplasmin | ↓ |
| Factor VII | ↓ ↓ | Protein C inhibitor | ↓ | Prekallikrein | ↓ |
| Factors V, IX, XII, XIII | ↓ | Protein S | ↓ | HRGP | ↓ |
| Factor VIII | ↑ | Heparin cofactor | ↓ | t-PA | ↓ |
| TPT | ↑ | | | D dimer | ↑ |
| Quick's value | ↓ | | | | |
| PTT | ↑ | | | | |

**Tab. 35.4:** Abnormal coagulation factors, coagulation inhibitors and fibrinolytic system values in hepatic cirrhosis (TPT = thromboplastin time; PTT = partial thromboplastin time; HRGP = histidine-rich glycoprotein; t-PA = tissue plasminogen activator)

of portacaval anastomoses. The serum value of *copper* may be increased. In correlation with the dynamics of fibrogenesis, there is often a rise in *P-III-P* and hyaluronan. (87) • Increased γ-globulins and decreased cholinesterase may point to cirrhosis. (88, 90)

**Liver function parameters:** The most common endogenous liver function parameters, such as lowered *cholinesterase, albumin* (17) and *Quick's value*, are helpful for diagnosis. Since 1982, we have included the determination of *bile acids* as a relatively sensitive and specific follow-up procedure. Abnormal *coagulation factors* and *fibrinolysis values* are of particular diagnostic and prognostic importance. Factor 5 has a short half-life. (s. tab. 35.4) • These endogenous parameters can provide additional help in evaluating the remaining liver function, especially when used in combination, and may thus facilitate prognostic evaluation. An increase in bilirubin and subsequent permanent *jaundice* are unfavourable prognostic signs. (140) *Urobilinogenuria* is mostly present. • *Galactose elimination capacity* (150, 153) and the *indocyanine green test* are reliable exogenous liver function tests. (68, 167) Good results have also been obtained using the *caffeine test, aminopyrine breath test* (43) (s. pp 108−109) and *MEGX test*. (124, 162) The formation of portosystemic collaterals can sometimes be assessed with the help of the *ammonium tolerance test*. (s. p. 107) • In a more advanced cirrhosis, there is a decrease in BCAA (valine, leucine, isoleucine) and an increase in AAA (phenylalanine, tyrosine, methionine).

**Additional parameters:** Decreased serum values of *zinc* (105, 196) and *selenium* (27, 181), *thrombopenia* or *thrombopathy* (128) as well as increased values of *endotoxins* (33, 35) and *homocysteine* are also considered to be important laboratory parameters. Increased values of anticardiolipin antibodies are a hint of existing portal vein thrombosis. • Determination of $α_1$-*foetoprotein* (s. pp 106, 778) or *des-gamma-carboxy prothrombin* (s. p. 779) should be carried out to obtain a basic value, then checked at longer intervals; if values increase, they must be monitored at shorter intervals. This also applies if there is a progressive rise in AP and γ-GT.

## 6.5 Imaging procedures

Imaging techniques have significantly improved the diagnosis of cirrhotic diseases. They supply *detailed information* on (*1.*) structural changes in the liver, (*2.*) development of portal hypertension and formation of collaterals, (*3.*) occurrence of ascites at a very early stage, (*4.*) haemodynamics, and (*5.*) vascular changes. (s. tab. 35.5)

### 6.5.1 Sonography

*Portal hypertension* can be reliably detected and evaluated by way of sonographic criteria. (s. pp 129, 251) The sensitivity of sonography is limited by the extent of the cirrhosis-induced changes and reaches 85−90% in pronounced stages of cirrhosis. Specificity is high. The nodularity of the liver surface is, in general, easily visible, especially using a 7.5 MHz annular-array transducer. (120) Occasionally, however, the surface is so finely undulant that it appears smooth in sonography. The reflex pattern is inhomogeneous, irregular and coarse; the vessels are rarefied and tortuous. Splenomegaly as well as dilated portal vessels with collaterals are in evidence. Any reduction in size of the quadrate lobe (segment IV) (<3 cm in diameter) is an important indicator. The caudate lobe is enlarged (especially in alcoholic cirrhosis) in relation to the right lobe. Regeneration nodes can appear as focal lesions; they may be misinterpreted as malignant foci. (s. figs. 6.6; 35.11)

**Fig. 35.11:** Liver cirrhosis with ascites (▲). Re-opened umbilical vein (→), hepatic bifurcation and hilum of the liver with ramification of the portal vein (⇒)

Sonography is also considered to be a routine technique for evaluating the course of *cirrhosis*. It does not, how-

| | Diagnosis of cirrhosis | Diagnosis of portal hypertension | | | Diagnosis of HCC |
|---|---|---|---|---|---|
| | | Portal vein | Splenomegaly | Collaterals | |
| 1. Sonography | + + | + | + + + | + + | + |
| 2. Colour-encoded duplex sonography | + + | + + | + | + + | + |
| 3. CT | + + | + + | + + | + + | + + + |
| 4. MRI | + + | + + + | + + | + + + | + + |
| 5. Angiography | (+) | + + + | + + + | + + + | + + + |

**Tab. 35.5:** Diagnostic reliability of imaging techniques in liver cirrhosis

ever, provide any information about the activity of disease, degree of fibrosis or initial stage of a malignant process. (14, 38, 48, 80, 92, 93, 101, 120, 168, 174, 191) • EUS has proved successful in evaluating varices in the distal oesophagus and cardia area. (23) (s. pp 137, 354)

### 6.5.2 Colour-encoded duplex sonography

Colour-encoded duplex sonography facilitates characterization of the portal and hepatovenous haemodynamics and differentiation between the hepatofugal and hepatopetal direction of flow. (56) There is a flattening of the flow wave in hepatic veins. CEDS can show a shortened liver transit time (using sonographic contrast medium), collaterals, thrombosis or the reopening of vessels, spontaneous portosystemic shunts (60, 147) and arterioportal fistulas (22) as well as determining the portacaval pressure gradient. (22, 60, 96, 113, 147, 169) (s. figs. 14.13; 35.12) (s. p. 137) • Colour-encoded duplex sonography is indispensable for establishing indications and excluding contraindications regarding TIPS; it is also used for monitoring a TIPS placement.

**Fig. 35.12:** Colour-encoded duplex sonography: retrograde portal flow (flow inversion) in both branches and in the trunk of the portal vein due to arterioportal shunts

### 6.5.3 Computer tomography

CT scanning basically provides the same information as sonography, but the surface tubers or inhomogeneous internal structure are usually represented more clearly. Generally, regeneration nodes cannot be differentiated. The portal system and hepatic veins as well as collateral vessels are discernible. Even small collections of ascitic fluid and some increases in density are recognizable. The caudate lobe is more enlarged in compensated than in decompensated cirrhosis. (80, 195) CT is particularly valuable in detecting small hepatocellular carcinomas. (79, 103)

**Fig. 35.13:** Cirrhosis with regenerative node (◀═), recanalized umbilical vein (= caput Medusae) (←) and ascites (◀•••) in CT

### 6.5.4 Magnetic resonance imaging

No further diagnostic information is gained by MRI, even though histological results can be improved to a certain extent by applying special techniques. By measuring the signal intensity of the liver, it is generally possible to quantify the extent of liver cirrhosis. Even the uptake of contrast medium as an expression of the still functioning proportion of the parenchyma can facilitate quantification. As a rule, liver perfusion is reduced in relation to the increase in arterial blood flow. The relative reduction in the volume of the right lobe of liver compared to the caudate lobe correlates closely with the extent of the cirrhosis. However, this has no relevance in the context of cirrhosis. (75, 76, 79, 80, 103, 106, 108, 172, 192)

### 6.5.5 Radioisotope scanning

This technique reveals decreased uptake of the radioisotope with an irregular pattern. Regeneration nodes cannot be visualized. There is enhanced storage in the spleen and bone marrow. (s. fig. 9.1)

## 6.6 Liver biopsy and laparoscopy

**Laparoscopy:** The direct visualization of the nodular liver by laparoscopy is the procedure with the greatest value for primary morphological diagnosis. The diagnostic margin of error regarding percutaneous biopsy in cirrhosis is so high that there can be no indication for biopsy using a Menghini needle! *Only a compact biopsy sample turns histology into a diagnostic gold standard;*

furthermore, such a sample allows all other specific evaluation techniques to be carried out, if necessary. • It is particularly important to obtain **photolaparoscopic documentation** of the liver surface, regeneration and scar areas, portal hypertension, spleen (or splenic infarction) (s. fig. 35.10) and other relevant, individual, abdominal findings. (89, 91, 129, 137) Although percutaneous biopsy using a Vim-Silverman needle usually produces a compact biopsy punch, it entails a higher and less controllable bleeding risk. Only an **adequate biopsy sample** yields the necessary results: (*1.*) confirmation of diagnosis, (*2.*) assessment of the degree of activity (= grading), (*3.*) evaluation of the extent of fibrosis (= staging), and (*4.*) specific histochemical examinations if a certain aetiology of cirrhosis is given.

**Connective tissue collagen** in biopsy specimens can be shown, for example, by the following staining:

| | |
|---|---|
| **elastic fibres (e. g. sinusoids)** | **= elastin** |
| **reticulum fibres** | **= silver** |
| **portal and central zones** | **= van Gieson** |
| **basal membrane** | **= PAS** |

*Both the risks and the possibility of obtaining uncertain results are far greater with percutaneous biopsy than with laparoscopically directed biopsy.* The latter produces a detailed diagnosis in 97−100% of cases, a result also confirmed by our own observations. (46, 90, 123, 129) • Insufficient training in laparoscopy or the non-availability of this examination technique do not constitute an indication for percutaneous biopsy in liver cirrhosis, at least for initial diagnosis. (s. figs. 7.8, 7.15; 16.5; 28.13; 35.2−35.4) (s. pp 160, 161, 408)

### 6.7 Endoscopy

Gastroscopy (s. figs. 14.10, 14.14; 19.7, 19.9), rectocoloscopy (s. fig. 19.13) and, in certain cases, rectal endosonography are required for evaluating oesophageal varices, portal hypertensive gastroenteropathy (41, 55, 64, 130, 133, 141, 190), gastric antral vascular ectasia (133), peptic ulcer (55, 134, 170, 205), intestinal (21, 158) and anorectal (70) varices, etc.

# 7 Prognostic classification

The clinical picture of liver cirrhosis displays a great variety of forms. This makes it very difficult to judge the prognosis and to establish an appropriate treatment plan, particularly with regard to surgical intervention. It was indeed surgeons who proposed a classification suitable for improved evaluation of the risks involved in surgery (C. G. CHILD, J. G. TURCOTTE, 1964). By means of simple parameters, it is possible to assess the functional reserves of the liver with sufficient reliability. Some parameters show the severity of portal hypertension (e. g. ascites, encephalopathy), while others yield information about the metabolic functions of the liver (e. g. jaundice, albumin value, hyaluronan) (17, 87, 140); these criteria were extended by the addition of Quick's value (R. N. H. PUGH et al., 1973). Clinicians hope to improve the value of this classification by multiplying the criteria of class A by 1, of class B by 2 and of class C by 3, so that an overall score ranging from 5 (= most favourable prognosis) to 15 (= worst prognosis) is achieved. A close correlation between the deterioration of the Child-Pugh grade and the increasing size of the oesophageal varices could be shown. (2, 35, 46, 59, 78, 107, 139, 140, 144, 157, 176, 203) (s. tab. 35.6)

**Criteria:** Criteria such as ascites, encephalopathy and nutritional status are obviously blurred and, to a certain extent, may be interpreted subjectively. For example, the degree of **ascites** (depending on the examination method chosen) as well as the determination of patient response to treatment (depending on the medication used) are criteria that are hard to standardize. By contrast, **encephalopathy** can be easily classified according to its stages. (s. tab. 15.5) • **Liver function tests** may provide information about the severity of the functional disorder at an early stage of cirrhosis. We have always preferred to use the two liver function tests **GEC** and **ICG** as additional methods of evaluation, whereby ascites was determined sonographically and subjected to largely standardized treatment. Reproducible functional values make it much easier to distinguish between class A and B as well as between the scores 5−7 and 8−10. They are no substitute for classification (s. tab. 35.6), but may provide valuable information in individual cases. These two function tests are reliable in quantifying the **liver cell mass** (e. g. by means of GEC) as well as the effective **liver blood supply** (e. g. by means of ICG) as prognostically useful parameters.

| Child-Turcotte stage and Pugh modification | A<br>1 point | B<br>2 points | C<br>3 points |
|---|---|---|---|
| 1. Bilirubin (mg/dl, µmol/l)<br>2. Albumin (g/dl)<br>3. Ascites<br>4. Encephalopathy<br>5. Quick's value (%)*) (or INR) | <2.0 < 35<br>>3.5<br>none<br>none<br>>70 (<1.7) | 2−3.0 35−51<br>2.8−3.5<br>easy to treat<br>stages I, II<br>40−70 (1.8−2.3) | >3.0 > 51<br><2.8<br>difficult to treat<br>stages III, IV<br><40 (>2.3) |
| *Points score (used by Pugh)* | 5−6 | 7−9 | 10−15 |
| Survival rate: 1 and 2 year(s) | 100%; 85% | 80%; 60% | 45%; 35% |

**Tab. 35.6:** Classification of hepatic cirrhosis according to Child-Turcotte (1964) and Pugh (1973) (stage A = good compensation, stage B = significant functional loss, stage C = decompensation) *) Quick's value is additionally used by Pugh (INR = international normalized ratio)

# 8 Differential diagnosis

Differential diagnosis of liver cirrhosis is concerned with two questions: (*1.*) *confirmation of the diagnosis* and (*2.*) *clarification of the aetiology.* (59, 68, 90, 107, 114)

▶ A diagnosis with an accuracy of almost 100% is guaranteed by using **laparoscopy** and **biopsy,** whereby in the latter technique, samples are taken from both liver lobes, if necessary. It is important to obtain a compact biopsy sample − albeit in larger fragments. Crumbly material is of no use! If such tissue crumbs have been obtained by using a Menghini needle, the *Vim-Silverman needle* has to be used for a second biopsy (and should have been used in the first place in targeted biopsy in liver cirrhosis!). A reticulin preparation, which reveals the extent and distribution of connective tissue more clearly, is diagnostically valuable. • Differentiation has to be made between: (*1.*) **focal nodular hyperplasia,** which does not show any lobular areas cut off by connective tissue, (*2.*) **liver fibrosis** (s. figs. 7.16; 21.14; 22.15; 28.6, 28.7), and (*3.*) **scar tissue** within cirrhosis, e. g. in a scarred liver. (s. p. 405) (s. fig. 35.14)

*Fig. 35.14:* Postnecrotic scarred liver after severe viral hepatitis B. Atrophy of the left liver lobe with regenerations, broad cicatricial areas and scarred furrows (s. figs. 21.13; 22.16; 35.1!)

**Clarification of the aetiology** of cirrhosis is usually no problem as long as the potential causes are investigated carefully. In this context, an overview of the numerous causes of cirrhosis as a check list in chart form is very useful. (s. tab. 35.2) The necessary diagnostic parameters can then be applied efficiently. Specific histochemical investigations (e. g. in storage diseases) are carried out accordingly. It is important to categorize cirrhosis based on its aetiology as some forms can then be treated more effectively. • Certain sequelae or complications which impede a differential diagnosis are prevalent in some forms of cirrhosis; they are often the primary reason why the patient consults a physician. (s. tab. 35.2)

# 9 Consequences and complications

During the course of cirrhosis, it is almost impossible to differentiate between *metabolic consequences* and *complications* due to the fact that transitions are fluid both in terms of terminology and clinical features. Metabolic consequences may be complications in themselves, or play a special role in the occurrence of acute sequelae, or even turn a complicative event into a deleterious situation. The initial cause of such developments often remains unknown. Usually, a vicious circle of impaired mechanisms precedes relevant metabolic insufficiency or other complications. • The development of such events can be triggered by the course of disease itself or by the patient's behaviour, or even by therapeutic interventions.

The clinical picture of cirrhosis is overlapped by the symptomatology of the respective metabolic sequelae, or in some cases the complicative event predominates. Occasionally, a wide spectrum of symptoms and findings may be observed. This calls for detailed diagnostic clarification and varied medical treatment by an internal specialist as well as intensive care or sometimes invasive measures.

In cirrhosis, both the overall hepatic *intermediary metabolism* (s. p. 32 and footnote \*); s. tab. 3.1) and the *microcirculation* are severely impaired.

## 9.1  Negative energy balance

Cirrhotic patients often suffer from a negative energy balance even at an early stage, predominantly due to protein deficiency, so-called *protein-energy malnutrition* (PEM). This pathological metabolic situation found in 70−80% of cases can be recognized by reduced oxygen consumption. The administration of β-blockers in patients with cirrhosis causes a favourable metabolic effect, whereby energy expenditure and catecholamine levels are decreased.

The energy required for hepatocellular metabolism is mainly provided by **oxidation** of short-chain fatty acids and amino acids via the citric acid cycle, usually in the mitochondria. Fructose and ethanol are also available for oxidation. In this process, **O₂ partial pressure** falls from 13% in the periportal area to 6% in the pericentral area, which means that the latter region is the most prone to hypoxic cellular damage.

The **energy supply** required by cirrhotic patients is achieved by mobilizing fats: the patient's fatty tissue is reduced and body weight decreases; the continuing energy requirement is met by the breakdown of muscle proteins with the result that amino acids are formed, which in turn are used for gluconeogenesis in the liver. Catabolism increases and leads to muscular atrophy, which is known as *wasting syndrome.* (29, 32, 62, 86, 104, 116, 117, 126)

## 9.2  Carbohydrate metabolism disorders

▶ The central role of the liver in carbohydrate metabolism is underlined by the term **glucostate** (K. Jungermann, 1986). The

ingestion of carbohydrates leads to the production and storage of glycogen; it is produced mainly in the pericentral area. A large amount of the glucose absorbed passes directly through the liver to the peripheral organs, where it is primarily utilized. The remaining $C_3$ bodies (alanine, lactate) are returned to the liver, where glycogen synthesis takes place predominantly in the periportal zone. Gluconeogenesis, i.e. hormone-regulated neoformation of glucose from lactate and glucoplastic amino acids, and glycolysis occur simultaneously and continuously in the same hepatocyte. Usually, about 80% of the glucose released comes from glucogenolysis and some 20% from gluconeogenesis. The energy yield from oxidative breakdown of fructose and glucose, for instance, is 34 and 38 ATP, respectively; the energy from the β-oxidation of fatty acids, such as hexaonate or palmitate, is 44 and 129 ATP, respectively. (s. p. 40) (s. figs. 3.6, 3.7) • In liver cirrhosis, **three forms** of *carbohydrate metabolic disorders* may be expected: (*1.*) hypoglycaemia, (*2.*) hepatogenic diabetes mellitus, and (*3.*) impaired glycogenolysis and gluconeogenesis (T. Yoshida et al., 1998).

### 9.2.1 Hypoglycaemia

Hypoglycaemia is a rare event. It is nearly always due to reduced gluconeogenesis, particularly following loss of parenchyma (usually >80%). Chronic alcohol abuse or acute alcohol intoxication can lead to hypoglycaemia. (s. p. 522)

### 9.2.2 Hepatogenic diabetes mellitus

Glucose intolerance is found in 50−80% and manifest diabetes in 10−15% of cirrhotic patients. Depending on the severity, glucose intolerance or manifest diabetes may also be observed in fatty liver in 40−70% and 10−40% of patients, respectively; in haemochromatotic cirrhosis, the frequency of diabetes is 60−70%. The corresponding liver disease is generally the cause of the disturbed carbohydrate metabolism, which it precedes. • At the same time, increased insulin and glucagon values (2 or 3 times above normal) can be detected (163); administration of insulin only causes a minor decrease in the glucose serum values. Thus there is no insulin deficiency, but *insulin resistance* (W. Creutzfeldt et al., 1970); this may be caused by a TNF-induced disturbance in the tyrosine phosphorylation of the insulin receptor. Insulin resistance in cirrhosis is a multifactorial process. *Hyperinsulinaemia* is due to a reduced breakdown of insulin in the liver and may, among other things, be caused by increased insulin secretion stimulated by hyperglycaemia. In this process, however, hyperinsulinaemia is not sufficient to overcome peripheral insulin resistance; there is a reduction in insulin-dependent glucose absorption and its turnover in the skeletal musculature and fatty tissue. • *Treatment* of hepatogenic diabetes is by dietary measures or, depending on the case, by sulphonylurea (G. Marchesini et al., 1998) or (preferably) benzoic acid derivatives, e.g. repaglinide. Zinc leads to an improvement in glucose metabolism. Biguanides are contraindicated. (105, 138, 166, 177)

### 9.2.3 Glycogenolysis disorders

The glycogen content of the liver and glycogenolysis are reduced to 20−30% of the normal level. The clearly decreased glycogenolysis is compensated by increased gluconeogenesis (3 or 4 times above normal). This requires amino acids from the breakdown of muscle protein. Absorption of glucose in the liver is reduced, particularly in portacaval anastomoses, while the release of glucose is unaffected.

## 9.3 Protein metabolism disorders

▶ The protein and amino-acid metabolism of the liver is characterized by **three essential functions:** (*1.*) production and breakdown of proteins, (*2.*) production and breakdown of amino acids as well as regulation of their concentrations in the blood, and (*3.*) detoxification of ammonium via the synthesis of urea (= excretory form) and glutamine (= non-toxic transport or storage form) with simultaneous regulation of the acid-base balance. The breakdown of branched-chain amino acids occurs only in the musculature by way of deamination. (s. pp 38, 43)

### 9.3.1 Catabolism

In cirrhotic patients, a reduced synthesis rate of most proteins is found at an early stage, with albumin synthesis being the least compromised factor at first. Fat storage, muscle mass and protein turnover are reduced. This ultimately leads to *catabolism* (so-called stress metabolism) and increasing *muscular atrophy* (so-called wasting syndrome). The latter condition can also result from sympathicotonia with elevated catecholamine values; similarly, decreased values of IGF1 inhibit the formation of muscle tissue.

### 9.3.2 Amino-acid imbalance

The regulation of the amino-acid values in the blood plasma is increasingly disturbed, so that significant changes in their distribution pattern ultimately occur. There is a decrease in **branched-chain amino acids,** probably due to greater absorption in the muscles and increased metabolic degradation (possibly as a consequence of hyperinsulinism). This decrease can be prevented by the administration of β-blockers. • The rise in **aromatic amino acids** is thought to be caused by their reduced breakdown in the liver. They are the initial products for the formation of neurotransmitters and mediators; this explains the increase in serum values, e.g. of serotonin and noradrenaline, in liver cirrhosis. The plasma value of methionine is also elevated due to S-adenosylmethionine synthase deficiency, with simultaneously reduced methionine clearance. As a result, there is insufficient formation of glutathione; the phospholipid synthesis required for the biomembranes is reduced, and decreased polyamine synthesis compromises regeneration. (34) • A reduction in urea synthesis (by some 30%) results in hyperammonaemia and metabolic alkalosis. The turnover and concentration of alanine remain unchanged in cirrhosis; glutamine values are increased. In addition to that, hyperinsulinism leads to a decrease in urea synthesis, as does zinc deficiency. (116, 117, 163) (s. p 266)

## 9.4 Lipid metabolism disorders

▶ The role of the liver in lipid metabolism is characterized by **five important functions:** (*1.*) β-oxidation and ketogenesis, (*2.*) lipogenesis, (*3.*) lipoprotein metabolism, (*4.*) cholesterol metabolism, and (*5.*) bile acid metabolism. • Short-chain fatty acids from the food are released in the intestine by lipolysis and transported to the liver. Beta-oxidation takes place in the mitochondria. In this process, acetyl coenzyme A is produced, which is oxidized to form $CO_2$ via the citric acid cycle or used to form **ketone bodies** in carbohydrate deficiency. After being resorbed in the enterocytes, long-chain fatty acids from the food are again incorporated into the triglycerides; they are passed on via the lymph to the periphery in the form of chylomicrons or transported to the liver as chylomicron remnants. They may also be β-oxidized in the mitochondria. • In **lipogenesis,** carbohydrates are converted via acetyl-coenzyme A, mainly on the cytoplasmic side of the endoplasmic reticulum. Lipogenesis is predominantly controlled by the insulin-glucagon quotient. • **Lipoproteins** are required in order to transport water-insoluble lipids from the site of their synthesis to the site where they are used or broken down. (s. p. 42)

In **liver cirrhosis,** there are several changes: reduction in LCAT (with "cholesterol ester fall"), HDL and LDL as well as in VLDL, with a corresponding change in their distribution pattern; occurrence of hypertriglyceridaemia and atypical lipoproteins; reduction in phospholipid synthesis (28), possibly with greatly impaired structure and function of the biomembranes. Hepatic extraction of bile acids is reduced with the result that they reach the peripheral circulation − even in the early stages of cirrhosis! − and give rise to increased serum values. Bile acids have cholestatic and cytotoxic effects. When bile acid metabolism is markedly compromised, enteral absorption of fat-soluble vitamins is impeded, so that *A, D, E* and *K hypovitaminoses* may be observed.

## 9.5 Hypovitaminoses

The manifold relationships between the metabolic functions of the liver and the vitamins fulfil vital tasks in helping the organism to stay healthy. Nutrition low in vitamins or age-related reduction in intestinal vitamin resorption as well as chronic alcoholism may be responsible for the development of hypovitaminosis. Standard values of vitamins (including fat-soluble vitamins) in the serum do not exclude a deficit. Deficiency is often recognized for the first time owing to the manifestation of clinical symptoms, and now requires substitution. **Substitution therapy** may be recommended, even if no vitamin deficiencies have become manifest at this stage. (s. p. 47) (s. tab. 28.2!)

Deficiency of **water-soluble vitamins** is far less precarious than a deficit of fat-soluble vitamins. While the first condition is generally rare, it can nevertheless often be observed in severe alcoholism. In liver cirrhosis, it was possible to detect a reduced amount of vitamins $B_2$, $B_6$, $B_{12}$, C and niacin or pantothenic acid in the liver as well as hypofunction of vitamins $B_1$, $B_2$, $B_6$, C and folic acid. Hypovitaminosis may develop due to the reduced formation of specific transport proteins or the decreased activation or secretion of vitamins despite the sufficient supply of water-soluble vitamins through food intake.

The **fat-soluble vitamins** D and K are activated in the liver, and vitamin A is stored there. Their cellular effect is displayed in the cytosol (vitamin K, and also E) or in the nucleus (vitamins A, D). Transport to the target organs is facilitated by specific carrier proteins (A, D) or by VLDL (E, K). (s. p. 47)

### Hypovitaminosis A

The vitamin A content of the liver and plasma as well as of the retinol-binding protein (RBP) is reduced in cirrhosis. The decreased plasma value of zinc, particularly in existing portacaval anastomoses, correlates with these findings. The **symptoms** observed in hypovitaminosis A and zinc deficiency are largely the same: night blindness, labyrinthine deafness and/or vertigo, disturbed sense of taste and smell (25), skin changes. Such deficiency symptoms in hypovitaminosis A should be treated primarily by substituting zinc. Possible **causes** of vitamin A deficiency are (*1.*) disturbed resorption, (*2.*) reduced formation of RBP in the endoplasmic reticulum, (*3.*) zinc deficiency, and (*4.*) increased breakdown of retinoids due to the enhanced activity of cytochrome P450.

### Hypovitaminosis E

Vitamin E plays an important role in cell metabolism as an antioxidant for the elimination of reactive oxygen intermediates. Subsequent to intestinal resorption, vitamin E is transported in chylomicrons into the liver, from where it reaches other organs together with VLDL. • Vitamin E deficiency is observed in chronic liver diseases caused by alcohol, Wilson's disease, haemochromatosis and abetalipoproteinaemia. In vitamin E deficiency, neurologic disturbances (areflexia, dysbasia, ocular palsy, reduced perception of vibration) occur; haemolysis can likewise be induced or become more pronounced due to epoxide formation of unsaturated fatty acids within the erythrocyte membranes.

### Hypovitaminosis K

Vitamin K is necessary for the formation of coagulation factors II, VII, X and XI as well as of proteins C, S and M; in addition, it is indispensable for the production of osteocalcin, which stimulates osteoblast activity. It is transported from the liver to the bloodstream in the VLDL. • A deficiency is characterized by symptoms similar to those observed in haemorrhagic diathesis. It can be caused by intestinal resorption disturbance or loss of hepatocellular function (reduced carboxyl transfer to specific vitamin K-dependent proteins).

### Hypovitaminosis D

Some 20% of the daily vitamin D requirement are supplied by food intake, while about 80% are produced via endogenous synthesis through transformation of 7-dehydrocholesterol under the influence of ultraviolet light. Within the liver, $D_3$ (= cholecalciferol) is activated by 25-hydroxylation. It is excreted into the bile to become part of an enterohepatic circulation. In liver cirrhosis, and particularly in cholestasis, this circulation is impaired, so that vitamin D metabolites are activated in larger amounts and excreted in the faeces. The resulting clinical picture is usually a mixture of osteoporosis and osteomalacia.

## 9.6 Endocrine disorders

▶ Liver metabolism is controlled by hormones, and the plasma values of numerous hormones are controlled by the liver. The

essential interactions of steroid, effector and thyroid hormones with the liver have already been discussed. *(see chapter 3.9)* (s. tabs. 3.9−3.12)

Patients with liver cirrhosis often suffer from endocrine disturbances, such as latent or even manifest diabetes mellitus; in most cases, the plasma levels of the growth hormone (STH) are increased; **low-T$_3$ syndrome** (with T$_4$ in the normal range) is generally accompanied by euthyroidism. Substitution therapy is not indicated in a euthyroid metabolic condition. • Disturbed sexual function is particularly significant. In the so-called **hepato-testicular syndrome,** gynaecomastia (s. fig. 4.10) is found in about 50% and impotency or infertility in about 80% of cases. Such disturbances (especially testicular atrophy, which in some cases is a direct consequence of alcohol abuse) are more frequent and more severe in cases of haemochromatotic and alcoholic cirrhosis. Feminization takes place. The analogous **hepato-ovarian syndrome** corresponds with an early onset of dysmenorrhoea or amenorrhoea and loss of libido. • The last two syndromes can be subsumed under the term **Silvestrini-Corda syndrome** (L. Corda, 1925). Findings include a reduced breakdown of oestrogens and decreased testosterone synthesis or secretion.

## 9.7 Bacterial and viral infections

**Bacterial infections** can be detected in 45−50% of patients with cirrhosis. Some 7% of fatalities in compensated cirrhosis and 20% of fatalities in decompensated cirrhosis are due to infections. The bacterial translocation to mesenteric lymph nodes is increased in relation to the Child stage. • The following *organic manifestations* predominate: (*1.*) spontaneous bacterial peritonitis in ascites, (*2.*) infections of the urogenital tract, and (*3.*) infections of the bronchopulmonary system. Tuberculosis (lungs, peritoneum, kidneys) as well as bacterial meningitis (112, 132) must also be taken into account in differential diagnosis. Diagnostic difficulties are often due to a lack of fever or leucocytosis. • This weakness of the endogenous immune system is also involved in **viral infections:** in 63% of patients with cirrhosis, for example, cytomegaly infection was observed prior to liver transplantation, while the infection rate was only 2.5% in the control group. (31, 52, 102, 122)

**Causes:** The following causes are seen as being responsible for an acquired immune deficiency syndrome in liver cirrhosis (B. A. Runyon, 1995): (*1.*) hypofunction of the RES (a decrease in the filter or clearance function and phagocytosis capacity as well as reduced formation of immune modulators) (s. p. 65), (*2.*) reduction in hepatic synthesis of opsonins (s. p. 66), (*3.*) compromised function of leucocytes, (*4.*) impaired proliferation and activation of T lymphocytes, and (*5.*) increased mucosa permeability to bacteria. Both bacteria and bacterial lipopolysaccharides enter the organism in large numbers. They are responsible for increased serum levels of the cytokines (e. g. interleukins 1 and 6, TNF, γ-interferon), and there is increased production of these substances together with their reduced breakdown in the cirrhotic liver. Cytokines are formed in the monocytes of blood and in the mononuclear cells of various organs (above all in ascites).

## 9.8 Hepatic osteopathy

### 9.8.1 Definition

**Osteoporosis** is generally defined as an imbalance between the breakdown and neoformation of osseous substance, resulting in bone loss. Ostalgia is evident, and in the later stages, fractures of the vertebral bodies, femoral neck and antebrachial bones are observed.

In **osteomalacia,** the bone matrix is quantitatively and qualitatively normal, while the bones show a reduced content of minerals. There is ostalgia and muscle weakness as well as arcuation of the long tubular bones. X-ray imaging shows band-shaped zones of decalcification, usually in symmetrical arrangement, particularly at the ribs, femoral neck and pelvis (so-called *Looser-Milkman's syndrome*).

The term **hepatic osteopathy** (J. E. Compston, 1986) describes skeletal changes in chronic liver diseases, including osteoporosis, which is by far the most prevalent form, and osteomalacia, which is detected very rarely, as well as their respective mixed forms.

### 9.8.2 Frequency

In cirrhosis, reduced bone density of the vertebral bodies could be observed in 16% and of the antebrachial bones in 23% of patients (compared to 7% and 5% respectively, in the control group). Fractures of the vertebral bodies were detected in 16% and of the antebrachial bones in 21% of cases (compared to 8% and 8% respectively, in the control group). Hepatic osteopathy usually occurs independently of the cause and type of the chronic liver disease. However, alcoholism, haemochromatosis and Wilson's disease result in osteoblastic hypofunction, so that osteopathy is more likely to occur in these patients, even prior to the development of cirrhosis. The occurrence of osteopathy is closely correlated with the severity of the liver disease and with hypogonadism. In liver cirrhosis, the prevalence of osteopenia is about 30%. (49, 73)

### 9.8.3 Pathogenesis

The pathogenesis of hepatic osteopathy is primarily characterized by disturbed bone formation due to (*1.*) reduced osteoblast surface (with the number of osteoblasts being in the normal range) and (*2.*) reduction in osteocalcin. The latter substance is a bone-matrix protein formed by the osteoblasts. Therefore, the serum value is considered to be a marker of osteogenesis. There is no increase in osteoclasis. The causes and risk factors of disturbed bone metabolism are manifold and not totally understood as yet. (73)

To date, we do not know what kind of changes in **vitamin D metabolism** or in the binding proteins may be (partially) responsible for these disturbances. Moreover, there are no reliable findings as to

the role of **parathyroid hormone** and **calcitonin** in the development of hepatic osteopathy; this is also true for **gastrocalcin,** which (like calcitonin) makes the serum level of calcium decrease. Reduced enteral resorption of calcium is only observed in severe cholestasis, which causes no osteopathy however. While a deficiency of vitamin D can have pathogenetic effects, it does not in itself lead to osteopathy. An increased value of $D_3$ may be a predictor of a developing osteopathy. In addition, there is a correlation between the serum values of **gastrin** and osteopathy − but nothing else is known about this. • The intake of **antiepileptics** over a longer period of time triggers an induction of the cytochrome P 450 system, so that vitamin D is increasingly broken down, a loss which can, however, be substituted. • **Glucocorticoids** cause a reduction in enteral calcium resorption and the serum level of oestrogen; they are also responsible for calciuria and impeded osteoblast activity. These factors lead to a decrease in bone density and create what is called the *cortisone effect.* • By contrast, **cyclosporine** increases osteoblast activity.

### 9.8.4 Clinical symptoms

**Hepatic osteopathy** remains latent for a long time. *Backache* is considered to be the earliest hint of this type of complicative development in cirrhosis. The further course is characterized by trabecular osteopenia with loss of the cancellous bone structure. This causes *compression fractures* of the vertebral bodies with increasing kyphosis and a corresponding decrease in body height. Further sites susceptible to *fractures* are the femoral neck and the antebrachial bones. • Osteopathy does not yield any *biochemical findings*: the serum values of calcium, phosphate, parathyroid hormone, 25-hydroxy-cholecalciferol, osteocalcin and alkaline phosphatase are within the normal range. • Osteoporosis cannot be detected by *X-ray imaging* until the late stages. CT scanning allows density measurement of the skeleton. New radiological techniques (e. g. dual energy X-ray absorption) may provide an earlier diagnosis in the future.

**Osteomalacia,** a very rare manifest form of hepatic osteopathy, causes pain mainly in the muscles, but less so in the bones. *Biochemically,* AP is markedly increased; there is a deficiency of calcium, phosphate and 25-hydroxycholecalciferol. *Radiologic diagnosis* shows signs of Looser-Milkman's syndrome: coarsening of cancellous bone structure, narrowing of the compacta in the tubular bones, reduced density of the skeletal system, and band-shaped zones of decalcification.

### 9.8.5 Treatment

The most important **prophylactic measures** for preventing the development of hepatic osteopathy are (*1.*) avoidance of harmful *noxae* (alcohol, nicotine), (*2.*) *avoidance of risk factors* (e. g. overweight; calcium, phosphate or vitamin D deficiency; use of glucocorticoids, cholestyramine and antacids containing aluminium), (*3.*) administration of vitamin K2 (menatetrenone) in women with risk factors, and (*4.*) routine **physical exercise.** (s. p. 650) We have instructed our chronic liver patients to carry out the following exercises on a regular basis:

Two or three times per day, 10−15 slow knee-bending (= thigh muscles), 10−15 standing on tiptoe (= calf muscles), 10−15 upper arm flexing (= biceps), and 10−15 bending from the waist (= back muscles). This guarantees that about 60% of the musculature is trained under simple conditions at home.

The **drug therapy** used to date aims to achieve broad substitution. Therapy should be carried out for up to 24 months. • (*1.*) The daily *calcium requirement* is about 1.2−1.6 g. Nutrition usually contains about 0.6 g, so that 3 x 200 mg to 3 x 300 mg per day should be substituted (e. g. in the form of calcium carbonate). • (*2.*) In order to avoid *hypogonadism*, we recommend a daily administration of conjugated oestrogens (e. g. 2 mg, twice a week, applied dermally to avoid passage through the liver), possibly combined with gestagens. The daily requirement of oestrogen is about 0.6 mg. In men, the administration of testosterone may be indicated. • (*3.*) *Vitamin D* is only indicated when hypovitaminosis has been detected (e. g. as cholecalciferol, 1α- or 25-hydroxylated derivatives, or 1,25 dihydroxylated derivatives). These substances should only be applied as substitution therapy when there is a corresponding deficiency. • (*4.*) In individual cases, *calcitonin* (as nasal spray) and *biphosphonates* are further options. • In the osteomalacic form of osteopathy, treatment with calcium and vitamin D or its derivatives may be required. However, the serum value of calcium must not be allowed to exceed 11.0−11.5 mg/dl.

## 9.9  Hepatic encephalopathy

Disturbances of personality, consciousness and intellectual functions are often observed in acute or chronic liver diseases. In 50−80% of cirrhosis patients, such neuropsychiatric signs of HE are found with varying intensity and duration (even with variable, symptom-free intervals) as well as in different combinations. (s. tab. 10.1) While it is relatively easy to **diagnose** *manifest HE (stages I−IV)* (s. tab. 15.5), other potential causes of this clinical picture have to be excluded by differential diagnosis in each individual case (e. g. intracerebral bleeding, infections, metabolic imbalance, cerebral diseases). There is a close correlation between liver function and severity of HE − and thus also with life quality. (11) Diagnosis of *latent HE (stages 0, 0−I)* can only be made with the help of psychometric test procedures (8) or special EEG techniques. Nuclear resonance imaging and SPECT (172) have been used in scientific studies. *(see chapter 10!)*

Numerous **biochemical factors** may be causal agents in HE. It may also be attributable to an increase in serum ammonia resulting from Helicobacter pylori. (s. tab. 15.2) Avoidance of causative factors is the most important measure for the prevention of HE and their elimination a prerequisite for successful treatment. (s. p. 281)

The **pathogenesis** is multifactorial. In cirrhotic patients with latent HE, regional differences in cerebral ammonia uptake are present; this corresponds to histopathological changes in HE. Although increased ammonia values have a primary pathogenetic significance, other neurotoxins, neurotransmitter disturbances, amino-acid imbalances, high levels of benzodiazepines, zinc deficiency, increased manganese concentration, etc. also figure prominently. With the help of spin-lattice ($T_1$) relaxation time, significant correlation has been demonstrated between HE severity and the putative deposition of manganese in the globus pallidus, caudate nucleus and posterior limb of the internal capsule. (165) • Values of enterocyte phosphate-activated glutaminase are increased in cirrhosis and correlate closely with latent HE (stages 0, 0−I). H. pylori infection is not correlated with HE. (164) • *None of these substances or disturbances on its own has a comagenic effect. It is probable that the astrocytes are the pathogenetic end point upon which the cascade of causes has its impact.* (s. pp 265−269!)

The **clinical picture** comprises both *acute* and *chronic HE*. In addition, routine usage of a simple test programme used for practical as well as clinical purposes (s. p. 202) (s. tab. 10.7) has repeatedly shown *"acute-on-chronic" stages* during long-term monitoring. Starting with the normal finding of "no HE", the stages may be grouped, depending on their individual variability, as 0, 0−I (= latent HE) and I, I−II, II (= manifest HE). Furthermore, there is a link between extrapyramidal signs and the latent HE. Due to the fact that HE can be detected quite reliably at an early stage during its latent period, therapeutic measures are also recommended in addition to the elimination of the causal factors. (s. pp 270−277)

**Treatment** is based on (*1.*) elimination of the causal factor(s) (s. tabs. 15.1, 15.2) and (*2.*) reduction or normalization of the ammonia level (s. p. 266). The latter consists of: *intestinal detoxification* using lactulose (47, 98, 119) paramomycin, neomycin or metronidazole; *protein restriction* (0−30 g for the first to third day, gradually increased up to 1 g/kg BW/day) (despite some controversial results); sufficient *calorie* intake (glucose), *application of urea cycle intermediates* (145), administration of *zinc* (104, 196) and, if necessary, of *branched-chain amino acids* and *flumazenil*. Elimination of gastric infection due to *Helicobacter pylori* has proved to be an effective treatment measure for normalizing hyperammonaemia (caused by this condition). A decrease in ammonia can also be achieved by *acetohydroxamic acid*, which is a powerful inhibitor of bacterial ureases of Helicobacter pylori. (164) Animal experiments have demonstrated that N-carbamoyl-L-glutamate plus L-arginine protects rats with cirrhosis from acute ammonia intoxication. Experience has shown that the very frequent occurrence of latent HE (stages 0, 0−I) can largely be avoided by careful prophylactic measures and that early treatment almost always helps to prevent the latent phase from developing into a manifest one (stages I−IV), i.e. there is no necessity for inpatient treatment! *(see chapter 15.9!)*

## 9.10 Ascites

Impairment of **cerebral functions** and disturbances of the **water and electrolyte balance** are the two most important and most common manifestations of decompensated liver cirrhosis. • They may be reliably detected at an early stage by means of daily *body weight control* and simple *psychometric tests*. A **documentation sheet** filled in by the patient has proved to be worthwhile: latent oedemas or the onset of ascites as well as latent encephalopathy can be detected in this way and thus treated at an early stage. **Long-term standing** leads to a reduction of natriuresis with subsequent water retention and a deterioration of renal blood flow (like a vicious circle). This is caused by activation of the RAAS and the sympathetic nervous system. Such a dangerous situation (which can arise for example after two hours of standing at a sports event with excessive emotional participation) is often underrated, as we ourselves observed in several patients! (s. p. 292) (s. fig. 15.3) *(see chapter 16!)*

About 50% of patients with cirrhosis develop ascites within ten years. In the case of a "simple" ascites (s. tab. 16.8), a therapy with diuretics is generally successful − in contrast to a "problematic" or refractory ascites.

The development of ascites causes numerous **complications** which worsen the prognosis of cirrhosis considerably. (s. tab. 16.9) • Every day, 40−80% of the ascitic fluid and 4% of the ascitic albumin are exchanged between the plasma and the ascites. In the absence of oedema, 400−500 ml (max. 750 ml) ascitic fluid can be removed from the abdominal cavity by means of diet and medication. (s. p. 306) • **Side effects** caused by diuretic agents (hypovolaemia, hyponatraemia, hypokalaemia, disturbances of the acid-base balance) must be avoided. (s. p. 308) • The occurrence of **spontaneous bacterial peritonitis** is life-threatening. The prognosis could be markedly improved by early diagnosis, elimination of risk factors and efficient antibiotic treatment (e.g. amoxicillin-clavulanic acid) accompanied by simultaneous intestinal decontamination. (s. p. 304)

A step-by-step plan has proved effective for the **treatment** of ascites, with *therapeutic steps 1−4* being employed successively if the previous stage was unsuccessful. However, progressing from step to step not only increases the effectiveness of the treatment, but also the frequency and severity of side effects. Nevertheless, a single paracentesis, during which an average of 5 litres of ascitic fluid were evacuated, resulted in normal cardiac, renal and hormonal parameters within 2 days. Paracentesis is considered to be a safe and efficient method. (135) *(see chapter 16.8)*

1. **Basic therapy** (s. tab. 16.11) (s. p. 305)
2. **Diuretic therapy** (s. tab. 16.12) (s. p. 306)
3. **Osmotic diuresis** (s. p. 308)
4. **Paracentesis** (s. p. 309)

• **Furosemide** can cause hypovolaemia due to its rapid effect with subsequent unfavourable activation of the RAAS, especially after i.v. injection. Nevertheless, i.v. furosemide may be indicated in dilutional hyponatriaemia (s. p. 308). Generally, however, spirono-

lactone on its own has proved more effective than in combination with (RAAS-activating?) furosemide. (155) We actually prefer a *combination* of spironolactone with xipamide, torasemide or clonidine. (s. p. 307)

• **Paracentesis** should be combined with an i.v. solution of albumin (our own experience has shown that an i.v. solution of 20−40 ml plasma expander directly before i.v. albumin administration increases the oncotic pressure, so that albumin remains efficacious for a longer time in the blood circulation). • Apparently, 3 mg terlipressin is as effective as i.v. albumin in preventing a decrease in effective arterial blood volume. (s. p. 309)

• **Hydroxyethyl starch (HES)** in repeated administration may be the cause of increased portal hypertension; liver insufficiency or sepsis can occur due to lysosomal storage of HES in Kupffer cells and hepatocytes.

• **Losartan** is a highly selective angiotensin-2-receptor (type 1) antagonist; it decreases portal hypertension as well as improving glomerular filtration and natriuresis with good aquaretic response. (200) (s. p. 360)

When diuretics are administered at the same time, it is not absolutely necessary to adhere to strict **salt restriction**. We followed the recommended 6−8 g/day. Indeed, such a moderate restriction is usually observed more reliably by the patient. • Reducing **water intake** to 1.5−2.0 l/day is also sufficient. Only a hyponatraemic condition of <130 mmol/l requires a reduction in fluid intake to <1,000 ml/day. • Determination of **fractional sodium elimination** ($FE_{Na}$) may point to potential success even before treatment has begun: with a value of >0.5%, treatment steps 1 and 2 (see above) will achieve a probable success rate of about 95%. This favourable initial situation is supported by a still sufficient spontaneous **sodium excretion** of >40 mmol/day. Therapy resistance must be anticipated when fractional sodium elimination is <0.1% and sodium excretion is <10 mmol/day. • If treatment steps 1−4 are unsuccessful or renal function is clearly impaired initially and $FE_{Na}$ is <0.1%, the insertion of a **peritovenous shunt** (PVS) should be considered. This procedure is designed to make use of the principle of ascites reinfusion for as long as possible. (s. tabs. 16.14−16.18) (s. p. 311) • **TIPS** may also prove to be an alternative to PVS, especially when using a polytetrafluoroethylene-covered stent to prevent occlusion. (111) (s. fig. 16.15) (s. pp 259, 314, 362)

Chronic hepatitis C is occasionally associated with cryoglobulinaemia and glomerulonephritis. • In all forms of cirrhosis, the intrarenal circulation is impaired and there is a redistribution of blood flow away from the cortex. A thickening of the mesangial stalk and capillary wall *(= cirrhotic glomerular sclerosis)* is often evident. These changes predispose to the hepatorenal syndrome. • The occurrence of (particularly iatrogenic) **hepatorenal syndrome** with the following findings must be prevented. (35, 95, 111, 118) *(see chapter 17!)*:

| | | |
|---|---|---|
| **Creatinine clearance** | < | **40 ml/min** |
| **Proteinuria** | < | **500 mg/day** |
| **Natriuresis** | < | **10 mmol/l** |
| **Hyponatraemia** | < | **130 mmol/l** |
| **Oliguria** | < | **500 ml/day** |

## 9.11 Pleuropulmonary complications

▶ In the course of primary **liver diseases** as well as during any requisite invasive measures, numerous pleuropulmonary disturbances or diseases may occur due to functional and/or mechanical conditions. They are closely associated with each other. Pleuropulmonary complications can have considerable adverse effects on the basic liver disease and thus worsen its prognosis. (3, 5, 71, 72, 159, 160) (s. tab. 35.7)

| Pleuropulmonary complications | Liver disease |
|---|---|
| 1. **Hepatopulmonary syndrome (HPS)** | Liver cirrhosis<br>Chronic hepatitis<br>Acute liver failure |
| 2. **Portopulmonary hypertension (PPH)** | Liver cirrhosis<br>Chronic hepatitis<br>Schistosomiasis<br>Alagille's syndrome<br>Hypoplastic portal vein<br>Multifoc. nod. hyperplasia |
| 3. **Pleural effusions** | Liver cirrhosis<br>Chronic hepatitis<br>Acute viral hepatitis<br>After liver transplantation<br>Echinococcosis<br>Liver abscess<br>After sclerotherapy of oesophageal varices |
| 4. **Pulmonary emphysema** | $\alpha_1$-antitrypsin deficiency |
| 5. **Chronic obstructive respiratory disease** | $\alpha_1$-antitrypsin deficiency<br>Mucoviscidosis<br>Sarcoidosis |
| 6. **Interstitial pneumonia** | Autoimmune hepatitis<br>Overlap syndrome<br>PBC<br>Sarcoidosis |

***Tab. 35.7:*** Common associations of pleuropulmonary complications in the course of certain liver diseases

Primary **pulmonary diseases** (e. g. primary pulmonary hypertension, pulmonary fibrosis, chronic obstructive respiratory diseases) cause chronic **hepatic congestion** due to chronic pulmonary heart disease, possibly leading to insufficiency. • **Hypoxaemia** as a result of acute or chronic respiratory insufficiency can impair metabolic liver functions considerably. In 40−70% of patients with cirrhosis, hypoxaemia can be found; in about 50% of cases with advanced cirrhosis, a reduced diffusion capacity for CO is detectable. • Furthermore, pulmonary tissue contains a high level of glutamine synthetase, so that **ammonia detoxification** is possible (ultimately by perivenous hepatocytes) before the blood reaches the systemic circulation. In existing pulmonary diseases, localized ammonia detoxification is impaired.

### 9.11.1 Hepatopulmonary syndrome

The hepatopulmonary syndrome (HPS) may occur in patients with chronic liver disease or in the course of acute hepatic failure. It is characterized by the following **criteria**: (*1.*) exclusion of an underlying pulmonary or cardiac disease, (*2.*) increase in the alveolocapillary oxy-

gen difference with or without arterial hypoxaemia (<70 mm Hg $O_2$ partial pressure) and with a marked decrease in the $O_2$ value when the body position is changed from lying to standing, and (*3.*) evidence of intrapulmonary vascular dilatations and **arteriovenous shunts**, resulting in **ventilation-perfusion disturbance**. • The frequency of this pulmonary gas exchange disturbance is $30-50\%$ in cirrhosis patients. The most important clinical finding concerning HPS is **hypoxaemia**. Hypocapnia is also a very frequent symptom and is generally associated with pulmonary vasodilation. (2) • Hypertrophic **osteoarthropathy** (hour-glass nails, drumstick fingers) (s. fig. 4.18) likewise belongs to this complex in terms of aetiopathogenesis. *(see chapter 18!)*

### 9.11.2 Portopulmonary hypertension

#### Definition

Portopulmonary hypertension (PPH) is characterized by (*1.*) elevated pulmonary artery pressure (>25 mm Hg), (*2.*) increased pulmonary vascular resistance (>120 dyne/sec/cm$^5$), and (*3.*) normal pulmonary capillary wedge pressure (<15 mm Hg). • *The presence of portal hypertension is considered to be a prerequisite for the development of PPH.*

#### Frequency and causes

PPH was detected in 2% of patients with liver cirrhosis, compared to 0.1% in the control group, i.e. *the risk of PPH is 20 times higher in cirrhosis patients.* The prevalence of PPH in liver cirrhosis with portal hypertension was 0.73% in autopsy examinations, compared to 0.13% in all other autopsies. • PPH has not only been described in portal hypertension due to liver disease (cirrhosis, chronic hepatitis, fibrosis, etc.), but also (with or without portal hypertension) in *focal nodular hyperplasia*, *schistosomiasis, Alagille's syndrome* and *portal vein thrombosis*. Important extrahepatic causes of PPH include portal hypertension due to *hypoplasia of the portal vein* and *lupus erythematosus.* (66, 118, 148) *(see chapter 18.7!)* (s. tab. 35.7) (s. fig. 35.15)

### Morphology and pathogenesis

**Morphology:** In PPH, there is evidence of medial hypertrophy in the area of the pulmonary arteries and arterioles, intima fibrosis (so-called *plexogenic arteriopathy*) and fresh or recanalized thrombi. These changes are unevenly spread throughout the lung; they do not correlate with the severity of PPH. Plexiform damage of the small ($50-300$ μm) pulmonary arterial vessels is prevalent in patients who are also suffering from portal hypertension (J. R. RUTTNER et al., 1980).

**Pathogenesis:** The mechanism responsible is based on the effect of vasoactive or toxic substances arriving directly at the pulmonary vascular system from the portal vein system by circumventing the liver (e. g. NO). Thus pulmonary hypertension is also detected surprisingly often in patients with shunt surgery. Endothelin-1 is considered to be a strong vasoconstrictor; this substance has been detected in high concentrations in the pulmonary vascular endothelia of PPH patients. In addition, microembolisms entering the pulmonary arterioles may also play a pathogenetic role; such emboli can reach the lungs via spontaneous or surgical portosystemic shunts (R. M. SENIOR et al., 1968). A similar mechanism may be responsible for this condition in drug addicts suffering from PPH who have developed pulmonary microembolisms due to water-insoluble drug components injected intravenously. (s. fig. 35.15) *(see chapter 18.7!)*

**Complaints:** In $80-85\%$ of patients with PPH, there is stress dyspnoea and occasional syncopes, thoracic pain

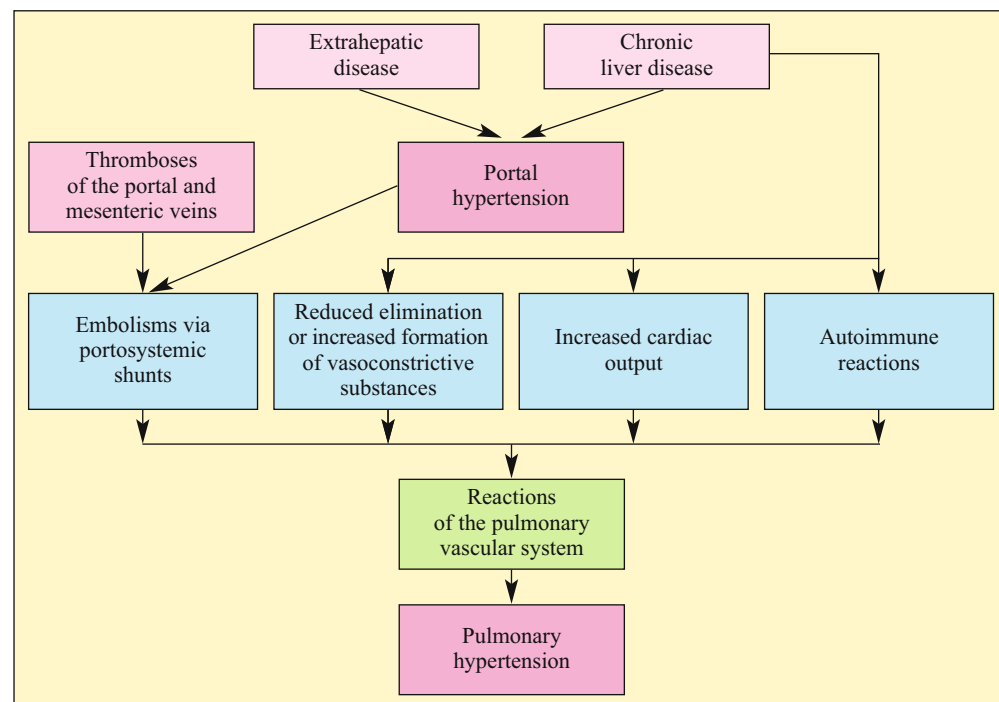

*Fig. 35.15:* Potential pathogenetic mechanisms associated with the coexistence of portal and pulmonary hypertension (based on B.J. ROBALINO et al., 1991 and M. WETTSTEIN et al., 1995)

on palpation with a feeling of tightness, marked fatiguability, lack of concentration and vertigo.

**Findings:** In $80-85\%$ of cases, a loud $P_2$ heart sound and systolic murmur can be heard on auscultation. Occasionally, there is haemoptysis or oedema; ascites is rare. • The *ECG* shows the signs of right ventricular overload (e. g. right bundle-branch block, P pulmonale). *Thoracic imaging* often displays prominent pulmonary arteries and cardiac hypertrophy. *Echocardiography* is of great diagnostic value. The diagnosis is confirmed by *right cardiac catheterization*.

**Prognosis** for PPH is poor: the mean survival time is about 15 months with a 6-month mortality of 50%. The most common causes of death are right heart failure, dysrhythmia and infections.

**Treatment** still remains difficult, because few clinical studies are available. High doses of **calcium antagonists** are recommended, but their frequent side effects have to be taken into account, particularly with a cardiac output of <2 l/min. (146) In severe cases, pulmonary pressure reduction by permanent infusion of **epoprostenol** over several weeks or long-term administration of **oxygen** may be helpful. Good experience has been made with the endothelin-receptor antagonist **bosentan** (2 x 125 mg/day). (36) (s. p. 338!)

On retrospective assessment of a large number of cirrhotic patients, some of whom we treated for more than 10 years, it is our impression that long-term administration of **spironolactone + molsidomine + β-blocker** is of therapeutic value for portal hypertension and, at least as far as this problem is concerned, also for primary and progressive pulmonary hypertension. Such combination therapy is also pharmacologically plausible. (s. p 743)

### 9.11.3 Hydrothorax

Hepatic hydrothorax (= absence of a non-hepatic cause) has been detected in $4-10\%$ of patients suffering from **liver cirrhosis**. Two thirds of the pleural effusions were isolated and localized on the right side, whereas the remaining one third were found on the left side or on both sides with equal frequency. Ascites is present in almost all cases, but is not obligate. (37, 53, 63, 67, 99, 149) Hydrothorax is usually caused by small diaphragmatic defects through which ascitic fluid can penetrate into the pleural cavity (37); diaphragmatic lymphatic vessels may also play a causal role. An ascites-related pleural effusion can be confirmed by intraperitoneal injection of methylene blue or $^{99m}$Tc-sulphur colloid due to the subsequent, rapid migration of the substrate into the hydrothorax. *Bacterial infection*, similar to spontaneous bacterial peritonitis, is possible. • Hydrothorax is sometimes observed in **acute viral hepatitis**. The frequency is 0.16%. We have encountered a total of 6 cases. (s. pp 298, 299) (s. tab. 35.7) (s. fig. 16.8)

*Therapy* includes paracentesis + thoracocentesis + i.v. albumin solution, pleural drainage or pleurodesis with talc. Recently, pleurodesis using argon beam coagulation + minocycline hydrochloride has been recommended. In the case of refractory hepatic hydrothorax, TIPS or liver transplantation may be indicated. (53)

▶ An evaluation of **25,682 clinical data sheets** from $1952-1963$ (Dept. of Internal Medicine, University Hospital, Giessen) revealed the existence of a total of pleural effusions (combination of "banal" effusion and hydrothorax) in 9.8% of cases (confirmed by X-ray imaging or autopsies). In **4.3%**, pleural effusion was found to be hepatogenous. • *Localization was bilateral in 69%, left-sided in 18.7%, and right-sided in 12.3% − a controversial result when compared with some statements made in the literature.* (s. p. 298 and footnote*))

## 9.12 Gastrointestinal bleeding

Acute upper or lower gastrointestinal bleeding is a common complication in liver cirrhosis and is often life-threatening. Several **bleeding sources** have to be taken into account, which may occur in combination in the individual case. *(see chapters 19.2−19.4!)*

1. **Gastric antral vascular ectasia (GAVE)**
2. **Portal hypertensive gastroenteropathy**
3. **Oesophageal and/or fundus varices**
4. **Ectopic varices**
5. **Anorectal varices**

**Peptic ulcer** is not cirrhosis-related. Duodenal ulcers are more common than gastric ulcers. Frequency of peptic ulceration in cirrhotic patients is about $8-10\%$, although $60-70\%$ of these cases are asymptomatic. Gastric ulcers heal more slowly and recur more frequently than in non-cirrhotic patients. (55) This condition may be caused by chronic alcohol abuse, portal hypertension or Helicobacter pylori infection ($40-50\%$, with elevated gastrin in the serum). (134, 205) • **Mallory-Weiss syndrome** is often associated with cirrhosis, but there is in fact no causal relationship between the two. • **Gastroparesis** with delayed gastric emptying is frequently observed. (190)

### 9.12.1 Portal hypertensive gastroenteropathy

Altered vascular microarchitecture with dilatation and/or narrowing of the capillaries and veins develops as a result of portal hypertension. Gastroscopy reveals a whitish-reticular, mosaic-like pattern of the gastric mucosa, containing limited reddish and oedematous areas. Frequently, there are pink spots and circumscribed red marks. In severe cases, dark pink patches are present. There are lesions of the endothelial cells with increased permeability of the capillaries, so that petechial or striated bleeding is observed in gastric (175) and/or intestinal mucosa (as well as in portal colopathy). (21, 158) These frequent changes due to portal hypertensive gastropathy were previously (but incorrectly) called "erosive gastritis". They may cause gastric or intestinal paraesthesia or pain, but can also (less frequently) lead to occult bleeding or haematemesis. It is possible to achieve good results with the help of β-blockers. • Regarding the differential diagnosis, it is important to consider *angiodysplasia* (s. fig. 19.5) and *gastric antral vascular ectasia*. The latter resembles a watermelon with

stripe-like haemorrhages. In the case of bleeding, endoscopic coagulation may be required. (s. tab. 19.4) (s. fig. 14.14) (s. pp 351, 352) (41, 64, 130, 133, 141)

### 9.12.2 Oesophagofundal varices

Acute bleeding must be anticipated in about 30% of patients with oesophagogastric varicosis and a pressure rise to >12 mm Hg. Physical overexertion can increase the portal vein pressure to dangerous levels. (18) Haemorrhaging mainly occurs in the lower third of the oesophagus and in the oesophagogastric transition zone, mostly due to venous anastomoses in the mucosa. Patients with small varices have a correspondingly lower bleeding risk. (s. figs. 14.8−14.10!) *(see chapter 19.3)* • There is a close association between **liver function** and relapse bleeding rate or mortality. Thus, all measures designed to improve **liver function** are beneficial, even though they are polypragmatic and perhaps of limited success only. • **Primary prophylaxis** is indicated in patients with an increased bleeding risk (s. tab. 19.6); the portal vein pressure should be reduced by means of long-term pharmacological treatment. (69) In this context, the following drugs can be recommended: propranolol (occasionally in combination with nitrate (58) or octreotide), nadolol (110), carvedilol (183), irbesartan (42), molsidomine and spironolactone. (s. pp 259, 359) Primary prophylaxis using ligation (161) or sclerotherapy (125) ought to be started when small oesophageal varices are present. Primary shunt surgery is not indicated. • Mortality due to **initial bleeding** is 20−50%. The goal must be rapid and complete haemostasis. In principle, sclerotherapy and ligature are equally effective; the results depend upon the site of bleeding and the nature of the varices as well as upon the clinician's experience. (s. pp 355, 358) A balloon tamponade may be a valuable tool in guaranteeing the patient's transportability, bridging massive bleeding or coping with an emergency. (s. p. 358) A reduction in portal pressure by *previous (!) administration of medicaments* (18, 58, 74, 115, 151, 161) (e.g. terlipressin bolus 1−2 mg and then 1−2 mg every 4−6 hr; octreotide bolus 50 μg, 25−50 μg/hr; propranolol 2 x 10−160 mg/day; molsidomine 2 x 8 mg/day) is most helpful. (s. pp 360, 863) • About 70% of patients whose initial bleeding was successfully dealt with suffer another haemorrhage within the first year. **Relapse prophylaxis** is effected pharmaceutically in order to reduce the portal vein pressure (18, 113, 115), by careful monitoring using (long-term) endoscopy and by eradicating any new varices. The insertion of **TIPS** reduces the rate of recurrent bleedings considerably and may help to bridge the time gap until **liver transplantation** can be carried out. (26, 156, 188) (s. pp 362, 665)

### 9.12.3 Ectopic varices

Ectopic **intestinal varices** usually occur in combination with oesophagogastric varices. If gastroscopy shows no bleeding source, (rare) bleeding from ectopic intestinal varices should be suspected.

Diagnosis is established by *scintigraphy* (accuracy is 90−95%). For more exact localization of bleeding detected by scintigraphy, *angiography* is subsequently used. In this context, CT angiography also provides much better diagnostic results. • This is also true of the (very rare) ectopic **peritoneal varices**, which can cause intra-abdominal haemorrhage. (s. p. 257)

### 9.12.4 Anorectal varices

Anorectal varices originate from the **superior rectal vein**, which is connected to the portal vein system. This portacaval anastomosis drains the blood into the *iliac vein*. Occasionally, massive bleeding may occur from rectal varices. Endoscopy is required for diagnosis and sclerotherapy. (70) (s. p. 256)

## 9.13 Febrile phases of disease

Patients suffering from cirrhosis very often report fever episodes, similar to those witnessed in inpatients. Such episodes not only cause additional physical weakness and increase suffering, they also present a considerable **danger** for the cirrhotic patient. Among other things, fever causes (*1.*) catabolic metabolism, (*2.*) increased sympatheticotonia, (*3.*) disturbed water and salt balance (some 500 ml liquid and about 25 mmol salts are lost in 24 hours per degree of temperature rise!), and (*4.*) hypoxia of the hepatocytes. • This may cause or contribute to hepatic encephalopathy, portal ascites or hyperdynamic circulatory disturbance, with significant negative effects on renal function and hypoxia-induced metabolic liver insufficiency. The frequency of "cirrhosis-related fever" is 20%.

Patients with cirrhosis often suffer from **bacterial infections**. (s. p. 731) In most cases, the respiratory tract and urogenital system are affected. Interleukin 6 may often increase in decompensated cirrhosis. Directed bacteriological diagnosis is required immediately; depending on the case, administration of antibiotics is recommended even before any evidence of bacteria has been obtained. (31)

**Viral infection** may likewise cause fever in cirrhosis. Even a mild viral infection can trigger viral hepatitis concomitant with underlying cirrhosis as well as producing a virotoxic effect with the risk of decompensation − in addition, the "fever" is in itself responsible for typical biochemical reactions in this condition.

**Endotoxins** are a further cause of fever episodes, particularly from gram-negative bacteria. The **spill-over effect** (*prehepatically* via portacaval anastomoses, the lymphatic system or mastocytes, as well as *intrahepatically* in RES insufficiency) leads to **endotoxinaemia**, which is responsible for numerous, sometimes dangerous, biochemical reactions, such as hepatic encephalopathy and the activation of the coagulation cascade. • Long-term administration of *lactulose* can suppress a gram-negative intestinal flora and thus prevent the onset of endotoxaemia.

**Protein degradation products** may also trigger a febrile episode; aetiological differentiation of the fever caused by such metabolic products is usually impossible. There are no effective therapeutic measures. Differential diagnosis of "fever of unexplained origin" (R.G. Petersdorf et al., 1961) can be very difficult in cirrhosis, a situation which presents an additional risk to the patient. • *In unexplained fever, laparoscopy is indicated*. (s. tab. 7.10) (s. p. 156)

The degradation products of androgenous steroids are a further suspected cause of such febrile episodes, since severe fever could be induced by i.m. injection of **aetiocholanolone** (3α-hydroxy-5β-H-androstane-17-on) (A. KAPPAS et al., 1957). In 1958 P.K. BONDY et al. for the first time detected an increase in aetiocholanolone in the plasma of patients with unexplained fever episodes, and thus they coined the term *aetiocholanolone fever*. Other steroids of the 5β-H configuration also revealed this pyrogenic feature. Aetiocholanolone may be the product of disturbed hepatocellular metabolism. Further observations and examinations have meanwhile been reported. (51, 136)

▶ *We detected markedly increased aetiocholanolone plasma values in numerous patients with liver cirrhosis and sudden febrile episodes* − however, we could not show a direct correlation. • In 1966 F. SCHILLING reported that **aetiocholanolone fever** could be cured by *administration of indometacin. We were able to confirm this result (which had also been reported by* M. VLAHO et al. in 1976) *in those patients who had received indometacin as a suppository.* Indeed, we made use of this effect as differential therapy, but did not seek the underlying causes of a febrile episode unless the rectal administration of indometacin had been unsuccessful after 1−3 hours. Glucocorticoids, even when administered in a higher dosage, mostly proved ineffective, whereas a subsequent dose of indometacin caused the fever to subside within a very short time. While these may be **clinical observations**, they are remarkable enough to be reported. We suggest administering indometacin prior to any treatment with antibiotics. To our knowledge, renal insufficiency, as is known in cirrhosis (198), has not been observed following this single dose of indometacin.

## 9.14 Cholelithiasis

Cholelithiasis is found 4−5 times more often in patients with liver cirrhosis than in healthy persons. Follow-ups showed the development of cholelithiasis in 11.5% or 23.3% (−59%) of cases with women being mainly affected (♂ = 15−20%, ♀ 30−35%). In stages Child B and C, frequency is 35−45%. In more than 80% of cases, asymptomatic cholelithiasis is observed. (1, 6, 39, 44, 54) Predominantly brownish-black bilirubin concrements (= calcium bilirubinate) are detectable. (s. figs. 35.16, 35.17) The duration and degree of severity of cirrhosis as well as prior alcohol abuse are thought to be important risk factors. Cholelithiasis has no influence on survival in cirrhosis. Surgical intervention poses a high risk and is therefore only indicated in life-threatening situations. • The cause is believed to be reduced contractility of the gall bladder in cirrhosis with disturbed emptying. (This can be checked with $^{99m}$Tc-mebrofenin.) Hypersplenism, which is responsible for increased haemolysis and a reduction in UPD glucuronyltransferase activity in the liver, is assumed to be a further cause of this close association between cirrhosis and cholelithiasis. Hepatic secretion of unconjugated bilirubin is twice as high as

*Fig. 35.16:* Cholelithiasis in liver cirrhosis: pigment calculi

*Fig. 35.17:* Pigment calculus in liver cirrhosis, grid microscopy displaying characteristic plate-like bilirubin bodies

normal and bile acid concentration is reduced, whereas the bile itself is oversaturated with cholesterol.*⁾

## 9.15 Hepatocardiovascular syndrome

Apart from lung and kidney, heart and circulation are often involved, either primarily or secondarily, in liver diseases; this applies especially to cirrhosis.

**Hyperdynamic circulation** has a close correlation to portal hypertension, which results in (*1.*) reduction in vascular resistance and (*2.*) vasodilation of the splanchnic arteries and arterioles with increased blood volume in this vascular system. This leads to underfilling of the

_____

*⁾ *Kuntz, E.:* Erkrankungen der Gallenblase und Gallenwege. (Diseases of the gall bladder and biliary tract) J. F. Lehmanns Verlag München, 1974. 344 pages, 126 figures.

heart and reduction of the arteriovenous oxygen difference. The consequences of this are adaptive tachycardia and increased cardiac output as well as arterial hypotension. As a result of such a hyperdynamic circulation, there is a decrease in the *effective blood volume* (= central and peripheral blood volume in the cardiac chambers, lungs and main arteries). The splanchnic hypervolaemia increases the portal hypertension as a vicious circle. The relative hypervolaemia in the arterial system and hypotension cause a compensatory activation of the RAAS and the sympathetic nervous system. This is followed by an increase in the intrahepatic vascular resistance with continuous deterioration of the haemodynamics. This vicious circle finally leads to an enlargement of the collateral vessels with development of varices as well as to ascites and the hepatorenal syndrome.

**Pathogenesis** of vasodilation is multifactorial. The systemic or local effective vasodilators include: NO, glucagon, substance P, VIP, TNF, calcium-gene-related peptide, prostacyclin, etc. (12, 19, 33)

**Clinical findings** comprise: resting tachycardia and hypotension with large amplitude; dry and warm skin; flushed extremities, bounding pulses and capillary pulsations in the fingers; occasionally, an ejection systolic murmur is audible; QT time is often prolonged in correlation to the severity of cirrhosis. (182) • These cardiovascular findings are usually not a cause of heart insufficiency. After liver transplantation, there is complete regression. • Beta-blockers are recommended as therapy.

**Cirrhotic cardiomyopathy:** This term is defined as a left ventricular functional disorder due to stress (e. g. hyperdynamic circulation) or as pharmacological stimulation. But also the possibility of (toxically induced?) subclinical myocardial damage is discussed, especially because elevated troponin 1 serum values are detectable in every third patient. (81, 142, 187) (Troponin is connected with propomyosin in the actin filaments at regular intervals and, as a "relaxing protein", has an important function in muscle metabolism, also in the heart).

**Pericardial effusion:** In ascites, there is often (50−60%) a generally small pericardial effusion, which today can be recognized reliably with the help of echocardiography.

## 9.16 Hepatocellular carcinoma

HCC is the fourth most common tumour worldwide. In 68−89% of patients with HCC, cirrhosis was also detected, i. e. about 6 times more often than in patients without cirrhosis. The incidence of HCC in cirrhosis is between 4% and 55% (2−5% per year), depending on (*1.*) aetiology of cirrhosis, (*2.*) type of cirrhosis, and (*3.*) observation period. Men are affected about 8 times more often than women. (45, 94, 180) *(see chapter 37.3)*

**Aetiology of cirrhosis:** Cirrhosis due to hepatitis B, C and D as well as haemochromatosis, alcohol, NASH and $\alpha_1$-antitrypsin deficiency increases the risk of developing HCC considerably; there is a less obvious association with primary and secondary cholangitis or with autoimmune hepatitis. (84, 85, 143, 178)

**Type of cirrhosis:** Macronodular cirrhosis (which is usually a posthepatitic form of cirrhosis) is the type most often associated with HCC (about 55% of cases). Compared to micronodular cirrhosis (usually alcohol-induced), development of HCC must be anticipated in 5−10% of patients. In this context, the actual presence of coarse-nodular cirrhosis seems to pose a greater risk of HCC than the aetiology of the underlying cirrhosis. • The adenomatous and hyperplastic transformations frequently found in cirrhosis tend to develop into HCC.

**Observation period:** The time lapse between the onset of cirrhosis and that of HCC is unpredictable. Small cancerous foci may be observed at a early stage of cirrhosis, which to date could only be demonstrated by SPECT in vivo. Clinically recognizable HCC is reported to take about 4 years on average to develop into HBV-induced cirrhosis (H. OBATA et al., 1980) and about 8 years into alcoholic cirrhosis (C. M. LEEVY et al., 1964).

**Diagnosis:** Long-term monitoring of a cirrhotic patient is achieved by determination of $\alpha_1$-**foetoprotein** (s. p. 106). As soon as the initial value has been established, follow-ups are carried out at long intervals (usually every 6−12 months if the values are normal) and at short intervals if the values are elevated. However, sensitivity is only about 60%, so that a normal value does not necessarily exclude HCC. Specificity is 75−90%. Despite the unsatisfactory sensitivity, AFP determination is still useful for monitoring the development of "still normal" or "already moderately elevated" values. • The simultaneous determination of **des-gamma-carboxy prothrombin** (DCP) (sensitivity 50−60%, specificity 80−100%) can improve the diagnostic value or the assessment of the course. (s. p. 725) • **Sonography** serves as a tool in monitoring cirrhosis simultaneously, yet it should be noted that the sonographic differentiation of small-sized malignant foci is generally quite difficult in the cirrhotic liver. Sensitivity is 70−80% and specificity 90−95%. Follow-ups are recommended at 6−9 month intervals. Regular monitoring at short intervals with the help of AFP determination and sonography is recommended in macronodular cirrhosis or in the presence of HCC risk factors. (93) • Suspected development of HCC is an indication for contrast-medium (= lipiodol) **computer tomography** (or spiral CT) in order to guarantee a relatively early diagnosis. (s. fig. 37.6) **MRI** (or spiral CT) has also been used to distinguish between adenomatous hyperplastic nodes and HCC in cirrhosis. (79, 103, 108, 197) • Cytologic confirmation of HCC can be substantiated by US/CT-guided **fine-needle biopsy**; this is especially true for intrahepatic foci. • In view of the bleeding risk, we would discourage clinicians from resorting to percutaneous biopsy and consider **laparo-**

**scopy** to be indicated instead. (s. figs. 37.1, 37.7, 37.8) The primary use of laparoscopy as a morphological tool (subsequent to imaging diagnostics) has the following *advantages*: (*1.*) inspection of the total liver surface facilitates a much more reliable detection of foci, (*2.*) practically any superficial focus can be accessed by forceps biopsy, (*3.*) use of Robber's forceps is far less dangerous than any needle biopsy of the liver, (*4.*) explorative laparoscopy provides the required staging result, and (*5.*) any kind of "blind" percutaneous biopsy is definitely more dangerous than forceps biopsy, which is carried out under visual control with the possibility of monitoring potential rebleeding and applying respective coagulative measures. *(see chapter 37.3)*

# 10 Prognosis

The prognosis for cirrhosis patients depends upon the respective complications in each case. The underlying morphological processes, such as necrosis, fibrosis and regeneration, combine to widely differing degrees in the single cirrhotic patient. There are also individual divergencies in haemodynamic responses and the corresponding effects on the kidneys, lungs and liver, etc. Thus it is very difficult to give an accurate prognosis in each case. Furthermore, such a prognosis can only cover a relatively short period of time (a few months up to a year). (2, 46, 59, 78, 107, 139, 144, 157, 176, 203, 204)

Various indices have been developed using weighted parameters to calculate the probability of fatality or survival in the individual case. **Classification** of cirrhosis according to the *criteria* devised by CHILD and TURCOTTE (1964) and the *modification* established by PUGH (1973) has been widely accepted. Our experience shows that the additional use of the *GEC* and the *ICG test* makes the classification more reliable, particularly in stages A (= score 5−7) and B (= score 8−10). (s. tab. 35.6)

The prognosis of cirrhosis caused by toxins (alcohol or medicament abuse, chemical agents, iron storage, etc.) is usually markedly improved by *eliminating the causal noxa*. Recognition and treatment of *secondary immunoreactions*, which may occur concomitantly, are also important. As a result of such reactions, the prognostically favourable effect of abstention (e. g. alcohol, pharmacons) may be reduced unless adequate countermeasures with drugs are possible.

In compensated cirrhosis, the 10-year survival rate is between 45 and 50%. Long-term compensation (for many years) can also be maintained in 40−45% of cases. Of the compensated patients, severe complications develop in 55−60% and decompensation occurs in 45−50% of cases. The mean survival rate for compensated cirrhosis is 8.9 years, for decompensated cirrhosis 1.6 years only. (139, 144, 176)

Complications such as variceal bleeding, hepatic encephalopathy, ascites and infections as well as reduced renal function also influence the **mortality rate** of liver cirrhosis (in Germany some 25,000/year). The main causes of death are hepatic coma or liver failure (25−40%), bleeding (20−30%), infections (about 10%) and HCC (about 5%). Spontaneous bacterial peritonitis is fatal in 50−70%, and with liver dysfunction even in 90% of cases. Occurrence of the hepatorenal syndrome is almost invariably fatal.

> Prognosis of liver cirrhosis depends upon preventing complications as far as possible. • At the same time, all options should be used to stabilize compensation and improve liver function.

# 11 Treatment

In principle, **six treatment forms** can be implemented to combat the complex pathological events in liver cirrhosis, which may be extremely variable due to numerous complications. These are: (*1.*) causal treatment, (*2.*) treatment of pathogenetic primary reactions, (*3.*) treatment to prevent progression of cirrhosis, (*4.*) treatment of symptoms, (*5.*) treatment of complications, and (*6.*) liver transplantation.

## 11.1 Causal treatment

Once alcohol-induced cirrhosis has been detected, absolute **alcohol abstention** is essential. This abstention also includes the concealed amounts of alcohol in drinks and foodstuffs or in pharmaceuticals and tonics as well as the use of after-shave products, which may contain a high volume percentage of alcohol. Even fruit juices are allowed to contain a certain amount of alcohol, due to fermentation in the bottle. And so-called alcohol-free beer is in fact a beverage with a low alcohol content. Apart from that, intestinal fermentation caused by certain fungi may result in the production of considerable amounts of alcohol. All these factors can come together to produce "alarming" quantities of alcohol in the body and can even lead to a situation where a phase of abstinence is followed by renewed addiction. Women in general and patients with cirrhosis who have undergone gastric resection are predominantly at risk with regard to this complex problem. All too often, these facts are underrated or go largely unnoticed as far as their cumulative effect is concerned. Beware of *cliché-ridden expressions* designed to trivialize the matter such as a "sip of wine", a "sip of beer" or a "nip of brandy" − this form of self-deception is simply not acceptable. (s. pp 59; 522−524)

Likewise, in cirrhosis due to medicaments or toxins, causal treatment entails elimination of the underlying

**noxa(e)** (pharmaceuticals, chemicals, drugs) and a simultaneous "ban" on alcohol. Alcohol has an additive and sometimes intensifying effect as a noxa. In a particular course and stage of cirrhosis due to viral hepatitis B or C, treatment with **interferon** may (still) be used as causal therapy. Hereby, the frequency of decompensation of HCV cirrhosis or of HCV-induced carcinoma could be lowered, although not significantly.

## 11.2 Treatment of pathogenic reactions

Treating pathogenic primary reactions does not cure the underlying cause of cirrhosis, but is an effective intervention in its pathogenesis. Continuous therapy may result in reduced inflammatory or immunological activity and decreased fibrogenesis despite the (regrettable) development of cirrhosis; thus it can bring about a tendency towards stabilization or inactivation of the overall process: e. g. *iron depletion* in haemochromatosis, *removal of copper* in Wilson's disease, *protection against ultraviolet light* in certain forms of porphyria cirrhosis, *immunosuppression* in autoimmune cirrhosis, and reduction in *portal hypertension* by medication.

## 11.3 Treatment of progression

The above-mentioned measures do not combat the cause(s) or eliminate the primary pathogenetic reactions (with a few exceptions). The general aim is to prevent progression of the disease, ideally until the cirrhosis comes to a halt. When such medication is administered effectively, complicative developments can also be prevented. Pathogenetic primary reactions often initiate a cascade of secondary mechanisms, in particular of a biochemical nature. This is true, for example, of the inhibition of concomitant cholestasis during the course of cirrhosis by *ursodeoxycholic acid* (97), the reduction in lipid peroxidation by *silymarin*, the inhibition of fibrogenesis by *colchicine* (82) or *silymarin* (sometimes with improved quality of life), and the elimination of hyperammonaemia by *ornithine aspartate*. (145) (s. p. 279)

> Fundamentally, "treatment" of cirrhosis should begin during its chronic precursory stages, i. e. *chronic hepatitis* or *chronic cholangitis*. A chronic disease confirmed by detailed diagnostics usually still responds to effective treatment measures, which are, however, of no help once the cirrhotic stage has been reached.

## 11.4 Symptomatic treatment

▶ From the subjective point of view concerning the pathological events, it is usually those symptoms which considerably impair the state of health and lifestyle that are the most obvious. The patients "feel" tired, worn out, lack concentration, are unenthusiastic and unmotivated; they are inappetent and show muscular weakness; occasionally they suffer from pruritus − they "feel ill", or even "chronically poisoned" (as we were often told by such patients who used these words). First and foremost, the patient seeks advice and help, even polypragmatic help in view of the often widely varying symptomatology.

▶ When liver cirrhosis has already been confirmed by detailed diagnosis and its (possible) secondary reactions or complicative developments have been determined (this is the *primary prerequisite* "of the physician"), it is possible to apply symptomatic treatment measures in a more effective and more targeted and thus also more efficient way (which is what "the patient" *principally expects*). • In most cases, this forms a basis of mutual trust as it generally guarantees the patient's readiness to cooperate with regard to strict directions, certain treatment and follow-up measures as well as invasive therapy.

### 11.4.1 Nutrition

The question *"What can I eat?"* is nearly always of prime importance and it implicitly includes the basic idea of what the cirrhotic patient should avoid or what diet to give preference to. First of all, it should be clear that there is no such thing as a special **liver diet** designed to have instant curative effects on liver disease (despite the fact that many such diets have been extolled). • The diet of a cirrhotic patient is based on the principles of *nutritional physiology*, the *aetiology* of the cirrhosis, the patient's *body weight* and *age* as well as on any *complications*. (117) (s. pp 536, 850)

The calorie content of the diet should be adapted to the current body weight. As a rule, the percentage ratio between **calories** derived from carbohydrates, protein and lipids is considered well-balanced at 40:20:40 or 50:20:30, with a minimum of 2,000 calories per day. The recommended **protein** intake is about 0.8−1.2 (−1.5) g/ kg BW; when there is a tendency towards encephalopathy, the protein content needs to be reduced accordingly, with an intake of mainly lactovegetative proteins. (s. p. 278) In catabolism or muscular atrophy, the protein intake must be increased to more than 100 g/day and/or **branched-chain amino acids** (34, 65, 77, 104, 109, 121, 152, 177, 199) or formula diets are recommended. The nitrogen balance must be in equilibrium. (86, 116) The daily intake of food should always be spread over **5 meals** (i. e. 3 main meals and 2 snacks, as with diabetic patients): this makes digestion easier, and the catabolic phases become shorter. With regard to energy, a cirrhosis patient is in a condition of fasting. **Salt intake** should not exceed 7 (−8) g/day; as soon as signs of water retention in the tissue appear (s. fig. 16.2), salt consumption should be reduced further. (s. p. 305) • In addition, disease-induced **maldigestion/malabsorption** (e. g. deficiency of pancreatic enzymes or bile salts, portal hypertensive enteropathy) is responsible for a lack of essential

nutritional components (often latent for a long time). In older people, reduced absorption of fat-soluble vitamins (184, 185) and arachidonic acid (131) (among other things) is also to be expected. However, one should not wait for a vitamin deficiency to arise; besides, biochemical evidence of reduced vitamin values is costly and unreliable. Daily intake of *multivitamin tablets* (as a dietary supplement) should thus be considered for obvious reasons. This is also true of a complementary supply of *electrolytes, zinc* (105, 196) and *selenium*. (27, 181) • If steatorrhoea is observed, *MCT* (about 3 x 15 ml/day, equivalent to some 400 kcal) are given, possibly coupled with the administration of *"essential" phospholipids* to achieve the best results. (28)

I have been told that **raw goat's milk** (2 x 0.25 l/day, stored in the refrigerator) is used "successfully" to treat liver cirrhosis in some regions. Ubiquinone (?) is thought to be the active substance − this agent is also said to have prevented the occurrence of cirrhosis in animal experiments.

▶ Malnutrition, which is observed in 60−80% of cirrhotic patients, may be so severe that **parenteral nutrition** is called for. (29, 117) Glucose infusions as a main source of energy (6−10 g/kg BW/day), amino-acid solutions (1.0−1.5 g/kg BW/day) and lipid infusions (0.3 g/kg BW/day) can be used for this purpose to guarantee a supply of about 2,270−3,000 kcal. • Parenteral nutrition should guarantee an adequate supply of *vitamins, electrolytes, zinc* and *choline* as well as *albumin*. (24) In encephalopathy, preference is usually given to *branched-chain amino acids* instead of total amino-acid solutions. Administration of *insulin* may be necessary in impaired glucose tolerance. • In pronounced catabolism, the nitrogen balance can be considerably improved by administering recombinant growth hormones. • *Laevulose, xylitol or sorbitol should not be administered as they are not sufficiently transformed into glucose in the cirrhotic liver, with the result that lactate acidosis and hypoglycaemia occur due to the increased formation of lactate. In addition, these substances also lead to a further reduction in energy-rich phosphates, which are generally already decreased.*

### 11.4.2 Physical activity

Appropriate **physical activity** (with anabolic effects) is generally recommended for cirrhotic patients in order to prevent muscular atrophy and hepatic osteopathy. We had positive experience with a *muscle-training programme* carried out 2 (or even 3) times a day. Almost 60% of the musculature is activated in this way − irrespective of age or weather conditions and without the need for particular clothing or equipment. (s. pp 650, 732) • Swimming or water gymnastics are recommended activities, if possible. Physical overexertion must be avoided. (18, 57, 154) This also applies to the use of home-training equipment. An unfavourable rise in HVPG due to increased physical exercise can be prevented by propranolol. (18) • We recommend a **horizontal position** for about an hour after each of the 3 main meals. The positive effects of a recumbent position on numerous biochemical parameters, particularly in disturbed water and salt balance, remain undisputed − and are just as obvious as the negative effects of a long-term upright posture. (154) The latter may even trigger complicative

developments when there is simultaneous emotional (sympatheticotonic) excitement (e.g. when watching sports events!). • Vocational **rehabilitation** is the ultimate aim and the patient ought to be given tasks based on physical aptitude. If the physician agrees, patients should continue in their current profession. *The diagnosis "liver cirrhosis" does not automatically mean incapacity for work or vocational disability!* • Utmost care should be taken by the patient in keeping personal **records** (documentation sheet) in order to detect latent HE or latent water retention, which points to a commencement of decompensation. (s. fig. 15.3) (s. pp 275, 305)

### 11.4.3 Psychological guidance

▶ *Detailed and confirmed diagnosis* enables the physician to offer reliable guidance, which gives the patient the necessary confidence in the former's proficiency and experience. This is the first important *prerequisite* regarding active medical care. • The patients, who have various subjective complaints and are usually weakened by malnutrition, besides being severely restricted in their everyday lives, are first and foremost seeking *tangible help* to ease their own subjective suffering. The patient has more trust and readiness to cooperate if the physician shows understanding for these subjective complaints, takes them seriously and treats them (even if the treatment measures are gradual or polypragmatic). This is the second important *prerequisite* regarding active medical care. • Usually, it is the patient's desire to be informed as fully as possible in a comprehensible manner about the respective disease. The physician's patience and readiness with respect to *elucidation* as well as in explaining the disease itself and the cirrhosis-related circumstances in an understandable manner, or even suggesting that a *second opinion* should be obtained from another hepatologist, reassure the patients that they are in the hands of a competent specialist. This is the third important *prerequisite* regarding active medical care.

Understandably, there are always questions concerning **prognosis**. *Cirrhoses come in many different shapes and sizes!* The individual *aetiology* of cirrhosis (more than thirty different causes are known; s. tab. 35.2) initially determines the prognosis − this is all the more essential since certain forms respond well to treatment. In addition, prognosis is influenced by maintaining *compensation*, which, in turn, is supported by an *appropriate lifestyle*. The patient is fully aware of the fact that any kind of *active participation* is really worthwhile, that even phases of decompensation can be overcome and that early detection of such phases as well as of complicative developments offers the best chance of stabilization, provided that treatment commences as early as possible. The patient experiences how the *aetiology* of the cirrhosis, personal *cooperation* and the early detection of *complications* form an important **triad**, and that conse-

quently the prognosis of liver cirrhosis need not be as poor as is generally assumed. • *We treated numerous cirrhotic patients over a long period, a large number of whom we accompanied for 10−15 years despite some interspersed "acute-on-chronic" events.*

Even an **infaust prognosis** should not be withheld from the patient, particularly in those cases where specific questions are asked about the true situation. In these conversations, the physician, who is naturally deeply involved, should explain the situation step by step, revealing one unfavourable fact after the other. In this way, all medical and nursing measures can be discussed frankly. The patients also need time to settle their personal and family affairs and to have a chance for contemplation as well as for finding spiritual support.

Such a joint approach and communal experience concerning cirrhosis requires the physician to show empathy and persuasion, but also to discern the degree to which the patient is able to grasp and understand the medical facts and findings intellectually and emotionally. Time and again, the three prerequisites described above have proved to be mainstays in the relationship between physician and patient.

### 11.4.4 Drug therapy

▶ A review of the past 50 years (since 1955), during which time we have experienced numerous developments in hepatology, shows that a fascinating spectrum of treatment options has been established, which nobody could ever have dreamed of. • This is true first and foremost of the *treatment of pathogenetic primary reactions*, some examples of which have been outlined in the individual chapters describing the corresponding diseases. The same applies to the pharmacological treatment of *progressive tendencies* typical of cirrhosis, such as cholestasis, fibrosis, hyperammonaemia, electrolyte imbalance, lipid peroxidation, etc.

Dealing with complications is not what we consider to be the most important aspect of treating cirrhosis. A primary objective should be to carry out prophylactic measures for preventing such complications in the first place, insofar as this is possible.

As we have shown in the case of **encephalopathy** and **ascites** − *the two earliest and thus most common decompensation syndromes* − successful **prophylaxis** for about 1 year is less of a financial burden than (just) 1 week of inpatient treatment after manifestation. Even more important is the absolute danger to the patient inherent in a progressive course. • *Prevention of complications is always better and cheaper − for all parties involved!*

The use of the following substances has proved suitable in terms of pharmacological plausibility and clinical results, provided there are no particular circumstances, forms of treatment, intolerance or individual imponderables to contraindicate their application.

**Step 1:** (*1.*) *lactulose* (2−3 stools/day) and (*2.*) *spironolactone* (50 mg per day or every second day). This dosage is practically free of side effects − even during long-term administration. (s. pp 278, 306, 858)

**Step 2:** Additional administration of (*3.*) *ornithine aspartate* (1−3 x 6 g/day). This may be indicated by the detection of latent HE (stages 0, 0−I). Usually, the administration of (*4.*) *zinc* (15−30 mg/day) is also indicated in this context. (s. pp 279, 857, 862)

**Step 3:** Reduction in portal pressure (42, 74, 113, 115) increased at an early stage, and prevention of variceal bleeding as part of a primary prophylaxis are important measures. In our experience, the development of pulmonary hypertension can be delayed (or even prevented). (s. p. 337) This might be achieved, for example, by administering (*5.*) *molsidomine* and (*6.*) *beta blockers* (in combination with spironolactone as in Step 1). The frequent occurrence of portal colopathy (30−40%), even with colitis-like abnormalities, can be reduced by propanolol. (21, 158) • A combination of isosorbide-5-mononitrate with nadolol has been successful in cases where treatment with beta blockers alone did not prove effective. (s. pp, 258, 355)

**Fat-soluble vitamins:** Oral intake of vitamins A, D and E is usually sufficient − as is the dosage contained in multivitamin preparations when taken daily. Biochemical evidence of deficiency or the occurrence of diseases due to deficiency usually require vitamins *A, D, E* and *K* to be supplied parenterally as a compound preparation. (184, 185) (s. p. 47)

**Silymarin:** At present, there is no unequivocal confirmation of the positive effects of silymarin as a cytoprotective agent against various noxae; in particular, the scavenger effects attributed to this substance and its alleged regenerative properties have not been confirmed in cirrhosis. (s. p. 867)

**Phosphatidylcholine:** As is the case with silymarin, there is a vast amount of information in the literature about this substance. Animal experiments have shown that the development of septal fibroses and the occurrence of cirrhosis could be prevented despite chronic alcohol consumption. The studies available to date on cirrhotic patients provide insufficient information. (s. p. 865)

**Colchicine:** Inhibition of progressive fibrosis in cirrhotic patients with a markedly improved survival time was reported (dosage: 1 mg/day, 5 days/week). (82) However, this was not confirmed in a later study. We have no information about potential side effects, particularly during long-term treatment (which is usually desirable in cirrhosis therapy). (s. p. 868) • The use of **proline-4-hydroxylase** results in the significant inhibition of collagen synthesis in animal experiments. No clinical data are available to date.

**Coagulation parameters:** Detection of pathological laboratory values is not an indication for substitution. Such measures are unnecessary before clinical manifestations are observed. Propranolol ameliorates thrombopenia. (151) (s. pp 346, 347)

*Liver cirrhosis is the final stage of disease of the largest metabolic organ, with diverse functionally, biochemically and morphologically related complications.* Decompensa-

tion mechanisms should therefore be avoided with the help of targeted treatment. The aim is to maintain the stage of compensation for as long as possible and to recognize complications at their onset. • The costly and complex treatment strategies for dealing with cirrhotic complications, often involving intensive care, are described in the respective chapters.

## 11.5 Monitoring

> Regular monitoring is essential and should be carried out in a targeted and economical way. The basic parameters used in the follow-up should be limited to obtaining really informative results!

▶ In the course of some 40 years, we have accompanied cirrhotic patients for considerable periods of their lives, many for more than 10 years, some even for more than 15 years. This often resulted in experiences that modified and ultimately standardized our follow-up programme. • Basic control parameters, i.e. parameters important in all forms of cirrhosis, are supplemented by more informative investigations (such as iron, copper or phosphatase values) in cases with a particular aetiology. Such a **standard programme**, *which nevertheless leaves room for individual concepts, has proved successful over many years.* (s. tab. 35.8)

| | | |
|---|---|---|
| **1. Interim anamnesis:** | | |
| **2. Therapeutic status:** | | |
| **3. Clinical findings:** | | |
| **4. Documentation sheet:** | | |
| **5. Laboratory parameters** | | |
| GPT: | γ-GT: | every (2−)4 weeks |
| Na: | P: | every (2−)4 weeks |
| ChE: | Quick: | every (4−)8 weeks |
| Electrophoresis: | Alb.: | every (3−)6 months |
| | γ-Glob.: | every (3−)6 months |
| **6. Particular values:** | | |
| **Doctor's orders:** | | |

*Tab. 35.8:* Standardized (uniform and easy-to-document) evaluation programme for the long-term follow-up of compensated cirrhotics. (Time intervals in accordance with the current situation, particular values in accordance with the given cirrhosis aetiology)

**1. Interim anamnesis:** Important events during a certain period of time are noted in a concise manner − otherwise the abbreviation n.a. (= no abnormality discovered) is sufficient.

**2. Therapeutic status:** The name and dosage of the pharmacons used in the meantime; the name and date of any medicine discontinued or newly prescribed; side effects/intolerances observed, if any; (all relevant details concerning the remedies are recorded, which facilitates interim repeat prescriptions).

**3. Clinical findings:** Relevant changes in findings are recorded tersely; unchanged status is noted with the abbreviation n.c. (= no changes).

**4. Documentation sheet:** Presentation of the documentation sheet by the patient containing details of body weight and handwriting specimens during the respective follow-up phase. This form (which can easily be drawn up by the patient) may contain, on the front and back, daily entries for 2 follow-up months. This patient-made documentation is the *cheapest and most reliable follow-up method* with regard to early detection of the two most sensitive signs of decompensation: latent HE and latent ascites. (s. fig. 15.3) (s. pp 275, 305)

**5. Laboratory parameters:** These are of *secondary importance* in the long-term follow-up of compensated liver cirrhosis. *GPT* is sufficient for evaluating enzymatic activity, while *γ-GT* is suitable for initial detection of concomitant cholestasis or toxic components (in some cases, there are also hints of malignancy or sometimes regeneration). Depending on the individual situation, these two values have to be checked at intervals of (2−)4 weeks. In order to monitor liver function, *cholinesterase* and *Quick's value* are determined at intervals of (4−)8 weeks, while *electrophoresis* (for evaluating mesenchymal activity and albumin synthesis) is conducted every (3−)6 months. • Control of *sodium* (Na) and *potassium* (P) is carried out according to the individual situation. However, these two electrolytes are nearly always within the normal range if the findings in the above mentioned documentation sheet referring to latent HE or latent oedema are also normal − a fact which can be explained in terms of pathophysiology. • With specific forms of cirrhosis, one or two *additional parameters* of particular significance are applied.

> The aim is to maintain the **stage of compensation** in an undisturbed state for as long as possible, to use all possible measures to prevent negative effects, and to detect and treat the onset of any decompensation mechanisms as early as possible. This is essential and decisive both for prognosis and for structuring a worthwhile daily life. • The requirements of *quality management* are also met as far as possible by adhering to a standardized **follow-up programme**, which can be documented. • This well-established overall concept has also been successful in reducing the expense involved. The **costs** of caring for one cirrhotic patient have been calculated at approx. 13,000 US dollars per year (T. Szucs et al., 1997).

## 11.6 Liver transplantation

All patients with end-stage cirrhosis should be considered for liver transplantation in good time. Selection initially requires a thorough and critical evaluation of the indication with regard to the patient's general physical and mental condition. The **risk factors**, which have to be assessed in advance, include: (*1.*) cardiac, pulmonary and renal function, (*2.*) coagulation system, (*3.*) albumin value, (*4.*) obesity, (*5.*) prior complex hepatobiliary surgery, (*6.*) portal vein thrombosis, (*7.*) autoimmune disease, (*8.*) viral infection, (*9.*) coexisting diseases, (*10.*) problems related to addiction, (*11.*) unfavourable familial and social environment, and (*12.*) individual unwillingness to cooperate. • These twelve evaluation criteria provide an initial overview of the extent of the risk factors which can be identified in advance and which are of significance for the patient's registration at a transplantation centre. • For many patients in a life-threatening situation, liver transplantation remains the only chance of survival.

# Clinical Aspects of Liver Diseases

## 36 Benign hepatic lesions and tumours

# 36 Benign hepatic lesions and tumours

## 1 Definition

The term **lesion** denotes a circumscribed impairment of function or tissue structure, while the word **tumour** describes a circumscribed swelling or the growth of body tissue. • **Benign hepatic focal lesions** are circumscribed alterations. They differ markedly from the surrounding hepatic tissue, which shows a normal or diffusely changed structure. Differences in tissue type or chemical composition are revealed by imaging procedures. Benign hepatic coin lesions can appear either in solitary or multiple form. They may be only $1-2$ mm in size or cover large hepatic areas, and even a complete lobe.

## 2 Classification

Benign hepatic focal lesions are usually detected as an incidental finding in sonography. As a rule, there are no subjective or characteristic complaints, no identified neoplastic disease and no objective clinical findings.

### 2.1 Sonomorphological classification

Sonomorphological differentiation may be helpful in classifying incidentally detected liver foci: (*1.*) anechoic, (*2.*) hypoechoic, and (*3.*) echogenic lesions. The cyst as a typical anechoic focus displays the following characteristics: a delicate margin, dorsal sound reduction and a completely anechoic lumen. • Focal hepatic lesions or coin lesions are exceptionally variable with regard to size, number, internal echo (homogeneous or structured), demarcation from the surrounding hepatic tissue and secondary findings (displacement effects, compression). • *It is extremely important to rule out malignant hepatic tumours.* (s. tab. 36.1)

| Anechoic lesions | Hypoechoic lesions |
|---|---|
| Caroli's syndrome | Adenoma |
| Cysts | Echinococcus alveolaris |
| Echinococcus alveolaris | FNH |
| Fresh haematoma | Focal non-fatty changes |
| Liquefied abscess | Fresh abscess |
| Osler's disease | Hamartoma |
| | Lymphoma |
| **Echogenic lesions** | NRH |
| Fibroma | Old haematoma |
| Focal fatty changes | Peliosis hepatis |
| Granuloma | Regenerative nodes |
| Haemangioma | |
| Hamartoma | |
| Lipoma | |
| Regenerative nodes | |

***Tab. 36.1:*** Sonomorphological classification of benign hepatic focal lesions according to their (predominant) echogenicity

### 2.2 Histological classification

Differential diagnosis of circular hepatic foci helps to decide whether therapeutic measures are necessary, not required, or not feasible. • The histological *classification* of benign coin-like hepatic lesions differentiates between (*1.*) hepatocellular tumours, (*2.*) cholangiocellular tumours, (*3.*) mesenchymal tumours, and (*4.*) tumour-like lesions. There may also be evidence of (*5.*) calcareous foci. (4, 7, 12, 15) (s. tab. 36.2)

1. **Hepatocellular tumours**
   Adenoma
   Focal nodular hyperplasia (FNH)
   Nodular regenerative hyperplasia (NRH)
   Regenerative nodes

2. **Cholangiocellular tumours**
   Bile-duct papillomatosis
   Biliary hamartoma
   Caroli's disease/syndrome
   Intrahepatic bile-duct adenoma
   Intrahepatic bile-duct cystadenoma

3. **Mesenchymal tumours**
   Angiolipoma
   Angiomyolipoma
   Benign haemangioendothelioma
   Cavernous haemangioma
   Chondroma
   Fibrous tumour
   Focal fatty changes
   Glomangioma
   Leiomyoma
   Lipoma
   Lymphangioma
   Mesenchymal hamartoma
   Mesothelioma
   Myelolipoma
   Myolipoma
   Myxoma
   Schwannoma

4. **Tumour-like lesions**
   Abscess
   Cysts
   Granuloma
   Haematoma
   Inflammatory pseudotumour
   Peliosis hepatis

5. **Calcareous foci**

***Tab. 36.2:*** Histological classification of benign hepatic coin lesions

## 3 Diagnosis

### 3.1 Anamnesis

In most cases, benign liver tumours are detected by chance during sonography. Any *information* elicited during anamnesis about the long-term use of contraceptives, androgens or medication as well as any possible

intake of chemicals, potential infections with parasites or zoonoses, abdominal trauma or febrile diseases and previous episodes of jaundice may be important.

## 3.2 Complaints

There are usually no subjective complaints − except when there are large space-occupying lesions which cause anorexia, weight loss, upper abdominal pain upon pressure, haemorrhaging in the tumour or tumour rupture. Febrile conditions and pain may point to infection, liver abscess or echinococcosis.

## 3.3 Findings

**Anamnesis** and **complaints** are often of little diagnostic value. Moreover, clinical examination generally reveals non-characteristic findings such as hepatomegaly, abdominal pain upon pressure, diaphragmatic elevation, right-sided pleural effusion or hepatic vascular murmur (e. g. in large haemangiomas). • **Laboratory parameters** are generally normal. Sometimes transaminases and γGT are elevated; occasionally, there is an increase in AP and respective values relating to cholestasis. In the case of an inflammatory process, CRP and BSR are often elevated; ChE and iron may be decreased.

## 3.4 Imaging procedures

The following imaging procedures can be used for the detection and differential diagnosis of benign hepatic lesions or tumours: (*1.*) sonography, (*2.*) computer tomography, (*3.*) scintigraphy, and (*4.*) magnetic resonance imaging. These methods show clear differences in their ability to detect tumours of minimum size, in their sensitivity and specificity, and in the costs involved. • Echogenic and anechoic foci can obviously be detected by sonography at a much smaller diameter than hypoechoic foci. In scintigraphy, hepatic tumours in the portal area and in the centre of the liver must have a larger diameter in order to be visualized. By combining scintigraphy and CT, it is generally possible to differentiate FNH from adenoma. In CT and MRI, detection of a tumour depends on its structure. • Sensitivity, i. e. the rate of correct positive results, should be as high as possible, but there are clear differences here. The specificity of these diagnostic procedures is high at 90 to 95%.

**Sonography** is the method of choice on the basis of the following *criteria*: (*1.*) it has a high diagnostic yield (including extrahepatic areas), (*2.*) it is cost-effective, (*3.*) it can be used in various locations, (*4.*) it is not time-consuming, and (*5.*) it does not burden the patient. The use of new techniques (contrast-enhanced power Doppler sonography, phase-invasion harmonic imaging) can help to make the assessment more reliable in individual cases. US is clearly inferior to CT when it comes to diagnosing metastases. (3, 6) • *It should be noted that the*

*respective diagnostic reliability is highly dependent upon the investigator's experience.* (s. tab. 36.3)

**Computer tomography** has a greater sensitivity than sonography; however, there are higher costs involved, it takes more time, requires more space and entails exposure to radiation. More sophisticated methods such as helical CT or CT arterioportography allow a more differentiated application in certain constellations (e. g. malignant lymphoma, metastases of parvicellular bronchial carcinoma, or breast cancer). Permanent-location CT with administration of bolus contrast medium is suitable for the differentiation of haemangioma. Sonography and CT are considered to be useful complementary techniques in diagnosing hepatic focal lesions, since in this way foci can be detected which are missed by the respective other method. (1, 3) (s. tab. 36.3)

| Criterion | US | CT | MRI | SC | FNB | Lap |
|---|---|---|---|---|---|---|
| **Detectable size of focus (cm)** | > 0.5 | > 0.8 | > 1.0 | > 2.0 | > 1.5 | > 0.1 |
| **Sensitivity (%)** | 50−70 | 60−90 | 70−95 | 40−60 | 75−90 | ca. 100 |
| **Specificity (%)** | 90 | > 95 | > 95 | > 95 | ca. 100 | ca. 100 |
| **Additional information** | + | + | + | ∅ | ∅ | ++ |
| **Costs** | (+) | ++ | +++ | ++ | (+) | + |

***Tab. 36.3:*** Respective values of the different diagnostic methods regarding the detection of hepatic focal lesions (US = ultrasound, CT = computer tomography, MRI = magnetic resonance imaging, SC = scintigraphy, FNB = fine-needle biopsy, Lap = laparoscopic findings at the liver surface)

**Magnetic resonance imaging** may provide additional differentiation of unclarified findings − particularly in the diagnosis of haemangioma. Hypovascular lesions are detected more easily with SPIO-enhanced MRI, whereas detection and characterization of hypervascular lesions are improved with gadolinium-enhanced MRI. (8, 14) (s. tab. 36.3)

**Scintigraphy** can be indicated for differentiating an adenoma from FNH (combination of colloid scintigram and hepatobiliary sequential scintigraphy) and for diagnosing haemangioma. (13)

**Angiography:** Visualization of hepatic veins or arteries is rarely required. Angiography is indicated for diagnosing metastases of active endocrine tumours. This technique may also be necessary in the planning phase of liver surgery. A further possible indication is its use in carrying out therapeutic measures.

## 3.5 Biopsy and laparoscopy

Reliable differentiation between a benign and a malignant hepatic tumour is not possible using imaging procedures; thus, an indication is given for US-guided or CT-controlled **fine-needle biopsy**. (s. tab. 36.3) (s. p. 135) However, FNB is diagnostically inferior to thick-needle

biopsy (> 1.2 mm) − although the bleeding risk is clearly much lower. The indication for **biopsy** should be viewed critically, particularly when considering the use of a thick needle. (5) • *In all cases where the findings cannot be substantiated by imaging procedures and where treatment implications can be expected as a result of diagnostic clarification, **laparoscopy** is indicated. The combination of laparoscopy and biopsy yields the highest diagnostic sensitivity and specificity. The diagnostic reliability is almost 100% in focal lesions on the liver surface.* (10, 11) Tissue samples for histological examination can be gained from selected tumour areas by careful, directed **forceps biopsy** (also by FNB). Laparoscopy makes possible the photographic documentation of the findings as well as of any additional important pathological changes in the abdominal cavity − this may prove very helpful. (s. tab. 36.3.) *(see chapter 7!)*

# 4 Differential diagnosis

## 4.1 Adenoma

**Epidemiology and aetiology:** Adenomas have an incidence of 4−10/100,000 inhabitants/year. They are almost exclusively found in women during their reproductive years. Children are rarely affected. (28) In men, the risk is higher when they take anabolic agents. In about 90% of cases, there is a correlation with the intake of oral contraceptives over many years; this was pointed out for the first time by J. K. Baum et al. in 1973. (19, 21, 25, 31, 32) There is also an association with the polycystic ovary syndrome. (33) An adenoma can develop in glycogenosis types I and III (with multilocular nodulation) (29) as well as in type IV. (16) The administration of various other drugs (e. g. carbamazepine) has also been associated with adenomas.

**Morphology:** Adenomas are mostly solitary (75%) and located mainly in the right liver lobe (65−70%). The rare occurrence of multiple adenomas (> 3 lesions) is termed *adenomatosis* of the liver. (20) A familial form has been observed, showing the association with germ-line hepatocyte nuclear factor alpha. (18) Usually, adenomas develop close to the surface beneath the liver capsule. They vary greatly in size, reaching a diameter of 10 cm (2 to > 30 cm); even pediculate nodes have been observed. Adenomas are hypervascularized and have a firm, rubber-like consistency. Due to their bright red to light brown colour, they stand out from the rest of the hepatic tissue. (s. fig. 29.11!)

▶ **Histology:** The parenchyma is formed from pluricellular trabeculae and two (or three) layers of hepatocytes, the width of which varies from location to location. The hepatocytes are rich in glycogen, often pleomorphic and enlarged, and usually show fine-droplet fatty deposits. No evidence of acinar architecture or Kupffer cells is found; only very few preexisting and incorporated portal fields, central veins or bile ducts are detectable. There are numerous arteries and ectatic sinusoids; the latter contain no Kupffer cells. It is from here that haemorrhages into necroses occur; they are nearly always found in larger nodes. These haemorrhages may also penetrate the adjacent liver parenchyma and rupture into the abdominal cavity. There are no fibroses or inflammatory reactions. Reticular fibres are delicate or have disappeared completely. Adenomas often possess a capsule made of fibre tissue or compressed liver parenchyma, so that adenoma nodes are usually easy to enucleate from their hepatic bed. (24)

**Diagnosis:** Small adenomas do not cause any discomfort. Large adenomas may become palpable or cause pain upon pressure and have displacement effects. **Laboratory parameters** are generally normal, although AP is sometimes increased; the serum value of AFP remains unchanged. The administration of oestrogen results in a subnormal γ-GT value. • **Sonography, CT** and **MRI** do not show any abnormalities, since the tissue is hepatogenic and thus somewhat hypoechoic or hypodense on a non-enhanced CT scan, but hyperdense in the arterial phase. In some cases a space-occupying lesion is detectable. There may be evidence of circular vascularization, from which irregular vessels penetrate the adenoma. (17, 27) (s. pp 132, 173, 177) Hypervascularized adenomas can be seen in colour Doppler sonography (as well as in coeliacography or MR angiography). Differential diagnosis of haemangioma, HCC or metastases may be rendered more difficult by haemorrhages. • **Scintigraphy** using $^{99m}$Tc sulphur colloid shows no activity enhancement. Functional scintigraphy reveals a normal flow and reduced or no enhancement in the parenchymal and excretory phases. • **Laparoscopy** facilitates a *"split-second visual diagnosis"*, with histological confirmation by forceps biopsy, if required. (s. tab. 36.3) (s. fig. 29.11!)

**Complications:** Intense pain may occur due to haemorrhage in the adenoma or haemorrhagic penetration of the neighbouring liver parenchyma. A rupture causes haemoperitoneum accompanied by symptoms typical of acute abdomen and circulatory shock. An association between menstruation and adenoma rupture has been reported. The risk of bleeding is relatively high at 30−40%. Malignant degeneration is a potential danger (approx. 10%). (23, 25, 28, 31, 32) • *We are able to add one observation of our own regarding malignant degeneration.* (s. p. 549) (s. fig. 29.14!)

**Prognosis:** All in all, prognosis is relatively good. While some adenomas became smaller or even went into remission as soon as oral contraceptives were discontinued (18), there were other cases in which the tumour maintained its size or indeed continued to grow. Even after regression of the adenoma, there is always a danger of hepatocellular carcinoma developing. Systemic AA amyloidosis or paraneoplastic symptoms are rare complications. (20) Monitoring is effected by US or CT, as appropriate. Determination of hormone receptors could provide an additional prognostic criterion in the future. Alkaline phosphatase, γ-GT and ChE, for example, may serve as laboratory parameters.

**Treatment:** Imaging procedures cannot exclude the presence of malignant adenoma degeneration. This uncer-

tainty, together with a high risk of haemorrhage and rupture, which increases with further growth of the tumour, provides the basic indication for enucleation or resection of the adenoma, particularly in the event of an unexpected trauma of the liver. Embolization prior to resection leads to a reduction in size of larger adenomas, thus giving better results. Surgery is indicated from the outset: (*1.*) when an already large adenoma (> 5 cm) is present at initial diagnosis, (*2.*) in pediculate tumours, (*3.*) in cases of proven haemorrhage or subcapsular haematoma, (*4.*) when there is an increased risk of abdominal trauma in everyday life, and (*5.*) prior to a planned pregnancy. • *In general, every resectable adenoma should be removed surgically.* (20, 22, 26, 30, 36, 38)

## 4.2 Focal nodular hyperplasia

**Epidemiology and aetiology:** Focal nodular hyperplasia (FNH) was first described by M. Simmonds in 1884. It is about twice as common as adenoma and is the second most frequent type of benign liver tumour. Its incidence is 20 (−30)/100,000 inhabitants/year; in autopsy statistics, frequency is 0.3−8.0%. FNH has also been observed in children (52), as has the simultaneous occurrence of FNH and adenoma. Cigarette smoking is deemed to be a risk factor. FNH affects mainly women (80%); in some 60−70% of women, there is a connection with the long-term intake of oral contraceptives. (47) There is also an association with the Klinefelter syndrome. (55) When these hormonal preparations are discontinued, FNH (like adenoma) often goes into remission. A hyperplastic reaction to a pre-existing arterial malformation is thought to be one of the pathogenetic possibilities. This view is substantiated by evidence of other concomitant vascular abnormalities (e.g. haemangioma in 20−25% of cases, aneurysms, teleangiectasia) and malformations (e.g. brain tumour) or indeed the occurrence of FNH among family members. The development of FNH is probably caused by increased arteriohepatic perfusion and additional local portovenous thrombosis, resulting in nodular hyperplasia of the hyperperfused parenchyma. (9, 41) Recently, increased values of the genes angiopoietin 1 and 2 have been reported. (50)

**Morphology:** FNH is usually solitary; multiple nodes of varying sizes (up to 20 cm) are only detected in about 20% of cases. (39, 54) FNH is present predominantly in the right liver lobe (50−60%), in individual cases also as a pediculate tumour. There is generally no capsule. FNH has a firm consistency. In about two thirds of cases, strikingly large arteries can be seen supplying the tumour. Tumours located close to the surface are reddish-brown to yellowish-brown in colour. (s. fig. 29.12!) • A **progressive type** of FNH is a rare variant; however, this type may recur following partial liver resection. (54) The **teleangiectatic type** of FNH displays a molecular pattern closer to that of adenomas than to FNA; there-

fore these atypical lesions should be referred to as "teleangiectatic hepatocellular adenomas". (s. fig. 36.1)

**Fig. 36.1:** Focal nodular hyperplasia: sharply delineated, ochre-coloured, non-encapsulated, nodulated lesion with star-shaped radiating septa

▶ **Histology:** Hepatocytes are rich in glycogen. There is no lobular structure, since portal fields and central veins are absent. However, there are Kupffer cells as well as sinusoids with varying dilatations. Numerous bile-duct proliferations are found, particularly within the connective tissue septa. These findings may lead to *misdiagnosing* "cholangiocarcinoma in cirrhosis", since numerous, sometimes chaotic, blood vessels are present. Connective tissue bands originating from a *central scar* and directed towards the periphery contain biliary tract elements, numerous arteries and veins as well as infiltrates and occasional epithelioid cell granulomas. Thick-walled blood vessels sometimes show mucoid media degenerations. These *hypervascular septa* cut off parenchymal areas of varying sizes and form pseudoacini. The result is a wheelspoke-like structure and the clinical picture of *pseudocirrhosis*. (34, 40, 48) (s. fig. 29.13!)

**Diagnosis:** When FNH reaches a certain size (7−10 cm or more), upper abdominal pain upon pressure, displacement effects and hepatomegaly occur, i.e. FNH remains asymptomatic for a long period of time. Laboratory parameters are normal. Cholestasis is a rare finding. • **Sonography** shows a hypoechoic image corresponding to that of the liver. Occasionally, it is possible to identify a fibrous *"vascular star"* together with vessels in a radial or circular arrangement similar to a *"wheelspoke pattern"*. This is clearly visualized by colour Doppler sonography. (32, 42, 44, 46, 56) (s. figs. 6.14; 36.2) **CT** usually shows a hypodense tumour with smooth boundaries and short, inhomogeneous, massive enhancement during the arterial phase (12−25 sec), with contrast adaptation to the neighbouring parenchyma occurring after 45−120 sec. There may also be signs of the central scar. Spiral CT increases diagnostic accuracy. (34, 35, 37, 57) (s. fig. 36.3) • Following administration of Gd-DTPA, **MRI** yields similar results to CT. The fibrous vascular star appears hyperdense ($T_2$). (42) • Due to the phagocytosis capacity of the RES, **scintigraphy** shows storage of colloids (in 70% of cases), whereby enhanced storage is considered to be pathognomonic. Some 30% remain "cold" due to increasing weakness of the RES. By means of functional scintigraphy, it is possible to detect hypervascularization as well as (mild to
***Fig. 36.2:*** Colour-encoded Doppler sonography of FNH with wheelspoke structure (s. fig. 6.14!)

***Fig. 36.3:*** CT in the portal venous phase: FNH with star-shaped scar

normal) enhancement during the parenchymal phase and retarded excretion (= trapping) as a result of rarefied bile ducts, showing that the remaining liver tissue has long been freed of $^{99m}$Tc IDA (= afterstorage). Sensitivity is 87%, specificity is 100%. • **Angiography** displays early central hypervascularization with rapid centrifugal filling of the tortuous, wheelspoke-like arrangement of arteries and delayed venous visualization. • Clear differentiation, for instance from HCC, is often impossible when using imaging procedures. An unclear diagnosis calls for **laparoscopy** (10, 11), possibly with refined forceps biopsy or fine-needle biopsy. (53) • Thick-needle biopsy is contraindicated due to the risk of bleeding (and especially since FNH does not require histological examination as a rule).

**Complications:** In 10% of cases, there is a potential risk of vein obstruction (51) or bleeding. Occasionally, portal hypertension develops, in some cases with pulmonary hypertension. Spontaneous regression has been reported. (49) • Malignant degeneration is extremely rare.

**Treatment:** Monitoring by imaging procedures suffices in the first instance. A marked increase in size and particularly haemorrhage or rupture are indications for embolization or surgery. (36, 38, 45)

## 4.3 Nodular regenerative hyperplasia

> ► The first description was given in 1953 by S. RANSTRÖM, who called this condition "miliary hepatocellular adenomatosis". The term "nodular regenerative hyperplasia" (NRH) was introduced by P. E. STEINER in 1959.

In NRH, the liver is interspersed with numerous diffuse nodes, which are $1-3$ mm in size (occasionally up to 3 cm) and yellow to yellowish brown in colour with blurred boundaries; they consist of hyperplastic hepatocytes. No fibroses or perinodal connective tissue septa are evident. The multilayered, disordered trabeculae do not have a lobular structure. (66, 69) CD $8^+$ cytotoxic T cells infiltrate the acinus. The nodes lack central veins and bile duct proliferations. The internodular parenchyma becomes atrophied due to pressure. It is possible by means of reticulin staining to demonstrate the nodes with the irregular trabeculae, whereas the altered vessels are best shown using elastica staining. The liver surface is smooth. (78) In the course of disease, presinusoidal, and later sinusoidal, portal hypertension with hepatosplenomegaly and oesophageal varices are usually observed. (64, 65, 67) (s. fig. 36.4)

***Fig. 36.4:*** Macroregenerative nodes in liver cirrhosis with Budd-Chiari syndrome

Men and women are affected with the same frequency at almost any age. Familial forms have been described. (63) There is an association with polyarthritis, coeliac disease (58), PSC, PBC (61), sarcoidosis, Budd-Chiari syndrome, and collagenoses or myeloproliferative diseases. A connection with thorotrast (59), immunosuppressives, cytostatics and contraceptives or androgens as

well as with antirheumatics, arsenic, vinyl chloride and the so-called "toxic oil syndrome" is also postulated. • As a pathogenetic factor, disturbance of the microcirculation is discussed: reduced blood perfusion can lead to atrophy of the ischaemic acini with subsequent stimulation of hyperperfused areas, resulting in nodular hyperplasia. (9, 41) • Occasionally, transaminases, AP and γ-GT are increased. With the help of sonography, it is possible to find an inhomogeneous reflex pattern in the case of larger nodules. CT may show hypodense lesions with peripheral-central enhancement of the contrast medium. Imaging techniques can misjudge the NRH as a micronodular cirrhosis. (62, 68) Diagnosis is confirmed by laparoscopy (60) with forceps biopsy or 2 (−3) large biopsy specimens. (10, 11) • As a rule, NHR progresses slowly and has at least one stationary stage. However, ALF has been reported in four patients. • *Therapy* consists of treating portal hypertension (TIPS or surgical shunt); liver transplantation may be indicated. (64)

▶ **Partial nodular transformation:** This form is characterized by morphological changes similar to those observed in NRH, but with only partial liver involvement. (67) Formation of nodes is limited to the area where the larger vessels begin, i. e. perihilar region. The pale nodes may reach a size of up to 4 cm. Haemorrhage and necrosis may occur in larger nodes.

## 4.4 Haemangioma

**Epidemiology and aetiology:** F. Th. Frerichs described a haemangioma for the first time in 1861. • With a frequency of 2−8% and an incidence of 800/100,000 inhabitants/year, it is the most common benign tumour of the liver and is about 40 (−100) times more frequent than adenoma. It occurs in all ages, but is observed slightly more often in women than in men. There is no association with the intake of oestrogen or progesterone, although a higher frequency has been recorded in multiparous women. Puberty, pregnancy and oestrogens may cause an increase in tumour size. The aetiology is unknown. Haemangiomas have also been detected in children (81, 91); this finding suggests that these tumours are true neoformations. There is no known malignant degenerative tendency. Haemangiomas may become thrombosed, fibrosed or calcified.

▶ **Histology:** Due to vascular malformation, thin-walled spaces, which are filled with blood and lined with endothelium, develop; they are separated by septa. The blood is thrombosed or the thrombus becomes organized. The surrounding liver parenchyma is unchanged. (s. fig. 36.5)

**Morphology:** Haemangiomas appear in solitary or (in some 20−30% of cases) multiple form. (83) They are usually located beneath the liver capsule and are clearly differentiated from the parenchyma by a pseudocapsule. Their usual size is 1−4 cm and they are found in both liver lobes, apparently with a higher frequency in the left lobe. It is worth mentioning that the haemangiomas

***Fig. 36.5:*** Cavernous haemangioma: thin-walled spaces lined with endothelium, partially septated, filled with blood. The surrounding parenchyma appears to be unchanged (HE)

***Fig. 36.6:*** Grape-shaped, multi-chambered, livid bluish haemangioma (right liver lobe)

***Fig. 36.7:*** Giant (larger than a fist) cavernous haemangioma with a smooth surface in the left liver lobe. Numerous blood vessels and peliosis-like livid blue foci of up to 0.5 cm in size in the capsule area

situated in the right lobe are predominantly found in the usual percutaneous biopsy area (which needs to be taken into account in prepuncture sonography). Haemangiomas continue to grow due to enlargement of the respective cavernous spaces. *Laparoscopically*, haemangiomas appear as bluish red or crimson red structures, sometimes tuberous, usually protruding slightly beyond the liver capsule; a multi-chambered structure is visible in most cases. (s. fig. 36.6, 36.7) • More rarely (about 7%), voluminous tumours, which may spread over the whole liver lobe, develop (so-called *giant haemangioma:* in excess of > 10 cm). (73, 74, 77, 82, 84, 85, 92) Up to now, only about 20 cases involving *giant pedunculated forms* have been observed.

**Diagnosis:** Haemangiomas are usually asymptomatic and, as a rule, discovered incidentally. Having reached a particular size, however, they may cause upper abdominal pain, nausea and inappetence. Acute pain results from bleeding in the tumour, thrombosis or rupture. Palpation may suggest hepatomegaly or an unusual kind of resistance. • Laboratory values are within the normal range. Thrombopenia and/or a reduction in fibrinogen may be present in thrombosis. (75, 80, 87, 94)

**Sonography** shows a hyperechoic structure (60−70%) with smooth boundaries, but no hypoechoic margin or sound shadow (so-called *white tumour*). There may be an efferent and an afferent vessel. As the size of the haemangioma increases, thrombosis develops, while connective tissue organisation and regressive liquefaction become evident. Inhomogeneous and irregular internal structures result from this, making diagnostic classification difficult. Sensitivity is about 80%. (75, 79, 95) (s. fig. 6.15) • **Computer tomography** shows a hypodense tumour. After intravenous bolus contrast-medium injection, enhancement increases in a peripheral-central direction followed by a focal globular contrast and subsequently a rapid reduction of the contrast-rich zone *("iris diaphragm phenomenon")*; this occurs in ca. 60% of cases. The haemangioma becomes isodense with the liver parenchyma. The isodense phase may last up to 90 minutes. The sensitivity of this examination is about 90%. (90) (s. figs. 8.5, 8.9) • **MRI** displays a low-signal $T_1$ time and pronounced hyperintensity in the $T_2$-weighted picture with well-defined margins, which means that even haemangiomas smaller than 1.0 cm can be detected. The *"cotton wool sign"* is followed by *"light bulb sign"*. The heterogeneous structure points to thrombosis, fibrosis, etc. Both the specificity and sensitivity of MRI are 85−95%. (72, 95) (s. figs. 8.7; 36.8 a−c)

In the blood pool scintigram (Tc$^{99m}$-marked autologous erythrocytes), **scintigraphy** shows the pathognomonically useful filling-in phenomenon. Activity enhancement increases from the periphery towards the centre and is detectable for several hours. By contrast, the haemangioma remains negative both in static as well as in liver-function scintigraphy; this is because the haem-

***Fig. 36.8:*** a) Adenoma (↑), with additional haemangioma (a−c = the same female patient)

b) Haemangioma (⇑) in MRI: $T_1$-weighted axial (portovenous) ("cotton wool sign")

c) Haemangioma (⇑): $T_2$-weighted ("light bulb sign"), with fat suppression

angioma possesses neither hepatocytes nor RES cells. (70, 72, 79, 86) • **Fine-needle biopsy** (78) is occasionally favoured. *We consider any percutaneous biopsy, particularly thick-needle biopsy, to be contraindicated because of the risk of bleeding (it is also of little help from a diagnostic viewpoint, especially since better diagnostic tools are available); moreover, we feel that there is no justification in using exploratory laparotomy for diagnostic purposes.* • In order to obtain a definitive diagnosis, **exploratory laparoscopy** is the method of choice, particularly since haemangiomas are usually situated in the subcapsular area, which means that a *"split-second visual diagnosis"* is possible ("one-second biopsy" is not indicated!). (10, 11) (s. figs. 36.3, 36.4)

**Complications:** Blunt abdominal trauma increases the risk of rupture, which can also occur spontaneously. The mortality rate is 60−80%. (71) Large shunt volumes may give rise to the development of cardiac insufficiency, particularly during childhood. The development of portal hypertension has also been observed. (92) Anaemia, thrombopenia and hypofibrinogenaemia may occur due to the haemangioma-thrombocytopathy syndrome (= *Kasabach-Merritt syndrome*). (82)

**Treatment:** A ruptured haemangioma requires immediate surgical intervention; it is often necessary to ligate the hepatic artery. Enucleation is sometimes possible. (76, 87) Resection or arterial embolization are recommended for very large and symptomatic haemangiomas. Inoperable tumours should be reduced in size by external irradiation or interferon-α therapy. Liver transplantation is a rare indication. (88, 89, 93) • All in all, prognosis is good. (94)

## 4.5 Infantile haemangioendothelioma

This benign infantile tumour is of embryonic origin and usually diagnosed within the first months of life, whereby girls are twice as often affected as boys. In most cases, capillary haemangiomas of the skin and mucosa as well as of other organs are also in evidence. Cardiac and vascular malformations are likewise often found.

▶ **Morphology:** Haemangioendotheliomas appear in solitary or (seldom) multiple form and may reach a size of some 15 cm. The unencapsulated tumour foci have blurred boundaries. They are sponge-like and reddish brown in colour, but may become firm and grey in bigger tumours. Vascular segments of differing width are connected with each other and embedded in loose, cell-rich mesenchyma. • Two **histological types** can be differentiated: *type I* is characterized by a layer of cuboid endothelial cells, while *type II* shows papillary proliferations and several layers of pleomorphic cells (which are similar to those found in angiosarcoma). • Malignant degeneration of the haemangioendothelioma is possible. (97)

**Diagnosis:** Hepatomegaly and an occasional systolic vascular murmur above the tumour are clinically detectable. Patients suffer from anorexia, vomiting, weight loss and lethargy. Laboratory investigation often reveals thrombopenia, haemolytic jaundice and anaemia. Dis-

seminated intravascular coagulopathy (= *Kasabach-Merrit syndrome*) can occur. Signs of cardiac insufficiency are present at an early stage due to arteriovenous shunts with cardiac volume overload. Acute pain is a sign of haemorrhage in the tumour or of a ruptured tumour. Diagnosis is established by imaging techniques; angiography has been widely replaced by colour Doppler sonography or angio-MR. Occasionally, laparoscopy has also been used. (96, 98−102)

**Treatment:** If it is possible, elective resection is indicated. (98) However, due to cardiac or (increasing) hepatic insufficiency, invasive techniques cannot usually be attempted. External irradiation may be used in an effort to minimize the tumour. Ligature or embolization of the afferent hepatic artery is sometimes indicated. Steroid therapy has proved unsuccessful. The use of interferon-α is a new therapeutic approach: tumour regression is accelerated and cardiac insufficiency is compensated. (103) Liver transplantations have also been carried out successfully. • This infantile, benign tumour may regress with increasing age.

## 4.6 Fat-containing tumours

**Focal fatty changes:** Circumscribed fatty foci ("yellow spots") were seen relatively often during laparoscopy in the past. (14) We ourselves also observed them on many occasions. (s. fig. 31.6) • Sonography and CT have shown these rare benign foci to be more frequent than previously supposed. They may occur in focal or segmental form. (s. figs. 8.3, 8.4)

**Lipoma:** Hepatic lipoma is very rare. Research of the literature shows that S. Young was the first to publish a documented observation of this tumour in 1951. Although lipomas grow slowly, they may reach a considerable size. They consist of fatty tissue (adipocytes) with a lobular structure; according to (rare) observations made to date, there is no capsule. The lipoma is hyperechoic, which usually makes it easily identifiable by sonography and CT. There is no evidence of vascularization and no tendency towards malignant degeneration. Larger lipomas should be removed surgically, particularly when they have become symptomatic. (104, 105)

**Myelolipoma:** This rare type of mesenchymal tumour, which contains adipocytes and blood-forming tissue, can grow to an enormous size (e. g. 26 x 16 x 12 cm). When reaching a certain diameter in a specific location, it usually becomes symptomatic. It has a yellowish colour and contains fatty tissue as well as myeloid elements. Due to its echogenicity, the presence of this benign focus can be demonstrated by sonography and CT. Angiography shows a tumour that is usually avascular. Large or symptomatic tumours require surgical treatment. • Definitive diagnosis of these forms of fat-containing tumours is provided by biopsy, with thick-needle biopsy being the most reliable technique. (106, 107)

**Angiolipoma:** This benign mesenchymal tumour consists of fatty cells and numerous blood vessels, which have a tendency to thrombose. In general, angiolipomas occur singly in both liver lobes.

**Angiomyolipoma:** The first observation of an angiomyolipoma was reported by K. G. Ishak in 1976. Up to now, about 100 cases have been published. Owing to its fat content, this benign tumour also has a yellowish-red colour. The largest tumour reported to date was 36 cm in diameter. Women are mainly affected. (116, 118) The right liver lobe is the preferred location. Fatty cells, blood vessels and smooth muscle cells can be demonstrated histologically. The vessels may be thick-walled and are usually arranged in an island-like configuration. The tumour appears as a hyperechoic focus in sonography and as a hypodense focus in CT and MRI. (108, 117, 120, 122, 123) Hypervascularity is observed in arteriography. Multiple angiomyolipomas have been reported (121), occasionally also in kidneys and lungs. (112) The occurrence of spontaneous rupture (114) or disseminated intravascular coagulopathy was reported as a rare complication. Due to their vascular richness, diagnostic evidence of angiolipomas and angiomyolipomas should be obtained by fine-needle biopsy (110, 117), possibly together with immunohistochemistry. Malignant degeneration has not yet been observed. (109, 111–113, 115, 116, 119)

## 4.7 Chondroma

To date, there has only been one single observation of a chondroma. (124) This tumour was excessively large (19 x 15 x 9.5 cm); it was hypervascularized, had a multilobular structure and did not possess a capsule. Focal calcifications were detectable. Chondrocyte-like cells and a chondroid matrix were found. Such a tumour can be visualized by imaging procedures. Laparoscopically, a hard, nodular surface is detectable. Diagnosis can only be confirmed histologically.

## 4.8 Leiomyoma

Up to now, only very few cases have been described. These tumours also become symptomatic once they have acquired a certain size and may grow to reach excessive proportions in the liver (e. g. 19.5 x 12 x 12 cm). (125)

## 4.9 Schwannoma

Schwannoma (neurinoma) is a benign tumour originating from Schwann cells. It is very rare. (126) Recently, a schwannoma of the bile duct causing obstructive jaundice was reported. (127)

## 4.10 Glomangioma

Glomus organs are small a. v. anastomoses for thermoregulation of the extremities. Glomangiomas are therefore most frequently located in the toes and fingers. However, they are also found in the respiratory and gastrointestinal as well as in the genital organs. A glomangioma as a benign solitary tumour in the liver was recently reported for the first time. This smooth, well-defined subcapsular lesion could be clarified histologically with the help of imaging-guided biopsy and later on confirmed by evaluation of the surgically excised tumour. (128) • Malignant transformation of glomangioma is possible.

## 4.11 Mesenchymal hamartoma

> ► R. Maresch described hamartoma as a cystic tumour structure in 1903; it was termed mesenchymal hamartoma by H. A. Edmondson in 1956.

This benign tumour is caused by faulty tissue composition of certain organs, including the liver. The tumour is predominantly found in the right liver lobe; it grows rapidly and progressively. This type of cystic tumour is mainly observed within the first year of life. Boys are more often affected than girls. In adults, mesenchymal hamartoma is very rare. Pre-existing composition disorders of the liver tissue can be stimulated into growth by steroids. Hamartomas remain asymptomatic until attainment of a certain size results in compressional or displacement phenomena. In their interior, they contain cysts filled with a yellowish, gelatinous substance. The stroma presumably derives from the connective tissue of the portal fields, from which the hamartoma may also originate. Malignant degeneration has been reported. Due to its tendency to grow, early surgical removal of the tumour is indicated. (129–131)

## 4.12 Mesothelioma

Mesotheliomas of the liver are extremely rare. They consist of parallel bundles of collagenous and reticular fibres as well as fibroplastic and epithelial cells. (132) The reported observation of a hepatic mesothelioma weighing some 2,800 g remains a rarity. (133)

## 4.13 Fibrous tumour

A solitary fibrous tumour was first described in pleural tissue by P. Klemperer et al. in 1931. Meanwhile, this rare entity has been reported in various organs, with the liver being affected in 26 cases. The tumour shows cellular areas (consisting of bundles of spindle cells arrayed haphazardly or in a storiform pattern) and relatively acellular areas (containing abundant collagen bundles). There is evidence of cellular atypia, mitotic activity and ectatic vessels. This tumour possesses malignant potential with the ability to metastazise. (134)

## 4.14 Cysts

Liver cysts can occur in solitary or in multiple form. They may be congenital or acquired. The reported frequency

varies between 1% and 20%. The cysts are lined with a layer of cuboid cells and mostly filled with fluid. They are usually detected by chance. When cysts compress bile ducts or vessels, they become symptomatic. (136) • In *sonography*, the cyst appears as an anechoic (black) space with well-defined margins and distal sound amplification. (s. fig. 6.10) Haemorrhage into the cyst cavity and debris can mimic a cystadenoma or even cystadenocarcinoma. The presence of septa suggests a neoplastic cyst. (136) • In *computer tomography*, their content can generally be determined at +0 to +15 Houndsfield units. The i.v. administration of a contrast medium shows no evidence of enhancement. (s. figs. 8.6; 36.9) • Cysts are easily detected by *magnetic resonance imaging* ($T_1$ image = dark; $T_2$ image = light with high signal intensity). *Laparoscopy* provides a very impressive view of cysts. (s. figs. 36.10, 36.11)

*Fig. 36.11:* Giant (fist-sized) solitary cyst in the right liver lobe

*Fig. 36.9:* CT with contrast medium: solitary liver cyst. (s. figs. 8.6; 36.7)

*Fig. 36.10:* Multiple cysts with several chambers in the area of the right liver lobe

Four **types of cysts** can be differentiated: (*1.*) dysontogenetic cysts, (*2.*) parasitic (or infectious) cysts, (*3.*) neoplastic cysts and (*4.*) post-traumatic cysts. The cause of cystic neoplasms is unknown. Traumatic cysts (C. WHIPPLE, 1898) occur from an injured intrahepatic bile duct after blunt abdominal trauma. (136)

▶ **Treatment:** *Asymptomatic cysts* do not require treatment; large cysts which might rupture are an exception. • *Symptomatic cysts* (usually > 5 cm) are generally sclerosed. Reliable sclerotherapeutic agents include aethoxysclerol (1%), alcohol (95%) (146), minocycline hydrochloride (135, 150), tetracycline hydrochloride (1 g), and sodium chloride solution (10%). The sclerosing procedure is successful and low in side effects. Percutaneous aspiration of the cysts has a high relapse rate. Sclerotherapy does not prevent relapse, since a sclerotherapeutic agent destroys the cells, but not the cyst walls. Parasitic cysts require specific therapeutic measures. • Under laparoscopy, cysts which prove to be problematic may be treated reliably by fenestration (T. Y. LIN et al., 1968). (137) Surgical procedures (e.g. cyst excision, resection, cystjejunostomy, cystenterostomy) are rarely indicated and involve a much higher risk. (136, 141, 148)

### 4.14.1 Polycystic liver disease

The incidence is 1:500 to 1:5,000 births/100,000/per year. The gene responsible is located on chromosome 16; often another gene located on chromosome 4 is also involved. This autosomal dominant polycystic disease of the liver and kidneys can occur in (*1.*) children and (*2.*) adults (♂ : ♀ = 1 : 5). The intrahepatic bile ducts are widely dilated and lined with bile-duct epithelium. Each liver segment may be interspersed by cysts of varying sizes which are connected with the biliary duct system. The cysts are surrounded by a fibrous capsule. Both the number and size of the cysts increase in later life. Usually, polycystic degeneration of the kidneys also occurs. (136, 149) (s. fig. 8.6) Pancreatic cysts or colonic diverticulosis are less frequent. Occasionally, the cysts cover the liver in a balloon-like manner. (s. fig. 36.12) Rupture of large cysts may give rise to the clinical picture of acute abdomen. Compression leads to portal hypertension,
jaundice (139), cholestasis and leg oedema. • Renal insufficiency is also a dangerous complication.

Fig. 36.12: Polycystic liver with spheroid, balloon-like cysts in the right liver lobe

▶ **Treatment** may be by laparoscopic or surgical fenestration (137, 138, 140, 142−145), injection of alcohol (40%) (146) or minocycline hydrochloride (135, 150), as well as surgical management. (141) Liver transplantation is a rare indication. (147)

### 4.14.2 Parasitic cysts

The cysts of Echinococcus granulosus (cysticus) (s. figs. 25.16, 25.17, 25.19) and Echinococcus multilocularis (alveolaris) (s. fig. 25.21) are of particular clinical importance. *(see chapter 25.2.3)*

## 4.15 Cholangiocellular tumours

### 4.15.1 Caroli's disease/syndrome

▶ This congenital clinical picture was first described in the form of intrahepatic stones by H.R. VACHELL et al. in 1906. • Later on, in 1958 J. CAROLI et al. were able to establish the association between characteristic congenital bile-duct alterations, cholangitis, cholangiolithiasis and renal cyst formation. In 1964, J. CAROLI et al. differentiated a particular form with simultaneous congenital liver fibrosis (which had already been described by D.V.S. KERR et al. in 1961). Both forms are autosomal recessive.

**Caroli's disease** is characterized by congenital, segmental dilatation of the intrahepatic bile ducts, causing bile sludge formation and the development of gallstones. Clinical findings include hepatomegaly, cholestasis and subicterus as well as cholangitis with upper abdominal pain and biochemical signs of inflammation. (152, 154) (s. tab. 38.2) Diagnosis is by CT (151, 153) (s. pp 174, 662), hepatic arterial Doppler sonography (153) and ERC. (s. fig. 36.13)

Fig. 36.13: ERC findings in Caroli's disease: mainly segmental, sack-like dilatations of the intrahepatic bile ducts with some small-diameter connections to the efferent bile ducts

**Caroli's syndrome** is characterized by the additional occurrence of congenital liver fibrosis. Occasionally, fibroangiomatosis of the bile ducts is observed and microcysts are present in the kidneys. This condition may also lead to portal (presinusoidal) hypertension. • Choledochal cysts, polycystic degeneration of the liver and kidneys, Laurence-Moon-Biedl syndrome and ectasia of the renal tubules have also been associated with Caroli's syndrome. • Apart from cholangitis and hepatolithiasis, potential complications include liver abscess, pancreatitis, amyloidosis, malignant tumours and liver failure. • *Treatment* consists of biliary drainage, antibiotics, surgical procedures and liver transplantation. Ursodeoxycholic acid may be used as an adjuvant.

### 4.15.2 Hepatobiliary cystadenoma

This rare benign tumour probably develops from congenital bile-duct malformations. It is found mostly in women (>90%), mainly after the age of 45−50 years. The tumour grows very slowly, yet can reach a considerable size (5−25 cm). Cystadenomas occur as solitary, but multilobular cystic tumours. The cysts are frequently separated by septa. The *mucous type* consists of a mucous/gelatinous, bile-coloured fluid, often containing old blood. Occasionally, a *serous type* of cystadenoma without mesenchymal stroma is found. There is evidence of ovary-like stroma together with unilaminar bile epithelium, which is folded in a polyploid or papillary manner in places. (155) (s. fig. 36.14) The collagenic capsule is rich in vessels. Surrounding the tumour, numerous abnormal bile ducts and arterial vascular clusters are evident. • Cholestasis or even obstructive jaundice develops. (156) Diagnosis of this cystic lesion (mainly in the right lobe) is by imaging techniques. Differential diagnosis may be extremely difficult (and is often only possible by means of surgery). • Due to the tendency of

cystadenoma towards malignant degeneration, resection should be carried out as soon as possible. (157−160)

**Fig. 36.14:** Hepatobiliary cystadenoma with ovary-like stroma (HE)

**Bile-duct adenomas** are rare. Usually, they are solitary and <2 cm in size. This type of adenoma is more often detected in men than in women (3:1) and it occurs in patients mainly over the age of 50. It is nearly always localized beneath the liver capsule. This adenoma has the form of a firm, whitish node and consists of bile-duct proliferations. It contains biliary acini and tubules which are lined with a layer of cuboid epithelium within loose fibrous, partially hyaline stroma. There is evidence of mononuclear inflammatory cells and, occasionally, lymph follicles. It is discussed that such biliary adenomas are peribiliary gland hamartomas. (162) There are no clinical or biochemical abnormalities, nor is there any tendency towards malignant degeneration. (161, 163)

**Bile-duct papillomatosis** is another very rare finding (up to now about 50 cases have been reported) which occurs mainly in elderly women. There are papillomatous proliferations in both intrahepatic and extrahepatic bile ducts. Clinically, it is characterized by recurrent episodes of jaundice and cholestasis as well as ascending cholangitis and haemobilia. The bile ducts can be dilated; their wall surface is irregular. The course of disease is progredient; the prognosis is poor. Recently, encouraging results have been reported following intraluminal iridium[192] therapy (165) and liver transplantation (164). Malignant degeneration into cholangiocarcinoma is possible.

### 4.15.3 Biliary hamartoma

Benign biliary microhamartomas (= *Meyenburg's complex*) were described by H. von MEYENBURG in 1918. They consist of small cysts developing from dilatations of the small (interlobular) bile ducts and are surrounded by fibrous stroma. The cysts are remnants of ductal plate malformations. Occasionally, typical ductal plates can also be detected. The hamartomas can reach a diameter of up to 0.5 (−1.0) cm. (s. fig. 32.18) Macroscopically,

they appear as firm, greyish-white nodules which are clearly delineated from the liver parenchyma. Subcapsular nodules may also be detected by laparoscopy. (168) They are sometimes misinterpreted as small metastases. Here, MRI is of great diagnostic value. (167) • Microhamartomas are often associated with malformations of the small branches of the portal veins. They may represent a transition to the autosomal dominant form of polycystic degeneration. These tumours have a tendency to develop into cholangiocarcinoma. (166−169)

### 4.16 Abscesses

Depending on their cause, liver abscesses are classified as (*1.*) pyogenic or (*2.*) parasitic. This factor largely determines differential diagnosis, diagnosis and therapy. Fresh abscesses usually have blurred margins; following consolidation, they have a round to elliptical form. Evidence of gas bubbles is seen as pathognomonic. The abscesses are generally hypoechoic and hypodense. *(see chapter 27!)*

### 4.17 Hepatic lymphangioma

This rare, congenital benign tumour consists of multiple, small (1−4 mm in diameter) dilations of intrahepatic lymph vessels, which communicate with each other. They contain chylous fluid. Mostly, there are lymphangiomas in other organs as well. (170)

### 4.18 Peliosis hepatis

Peliosis hepatis may be caused by various kinds of medication (173) or chemical agents and is associated with numerous diseases (of a viral, bacterial, parasitic or metabolic nature). Its aetiopathogenesis is unknown. It has also been detected in small children. (172, 174) *Histologically*, there are spaces lined with endothelium corresponding to dilated sinusoids and Disse's spaces. They are filled with blood (so-called "globoid bleeding"). Their size varies from 0.5−2.0 mm and can even reach >1 cm. The hepatocytes and venules are unchanged. (s. p. 398!) (s. figs. 21.8; 36.15)

**Fig. 36.15:** Peliosis hepatis: non-endothelialized cavernous blood-filled cavities surrounded by hepatocellular trabeculae (s. fig. 21.8)

*Clinical findings* include fever, abdominal pain and hepatomegaly. *Laboratory values* reveal occasional subicterus and elevated transaminases. (172) *Imaging procedures* often yield no findings or merely uncharacteristic changes. (171) Definitive results are obtained by *laparoscopy* (175): characteristic foci of a livid-reddish to dark-blue colour are found, mostly rounded and subcapsular, often with net-like confluence. The findings are so typical and distinctive that histological examination is no longer necessary; however, biopsy may be justified under visual control. The most important *complications* are haemorrhages and, especially following trauma, rupture of the liver capsule with bleeding into the abdominal cavity. (171, 172)

## 4.19 Granulomas

It is generally not possible to detect granulomas by means of imaging procedures. When the foci are densely grouped, it is possible to see an inhomogeneous reflex pattern during sonography and a variable pattern in the CT scan. The causes are manifold and vary greatly. (s. tab. 21.1) • Diagnosis is facilitated by laparoscopy and forceps biopsy, provided the foci are located on the surface (which is mostly the case). If the surface is free of foci, multiple biopsies from both liver lobes done under laparoscopy generally yield reliable results. (s. p. 398) (s. figs. 21.9, 21.10; 24.14; 29.6; 38.5)

### 4.19.1 Sarcoidosis

▶ A cutaneous form of sarcoidosis ("Mortimer's disease"), first described by A. Hutchinson in 1877, was observed in further courses of disease by E. Besnier ("lupus pernio") and C.P. Moeller-Boeck ("sarcoidosis", "miliary lupoid") in 1899. In 1917 these single findings were synthesized by J. Schaumann. Various terms, such as Besnier-Boeck-Schaumann disease, benign lymphogranulomatosis or Boeck's disease, have been used in the past to describe this condition. However, the term sarcoidosis has gained more and more acceptance.

Sarcoidosis is a primary multisystemic, granulomatous disease of (still) unknown aetiology with enhanced immunity at the site of manifestation. The lungs and the intrathoracic lymph nodes are nearly always affected. In many cases, the extrathoracic organs are involved as well. Sarcoidosis is characterized by the presence of epithelioid cell granulomas, which do not show caseous changes.

**Frequency:** Men and women are affected with the same frequency. Manifestation mainly occurs between the ages of 20 to 40, predominantly in winter. The incidence is highest in Scandinavian countries, the USA and Japan (always with considerable regional variations) at 5−40/100,000 inhabitants/year.

**Localization:** Based on X-ray findings, *intrathoracic sarcoidosis* can be divided into four stages: 0, I−III. • The *extrathoracic manifestation* of sarcoidosis affects the lymphatic system and bone marrow as well as the bones, skin, eyes, lacrimal and salivary glands, urogenital system, musculature, nervous system and endocrine glands. Extrathoracic manifestations without radiologically demonstrated thoracic findings are rare. At least two organs must exhibit granulomas to substantiate the diagnosis of sarcoidosis.

**Aetiopathogenesis:** For a long time, mycobacteria were already considered to be the cause of sarcoidosis. Recently, this hypothesis was reinforced when *mycobacterial DNA* and *RNA* were found in sarcoidosis tissue (H. H. Popper et al., 1994) and the presence of *acid-fast L forms* was detected in patients' blood (P. L. Almenoff et al., 1996).

▶ Since 1964, our study group, consisting of L. Mandi et al. (Debrecen/Hungary) and E. Kuntz, has been intensively involved in investigating the striking regional differences in sarcoidosis. We postulated an immune reaction − with a genetic disposition − against a mycobacterial substrate. • Among other things, we found **Ziehl-Neelsen positivity** of pollen obtained from numerous trees and plants. A high correspondence of sarcoidosis frequency with certain ZN-positive pollen locations became obvious as we catalogued our findings. This might also explain familial aggregation as a result of similar exogenous exposure. • **Injection** of ZN-positive pollen, embedded in paraffin, into the testicles of guinea pigs resulted in the *dissemination* of histological findings fully corresponding to sarcoidosis. By contrast, ZN-negative pollen did not elicit this reaction in animal experiments.

**Liver:** The liver is involved in sarcoidosis in 60−80% of cases. Initially, loosely concentrated *epithelioid cells* are found which combine to form small *epithelioid granulomas* mainly in the portal and periportal area. These small granulomas may join together and form conglomerates up to the size of lentils. Within the epithelioid cell granulomas, there is evidence of one or more *Langhans' giant cells*, which are rich in the angiotensin-converting enzyme. Epithelioid cells and giant cells release $\alpha_1$-antitrypsin and lysozymes as well as other substances; epithelioid cells also release interleukin-I. Within the giant cells (displaying a rosette-like arrangement of nuclei), *asteroid bodies* (5−20 μm) resembling a sea anemone are often found. Moreover, there is evidence of *Schaumann bodies* (25−200 μm) (more frequently in lymph nodes than in the liver) and small *vesicles*. • Inflammatory *cellulation* is low: it consists of eosinophils, T lymphocytes (CD4$^+$) and plasma cells. Granulomas may increase in size, but may also heal by way of fibrosis. • Chronic cholestasis (ductopenia, cholate stasis, copper storage) as well as the histological picture of PBC (or less frequently of PSC) can be found in 50−60% of cases. (quot: 179) • *This would suggest a connection with the mycotoxin theory of PBC (E. Kuntz, 1984), whereby molecular mimicry (M. E. Gershwin, 1991) is of potentially pathoge-*

*netic significance in sarcoidosis as well*. (s. p. 643) • Pronounced fibrosis leads to *portal hypertension*. Formation of *NRH* was evident in 9% and *cirrhosis* in 6% of cases.

**Clinical findings:** Usually, there are no subjective complaints. As the lungs become increasingly affected, fatigue and (exercise-related) dyspnoea may occur. Extrathoracic manifestations can cause corresponding symptoms. Hepato(spleno)megaly is observed in 5−10% of cases. In an acute stage, polyarthralgia, erythema nodosum and fever are generally found. Kveim's test is positive, while the BCG test is clearly reduced or negative. (176, 177, 180, 181)

**Biochemistry:** In most cases, eosinophilia and monocytosis are present in leukopenia and lymphopenia. BSR and CRP are normal or only slightly elevated. The γ-globulins may be increased. Cholestasis is often found, whereas jaundice is rare. Hypercalcaemia is a striking feature; occasionally there is evidence of augmented ACE and lysozymes in the serum.

**Histology:** The most reliable method of obtaining the slightly prominent, whitish granulomas on the liver surface, the size of a pin-head up to a lentil (so-called *fly agaric liver*), is by *laparoscopy* and *forceps biopsy*; otherwise, *thick-needle biopsies* can be performed on suspicious areas of the right and left liver lobe. The diagnostic accuracy of this procedure is more than 98%, while that of percutaneous liver biopsy is only 30−70%. (s. figs. 21.9, 21.10) (s. p. 398) • Fibreoptic *bronchoscopy* used for taking mucosa samples also facilitates histological diagnosis.

**Imaging procedures:** Enlargement of abdominal lymph nodes can occasionally be detected by sonography, CT or MRI. (180) The liver may exhibit an inhomogeneous reflex pattern due to fibrosis.

**Treatment:** Intrathoracic sarcoidosis has a high rate of spontaneous remission with possible fibrosis residues. • Extrathoracic manifestations may cause considerable symptoms and secondary disorders, depending on the organs affected. This is also true of the liver. Treatment consists of monitored waiting and administration of glucocorticoids (usually as long-term therapy). Liver transplantation is necessary in some cases.

## 4.20 Inflammatory pseudotumour

The synonyms used for inflammatory pseudotumour include myofibroblastic inflammatory tumour, histiocytoma, pseudolymphoma, fibroxanthoma and plasma cell granuloma. This condition was first described by G. T. PACK et al. in 1953. It is a rare type of tumour (about 100 reports so far) which can occur at any age (but mainly between 30 and 40), with men being affected three times more often than women. The tumour mostly affects the liver (90%), but also numerous other organs (lung, stomach, parotis, pleura, ovaries, thyroid gland,

lacrimal glands, etc.). A tumour size of up to 25 cm has been reported. Its pathogenesis is not clear. Bacterial and viral infections (e. g. EBV) are discussed as possible trigger factors. An association with systemic inflammatory diseases, e. g. Crohn's disease (183), has been reported.

**Histology:** There are obvious fusiform cells, foamy histiocytes, plasma cells and lymphocytes, but no irregular mitosis. Extensive connective tissue may occasionally form incomplete capsular boundaries. The pseudotumour is vascularized despite the presence of numerous obliterated vessels. (185) The bile ducts exhibit inflammatory alterations. Fatty degeneration and occasional central necrosis as well as bleeding are evident. This gives rise to simulated HCC. Malignant degeneration is rare. (184) • The main symptoms include fever, epigastric pain, weight loss, elevated transaminases, inflammatory laboratory parameters, cholestasis and increased gamma globulins. (182, 185−187) Sonographically, a hypoechoic space-occupying lesion can be seen. In CT, the tumour is hypodense with a blurred margin; following CM application, it shows mild, heterogeneous and delayed enhancement. MRI displays low signal intensity in $T_1$ images and significant signal enhancement in $T_2$ images. Occasionally, a thick hyperintensive periphery is present.

**Treatment:** Spontaneous retrogression is rare. The administration of prednisolone and antibiotics has been used with controversial results. In general, there is an indication for surgical resection, which is deemed a successful method of treatment.

## 4.21 Calcareous foci

Calcareous foci in the liver are detected incidentally in X-ray or sonographic examination of the abdomen. It may be quite difficult to identify their aetiology as calcification can be observed in numerous diseases. Diagnostic clarification often has no prognostic or therapeutic implications. However, in many cases, the irrelevance of such a diagnosis can only be determined retrospectively after numerous examinations (imaging procedures, laparoscopy with targeted biopsy) have been carried out. (190, 192) Different calcified foci, such as calcified vipoma (189), calcified metastasis (s. figs. 37.24, 37.25), microlithiasis in cystic fibrosis (191) or calcification of the hepatic artery (193), are rare observations. Calcification of an echinococcus cyst is the most common type of calcareous focus. (s. fig. 25.18) (s. tab. 36.4)

A so-called **porcelain liver** should be clarified by differential diagnosis. (188) This condition is characterized by focal calcareous deposits in the liver capsule, which can be detected by X-ray examination as well as by sonography and CT. It may be caused by phleboliths, pseudolipoma, histoplasmosis, calcified larvae, small capsule haematomas, small abscesses, etc.

| Calcification of benign lesions |
|---|
| Aneurysm of the hepatic artery |
| Arteriovenous fistula |
| Calcification of the hepatic artery |
| Cavernous haemangioma |
| Echinococcus cysts (s. fig. 25.18) |
| Granulomas: histoplasmosis, brucellosis, tuberculosis |
| Gumma (hepar lobatum) |
| Haemangiomatosis |
| Haematoma |
| Haemochromatosis |
| Intrahepatic bile-duct calculus |
| Intrahepatic dislocated staghorn calculus (s. fig. 36.13) |
| Liver abscess |
| Microlithiasis in cystic fibrosis |
| Portal vein thrombosis |
| Posttraumatic cysts |

| Calcification of malignant tumours |

*Tab. 36.4:* Calcification of benign and malignant liver foci

► A case involving an **unusual calcification of tremendous size** in the right liver lobe was the subject of much speculation. It was not until laparotomy was carried out that this case was resolved (s. fig. 36.16):

*What was discovered was a **monstrous gall-bladder staghorn calculus** which had migrated to and become embedded in the liver parenchyma. In order to be removed, it had to be cut into four parts (which are well-preserved and still at our disposal). With a length of 12 cm, a diameter of 4−5 cm and a dry weight (!) of some 120 g, it may well be the largest gallstone ever reported. • Our investigations of the literature revealed a previous maximum weight of 110 g (published in 1917).* (s. p. 736, footnote\*): E. KUNTZ)

*Fig. 36.16:* Giant gall-bladder staghorn calculus, dislocated into the right liver lobe and embedded in the parenchyma. **(Probably the largest gallstone reported to date: 12 x 5 cm, 120 g dry weight)**

# 5 Surgical treatment

Most benign tumours are asymptomatic and do not require surgical intervention. A smaller group of benign liver foci are treated conservatively or require interventional treatment. • Other tumours are difficult to differentiate as either benign or malignant, or they tend towards malignant degeneration and should be removed surgically in any case. Surgery is indicated in unresolved findings, or when the tumour begins to increase in size with secondary compressional effects, or when there are any complications. Postoperative morbidity is low with negligible mortality; life expectancy and quality of life are not compromised.

1. **Ligature or embolization of the hepatic artery**
   − in acute bleeding
   − in angiomatosis with large, functionally effective arteriovenous shunts

2. **Atypical liver resection, enucleation, local tumour excision** (without liver hilus preparation)
   − method of choice and relative indication in clearly benign hepatic tumours showing symptoms and a clear increase in size of tumour (haemangioma, FNH, lipoma, *etc.*)

3. **Anatomical, segment-oriented liver resection** (including liver hilus preparation in most cases)
   − necessary in unresolved or ambiguous hepatic tumours (e.g. suspected adenoma) as absolute indication due to risk of malignancy and in complications (e.g. haemorrhage, rupture). The aim is radical removal of the tumour with a sufficient safety margin (as in malignant tumours)

4. **Partial/total vascular ligation**
   − useful additional technique for better intraoperative control of haemorrhage and haemostasis, particularly suitable for well-vascularized tumours or those close to the inferior vena cava

5. **Various modifications of in/ante/ex situ resection**
   − relatively rare techniques which may, however, be useful (with additional protection of the liver and possible autotransplantation) for improving technical resectability when the size or location of the tumour presents problems (e.g. confluence of the hepatic veins)

6. **Hepatectomy and allogenic liver transplantation**
   − exceptional techniques applied in multiple tumours, diffuse changes (e.g. haemangiomatosis) or concomitant liver diseases often of a metabolic nature (e.g. glycogenosis). Radical oncological treatment for eliminating the risk of malignant tumour development

*Tab. 36.5:* Surgical treatment options for benign hepatic tumours (according to B. RINGE et al., 1997) (197)

It is important that the *preoperative examination* is carried out meticulously and that the tumour can be adequately assessed by imaging techniques regarding its intrahepatic location, size, extent and segmental affiliation. When participation of vascular or biliary structures or involvement of extrahepatic organs is suspected, additional investigations are called for. • The *hepatological status* is determined as follows: enzymatic and mesenchymal activities, cholestasis and jaundice, functional test values (e.g. cholinesterase, albumin, coagula-

tion status, indocyanine-green test, galactose elimination capacity). • The surgical strategy is chosen in accordance with the tumour type and any additional individual factors. Atypical resection, enucleation or excisional separation of the local tumour are considered to be less invasive and therefore less inconvenient for the patient. (194−198) (s. tab. 36.5)

# Clinical Aspects of Liver Diseases

## 37  Malignant liver tumours

# 1 Historical review

► C. A. Rokitansky (1849) was probably the first author to refer to primary liver carcinoma as an independent disease. Until then, the problem had been to accept the existence of both primary and secondary (metastatic) liver tumours and to differentiate between them histologically. • In 1854 E. Noeggerath described a congenital hepatic carcinoma as being a mechanical obstetric obstacle. In 1859 T. Billroth reported the presence of hepatic metastases from a cylindroma. A. Kelsch and B. L. Kliener presented the first case reports of a primary liver tumour in 1876. C. Sabourin (1881) made significant histological progress by differentiating between hepatocellular and cholangiocellular carcinomas. He reported on four more patients suffering from primary hepatic carcinoma and coined the term "hepatoma". J. A. P. Price (1883) described the development of carcinoma from cirrhosis, which led to the introduction of the term *"cirrhosis hepatis carcinomatosa"*. V. C. Hanot et al. (1888) attempted to differentiate liver tumours according to macroscopic and microscopic criteria. • H. Eggel (1901) confirmed the association between cirrhosis and liver carcinoma, actually finding cirrhosis in 85% of all liver carcinomas. He distinguished carcinomas according to nodular, massive or diffuse growth, evaluating all cases that had been published since 1865. (5) Primary cystadenocarcinoma of the liver was differentiated for the first time in 1909 (P. Bascho). To our knowledge, the first right-sided lobectomy for hepatic carcinoma was carried out in 1911 (W. Wendel). • In 1932 T. Yoshida succeeded in creating a hepatocellular carcinoma in animal experiments by using o-amidoazotoluol: this marks the beginning of the search for chemotoxicological causes. M. M. Steiner (1938) wrote a detailed report on primary liver carcinoma in children. (239) L. Lisa et al. (1942) observed that metastases were rarely found in a cirrhotic liver. In 1952 C. Berman presented an overview of about 2,000 cases of primary liver cell carcinoma which had been reported up to that time. • In 1950 G. M. Findlay postulated an association with chronic viral hepatitis, which he had detected in his epidemiologic examination of soldiers stationed in regions south of the Sahara desert, a finding that was also reported by M. Payet et al. in 1956. This supposition was confirmed when the hepatitis B virus was discovered (J. B. Smith et al., 1965; S. Sherlock et al., 1970). (4, 13, 151)

***Fig. 37.1:*** Grey-coloured, medium-coarse tubercular cirrhosis in haemochromatosis with hepatocellular carcinoma: in the foreground, white, flat tumour granuloma of the right hepatic lobe with vascularization at the tumour margin and small "cancer umbilicus"; in the background, two additional tumour granulomas. Carcinomas infiltrating the peritoneal serosa in the right upper abdomen

***Fig. 37.2:*** Liver metastases in the right hepatic lobe in breast cancer with pronounced chaotic vascularization. Dissipated light reflex due to tumourous tubercles on the surface

# 2 Classification

## 2.1 Systematization

**Malignant liver tumours** may be grouped as follows: (*1.*) primary forms, i. e. originating in the liver (s. figs. 29.14; 30.2; 37.1, 37.7, 37.8), (*2.*) secondary forms, i. e. arising from metastases (s. figs. 37.2, 37.16, 37.17, 37.21, 37.28−30), and (*3.*) extrahepatic tumours infiltrating the liver from the outside (e. g. gall-bladder carcinoma). (s. fig. 37.3)

**Primary liver tumours** originate in principle from all histogenetic cell elements found in the liver: hepatocytes, bile-duct epithelia, periductal biliary glands, neuroendocrine cells and mesodermal structures (such as endothelial cells, Ito cells, Kupffer cells) as well as fibroblasts,

nerve cells and muscle cells. However, they may also occur as mixed forms. In rare cases, ectopic tissue in the liver may be the starting point for malignant tumours. (s. tab. 37.1)

Primary liver tumours can be categorized according to macroscopic criteria. The solitary coarse-granulomatous type is predominantly found in the right lobe, while the nodular multi-granulomatous type is most common in cirrhosis. The diffuse infiltrative type is relatively rare
**Fig. 37.3:** Gall-bladder carcinoma subsequent to cholelithiasis with chronic cholecystitis and shrunken gall bladder. Bulbous carcinoma infiltrating the right lobe of liver

| Primary liver tumours |

**Tab. 37.1:** Systematization of primary and secondary malignant liver tumours

(5−10% of cases). A combined type is observed on occasions. The right lobe is affected seven times more frequently than the left lobe. Some 3−5% of malignant liver

tumours are of primary origin. • In contrast, 95−97% of all malignant liver tumours are assumed to be **secondary liver tumours**, so-called *liver metastases.* (s. tab. 37.1)

## 2.2 TNM staging system

In medical letters/reports, an identified tumour is (correctly) classified according to the so-called TNM staging system. In this process, unclear or even incorrect interpretations are sometimes given either due to inconsistent use of the terminology or lack of sufficient experience with this kind of classification. Thus it is appropriate to explain this system with interpretations. The anatomical spread of malignant liver tumours is also described according to the TNM staging system. It is extremely important to assess the histologically verifiable invasion of vessels in the preparation as well as to clarify the question of whether the resected tissue still contains tumourous foci. (s. tab. 37.2)

| $T$ | **Primary tumour** |
| --- | --- |
| $T_{is}$ | Preinvasive carcinoma (carcinoma in situ) |
| $T_1 - T_4$ | Size and/or local extension of the primary tumour |
| $T_1$ | Solitary node <2 cm, no vascular invasion |
| $T_2$ | Solitary node <2 cm, with vascular invasion *or* Multiple nodes, limited to one lobe, no node >2 cm, no vascular invasion *or* Solitary node >2 cm, no vascular invasion |
| $T_3$ | Solitary node >2 cm, with vascular invasion *or* Multiple nodes, limited to one lobe, each <2 cm, with vascular invasion *or* Multiple nodes, limited to one liver lobe, one node >2 cm, with or without vascular invasion |
| $T_4$ | Multiple nodes in more than one liver lobe or a tumour affecting a larger branch of the portal or hepatic vein |
| $T_x$ | Minimum requirements for determining the locus or the degree of extension of the primary tumour are not fulfilled |
| $N$ | **Regional lymph nodes** |
| $N_0$ | No regional lymph node metastases |
| $N_1$ | Homolateral lymph nodes affected |
| $N_2$ | Bilateral or contralateral lymph nodes affected, or regional lymph nodes almost grown together |
| $N_3$ | Lymph nodes grown together and/or extended |
| $N_x$ | No assessment possible |
| $M$ | **Distant metastases** |
| $M_0$ | No distant metastases |
| $M_1$ | Distant metastases |
| $M_x$ | No assessment possible |

**Tab. 37.2:** Pretherapeutic/preoperative TNM staging of malignant tumours (<u>T</u>umour/<u>N</u>odules/<u>M</u>etastases). In postoperative morphologic TNM staging, T, N and M are preceded by the letter "p"

This TNM staging system comprises the following stages with a respective survival time of 3 years after resection of HCC:

| | | | |
|---|---|---|---|
| stage I | = $T_1$ No Mo (83%) | stage IV A | $T_4$ N, Mo (10−25%) |
| stage II | = $T_2$ No Mo (70−75%) | stage IV B | T, N, $M_1$ |
| stage III A | = $T_3$ No Mo (45−50%) | | |
| stage III B | = $T_1$ $N_1$ Mo (20−40%) | | |

# 3 Hepatocellular carcinoma

## 3.1 Definition

Hepatocellular carcinoma (HCC) originates in the hepatocytes; consequently, HCC resembles liver parenchyma in morphology. It may present as highly differentiated, moderately differentiated or undifferentiated (anaplastic). The most common (and basic) structure is the trabecular localization of tumour cells around sinusoidal vessels. • Clinically, HCC is considered to be an extremely malignant, rapidly progressing form. Therapeutic measures still remain limited.

## 3.2 Epidemiology and frequency

HCC is one of the most common malignant primary liver tumours worldwide. Of all malignant tumours, it ranks fifth in frequency in men and eighth in women (♂ = 6%, ♀ = 3%). Between 500,000 and one million new cases are reported each year. The annual mortality rate is virtually the same as its annual incidence. Its **geographical distribution** varies greatly and correlates almost 100 per cent with the regional incidence rates of HBV and HCV infection. There are areas showing low incidence with < 5/100,000 inhabitants/year (e. g. Scandinavia, Australia, USA., Central Europe), moderate incidence with 5−20/100,000 inhabitants/year (e. g. East/South-East Europe, Mediterranean region) and high incidence with 20−150/100,000 inhabitants/year (e. g. Asia, Africa).

During the course of the 20th century, the statistical **frequency** of HCC rose constantly − owing to an increase in autopsies and improvements in diagnostic procedures. • In 1910, for example, autopsy records showed HCC in only 0.04% of cases; in 1930 the figure was 0.13%, in 1960 0.23%, and in 1970 0.6−0.8%. In 1986 the frequency of HCC was given at about 1% of cases based on autopsy findings. The ratio of HCC to liver metastases is about 1 : 50.

HCC affects persons of all **age groups**. In Asian and African countries, the morbidity peak is reached in adolescence or between the ages of 20 and 40 years, corresponding to predominantly perinatal or postnatal infection with hepatitis viruses. In countries with a low incidence, the morbidity peak is between the ages of 50−60 years. • HCC has also been observed in babies and infants.

The HCC **gender ratio** between men and women is about 3 : 1, but up to 8 : 1 in countries with a high incidence. In a cirrhosis-free liver, however, men and women are affected by HCC at the same rate, i. e. the gender ratio of cirrhosis seems to determine the ratio of HCC as well. Androgens are thought to be of aetiopathogenetic significance, since carcinoma cells have been shown to carry androgen receptors which display qualities favouring growth, and a carcino-protective effect was observed in animal experiments when androgen was withdrawn. Sex hormones appear to be so-called cocarcinogens. (24, 44, 48, 83)

## 3.3 Risk factors and causes

**Animal experiments:** A considerable number of chemical agents have proved to be directly carcinogenic in animal experiments. This is most likely to apply to humans as well (but as yet no supporting evidence has been presented). Both a linear dosage-effect relationship and a respective time-exposure relationship can be observed: the higher the dosage and the longer the exposure, the greater is the likelihood of carcinoma formation. Carcinomatous degeneration occurs predominantly in epithelial or mesenchymal tissues. (s. tab. 37.3)

**Azo-compounds**
1. 2,2-azonaphthalin
2. 2,2-diamino-1,1-naphthyl
3. m-methyl-p-dimethylaminoazobenzene
4. o-aminoazotoluene
5. p-aminoazobenzene
6. p-dimethylaminoazobenzene (butter yellow)
7. p-monomethylaminobenzene

**Hydrocarbon compounds**
1. 2-aminofluorene
2. 4-aminostilben
3. 2-anthramine
4. 1,2-benzanthracene
5. 1,2,5,6-dibenzanthracene
6. 3,4,5,6-dibenzkarbazole
7. Acetylaminofluorene
8. Carbon tetrachloride
9. Ethylurethane
10. Methylcholanthrene
11. Thioacetamide

**Tab. 37.3:** Chemical substances displaying carcinogenicity, as has been demonstrated in experiments or is very probable

The figures and observations relating to the epidemiology and frequency of HCC are almost exclusively the result of individual or combined **risk factors**. The extent of risk regarding HCC correlates with (*1.*) aetiology, (*2.*) duration, and (*3.*) inflammatory activity of the liver disease. In 10−15% of patients, no risk factor could actually be determined in the development of HCC. (s. tab. 37.4)

**Genetic mechanisms:** A *genetic disposition* is suspected in HCC, as in other malignant tumours. Some 22% of patients suffering from HCC had other organ tumours as well. (135) • Several *hereditary metabolic diseases*, with or without cirrhosis, may increase the risk of HCC considerably. These include tyrosinaemia (type I), glycogenosis (type I), alpha$_1$-antitrypsin deficiency, galactosaemia, porphyria cutanea tarda, acute intermittent porphyria and idiopathic haemochromatosis. </td></tr>
</table>

**Tab. 37.4:** Risk factors (carcinogens and cocarcinogens) regarding hepatocellular carcinoma, which have already been proved (including some references) (s. tabs. 29.10; 37.3)

with diabetes mellitus and obesity (29, 65) also have a higher risk of developing hepatocellular carcinoma. • HCC has only rarely been associated with Wilson's disease; copper seems to have a carcino-protective effect. (172) (s. tab. 37.4)

**Chemicals:** A number of chemicals can cause malignant hepatic tumours, including HCC, both in animal experiments and in the everyday life of humans. These include vinyl chloride, aromatic amines, nitrogen compounds, polycyclic aromatic hydrocarbons and alkylating substances. Similarly, mycotoxins and phytotoxins (aflatoxin, cycasin, ochratoxin, safrol, etc.), betel quid chewing as well as inorganic substances (arsenic, asbestos, cadmium, chromium, etc.) can have a carcinogenic effect. In addition, substances emitting ionizing radiation must be mentioned in this context. (s. tab. 37.4)

**Medication:** The aetiological relationship between the intake of certain types of medication and the develop-

ment of HCC is well known. These include methotrexate, methyldopa, androgens/anabolic steroids, oestrogen derivatives/oral contraceptives and cyproterone acetate. (s. tabs. 29.9; 37.4)

**Alcohol and tobacco:** Alcohol is considered to be a *cocarcinogen*, i.e. it requires additional noxae (e.g. tobacco smoke, aflatoxin) to be able to induce HCC as a carcinogen. The combined effects of alcohol and aflatoxin result in a 35-fold increase in carcinogenicity. Aflatoxin may cause a specific type of mutation within the tumour suppressor gene p53 and thus trigger initiation (i.e. the first step in the development of a tumour). The risk of HCC developing with underlying alcoholic cirrhosis is about 15% or 22.6% (i.e. there is approximately a 4-fold increase in the HCC risk); abstention from alcohol does not lower the risk of HCC significantly. (159, 163)

**Hepatitis viruses:** In chronic infections, **HBV DNA** may become integrated into the genetic material of the hepatocytes; this has a strong, time-dependent carcinogenic effect. Alcohol speeds up the incorporation of viral DNA into the host genome. HBV carriers (those suffering from liver disease as well as healthy persons) have an HCC risk which is 200 times higher than that of other people. Integration of viral DNA into the tumour cells is well documented. Integrated HBV DNA shows a number of modifications. Genetic damaging of hepatocytes by the integrated viral DNA (also in serologically HBV-negative patients, who may be molecular-biologically positive) is considered to be the initiation of carcinogenesis. In this process, the HBV subtypes apparently behave like the HBV type itself. HBxAg is undoubtedly of pathogenic significance; possibly it also damages p53. HBV protein (and the core protein of HCV) are able to activate NF-kappa B, which is considered to be important in HCC pathogenesis. *Vaccination* against HBV infection is thought to be an effective prophylactic measure against the development of HCC. • Superinfection with **HDV** has a potentiating effect, resulting in the earlier occurrence of both cirrhosis and HCC − but not in a higher incidence of HCC. Animal experiments show that HBV can induce HCC without further cofactors. This evidence of the strong carcinogenicity of HBV also explains why, for example, HBsAg-positive men have a risk of developing HCC which is 98 times higher than that of an HBsAg-negative control group of the same age. A higher familial frequency has also been observed. (67, 110, 151, 167) • **HCV** is equally carcinogenic; in certain regions, its carcinogenicity is actually 2.7 times higher than that of HBV, whereby different molecular mechanisms are responsible for the development of HCC. HCV is not integrated into the hepatocellular genome. Prevalence of HCV antibodies in HCC patients has been shown to be considerable (albeit varying between individual countries), e.g. 27% vs 4%, 55% vs 10%, 30% vs 1%, and 71% vs 5%. This corresponds to a 27-fold increase in the risk of HCC.

Genotype 1 b is associated with a higher risk of HCC as well as a decrease in IGF. Simultaneous infection with GBV-C does not increase the HCC risk. The likelihood of HCC occurring subsequent to an HCV infection is 21.5% after 5 years, 53.2% after 10 years, and 75.2% after 15 years. HCV cirrhosis is associated with HCC at a malignant transformation rate of $2-8\%$ per year. (67, 127, 157, 164, 167)

**Liver diseases:** An association with AIH and with secondary biliary or CDNC-induced biliary cirrhosis has been reported (94, 116, 155), albeit as a rare event.

**Cirrhosis:** In $70-80\%$ of cases, HCC develops in underlying (mainly multicentred, coarse-granulomatous) liver cirrhosis, i. e. some 20% of cirrhotic patients suffer from HCC. • *Cirrhosis of any aetiology must thus be considered a precarcinogenic factor.* • In Europe and the USA, cirrhosis is mostly alcohol-induced. In HCC patients in Africa or Asia, cirrhosis is less common: generally perinatal, postnatal or juvenile HBV infections, most likely involving large numbers of viruses, result in the formation of HCC before cirrhosis can develop. Chronic viral hepatitis, just like cirrhosis, causes an increase in hepatocellular proliferation. Unless the genetic damage induced by viral DNA can be repaired by enzymes produced in the hepatocytes, it is passed on via mitoses to the daughter cells. An increased DNA synthesis rate within the cirrhosis is accompanied by an elevated risk of malignant transformation. Cirrhosis increases the susceptibility of the hepatic tissue to other carcinogens. A rise in the mitosis rate thus also results in an increase in genetic alterations. This causes oncogens to be activated, while tumour suppressor genes or mutation repair genes become inactivated. (19, 44)

## 3.4 Pathogenesis

**Development of HCC** begins in the small diploid hepatocytes, which have a higher growth rate. Pathogenesis is a multifactorial event. The sequential course has three main phases: (*1.*) **initiation:** various noxae cause a genetic defect, which can be repaired by endogenous mechanisms and is thus reversible; (*2.*) **promotion:** if the genetic damage is beyond repair, the initiated hepatocytes are stimulated and mitosis begins, with the result that the genetic damage is transferred to the daughter cells; (*3.*) **progression:** clonal expansion of the altered ("malignatized") cells occurs.

**Tumour-suppressor gene:** The tumour-suppressor gene p53 is located on chromosome 17. Noxae may cause mutations of this gene, which results in the loss of its suppressor effect. (6, 126) • *An autosomal dominant mutation of p53 is also encountered in humans, so that a tumour can develop during adolescence,* the so-called **Li-Fraumeni syndrome.**

**Carcinogens** are cancer-causing substances which are able to initiate genetic damage of the hepatocytes (or of bile-duct epithelia or sinusoidal endothelial cells) without the assistance of additional noxae. **Cocarcinogens** require other cocarcinogens or carcinogens in order to cause malignant transformation. • The **interaction** between hepatitis viruses, alcohol, chemical agents, hormones, etc. is a crucial factor in the development of manifest HCC. In this context, constituents of tobacco smoke, nutritional factors (e. g. choline deficiency, vitamin $B_6$ deficiency, aethionine surplus) or

occasionally enhanced fatty acid synthesis (130) may act as cocarcinogenic factors.

**Growth factors** (HGF, IGF, etc.) are also of crucial importance in pathogenesis, as is a compromised immune defence system. Increased expression of angiopoietin 1 and 2 plays an important role in the vascular development of HCC. (165)

**Aetiopathogenesis is multifactorial as an interaction of genetic, exogenous and/or endogenous factors. In a molecular-biological context, HCC is regarded as an extremely heterogeneous tumour.**

## 3.5 Morphology

### 3.5.1 Macroscopic forms

The macroscopic or histologic differences in the morphology of individual hepatocellular carcinoma types are of little epidemiological or clinical significance. • Macroscopically, HCC has a whitish-yellow colour, is often permeated by bile and shows a soft consistency. There are often haemorrhages in the nodes as well as central necrosis. HCC is mainly supplied with arterial blood. Its doubling time is 30 to 400 days, with an average of 120 days. Occasionally, infiltration into the portal vein system or the hepatic veins occurs (s. fig. 6.16), with intrahepatic metastases and thromboses in the branches of the portal or hepatic veins. (138) HCC may also become manifest simultaneously with cholangiocarcinoma. (95) • **Three forms** (nearly identical with the three forms described by H. Eggel in 1901) (5) can be differentiated: (*1.*) expansive type, (*2.*) infiltrative type, and (*3.*) combination type. • A rare form is the **pedunculated HCC** (only about 100 cases have been reported). It occurs mostly on the underside of the right lobe and protrudes beyond the upper edge of the liver. This form (occasionally >1 kg in weight) can be more easily resected, leading to a better prognosis. (124, 178) (s. tab. 37.5)

*Tab. 37.5:* Macroscopic forms, microscopic typing and degree of tumour differentiation in hepatocellular carcinoma

## 3.5.2 Microscopic tissue types

**Dysplasia:** This condition is defined as variably large, different-shaped hepatocytes, mostly in localized groups, with enlarged, pleomorphic and hyperchromatic nuclei as well as enlarged nucleoli. These dysplastic hepatocytes may often be polyploid. Dysplasia can occur as a *macrocellular* (with eosinophilic cytoplasm) or *microcellular* (with basophilic cytoplasm and increased proliferation) variant. The latter is considered to be a precancerous stage. • **Dysplastic foci** with a diameter of $1(-2)$ mm consist of enriched, predominantly small-cellular dysplastic hepatocytes. • **Dysplastic nodes** with a diameter of $0.3-1.0$ cm contain an atypical architecture and cellular atypias; trabecular or pseudoglandular structures are evident. Atypical hepatocytes are often clear-cellular, basophilic or steatotic. Fluent transition into HCC is seen occasionally. (87, 95)

▶ *Histologically, six growth forms of HCC can be differentiated.* (s. tab. 37.5) The most common form is the **trabecular type**, usually comprising highly differentiated carcinomas with polygonal tumour cells similar to hepatocytes; they grow in multilayered trabeculae and enclose blood spaces lined with endothelium (usually without Kupffer cells). • The **pseudoglandular type** is generally found in combination with the trabecular form. It is characterized by the formation of gland-like structures containing detritus and bilic or liquid material. • The **scirrhous type** shows excessive deposits of sclerosed connective tissue, which is relatively low in cells. The moderately differentiated tumour cells lie between the septa, which resemble connective tissue. This type is mostly found after chemotherapy or radiation therapy. • The **solid type** is an undifferentiated HCC, with the tumour cells displaying considerable cellular polymorphism; the trabecular tissue pattern has disappeared. The tumour is compact due to compression of the sinusoids. • Differentiation is, however, only possible in rare cases, since there is often considerable heterogenicity within the tumour, i.e. different tissue types may be found in the same HCC. (s. figs. 37.4, 37.5) • **Fibrolamellar HCC** is rare; it consists of solid cell trabeculae with connective-tissue septation and a capsule. (s. figs. 37.10, 37.11) • **Spindle cell-like differentiated HCC** is likewise a very rare histological form with a fascicular-sarcomatous growth pattern. (111) Prognosis is significantly poorer than with other forms of HCC (S. Kakizoe et al., 1987).

**Fig. 37.4:** Highly differentiated, macrotrabecular hepatocellular carcinoma with hydropic swelling of the tumour cells (condition after alcohol injection)

▶ *Histological* **tumour differentiation** *ranges from the highly differentiated grade 1 to the undifferentiated grade 4.* (s. tab. 37.5) It does not provide sufficiently reliable information for giving a prognosis of HCC. This also applies to the above-mentioned histological growth forms − with the exception of the fibrolamellar type, which generally has a more favourable prognosis.

**Fig. 37.5:** Partly solid, partly pseudoacinar HCC with bile pigment in canalicular structures

## 3.5.3 Cytological differentiation

▶ **Polygonal** cells are predominantly found in HCC. They have dense nuclei and lumpy, eosinophilic cytoplasm, which subsequently becomes basophilic. Bile canaliculi are often observed. • **Pleomorphous** cells are present in immature tumours. They are often smaller than the hepatocytes and may vary in their overall cell size as well as in the size of the nucleus; occasionally, they grow to form multinuclear cells or multinuclear giant cells containing bizarre nuclei. • Typical *hyaline inclusion bodies* with autofluorescence are sometimes detected, pointing to disturbed protein secretion; they can be differentiated immunohistochemically, e.g. in the form of ferritin, $\alpha_1$-foetoprotein or $\alpha_1$-antitrypsin. The detection of *Mallory bodies* in tumour cells is likewise typical for HCC. They are caused by disturbed metabolism of the intermediate filaments. *Ground glass cells* are also found (due to HBsAg expression or enhancement of fibrin). *Nuclear inclusion bodies* are caused by invaginated cytoplasmic substances. Bile may still be produced, particularly within a highly differentiated HCC; morphologically, this is expressed in the formation of *bile thrombi*. • The glycogen content in the tumour cells varies. When a large amount of glycogen (and water or lipids) is stored, HCC takes on a **clear-cellular** "hypernephroid" form. • **Small-cellular** carcinomas are also occasionally in evidence. (s. tab. 37.5)

A **grading of HCC** with regard to these different forms is usually without clinical importance: (*1.*) the forms do not necessarily correlate with the clinical course and (*2.*) different forms can appear in one and the same patient.

## 3.5.4 Metastatic spread

HCC metastasizes intrahepatically, haematogenically $(50-60\%)$ and lymphogenically $(30\%)$ into the regional lymph nodes, mainly (and also initially) below the diaphragm. • Haematogenous metastases affect the lungs $(40-50\%)$ and skeletal system; metastases are only rarely found in the kidneys or brain. • However, infiltrating growth affects neighbouring organs (e.g. gall bladder, diaphragm, kidneys, hepatic vessels, bile ducts). (78, 179)

## 3.6 Symptomatology

### 3.6.1 Subjective complaints

HCC develops without subjective complaints. Even further tumour growth often remains undetected; alterna-

tively, the complaints are explained as general symptoms relating to cirrhosis or to an existing chronic liver disease. HCC is hence usually detected (too) late. *Complaints* are very varied:

| | |
|---|---|
| pain in the upper abdomen | weight loss |
| bloating, flatulence | fatigue, weakness |
| inappetence, nausea | stool irregularities |

The patient is suspected to be suffering from HCC when the subjective complaints continue to worsen and when an increase in complaints, which may occur quite abruptly in some cases, cannot be explained by the progression of cirrhosis. Most patients are affected by pain radiating into the right side of the back or into the right shoulder and neck area. This is due to an irritation of the phrenic nerve caused by expansion of the tumour towards or even into the liver capsule. Anorexia is more pronounced. Occasionally, the course of HCC is acute, resembling liver failure or liver abscess.

### 3.6.2 Clinical findings

The clinical situation deteriorates rapidly: febrile temperatures and leucocytosis as well as subicterus are observed; there are also signs of encephalopathy. An arterial murmur can often be heard on auscultation, since the tumour is mainly supplied with blood from the hepatic artery. A sudden "blossoming" of vascular spider naevi is frequently seen with underlying cirrhosis. Virchow's lymphadenopathy may be present. (84) Fever and leucocytosis frequently occur in tumour necrosis. Clinical findings include:

| | |
|---|---|
| fever | arterial murmur |
| subicterus | tenderness upon pressure |
| meteorism/ascites | palpable tumour |
| latent encephalopathy | perihepatic friction |

**Paraneoplastic findings:** Occasionally, there are paraneoplastic symptoms or syndromes which vary greatly from individual to individual, such as erythrocytosis (due to enhanced expression of erythropoietin), polycythaemia, hyperparathyroidism with hypercalcaemia, hyperthyroidism, painful gynaecomastia (14), osteoarthropathy, pseudoporphyria, hypercholesterolaemia, hypertension (16), polyneuropathy, polymyositis (64), water diarrhoea syndrome, dermatomyositis, and an increase in the vitamin $B_{12}$-binding protein. Large and glycogen-rich tumours cause hypoglycaemia (possibly due to enhanced expression of IGF2).

## 3.7 Diagnosis

The efficacy of therapeutic measures, particularly the prospect of curative treatment and thus prognosis, depend upon the *early diagnosis* of HCC.

### 3.7.1 Laboratory findings

While **non-specific signs of inflammation** may also be present in liver cirrhosis, they are much more obvious in HCC. For example, positive CRP values as well as an increase in the BSR, α-globulins, $α_1$-antitrypsin and fibrinogen can be found. A constellation of decreased serum iron and elevated serum copper (140) points to a consuming inflammatory process or malignant tumour. (s. tab. 5.10) Usually, the haemogram shows leucocytosis and anaemia. Nitric oxide values in the plasma are elevated in correlation with tumour size. (s. tabs. 37.6, 37.11, 37.12)

| |
|---|
| 1. **Non-specific parameters** <br> • CRP +, BSR ↑, $α_2$-globulins ↑, γ-globulins ↑ <br> fibrinogen ↑, cholinesterase ↓, D-dimer ↑ |
| 2. **Iron/copper constellation** <br> • iron ↓, copper ↑, ferritin ↑ |
| 3. **Cholestasis** <br> • γ-GT ↑, AP ↑ |
| 4. **Enzyme constellation** <br> • GPT ↑, GOT ↑, LDH ↑, HBDH ↑, GDH ↑ |
| 5. • GOT/GPT        = >2 <br> • γ-GT/GOT      = >12 <br> • (GPT + GOT)/GDH  = <15 |
| 5. **Serology** <br> • $α_1$-foetoprotein ↑ (+ ferritin ↑) = ↑↑ <br> • des-γ-carboxy prothrombin ↑ <br> • aldolase A ↑ <br> • α-L-fucosidase ↑ |

***Tab. 37.6:*** Laboratory findings arousing suspicion in HCC, with increasing diagnostic reliability given by continuous deviation from normal values

Conspicuous **enzyme activities** include a disproportionate increase in γ-GT, AP (especially the Regan isoenzyme, which is identical to the placenta isoenzyme) and LDH. This constellation is thought to be an important indicator of HCC, particularly when HBDH is also elevated. Intrahepatic cholestasis is invariably present in HCC. More and more foetal γ-GT is produced in carcinomatous hepatocytes and is detectable at the biliary pole of the cells. Transaminases rise only slowly; the enzyme quotients may provide revealing information. (s. tab. 5.6) • Hepatic **synthesis capacity** (albumin, cholinesterase, Quick's value) decreases progressively. ChE is also greatly reduced in cases of malignant ascites. • The *indocyanine green test* is considered to be conclusive for evaluating the residual liver parenchyma prior to hepatectomy. A combination of the *ICG test* and *galactose elimination capacity* is an even more reliable tool, according to our experience.

**$α_1$-foetoprotein:** AFP has gained great importance as a laboratory value pointing to HCC. (s. p. 106) First discovered in hepatomas by G. ABELEV et al. in animal experiments in 1963, this type of oncofoetal protein was also detected in human HCC by Y. S. TATARINOV in 1964. AFP

is a glycoprotein formed initially within the yolk sac and later in the liver and gastrointestinal tract of the foetus. Serum values of about 70,000 µg/l are found in neonates, decreasing to the normal value of < 10 µg/l within 9−12 months. Higher values can be detected in liver cell regeneration (acute and chronic hepatitis, cirrhosis) and particularly in HCC (> 20 µg/l). Thus, a continuous increase in AFP values arouses suspicion; a value of > 100 µg/l is highly suspicious for HCC. There is only a moderate correlation between AFP and the respective tumour size and doubling time. A false-negative AFP value is detected in about 20% of patients suffering from HCC. The response to chemotherapy usually corresponds to decreasing AFP values. • Specificity is between 76−91%, sensitivity 39−64% (approx. 85% when ferritin is increased at the same time). Serum values of > 2,000 µg/l may ultimately be reached. Liver metastases usually show values of < 150 µg/l, with no tendency to rise. AFP values in the normal range exclude HCC in 90−95% of cases. Generally, no AFP is produced in very mature or very immature tumour cells. AFP production in elder patients is lower; it is mostly higher in virus-related cirrhosis than in alcoholic cirrhosis. (40, 75, 152, 154)

Diagnostic importance is also attributed to **des-γ-carboxy prothrombin** (60−80% positivity in HCC) (H. A. LIEBMAN et al., 1984). (90, 120, 133, 154) It is synthesized in the normal hepatocytes and therefore also in HCC. The diagnostic accuracy in small hepatocellular carcinomas (< 3 cm) could be greatly improved by determining this precursor prothrombin (PIVKA II) in combination with AFP. • A decrease in the **factor-II index**, i. e. (factor VII + factor X) − (factor II) = > 15, has proved to be a specific and independent marker of HCC. • In addition, isoferritins, Regan-AP, telomerase activity (99) and L-fucosidase as well as CEA variants may be helpful in the demarcation of HCC. • *Laboratory diagnosis of HCC is indeed much more reliable if various important parameters are added*. (s. tab. 37.6)

### 3.7.2 Imaging procedures

**Sonography:** *Sonography is the method of choice in monitoring the course of risk patients, particularly in combination with AFP determination at (4−)6 month intervals.* In this way, a longer survival time could be achieved. Under optimal examination conditions with an experienced investigator, foci are detectable at a size of 1 cm. However, demarcation of HCC in a cirrhotic liver is very difficult, if not impossible, due to its inhomogeneous reflex pattern. Small foci (< 2 cm) are usually hypoechoic; when they grow, their echogenicity increases (due to deposition of fat, connective tissue formation or necrosis) and a hypoechoic margin with a rather blurred *halo* (= tumour cells plus compressed liver parenchyma) is often in evidence. A *bull's eye* is also detectable (= hypoechoic centre surrounded by a hyperechoic edge). At a size of > 4 cm, the reflex pattern becomes inhomo-

geneous. However, HCC has no typical image. In 50 to 70% of cases, diagnosis is successful at a size of 2 cm and more. Detection of HCC also depends on its degree of differentiation: well-differentiated liver carcinomas are barely distinguishable from normal hepatic tissue. A hypoechoic halo points to a fibrous capsule and − in combination with a mosaic structure within the focus − arouses suspicion of a carcinoma. (2, 25, 34, 38, 40, 46, 87) • The use of **colour-encoded Doppler sonography** shows hypervascularization even in the early tumour stage and thus provides diagnostic differentiation from regeneration nodes and adenomatous hyperplasia. Visualization of tumour vessels is improved by intravenous injection of a contrast medium. When HCC infiltrates the portal vein, arterial vessels can be identified in the tumour thrombus in 60−70% of cases. (8, 11, 56, 61, 71, 123) • The use of **intraoperative US** as well as **laparoscopic US** (20, 68) results in a 20% higher detection rate of HCC than in preoperative diagnostics. When all space-occupying lesions of the liver are included, the diagnostic results are up to 40% better than those gained by conventional sonography. The haemodynamic pattern *"nodule-in-nodule"* (= a vascular spot in a hypovascular nodule) is a sign of a suspicious node − this could, in turn, be an early stage of HCC. (91, 181) • Characterization of liver tumours with contrast-enhanced sonography and digital grey-scale analysis offers the possibility of an investigator-independent differential diagnosis. (11)

**Computer tomography:** The detection of small carcinomas, especially of tumours in cirrhosis, is unreliable using conventional CT scanning. However, when the tumour has reached a certain size, capsule formation, fatty transformation of the tumour mass, vascular infiltration and development of arterioportal shunts are evident. Abdominal lymph node metastases can be found. Sensitivity is about 60%. (s. fig. 37.6) • The introduction of **lipiodol CT** has resulted in a considerable improvement in HCC diagnosis: the oily contrast medium injected into the hepatic artery under angiographic monitoring is stored within the tumour tissue, so that any tumour above a size of 3 mm can be identified in conventional CT scanning in full contrast for a period of 1−2 weeks. Sensitivity is about 70%, specificity about 80%. (23, 113) • **Spiral CT** has proved to be most effective (sensitivity 90%). This technique offers a biphasic examination supported by contrast medium, with the first (hepatic-arterial) phase showing mainly hypervascularized HCC and the second (portal-venous) phase showing mainly hypovascularized HCC. (10, 37) • **CTAP** (CT following arterioportography) is considered to be a very sensitive method for the detection of HCC in a non-cirrhotic liver (CTAP is not suitable in cases of portal hypertension and portosystemic shunts). The sensitivity of CTAP is 85−90%. • Although **CT arteriography** is an invasive procedure, it shows the highest sensitivity in extensive cirrhosis, because HCC is predominantly supplied with arterial blood.
***Fig. 37.6:*** HCC: nodular liver surface in cirrhosis. Tumour formation in the right lobe of liver, in parts at the margin; central hypodensity with peripheral hypervascularization (CT after CM)

**Angiography:** HCC appears as a hypervascularized tumour in angiography via the hepatic artery. The vessels show irregular internal diameters; due to arteriovenous anastomoses, the hepatic veins are rapidly filled, giving retrograde visualization of the portal vein. Poorly vascularized or non-vascularized areas present in the tumour develop due to necrosis or bleeding. Evidence of a hypervascularized *"bush pattern"* in a cirrhotic liver is considered to be an obvious sign of HCC. In terms of sensitivity, angiography is, however, inferior to other imaging techniques. There is no alternative to angiography when assessing surgical strategies or chemoperfusion and chemoembolization; angiography is often combined with simultaneous regional tumour treatment.

**Magnetic resonance imaging:** Malignant tumours generally show longer relaxation times in comparison to healthy liver tissue. This results in hypointensity in $T_1$-weighting and hyperintensity in $T_2$-weighting − in contrast to healthy liver parenchyma. $T_2$-signal intensity is more sensitive in the diagnosis of advanced HCC as well as in the assessment of a tumour capsule; this is prognostically significant. Early stages of highly differentiated HCC can be defined better in $T_1$-weighting. Diagnosis is further improved by the use of contrast medium. (28, 113, 170, 173)

**Scintigraphy:** The approaches used to date in scintiscanning have proved to be inadequate for diagnosing HCC and are also inferior to other imaging techniques. • New methods (Tc-GSA) as well as immunoscintigraphy, ^{18}F-FDG PET or **SPECT** (3, 86, 156, 160) have not yet been evaluated with regard to their diagnostic sensitivity or specificity in detecting HCC or in preoperative staging. Their main value consists in better detection of extrahepatic tumours; they may also have a direct impact on operative management. (1)

**Plain X-ray:** The rare event of HCC calcification is characterized by the so-called *sunburst sign*.

### 3.7.3 Morphological diagnosis

**Percutaneous fine-needle biopsy:** This technique is associated with the risk of tumour cell spreading. The frequency of subcutaneous implantation metastases is reported to be 2%; they generally appear within 3 months. When this procedure is indicated, the bleeding risk from the usually hypervascularized tumour must also be taken into account. The cytologic-diagnostic sensitivity is 80−85% of cases; specificity is 97−100%. (31−33, 128)

**Percutaneous thick-needle biopsy:** We consider this technique to be *contraindicated*, mainly because of the bleeding risk involved: (*1.*) HCC is usually a densely vascularized tumour, (*2.*) the tumour tissue does not possess the requisite spontaneous contractility for mechanical closure of the biopsy canal, (*3.*) local coagulation is usually disturbed in the tumour tissue. Punctures into the necrotic centre of a tumour may cause uncontrollable haemorrhagic oozing. The risk of implantation metastases is the same as in FNB. (33) • This raises the question of whether histological or cytological confirmation of the diagnosis is really necessary. In this context, cytological assessment of the malignancy is equal or even superior to histology. However, cytological delimitation of highly differentiated HCC from adenomatous hyperplasia may be very difficult in certain cases. Diagnosing the tumour type is much more accurate by histological examination than by cytology.

Surgery is indicated if a resectable space-occupying lesion in liver cirrhosis with sufficient evidence of HCC has been determined by imaging techniques and the AFP value is > 400 µg/l. Operability in terms of internal medicine as well as hepatology has to be established. • Provided laboratory, sonographic and radiological findings are largely unambiguous, surgery is indicated even without an increase in AFP values; preoperative percutaneous biopsy should *not* be carried out in such cases.

Morphological clarification of the findings is necessary if differential diagnosis of a hepatic space-occupying lesion is unclear. • Cytological or histological confirmation of tumour malignancy is likewise required prior to palliative therapy, even in patients with no chance of curative treatment.

**Laparoscopy:** This technique should always be used to achieve the required morphological clarification. (s. figs. 37.1−37.3, 37.7, 37.8, 37.16, 37.17) (9, 88, 157) • It initially serves as **explorative laparoscopy** in the careful inspection of the abdominal cavity using various body positions in order to gain as reliable a picture as possible of malignant metastases, particularly in the region of diaphragm, peritoneum and ligaments. (s. figs. 37.27, 37.28) Inspecting large areas of the visible surface of the liver as well as certain parts of the underside when lifted by a probe allows excellent differentiation of all the respective findings − especially in cirrhosis. *Explorative*
**Fig. 37.7:** Small to medium-nodular, alcoholic cirrhosis with undifferentiated, multilobular hepatocellular carcinoma and subcapsular vascularization

**Fig. 37.8:** Large-bulbous hepatocellular carcinoma due to alcohol abuse and active chronic hepatitis B with cirrhotic transformation in some places

*laparoscopy also facilitates* **staging***, which cannot be achieved as effectively by imaging diagnostics.*

All findings are documented by **photolaparoscopy**. (s. p. 156) Sufficiently large and compact tissue particles can be obtained from foci lying close to the surface by using **biopsy forceps**. Highly vascularized areas can thus be avoided. The site of extraction can be coagulated immediately, so that prolonged biopsy bleeding or late bleeding is almost completely excluded. • Foci that lie at a deeper level or those which cannot be reached with forceps should be evaluated by **fine-needle biopsy**. Assisted by sonography, this can be carried out at the same time as or after deflating the pneumoperitoneum, while the position of the trocar (or alternatively the Veres needle) is maintained. If necessary, a clear view into the abdo-

minal cavity can be regained by quick insufflation using the trocar.

> **Explorative laparotomy**, as is occasionally recommended in the literature, is *contraindicated* in our opinion. • *All* comparisons with respect to the degree of risk, stress or inconvenience to the patient, expenditure of time, material, staff and the costs involved, and particularly the diagnostic benefits, speak *against* laparotomy and *in favour of* **explorative laparoscopy.**

## 3.8 Prognosis

The prognosis of HCC is determined by the tumour mass and its speed of growth at the time of diagnosis. Signs of a *poor prognosis* are included in the (p)TNM classification. (s. tab. 37.2)

> 1. Considerable size of tumour (> 5 cm)
> 2. Infiltrative or multilocular growth
> 3. Metastatic spread

The **natural course** of disease shows an average survival rate of 5 months (2−8 months). Longer courses of HCC have only been observed occasionally; some 3% of patients survive for 5 years. • The number of tumour nodes as well as the existing cirrhosis correlate with the likelihood of recurrence. In contrast, the histological degree of tumour differentiation as well as potential capsule or bile formation by the tumour are unlikely or still disputed risk factors for a relapse. This is also true of the biological features of the tumour, such as ploidy, mitosis rate and proliferation marker index. (57, 108)

By including clinical and laboratory parameters (ascites, jaundice, hyperalbuminaemia), K. OKUDA et al. (1985) introduced a **classification** into stages in order to improve prognostic accuracy regarding survival time. (s. tab. 37.7) The survival rate in the untreated course was calculated to be 11 months in stage I, 3 months in stage II, and 1 month in stage III. The corresponding 1-year survival rates are 39%, 12%, and 3%. A survival rate of 29 months can be expected for tumours with < 25% invasion of the liver in stage I; the corresponding figure for 25−50% liver invasion is 8 months. With smaller tumours (< 3 cm), the survival rates are slightly better: 1 year = 91%, 2 years = 55%, 3 years = 13%. In older patients and in those with moderately increased γ-GT values, tumour growth is retarded. Evidence of antibodies against the tumour suppressor gene p53 point to an unfavourable prognosis.

Another alternative HCC staging system is the so-called **CLIP score** (35, 36). This also combines morphological criteria of the HCC with liver functions (Child-Pugh) and, additionally, with portal vein thrombosis as well as AFP. (s. tab. 37.8) • **BCLC classification** can be recom-

| | 0 points | 1 point |
|---|---|---|
| A: Liver invasion | ≤ 50% | > 50% |
| B: Ascites | no | yes |
| C: Bilirubin | ≤ 3 mg/dl | > 3 g/dl |
| D: Albumin | > 3 mg/dl | < 3 g/dl |
| A+B+C+D = | 0 points: | stage I = 8.3 |
| A+B+C+D = | 1−2 points: | stage II = 2.0 |
| A+B+C+D = | 3−4 points: | stage III = 0.7 |

**Tab. 37.7:** Classification of the stages of hepatocellular carcinoma and survival time in months (untreated) (K. Okuda et al., 1985)

| Criteria | Points | | |
|---|---|---|---|
| | 0 | 1 | 2 |
| 1. Child-Pugh | A | B | C |
| 2. HCC morphology | solitary | multifocal | multifocal |
| | <50% of liver | <50% of liver | >50% of liver |
| 3. α₁-fetoprotein | <400 µg/l | >400 µg/l | |
| 4. portal vein thrombosis | no | yes | |

| Survival rate | | | |
|---|---|---|---|
| points | mean rate | 1 year (%) | 2 year (%) |
| 0 | 36 | 84 | 65 |
| 1 | 22 | 66 | 45 |
| 2 | 9 | 45 | 17 |
| 3 | 7 | 36 | 12 |
| 4−6 | 3 | 9 | 0 |

**Tab. 37.8:** CLIP staging system of HCC and the respective survival rate (35, 36)

mended for staging-adapted management of HCC. (107, 108)

**Complications:** Acute liver failure, arterioportal fistula formation, oesophageal varices (15) and pulmonary hypertension have been reported as complications. • In most cases, the **cause of death** is anorexia with *tumour cachexia*, accompanied by signs of circulatory and renal failure. Occasionally, there is intraperitoneal haemorrhage, portal vein thrombosis (138, 146) and *tumour rupture* with formation of haemorrhagic ascites. (121)

**Spontaneous regression:** As far as I know, it was E. B. Gottfried et al. (1982) who first reported spontaneous regression of HCC. In the meantime, further (> 25) unusual observations of this kind have been published. However, recurrence after such regression has also been reported. (52, 62, 69, 76, 104, 112, 119, 162, 166)

## 3.9 Therapy

Surgical, local-interventional, regional and systemic procedures and palliative measures are available for the treatment of HCC. • Longer survival periods can be achieved by surgery, which is considered to be the only form of potentially curative treatment for small tumours (< 3 cm, or even < 5 cm).

At present, merely 5% of patients suffering from HCC have any chance of being cured. Some 25−30% of *inoperable* patients were rendered *operable* by means of preoperative selective irradiation with yttrium⁹⁰ microparticles (intra-arterially) or by several cycles of cisplatin + IFN-α₂ᵦ + doxorubicin + 5-fluorouracil. The results could be further improved by postoperative treatment with lipiodol-J¹³¹. • In this context, the overall chance of recovery is reported to be 15%.

▶ An **interdisciplinary consensus conference** to decide upon the best therapy possible must be held before any treatment of a carcinoma begins. A gastroenterologist, a surgeon, an oncologist and a radiologist should participate, irrespective of the department in which the patient is being cared for. The treatment plan agreed upon must then be explained to the patient and (with the patient's consent) also to the closest relatives. • So-called *"virtual liver surgery"* will play an important role in this connection in the foreseeable future.

### 3.9.1 Surgical therapy

**Resection**

Only about 30% of tumours are still resectable by the time HCC is diagnosed. • The following are considered to be **contraindications** for resection: (*1.*) multicentric tumours, (*2.*) metastases, (*3.*) invasion of the tumour into the portal or hepatic vein, (*4.*) liver malfunction (jaundice, hypoalbuminaemia, considerable reduction in Quick's value and cholinesterase), and (*5.*) decompensated portal hypertension (ascites, encephalopathy). • **Surgical techniques** include: (*1.*) right-sided or left-sided hemihepatectomy, (*2.*) right-sided or left-sided lobectomy, (*3.*) segment IVb resection, and (*4.*) atypical resections and wedge excisions. (s. pp 800, 870) Resection of the small left lobe of liver is tolerated best. When the larger right lobe is resected, there is a risk of liver insufficiency due to inadequate residual functional capacity. Preoperative administration of ¹³¹J-lipiodol (60 mCi/injection) showed promising results. (143) • The following procedure was hence recommended for the safe removal of liver parenchyma: first, embolization of the portal vein branch associated with the tumour is carried out; this results in atrophy of the embolized lobe and hypertrophy of those segments to be maintained, with a correspondingly better functional capacity. • If non-resectability is revealed during the operation, a catheter should immediately be implanted in the hepatic artery for regional chemotherapy. • For patients without cirrhosis, **mortality** is 1−3%, for those with cirrhosis 7−25%. The **survival rate** is 25−60% after 5 years, depending on tumour size; this rate sinks to 25−35% when the capsule or the portal vein are infiltrated. Decisive factors are the radicalness of the intervention and the functional capacity of the residual liver parenchyma.

Intraoperative blood loss should be kept as low as possible in order to limit morbidity. Patients in **Child-Pugh** stage A showed a 5-year survival rate of 27−53% (cf. disease-free survival rate of 20−33%), and in stage B of about 30%; stage C is usually non-resectable or has no surgical benefits. Preoperative staging with the help of laparoscopy is absolutely necessary. It is decisive for choosing the correct kind of management (the original procedure had to be changed in 20−30% of patients due to the laparoscopic findings). (9, 88) (7, 17, 63, 80, 96, 98, 117, 125, 141, 182) (s. p. 799)

The **radicalness of the intervention** has to be assessed by the pathologist on the basis of the findings of the resected preparation as well as the surgical report. First, the pTNM stage is determined. (s. tab. 37.2) Then, the so-called **R classification** is carried out in order to establish whether the resection was curative. *R0 resection* means that the tumour was completely removed, no tumourous residues were left behind, and the resection margin is tumour-free. *R1 resection* implies that there are still tumour cells at the resection margin. *R2 resection* signifies that macroscopically visible tumour tissue is left. When the tumour markers normalize within the first 4 postoperative months after R0 resection, this is defined as *R0a resection*, and without normalization as *R0b resection*. (7) • In cirrhosis patients with small HCC, **liver function** is the most important factor for long-term survival. In this context, the indocyanine green test, MEGX test and the Okuda stage system have proved useful. Under favourable conditions, *relapse resections* are also possible. • Resection therapy is sometimes used as "bridging" prior to a liver transplantation.

**Recidivation** is generally due to undetected small intrahepatic foci. Especially in cirrhosis, the recurrence rate is very high as a result of this factor. A further cause of recidivation after primary R0 resection is attributed to the multicentricity of the HCC, i. e. synchronic or metachronic development of additional tumours which are independent of the primary tumour. Therefore, the **secondary prophylaxis** takes on a special meaning (systemic or intra-arterial chemotherapy, interferon, retinoids, autologous lymphocyte transfusion, etc.). An increase in ornithine decarboxylase and spermidine is apparently a high risk factor for recurrence. • Even after recidivation, repeated resection or interventional procedures (e. g. RFTA) are sometimes successful.

**Cryosurgery:** Cryotherapy of tumours was introduced by I. S. Cooper in 1963. • Intraoperative insertion of a probe into the liver tumour is carried out directly. Necrosis is induced in the tumour tissue by the application of fluid nitrogen as well as by the subsequent rethawing of the iced area (ca. −50 °C). This procedure is usually repeated. It is indicated in cases of non-resectable liver tumours and for the freezing of margins following resection. (21, 175) (s. p. 798)

**Liver transplantation**

With insufficient functional reserve capacity of the liver and/or non-curative resectability of the tumour, liver transplantation is generally indicated. However, such a procedure does not yield better long-term results than resection, particularly since the frequency of **relapse** (some 65% of cases) in the transplanted liver is higher due to the fact that *immunosuppression* is constantly required. A further problem is that the tumour-doubling time (102−195 days) is shortened to about 26 days. Relapses originate from preoperatively undetected metastases, which show strikingly rapid growth. • In order to limit these relapses, a method called **neoadjuvant chemotherapy** has been recommended, e. g. intra-arterial or systemic administration of cisplatin and doxorubicin, possibly in combination with interferon. The survival rates after 1, 2 and 3 years were reported as 70%, 60%, and 59%, respectively. Another form of neoadjuvant therapy was based on 5-FU (continuous infusion for 6 months), with intermittent administration of adriamycin and cisplatin prior to transplantation. This procedure showed a survival rate after 1, 2 and 4 years of 73% vs 55%, 61% vs 40%, and 61% vs 22%, respectively. The relapse rate was only 18%. • *Indications for liver transplantation should always be considered with great caution.* Careful preoperative examination regarding **HBV** or **HCV infection** (PCR, if necessary) is recommended, since there is a very high risk of the transplanted liver being infected by viruses from extrahepatic tissues under immunosuppression. • *Survival rates* in HCC cases without and with cirrhosis are almost equal at up to 85% after 1 year, 30% after 3 years, 20−45% after 5 years, and about 20% after 10 years. A long-term survival rate is only to be expected in patients with small solitary tumour nodes (< 5 cm) or not more than 3 nodes of < 3 cm in diameter and without signs of vascular invasion (so-called Milano or Mazzaferro criteria). (114) A hyperextended indication is only given in rare cases. These rates largely correspond to the results obtained in non-malignant liver diseases. Transplantation is regarded as being better than resection in cirrhosis patients with early detected HCC, since the precancerous potential of cirrhosis is totally eliminated at an early stage. In every case, preoperative and/or postoperative chemotherapy should always be considered. The previous **operative mortality rate** of 15−20% has now been further reduced. (22, 56, 88, 117, 122, 144, 153, 158)

### 3.9.2 Interventional therapy

After discussing the clinical and imaging findings as well as the result of exploratory laparoscopy, it is important to decide on the most promising management in the interdisciplinary conference. • Once resection techniques and liver transplantation have been ruled out, the next alternative are interventional procedures (s. tab. 37.9).

**1. Percutaneous injection therapy**
- ethanol
- acetic acid

**2. Transcatheter arterial therapy**
- transarterial chemotherapy
- transarterial embolization
- transarterial chemoembolization
- transarterial radiation
  - $^{131}$J-lipiodol
  - $^{90}$yttrium

**3. Percutaneous thermoablation therapy**
- laser-induced thermotherapy
- microwave coagulation
- radiofrequency ablation

**Tab. 37.9:** Local-interventional procedures in the management of HCC

### Percutaneous injection therapy

**Percutaneous ethanol injection** (PEI): This procedure was described by N. SUGIURA et al. in 1983. In solitary HCC with a size of < 3 (−5) cm in diameter, alcohol (96 vol.%) is injected into the tumour using sonographic, laparoscopic (79) or CT monitoring. This technique (5−10 ml, about 3 times a week, regularly over a period of 3−4 months) is a relatively inexpensive procedure which is technically simple and well tolerated (albeit usually very painful!). Due to the fact that HCC has a soft consistency compared to the firmer liver tissue, it is possible to a large extent to infiltrate the tumour selectively and limit necrosis as desired. (s. fig. 37.9)

**Fig. 37.9:** Subcapsular HCC in liver cirrhosis: mostly necrotic following ethanol injection

Imaging findings after PEI are: in US, alcohol distribution appears like an echogenic cloud and the tumour becomes relatively hyperechoic; in Doppler sonography, the colour signals disappear; in CT, gas formation is sometimes visible. More than 70% of the tumour mass may be necrotized. Under favourable conditions, a complete response can be achieved in 80% of cases. • Adverse events include acute cholecystitis, cholangitis, haemorrhages, liver abscess, pleural effusion, portal vein thrombosis, etc. • The PEI technique has no significant effect on tumours with a size of > 5 cm and multilocular tumours. Some cases of stitch-track metastases have been reported. The relapse rate is approx. 60%. The survival rate is 68−80% after 3 years and about 50% after 5 years. Long-term success depends upon the number and size of the tumours as well as on the respective liver function. PEI is contraindicated in Child-Pugh stage C. (18, 72, 79, 85, 89, 105, 115, 118, 134, 139, 177)

**Percutaneous acetic acid injection** (PAI): Injection of acetic acid (40−50%, 2−5 ml, 2−4 sessions) into the tumour also resulted in necrotic destruction of the tumour tissue (M. IMAMURA et al., 1995). PAI is considered to be just as effective as PEI; the success was most evident when the intratumoural retention of acetic acid persisted for about three days after completion of the treatment. (66, 102, 132)

### Transcatheter arterial therapy

As an alternative to percutaneous injection therapy, there is a possibility to develop new local-interventional treatment strategies by selectively exploring the tumour-feeding branch of the proper hepatic artery.

**Transarterial chemotherapy** (TAC): The systemic administration of cytostatics, both as mono- or polychemotherapy, led to unsatisfactory results accompanied by considerable side effects. By transporting cytostatics transarterially to the tumour itself, it was possible to build up a high concentration of these substances in the arteries supplying the HCC. Due to the fact that there were far fewer side effects, the dosage of cytostatics could be optimized. A further advantage of this method is that the extratumoural parenchyma has a portal venous blood supply; thus the arterially transported cytostatics do not cause any significant peritumoural liver damage. This transarterial chemoperfusion could be improved even more by positioning the selective-arterial catheter exactly and by implanting a port system. (43) (s. p. 801)

**Lipiodol** (= iodized ester of poppyseed oil) used as a contrast medium for lymphography accumulates selectively in the tumour over a longer period of time. As a result, local-interventional (oily) *lipiodol chemotherapy* (TOCE) was developed. Lipiodol acts as a carrier for the admixed cytostatic agents, so that the latter retain their effect in the tumour long-term in a high (systematically unacceptable) dose. Hereby, cisplatin or epidoxorubicin (101) is emulgated in lipiodol. It was possible to achieve 1-year survival rates of 36−55%. Other cytostatics did not prove to be any more effective.

**Transarterial embolization** (TAE): By occluding the smaller tumour-feeding arteries, it is possible to achieve a hypoxia-induced necrosis of the HCC. This is more successful if the tumour is encapsulated. Such embolization can be carried out using collagen particles, polyvinyl alcohol, gelfoam or galactose spheres. However,

the HCC cannot be eliminated completely, because the malignant cells in its periphery, which are supplied by the portal venous system, remain intact, so that recidivation frequently occurs (30−50%) at the same place. (109) With (repeat) embolization, 1- and 2-year survival rates of 65% and 38% respectively could be achieved. (70) (s. p. 801)

**Transarterial chemoembolization** (TACE): The direct application of a cytostatic agent (using the DSA technique via the femoral artery) into the tumour-feeding artery, followed by temporary occlusion of the vessel, leads to (*1.*) high intratumoural concentration of the cytostatic agent, (*2.*) longer action time of this subsance, and (*3.*) therapeutically important ischaemia of the HCC. As a rule, lipiodol is applied together with cisplatin (or mitomycin-C, epiduricin, doxorubicin); this is followed by embolization (see above). Evaluation of therapy success is best carried out using MRI, but coded phase-inversion harmonic sonography is likewise highly sensitive and accurate. TACE is also possible under outpatient conditions. *Repeated embolization* is recommended at intervals of about 4 weeks; this creates extensive tumour necroses. Remission was achieved in 30−60% of patients. • The following *side effects* have been observed: fever, nausea, vomiting, upper abdominal pain (= *post-embolization syndrome*), lipiodol embolisms, pancreatitis, gall-bladder infarction, tumour rupture and liver failure. (77) Chemoembolization is thus a very aggressive form of treatment and should only be considered in patients with a well-functioning liver. The administration of BCAA after TACE has proved beneficial (increase in serum albumin, reduction in mortality, improvement in quality of life). (142) • The 1- and 2-year survival rates were given as 82% and 63%, respectively. A further improvement in the survival rate was observed following the oral administration of pravastatin (20−40 mg/day). (81) For HCC which is primarily supplied by venous blood, chemotherapy is contraindicated, as is also the case with portal vein thrombosis and renal insufficiency. • It is open to question whether it is possible (and whether it makes sense) to improve the results of a subsequent resection by primary reduction in the tumour mass through chemoembolization or even by treating resectable HCC with chemoembolization from the onset. (30, 51, 77, 132, 145, 176, 180) (s. p. 801)

**Combination therapy:** The use of local-interventional procedures is restricted to a maximum tumour size of 5 cm in diameter. Therefore, a combination of two local techniques is seen as promising. • The joint application of PEI and TAE has proved its efficacy for some time. (177) Similarly, there have been reports about the successful use of TACE following laser thermal ablation. (136) Further encouraging options include a combination of TACE and RFTA, TACE with microwave coagulation (149) or TACE with cryotherapy. Using TACE, the size of the HCC can be reduced in some cases, making it possible to carry out subsequent ablation with better results.

**Transarterial radiation** (TAR): Intra-arterial radiation of $^{131}iodine$ *lipiodol* into the tumour tissue has shown good results with a six-month survival rate of 48−52%. This procedure has hardly any influence on hepatic arterial perfusion. For this reason, the technique can also be used in portal vein thrombosis. (26, 97, 143) • Transarterial injection of $^{90}yttrium$ particles did not lead to tumour regression in the first study carried out in 1992. (150) A new administration form consisting of 30 μm-sized particles of resin loaded with $^{90}$yttrium was recently developed. The radiation dose amounts to approx. 2 giga-becquerel. The rays penetrate the tissue to a depth of about 2.4 mm. The results obtained so far have proved excellent (A. KENNEDY et al., 2004).

**Percutaneous thermoablation therapy**

Targeted, temperature-related tumour necrotization can be achieved either through extreme refrigeration (= *cryotherapy*) or overheating (= *thermotherapy*). In the latter case, microwaves, laser-induced radiation or high-frequency current are generally used. The energy is applied with the help of a specially developed probe.

**Laser-induced thermotherapy** (LITT): In 1983, S.G. BOWN applied this technique for the first time as minimally invasive percutaneous ablation therapy. By means of quartz fibres, Nd : YAG laser light (1,064 nm) is conducted directly into the tumour via a probe. The laser light is converted into heat, thus causing a coagulation necrosis of the tumour. Necroses of up to 4(−5) cm in diameter may result. Probe application is carried out by MR-guiding; this technique is also used for monitoring success. The procedure is considered to be both safe and efficacious. (45, 129) (s. p. 800)

**Microwave coagulation therapy** (MCT): Necrotization of liver tumours by means of microwave coagulation (2,450 ± 50 MHz) is another thermoablation technique (T. SEKI et al., 1994). The tumour is punctured using a 14 G needle, through which a special probe is inserted. Good results were obtained by using this US-guided procedure. The 4-year survival rate of patients with superficial HCC was 64.2%; the local recurrence rate was 27.1%. In 12.8% of cases, no evidence of surviving tumour tissue was observed following treatment. (47, 74, 131) When MCT was compared with RFTA, the results, side effects and complications proved to be more or less equal. MCT is also recommended in metastases. (357)

**Radiofrequency thermal ablation** (RFTA): S. ROSSI et al. (1990, 1993) were the first to introduce this procedure. Under analgosedation and local anaesthesia, an expandable, cooled-tip needle electrode is inserted percutaneously into the tumour with the help of US, CT or MR guidance. There are various types of probes with some differences. Due to high-frequency alternating current (480−500 kHz), the tumour tissue is gradually heated (up to max. 105 °C). A necrosis voume of 4(−5) cm in diameter can be achieved. An indication is given for 1−3 foci, each with a maximum size of 5 cm in diameter. This also applies to compromised liver func-

tion. One or more sessions are necessary for this treatment. Morbidity is <10%, lethality 1–2%. The 3-year survival rates were 80–85% in Child A and 30–35% in Child B. After ablation of the tumour, success is monitored using CT plus CM: in the case of complete ablation, there is no enhancement of CM. Local recidivation is observed in 10–15% of cases. Therefore, a regular monitoring (laboratory parameter together with US or MRI) is required. In the case of recidivation, subsequent therapy with the help of TACE is promising. The following adverse events have been observed: liver insufficiency, colon perforation, portal vein thrombosis, liver abscess, pleural effusion, pneumothorax, haematoma, haemoperitoneum, needle-tract seeding, etc. RFTA can also be carried out laparoscopically (147) or operatively. • Overall, the results of RFTA are better than those of PEI (2-year survival rate: 64% vs. 43%); this is especially true of the disease-free survival rate. It would appear that RFTA is just as effective as resection therapy. (21, 42, 59, 60, 82, 106) (s. p. 800)

### 3.9.3 Medicinal therapy

**Systemic chemotherapy:** This kind of treatment yields a response rate of 5–15% only, irrespective of whether monotherapy or polytherapy was used. (100) A major cause of the low efficacy is the considerable quantity of mixed-functional oxidases in the tumour cells together with an overexpression of the multidrug resistance gene localized on chromosome 7. This MDR can be compensated to a large extent by chemosensitizers (e. g. calcium antagonists). However, there was no clinical success and the side effects were stronger. • In a recent study, the combination of gemcitabine plus oxaliplatin seemed promising. (161) The application of 5′fluorouracil + cisplatin + IFN also proved to be well-tolerated and favourable. (92) With such chemotherapy, there are generally considerable side effects, particularly in the case of an underlying cirrhosis. • Overall, HCC shows hardly any response to systemic chemotherapy, so that this treatment does not really represent a therapeutic option.

**Hormone receptor antagonist:** The hepatocytes possess oestrogen receptors and react to oestrogen with proliferation. Therefore, it seemed advisable to apply anti-oestrogens as part of the therapy. However, the efficacy of these substances, e. g. tamoxifen at 10(–20) mg twice daily, could not be confirmed. *Toremifen* appeared to be more successful. • *Cyproterone acetate* proved inefficacious as an anti-androgenic agent. *Flutamide* likewise showed no effect.

**Immunotherapy:** *Interferon-alpha* has an antiproliferative effect on tumour cells. Previous studies, however, have shown no success in HCC, not even when IFN was combined with cytostatics. • In order to improve the severely weakened immune system of tumour patients, *immunostimulants* (e. g. autologous lymphocyte infusion, thymostimulin) were used. (137) The incorporation of lipo-

somes loaded with monoclonal antibodies into tumour cells is a further therapeutic option. • In *gene therapy*, the incorporation of so-called suicide genes by means of retroviruses (possibly even adenoviruses) has aroused particular interest. So far, however, the experimental gene transfer has not been sufficient to eliminate the respective tumour mass.

**Somatostatin:** Somatotropin release inhibiting factor (SRIF) displays antimitotic effects regarding various non-endocrine tumours. In animal experiments, *octreotide* retards tumour growth. The subcutaneous administration of octreotide (250 μg, 2x/day) resulted in a considerable improvement in survival time and quality of life. (93) There are still no clinical results available regarding the use of *lanreotide*, which has a longer action time.

**3-bromopyruvate** has proved efficacious as an intra-arterial injection. (58) Likewise, i.m. administration of **arginine deiminase** ($160 \ IU/m^2$) was effective and well-tolerated. (41)

### 3.9.4 Adjuvant measures

There are several adjuvant measures which are deemed to be unconventional, i.e. the purported therapeutic efficacy has not yet been confirmed in controlled clinical studies. In the field of oncology, a multitude of treatment approaches ("cancer diets", medication, physical or instrumental therapy forms, psychological methods, etc.) have been propagated. • These should not be considered as alternative techniques, since they cannot replace the frequently tested and well-established methods used in surgery, radiology and chemotherapy. Thus they are also known as "supplementary", "additive", "adjuvant", and "complementary" measures or "best supportive care". • It is understandable that many tumour patients or their relatives emphatically demand these treatment options in addition to the traditional mainstream medical care when the diagnosis of "cancer" has been made. Up to 70% of all tumour patients try out such unconventional methods in the course of their disease. • Numerous cancer diets have been extolled – none of which came up to previous expectations. Everybody is, however, at liberty to add various supplements (beetroot, probiotics, vitamins C and E, etc.) to their daily diet in line with the physiological principles of nutrition. • Apart from that, special psychological treatment methods have been used, such as autosuggestion, crisis therapy, meditation and visualization. Psychotherapeutic and spiritual assistance can, without doubt, have positive effects on tumour symptomatology. A combination of dietary recommendations + physiotherapy + psychotherapy should indeed be included in the overall concept of cancer therapy.

Both the physician and the patient are confronted with a wide range of *unconventional therapeutic measures.* It is understandable that patients and their relatives resort, in their desperation, to any methods which may offer a therapeutic chance: "We have nothing to lose, but maybe we can defeat the cancer in the end; time and again, one hears of such healing or remission." And which doctor would want to destroy hope even in the face of oncological reality? • The alternatives indeed cover a broad spectrum. (s. tab. 37.10)

**Tab. 37.10:** Some adjuvant or unconventional therapeutic methods used in malignant diseases

Experiencing and coping with the diagnosis of carcinoma (and also "accepting" it) puts any patient under severe stress. As a consequence, the **immune system,** which is of essential significance in fighting the malignant disease, is usually weakened. • Subsequent *surgery* burdens the immune system even more. Unfortunately, *chemotherapy*, in addition to its cytostatic effectiveness, also results in massive long-term suppression of the immune system. This is equally true of *radiology.* • *The* **survival time** *varies considerably both in the natural course of disease and/or subsequent to invasive therapeutic measures mainly as a result of differences in individual defence systems.* • In comparative studies, the patients treated symptomatically (*how*? and *with what*?) often fare better in terms of survival time and the remaining quality of life − without painful therapeutic interventions, which often involve numerous side effects. The greatly varying efficiency of individual immune systems makes it difficult to compare the clinical and thus also statistical data obtained from group studies, and this might also account for the divergent results. • The tested, carefully considered and (largely) well-established techniques of (*1.*) *surgery*, (*2.*) *radiology*, and (*3.*) *chemotherapy* continue to serve as unchallenged pillars

in the treatment of malignant tumours. In future, (*4.*) *immunotherapy* will also play a more important (perhaps decisive) role − even though the patient's "immune status" cannot (unfortunately) be measured adequately.

Nevertheless, all possibilities of activating the **immune system** should be made use of. These adjuvant measures can (and should) precede or simultaneously supplement any invasive treatment procedures.

**Selenium** is an essential trace element. As an important constituent of glutathion peroxydase and thioredoxin reductase, it must be considered an extremely valuable antioxidant. The daily requirement of 75 μg is very often not achieved, especially by tumour patients, so that substitution is necessary. In addition, malignant diseases generally show a reduction in the serum value of selenium. Moreover, it intensifies the cytotoxicity of T lymphocytes and natural killer cells, leading to a corresponding effect on tumour cells. This effect can be enhanced through the stimulation of IFNγ. The application of cytostatics thus becomes more favourable in every respect. A daily dose of 200 μg (−1,000 μg) selenium is recommended. • Even in *acute infections*, i.v. administration of selenite has proved extremely useful. (s. p. 304)

**Zinc** is of essential importance for the normal functioning of the immune system. (s. pp 50, 616) In abdominal surgery, we usually detected pronounced *zincuria* (s. tab. 3.15), which, in our experience, could not be prevented by intravenous (even high-dosage) administration of zinc. Zinc deficiency, however, has negative effects on the immune system. • We found that such postoperative zincuria could (almost) always be prevented in abdominal surgery by the peri- and postoperative administration of the aldosterone antagonist **potassium canrenoate.** *At the same time, major postoperative intestinal atonicity (probably due to potassium deficiency in the cells) was no longer observed in this condition!* • This was the rationale for administering zinc and potassium canrenoate intravenously in all such cases involving abdominal surgery 1 day prior to and 3−4 days after the operation. *We would like to share these positive clinical experiences, which are free from side effects.*

At this point, it is also worth mentioning several efforts aimed at preventing **metastasis formation** subsequent to surgical manipulation of the organ containing the primary tumour. • As early as 1984, **D-galactose-specific lectin** was discovered on hepatocytes. Lectins seem to play a major part in the "docking" of tumour cells on other organ cells. Apparently, the organ specificity of malignant cells is determined by the lectin pattern on the surface of their target cells, with which the corresponding sugars on the tumour cells link up. Animal experiments, based on the **lectin-receptor theory** (G. UHLENBRUCK et al., 1986), have shown that the formation of liver metastases was almost completely prevented by

administering D-galactose prior to tumour inoculation. In two pioneering clinical studies (compared to a control group), formation of liver metastases subsequent to colorectal tumour surgery could be suppressed in 50% of patients within 3 years. A 5% D-galactose solution (1.6 g/kg BW) was infused 1 hour prior to surgery, and this was repeated until the third postoperative day. (351) • This use of galactose (or other carbohydrates?), which is free from side effects, should indeed be investigated. Such procedures can probably also be recommended in the puncture of tumours as a means of preventing tumour cell spread.

### 3.10 Fibrolamellar carcinoma

In 1956 this rare kind of tumour was described by H. A. EDMONDSON in a 14-year-old girl as a "fibrosing variant of HCC in adolescents" (235); subsequent to tumour resection, the patient was without relapse for 2 years. J. R. CRAIG et al. (1980) outlined in great detail the specific clinical and histological criteria of fibrolamellar hepatocellular carcinoma (FHCC). Some 2−3% of HCC cases are assigned to FHCC, i. e. the frequency is 20−60 cases/year in Germany. • FHCC shows the following features: (*1.*) it develops in a non-cirrhotic liver (cirrhosis frequency about 4%); (*2.*) it is found in younger people (particularly between the ages of 5 and 35); (*3.*) men and women are affected with the same frequency; (*4.*) it is not associated with HBV or HCV infection (HBsAg is positive in 6−8% of cases); (*5.*) AFP values are not at all or only rarely increased (7−11%); (*6.*) FHCC is most frequently localized in left liver lobe, generally as a grey, firm tumour. • With increasing growth, abdominal pain and weight loss occur. As the tumour grows in size, transaminases, AP, γ-GT and copper values increase. (188, 194, 195) • With regard to **imaging procedures,** sonography yields a hyperechoic pattern, while CT and MRI scanning show FHCC as a large, solitary and solid tumour. (184, 186, 187) The tumour resembles FNH by virtue of a generally recognizable central scar and multiple fibrous septa. FHCC was therefore suspected to be a malignant variant of FNH. In MRI, both the scar and the septa show hypodense signal intensity in $T_1$ and $T_2$ images. In contrast to FNH, haemorrhages, necroses or central fibrous scars and calcifications are occasionally observed in this hypervascularized tumour. Metastatic spread occurs late and initially into the abdominal lymph nodes. • The **diagnosis** is based on histology (because of hypervascularization by means of FNB or targeted biopsy under laparoscopy): large eosinophilic tumour cells with large nuclei and dense nucleoli are found. The polygonal tumour cells contain a copper protein as well as inclusion bodies (consisting of $\alpha_1$AT, $\alpha_1$FP, fibrinogen, ferritin, etc.). Eosinophilia is caused by a great surplus of mitochondria. Lamellar connective tissue lies between the trabecular formations. (183, 185, 191, 193−195) • A high vitamin $B_{12}$ value in the serum is typical because the

tumour cells trigger enhanced synthesis of transcobalamin I. Neurotensin and ceruloplasmin are also considered to be tumour markers. • The **prognosis** of FHCC is generally more favourable than that of HCC and cholangiocarcinoma. Some 50−80% of patients are resectable. The survival rate after 5 years was 40-60% (the overall survival rate equals 3−16 years following surgery, but is no more than 2 years without surgery). After liver transplantation, the prognosis of FHCC is better than in the case of HCC and CCC. (189, 190, 192, 195) (s. figs. 37.10, 37.11)

***Fig. 37.10:*** Fibrolamellar hepatocellular carcinoma as is usually seen in a non-cirrhotic liver

***Fig. 37.11:*** Fibrolamellar hepatocellular carcinoma: large, polygonal cells with granular-eosinophilic cytoplasm (based on a surplus of mitochondria)

## 4 Cholangiocellular carcinoma

**Intrahepatic localizations** must be distinguished from extrahepatic CCC. They are subdivided into **three areas** of the large bile duct: (*1.*) the upper third from the liver hilum to the opening of the cystic duct (frequency about 49%); (*2.*) the medial third of the common bile duct (frequency about 25%); (*3.*) the lower third reaching to the opening into the duodenum (frequency about 19%). Diffuse involvement of the whole extrahepatic area was found in 7% of cases. • Tumours situated in the upper third are designated proximal, central or hilar CCC and are also known as **Klatskin tumours**. (204) • Distal localizations of the extrahepatic CCC must be clearly differentiated from carcinomas of Vater's ampulla and of the pancreas head.

## 4.1 Definition

Cholangiocellular carcinoma (CCC) is a malignant tumour originating in the cholangiocytes of the intrahepatic small bile ducts *(peripheral CCC)* or the larger bile ducts *(prehilar CCC)*. There are four CCC types. The intrahepatic type is found with a frequency of 10%; this type is far more rare than hepatocellular carcinoma. More than 90% are adenocarcinomas. The tumour cells are characterized by their keratin content. CCC occurs mainly between the ages of 60−70, with men and women being equally affected. Prognosis is poor; the survival time is 1−2 years.

## 4.2 Morphology

In more than 90% of cases, a (rather slow-growing) adenocarcinoma can be detected. Evidence of glandular and trabecular structures with substantial connective tissue-like stroma is typical. A reliable histologic diagnosis is only possible if carcinomatous changes in the bile ducts can be demonstrated, a process which is very rarely observed in a liver biopsy specimen. Usually, a highly differentiated tumour is present; lesser degrees of differentiation are only seldom found. Distinguishing between CCC and metastases or adenocarcinomas (e. g. of the gastrointestinal tract or pancreas) can prove extremely difficult. Evidence of keratin 7, 19 or 903 in the tumour cells is characteristic of CCC. Expression of lamina-γ-2 is believed to play an important role in growth-related morphology. (196, 197) (s. fig. 37.12)

**Morphological classification:** Precise characterization of CCC in terms of growth pattern and staging is very important for optimal treatment planning and for determining a prognosis. (203, 206−208)

(*1.*) *Mass-forming type:* This form appears firm and coarse due to profusely developed stroma. The tumour is only slightly vascularized. It generally has a greyish-white, sometimes dark green colour and can reach a size of up to 15 cm in diameter; the margins are well circumscribed, but irregular. Central necrosis may be present. Satellite or daughter nodules are frequent and vary in size. Usually, this tumour type does not produce bile. Evidence of keratin 903 is considered to be typical. (196) In comparison to the other types of CCC, metastases are more frequently found in hilar and parapancreatic lymph nodes as well as in the peritoneum; the tumour itself often has a haematogenous spread. Vascular invasion is rare. (205, 212)

(*2.*) *Periductal-infiltrating type:* This form grows along the bile ducts; it is therefore elongated, spiculated or branch-like. The bile ducts proximal to this CCC may be dilated if the lumen is narrowed or even obstructed. The tumour remains unidentifiable for a long time.

(*3.*) *Intraductal-growing type:* This form is mostly a papillary adenocarcinoma. It comprises innumerable frond-like infoldings of proliferated columnar epithelial cells and a slender fibrovascular core. The tumour is generally small, but often spreads superficially along the mucosal surface, forming a kind of "papillomatosis". Mostly, it produces a profuse amount of mucous, resulting in focal or segmental biliary obstruction with respective dilatations. Such a papillary adenocarcinoma has low-grade malignancy. • Some papillary tumours produce a large amount of mucin. This *mucinous tumour* is seen as a variant of the intraductal-growing type. (198)

***Fig. 37.12:*** Cholangiocellular carcinoma with tubular glands (HE)

**Cholangiohepatocellular carcinoma** arising from both cell types is a mixed form. (213) It sometimes appears as a subtype with two separate tumour forms or as a subtype with mixed HCC and CCC components. This type of carcinoma can develop in different parts of the liver; its subtypes may also be seen in close proximity to one another or even appear within the same tumour. It is rarely found in liver cirrhosis. Typically, there is extensive mucin production and evidence of glandular biliary epithelia. With the help of specific keratin patterns, these tumours can be identified immunohistochemically. Prognosis is poorer than in the case of the respective singular form.

**Mucoepidermoid carcinoma** was first described by L.E. Pianzola et al. in 1971. (222) It is a rare entity; this subtype constitutes only 2−3% of all CCC. Up to now, 41 cases have been reported. The tumour contains components of both adenocarcinoma and squamous cell carcinoma. It is discussed that this condition derives from a squamous metaplasia of the terminal ramifications of the bile canaliculi (222) or from adenocarcinoma cells. A combination of HCC and mucoepidermoid carcinoma has been observed. (219) This tumour contains components of both cell types. A male predominance was found. The clinical findings and laboratory data are similar to CCC. Pathogenesis is unknown; various congenital cysts of the biliary tract (218) and non-parasitic cysts (221, 223) as well as hepatic cholelithiasis (usually associated with infection) have been proposed as aetiological factors. (217) • Although its resectability was

shown to be better than that of CCC, the prognosis is poor. (220, 224) (s. tab. 37.1)

## 4.3 Epidemiology

CCC is rare, comprising about 7% of malignant liver tumours. The tumour is most common between the ages of 60−70. Men and women are affected with the same frequency. Incidence is dependent upon regional risk factors; on average, it ranges from 1-8/100,000 inhabitants.

## 4.4 Pathogenic risk factors

The pathogenesis of CCC is associated with numerous risk factors. (1.) *Intrahepatic cholelithiasis* results in CCC in 5−10% of cases; chronic cholangitis is usually present. (216) (2.) *Parasitic infestation* of the bile ducts (e. g. Clonorchis sinensis, Opisthorchis felineus and Opisthorchis viverrini [202] may be associated with CCC in up to 60% of cases when it has been present for several years. (3.) *Congenital anomalies* of the bile ducts (biliary atresia, cysts, dilatations, Caroli's syndrome, Alagille's syndrome) (200) pose a considerably higher carcinoma risk. (4.) *Primary sclerosing cholangitis* increases the morbidity risk to 15−30%. (209, 210) Subsequent diagnosis of CCC was confirmed in 40% of a group of patients who had died from PSC and in 35% of liver transplant patients. The prevalence of CCC in patients suffering from chronic inflammatory intestinal diseases was also increased by 0.2−1.4% with pathogenic association between PSC and ulcerative colitis, whereby CCC occurred earlier in these cases (i. e. from the age of 40). A higher frequency of mutations of the oncogenes (e. g. K-ras, c-myc, p16) and tumour suppressor gene p53 (210), with a strong expression of p53 in tumour tissue, was confirmed in patients with PSC-associated CCC. (5.) *Thorium dioxide,* which is stored lifelong in the RES, led to the development of CCC in numerous cases, with an average latency period of 35 years. (6.) *Chemical agents* such as dioxin, nitrosamine and aflatoxin are considered to be risk factors for the development of CCC. (7.) *Medication* (isoniazid, anabolic steroids, methyldopa, contraceptives) has sometimes also been associated with an increased occurrence of CCC.

## 4.5 Clinical features and diagnosis

**Symptoms:** The clinical symptomatology principally depends on the localization of the tumour. Extrahepatic CCC manifests in most cases as obstructive jaundice. In intrahepatic localization of CCC, the developing clinical picture reveals abdominal pain, nausea, inappetence, loss of weight and weakness; cholangitis is often observed. (199)

**Biochemistry:** Non-specific signs of inflammation, cholestasis parameters and increasing jaundice are found. The tumour markers AFP and CEA are normal, while the tumour markers CA 19−9 and CA 50 are usually elevated. There may also be mutations of the cyclin-dependent kinase inhibitor p16/MTS1. (s. tab. 37.11)

**Laboratory findings**
1. *Non-specific signs of inflammation*
   - BSG ↑, CRP +, serum iron ↓, copper ↑, haptoglobin ↑, fibrinogen ↓, D-dimer ↑ $\alpha_2$-globulins ↑, ChE ↓, anaemia
2. *Cholestasis*
   - AP ↑, LAP ↑, γ-GT ↑
3. *Jaundice*
   - Serum bilirubin ↑
4. *Tumour markers*
   - $\alpha_1$FP normal, CEA normal CA 19−9 ↑, CA 50 ↑

**Imaging diagnostics**
1. Sonography
   ↓
2. CT and CT angiography − − − → MR
   ↓
3. ERCP (or PTC)

**Morphological diagnostics**
1. Laparoscopy and biopsy
2. Percutaneous biopsy
3. Percutaneous fine-needle biopsy
4. ERC with brush biopsy

*Tab. 37.11:* Diagnostic parameters and examination techniques in cholangiocellular carcinoma

**Sonography:** In this biochemical constellation, sonography (also colour-encoded duplex sonography with visualization of the intrahepatic bile ducts) is the examination technique of choice, particularly when obstructive jaundice is suspected. There is evidence of prestenotically dilated bile ducts as well as, in some cases, accompanying strand-like, hyperechoic, infiltrating structures, which may be surrounded by a hypoechoic margin. The tumour itself can be identified in most cases, particularly when it is localized in the liver hilum.

**CT:** This technique is useful for assessing intrahepatic carcinoma and detecting peripheral CCC. Occasionally, proximally dilated bile ducts can also be visualized. The gall bladder and the common bile duct are inconspicuous. Differential diagnosis of metastases or HCC can be extremely difficult. (214, 215) • **MR** cholangiography has become an important procedure due to more sophisticated technology. (s. fig. 37.13)

**Cholangiography:** If *ERCP* proves unsuccessful or if it is not possible to assess the bile ducts or the extent of tumour expansion, *PTC* is indicated. Nevertheless, ERC remains the method of choice, especially when combined with brush biopsy.
*Fig. 37.13:* Cholangiocellular carcinoma ( ↑ ) in CT with contrast medium

**Scintigraphy:** Hepatobiliary sequential scintigraphy imaging using $^{99m}$T-etifenin can often provide additional information about tumour localization. Fluoro-2-deoxy-D glucose PET may be helpful in the diagnosis of perihilar CCC or metastasis.

**Angiography:** CT arteriography, CT arterioportography or MR angiography may help to detect vascular invasion and irregularities. Cholangiocellular carcinomas are poorly vascularized.

**Laparoscopy:** Laparoscopy should be used to confirm the diagnosis morphologically. This technique provides photodocumentary findings and also affords the possibility of targeted thick-needle, fine-needle or forceps biopsy. Tumour biopsy is only deemed necessary prior to palliative therapy. Moreover, *explorative laparoscopy* offers a much better overview of the whole abdominal area than does explorative laparotomy − and the risk involved is considerably lower. Carrying out laparotomy staging prior to liver transplantation is, in our opinion, also far less efficient and thus not indicated; instead, laparoscopy should be the technique of choice. (s. pp 150, 155, 161, 781)

### 4.6 Therapy

Resection or liver transplantation are considered to be the only curative forms of treatment for cholangiocellular carcinoma. • External or intracavitary radiation therapy is the method of choice when it comes to palliative measures. • The spectrum of adjuvant or alternative therapy procedures used in HCC is broad, as it is for all oncological conditions.

#### 4.6.1 Invasive and surgical techniques

Classification of intrahepatic CCC is also made according to the TNM staging system. Due to the low frequency rate of CCC, experience of treating this tumour

surgically by **resection** is limited. Patients with resectable tumours were reported to have a survival time of 12−24 months − which is not essentially longer than the normal course of disease. Survival times of more than 5 years have been reported in about 10% of cases. In 80−85 of patients, however, the tumour was not resectable at the time of diagnosis. (199, 201, 203, 211)

Results to date concerning **liver transplantation** have been disappointing, so that this treatment is not considered to be indicated for CCC. Recurrence of CCC in a transplanted liver is most likely caused by immunosuppression. Attempts are hence being made to prevent such recurrence by combining liver transplantation with subsequent irradiation of the portal liver hilum and simultaneous administration of 5-FU.

**Drainage therapy** results in subjective improvement and decreases the risk of cholangitis. Techniques used include *biliodigestive anastomosis, percutaneous transhepatic drainage* or an *endoprosthesis* to bridge bile-duct stenosis.

#### 4.6.2 Chemotherapy and radiotherapy

To date, **chemotherapy** for CCC has remained unsuccessful, no matter what kind of substance is used in monotherapy or polytherapy (e.g. 5-FU plus leucoverin). Local chemotherapy using arterial infusion of cytostatics may be indicated in individual cases. • **Radiotherapy** has no influence on survival time, but usually reduces pain.

#### 4.6.3 Adjuvant measures

Even in cases of CCC which appear to be hopeless in terms of oncology, both the patient and the attending physician still have a broad spectrum of **adjuvant** and/or **unconventional therapeutic approaches** at their disposal. It is essential to provide sympathetic counselling and guidance for the desperate patient, who is prepared to seize any chance of preventing unnecessary suffering and harm. (s. p. 786) (s. tab. 37.10)

## 5 Cystadenocarcinoma

Primary biliary cystadenocarcinoma (CC) was first described by P. Bascho in 1909. It is a rare tumour (up to now, about 120 cases have been reported), which generally occurs in malformations of the bile ducts. CC mainly affects women and is predominantly found in the right lobe of liver. Cystadenomas or choledochal cysts are considered to be a probable precursor. (226, 229, 230, 232) Diagnosis can be reached with the help of imaging techniques (225, 228) and histology (226, 232). Sometimes, CC develops without ovarian-like stroma. (227) The marker CA 19-9 may be increased. The tumour is usually made up of plurilocular cysts with

papillary folds lined with carcinomatous epithelium and contains bile-stained mucinous material. It is surrounded by a fibrous capsule consisting of dense hyaline stroma. (226) CC with a "pseudosarcomatous growth pattern" has been described (P.D. Unger et al., 1987). After resection, the survival rate is up to 5 years. (231) (s. tab. 37.1)

# 6 Hepatoblastoma

The most common liver tumour in children is malignant foetal hepatoblastoma. (235) (s. tab. 37.1) It constitutes 30−45% of all primary liver tumours and 50−60% of all malignant tumours occurring in childhood. (236, 238−240) Hepatoblastoma is often associated with a congenital anomaly, especially with familial adenomatous polyposis coli. (233) The tumour is partially lobulated by fibrous septae and well-vascularized. Arising in the endodermal liver epithelium, it usually becomes manifest prior to the third year of life, but rarely in older children or adults. (241) Boys are affected more than twice as often as girls. • *Histologically*, there are *three types*: (*1*.) epithelial type with embryonal hepatocytes or foetal hepatocytes, (*2*.) mixed-cellular type containing epithelial and mesenchymal components, and (*3*.) anaplastic type with small, undifferentiated cells. • *Embryonic hepatocytes* are small, partially spindle cell-like, cuboidal or polygonal, and display uniform hyperchromic cell nuclei. The sparse cytoplasm is easy to stain. The cells have band-like or rosette-like structures. *Foetal hepatocytes* are larger and possess a marked cytoplasm; they contain abundant glycogen and form canaliculi as well as cellular trabeculae between the sinusoids. Epithelial cell nests of bright and dark cell elements alternate. Haematopoietic foci are detectable in the area of the foetal hepatocytes. (s. fig. 37.14) • *Macroscopically*, there is usually a solitary medullar tumour, 5−15(−25) cm in size, which mostly develops in the right lobe of liver. A tumour capsule is found in 50% of cases. It may contain necroses, haemorrhages and calcifications. This tumour grows relatively rapidly. Metastatic spread affects the infradiaphragmal lymph nodes, lungs and brain. Immunohistochemistry shows an expression of cytokeratin 7, 8, 18 and 19, or AFP as well as vimentin. • Hepatomegaly, fever, anaemia, growth retardation, sexual precocity (due to ectopic gonadotropin) and abdominal pain as well as high or non-decreasing values of $\alpha_1$-foetoprotein (which normally decreases in the first years of life in healthy infants) are suggestive of the kind of tumour. Imaging techniques and biopsy facilitate the diagnosis. (234) Cystathionine is mostly increased in the urine. Early detection allows curative resection in about 20% of children. Preoperative chemotherapy may reduce the tumour size, leading to better surgical results. (235, 236, 240) Liver transplantation is sometimes indicated. (237)

**Fig. 37.14:** Hepatoblastoma (3 years old boy) with mainly fetal differentiation (HE)

# 7 Mesenchymal liver tumours

## 7.1 Embryonal sarcoma

Undifferentiated embryonal sarcoma (UES) was first described by J.T. Stocker et al. in 1978. (246) (s. tab. 37.1) This mesenchymal tumour is mostly encountered during childhood and adolescence, occurrence in adults is a rare event. (243) There are no gender-related differences. It is predominantly localized in the right hepatic lobe. The tumour presents as a well-circumscribed node with a size up to 20 cm in diameter comprising cystic zones (of necrotic tissue and blood). An association with a mesenchymal hamartoma is discussed (244), especially since alterations in chromosome 19q have been detected in both conditions. • The polynuclear tumour cells are star-shaped or fusiform with numerous mitoses. In addition, there are large cells with PAS-positive, diastase-resistant globular inclusions. The tumour cells show no differentiation; they are surrounded by pronounced myxoid stroma. (12, 245, 247) • In a CT scan, the tumour appears hypodense with a peripheral capsule. (242) This malignancy is not (or only slightly) vascularized. It grows rapidly and can infiltrate the neighbouring organs or metastasize in the lung or abdomen. US shows a solid space-occupying lesion with an inhomogeneous reflex pattern and circumscribed cystic areas. • If feasible, resection is indicated, possibly in combination with chemotherapy. A ligature of the hepatic artery may also be applied. Recidivation after resection therapy is frequent. The 3-year survival rate is about 30%. (247, 248)

## 7.2 Epithelioid haemangioendothelioma

Epithelioid haemangioendothelioma is a malignant mesenchymal tumour, which was first described in the liver by S.W. Weiss et al. in 1982. (s. tab. 37.1) It is probably a variant of haemangiosarcoma, but with a much better prognosis (approx. 50% of patients survive for more than 5 years). This multifocular, vascularized tumour with low-grade malignancy can affect the liver

primarily or appear in the liver as a metastasis. Women are more affected than men. Usually, the liver is interspersed with multiple, firm and greyish-white lesions up to 3-11cm in diameter. (12) There are no differences in frequency with respect to age. The tumour cells grow along the vessels, whereby the portal fields and the acinar structure are unchanged. These cells are irregular-shaped, dendritic or spindle-like; they may display intracytoplasmatic vacuoles as well as so-called *Weibel-Palade bodies* (E.R. WEIBEL et al., 1964) as markers of arterial endothelia. The stroma contains collagenous fibres, mucopolysaccharides and, later on, calcifications as well. (250) Often, a Budd-Chiari syndrome is mimicked. (262) Immunohistochemical demonstration of factor VIII antigen is helpful in differential diagnosis. An association with vinyl chloride and contraceptives as well as with NRH has been postulated. (258) • Some laboratory parameters (AP, GPT, GOT, bilirubin) are increased. (249, 253, 255, 257) • Imaging procedures show a space-occupying lesion without characteristic findings. (256, 260, 261) Diagnosis can only be reached by means of histology (249, 251-253, 255, 257), best guaranteed with (forceps) biopsy under laparoscopy. (252) • The tumour grows slowly, but may metastasize. (249, 253, 254) Resection mostly cannot be carried out. Liver transplantation is the therapy of choice, occasionally combined with IFN. The 5-year survival rate is > 75%. (254, 255, 259)

## 7.3 Angiosarcoma

Angiosarcoma is the most frequent mesenchymal tumour; it has a soft consistency. (12) *Macroscopically*, conglomerate sponge-like nodes are found, which are partially greyish-white and interspersed with haemorrhages or central necroses. They are highly vascularized and show blurred margins. Smaller satellite nodes may also form. • *Histologically*, this tumour consists of polymorphous, fusiform sinusoidal endothelial cells, which line blood spaces and grow in a confluent infiltrative manner. The rate of mitoses is high. There are peliosis-like dilated cavities. Polynuclear giant cells may be present. Infiltration of tumour cells in portal or central veins as well as extramedullary foci of haemopoiesis are usually demonstrable. Liver cell plates, provided they remain in position, are characteristically "enwrapped" by tumour cells. Immunohistochemically, factor VIII-associated antigen can be detected. (s. fig. 37.15) • Angiosarcoma is closely associated with the effects of thorium dioxide (266) (s. p. 569!), chronic arsenic poisoning (270) (s. p. 569!) and exposure to vinyl chloride (268) (s. p. 568) or radium as well as with neurofibromatosis or haemochromatosis. Transition of infantile haemangioendothelioma and cavernous haemangioma into angiosarcoma has been reported. It has also been observed following the intake of phenylhydrazine and anabolic (264) or contraceptive steroids. Older people are predominantly affected, men more than women (3−4:1). In childhood, girls are the main sufferers. (263) • The

tumour progresses quickly, grows multicentrically (in the shape of a cavernoma or node) and is localized in both hepatic lobes. The survival time is less than 1 year. Metastatic spread occurs in the lungs and hilar lymph nodes as well as, occasionally, in the spleen and bones. (269) Diagnostic biopsy (even as FNB) is contraindicated in this highly vascularized tumour. (265) The diagnosis is usually made by CT angiography or MR angiography. (267) Vascular murmur "over" the liver may be audible. A sudden complication is a rupture with haemoperitoneum; DIC sometimes develops. The course is irrepressibly progressive; the prognosis is poor.

**Fig. 37.15:** Hepatic haemangiosarcoma

## 7.4 Leiomyosarcoma

Leiomyosarcoma originates from smooth-muscular elements of the liver, which are located in the walls of vessels and around bile ducts. (12) Men and women are affected with the same frequency, predominantly in middle age. It is a very rare mesenchymal tumour (only about 50 cases have been reported so far). This tumour grows slowly, the colour is greyish-white and the consistency is firm; it can reach up to 35 cm (!) in diameter. Occasionally, there are multiple nodes. (273) It not only occurs in the liver (mainly in the right hepatic lobe), but is also found in the round ligament, the hepatic or portal veins (272) and inferior vena cava (275) (possibly together with the Budd-Chiari syndrome). The tumour cells appear homogeneous and spindle-like with eosinophilic cytoplasm. Clinical findings or imaging results are non-specific; splenomegaly and ascites may occur. (271, 273, 274, 276) Therapy consists of tumour resection.

## 7.5 Rhabdomyosarcoma

Rhabdomyosarcoma is a mesenchymal tumour of grey colour with partially cystic growth. (12) It mainly occurs during childhood. (277) The tumour cells appear small, round or spindle-like, hyperchromatic, occasionally with eosinophilic cytoplasm. (279) They show various stages of differentiation of embryonal skeletal muscle cells. This tumour originates from peribiliary located muscu-

lar structures. (277) • An association with the long-term use of oral contraceptives has been reported. (278)

## 7.6 Fibrosarcoma

Fibrosarcoma is a mesenchymal tumour originating from fibroblasts; it can therefore occur ubiquitously in the whole body. (12) It was first described by R.H. Jaffe in 1924. About 35 cases have been reported so far. This type of tumour has a firm consistency and contains cystic structures with focal necroses and haemorrhages. It possesses a fibrous pseudocapsule and consists of fascicularly arranged, spindle-like or fusiform tumour cells embedded in parallel collagen fibres. The non-epithelial stroma marker vimentin is overexpressed. These cells may exhibit marked polymorphism. Fibrosarcoma mainly occurs in men of advanced age. Therapy consists of tumour resection and adjuvant chemotherapy. (280, 281)

## 7.7 Fibrous histiocytoma

Malignant fibrous histiocytoma (MFH) is a rare mesenchymal tumour of histiocytic origin. This tumour was first described by L. Ozello et al. (1963) and J.E. O'Brien et al. (1964). It has not yet been clarified which cell type this tumour derives from and whether it is a single entity. The tumour tends to develop in the tissue of the extremities and in the retroperitoneum. MFH rarely occurs in the liver (so far, reports of 22 cases have been published). (12) The tumour cells contain a vacuolated cytoplasm with oval-polymorphic nuclei; giant cells may be present. (283, 284) MFH shows a firm consistency and greyish-yellow colour. There are no typical findings. (282, 285, 286) It appears most frequently in patients of advanced age. Diagnosis is confirmed immunohistochemically. The prognosis for this extremely aggressive tumour is poor. Resection at an early stage with subsequent chemotherapy constitutes the only possible therapeutic option.

## 7.8 Malignant schwannoma

Malignant schwannoma is a very rare mesenchymal tumour derived from the Schwann cells or nerve-sheath cells. It is also termed neurilemmoma or neurinoma. Up to now, only about 10 cases involving the liver have been reported. This tumour is mostly associated with neurofibromatosis. Men are more frequently affected than women. Schwannoma usually occurs in the ages between 20−50 years. It shows a firm consistency and has a greyish-white colour. Generally, there are multiple lesions. In the tumour itself, necroses and haemorrhages are found. Schwannoma consists of strands of spindle cells which interweave to form a herringbone pattern. The stroma contains strong bundles of collagen fibres. There are cell polymorphisms and mitoses as well as areas of densely grouped cells. Expression of S-100 anti-

gen from the tumour cells is increased. A high level of alkaline phosphatase is a characteristic finding in spite of normal transaminases. Prognosis is relatively poor. (287, 288)

## 7.9 Hepatic liposarcoma

The first liposarcoma observed in the liver was reported by J.I. Kim et al. in 1987. (289) Up to now, about 10 cases have been published. Bright yellow tissue containing mature fat cells admixed with scattered immature lipoblasts were found in various stages of development. Moreover, hyperchromatic nuclei in pleomorphic tumour cells, eosinophilic cytoplasm and fusiform cells were evident. (290) On US, liposarcoma is generally inhomogeneous with hypoechoic or hyperechoic features. Also on CT, this myxoid tumour is inhomogeneous and has Hounsfield units ranging from near-water density to that of muscle and may exhibit contrast enhancement. In addition, cystic areas and septated areas may be seen in MRI.

## 7.10 Hepatic osteosarcoma

Primary hepatic osteosarcoma is a very rare mesenchymal tumour, which was first described by J.H. Maynard et al. in 1969. It is of greyish-white to pale yellow colour and shows a gritty consistency. It grows rapidly with an aggressive behaviour. The survival time is short. • Histologically, there are different components, such as osteoblastic, chondroblastic and fibroblastic cells. Numerous osteoblastic-like giant cells are present. Expression of vimentin is positive, whereas actin, desmin and cytokeratin are not detectable. The tumour cells produce lace-like osteoid. (291, 292)

# 8 Neuroendocrine tumours

These tumours generally grow slowly. They develop from the neuroendocrine system, which is considered to be part of the APUD system (= **a**mine **p**recursor **u**ptake and **d**ecarboxylation) (A.G.E. Pearse et al., 1978). However, due to the secretion of biologically active hormones, they give rise to manifold clinical symptoms. Such tumours very seldom develop primarily in the liver. They meanwhile present a real diagnostic challenge for today's sophisticated imaging procedures. (297)

## 8.1 Hepatic gastrinoma

This primary hepatic gastrinoma is a rare event, although the liver is a very common site for gastrinoma metastases. Hepatic gastrinoma is a subtype of the neuroendocrine tumour. It tends to occur in slightly younger patients compared to others with a Zollinger-Ellison syndrome. Males are more frequently affected than

females. Gastrin levels in the serum are high. Imaging procedures for diagnosis include somatostatin-receptor scintigraphy with $^{111}$In DTPA octreotide. Because of the slow growth and the feasibility of resection, the prognosis is relatively good. (293–296)

## 8.2 Primary hepatic carcinoid

The term "carcinoid" was coined by S. OBERNDORFER in 1907 as a result of observations involving tumours in the small intestine. It was H. HARTMANN who first reported a primary hepatic carcinoid in 1920. To date, only a few cases have been described in the literature. Its histology is similar to that of adenocarcinoma, but it is aggressive. • Hepatic carcinoids are mostly metastases arising from primary carcinoids in the area of the appendix, stomach or colon. Such carcinoids may infiltrate the liver diffusely or may form nodes and cysts. Both primary and metastatic forms have a brownish colour and grow slowly. Endocrine tumour cells show ribbon-like or rosette-like patterns; they may develop along the intrahepatic bile ducts and possibly lead to the formation of hepatic carcinoid tumour. The inclination to infiltrative growth and metastatic spread apparently depends on the localization and size of the tumour. (298, 301) Expression of neuroendocrine marker proteins (chromogranin A, synaptophysin, neuro-specific enolase, etc.), but also of CEA, is found. (300) A relatively specific marker is the enhanced excretion of 5-hydroxyindolacetic acid in the urine (> 30 ng/24 hr).

Biochemical parameters are only slightly altered. Imaging techniques provide evidence of space-occupying lesions. In sonography, this tumour is echogenic and shows many cystic areas. Lesions are markedly hypervascular on colour Doppler US and angiography. (299) The diagnosis, however, is only secured histologically or by scintigraphy with I$^{131}$-meta-iodobenzylguanidine or octreotide. The *carcinoid syndrome* is triggered by the release of serotonin from the tumour cells into the blood circulation. A larger amount of serotonin in the blood causes a "flush" (= pronounced redness of the face and upper body due to vascular dilatation, which may last several hours) as well as sweats, hypotension and bronchiospasms. • Octreotide or ketanserin are useful medicinal agents. Surgery (resection or possibly transplantation) is indicated. Chemoembolization also shows good results.

## 9 Malignant lymphoma

Primary malignant lymphoma of the liver is very rare (A.A. ATA et al., 1965); so far, about 100 cases have been described. It can occur both in children and in adults; however, men older than 50 years are predominantly affected. There is a close association to immunosuppressed patients, especially in HIV infection. (304) Single observations regarding a pathogenetic relationship with EBV infection, hepatitis B and C, PBC (308), coeliac disease and lupus erythematosus have not been confirmed so far. • *Histology* shows lymphomatoid infiltrations in the portal fields; they can penetrate the neighbouring parenchyma. These lymphomas derive from the lymphocytes and Kupffer cells of the portal fields. About two-thirds of the hepatic lymphomas are B cell type and one-third are T cell type, the latter usually consisting of anaplastic large cells (H. STEIN et al., 1985). Malignant lymphomas generally develop as solitary nodes, less frequently in the form of multiple nodes, and, occasionally, as diffuse infiltrations throughout the entire liver. Special forms include low-grade malignant B cell lymphoma of the *MALT type* and *γδ-T cell lymphoma*. (307) The latter affects mainly younger adults, and its course is more aggressive. In this subtype, the spleen and bone marrow are also involved. • Clinical and imaging findings are not characteristic; in most cases, fever, loss of weight and night sweats are found. Transaminases may be increased. Diagnosis is confirmed by histology and with the help of immunohistochemical examinations of epithelial and lymphatic antigens. Reactive lymphatic hyperplasia must be ruled out as a differential diagnosis. • The mean survival time is 1–2 years. Therapy consists of resection and chemotherapy. (302, 303, 305, 306, 309)

## 10 Liver metastases

### 10.1 Definition

**Metastasis** ("tumour spread") is a secondary focus of disease caused by haematogenic, lymphogenic or ductal transport of living or dead matter from the primary focus of disease. • In the narrow sense of the term, **metastasis** is the secondary or "daughter" focus ("filia") of a malignant primary tumour. It may manifest as *local metastasis* (with a local relationship to the primary tumour as a neighbouring metastasis due to continuous tumour growth, e. g. in gall-bladder carcinoma), *regional metastasis* (within the regional lymphatic system) or *distant metastasis*. Metastases occur spontaneously or due to mechanical transportation. • **Liver metastasis** develops via the portal vein (particularly in carcinomas of the gastrointestinal tract), via the hepatic artery (e. g. from the lung, breast, oesophagus, pancreas, and in melanomas) or via retrograde lymphatic permeation and extension along the vascular lumen. This occurs in 30–35% of all malignancies and in 45–50% of abdominal tumours. In 95–97% of cases, liver metastases cause malignant hepatic lesions.

### 10.2 Morphology

Liver metastases may occur as well-demarcated solitary or multiple nodes and can ultimately infiltrate almost

the whole liver tissue. This metastasis itself results in extreme *hepatomegaly* (> 5,000 g). In most cases, there are clearly limited nodes of a greyish-white colour and firm consistency. The consistency depends on the ratio of cancer cells to fibrous stroma. Metastases tend to bulge from the liver surface; localization is very rarely confined to the interior of the liver. A solitary node is found in some 10% of patients at the time of diagnosis; in 15−20% of cases, only one lobe is affected. • There is often a central depression due to tumour necrosis caused by insufficient blood supply within the tumour (= *cancer umbilicus*). (s. figs. 37.16, 37.17) Sometimes, the metastases are enclosed in a fibrous pseudocapsule. (348) The immediate surroundings of the metastasis are occasionally characterized by a dark, bluish-red discolouration due to venous hyperaemia (= **Zahn's infarct**). In rare cases (particularly in small-cellular bronchial carcinoma), diffuse metastasis develops (s. figs. 37.17, 37.18), which resembles liver cirrhosis and may cause acute liver failure. (312, 329) • *Histology* is often similar to that of a primary tumour. (s. figs. 37.19, 37.20) However, there may also be considerable deviation, which makes classification of the primary tumour difficult and uncertain, or indeed impossible. (314) • In *liver cirrhosis,* metastases are less frequent, whether due to the altered vascular structure of the cirrhotic liver, an enhanced content of metalloproteinases, decreased expression of adhesion molecules or the fact that the patients do not survive long enough for the formation of metastases to become evident − the short survival time is a result of the combination of cirrhosis and carcinoma. (349) Fatty liver or angiostatin suppresses angiogenesis in metastases. (335) By contrast, alcohol consumption enhances liver metastasis in colon carcinoma. (343) • *Spontaneous regression* has been reported. (321, 333)

Adjacent tissue often shows local, *non-specific reactive hepatitis* (activation of Kupffer cells, small round-cellu-

lar infiltration of the sinusoids and portal fields, single-cell necroses, nodular infiltrations). (s. fig. 21.1)

## 10.3 Symptomatology

The occurrence and growth of liver metastases are accompanied by increasing lassitude and malaise, a per-

***Fig. 37.16:*** Large metastasis in the right hepatic lobe with distinct "cancer umbilicus" subsequent to breast cancer (serosa, peritoneum and ligaments without pathological findings)
**Fig. 37.20:** Metastasis of a malignant granulosa cell tumour of the ovary (HE)

vasive feeling of weakness, febrile attacks, upper abdominal pain, inappetence, night sweats and weight loss. Pronounced hepatomegaly is often found, together with a hardening of the liver and occasional palpability of the tumour nodes. The spleen may also be enlarged. Jaundice usually develops as the tumour continues to grow. Pleural effusion, oedema (reflecting obstruction of the inferior vena cava), ascites (reflecting peritoneal metastases) (s. figs. 37.21, 37.22), haemoperitoneum (354) and thrombosis of the portal vein may occur. Sometimes, there is a swelling of the lymph nodes, especially in the right supraclavicular region. • Tumour cells have a limited lifespan in the blood circulation ($< 24$ hr) if the defence system of the body is intact. Even if a peritoneovenous shunt is carried out in malignant ascites, metastatic spread is rare.

**Fig. 37.21:** Pronounced peritoneal metastasis (with simultaneous liver metastases) in ovarian carcinoma

## 10.4 Diagnosis

**Biochemistry:** Non-specific signs of inflammation become more pathological. A rise in γ-GT, initially as an isolated value, is characteristic; this is then accompanied by higher cholestasis-related parameters. In addition, there is an increase in LDH, GPT, GOT and the DeRitis

**Fig. 37.22:** Chylous ascites, greenish-coloured due to bile, in colon carcinoma, with metastases in the liver and peritoneal cavity

quotient. Gamma GT is also seen as a control parameter in chemotherapy. In colorectal liver metastases, the serum value of endothelin 1 is often elevated. (356) • While **tumour markers** can be helpful for establishing the diagnosis and for classifying metastases, they are of even greater importance in monitoring the course of disease. (s. tab. 37.12)

**Tab. 37.12:** Laboratory findings and tumour markers arousing suspicion in liver metastasis

**Sonography:** Metastases can be detected from a size of $> 0.5$ cm. Due to their high water content, they appear as hypoechoic lesions. (s. p. 134) (s. figs. 6.13; 37.23) With continued growth, central echo amplifications occur due to regressive tissue changes. In metastasis, a halo has a specificity of 86% and a sensitivity of 88% − a finding which, however, also applies to benign tumours. A bulging liver surface or displacement of the vessels and bile ducts may also point indirectly to

metastases. Normal sonographic findings do not exclude metastasis of the liver. • With a sensitivity of 96%, *endosonography* is the gold standard. (330, 346, 350) • Detection of *calcified liver metastases* by sonography or CT is rare (327); we were able to observe this event subsequent to surgical removal of a colon carcinoma and a breast carcinoma. (s. figs. 37.24, 37.25)

***Fig. 37.23:*** Numerous centrally liquefied liver metastases (differential diagnosis: liver abscesses)

***Fig. 37.24:*** Calcified liver metastasis and other small hypoechoic tumours; condition after resection of a colon carcinoma

**CT:** Most metastases are hypodense prior and subsequent to the application of contrast medium. Sensitivity is 92% in foci of > 15 mm, but only 55% in smaller ones. When there is concomitant fatty degeneration, CT is inferior to sonography for the detection of metastases. The best results were achieved by using spiral CT and *CTAP* with a sensitivity of 92−93%; all metastases larger than 6 mm could be identified. (322, 337, 346, 358) (s. p. 175) (s. figs. 37.26, 37.27)

**MRI:** Metastases usually show low signal intensity in $T_1$-weighted images and high signal intensity in $T_2$-weighted images. Necrotic metastases may show a signal intensity in $T_2$-weighted images similar to that of haemangioma. In contrast-amplified $T_1$-weighted images, perifocal oedemas can be distinguished from the

***Fig. 37.29:*** Laparoscopic staging: metastases at the falciform ligament in oesophageal carcinoma

***Fig. 37.30:*** Laparoscopic staging: Melanotic and non-melanotic metastases of melanoma (right liver lobe with transition to right abdominal peritoneum; liver capsule/peritoneal adhesions)

tumour. Haemorrhages are signal-intense in $T_1$-weighted images. Sensitivity is $85-95\%$ and can be further improved when superparamagnetic iron oxides are used. (322, 337, 359) (s. p. 178) (s. fig. 8.8)

**Laparoscopy:** If it has not been possible to make a clear diagnosis, explorative laparoscopy now becomes the method of choice. (s. figs. 37.16, 37.17, 37.30) This technique allows excellent *inspection* of the whole abdominal cavity, also for the purpose of **staging,** as well as facilitating targeted, low-risk biopsies, preferably using forceps. With the help of this method, we very often found small metastatic foci, for example on the peritoneum (s. fig. 37.28) or the falciform ligament (s. fig. 37.29), which could not be detected prior to surgery by any other technique (not even by explorative laparotomy).

All findings are documented using **photolaparoscopy** and, together with histology, they can facilitate a more reliable assessment both for the pathologist and for *interdisciplinary discussion* of any therapy concept which may be necessary − this applies to other diseases as well. (334, 345, 353) (s. pp 155, 156) • **Fine-needle biopsy** allows cytological diagnosis in a high percentage of cases.

## 10.5 Metastases in children

In children, metastases are also found far more frequently than primary liver tumours. Generally, we may expect metastases from the same tumour types in children as are observed in adults. However, two types of tumour are particularly important in this respect.

(1.) **Wilms' tumour:** This extremely malignant embryonic adenosarcoma of the kidney causes liver metastases in $20-25\%$ of cases.

(2.) **Neuroblastoma:** Liver metastases develop with extreme rapidity within the first $6-9$ months of life. The general condition is not compromised until later. This metastatic spread is a result of a sympathogonioma which has its origin in the adrenal medulla or autonomic ganglia. Such a clinical picture is also termed *Pepper's syndrome* (W. PEPPER, 1901).

## 10.6 Therapy

The manifestation of liver metastases and their prognosis are largely determined by the localization and degree of malignancy of the primary tumour. The survival time subsequent to the detection of metastases is about 1 year. Patients with liver metastases from colon carcinoma have the most favourable prognosis.

As a general principle, treatment of liver metastases should be preceded by an **interdisciplinary consensus conference** − this also applies to primary liver tumour. (s. p. 782)

## 10.6.1 Resection therapy

The choice of resection procedure is based on the size, location and number of the metastases. (310, 317, 319, 347) (s. pp 782, 870)

**Metastasectomy:** Using this method, small and superficial metastases can be removed without having to pay attention to vessels; a safety margin of 1 cm around the metastases should be adhered to.

**Segmental resection:** In some cases only a monosegment is resected, in other cases bisegmental or polysegmental resections are carried out to remove adjacent segments. Under certain conditions, multi-segmental resection is used for removing several segments from different areas of the liver at the same time. Perisegmental resection is necessary when a metastasis is located on the boundary between two separate segments. • In all these resection procedures, it is also necessary to adhere to a safety margin of 1cm (although the technique of parenchymal dissection used today makes it possible to resect with a smaller safety margin). (311, 316, 317, 323, 324, 331, 341, 363)

**Parenchymal dissection:** Instead of the parenchymal-fracture technique used in the past, ultrasound dissection or aqua-jet dissection is now applied.

**Parenchymal sealing** is usually carried out by means of fibrin spray if the wound surface is "dry" or by means of argon beamer if the wound surface is still bleeding.

To date, resection of liver metastases of colorectal or neuroendocrine tumours is the only treatment option which may result in definitive removal of the cancerous disease. Resection is indicated in those cases in which the primary tumour can be removed completely and when no further metastases are detectable. Repeated resection is also possible. Extrahepatic metastases or involvement of neighbouring organs are generally no longer regarded as contraindications. (311, 316, 317)

Morbidity should not exceed 30%. Lethality is between 0−3%. The 5-year survival rate following **R0 resection** in metastatic colorectal carcinoma is 20−40%, in neuroendocrine tumours 90−100%, in malignant melanoma 15−25%, and in breast cancer 10−30%. Prognosis is poor in metastasizing renal cell carcinoma and in gastric or pancreatic carcinoma. Both **R1** and **R2 resection** worsen the prognosis to the same extent.

The following factors are decisive for the success rate: (*1.*) age of the patient, (*2.*) distribution pattern and number of metastases, (*3.*) size of the largest metastasis, (*4.*) stage of primary tumour, (*5.*) extrahepatic metastases, (*6.*) lymph node involvement, (*7.*) respective value of the tumour marker, and (*8.*) intraoperative blood loss. (323)

For the follow-up after resection, sonography and determination of CEA and CA 19-9 (or other relevant markers) are necessary. In about 60% of cases, resected liver metastases recur; in about 30% of these patients, repeat resection is possible. (364)

In patients undergoing surgical resection of colorectal liver metastases, haematogenous tumour cell dissemination could be detected in preoperative blood samples in 30%, in intraoperative blood samples in 46% and in postoperative blood samples in 22% as well as in bone marrow samples in 16% of cases. • Thus, there are once again good reasons for using *neoadjuvant systemic chemotherapy* together with perioperative administration of *i.v. galactose infusions*. (338)

## 10.6.2 Cryotherapy

This technique, first described by J. ARNOTT in 1945, was applied by I.S. COOPER in 1963 for liver metastases. The treatment uses a probe, introduced (possibly by laparoscopy) into the tumour, which is subsequently frozen with liquid nitrogen at a temperature of $-196\,°C$. The result is necrotic degeneration of the tumerous tissue. Usually, two freezing procedures lasting 15 minutes each are carried out. The risk of damaging the large vessels is relatively low. The advantage of cryotherapy is that the tumour cells are kept in place mechanically with the help of the extracellular ice matrix, thus inhibiting dissemination of the tumour cells. The method is painless. Disadvantages include the high costs and the more pronounced parenchymal trauma. (326, 336, 344, 352, 355) (s. p. 781)

## 10.6.3 Liver transplantation

In the case of diffuse metastasizing in the liver due to a neuroendocrine tumour, transplantation may be indicated.

## 10.6.4 Local treatment

There are no clear recommendations concerning indications for percutaneous interventional procedures. It is uncertain whether the metastases have been completely removed when guiding is based on imaging techniques. Moreover, the extent of the placed necrosis can only be assessed in a limited way; however, evaluation is more exact if the resected tissue is analyzed histologically.

**RFTA:** The monopolar system which has been used up to now will probably be replaced in the near future by a bipolar system. Coagulation necrosis of up to 5 cm can be achieved. However, RFTA sometimes has a negative impact in areas near the large vessels, since the cooling effect may cause the tumour cells close to the vessel walls to survive, with a risk of recidivation. In special cases, RFTA can also be applied as an open (operative) technique. A combination of ablation therapy and resection is possible. RFTA has several advantages: it is relatively low in cost, there is less parenchymal loss, the procedure is safe and can be repeated. (339) (s. p. 785)

**LITT:** Even in the case of liver metastases, the laser applicator is positioned using a percutaneously or lapar-

oscopically inserted puncture needle. The procedure lasts 15−20 minutes. Repeat treatment is possible. (318, 342, 361) (s. p. 785)

**PEI:** Percutaneous injection therapy with alcohol or acetic acid is not recommendable in liver metastases. (325)

### 10.6.5 Local chemotherapy

**TAC:** Application of cytostatics is generally carried out using a port-catheter system via the gastroduodenal artery and the proper hepatic artery (R.D. SULLIVAN et al., 1964). Foci in excess of 2 mm are supplied by this artery in 80−100% of cases. Moreover, the blood flow can be slowed down by administering starch microspheres or similar substances, so that a higher concentration of cytostatics is achieved in the tumours. In order to avoid toxic damage, the right gastric artery must be ligated and a cholecystectomy carried out; cholangitis may develop as a side effect. (315) In about 30% of patients, positioning of the catheter is not possible or must be modified due to vascular anomalies. Therefore, it is necessary to perform a coeliacography preoperatively to check the anatomy of the vessels. TAC has been applied for the treatment of colorectal liver metastases using 5-FU/folinic acid, 5-FU/mitomycin or fluordesoxyuridin as a continuous i.v. infusion based on (still) varying schemes. This therapy option is not regarded as effective for liver metastases. (313, 398, 331, 332, 340, 360) (s. p. 784)

**TAE, TACE:** Both transarterial embolization and chemoembolization with the help of a port-catheter system via the proper hepatic artery (analogous to TAC) might be a therapeutic option regarding non-resectable liver metastases. An indication is also given if there is a high surgical risk involved. Embolization can be repeated several times. In metastatic neuroendocrine tumours, preoperative treatment with somatostatin analogues is recommended. The response rate in colorectal liver metastases is usually low. In combination with lipiodol, however, a response rate of 45% can be achieved in solitary metastasis. It should be noted that lipiodol enrichment only occurs at the margins of metastases. More positive results have been obtained with a combination of collagen + cisplatin + doxorubicin + mitomycin, particularly when administered at intervals of 6−8 weeks. (s. pp 784, 785)

### 10.6.6 Systemic therapy

In special kinds of tumours, the application of a certain substance can be helpful as adjuvant therapy.

**Anti-hormone therapy:** Gastroenteropancreatic tumours show a good response to the systemic administration of anti-hormonal substances, especially those which are directed against the biological activity and peptide secretion of these tumours. • As a result, **octreotide** ther-

apy can be applied as s.c. injection for a longer time. Follow-up is possible by determining serotonin and chromogranin A in the serum as well as 5-hydroxyindole acetic acid in the urine. • In metastasized insulinoma, **diazoxide**, a benzothiazide analogue, can block the release of insulin and increase glycogenolysis. However, this substance has considerable side effects.

**Interferon therapy:** The application of IFN is based on inhibiting protein synthesis and thus cell proliferation. Its indication is recommended in metastatic neuroendocrine tumours.

### 10.6.7 Systemic chemotherapy

Systemic chemotherapy is usually not indicated in noncolorectal liver metastases due to lack of response. The systemic administration of cytostatics (also in combination) possesses the status of palliative therapy. • However, in metastatic neuroendocrine tumours, a combination of octreotide + IFN had a positive effect on the survival time. Systemic chemotherapy produced remission rates of up to 60%. (320) • In metastatic breast cancer, systemic chemotherapy is indicated, usually in combination with hormonal and immune therapy. (316, 342) • In metastatic gastric carcinoma, palliative chemotherapy can achieve a remission rate of up to 40%, with a slight extension of survival time.

> As a rule, the suitability of a combination of cytostatics following operative or local interventional therapy should be discussed at an interdisciplinary conference.

**5-FU monotherapy:** In metastatic colorectal carcinoma, 5-FU/folinic acid has constituted the basis of systemic chemotherapy for more than 40 years: survival time is prolonged, tumour-related symptoms are diminished and quality of life improves. Folinic acid is seen as the main modulator of 5-FU efficacy. Various schemes are used in different dosages and forms: (*1.*) *O'Connel scheme*, (*2.*) *Ardalan scheme*, (*3.*) *Machover's scheme*, and (*4.*) *Rougier's scheme*. • In the meantime, the *De Gramont scheme* has been introduced in France (200 mg/m$^2$ folinic acid, 400 mg/m$^2$ 5-FU [bolus] and 600 mg/m$^2$ [22 hr i.v. infusion] on day 1 and 2, repeated on day 15), and the *AIO scheme* has been introduced in Germany (500 mg/m$^2$ folinic acid, 2.6 g/m$^2$ 5-FU [24 hr i.v. infusion] 6 x/week, 1-week interruption of therapy).

**Fluoropyrimidine-based prodrugs:** A new development are the oral prodrugs *ftorafur* and *capecitabin*. Both substances have already proved effective. Capecitabin should not be combined with folinic acid.

**Irinotecan-based combination:** Irinotecan is a camptothecin-derivative, which as a prodrug is converted into a cytotoxic agent by means of carboxylesterase. It is considered to be one of the most active cytostatics in

advanced colon carcinoma. The combination with 5-FU as an i.v. continuous infusion is recommended as a preferential form of treatment.

**Oxaliplatin-based combination:** Oxaliplatin has likewise been used successfully in combination with 5-FU. The most important limiting side effects of a long-term therapy are cumulative neuropathic symptoms.

▶ In metastatic colorectal carcinoma, it is possible to achieve complete surgical removal (R0) of the metastases in initially incurable resected patients due to the relatively successful systemic chemotherapy schemes used today. In about 20% of the patients with oligotropic metastatic spread, this **therapy triad** consisting of resection + chemotherapy + resection can lead to a 5-year survival rate of 25% (cf. primary curative resection).

### 10.6.8 Adjuvant measures

The information presented in section 3.9.4 (s. p. 786) similarly provides a basis for adjuvant or unconventional treatment and for general care of tumour patients with metastases. (s. tab. 37.10) • In addition, the perioperative use of **galactose** may be worth considering in surgical (or invasive) treatment of metastases, especially since it is without side effects and does not involve undue costs. • Furthermore, we would like to point out that the administration of **zinc** and **selenium** as well as **potassium canrenoate** is useful when planning a resection of metastases. (s. p. 787)

# Clinical Aspects of Liver Diseases

## 38 Systemic diseases and the liver

# 38 Systemic diseases and the liver

Systemic diseases originating in the *haemopoietic* or *lymphatic* systems and those belonging to the category of *rheumatic diseases* can affect the liver directly or indirectly.

**Haematopoietic system**
1. *Direct effects on the liver*
   = pathological extramedullary haemopoiesis in the liver
   = disturbed liver haemodynamics following haemolysis
2. *Indirect effects on the liver*
   = reduced defence against infections facilitates bacterial, viral or mycotic liver damage
   = toxic liver damage caused by drugs (e. g. cytostatics, immunosuppressants)
   = graft-versus-host reaction in bone-marrow transplants

**Lymphatic system**
1. *Direct effects on the liver*
   = pathological formation and deposition of lymphocytes or lymphoblasts with formation of infiltrates or focal lesions
   = cholestasis following mechanically mediated biliary dyskinesia
2. *Indirect effects on the liver*
   = reduced defence against infections facilitates bacterial, viral or mycotic liver damage
   = toxic liver damage caused by drugs (e. g. cytostatics, immunosuppressants)

**Rheumatic diseases**
1. *Direct effects on the liver*
   = rheumatism-related inflammatory or immunologically induced intrahepatic vasculitis with sequelae
   = non-specific reactive hepatitis
2. *Indirect effects on the liver*
   = toxic liver damage caused by drugs (e. g. antirheumatic agents, immunosuppressants)

**Tab. 38.1:** Relationship of the liver to the haematopoietic and lymphatic systems and to the category of rheumatic diseases

# 1 Systemic haematological diseases

## 1.1 Extramedullary haemopoiesis

▶ Intrahepatic haemopoiesis is a **physiological process** in foetuses and neonates. From 6$^{th}$ to 24$^{th}$ week of pregnancy, haemopoiesis takes place in the liver (and spleen) in a diffuse manner within the sinusoids. Thereafter, focal haemopoiesis may still continue in the liver up to about the second week of life.

Myeloid metaplasia beyond this physiological endpoint of intrahepatic haemopoiesis is regarded as a **pathological event.** Haemopoietic foci are seen in the sinusoids, in Disse's spaces and sometimes to a minor degree in the portal fields; they consist of erythropoietic and myeloproliferative precursors as well as polynuclear giant cells of the megakaryocyte type. This variety of cells provides important evidence in histological differential diagnosis for excluding leukaemic infiltrates and mononuclear

hepatitis. Myeloid metaplasia accompanies displacement of the bone marrow, e. g. in osteomyelofibrosis, bone-marrow carcinomatosis and myeloproliferative diseases. Occasionally, megakaryocytes are also present in the liver. Naphtol-AS-D chloracetate esterase-positive cells of granulopoiesis are a striking feature in this context. Hepatomegaly is generally found. Ascites can develop due to portal hypertension. (s. fig. 38.1)

**Fig. 38.1:** Extramedullary haemopoiesis in the liver with erythropoiesis precursors and intrasinusoidal megakaryocyte ( ↑ ) due to the so-called marrow-replacement syndrome or chronic myeloproliferative disease (HE)

## 1.2 Acute leukaemia

In acute myeloid leukaemia or lymphatic leukaemia as well as in acute leukaemic episodes in non-Hodgkin lymphoma, involvement of the liver may only be detectable clinically by the presence of hepatomegaly and subicterus. • **Laboratory parameters** usually show slightly elevated transaminase as well as bilirubin values, and distinct cholestasis is occasionally observed. (7) Acute hepatic failure can occur during the course of acute leukaemia. (1, 8, 26, 65) • **Histologically,** there are massive, yet uniform blast-cell infiltrates; these are found mainly within the portal fields in acute lymphatic leukaemia (about 95%) and within the sinusoids in acute myeloid leukaemia (about 75%). • Involvement of the liver is of no consequence with regard to the underlying disease and its **therapy**. Secondary infections require systemic treatment with antibiotics and/or antimycotics.

## 1.3 Myeloproliferative syndrome

The term myeloproliferative syndrome encompasses the following: (*1.*) chronic myeloid leukaemia, (*2.*) idiopathic osteomyelofibrosis and sclerosis, (*3.*) polycythaemia vera, and (*4.*) essential thrombocytosis. Inter-

mediate forms of these manifestations are possible. The pathogenesis is based on the transformation of a stem cell and its clonal proliferation. • Chronic lymphatic leukaemia is classified as malignant non-Hodgkin lymphoma. Overlaps between the different forms of disease are frequent. There is a tendency for fibrosis to develop in all types of the myeloproliferative syndrome with subsequent sclerosis of bone marrow in later stages. Certain forms may progress to acute leukaemia, which is termed blast crisis.

### 1.3.1 Chronic myeloid leukaemia

In CML, granulopoiesis is markedly accelerated, with increased formation of immature precursors. This occurs predominantly in the bone marrow. Accordingly, there is only a rare and slight involvement of the *liver* in CML, with the exception of a terminal myeloblast crisis. (s. fig. 38.2) Hepatomegaly may be very pronounced in some cases. Massive splenomegaly is generally evident; it often presents as a sugar-icing spleen *(perisplenitis cartilaginea)*. (s. fig. 38.3) Infiltrations of immature granulocytes and erythrocytes as well as of megakaryocytes are identifiable above all in the (generally dilated) sinusoids. Biochemically, there is an elevation of alkaline phosphatase and LDH. Complications include portal hypertension following obstruction of the sinusoids and as a result of increased hepatic blood flow. (18) Acute liver failure has been observed. (15) In the final stage, metastasis-like structures can appear in the liver (so-called *chloroma*). Imaging procedures reveal no abnormalities in the area of the liver parenchyma. (5, 11) • *Therapy* with imatinib was recently reported as being successful.

### 1.3.2 Osteomyelofibrosis

Osteomyelofibrosis is a chronic, progressive, fibrous obliteration of the bone marrow. Greyish-white discolouration appears with an increase in collagenous fibrils and later also in reticular fibrils. Clinically, there is hepatomegaly (and generally also splenomegaly) correlating with the stage of disease. Arthralgia also occurs occasionally. • *Laboratory parameters* may show a slight elevation of γ-GT, AP, transaminases and bilirubin. Leucocyte alkaline phosphatase is enhanced. • *Histologically*, extramedullary haemopoiesis, comprising erythrocyte and granulocyte precursors as well as dysplastic megakaryocytes, is found in the liver in > 90% of cases. (13, 16) (s. fig. 38.1) Infiltrates appear in the sinusoids, which are partly dilated and display fibrosis and deposits of haemosiderin. This results in portal hypertension (6, 12); ascites (10) and oesophageal varices are rare (about 7% of cases). Further potential complications include cholelithiasis (its relationship has not been clarified so far), Budd-Chiari syndrome and portal vein thrombosis. (2) • The diagnosis is established by liver

***Fig. 38.2:*** Terminal blast crisis of chronic myeloid leukaemia: numerous myeloid blasts in the sinusoids (HE)

***Fig. 38.3:*** Splenomegaly with perisplenitis cartilaginea (sugar-icing spleen) in chronic myeloid leukaemia

histology. Imaging procedures are of no significance here.

### 1.3.3 Polycythaemia vera

Liver involvement in Osler-Vaquez disease is rare or not detectable at all. There is, however, evidence of *hepatosplenomegaly* due to extramedullary haemopoiesis. Of importance here is the association with *Budd-Chiari syndrome* and *veno-occlusive disease*. Polycythaemia vera should be considered in cases of aetiologically unclarified *portal vein thrombosis*.

### 1.3.4 Essential thrombocytosis

With the exception of occasional hepatosplenomegaly, liver involvement is rare. There is again an association with *Budd-Chiari syndrome* and *veno-occlusive disease*.

## 1.4 Haemolytic syndrome

Numerous congenital or acquired diseases lead to *haemolysis*. (s. p. 218) (s. tab. 12.3) They are subsumed under the term haemolytic syndrome. Particularly, sickle-cell anaemia, thalassaemia and paroxysmal nocturnal haemoglobinuria are worthy of mention in this context.

### 1.4.1 Sickle-cell anaemia

This form of genetic *haemoglobinopathy* is characterized by chronic haemolysis and haemolytic crises. • **Acute haemolysis** is associated with acute right upper quadrant pain, leucocytosis, jaundice and elevated transaminases, AP and LDH. This hepatic crisis can mimic acute cholecystitis. It lasts 2−3 weeks. The condition is caused by a slowing down of the sinusoidal blood flow, which contains sickle cells, and, in addition, by a multiplication of the Kupffer cells. The liver is enlarged, rich in blood and violet-red. The sinusoids are dilated and contain agglutinates of sickle cells. The Kupffer cells contain ceroid and siderin as well as phagocytosed erythrocytes. (s. fig. 38.4) Single-cell necroses of hepatocytes with Councilman bodies are detectable. Acute liver failure, usually with cholestasis and deep jaundice, is a rare event. • **Chronic haemolysis** can lead to mostly asymptomatic gallstones (approx. 25% in children, 50−70% in adults). Furthermore, portal hypertension and portal fibrosis may develop. (3, 4, 9, 14, 19) *Therapy:* Exchange transfusion is indicated. Surgery must be avoided in cases where acute cholecystitis is only mimicked. • Successful liver transplantation has been reported.

**Fig. 38.4:** Erythrophagocytosis in Kupffer cells (arrows) in haemolytic anaemia

### 1.4.2 Thalassaemia

As a result of the crises entailing destruction of the red blood cells and the frequently required blood transfusions, liver siderosis develops. This may subsequently lead to fibrosis in some cases. Episodic cholestasis can be witnessed. In progressive siderosis, treatment with deferoxamine is indicated. *Pigment gallstones* (s. figs.

35.16, 35.17) can appear in the course of chronic haemolysis. (4)

### 1.4.3 Paroxysmal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria may also give rise to chronic haemolysis. This membrane defect of the erythrocytes is due to mutation of the PIG-A gene on chromosome X resulting in deficient biosynthesis of the glycosylphosphatidlinositol anchor. The erythrocytes are sensitive to lysis when the pH of the blood becomes more acidic during sleep. This clinical picture can lead to hepatomegaly, a rise in transaminases, iron deficiency and siderosis as well as centrizonal necrosis. *Thrombosis* of the portal and splenic veins as well as *Budd-Chiari syndrome* are possible complications. Sclerosing cholangitis is likely to develop due to ischaemia. (17)

# 2 Systemic lymphatic diseases

Hodgkin's disease and non-Hodgkin's lymphomas belong to this group. Liver involvement as a result of these diseases consists of infiltrates of lymphocytes or their precursors as well as the formation of lymphatic tissue nodes. The liver itself has no organ-specific lymphatic tissue.

## 2.1 Hodgkin lymphoma

▶ TH. HODGKIN described the so-called Hodgkin's lymphoma in 1832; in 1865 S. WILKS coined the term Hodgkin lymphoma. R. PALTAUF reported on lymphosarcomatosis in 1897. • The aetiology of this malignant systemic disease is unknown. Hodgkin's lymphoma invariably begins in the lymphatic tissue (= *lymphogranulomatosis*), mainly in the neck and mediastinum. The lymph node swelling is not painful.

Typical **Hodgkin cells** derive from undifferentiated reticular cells. They have a slightly basophilic cytoplasm and 1 or 2 glowing red or violet nucleoli in a very light, almost unstained nucleus. These cells are the mononuclear precursors of the polynuclear **Paltauf-Sternberg giant cells** (R. PALTAUF, 1897; C. V. STERNBERG, 1936). Such reticular giant cells are considered to be a reliable symptom of Hodgkin lymphoma in the liver (stage IV) when they are found in the typical cellular environment of a Hodgkin's granuloma. • **Five forms** of Hodgkin lymphoma are distinguishable histologically (1965, 1971):

| | |
|---|---|
| 1. nodular sclerosis | 40−80% |
| 2. mixed cellular form | 20−40% |
| 3. lymphocytotic type | 2−10% |
| 4. lymphocytopenic type | 2−5% |
| 5. unclassifiable form | 1−5% |

The **liver** is the most frequently affected non-lymphatic organ in Hodgkin lymphoma (30−50% of cases). Liver involvement is highest in the lymphocytopenic type

(which also has a particularly unfavourable prognosis) and in nodular sclerosis. Liver involvement is lowest in the lymphocytotic type. There is evidence of large, irregularly delineated tumour nodes and multiple, diffusely distributed nodules or even subcapsular miliary nodules. These macroscopic forms can also occur in combination; their histological properties are largely identical. Acute liver failure can develop. (35, 38) *Hepatomegaly* is frequently observed. *Splenomegaly* is generally associated with liver involvement. Non-involvement of the spleen is extremely rare (34); a normal-sized spleen generally rules out involvement of the liver. • *Hodgkin infiltrates* originate in the portal fields; they are arranged irregularly. Numerous reticulin fibres and dilatations of the sinusoids are frequently found in zones 2 and 3. The infiltrates consist of focally arranged histiocytes, epithelioid cells, eosinophils and small lymphocytes as well as *Hodgkin cells* and *Sternberg cells*. Central venous obstruction and endophlebitis can appear as a consequence of Hodgkin lymphoma in the liver. (20, 27, 39, 51, 57) (s. figs. 38.5−38.9)

*Fig. 38.5:* Hodgkin lymphoma: portal granuloma with Paltauf-Sternberg giant cell ( ↑ ) (HE)

*Fig. 38.6:* Hodgkin lymphoma: relatively well-defined, large intralobular granuloma with numerous Hodgkin cells (HE)

**Clinically,** there is *loss of weight* ( > 10% within 6 months), *fever* ( = Pel-Ebstein type, i.e. periodic fever at short intervals), *night sweats*, weakness, pain in the lymph nodes (following intake of alcohol) and pruritus

*Fig. 38.7:* Late stage of lymphocyte depleted in Hodgkin lymphoma (HE)

*Fig. 38.8:* Hodgkin lymphoma: node at the margin of the left liver lobe; clear, diffuse (reticular) fibrosis of the liver

*Fig. 38.9:* Hodgkin lymphoma: several foci up to the size of a lentil as well as a 1.5 cm tumour node in the greatly enlarged spleen

(particularly in the later stages). The so-called *B-symptomatology* (occurrence of weight loss, fever, night sweats) is mostly present when the liver is involved. (33)

**Laboratory investigation** reveals highly pathological "inflammatory criteria", which probably point to a consuming or malignant process. Alkaline phosphatase and bilirubin rise in the further course of disease (in about 80% of cases). Lymphopenia and eosinophilia are often in evidence. (36, 38, 41) (s. tab. 38.2)

| Non-specific "inflammatory criteria" (or indicators of a consuming process) | | | |
|---|---|---|---|
| ESR | ↑ | α-globulins | ↑ |
| CRP | + | haptoglobin | ↓ |
| fibrinogen | ↑ | copper | ↑ |
| iron | ↓ | cholinesterase | ↓ |
| haemoglobin | ↓ | D-dimer | ↑ |

**Tab. 38.2:** Non-specific "inflammatory criteria" (or indicators of a consuming process) (s. tabs. 37.6, 37.11, 37.12)

**Imaging procedures** display focal lesions, which appear hypoechoic and generally without a halo in sonography; in the further course of disease, the centre can yield a more hyperechoic structure. MR-SPECT has proved especially reliable in this connection. (25, 58, 62) • The diagnosis is established morphologically. This can be achieved most reliably by **laparoscopy** and targeted biopsy. (22, 51) Percutaneous biopsy has a low specificity; it must be carried out, if at all, under US or CT guidance (several samples should be obtained from both liver lobes). Liver involvement always corresponds to *Hodgkin stage IV* (= non-localized, diffuse or disseminated disease of one or more extralymphatic organs or tissues, with or without involvement of the lymphatic system). (43) • **Therapy** consists of polychemotherapy and/or intercurrent small-field irradiation, if applicable. The recurrence rate can be significantly reduced by mild chemotherapy prior to irradiation. In the case of recidivation, however, high-dose chemotherapy clearly shows greater efficacy. (53)

## 2.2 Non-Hodgkin lymphoma

The term non-Hodgkin lymphoma (NHL) subsumes a large number of different malignant diseases of the lymphatic system. Taken together, they have about the same frequency as Hodgkin's lymphoma. The annual incidence of the disease in Germany is about 15 per 1 million inhabitants.

▶ According to their clinical progression, they are classified into lymphomas of low and high malignancy. **Classification** is based on the Kiel Classification (K. LENNERT, 1978), the USA Classification (H. RAPPAPORT et al., 1978) or the New Working Formulation (1980). Staging corresponds to that of Hodgkin lymphoma (1971), i.e. liver involvement represents the prognostically critical stage IV. (s. tab. 38.3) • NHL occurs in three macroscopic **forms:**

| |
|---|
| 1. **micronodular, disseminated infiltrates** |
| 2. **macronodular multiple nodes** |
| 3. **solitary tumour masses** |

There is (primary or secondary) involvement of the **liver** in about 50% of patients with NHL (initially in approx. 20%, postmortem in >60%). The liver is seldom affected without simultaneous involvement of the spleen. However, liver involvement in NHL is of less importance than in Hodgkin lymphoma. In most cases, lymphocytic lymphomas result in miliary foci, whereas histiocytic lymphomas predominantly develop into tumour nodes. Macronodular, greyish-white nodes and solitary, greyish-white tumour masses are rare. Micronodular, disseminated infiltrates are produced by involvement of the portal fields, mainly in low-grade malignant forms of NHL. They appear as barely recognizable, fine-grained, white foci on the cut surface of the liver. • *Diagnosis* is confirmed morphologically with the aid of laparoscopy and targeted biopsy or forceps biopsy (22, 51), or by percutaneous biopsy under US or CT guidance. The use of immunohistochemical methods allows further differentiation and a more reliable diagnosis. (20, 21, 37, 52) (s. tab. 38.3)

| Low-grade malignant NHL |
|---|
| I. *Derived from lymphatic cells* |
|   1. Chronic lymphatic leukaemia |
|     − B-cell type (B-CLL) |
|     − T-cell type (T-CLL) |
|   2. Prolymphocyte leukaemia |
|   3. Hairy cell leukaemia |
|   4. Mycosis fungoides |
|   5. T-zone lymphoma |
| II. *Derived from cells secreting immunoglobulin* |
|   1. Immunocytoma |
|   2. Plasmacytoma |
| III. *Derived from germ centre cells* |
|   1. Centrocytic lymphoma |
|   2. Centroblastic-centrocytic lymphoma |
| **High-grade malignant NHL** |
|   1. Centroblastic lymphoma (lymphoblastic lymphosarcoma) |
|   2. Lymphoblastic lymphoma |
|     − B-type (EB virus-induced Burkitt lymphoma) |
|     − T-type |
|   3. Unclassified lymphoma |
|   4. Immunoblastic lymphoma (chiefly reticulosarcoma) |

**Tab. 38.3:** Classification of non-Hodgkin's lymphomas according to K. LENNERT, 1978 (Kiel/Germany)

**Clinically,** general symptoms of illness, such as fatigue, weakness, lack of appetite, loss of weight and fever are in evidence. A tentative diagnosis is based on hepato-(spleno)megaly and peripheral lymphadenopathy. • **Laboratory investigations** reveal "inflammatory criteria" in relation to the severity and form of NHL, as in Hodgkin lymphoma. (s. tab. 38.2) LDH and alkaline phosphatase

are generally elevated; a slight rise in transaminase values is sometimes evident. There is a strikingly frequent association with HCV infection (28, 29, 32, 44, 55, 60), with AIDS, and possibly also with azathioprine. • **Imaging procedures** can provide diagnostic evidence by displaying local lesions, usually as a singular space-occupying process of varying echogenicity and density. (42, 54, 58, 62) • The majority of cases are not diagnosed until they have reached an advanced stage. The symptomatology, course and prognosis depend on the type of NHL. Fulminant liver failure is relatively frequent − sometimes as the initial manifestation. (24, 30, 31, 40, 45, 50, 63) • New methods of treatment − in addition to or instead of interferon − are continuously being sought in the **therapy** of NHL. This includes transplantation of blood stem cells following whole-body irradiation combined with chemotherapy, chemoembolization or possibly tumour resection. Moreover, *rituximab* is available as an antibody against lymphoma cells.

### 2.2.1 Low-grade malignant NHL

The incidence of low-grade malignant lymphoma shows an increasing tendency. There are signs of a causal relationship with environmental factors (e. g. pesticides). Low-grade malignant NHL leads more often to liver involvement than do the other forms.

**Chronic lymphatic leukaemia:** CLL occurs as B-cell and T-cell types. B-CLL is the most common form (approx. 95%); it is based on the malignant transformation of B-lymphocytes and occurs mainly in older people. The surface of B-cells is coated with immunoglobulins of the heavy chain type. T-CLL results from malignant transformation of T-lymphocytes; it is comparatively rare (5%). All in all, CLL is the most common form of leukaemia (approx. 30%) and also the most common form of NHL. The liver is involved in >40% of cases. • *Histologically*, there are dense, uniform portal field infiltrates of small lymphoid tumour cells, whereas lymphoblasts are generally not detectable. The portal fields are extended, but the limiting plates usually remain intact and are only penetrated by the lymphocytic tumour cells in the later course of disease. (s. figs. 38.10, 38.11) Bridge-like infiltrates can then develop between the portal fields. Small infiltrates also occur in the liver lobule. The sinusoids show a cumulation of round cells. Jaundice and cholestasis develop following obstruction of the portal bile ducts. These findings can also be caused by compression of enlarged lymph nodes. (59) • *Complications* include portal hypertension (following fibrosis) (46), nodular regenerative hyperplasia and cholelithiasis (due to chronic haemolysis). Micronodular cirrhosis may also develop. • *Therapy* is carried out in accordance with haemato-oncological guidelines, especially with *alemtuzumal* (= antibody campath-1 H).

**Hairy cell leukaemia:** This designation is based on the microvillar "hairy" surface of the tumour cells. It is con-

***Fig. 38.10:*** Chronic lymphatic leukaemia: dense portal lymphoid cell infiltration (HE)

***Fig. 38.11:*** Chronic lymphatic leukaemia: dense portal lymphocytic infiltration extending into the liver parenchyma (HE)

sidered to be a special form of B-CLL. The disease begins insidiously, mainly at an advanced age, and it has a chronic progressive course. (23) Men are affected four times more often than women. Massive splenomegaly and panmyelophthisis are already detectable at an early stage. • In the **liver,** there is characteristic infiltration of the sinusoids with intralobular angiomatous changes, simulating the clinical picture of peliosis hepatis. (66) The associated angiomatous lesions are covered by hairy cells. (49, 64) A special feature of the hairy cell infiltrates is the presence of tartrate-resistant acid phosphatase, which is a reaction product of the tumour cells. Hepatomegaly is often present (in 40% of cases), whereas lymphadenopathy is very rare. In severe forms of infiltration, the picture of a nutmeg liver can develop. Colliquation of liver parenchyma with formation of lacunas can be detected as focal lesions by means of sonography and CT. Ascites can occur. • **Therapy** (with a generally favourable prognosis) consists of interferon-α or deoxycoformycin. Hairy cell leukaemia is resistant to radiation treatment and chemotherapy.

**Mycosis fungoides:** This malignant T-cell lymphoma begins in the skin, but may also affect internal organs. The liver is rarely involved; this is more frequently the case

with the leukaemic variant, the so-called **Sezary syndrome.** In the final stage of mycosis, however, portal field infiltrations are frequently detectable. They consist of atypical polymorphic lymphoid *Lutzner cells* (M.A. LUTZNER et al., 1971) and of larger cells containing hyperchromic and highly polymorphic nuclei (= *mycosis cells*). The disease is apparently caused by retroviruses. The prognosis is unfavourable; radiation therapy and cytostatic agents are ineffective.

**Immunocytoma:** This tumour originates in three types of immunoglobulin-secreting cells: (*1.*) lymphoplasmocytic, (*2.*) lymphoplasmocytoid, and (*3.*) polymorphic. In isolated cases, patients with Waldenström's macroglobulinaemia can also be assigned to this category. • *Clinical* symptoms include lymphadenopathy, splenomegaly, infiltration of the skin, fever, night sweats and pruritus. Immunoglobulins M and G are elevated. • The *liver* is involved in >90% of cases. The portal fields are only focally affected. The infiltrates are loosely and diffusely arranged. They frequently contain (50−80% of cases) PAS-positive, globular, nuclear and cytoplasmic inclusions, which represent retained immunoglobulins. The infiltrates also contain a scattering of mast cells and eosinophils. The limiting plates remain intact. Increased flooding of the sinusoids is regarded as a sign of a leukaemic course.

**Plasmocytoma:** Extramedullary plasmocytic lymphoma likewise has its origin in immunoglobulin-secreting B-lymphocytes. It is also termed *multiple myeloma.* The condition occurs most frequently in 7th decade of life and ends fatally after 1−2 (−3) years. • In the *liver*, there are sometimes sinusoidal and portal infiltrations of B-lymphocytes and plasmocytic tumour cells; nodular formation can also occur. Generally, however, liver involvement is found in 40% of cases. (47, 61) (s. fig. 38.12) • Recently, patients with non-response or relapse after high-dose chemotherapy were treated successfully with *thalidomide* (starting with 200 mg daily, the dose was increased by 200 mg every two weeks until it reached 800 mg per day). (48, 56) • **Plasma cell leukaemia** is a rare complicative variant which tends to have its own individual course.

*Fig. 38.12:* Intrasinusoidal accumulation of atypical plasma cells in plasmacytoma (HE)

**Centrocytic lymphomas:** These have their origin in lymphatic germ centre cells. *Liver involvement* occurs in about 50% of patients. The portal infiltrates consist of small cells with bright, irregularly shaped, indented nuclei. The portal fields are globularly distended as a result of the infiltration; the limiting plates remain intact, however, and the portal bile ducts are also undamaged.

**Centroblastic-centrocytic lymphomas:** This tumour type also develops from lymphatic germ centre cells. *Liver involvement* occurs in about 30% of cases. The portal fields are rounded due to infiltration; the limiting plates are penetrated in places. Follicular structures can occasionally be recognized.

### 2.2.2 High-grade malignant NHL

High-grade malignant lymphomas in the *liver* bring about destruction of the periportal limiting plates and fragmentation or neogenesis of the portal reticular fibres. All of these extremely malignant forms of NHL were classified as reticulosarcomas in the past, but only immunoplastic lymphoma can strictly be assigned to this category. High-grade malignant NHL is usually characterized by irregular portal infiltrates, which penetrate the limiting plates and show (rapid) destructive growth. (28, 37) Fulminant liver failure has also been observed. There is usually far less liver involvement in high-grade malignant NHL than in low-grade forms. • Good results (complete remission in up to 75% of cases) could be achieved by shortened CHOP 14 therapy (cyclophosphamide + hydroxydaunorubicin + vincristine + prednisolone) in 6 cycles, every 2 weeks.

# 3 Systemic rheumatic diseases

Rheumatic diseases can also cause direct or indirect liver damage. A common denominator is the frequent occurrence of HLA type B8. There is frequently a close association between rheumatic diseases or collagenoses and chronic viral hepatitis (B, C), autoimmune hepatitis, primary biliary cholangitis as well as cirrhosis.

| 6. Polymyalgia rheumatica | |

*Tab. 38.4:* Rheumatic diseases causing direct or indirect liver damage

## 3.1 Rheumatoid arthritis

The cause of this systemic disease, which has a chronic course, is unknown. Generally, several small and large peripheral joints are affected, usually symmetrically.

Women suffer far more frequently than men. **Clinically,** there is arthralgia of varying intensity and symptoms of chronic proliferative inflammation of the synovial fluid in the diseased joints. Systemic manifestations can be recognized on the basis of haematological, neurological, pulmonary, renal, cardiovascular and hepatic symptoms. **Laboratory parameters** show marked "inflammatory criteria" (s. tab. 38.2) as well as a rise in γ-globulins and immunoglobulins M and G. The *rheumatoid factor* is often detectable. (s. p. 118) Alkaline phosphatase may be elevated. (100)

*Liver involvement* occurs in 10−20% of cases. There is hepatomegaly and a slight elevation of transaminases. Histologically, inflammatory infiltrates and fatty changes in the liver cells may be present together with non-specific reactive hepatitis. (s. fig. 21.1) Slight fibrosis or rheumatic nodules may also occur in some cases after a lengthy period of disease. (67, 76, 79, 85, 91, 94, 101, 107)

## 3.2 Still's disease

Juvenile rheumatoid arthritis is termed Still's disease (G. F. Still, 1897). The disease begins in the finger joints and attacks the large joints and the cervical vertebral column in progressive steps. Lymphadenopathy is also present. • The *liver* and spleen may be considerably enlarged. Despite this, there are only very few histological findings, such as periportal lymphocytic infiltrates and Kupffer cell proliferations. (103)

## 3.3 Adult Still's disease

Adult Still's disease presents with seronegative polyarthritis, febrile attacks, lymphadenopathy, skin symptoms, hepatosplenomegaly, jaundice and involvement of the pleura and pericardium. • The *liver* is enlarged in about 30% of patients; transaminases may be slightly elevated. Periportal lymphocytic infiltrates and Kupffer cell proliferation can be demonstrated histologically. (68, 69)

## 3.4 Sjögren's syndrome

Sjögren's syndrome (H. S. C. Sjögren, 1933) is characterized by reduced secretion from the salivary and lacrimal glands with parotid enlargement (and occasional formation of calculi) together with chronic polyarthritis. Women in the menopause are mainly affected. Hyperfibrinogenaemia is common. The cause of the syndrome is unknown. • The *liver* is involved in 5−20% of patients with "sicca" syndrome. (88) Hepatomegaly and elevated alkaline phosphatase (25−40%) are detectable. Liver involvement can be ascertained on the basis of the findings of non-specific reactive hepatitis. (96, 99, 106, 107) An association with Budd-Chiari syndrome has also been reported. (89)

## 3.5 Felty's syndrome

Felty's syndrome (A. R. Felty, 1924) is a special form of seropositive polyarthritis. It leads to considerable changes in the articular structures. Characteristic findings include splenomegaly, leucopenia, lymphadenopathy and skin pigmentation. Men are mainly affected. • The *liver* is involved in about 70% of patients. Transaminases and γ-GT values are moderately elevated, and there is an occasional rise in alkaline phosphatase. Lymphocytic infiltrates of the sinusoids, proliferation of Kupffer cells and periportal fibrosis are detectable histologically. Nodular regenerative hyperplasia can develop, which may subsequently cause portal hypertension and macronodular cirrhosis. (71, 95, 104)

## 3.6 Polymyalgia rheumatica

*Clinically,* this pathological picture is characterized by severe pain in the area of the shoulder/upper arm, pelvic girdle and femoral musculature. Symptoms include fatigue, weakness, fever and loss of appetite. Women are affected far more frequently than men − generally after the age of 50. *Laboratory parameters* show highly pathological "inflammatory criteria" (s. tab. 38.2) as well as greatly elevated AP, but no antibodies or rheumatoid serological findings. • **Temporal arteritis,** which is a special form of polymyalgia rheumatica, is frequently found. • If larger arteries emanating from the aortic arch are likewise affected, this condition is known as **giant-cell arteritis.** (78, 81, 86, 87, 92) The thickened intima and the media contain histiocytic, lymphocytic and epithelioid cell infiltrates with polynuclear giant cells and plasma cells. Thrombosis frequently occurs in the affected arteries.

*Liver involvement* is common. Granulomatous arteritis of the hepatic artery and its intrahepatic branches gives rise to the clinical picture of granulomatous hepatitis. There are lymphocytic infiltrates in the portal fields together with liver cell necroses, so that chronic persistent hepatitis is in evidence. Fatty changes in the liver cells together with hypertrophy of the perisinusoidal lipocytes can also be observed. • *Therapy* is with glucocorticosteroids. (83, 86)

## 3.7 Polymyositis

Polymyositis can occur as a primary disease or a paraneoplastic syndrome. *Clinically,* there is weakness and pain in the shoulder and hip musculature, with muscular atrophy. *Laboratory parameters* show greatly elevated "inflammatory criteria" (s. tab. 38.2) as well as a rise in myosin AB. • *Liver involvement* is characterized by hepatomegaly, inflammatory infiltration of the portal fields, fatty changes in the liver cells and single-cell necrosis as well as necrotic foci.

## 3.8 Periarteritis nodosa

Necrotizing inflammation of small and medium-sized arteries as well as of the perivascular tissue (= periarteritis) with inclusion of adjacent veins leads to nodular-aneurysmal changes in the diseased arteries. The arterial capillaries remain unaffected. The vessel walls are permeated by polymorphonuclear leucocytes and monocytes; the inflammatory infiltration does not always involve the entire circumference of the vessel. Vascular branches are particularly affected. The aneurysmal distensions of the vessels show a tendency to rupture. • *Clinically,* there is evidence of fatigue, weakness, fever, lack of appetite, myalgia and arthralgia, together with abdominal pain. *Laboratory parameters* show highly pathological "inflammatory criteria" (s. tab. 38.2), in particular greatly elevated ESR and alkaline phosphatase.

If the *liver* is involved, the respective enzymes (GPT, GOT, γ-GT, GDH) are increased. There is frequently an association with HBV or HCV infection (50−75% of cases). Together with the skin and the kidneys, the liver is one of the most affected organs. There are cell necroses. Vascular involvement can lead to infarction, intrahepatic bleeding (98), acute cholecystitis (leading to perforation) (72) and thrombosis. Nodular regenerative hyperplasia can develop. • Aneurysms in the area of the medium arteries are detectable by arteriography. Percutaneous liver biopsy is not recommended because of the bleeding risk and the low success rate. • *Therapy* is with glucocorticosteroids in combination with azathioprine or cyclophosphamide. (70, 75)

## 3.9 Lupus erythematosus

Lupus erythematosus (LE) is a systemic autoimmune disease, occurring mainly in young women. Its aetiology is unknown. The *clinical* symptoms are chronic recurrent arthralgia with febrile attacks, lack of appetite, fatigue, decreased performance, skin changes on areas of the body exposed to light, lymphadenopathy and renal findings following localized vasculitis. Its *biochemistry* is characterized by highly pathological "inflammatory criteria" (s. tab. 38.2) as well as by the detection of antinuclear antibodies, DNA-AB and the LE factor. LE cells may be present in the blood or bone marrow (M. M. HARGRAVES et al., 1948). Anaemia, leucopenia and thrombopenia are also frequently in evidence. In rare cases, jaundice due to haemolysis occurs.

The *liver* is involved in 40−60% of cases, but with greatly varying intensity. Hepatomegaly is frequently present. Even acute liver failure has been observed. Discrete laboratory or histological findings relating to the liver can precede the diagnosis of LE by several years in some cases. The clinical picture of acute hepatitis with cholestasis has also been observed. Histologically, there is a broad spectrum of changes comprising fatty degeneration in the liver cells, chronic persistent hepatitis, giant cell hepatitis (73, 77), hepatic infarction (82), cholestasis, veno-occlusive disease (93), nodular regenerative hyperplasia, and cirrhosis with portal and pulmonary hypertension. (108) Lupus anticoagulans (antiphospholipid antibody) can lead to hepatic vein thrombosis. The activity of LE correlates very well with the activity of the liver changes. It is a striking feature that patients with liver involvement complain less frequently of arthralgia, but more frequently have gastric, thyroid and haematological complications. It should be noted that there is hepatic idiosyncrasy towards nonsteroidal antirheumatics. (90, 97, 102, 105)

## 3.10 Wegener's granulomatosis

Wegener's granulomatosis (F. WEGENER, 1936, 1939) is a necrotizing form of granulomatous vasculitis originating in the upper respiratory tract and lungs (rhinitis and sinusitis with sanguineous secretion, repeated nosebleeds, ulcers, encrustations and pulmonary infiltrations). Glomerulonephritis subsequently develops. Finally, generalized vasculitis can be detected. (80)

The *liver* shows vasculitis with necrotizing epithelioid cell granulomas. Non-specific reactive hepatitis is also present. *Therapy* is with cyclophosphamide (1−2 mg/kg BW/day). • We have given an extensive description of this clinical picture based on 132 cases in the literature as well as on our own experience. (84)

## 3.11 Eosinophilic granulomatous vasculitis

Churg-Strauss vasculitis (J. CHURG et al., 1951) is characterized by angitis with extravascular granulomas, eosinophilia and bronchial asthma. Allergic factors are held to be responsible for this disease. Reports on about 200 cases have been published so far; men are affected twice as often as women. • Histologically, there is necrotizing inflammation of the small arteries and accompanying veins with paravascularly arranged granulomas deriving from macrophages and giant cells as well as leucocytes and lymphocytes; the centre of a granuloma is strikingly rich in eosinophils. • Such changes also occur in the *liver*. Concurrent involvement of the liver and the omentum can result in a palpable tumour. *Therapy* is with glucocorticosteroids. (74)

# 4  Mastocytosis

Mast cell hyperplasia can affect several organ systems. Regarding the liver, 50% of cases present as hepatomegaly. Mast cell infiltrates are found in the portal fields. They can lead to occlusion of the small vessels with subsequent fibrosis or cirrhosis. (112) Moreover, there is evidence of marked lymphadenopathy and skin lesions. Polygonal cells with eosinophilic granules are

present in the portal fields. On staining with Giemsa and toluidine blue, the typical metachromatic cytoplasmic granules are sometimes identified. NRH, VOD and marked fibrosis have been reported and may be the cause of portal hypertension and ascites. (114, 116) Cirrhosis occurs in 5% of cases. (112)

# 5 Histiocytosis X

In 1938 A. H. T. ROBB-SMITH mentioned this condition for the first time. One year later, he and R. B. SCOTT together described a disease characterized by "fever, wasting, generalized lymphadenopathy and hepatosplenomegaly, which in the final stages was associated with jaundice, purpura, anaemia and leucopenia". This disease almost always resulted in death after an average duration of 15 weeks. The authors termed this condition "histiocytic medullary reticulosis". (117) • The term "histiocytosis X" was introduced by L. LICHTENSTEIN in 1953 (115), summarizing (1.) Letterer-Siwe disease (reticulosis in infancy), (2.) Hand-Schüller-Christian disease (lipogranulomatosis), and (3.) eosinophilic granuloma of bone. (120) Overlapping syndromes as well as mixed forms of these three diseases exist. The first two disease forms are mainly disseminated, while eosinophilic granulomas generally appear as solitary bone lesions (with a better prognosis). • The term "malignant histiocytosis" was introduced by H. RAPPAPORT in 1966. These disseminated forms were distinguished as being benign or malignant and acute or chronic by W. A. NEWTON et al. in 1973.

Histiocytosis X is considered to be a form of reticulosis because of the proliferation and aggregation of Langerhans' cells in the RES. These cells contain so-called *Birbeck granules* and the neural-specific protein S-100. The involvement of the liver and spleen (which is not evident in every case) becomes visible as hepatosplenomegaly. In most cases, there are diffuse, sinusoidal infiltrations consisting of large, mostly multinucleated, atypical his-

**Fig. 38.13:** Histiocytosis X: distinct portal inflammation, periductal infiltration by Langhans cells simulating cholangitis ( ↑ )

tiocytes (usually with hyperchromatic nuclei) and widespread phagocytosis of erythrocytes. (s. fig. 38.4) The Kupffer cells show hyperplasia. Periportal infiltration and cell necrosis are sometimes found. (s. fig. 38.13) Gross tumour-nodule formation in the liver and spleen is rare. (122) Mild portal fibrosis may be present. (111, 113, 118, 121) In some two-thirds of cases, periportal cholestasis with portal-duct proliferation can be demonstrated. (109) The clinical picture of primary sclerosing cholangitis may appear. (119) Occasionally, pronounced fibrosis with portal hypertension and oesophageal varices develops. (110) Transition into cirrhosis is possible. A suitable form of chemotherapy resulted in a 30−40% decrease in lethality. In portal hypertension, shunt surgery has been applied. Liver transplantation was successfully carried out without evidence of recurrent disease during a 7-year follow-up. (123)

# Clinical Aspects of Liver Diseases

## 39 Cardiovascular diseases and the liver

Due to its twofold vascular supply (portal vein, hepatic artery), the liver is closely integrated into the systemic circulation. The total blood flow through the liver is $1,500 \pm 300$ ml/min. Oxygen consumption amounts to 6 ml/min/100g LWW. (s. pp 17, 244) The portal vein supplies about two-thirds of the hepatic flow volume and is thus responsible for 50% of the oxygen requirement of the liver. The ratio between portal and arterial perfusion is about 2:1; this may, however, be reversed by compensatory autoregulation in cirrhosis patients. Blood from the portal and arterial systems reaches the sinusoids, where both mixing and pressure compensation occur. The hepatic blood flow is mainly regulated by inflow from the hepatic artery, which can be doubled when more oxygen is required. With continued demand for oxygen, the high capacity of the liver cell to extract oxygen (up to 95%) compensates for a limited blood flow. The hepatic flow volume is about $20-25\%$ of the cardiac output (CO). • In addition, the pressure in the lesser circulation is transferred directly to the pressure in the hepatic vein, so that the latter is almost equal to the pressure in the right atrium. The oxygen saturation of the arterioportal mixed blood in the sinusoids decreases continually with the flowing of the blood from the periportal zone to the central vein. The venous blood is then carried from the central veins and the venous branches into the inferior vena cava, usually through three (valveless) hepatic veins. • This anatomical proximity explains disturbances of the liver function as well as morphological damage resulting from shock situations, acute flow block in the hepatic veins and global heart failure. • **Cardiovascular diseases** may thus affect the heart or each of the three vascular systems:

1. Impaired cardiac function
2. Diseases of the hepatic vein
3. Diseases of the portal vein
4. Diseases of the hepatic artery
5. Hereditary haemorrhagic telangiectasia

# 1 Cardiocirculatory disorders of the liver

▶ The functional relationship between the heart and the liver has been known since ancient times. In animal experiments conducted in 1914, C. Bolton examined the effects of a ligation of the inferior vena cava on liver histology for the first time. • N. Jolliffe (1929) detected clinically measurable changes of the hepatic function in congestive heart failure. (10) • Systematic investigations carried out by S. Sherlock (1951) showed the consequences of passive liver congestion on hepatic morphology: complete cirrhosis was observed in 25.5% and an increase in reticular fibres in 27.5% of cases; the liver was without pathological findings in 47% of cases. • Autopsies carried out by P. Kotin (1951) showed "cardiac cirrhosis" in 10% of patients suffering from right heart insufficiency. (13) • Subsequently, the effects of cardiocirculatory disturbances on various partial functions and on the morphology of the liver, including the effects of drug metabolism, were presented in numerous publications.

**Pathophysiology**

▶ The close functional relationship between the heart and the liver is based upon **two physiologic facts:**

(*1*.) The *hepatic flow volume* is $20-25\%$ of the CO and is thus directly dependent on the cardiac ejection volume.

(*2*.) The *pressure* in the lesser circulation is transferred directly to the valveless hepatic veins and may thus also reach the central veins.

▶ Even though the pathophysiology of hepatic changes during circulatory shock and in chronic liver congestion is very complex, **two single mechanisms** may be held jointly responsible for the impairment of metabolic and excretory liver functions:

(*1*.) Reduction in blood flow through the liver with hypoxia.

(*2*.) Increase in hepatic vein pressure with centrilobular hyperaemia.

▶ Circulatory disturbances within the hepatic lobules are of central pathophysiological importance; **three different forms** can be differentiated:

(*1*.) *Disturbed outflow:* the microscopic correlate is centrilobular hyperaemia; macroscopically, the liver is enlarged and has a dark red colour.

(*2*.) *Disturbed inflow:* hypoperfusion due to arterial, portovenous or combined oligaemia results in centrilobular necrosis or even anaemic liver infarction.

(*3*.) *Disturbed flow:* primarily, this occurs intralobularly as a result of various disorders (e. g. DIC, intrasinusoidal fibrin precipitation, centrilobular increase in fibres).

The liver may be involved in numerous ways due to acute, short-term disturbances of the cardiocirculatory function or due to chronic, long-term heart failure:

| Acute heart insufficiency | Chronic heart insufficiency |
|---|---|
| 1. Shock liver<br>2. Acute liver congestion | 1. Chronic liver congestion<br>2. Congestive fibrosis<br>3. Cardiac cirrhosis |

**Tab. 39.1:** Pathophysiology of cardiocirculatory changes in the liver

## 1.1 Acute heart insufficiency

Shock liver and acute liver congestion often display very similar histological changes, while the pathophysiologic features, such as laboratory findings, functional tests and drug metabolism, vary considerably. • Cardiogenic shock resulting from myocardial infarction is considered to be both a typical and frequent cause of shock liver, while acute liver congestion (acute right heart insufficiency) is in most cases the consequence of pulmonary embolism. • During shock, the liver is involved in two ways: (*1.*) it is an important regulatory organ (= *liver in shock*), and (2.) its function and morphology are compromised by shock mechanisms (= *shock liver*).

### 1.1.1 Shock liver

This condition is characterized by reduced hepatic blood flow (CO ↓) and hepatocellular hypoxia, resulting in a loss of glycogen and the formation of hypoxic vacuoles in the hepatocytes; there are also coagulation necroses in acinar zone 3. It is a striking feature that the function of the liver is only mildly compromised and recovers quickly once the circulation is stabilized. Since the lattice fibre framework is generally intact, the centrolobular necroses do not leave behind any scars. During this phase, we only detected slightly delayed indocyanine green (ICG) elimination, while galactose elimination capacity and theophylline clearance were slightly inhibited. (18) This means that essential partial functions of the liver are relatively independent of the blood flow and that short-term hypoxia can be compensated by increased extraction of oxygen. By contrast, we also found greatly increased GOT and GPT values similar to those present in "hepatitis", with low-grade cholestasis and jaundice. The terms ischaemic hepatitis,

hypoxic hepatitis or acute hepatic infarction are alternative definitions. (4–6, 11, 25, 29) In shock liver, there is therefore a marked discrepancy between a relatively slight reduction in excretory and metabolic functions and considerable liver cell damage detectable by enzyme analysis. • The hepatic blood flow is decreased due to shock-induced hyperperfusion of the heart and brain with simultaneous vasoconstriction in the splanchnic nerve area (= *centralization of circulation*). However, liver cell damage often develops or intensifies as a result of subsequent reperfusion, whereby the substances that are introduced in increased amounts at this point (endotoxins, cytokines, biogenic amines, degradation products, etc.) are probably the main cause of such liver cell damage. (26) The damage occurring in shock liver and acute liver congestion may thus be due to ischaemia and/or ischaemic-toxic factors. (2, 3, 27) (s. fig. 39.1)

### 1.1.2 Acute liver congestion

In our investigations, patients suffering from acute right heart insufficiency showed considerable delays in ICG half-times. In an earlier study, we were able to demonstrate a close correlation with right-sided atrial pressure. Theophylline clearance was likewise greatly delayed. Standard enzymes showed only slightly increased or even normal values; hyperbilirubinuria, which is considered to be the most sensitive laboratory value in liver congestion, was generally present. Thus there is also a discrepancy between "liver function" and "cell damage" in this context — albeit exactly the reverse of that found in shock liver. (16, 18) Patients suffering from acute liver congestion have considerably impaired metabolic and excretory functions, even after clinical recompensation. Perisinusoidal oedema resulting from elevated hepatic vein pressure is of the utmost pathogenetic significance in acute liver congestion because it lengthens the transit route. In acute congestion, the liver is capable of taking up blood equivalent to 70% of its own weight (approx. 1.0–1.5 l), so that both circulatory overload and tachycardia are reduced.

**Morphology:** Within the first day following the onset of acute liver congestion, massive sinusoidal hyperaemia and perivenous cell necroses occur due to the fact that centrilobular oxygen saturation is lower than that of the lobular periphery. The reticular fibre framework usually remains intact. In addition, venous stasis may occur, especially in acute congestion, including dilatation of the central veins and sinusoids with blood pooling, resulting in hepatomegaly. Macroscopically, the liver appears heavy and dark red. Microthrombi may be present due to disseminated intravascular coagulation (DIC). They can form the basis of later diffuse calcification. This might be related to the disturbance of intracellular calcium homoeostasis due to ischaemia. (27) After recompensation, numerous granulocytes and pigment-loaded macrophages subsequently appear, followed by proliferating epithelial cells. The necrotized
***Fig. 39.1:*** Centroacinar shock necrosis and acute haemostasis in the liver (HE)

***Fig. 39.2:*** Acute blood stasis with centrilobular congestion and centricentral congestion paths

cells and erythrocytes are phagocytized by the Kupffer cells. Morphological repair starts after about 5 days and is completed within 3−4 weeks. (1, 16, 19) (s. tab. 39.1) (s. figs. 39.1, 39.2)

**Drug metabolism:** According to present knowledge, there is a delay in the elimination of certain drugs in patients with acute heart insufficiency. Thus, a *dose reduction* may have to be considered in some cases. In particular, these drugs include quinidine, cumarin/warfarin, digoxin, hydrochlorothiazide, lidocaine, mexiletine, procainamide and theophylline. (16, 18) • Our studies demonstrated a 30% reduction in the elimination rate of flow-limited (= ICG) and capacity-limited (= galactose, theophylline) substances. We found a normal glucuronidization capacity for *4-methylumbelliferone*, but a significant delay in the biliary excretion of *4-MU-monoglucuronide*. (15) These findings are considered to be the cause of conjugated hyperbilirubinaemia, which is common in patients suffering from a congested liver.

**Clinical features:** Acute liver congestion results in upper abdominal pain due to stretching of the capsule caused by liver enlargement; this might even mimic an acute

abdomen. There have also been courses with fulminant liver failure, particularly with existing chronic heart insufficiency. (8, 20, 24, 26) In addition to the laboratory findings given above, it is worth mentioning the increase in GDH, mainly localized in the centrilobular cells. The ratio (GOT + GPT) : GDH is < 10. (s. tab. 5.6) In general, LDH is markedly elevated. Mild jaundice is often in evidence; hyperglycaemia and renal impairment may occur. A decrease in Quick's value may point to DIC. An increase in transaminases due to ischaemia (with bioptic detection of centrilobular cell necroses) was observed even in cases of severe hypoxaemia caused by sleep apnoea in patients with considerable obesity (without cardiac or respiratory dysfunction!). (5) Imaging procedures show hepatomegaly and dilated hepatic veins. • *Treatment* consists of stabilizing the circulation and eliminating the causes.

## 1.2 Chronic heart insufficiency

The hepatic blood flow is decreased in chronic heart insufficiency, and there is disturbed venous outflow, i.e. cardiac output is diminished. There is also a pressure increase in the splanchnic nerve area with subsequent blood pooling as a result of the rise in CVP. The markedly reduced hepatic blood flow at first evokes an increase in oxygen extraction, but after its elimination, hypoxia with centrilobular cell necroses follows. The elevated CVP extends as far as the central veins, so that dilatation and hyperaemia of the sinusoids occur. Pericentral atrophy in the liver cell trabeculae develops at a later stage. (s. tab. 39.1) (s. fig. 39.3)

***Fig. 39.3:*** Chronic passive congestion with centroacinar parenchymal atrophy and fibrosis (HE)

**Chronic congestion** leads to an enlarged and plump liver with a dark red (purplish) colour. The central veins are dilated. In continued congestion, stasis paths develop between the central veins, resulting in the formation of confluent stasis areas. Various degrees of fatty changes in the liver cells as well as pigment deposits (lipofuscin, ceroid) appear. In the course of time, fibrosis of sinusoidal reticular fibres takes place; fibroses can also be observed

along the stasis paths. In about 15% of cases, periodic acid-Schiff positive and diastase-resistant hyaline globules can be found. They are typically located directly around the zones of centrilobular congestion in hepatocytes. These globules range in size from 3 to 20 μm; they occur either as one or two large globules or as clusters of smaller inclusion bodies. (12) The extent of the **congestive fibrosis** depends largely upon the degree of cardiac congestion. (s. fig. 39.3) In 147 patients with chronic pulmonary heart disease, it was possible to demonstrate congestive fibrosis by autopsy in 14−42% of cases (depending on the degree of severity and the duration of disease). (7) • Chronically indurated **nutmeg liver** (F. KIERNAN, 1833) develops gradually; the cut surface of such a diseased liver shows sunken, dark red centrilobular zones and slightly raised bulging, yellowish to pale brown (depending on the degree of fatty changes) peripheral areas of the lobules. • **Cardiac cirrhosis** was mentioned in older studies in up to 10% of cases. (13) Our own studies did not yield a single case of cardiac cirrhosis. (7) This clinical picture must be considered rare and is most likely in cases of constrictive pericarditis or in long-standing tricuspid valve insufficiency. It is assumed that the development of cardiac cirrhosis originates in sinusoidal thrombosing processes which extend to the vascular bed of the hepatic veins. (23, 30) Distinct regenerative nodes are not found in cardiac cirrhosis; this condition generally does not lead to extrahepatic cirrhosis-related complications.

**Clinical features:** With regard to the main findings of chronic heart insufficiency, the liver is symptom-free, apart from tenderness upon pressure in the right upper abdomen corresponding to *hepatomegaly*. On palpation, the liver is hard and has a smooth surface. *Splenomegaly* is detected in about 20% of patients.

In this condition, **hepato-jugular reflux** is *positive* if the venous channels between the hepatic and jugular veins are patent (i.e. long-standing pressure below the right costal arch accelerates the filling of the jugular veins, since the insufficient right ventricle is incapable of transporting the rising amount of blood supplied by the liver). • When the result is *negative*, the free passage between the hepatic veins and the jugular vein is interrupted. This sign is useful for diagnosing tricuspid regurgitation.

According to our own investigations, **P-III-P concentration** is the most important laboratory parameter (17): it is significantly higher in patients suffering from chronic liver congestion (due to the activity of fibrogenesis). There was also a correlation with the pressure in the right atrium. Moreover, the P-III-P value allowed a follow-up of chronic liver congestion or chronic congestive fibrosis. No correlation with hepatic biochemical standard values was found − these were normal or only marginally elevated. (14, 16, 17) Only the serum bilirubin was slightly increased in most cases. ICG elimination and the galactose elimination capacity were significantly

**Fig. 39.4:** Sonographic image of chronic liver congestion with dilated hepatic veins and inferior vena cava

reduced. Severe jaundice may occur in heart failure (22), in some cases with massive liver cell necroses.

Hepato(spleno)megaly is detected by **sonography.** The liver margin is rounded, the reflex pattern is dense and inhomogeneous. The hepatic veins are enlarged (at the confluence > 12 mm). (s. fig. 39.4) The inferior vena cava presents a rather rigid wall without respiratory-dependent lumen fluctuations. Smaller amounts of ascites are frequently detectable. *Echocardiography* and *colour-encoded Doppler sonography* are among the most important diagnostic and monitoring methods. (9) *CT* may yield additional findings of chronic liver congestion. (21)

# 2 Disorders of the hepatic veins

▶ The hepatic venous blood flow begins in the **central veins** of the lobules (so-called terminal hepatic vein), drains into the *sublobular veins* (= intercalated veins), from there into the *collecting veins* and then into the *truncal veins*. Perivenous connective tissue increases with the diameter of the vein. Venous blood reaches the *inferior vena cava* via three (valveless) **hepatic veins**; the confluence is below or within the diaphragm. From the **caudate lobe,** 1−2 small veins open directly into the inferior vena cava, as do a few small veins from the posterior segment of the right lobe of liver. (s. p. 17) • There are generally no **anastomoses** between the hepatic veins and the portal vein, except in liver cirrhosis. Similarly, no anastomoses are present between the hepatic veins and arteries either in a healthy liver or in a cirrhotic liver. • Normal **hepatic vein pressure** is about 6 mm Hg. **Oxygen saturation** of the hepatic veins amounts to approx. 67%.

With regard to the main diseases of the hepatic venous system, **three types** worthy of mention can be distinguished:

1. Budd-Chiari syndrome
2. Veno-occlusive disease
3. Endophlebitis obliterans hepatica

## 2.1 Budd-Chiari syndrome

### 2.1.1 Definition

The Budd-Chiari syndrome (BCS) is defined as partial or complete obstruction of the hepatic veins due to thrombosis. This may affect the whole hepatic venous system from the central vein to the large hepatic veins, even as far as the opening of the inferior vena cava into the right atrium. However, the obstruction can simply occur in individual branches of the hepatic veins and thus affect only certain areas of the liver. The syndrome may have an acute onset or begin insidiously and take a chronic course. The clinical picture is usually characterized by the *Chiari triad*: hepatomegaly, abdominal pain and ascites.

▶ REYNAUD (1829) was the first to report thrombosis in the vena cava with involvement of hepatic veins and the development of collateral circulation. In 1842 E. LAMBRON described inflammation of the hepatic veins concomitant with a liver abscess. • In 1845 the English internist G. BUDD reported three further cases: in two of them, hepatic vein thrombosis was likewise caused by liver abscesses, whereas no cause was evident in the third case although membranes were detected in the hepatic veins. • In 1899 the German pathologist H. CHIARI, who was working in Prague at that time, gave an account of two of his own patients and assessed the 8 cases which were known to him from the literature. However, more than 25 cases of veno-occlusive disease had already been reported prior to Chiari's publication. • The above-mentioned clinical picture with unclarified aetiology was defined by H. CHIARI (1899) as primary phlebitis of the large hepatic veins with secondary thrombosis, which he regarded as a separate entity. This gave rise to the term *endophlebitis obliterans hepatica* (s. p. 833), also called Chiari's disease.

### 2.1.2 Aetiology

Aetiologically, BCS is characterized by an extremely heterogeneous clinical picture, even though it is initially possible to categorize the majority of causes into four groups: (*1.*) hypercoagulopathies, (*2.*) infections, (*3.*) malignant diseases, and (*4.*) endotheliotoxic substances. In 80−90% of patients, BCS can be attributed to a specific cause. The disease has often been detected during pregnancy as well. The observation that women contract the disease twice as often as men following the introduction of oral contraceptives supports the aetiological theory that it is linked to an increase in the oestrogen/progesterone level. The discovery of new genetic defects causing hypercoagulability can also explain some cases of BCS. (56) • A membranous obstruction, especially close to the opening of the middle and left hepatic veins into the inferior vena cava, is considered to be an aetiological peculiarity. Such a "web" varies from a thin membrane to a thick fibrous band. (73) This unusual phenomenon is often encountered in India, Japan and South Africa (congenital?, phytotoxins?). A chronic course develops. (s. tabs. 14.5; 39.2) (s. pp 249, 548)

*Fig. 39.5:* Budd-Chiari syndrome due to essential thrombocythaemia. Long-standing thrombotic occlusion of a liver vein (van Gieson) (s. fig. 29.9)

### 2.1.3 Morphology

**Laparoscopy:** The liver is enlarged and displays a dark reddish cyanotic surface with a rounded margin. Congested veins and collaterals in the abdominal region suggest portal hypertension. Transformational processes may occur in a chronic course (in 30−40% of cases) or when the liver is only partially affected, so that even the picture of a cirrhosis has been observed. Ascites, occasionally also in its sanguinolent form, is detected in most patients.

**Liver biopsy:** Histology reveals pronounced centrilobular congestion as well as sinus ectasia, necroses and thrombi in the central veins, which are either fresh or are already organized. Parenchymal atrophies and nodal transformational processes can be observed after a longer period of time. (s. figs. 29.9; 39.5)

### 2.1.4 Clinical features

BCS is a rare disease and responsible for about 5% of all cases of portal hypertension. The highest incidence is observed in 3rd and 4th decades. Frequency varies considerably in different countries and regions depending on its aetiology. • The clinical picture is determined by the course of disease and therefore there is great variability in findings. In **chronic BCS,** abdominal pain is mild, and hepatomegaly develops only gradually. Splenomegaly, diarrhoea and ascites, including oedema in the legs, are occasionally in evidence. Oesophageal varices may develop as a result of postsinusoidal portal hypertension. Non-characteristic symptoms (fatigue, inappetence, weakness, meteorism) are present in most cases. All laboratory parameters may remain in the normal range for a long time. • A far smaller percentage of patients suffer from **acute BCS** with severe pain in the upper abdomen, nausea, vomiting and malaise. Jaundice is often present. Hepatomegaly develops rapidly. Acute BCS can present clinically as acute liver failure. (60) The *caudate lobe* is enlarged as it has efferent

hepatic veins of its own, which circumvent the main branches of the hepatic vein and lead directly to the inferior vena cava. (33) As a rule, in an enlarged caudate lobe, which may also compress the inferior vena cava, it is technically impossible to apply a portacaval shunt. In cases of severe parenchymal deterioration, there is a risk of hepatic encephalopathy and hepatorenal syndrome. The prognosis of acute BCS is very poor; the dramatic course of the disease rapidly leads to liver failure. (38, 40, 50, 51, 54, 60, 69)

1. **Hypercoagulopathies**
   Antiphospholipid syndrome (59)
   Antithrombin III deficiency
   Essential thrombocytosis
   Factor V mutation (39)
   Lupus anticoagulant
   Myeloproliferative disease (31)
   Paroxysmal nocturnal haemoglobinuria
   Polycythaemia vera
   Protein C deficiency (68)
   Protein S deficiency
   Sickle-cell anaemia

2. **Infections**
   Amoebic liver abscess
   Aspergillosis
   Crohn's disease
   Echinococcosis
   Hepatic abscess
   Schistosomiasis
   Syphilis
   Tuberculosis

3. **Malignant diseases**
   Adrenal carcinoma
   Bronchogenic carcinoma
   Fibrolamellar carcinoma
   Hepatocellular carcinoma
   Leiomyosarcoma
   Leukaemia
   Renal cell carcinoma
   Rhabdomyosarcoma

4. **Endotheliotoxic substances**
   Cytostatics (63)
   Azathioprine
   Phytotoxins

5. **Hormonal factors**
   Oral contraceptives (56)
   Pregnancy (46)

6. **Immunological factors**
   Behçet's disease (34)
   Hypereosinophilia
   Sarcoidosis (64)
   Sjögren's syndrome (53)

7. **Other aetiological observations**
   Abdominal trauma
   Laparoscopic cholecystectomy
   Membranous obstruction (73)
   Polycystic liver disease (35)
   Retroperitoneal neurilemmoma (65)
   Tumour in the right atrium (42)

8. **Cryptogenic**

*Tab. 39.2:* Possible causes of the Budd-Chiari syndrome (including some references) (s. figs. 29.9; 39.5)

### 2.1.5 Diagnosis

**Laboratory parameters** are irrelevant for diagnosis! Transaminases, LDH, GDG and alkaline phosphatase are in general moderately increased, and hyperbilirubinaemia can be detected in 20−25% of cases. The albumin level is usually reduced; hypoproteinaemia may be caused by protein-losing enteropathy. Evidence of disturbances in *blood coagulation*, with regard to both hypercoagulopathic status and haemorrhagic diathesis, is of significance. *P-III-P* serum values rise in chronic courses with increasing fibrosis. Liver function tests, however, generally show normal results.

**Sonography** shows hepatomegaly and inhomogeneous, hypoechoic zones. The hepatic veins are invisible or present as narrow structures only. The caudate lobe is enlarged and often causes an hourglass-like constriction of the inferior vena cava. Ascites is confirmed. Colour-encoded duplex (or Doppler) sonography is a valuable additional means of examination. The diagnosis proves to be correct in 85−90% of cases; the results are further improved by CT angiography or MR angiography. (23, 37, 45, 54, 69)

**Computer tomography,** especially when coupled with a contrast medium and in the form of CTAP, is an excellent tool for analyzing the venous blood flow and detecting any disturbances in inflow or outflow. Thrombosed hepatic veins are not visible; the parenchyma is characterized by an inhomogeneous, patch-like enhancement. (s. fig. 39.6) • **MRI** provides reliable evaluation by means of multiphase, contrast-enhanced, three-dimensional MR angiography.

**Angiography,** coupled with cavography and venography of the liver, is the most reliable examination method: venous obstructions can easily be localized, and the residual venous blood circulation always displays a spider web-like picture. • In some 20% of cases, the portal vein is also thrombosed, indicating arteriography in the form of indirect splenoportography. In addition, angiography also offers the therapeutic possibilities of interventional radiology. (36, 43)

**Histology:** In cases where histological evidence is required, samples should be taken from both liver lobes, since the expressivity of the histological picture can vary greatly in different sections of the liver in BCS. The best technique in this connection is **laparoscopy** (possibly combined with *targeted biopsy*). Although the risk of haemorrhage is generally high in biopsy, intense bleeding or delayed coagulation can be effectively reduced and more easily controlled under laparoscopy. As a rule, however, the laparoscopic image of BCS is impressive enough per se − especially if supported by imaging procedures − so that biopsy and the accompanying risks can indeed be avoided altogether.

**Fig. 39.6:** Budd-Chiari syndrome: pronounced collateral circulation resulting from thrombotic occlusion of the right hepatic vein. • Re-opening of the vessel and rapid reduction of the collateral vessels following successful balloon dilatation

### 2.1.6 Treatment

There are very few reports of **spontaneous remission** even in partial BCS. • The *therapeutic principle* in all cases is to remove liver congestion, limit and lyse any thromboses as well as eliminate ascites. (40, 51, 69) • Medication includes immediate **lysis treatment** followed by heparinization. Despite initial success, frequent complications have been reported (e. g. pulmonary embolism, re-occlusion, intraperitoneal bleeding). (66) • **Percutaneous balloon angioplasty** was first used by S. EGUCHI et al. in 1974 in membranous obstruction of the inferior vena cava and was subsequently applied in BCS. (73) (s. fig. 39.6) In some cases, a *stent implantation* proved to be successful. (49, 70, 71, 72) The significance of *percutaneous transluminal angioplasty* is not only based on its long-term therapeutic effect, but also on its combination with operative shunts or other surgical techniques. (36, 43) This method was improved by laser assistance (S. FURUI et al., 1988) • To date, a total of 23 different **surgical techniques** have been reported (32, 47, 50, 54, 58, 69), consisting mainly of shunt placements, preferably the mesocaval

shunt, bypass operations, resections, thrombectomies and liver transplantation. Even though it is technically difficult, dorsocranial liver resection with direct hepatoatrial anastomosis successfully corrects the venous perfusions of the liver physiologically. Meanwhile, the transjugular intrahepatic portosystemic stent shunt **(TIPS)** has proved effective. (44, 55, 57, 62) It is relatively quick and easy to apply, has proved to be a low-risk procedure and can be carried out before resorting to other invasive or surgical techniques. Thus it is possible to bridge the time required for planning any surgical intervention or **liver transplantation.** The latter is urgently indicated in an acute course. Continuous long-term anticoagulation is necessary even after transplantation, as is also invariably the case with all of the above-mentioned treatment measures. (44, 48, 61, 67)

**Constrictive pericarditis:** The clinical picture and hepatic changes of the liver are similar to those of the Budd-Chiari syndrome. Considerable thickening of the liver capsule may resemble *sugar icing*. The liver is enlarged and firm. Tense ascites is present. Histologically, the changes resemble those of cardiac cirrhosis.

## 2.2 Veno-occlusive disease

### 2.2.1 Definition

Veno-occlusive disease (VOD) is characterized by thrombosis of the central and small (sublobular) hepatic veins. It is also known as the *radicular form* of the Budd-Chiari syndrome or as the *Stuart-Bras syndrome*. (s. tab. 14.5) (75, 92, 93)

### 2.2.2 Aetiology

Toxic substances or physical impact cause direct damage to the centrilobular veins as well as to the small branches of the hepatic veins, resulting in subsequent thrombosis. • The first reports were published simultaneously in South Africa (G. SELZER et al.) and Jamaica (K. R. HILL) in 1951. This disease of the small branches of the hepatic veins is due to chronic intoxication with pyrrolizidine alkaloids, which can be found in plants such as genera Senecio, Crotalaria, Heliotropium and Cynoglossum. Intake occurs by drinking medicinal tea or through consumption of contaminated pulses and cereals. In 1974 and 1978, epidemic-like outbreaks of VOD were observed in Afghanistan and India after local inhabitants had eaten cereals contaminated with pyrrolizidine alkaloids. The real toxicity of these alkaloids is based upon their transformation into alkylating pyrrole derivatives, which are toxic to endothelial cells and hepatocytes. • Other important causes of VOD include cytostatics, immunosuppressives, radiotherapy (> 30 Gy), immunological reactions and alcoholic hepatitis. (s. tab. 39.3) (s. pp 548, 570)

<div style="border: 1px solid; background: #f5d5e0; padding: 10px;">

1. Alcoholic hepatitis
2. Allogeneic bone-marrow transplantation (80, 84, 85, 87)
3. Cytostatics (76, 78, 79, 86, 88)
4. Immunosuppressives
5. Lupus erythematosus (90)
6. Oral contraceptives (94)
7. Pyrrolizidine alkaloids (89, 91, 94)
8. Radiotherapy
9. Stem-cell transplantation (83)

</div>

*Tab. 39.3:* Possible causes of veno-occlusive disease (VOD) (including some references) (s. fig. 29.10)

### 2.2.3 Morphology

Histology provides useful diagnostic evidence. Sinusoidal endothelial damage can be found, including extravascular accumulation of erythrocytes in Disse's spaces as well as subendothelial oedema and cellulation. After 2 to 3 days, delicate fibres appear within the central and sublobular veins, occasionally also in the medium-sized hepatic veins, ultimately resulting in occlusion of the lumen. Fibrotic thickening of the vessel walls occurs. Stenosis and thrombosis of the small hepatic veins cause extensive sinusoidal congestion. The liver cells become necrotic or atrophic. • Micronodular cirrhosis develops in a chronic course. (s. fig. 29.10)

### 2.2.4 Clinical features

The clinical symptomatology is similar to that of chronic Budd-Chiari syndrome. About 10% of cases display an asymptomatic clinical picture over an extended period of time. • Spontaneous reversibility of VOD has been observed following administration of pyrrolizidine. (91) However, the disease may also progress rapidly to liver failure. A chronic course generally leads to liver cirrhosis with postsinusoidal portal hypertension. • *Laboratory values* reveal a slight increase in transaminases and occasionally in alkaline phosphatase as well as thrombocytopenia with a rapid decrease in haemoglobin. A rise in P-III-P is also significant in VOD, both for early diagnosis and monitoring purposes. (80) • The *wedged hepatic vein pressure* is increased. Due to its localization in the small hepatic veins, VOD cannot be diagnosed by means of *imaging techniques.* However, these techniques, particularly CEDS and CTAP, provide reliable evidence of gradually developing portal hypertension as well as the reduction or reversal of the portal blood flow during normal flow in the hepatic veins and the inferior vena cava. (81, 82) • *Histology* makes it possible to achieve a reliable diagnosis. (s. fig. 29.10)

### 2.2.5 Treatment

Once the cause of VOD has been determined, it must be eliminated (if possible). Treatment is symptom-oriented and primarily directed towards the conse-

quences of portal hypertension. In order to reduce portal hypertension, medication (spironolactone, molsidomin, beta blockers) and the application of TIPS are recommended. (77) Ultimately, indications for liver transplantation have to be considered. (87)

### 2.3 Endophlebitis obliterans hepatica

This is also called **Chiari's disease** (1899) and defined as a **truncal form** of the Budd-Chiari syndrome (1899). (s. p. 830) • It consists of primary, independent phlebitis of the large hepatic veins. (s. tab. 14.5) • Fibrinoid swelling of the intima with inflammatory, granulating processes, luminal obstruction and secondary thrombosis are characteristic findings. The large hepatic veins are affected with varying intensity and at different stages. This development is typical of the clinical picture. It is mainly caused by inflammatory processes of the immediate neighbouring structures or rheumatoid and paraneoplastic diseases. Total obstruction of the hepatic veins is infaust. Partial occlusion results in posthepatic portal hypertension and its sequelae.

# 3 Disorders of the portal vein

▶ The **portal vein** is formed by the retropancreatic union of the right and left gastric veins, the pyloric vein, the superior and inferior mesenteric veins and the splenic vein. Its trunk runs inside the **hepatoduodenal ligament** to the liver. Within the porta hepatis, the portal vein divides into a **right branch** (which also receives the cystic vein) and a **left branch** (into which the paraumbilical veins contained in the round ligament and the ventroflexus ramus from the left sagittal fossa open). • The rami of the portal vein branch out and reach the portal fields where they become **interlobular veins,** which generally fork into **two interlobular venules** (= leading veins). The latter transport the blood into distributory veins which continue in Y-form into the **afferent venules** (final ramifications) and transport portal blood into the **sinusoids.** • The portal vein is 5−8 cm in *length* and has a *diameter* of 1.2±0.2 cm. The normal *portal pressure* is 3−6 (−8) mmHg. (s. fig. 2.6) The portal blood flow amounts to 1150−1300 ml/min. (s. pp 17, 244)

<div style="border: 1px solid; background: #bce0ec; padding: 10px;">

Portal vein diseases may be *congenital* or *acquired*, or arise as a sequela of portal hypertension: (*1.*) portal vein anomalies, (*2.*) pylephlebitis, and (*3.*) portal vein thrombosis.

</div>

### 3.1 Anomalies of the portal vein

*Congenital anomalies of the portal vein are very rare.* This also applies to accessory portal veins with their individually varying patterns.

▶ **Accessory portal veins** are small veins at the surface of the hepatic serosa and in the surrounding peritoneal folds which normally originate in the diaphragm and the stomach. They can either open into the portal vein or enter the liver parenchyma independently. • **Anomalous accessory portal veins** may sometimes originate in the area of the portal veins around the gall bladder, the porta hepatis, the interior surface of the abdominal wall or the hepatorenal ligament, etc.

▶ **Anomalies** are described as a missing portal vein and intrahepatic branches with simultaneous hyperplasia of the hepatic artery. • The portal vein and its branches may also be located in front of the duodenum and the pancreatic head. Sometimes, even a

multitude of small vessels can be found instead of a single portal vein. Another anomaly has been described as a faulty opening of the portal vein into the renal vein, with the enlarged hepatic artery taking over the entire blood supply to the liver. • Moreover, there may be anomalous anastomoses between the portal vein and the branches of the greater circulation. • Besides aplasia or obliteration of the portal vein, congenital arterioportal fistulas (s. tab. 14.2) (s. p. 245) or portal vein stenoses also cause portal hypertension with subsequent *phlebosclerosis*.

In addition to the congenital anomalies, other clinical features may be responsible for disorders of the **portal vein system:**

1. Anomalous accessory portal veins
2. Aplasia
3. Arterioportal fistula
4. Cavernous transformation
5. Cruveilhier-Baumgarten syndrome
6. Faulty openings of the portal vein
7. Displacement
8. Obliteration
9. Portal vein stenosis

### 3.1.1 Cavernous transformation

This condition is primary angiomatosis of the portal vein: a spongy convolution of venous vessels branching in a tendril-like manner has formed instead of a trunk − predominantly in the area of the hepatoduodenal ligament. (95, 96)

Prehepatic portal hypertension develops as a result of the disturbed outflow from the splanchnic nerve area. However, both liver function and histology are normal. Occasionally, considerable mechanical jaundice has been observed. Clinical symptoms include abdominal pain, splenomegaly, haematemesis and oesophageal varices. The internal pressure in the spleen is increased, while the wedged hepatic vein pressure remains in the normal range. Successful diagnosis is based upon imaging techniques and colour-encoded duplex Doppler sonography. (97) (s. tab. 14.2) (s. p. 245)

### 3.1.2 Cruveilhier-Baumgarten disease

In the absence of physiological postnatal closure of the umbilical vein, an anastomosis will form between the portal vein and the abdominal wall. Hypoplasia of the portal system and liver can be observed at the same time. Prehepatic portal hypertension develops with visible and palpable venectasia in the abdominal skin, also known as *Medusa's head* (M. A. Severino, 1632). (s. p. 87) (s. fig. 14.13) A venous murmur (so-called *venous hum*) can often be heard periumbilically, generally in the centre of the Medusa's head. Splenomegaly causes splenogenous maturation arrest. The diagnosis is confirmed by imaging techniques. (s. p. 246!)

**Cruveilhier-Baumgarten syndrome:** This is a secondary syndrome observed in liver cirrhosis with pronounced

portal hypertension. Recanalization of the umbilical vein and of the paraumbilical veins develops. (s. fig. 39.7) • Clinical symptoms include splenomegaly, Medusa's head, periumbilical vascular murmur and ascites.

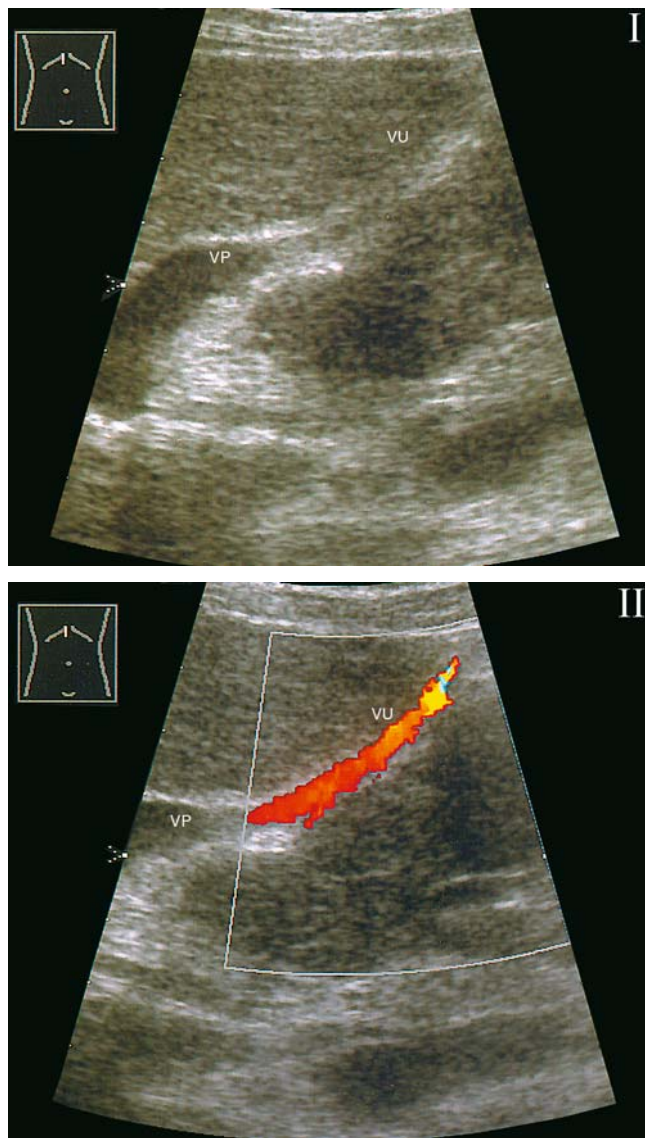

*Fig. 39.7:* I: Re-opened umbilical vein (VU) due to pronounced portal hypertension in haemochromatotic cirrhosis (VP = umbilical branch of the left portal vein) • II: Hepatofugal blood flow in the umbilical vein (VU) depicted by colour-encoded duplex sonography

**Acquired causes** may also be responsible for some of the congenital anomalies described above. Mention should be made of (*1.*) arterioportal fistulas, (*2.*) cavernous transformation of the portal vein (in portal vein thrombosis), (*3.*) fibrous obliteration of the portal vein, and (*4.*) cicatricial portal vein stenosis. These may also cause prehepatic hypertension. (s. tab. 14.2) (s. p. 246!)

### 3.1.3 Arterioportal venous fistula

Arterioportal venous fistulas (R. Sachs, 1892) between the arterial and portal system may occur perihepatically

following puncture, trauma, invasive surgery and tumour growth. Congenital arterioportal fistula is very rare. Only about 12 cases have been reported to date. (98) Clinical symptoms include prehepatic portal hypertension (102, 103), vascular murmur in the right hypochondrium, abdominal pain (103) and signs of hyperdynamic circulation. Sonography shows dilation of both the hepatic artery and the intrahepatic portal vein branches. Calcification of a liver biopsy-related fistula may occur. (100) The diagnosis is generally made by duplex Doppler sonography and confirmed by angiography, with the possibility of simultaneous embolization of the fistula. In the case of treatment failure, selective resection of the fistula is indicated. (99, 101) There is usually no change in portal hypertension after the development of *hepatoportal sclerosis*. (s. p. 246)

## 3.2 Pylephlebitis

Purulent inflammation of the branches of the portal vein is usually accompanied by subsequent portal vein thrombosis. Aetiologically, intrahepatic and extrahepatic purulent pylephlebitis share certain similarities. • Portal vein infections have their *origin* in inflammatory processes of neighbouring structures such as appendicitis, cholecystitis, liver abscesses (as was already postulated by H. CHIARI in the first cases published) (s. p. 830), suppurative hydatid cysts, colitis, diverticulitis, infected haemorrhoids, covered perforations (gall bladder, gastric ulcer) and malignant tumours (gall bladder, pancreas). • *Clinical symptoms* include fever, chills, abdominal pain, meteorism, enlarged and tender liver as well as splenomegaly. In most cases, inflammation parameters are clearly pathological. (s. tab. 37.6) Bacteriological haemocultures only yield positive results when the defence mechanisms of the liver RES have been overwhelmed. The clinical picture of septic portal vein thrombosis can often be observed. **Treatment** with local fibrinolysis and TIPS has proved successful.

## 3.3 Portal vein thrombosis

Thromboses in the vessels of the portal system constitute the most common cause of prehepatic portal hypertension. • Even in the **postpartal** phase, portal vein thrombosis may occur due to the obliteration of the umbilical vein spreading to the portal vein or due to an infection of the umbilical vein with subsequent pylephlebitis. • In the **adult,** this clinical picture is most commonly observed in liver diseases that cause the portal blood flow to slow down (or even reverse). All diseases which are accompanied by hypercoagulopathies also have a strong tendency to cause portal vein thrombosis. (106, 110, 112, 119, 121) Patients with liver cell carcinoma due to cirrhosis quite often develop thrombosis. Septic processes (such as appendicitis, diverticulitis, colitis) are a further common cause, particularly in immuno-

compromised patients. In addition, inflammatory tissue, tumours, lymphomas or fibrosis may narrow the lumen of the portal vein and trigger thrombosis. Thrombosis of the portal vein may also result from progressive thrombosis of the splenic vein. (s. tab. 14.2) Portal vein thrombosis can hence be caused by many factors. (107, 108, 119, 121–123) (s. tab. 39.4) (s. fig. 39.8)

***Fig. 39.8:*** Thrombosis of the portal vein (⇐) and splenic vein (→): contrast medium-free, hypodense structure; evidence of ascites

The severity of the clinical picture depends upon how rapidly and to what extent the portal vein obstruction develops. • Haemorrhagic infarction of the intestine, due to sudden thrombotic occlusion, causes severe abdominal pain, haematemesis and melaena, circulatory shock and, ultimately, the death of the patient. • In gradual obstruction, splenomegaly and hypersplenism develop, accompanied by collateral vessels in the form of a sponge-like venous network (= *cavernous transformation*), which makes partial compensation possible. Gallbladder varices, even with rupture and bleeding, have also been observed. (104, 109) The size of the liver is normal, as are the wedged hepatic vein pressure (with increased intrasplenic pressure) and histology. Impairment of liver function only occurs at a later stage (118), and *hepatoportal sclerosis* develops. • The diagnosis is mainly established by colour Doppler sonography (sensitivity > 90%) (114), CT (s. fig. 39.8) and angiography (e. g. CTAP). Angiographic findings are also useful for deciding on the respective *therapy*: thrombolysis with subsequent anticoagulant treatment (if possible!) (105, 113, 116), percutaneous transhepatic angioplasty and thrombectomy (both procedures can only be applied in the early stages of disease), TIPS (possibly, with local thrombolysis) or a shunt operation. The prognosis is poor.

**Zahn's infarct:** This well-demarcated hyperaemic area in the liver was first described by F.W. ZAHN in 1897. He called the phenomenon "atrophic red liver infarction", but without necrosis. Such a form of infarct is an oddity.

1. **Hypercoagulopathy**
   Antiphospholipid sydrome
   Antithrombin III deficiency
   Factor V mutation
   Factor VIII elevation
   Hyperhomocysteinaemia
   Myeloproliferative diseases
   Oral contraceptives
   Protein C deficiency
   Protein S deficiency
   Pregnancy
   Thromboembolism

2. **Inflammatory processes**
   Appendicitis
   Behçet's disease
   Cholangitis
   Cholecystitis
   Collagenoses
   Crohn's disease
   Diverticulitis
   Pancreatitis
   PSC
   Ulcerative colitis

3. **Infections**
   Actinomycosis
   Candida albicans
   Echinococcus
   Schistosomiasis
   Tuberculosis

4. **Invasive treatment**
   Abdominal surgery
   Alcohol injection
   Chemoembolization
   Dialysis
   Islet-cell injection
   Liver resection
   Liver transplantation
   Portography
   Sclerotherapy
   Splenectomy
   TIPS

5. **Delayed portal blood flow**
   Congenital fibrosis
   Liver cirrhosis
   Lymphoma
   Nodular regenerative hyperplasia
   Retroperitoneal fibrosis
   Stenoses/strictures

6. **Progressive splenic vein thrombosis**
   Pancreatitis
   Pancreatic carcinoma
   Splenectomy

7. **Malignant processes**
   Cholangiocarcinoma
   Cystic carcinoma
   Hepatocellular carcinoma
   Pancreatic tumour (= thrombophlebitis migrans)

8. **Intoxications**
   Arsenic
   Cytostatics
   Radiation

9. **Haematologic diseases**
   Paroxysmal nocturnal haemoglobinuria
   Sickle cell anaemia

10. **Cardiovascular diseases**
    Constrictive pericarditis
    Obstruction of inferior vena cava
    Pylephlebitis
    Tricuspid insufficiency
    Tumour of the right atrium
    Umbilical vein infection
    Veno-occlusive disease

11. **Trauma**

12. **Cryptogenic**

*Tab. 39.4:* Possible causes of portal vein thrombosis

(111, 117) Intrahepatic occlusion of hepatic vein branches results in a narrowing and atrophy of the liver cell trabeculae and consecutive dilation of the associated sinus-

oids. A dark bluish red area of the liver appears, which is most clearly visible when the liver is simultaneously congested. (Despite the term "infarct", no necrosis can be observed!) Zahn's infarct may also be found in the area surrounding liver metastases due to compression of the portal vein branches by tumourous tissue.

### 3.4 Portal vein aneurysm

Aneurysms of the portal vein are very rare. However, since the introduction of imaging procedures, this generally asymptomatic finding has been detected more frequently, in most cases by chance. In **intrahepatic localization** (first reported by H.S. Vine et al., 1979), the aneurysms are mainly situated in the right lobe and reach a size of up to 4 cm in diameter. The cause is not clear. Congenital malformation with subsequent portal hypertension has been postulated, as has acquired vessel wall weakness (e.g. in pancreatitis). The diagnosis is made by sonography and MRI. (124, 125) Caroli's syndrome has to be ruled out by differential diagnosis. Spontaneous rupture of such an aneurysm has been reported. (127) Treatment is not primarily required, but regular monitoring is necessary. In portal hypertension, however, the application of a shunt (surgically, transjugal-portacavally) may be indicated. (126)

# 4 Disorders of the hepatic arteries

▶ The **common hepatic artery,** a branch of the coeliac artery, runs in a retroperitoneal direction above the pancreas into the hepato-duodenal ligament. It continues as the **proper hepatic artery,** which branches into the **right hepatic artery** (with the cystic artery) and the **left hepatic artery** to supply the two liver lobes. Ramification of the hepatic artery varies greatly. • The branches of the hepatic artery accompany the bile ducts and the portal vein as far as the portal fields. Radicular branches subsequently fork off forming the **peribiliary plexus** within the connective tissue of the portal paths. The peripheral, medial and central areas of the hepatic lobules are supplied by **intralobular arterioles.** • A small percentage of the arterial blood supply is also guaranteed by influx from the superior mesenteric, inferior pancreatic-duodenal and supraduodenal arteries. • Only 40−50% of the oxygen requirement and 35% of the blood volume of the liver (350−500 ml/min.) are supplied by the hepatic artery. Hence, the clinical picture of diseased liver arteries is usually relatively mild, apart from bleeding caused by ruptures. (s. p. 16)

The most important clinical disorders of the hepatic artery are:

1. Aneurysm
2. Occlusion
3. Nodular periarteritis
4. Arteriosclerosis

### 4.1 Aneurysm

#### 4.1.1 Definition

While aneurysms of the hepatic arteries are in themselves rare, they nevertheless constitute 20% of all an-

eurysms of the splanchnic arteries. They are located extrahepatically in 80% and intrahepatically in 20% of cases. At 60%, the common hepatic artery is most frequently involved, followed by the right hepatic artery, which is affected in 30% of cases. A rupture (up to 80% of cases) constitutes a great risk to the afflicted, but often symptom-free patients. After confirmation of the diagnosis, treatment should begin immediately.

### 4.1.2 Aetiology

**Congenital** anomalies and aneurysms in the hepatic arteries are very rare. (129) **Acquired** aneurysms are the result of vessel wall damage, injuries or inflammatory processes. (131, 133, 136) • **Pseudoaneurysms** may occur after acute pancreatitis and the formation of pseudocysts. (135) (s. tab. 39.5)

| | |
|---|---|
| 1. **Congenital aneurysms** | 5. **Infections** |
| 2. **Vascular wall degeneration** Arteriosclerosis Fibromuscular dysplasia Media degeneration | Endocarditis Mycosis Pancreatitis Syphilis Tuberculosis |
| 3. **Abdominal traumas** | 6. **Vasculitis** Periarteritis nodosa Vasculitis |
| 4. **Iatrogenic causes** Bile-duct surgery Intra-arterial chemotherapy Liver biopsy Transhepatic interventions | 7. **Multiple pregnancies** |

*Tab. 39.5:* Possible causes of hepatic artery aneurysm

### 4.1.3 Clinical features

**Symptomatology** depends on the extent and localization of the aneurysm, which can vary considerably in size, ranging from the diameter of a millet seed to that of a walnut (there have been cases where aneurysms as big as a grapefruit were observed). Small aneurysms do not cause any symptoms and are only discovered incidentally during imaging procedures or surgery. In most cases, patients complain of uncharacteristic abdominal pain, which may precede a rupture by several months. Large aneurysms are characterized by a continuous murmur. (132)

After **perforation** (60–80% of patients), an aneurysm becomes manifest in the form of abdominal pain, which can be very severe. (129) When an intrahepatic haematoma reaches the bile ducts, haemobilia may result (about 40% of cases) (133), just as compression of the excretory bile ducts may lead to the development of jaundice (in some 50% of cases). (134, 138) Heavy bleeding into the free abdominal cavity constitutes an acute abdomen with signs of circulatory shock. Bleeding into the intestinal tract or into the portal vein is less frequent. Lethality due to rupture is 30–50%; the prognosis for massive bleeding with haemoperitoneum is even poorer.

### 4.1.4 Diagnosis

**Laboratory findings** are normal. However, alkaline phosphatase (and LAP) and possibly also bilirubin may be increased in biliary stasis.

With unclarified abdominal pain, **sonography** is usually the diagnostic procedure of choice. An aneurysm appears as a round or oval focus either intrahepatically or extrahepatically between the portal hilum and the pancreas. The hypoechoic, cystic focus may contain hyperechoic, thrombotic material. Occasionally, there is a connection to an afferent vessel. (128) A suspected aneurysm can be confirmed by **colour Doppler sonography,** with the possibility of distinguishing blood flow and arterial blood. An echo-free aneurysm provides a typical arterial sphygmogram.

**CT scanning** reveals a hypodense to hyperdense focal space-occupying lesion, with the hyperdense parts corresponding to the thrombotic structures within the aneurysm. Diagnostic accuracy is considerably improved by using contrast-medium CT.

**Angiographic scanning** of the hepatic artery confirms the diagnosis as well as giving an indication of the most appropriate therapeutic measures. • Due to the development of modern MRI techniques, invasive angiography is no longer necessary in most cases.

### 4.1.5 Treatment

Once detected, an aneurysm of the hepatic artery requires immediate treatment. Up to a certain size, intrahepatic aneurysms are treated by angiographic embolization. Coagulation by means of direct thrombin injection has also been described. (130) Larger aneurysms are treated by vascular surgery (ligation, vascular reconstruction, resection). (132, 137)

## 4.2 Arterial occlusion

Occlusion of the hepatic artery is responsible for a 50% reduction in oxygen supply. Even if an unimpaired oxygen supply via the portal vein is guaranteed, arterial occlusion usually causes ischaemic infarction. The clinical and morphological pictures are characterized (*1.*) by the speed with which an occlusion develops and (*2.*) by the presence of variants that can be used as a bypass or of collaterals that have already been established in gradual vascular occlusion. This results in a broad clinical spectrum, which may range from a symptom-free condition to liver hypoxia, including infarction up to hepatic coma.

### 4.2.1 Aetiology

Causes of occlusion are as follows: (*1.*) primary vascular diseases (nodular periarteritis, giant-cell arteritis, etc.), (*2.*) iatrogenic measures (intra-arterial catheterization,

i.v. cytostatic infusions, surgical interventions, etc.), (*3.*) traumas (dissections), (*4.*) embolisms (bacterial endocarditis, severe arteriosclerosis, mitral valve defect), and (*5.*) fibromuscular hyperplasia.

### 4.2.2 Clinical features

In acute occlusion with infarction, there is dull upper abdominal pain, often coupled with shock symptoms; the liver is tender upon pressure. Fever, jaundice and leucocytosis rapidly develop; Quick value decreases, and haemorrhages develop. Transaminase and alkaline phosphatase levels rise. Liver failure is imminent. Apart from possibly detecting hypoechoic foci, sonography provides no diagnostic information. Contrast-medium CT reveals hypodense regions with mostly blurred boundaries. In MRI, the infarct is low $T_1$-weighted, with a high signal intensity in the $T_2$ image. The diagnosis is confirmed by arteriography, which should be carried out without delay if there is suspicion of acute occlusion. • *Treatment* is symptomatic and aimed at stabilizing the liver function in order to allow time for the formation of collaterals (within a few days). A lethal course must be anticipated if the openings of the gastric and gastroduodenal arteries are involved in the occlusion. The prognosis for distal occlusions in the area of the right or left hepatic artery is more favourable.

**Ischaemic infarction:** Ischaemic infarction with haemorrhagic marginal zones not only occurs after occlusion (139−141), but also *without* vascular obstruction, e. g. in shock, diabetic ketoacidosis, pre-eclampsia or lupus erythematosus. Small infarctions have also been described as complications following liver biopsy. • Morphologically, fresh anaemic infarctions appear as coagulation necroses. Large infarctions may cause "bile lakes" with evidence of air. From the second day, a wall of leucocytes forms at the infarction margins, and pigment-loaded macrophages can be observed. The reticular fibre structures collapse, and the granulation tissue is vascularized. Ultimately, indrawn scars develop.

### 4.3 Nodular periarteritis

This *primary vascular disease* is a febrile systemic autoimmune reaction, presumably caused by excessive immune activities. In this process, immune complexes are deposited in the walls of vascular arterioles as well as in the larger arteries, giving rise to a progressive inflammatory reaction with round-cell infiltrates, pearl string-like thickening and proliferations of the intima. The narrowing of the lumen results in ischaemic necroses, which are also present in the liver in up to 65% of patients. Non-specific reactive inflammation in the portal fields may also be observed. As a rule, the gall bladder is involved just as frequently. Nodular periarteritis often leads to the development of aneurysms. • *Clinically*, there are highly pathological inflammation

parameters. (s. tab. 39.2) Marked increases in BSR and alkaline phosphatase are characteristic. Various pains in the abdomen, joints and renal areas occur; weight loss adds to a distinct feeling of being ill. If the liver is affected, transaminase values may be slightly increased. • *Treatment* consists of prednisolone and azathioprine, unless active viral hepatitis is present.

### 4.4 Arteriosclerosis

Arteriosclerosis affects the extrahepatic liver arteries with the same frequency as the mesenteric arteries, but less frequently than the splenic artery. • The intrahepatic branches of the hepatic artery are usually only involved in pronounced arterial hypertension. In these patients, thickening of the media can be found in the small arteries of the portal fields.

## 5 Hereditary haemorrhagic telangiectasia

This *dysvascular state*, also known as *Osler's disease* or *Rendu-Osler-Weber disease*, was first observed by the Canadian internist W. Osler in 1901. (152) It is a rare autosomal dominant hereditary disease (1 : 100,000) with high penetrance (almost 100%). The homozygous presence of the affected allele is a lethal factor. All types of vessels are affected by these vascular malformations. Thus, for example, arteriovenous fistulas, aneurysms and telangiectasias of the arterial and venous terminal vessels as well as phlebectasias are found. The liver is involved in 40−70% of cases. Star-shaped vascular ectasias can be found on the liver surface. Polymorphism of these angiodysplasias is caused by genetically determined damage to fibroelastic fibres within the vascular walls and the perivascular tissue. There is no evidence of any mesenchymal reaction or inflammatory activity. (142, 145, 146, 148, 154, 155, 157) • Osler's disease usually progresses through three phases: the asymptomatic *latent period* extends from childhood into puberty: the subsequent *haemorrhagic phase* is generally characterized by recurrent nasal bleeding; *manifest angiomatosis* has its onset in the 3rd or 4th decade. Various clinical features can be witnessed, including post-haemorrhagic anaemia, hyperdynamic circulatory problems due to arteriovenous fistulas with cardiac insufficiency, signs of portal hypertension with hepatomegaly (156), phases of hepatic encephalopathy and, in some cases, gastrointestinal bleeding. Dense vascular networks with vascular anomalies are found especially in the region of the mesenteric arteries. The diagnosis is based upon colour-encoded Doppler sonography (144, 149, 151, 156), CTAP and arteriography. (143, 147) The CO level is high, so that right-sided cardiac catheterization is indicated in these patients. Following a protracted course, which also requires frequent blood transfusions,

secondary biliary cirrhosis may develop. (150) • Embolization or surgical interventions (ligation of afferent vessels, partial liver resection) and even liver transplantation (146, 153) are indicated, provided such procedures are technically possible.

# Clinical Aspects of Liver Diseases

## 40 Treatment of liver diseases

# 40 Treatment of liver diseases

## 1 From mythology to provable treatment

### 1.1 In global medicine

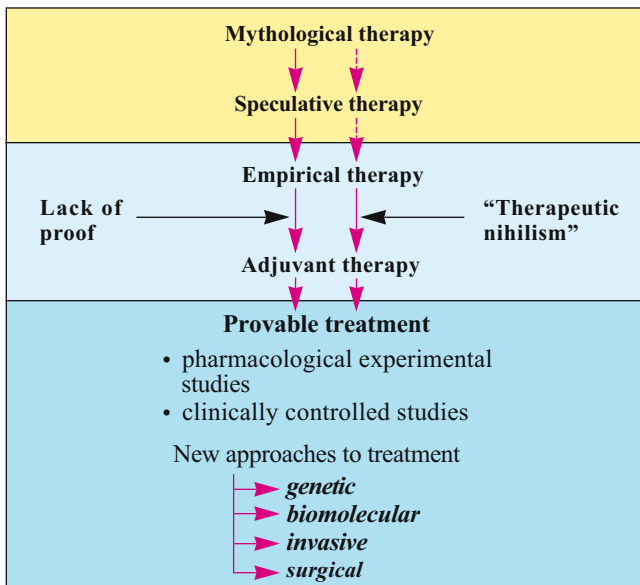
▶ Recommendations and discussions on the treatment of diseases and injuries are as old as medicine itself. According to our knowledge of earlier times, medicine has its origins in **mythological therapy.** This also applies to the treatment of liver diseases. • Understandably, *"surgical medicine"*, especially traumatology, enjoyed the highest scientific status in antiquity, since the actual "cause" and medical "effect" were most obvious in this field. • Mythological ideas and rituals were therefore of minor significance to the barber surgeon: in general, practical experience, manual skill and (mostly self-developed) appropriate instruments produced the desired result. By contrast, *"conservative medicine"* was characterized by mythology, steeped in ritual as well as (mantic) divination and, for many epochs, mostly left in the hands of the "priest doctor". In spite of sometimes astonishingly good diagnostic capabilities and prognostic accuracy, medicine on the whole − especially treatment of the patient − was subject to the prevailing mythology of the respective epoch. (s. tab. 40.1)

With the gradual rejection of "mythos" and a stronger tendency to "logos", therapeutic measures of a mythological and ritual nature were increasingly abandoned. At the same time, however, the absurd ideas of **speculative therapy** reached an unimaginable level of odiousness. Obscure mixtures, fantastic preparations as well as nauseating and even cruel treatment methods were more and more propagated and applied. An insight into these abnormalities of speculative medicine is given by K. F. PAULLINI (1699) in his book: *„Neu-vermehrte, heilsame Dreck-Apotheke"* ("Revised and Enlarged Curative Dirty Pharmacy").

With the coming of the Age of Enlightenment in the middle of the 18th century, accompanied by a rapid increase in medical knowledge, the calls for confirmed results became more and more urgent. This led to the advent of **empirical therapy**, which required subtle observation, critical analysis, careful examination and, above all, a written record of case histories. In this connection, surgical empiricism was more strongly based on morphological facts and objective methodological experience than the therapeutic empiricism of conservative medicine.

▶ Preventive therapeutic empiricism was applied for the first time around 1600, when it was discovered by "therapy comparison" that those seamen of the East India Company who drank lemon juice as a supplementary beverage did not contract scurvy. *This was the basis of (probably) the first* **"statistical" therapeutic study,** *which J. LIND carried out in 1747 in order to confirm a lemon juice theory in several groups of people by administering various substances, including a "placebo".* This theory was also confirmed by J. COOK in 1776, using a similar study design. Further therapeutic milestones of medical history include the comparative studies with *digitalis* (W. WITHERING, 1785), *smallpox vaccine* (E. JENNER, 1798) and *mercury treatment* of syphilis (J. PEARSON, 1800). Such comparative studies, which were based on individual observations, aimed at proving the effectiveness of treatments; this development ended the epoch of empirical therapy. (2) (tab. 40.1)

### 1.2 In hepatology

▶ During a period of about 3,000 years, hepatology also experienced these **historical medical epochs** of therapy, (*1.*) mythological, (*2.*) speculative, (*3.*) empirical, and (*4.*) provable. (s. tab. 40.1) • In addition to cataplasms − consisting of various herbs, oils or products derived from animals, mostly prepared and used according to mythologically related ideas − cupping, scarification, enemas, blood-letting and sternutators, the following materials were also used: dried wolf's liver with honey, donkey liver with parsley, raw ox liver dipped in honey, ox blood, etc. Some highly complex and fantastic mythological diets were applied as well. Therapeutic measures were often based on certain mythological numbers or ritual-dependent points in time and performed before statues of gods or in connection with animal sacrifice. *(see chapter 1.)* • From the mediaeval "dirty pharmacy" came numerous, disgusting therapeutic recommendations for patients with liver disease, e. g. consumption of the excrement of certain animals, ear wax, dirt scraped off sheep udders, earthworms, polypods dissolved in wine, or a certain number of live sheep's lice. (s. p. 437) • Empirical treatment increasingly made use of substrates of plant origin or extracts of Hyoscamus, Cheliodonium, dandelion or milk thistle, etc. To my knowledge, *comparative therapeutic investigations* such as those mentioned above were not performed in hepatology. Until modern times, treatment of liver diseases remained almost exclusively empirical − and thus scientifically unproven.


*Tab. 40.1:* Historical epochs of medicine: (*1.*) mythological, (*2.*) speculative, and (*3.*) empirical therapy, through to (*4.*) provable treatment

The occasionally pronounced *"polypragmatism"* was confronted by the opposite extreme of *"therapeutic nihilism"* in the sense of treatment based on expectation. This inevitably led to frustration on the part of the physician and to resignation on the part of the patient suffering from a liver disease. • Thus, the realization of provable treatment also became an urgent challenge in hepatology.

# 2 Clinical studies

The first ethical principles of biomedical research had already been developed in Germany prior to World War I: relevant instructions were issued by the Prussian Education Office in 1900. At the proposal of the German National Health Board, guidelines for modern curative treatment and for the performance of scientific studies in humans were issued in 1931 by the Ministry of Internal Affairs in Germany. • The following year (1932), P. Martini published his methodology of therapeutic research, and in 1937 A. B. Hill established the principles of medical statistics.

## 2.1 Types of clinical studies

Significant contributions have since been made concerning the importance, performance and evaluation of **clinical studies.** (5, 6) In recent years, statistical and legal issues in particular have been discussed. (3, 7, 8, 9) • Controlled clinical studies are rightly called for and they are indispensable for avoiding therapeutic misjudgement deriving from "trial and error" and for creating an objective basis for official decisions. They may be car-

ried out, as far as possible comparatively, as a retrospective or prospective investigation. • A **retrospective study** is a backward-looking review of facts and effects, i. e. against a time axis, to identify preceding causes. The data can be collected according to a fixed plan **(= prolective)** or generated before the study begins **(= retrolective).** Furthermore, a distinction is made between following the individual course from the time the causative factor appears through to the onset of effect **(= cohort)** and following the individual course from the onset of effect back to the earliest possible point in time when the causative factor appeared **(= trohoc)** (A. R. Feinstein, 1977). Thus, a retrospective study is deemed scientifically correct if its execution is justified and the methodology is clearly defined. • A **prospective study** starts from causative factors, observing the effect over the course of time. (6, 7, 9)

**Special cases** are the *open (non-blind) study* on the one hand and the *crossover study* on the other hand. • This means that the controlled clinical study is "fundamentally" (i. e. with some exceptions) the sole and most essential tool for obtaining proof of the efficacy of a given substance. If the conditions for a controlled clinical study cannot be met, then it must be dispensed with.

The **typology** of clinical studies differentiates four types according to their aims: (*1.*) pharmacological studies, (*2.*) therapeutic explorative studies, (*3.*) therapeutic confirmative studies, and (*4.*) drug-monitoring studies. The purpose of the last-mentioned group is to define the cost/benefit ratio more precisely, identify rare side effects and provide better dosage recommendations.

## 2.2 Problems of clinical studies

There is a vast array of literature dealing with still controversial aspects of controlled clinical studies. • *We should be aware that on the one hand, medicine is not an exact science and on the other hand, humans do not represent a quantifiable model with data on call as needed.* Problems in clinical studies often arise in **different fields:**

| | |
|---|---|
| 1. ethical | 4. psychological |
| 2. methodological | 5. heuristic |
| 3. legal | 6. economic |

Proof in the strict sense cannot be delivered by a controlled clinical study, which has been called the "sacred cow". (5) However, the probability of statistical error in terms of the chosen target criteria can be fixed in advance. In clinical studies, different interpretations of results are still possible, since "intuitive medical observation and judgement remain indispensable in the individual case" (E. Buchborn, 1982). • The **triad** of *empiricism, intuition* and *logic* is necessary in both diagnosis and treatment (R. Gross, 1988).

## 2.3 Placebo

A placebo (Latin, "I shall please") or ADT (= **a**ny what you **d**esire **t**hing) is a "dummy" without any active substance, identical in appearance to the respective active drug and not designed to be effective. This term has been known since the 14th century. (4) • In medicine, a placebo assumes **two roles:** (*1*.) as a therapeutic agent in the practical treatment of patients, intended to have an "effect" on a disease or a symptom, or exerting such effects without the physician's knowledge, and (*2*.) as a control substance in clinical studies with drugs. • In individual cases, even **objective** changes in physiological functions and **specific** effects may be demonstrable. The form of administration and the dosage of a placebo, the physician's personality (and that of the patient) and the intensity of the disease situation may lead to a weakening or potentiation of the placebo effect. The important (individual and social) ethical issues associated with placebo administration concern both the patient and the physician, who have to be informed in general about such procedures. These issues have been clarified by law after being discussed in detail and assessed on the basis of experimental findings.

> ▶ The placebo effect in controlled clinical studies should never be regarded as "zero", even though this is, of course, desired (or even imputed) from the statistical viewpoint.

Within the scope of clinical studies, valuable economic information on medical procedures can (and should) be obtained. Today, **economic assessment** assumes a special role in clinical studies, and because of its complex stratification and the general need for rationalization, e. g. in terms of the cost/benefit analysis, it is likely to become more and more important. The quality-adjusted life year (G. W. Torrance, 1987) should be included in the assessment. (s. p. 850)

## 2.4 Difficulty of evaluation

Proof of efficacy of a certain (surgical or medicinal) therapeutic measure − *and this also applies in hepatology* − is very difficult, as it mainly depends on **two factors:**

> 1. non-comparability of individual humans
> 2. non-comparability of individual diseases

Statistical methods cannot render either **non-comparability** of individual humans or that of diseases comparable − at best, they may compensate it by means of large patient numbers or are able to assess sameness under certain circumstances. (1, 5) • Statistical **comparability** of different patient groups can only be achieved if **three requirements** are met:

> 1. equality of structure
> 2. equality of observation
> 3. equality of representation

Even with great diagnostic effort, no convincing *structural equality* is obtainable. Consequently, randomization alone does not guarantee a valuable clinical study. Despite these problems, **three study types** should (and must) be used:

> 1. **Examination of effect**
>    = change in any one parameter
> 2. **Examination of efficacy**
>    = cure or improvement of disease
> 3. **Examination of superiority**
>    = improvement of parameters, or cure, or improvement of disease by conventional therapy vs. new therapy

## 2.5 Provability of treatment

In clinical studies involving drugs − *this also applies to hepatology* − the terms "effect" and "efficacy" have not always been appropriately distinguished, but were often (erroneously) considered identical. • The **effect** of a specific drug (or "liver therapeutic") showing changes in any measured parameters or reactions is easier to prove than its efficacy in the sense of cure or improvement of disease. Therapeutic **efficacy** (or efficacy of "liver therapy") is defined by the difference between the uninfluenced disease course (i. e. possible or usual course) and the disease course changed by therapeutic measures (i. e. actual course). *There is, however, no chance of ever observing and assessing the "possible" and the "actual" disease course simultaneously.*

The **marketability** of a pharmceutical preparation is controlled by an act of administration. In this context, **three criteria** must be satisfied for the licensing of medicaments, including "liver therapeutics":

> 1. *quality*        2. *safety*
>        3. **efficacy**

> The term **"quality"** is defined by the following criteria: purity, identity, content, galenic properties and temperature stability of a substance. • The term **"safety"** is defined in relation to acute and chronic toxicity, foetal toxicity and fertility, mutagenic and carcinogenic potential.

As regards the term **"efficacy",** no legal definition exists. As a rule, efficacy is defined by the sum of desired effects with regard to a certain therapeutic aim. Thus, in terms of the licensing regulations, the efficacy of a drug, including "liver therapeutics", may be defined as

*"the abstract quality of medicine to achieve therapeutic success with proper use, accidental and placebo success having been excluded"* (K. J. HENNING, 1978). The US Food, Drug and Cosmetic Act defines the term efficacy in a similar manner. • Mere proof of quality and safety is sufficient for medicine that does not have be licensed, but only registered; no proof of efficacy is required. This applies to homoeopathic remedies, for example. • The efficacy of medicinal remedies, including "liver therapeutics", may be regarded as a **continuum,** i.e. from *"very weak"* to *"highly potent"*. Thus, efficacy is also proven when the substance is shown to be only slightly effective or is only effective in some patients (individual cases). Principally (= exceptions are possible), proof of efficacy is to be provided by controlled clinical studies. No proof of superiority of the drug under investigation over the standard preparation is required by law. Nor does the licensing procedure check whether there is a potential need for the drug in question. • ***Thus the aim of clinical studies is to provide proof of safety and appropriate efficacy.***

# 3  Principles of liver therapy

## 3.1  Basic considerations

First of all, two terms need rectifying, since the superficial yet incorrect use of the designations *"liver therapy"* and *"protective therapy of the liver"* have rendered it fundamentally more difficult to make accurate statements. These terms are relics from the epochs of speculative or empirical therapy and constitute the origin of the catchword "therapeutic nihilism". (s. tab. 40.1)

### 3.1.1  Liver therapy

There has never been and there still is not any "liver therapy" in the true sense − and no such therapy will exist in future either. The liver as the largest biochemical performance centre of the body is constantly active in some 11 major metabolic areas with 60−70 integrated partial functions. In order to accomplish the many tasks, about 300 billion liver cells undertake approx. 500 biomolecular reactions daily − indeed an unbelievable feat. Consequently, it is not possible for drugs to have an effect on the liver as a whole. *However*, **therapies for liver diseases** *or therapies for hepatological symptoms are available*. With this linguistic correctness, our therapeutic efforts in hepatology become *realistic* and *objectifiable*. There are far more than 100 liver diseases plus variants and diverse complications. A large number of them can be treated successfully with pharmacological regimens − sometimes with strikingly good results − as well as, of course, by invasive and surgical therapy.

### 3.1.2  Liver therapeutic agents

In the strict linguistic and hepatological sense, there is no such thing as liver therapeutic agents. However, this *unfortunate term* is frequently − and indeed deliberately − used rhetorically in publications or for administrative reasons. Here, the expression **"hepatic agents"** (analogous to cardiac, otologic and diuretic agents, etc.) would be more correct and not so promising in the popular sense as the designation "liver therapeutic agents". • *In any case, one ought to be aware of the possible psychological effect of such a term, especially with regard to a "placebo".* (s. p. 846)

### 3.1.3  Protective therapy of the liver

Similarly, there is no generally protective therapy of the liver. Liver "protection" as such may include active vaccination against viral hepatitis A or B, for example, and, in a wider sense, also passive immunization after exposure or general avoidance of typical liver noxae. This can "protect" the liver from diseases. (12)

In **in-vitro** and **in-vivo experiments,** certain substances can be studied for their protective effect on the hepatocytes or endothelial cells (including biomembranes and organelles) under the influence of various noxae or toxins. *Many substances have been shown to display distinct protective properties experimentally under various investigative conditions.* Such studies are not, however, admissible in humans. • These experimental protective properties may also be of therapeutic value in individual cases (e. g. application of *silibinin* in Amanita poisoning).

A "liver-protective preparation" must therefore be capable of protecting the hepatocytes (as well as the sinus endothelium) from a particular liver toxin, or from 2 or 3 clearly defined (or, in the optimal case, all obligate) liver toxins, *by administration before or, at the latest, when the damage occurs.* The use of a substance in existing cellular damage would be classified as "therapy" and no longer "protection". The term protective liver therapy clearly implies prophylaxis − which, apart from the above exceptions (e. g. vaccination), is usually not feasible under the provisions of the respective health insurance system. (12)

## 3.2  Preconditions

The question of provability of a certain therapy is also dependent on various **factors** in hepatology: (*1.*) knowledge of the spontaneous course of a liver disease (not known in individual cases, but only globally assessable), (*2.*) endogenous factors (gender, age, genetics), and (*3.*) exogenous influence (e. g. lifestyle, noxae, patient compliance). These imponderables can scarcely (if at all) be integratively assessed or excluded even using subtle statistical methods. Randomization and double-blind clinical trials can do no more than balance out these differ-

ences. In order to obtain usable data, certain **statistical conditions** should be fulfilled as far as possible:

- homogeneous findings
  *in*
- homogeneous patients
  *with*
- homogeneous disease

These requirements are difficult to meet even in controlled clinical studies in hepatology. Moreover, the use of medication in liver disease is based on further essential **clinical conditions:**

1. Detailed hepatic diagnosis with exact classification of the liver disease
2. Identification and elimination of the causative noxa(e)
3. Elimination of concomitant negative factors or additional noxae

Therapeutic uncertainties or differing conclusions regarding drug effects or efficacy may thus be attributed to varying degrees of methodological **inaccuracy** as follows:

- different disease courses
  *with*
- different pathogenesis
  *in*
- different patients
  *and an*
- insufficient detailed diagnosis
  were submitted
  *to*
- joint statistical evaluation

## 3.3 Aims of treatment

Drug therapy of a particular liver disease or complicative development must have basic **treatment aims.** The primary therapeutic aim is to eliminate the existing causative factors and pathogenetic mechanisms. The final goal is always the *rehabilitation* of the liver patient. (s. tab. 40.2) (s. p. 881)

1. Eliminating or definitively overcoming the cause of disease (as far as possible) as well as promoting and speeding up its cure

2. Inhibition of inflammatory reactions
3. Curbing of mesenchymal reactions
4. Modulation of immunological reactions
5. Support/normalization of liver cell functions
6. Stimulation of hepatic regeneration

Rehabilitation

*Tab. 40.2:* Treatment aims in liver diseases

## 3.4 Forms of "liver therapy"

**Causal treatment** of liver diseases, which is rarely (if ever) feasible, should achieve the complete elimination of the actual cause(s) (e.g. elimination of the causative noxa, antiviral treatment, gene therapy in hereditary liver diseases). • **Treatment of pathogenetic primary reactions** (e.g. with interferon, immunosuppressants or penicillamine) is aimed at interrupting the "postcausal" pathogenesis. • **Treatment of disease progression** intervenes in the pathological process in a lasting and efficient manner and thus prevents or slows down the generally dangerous consequences (e.g. inhibition of cholestasis, fibrogenesis and portal hypertension). • Almost all substances used in hepatology are classed as **symptomatic treatment.** These substances help (*1.*) to combat malaise and disturbances secondary to the liver disease (e.g. antipruritics) and (*2.*) to influence the structures and functions of the hepatocytes and endothelial cells as well as the bile capillaries (e.g. antioxidants, essential phospholipids, UDCA, silymarin). (12)

## 3.5 Categories of "liver therapeutics"

A number of substances and preparations are available for the treatment of liver diseases. They can be categorized as follows (s. tab. 40.3):

1. **Prophylactics:** e.g. immunoglobulins or vaccines against hepatotropic virus infections
2. **Antidotes:** e.g. silibinin against Amanita poisoning or N-acetylcysteine in paracetamol intoxication, haemarginate in acute porphyria
3. **Primary liver therapeutics:** e.g. penicillamine, glucocorticoids, azathioprine, interferon-α, aimed at primary intervention in the aetiology or pathomechanism of liver disease.
4. **Secondary liver therapeutics:** e.g. fat-soluble vitamins in impending deficiency states, drugs to reduce portal hypertension, substances to relieve hyperammoniaemia, aimed at secondary prevention of the various sequelae of liver disease.

*Tab. 40.3:* Categories of liver therapeutic agents

## 3.6 Active substances

For several years, (negative) claims appeared in the press stating that the pharmaceutical market was oversaturated with more than 600 liver preparations. Although the originator of this claim was not identified, this utopian number made the rounds. • In fact, there are merely **25 substances** or **groups** of substances (of chemical or plant origin) listed in the pharmacopoeia. Here, the various preparations containing the same substance are numbered separately, which gives a total of **90−100 listed preparations**. • It is irresponsible that

some "liver therapeutics" still have an **alcohol content** of 25–66 vol.% (particularly homoeopathic and phyto-therapeutic remedies). (s. p. 60) Although the often quantitatively low intake of alcohol in a preparation may be "harmless" (even "3 times daily"), it will usually cause a relapse in an abstinent alcoholic. *In principle, there is no justifiable argument for keeping the alcohol content in a hepatological preparation!*

Some medicaments with **special indications** are used in various liver diseases or in certain complications. They are not found in the special category of liver therapeutics (pharmacopoeia), but are listed according to their main indication. Treatment with some of these active substances may possibly be accompanied by side effects. (s. tab. 40.4)

| Chemical substances (or groups) | |
|---|---|
| 1. Amino acids of the urea cycle | 10. Immunosuppressants |
| 2. Beta blockers | 11. Immunostimulants |
| 3. Bile acids | 12. Lactulose |
| 4. BCAA | 13. Nucleoside analogues |
| 5. Deferoxamine | 14. S-adenosyl-L-methionine |
| 6. D-penicillamine | 15. Somatostatin |
| 7. Diuretics | 16. Spironolactone |
| 8. Glucocorticoids | 17. Virostatics |
| 9. Haemarginate | 18. Vitamins (A–K) |
| | 19. Zinc |

| Phytotherapeutic agents (or groups) |
|---|
| 1. Colchicine |
| 2. Essential phospholipids |
| 3. Glycyrrhizin |
| 4. Silymarin |
| 5. Various herbal preparations |

***Tab. 40.4:*** Active chemical substances (or groups) and phytotherapeutic agents used in some liver diseases or their complications

**Active substances** with sufficiently proven efficacy in the field of hepatology *are only administered as "treatment" and not as "liver protection" (apart from the prophylactics mentioned above)*. These active substances are used in patients when, according to the diagnosed disease and the clinical and pharmacological results, they are actually indicated. • *Thus, it is the existing liver disease and/or complication and not the medication budget or the patient's wishes which decides the therapeutic indication.* Anything else would go against the principles of a physician or be uneconomical, and legally problematic in individual cases.

The second dimension of controlled studies, **"time",** is frequently given insufficient consideration in evaluating therapeutic results. In fact, it is only possible to assess whether the substances used in chronic liver disease have the required efficacy after an adequate treatment period. In the drug therapy of patients with chronic liver disease as carried out by the clinician and general practitioner, evaluation periods invariably extend over several years. In such cases, positive or negative results can

be obtained "empirically", but because they are not "statistically" confirmed, they are not "provable". In this context as well, *empiricism, intuition and logic* may diverge (s. p. 845), so that statistics, which as such are indispensable, may indeed prove to be an obstacle.

Perhaps the expectations or requirements of "liver therapy" are too high. With regard to other organs and their respective diseases, established medication often does not really achieve a "cure", but merely "functional improvements" (e.g. recompensation, inhibition of progression, stabilization in everyday life, improvement in quality of life, rehabilitation). In principle, these fully acceptable therapy aims apply to the treatment of liver diseases as well.

## 3.7 Dose adjustment of medicaments

Liver and medicaments are interrelated in **three ways**:

1. Medication *inducing* liver diseases
2. Medication *for* liver diseases
3. Medication *changed* by liver diseases

Apart from the kidneys, the liver is the most important excretory organ for drugs. In contrast to other mechanisms of drug elimination, which are relatively well understood, **liver metabolism** of drugs has proved extremely complicated. (s. pp 52–56) *Biotransformation* is influenced by variable and non-variable factors under physiological and pathological conditions. (s. tab. 3.18) • **Changes in pharmaceutical preparations** are alterations in the respective properties which occur due to the disturbed metabolization function of the liver cells and/or hepatic blood flow secondary to liver disease. Additionally, drug metabolism may be drastically modified by coexisting hypoalbuminaemia or cholestasis. Liver diseases do not only affect the elimination parameters (e.g. half-life, clearance), but also absorption (e.g. bioavailability) and distribution of the drug in the body. A further factor are the interactions of certain drugs with receptors at the site of action (e.g. increased sensitivity of the brain to diazepam in cirrhosis patients). Biotoxometabolites and lipid peroxidation, which are not normally typical of a certain medicament, must also be anticipated. • In principle, a **dose reduction** should be considered in severe and chronic liver disease, especially when the medicament is used regularly. On the other hand, a **dose increase** may be required in i.v. administration owing to reduced hepatic blood flow and using medication with a high elimination rate. • Disturbed drug metabolism may be further aggravated by alcohol consumption with its multiple biochemical effects. (s. p. 61) (s. tabs. 28.2, 28.3)

Despite great efforts, it has not been possible so far to make single **dose calculations** (*1.*) for a *certain* medicament, (*2.*) in a *certain* liver disease, and (*3.*) in a *certain*

patient. Some drugs have been classified into three groups on the basis of their hepatic extraction rate and route as well as their form of administration: drugs with a high, with a moderate and with a low risk of overdosage − however, such information is given with reservations. The difficulties regarding the correct dose adjustment of a medicinal remedy in therapeutic use require careful **monitoring** of the individual patient, sometimes also determination of the blood values, or consultation with a pharmacologist. (12)

▶ In view of these difficulties, it may be problematic to administer the *same* dose to *all* volunteers and to obtain pharmacologically *equivalent* results in **clinical studies.** This might also explain the occasionally great variation in study results (despite a carefully chosen trial design) and any potential "inefficacy" or undesired effect of the drug. (s. p. 56)

## 3.8 Significance of quality of life

Of the two dimensions of life, quantity and quality, clinical studies have inevitably paid far more attention to the former (i.e. length of life). The **quantity of life** (judged by survival probability, mortality rate or survival curves) seems to be the most important parameter for the assessment of treatment efficacy. A review of 99 publications which had appeared in leading surgical journals from 1981−1986 revealed that in 97% of the papers, no mention was made of quality of life after surgical procedures − in 341 publications on cardiac surgery, this was mentioned in only 8% of cases (J. O'YOUNG et al., 1985, 1987). Obviously, the prolongation of life was paramount in fixing therapeutic aims. (1, 10, 11, 13, 14)

Defining and measuring the **quality of life** has become important in recent years. This also applies to the conservative or invasive treatment of liver disease, and, in future, more attention will have to be paid to criteria for assessing the changed quality of life under certain therapies as well as the choice of certain treatment strategies (M. LUDWIG, 1988). The definition of good life quality implies that (*1.*) a person experiences the least possible impairment and handicap under a given therapy (= *clinical norm*), (*2.*) this person functions in accordance with existing social roles and derives satisfaction from this (= *social norm*), and (*3.*) the hopes and expectations of this person are fulfilled (= *individual norm*) (M. BULLINGER, 1988). • In one comprehensive survey of the literature, not one single study focusing on the quality of life in liver disease is cited. • Remarkably, a later study mentioned a significant reduction in the quality of life in *patients with chronic hepatitis C.* (11) In a further study, interferon treatment was not only shown to improve the disease, but also to enable the patients to resume their normal daily routine.

# 4 Nutritional therapy of liver diseases

The Hippocratic idea that *"dyscrasia"* was the cause of nearly all diseases meant that **dietetics** (= diaita) was necessary for the *"restoration to normal of the life order"*. (s. p. 6) Even in antiquity, special forms of nutrition were of great importance in the treatment of liver diseases. In addition to those dietary prescriptions which were within the reach of everyone (e.g. donkey liver with parsley and honey) (s. pp 7, 844), there were also extremely complicated diets for the treatment of jaundice which only "kings" could afford (CELSUS called jaundice the *morbus regius*). (s. p. 7) • During all historical epochs of medicine, dietetic measures have played an essential role in the treatment of liver diseases − even in the so-called "dirty pharmacy" of mediaeval times. (s. p. 844) Because dietetics also assumed such an important role in hepatology, nutrition, i.e. enteral intake of special beverages and food, was mainly based on mythological and later also on speculative ideas.

From the beginning of the 20th century, a **mild liver diet** was propagated, which in some cases was pursued with scientific meticulousness. The purists issued strict nutritional rules for patients concerning liver diets. In those days, we young clinicians often had great difficulty in implementing such guidelines in practical terms. • This one extreme was set against the other extreme of therapeutic nihilism, i.e. a **free choice of food** by the patient ("eat what you like"). (s. tab. 40.1)

▶ *Neither extreme is acceptable − in fact, certain liver diseases or complicative developments require special forms of nutrition.*

## 4.1 Artificial feeding

Artificial feeding is indicated when the liver patient is no longer *able* to, does not *want* to, or is not *allowed* to eat anything because of complicative situations. It may also be necessary to prevent malnutrition as well as to eliminate manifest dietary deficits rapidly and successfully. • Artificial feeding may be performed **enterally** by nasogastric tubes, gastrotomy or jejunostomy, and **parenterally** by central-venous catheter systems. This measure is carried out **short term** during inpatient treatment or **long term** on an outpatient basis at home.

### 4.1.1 Enteral feeding

Should artificial feeding be necessary, the enteral route of application should be given preference. This is feasible in 90% of hepatological problem cases. Nutrition consists of high or low molecular weight formula diets. Feeding may be continuous or in 4−5 phases. Nasogastric tubes are harmless even when oesophageal varices exist. Artificial enteral feeding must correspond with

the principles of energy and metabolism as well as containing vitamins, electrolytes and trace elements in optimum amounts. At the same time, it must be appropriate with regard to the underlying liver disease. • Enteral feeding has significant trophic effects on the intestinal mucosa in stimulating local IgA production, improving the integrity of the intestinal mucosa as a barrier against bacterial translocation and regulating the physiologically adapted intake of nutritional components, which are subsequently made available to the liver in a physiological first pass effect. Serious metabolic disturbances must be avoided; other complications occur only rarely. (17, 22, 23)

### 4.1.2 Parenteral feeding

Indications for artificial feeding via a central-venous catheter must be considered carefully. As a rule, it is possible only for a brief time, since the application period is limited by several **complications:** (*1.*) venous thrombosis, (*2.*) local infection, and (*3.*) systemic infection (in the usually immunocompromised liver patient). With prolonged parenteral alimentation, (*4.*) complications in the form of various liver damage must be anticipated. • The reported frequency of **liver damage** is 15−100%. This generally depends on the duration of parenteral feeding, but occasionally the composition of the infusion solution proves to be inappropriate. Laboratory parameters show increases in GPT, GOT and γ-GT as well as in alkaline phosphatase and bilirubin. As a rule, these changes are reversible; however, excessive elevations, especially catheter-associated infections, may necessitate the discontinuation of parenteral feeding. Deaths have occurred in up to 3% of cases. (15, 16, 18, 21) • Various forms of *morphological liver damage* may develop, possibly in combination:

| | |
|---|---|
| 1. Hepato/splenomegaly | 5. Fatty liver |
| 2. Cholestasis | 6. Steatohepatitis |
| 3. Jaundice | 7. Fibrosis |
| 4. Slight to moderate hepatitis | 8. Cholelithiasis |

The **pathogenetic mechanisms** of liver disease caused by artificial feeding are not fully understood. Various **theories** have been postulated: (*1.*) deficiency of essential fatty acids or essential phospholipids, (*2.*) exceeding the maximum glucose oxidation rate, (*3.*) lack of important substances (e. g. choline, taurine, glutamine, inositol, carnitine), (*4.*) in individual cases, the presence of toxic metabolic components (e. g. methionine, plant sterols) or newly formed biotoxometabolites. • It must be borne in mind that cirrhosis patients usually show *endogenous hyperinsulinaemia*. A high intake of glucose should thus be avoided, as should the additional administration of insulin. The so-called **sugar substitutes** (e. g. *sorbitol, mannitol, xylit, maltit*) are not to be recommended. (20) (s. pp 351, 383)

The calculated glucose requirement of the brain is 1.5 mg/kg BW per minute (i. e. 140−160 g carbohydrates,

560−700 kcal). Blood glucose and lactate levels must be monitored. Fats are the most important energy carriers; approx. 20−50% of the total calorie requirement should be provided in the form of lipids, preferably as MCT/LCT emulsion (1 g fat/kg BW). The latter are also readily metabolized by cirrhosis patients. (19−21) In cases of acute liver failure (s. p. 383), disturbances in amino-acid metabolism generally occur. Amino-acid infusions should be avoided in this disease phase − coma-adapted or liver-adapted amino-acid infusions may be indicated (0.4 g AA/kg BW/day with the possibility of dose increase up to 1.0 (−1.5) g/kg BW/day). Vitamins, electrolytes and trace elements must be sufficiently substituted. The adjuvant use of essential phospholipids and ornithine aspartate is pharmacologically plausible. The regimen of parenteral nutrition must be monitored daily. (18, 20)

## 4.2 Diet in malnutrition

Chronic liver diseases, especially cirrhosis and alcohol-induced conditions, are accompanied by malnutrition in 50−80% of cases. The prognosis of the liver disease largely depends on the nutritional state − there is also a direct relationship between the probability of survival after liver transplantation and preoperative malnutrition. (17, 19, 20, 23−27, 29, 32)

**Causes** of malnutrition include: (*1.*) reduced quantity and quality of nutrition, (*2.*) maldigestion and malabsorption, (*3.*) accelerated protein breakdown and protein loss as well as *reduced protein synthesis* (PEM), (*4.*) increased energy requirement, especially in the case of complications, and (*5.*) metabolic disturbances (e. g. insulin resistance, sympathicotonia, loss of metabolic efficiency). (s. p. 741)

The **resting energy expenditure** (REE) (in kcal) in chronic liver disease can be calculated according to the *Harris-Benedict equation*, considering the patient's body weight (W), height (H), and age (A). • Multiplying the REE (kcal) by factor 1.2−1.4 gives the energy requirement under normal daily conditions.

| | |
|---|---|
| Men | $= 66.0 + (13.7 \times W) + (5.0 \times H) - (6.8 \times A)$ |
| Women | $= 65.5 + (\ 9.6 \times W) + (1.7 \times H) - (4.7 \times A)$ |

The **proportions** of carbohydrates (4.0−5.0), fats (1.0−2.0) and proteins (0.8−1.5) (each in g/kg BW/day) in patients with chronic liver disease correspond to those of an ordinary diet; the basic calorie requirement is 35 kcal/kg BW/day. • From the metabolic viewpoint, and in the case of diabetes, daily **food intake** should be divided into 3 main meals and 2 snacks. As a prophylactic measure, it is advisable to restrict the use of common salt to 7−8 g (because of the very high NaCl content in the usual diet). Moreover, a preponderance of lacto-vegetarian proteins over proteins derived from meat and fish (with their higher production of ammonia) is

recommended. A sufficient intake of vitamins, electrolytes, trace elements and roughage should be guaranteed. (22, 27, 33, 34) (s. p. 741)

| Principles of lifestyle |
|---|
| 1. Alcohol abstinence
2. Avoidance of noxae and toxins
3. Reaching and maintaining a normal body mass index
4. Paying attention to the sensitive water-electrolyte balance (s. figs. 16.1, 16.3) (s. pp 288, 305, 741)
5. Avoidance of malnutrition and undernourishment (s. pp 587, 728, 851) |

**List of instructions:** These "principles of lifestyle" should be closely observed by the patient; they apply to every hepatological disease situation. We have always included these principles on a *list of instructions* given to our patients together with the *documentation sheet.* (s. fig. 15.3)

## 4.3 Special diets

Special dietary measures are of major, often even of decisive importance for several types of liver disease or associated complications. • Here, too, the false, universal claim that "there is no liver diet" is invalid. In the same way that treatment of a liver condition is indeed possible, there are also dietary measures for certain forms or complications of liver disease. • After an exact diagnosis has been established, there is often a necessity for dietary therapy depending on the respective hepatological situation.

At this point, we would like to emphasize once again that a strict lactovegetarian protein supply must be adhered to not only in latent encephalopathy, but also in (acute or chronic) liver diseases in which insufficient detoxification of ammonia is anticipated. When assessing the so-called protein tolerance threshold (s. p. 278), the *documentation sheet* (s. fig. 15.3) as well as a *psychomotoric test programme* (s. p. 203) can be of great help.

**Metabolic diseases:** A *fatty liver* does not require a low-fat diet, but standard nutrition based on general reference values for normal daily routine. With a normal body weight and an increased energy requirement (work, sports), the calorie intake has to be adjusted accordingly. • In *overweight patients,* a slow, continuous, yet systematic weight reduction should be strived for. Coexistent *hyperlipoproteinaemia* may require supportive treatment. *Diabetes mellitus* must be properly controlled. This also applies to concomitant *gout.*

**Cirrhosis:** In compensated liver cirrhosis without obvious malnutrition or undernourishment, no special diet is necessary, and normal balanced nutrition is adequate.

In liver cirrhosis, a lactovegetarian protein supply always has to be given preference; ammonia-forming animal proteins should only be present in the food in low quantities and consumed every few days. *Malnutrition* has to be eliminated by corresponding dietetic measures. In severe cases of disease, artificial feeding (enteral, or for a short time parenteral) may be recommended. (20, 25, 30−32) (s. pp 742, 850)

**Haemochromatosis:** Iron is ubiquitous in food. A *low-iron* diet must be observed consistently (using available food tables). Although a lactovegetarian diet is desirable, attention should be paid to the very high iron content of pulses, green vegetables and dried fruit. • *Black tea* (2−3 cups per day) should be drunk regularly. (s. p. 625)

**Wilson's disease:** With a normal diet, the daily copper supply amounts to 3−6 mg. In Wilson's disease, however, the copper content should be reduced to <1 mg/day (using the available food tables). As in haemochromatosis, a lactovegetarian diet is important, but attention should be paid to the very high copper content of coarse-grained wholemeal products, nuts, cheese (Emmental, Edam) and cocoa. The intestinal absorption of copper can be reduced further by potassium sulphide (3 × 20 mg). (s. p. 616)

**Encephalopathy:** The diagnosis of HE, even in the stage of latency (s. p. 272) (s. fig. 15.3), requires an adjustment of protein intake. This applies to both the daily amount (= cutting down) and the type of protein (= only lactovegetarian proteins). No reduction in fats is necessary. (26) Carbohydrates should be restricted to 2.5−3.5 g/kg BW. The return to standard nutrition should correspond to the gradually improving quantitative and later also qualitative protein tolerance threshold, varying from case to case. Should no nitrogen balance and no improvement in the HE symptoms be achieved with lactovegetarian protein intake, supplementation with *branched-chain amino acids* is indicated. The latter also stimulate muscular protein synthesis and promote the formation of glutamine in the brain. However, they are not equivalent to substitution by balanced amino-acid solutions. Commercially available protein preparations should be low in common salt. (s. pp 277, 732)

**Ascites:** The occurrence of a disturbed water-electrolyte balance in the late stage of latent oedema (s. fig. 15.3) (s. p. 297) requires immediate restriction of the salt intake (<3−6 g/day) − depending on the level of natriuresis: the intake of fluid is limited to 1.0 (−1.5) l/day, especially in hyponatriaemia. An intermittent *fruit and rice diet* (generally for 1−2 days) is recommended because it is extremely low in sodium, but rich in potassium. Marked *NaCl restriction* simultaneously leads to a reduction in protein intake. The use of commercially available low-salt protein preparations is therefore advisable (e. g. 60 g protein/100 g + 5 mval sodium/100 g, or 48 g protein/100 g + 13 g, or 15 g sodium/100 g).

NaCl restriction is contraindicated in natriuresis of <25 mmol/day. (s. p. 308)

**Storage diseases:** Some of the genetic metabolic diseases require special dietary measures, e. g. (*1.*) *disorders of the urea cycle* are treated by means of a diet similar to that applied in encephalopathy (s. p. 594), (*2.*) *Gierke's disease* necessitates a high-carbohydrate diet (s. p. 595), (*3.*) *Cori's disease* is treated with formula diets and a starch diet (s. p. 596), (*4.*) *galactosaemia* requires a galactose- and lactose-free diet (s. p. 597), and (*5.*) in *fructose intolerance*, a fructose- and saccharose-free diet must be given. (s. p. 597)

# 5 Drug therapy of liver diseases

A great number of different **active substances** have been discussed in connection with the treatment of the various liver diseases or their complications in the respective chapters. The effectiveness of these substances has either been *statistically confirmed* in controlled trials, or they have been *tested empirically,* or they seem to be *pharmacologically plausible* for a specific application. • Some of these therapeutic substances and their uses are presented in more detail in the following section.

| | | DNA-dependent polymerase | Reverse trans-criptase | Chain break |
|---|---|---|---|---|
| Amantadin | Uncoating | | | |
| Aciclovir | Replication | + | | + |
| Adefovir | " | + | | + |
| Famciclovir | " | | | + |
| Foscarnet | " | + | | |
| Ganciclovir | " | + | | + |
| Interferon | " | + | | |
| Lamivudine | " | + | + | |
| Lobucavir | " | + | | + |
| Vidarabine | " | + | | |
| Didanosine | Transcription of RNA to DNA | | + | + |
| Foscarnet | | | + | |
| Zalcitabine | | | + | + |
| Zidovudine | | | + | + |
| Interferon | Maturation | | | |
| Ribavirin | Replication | + | | |

***Tab. 40.5:*** Some modes of action and points of attack of virostatics

## 5.1 Virostatics

Viruses have no metabolism of their own; they are only able to replicate in living host cells. Replication can be inhibited by virostatics. Generally, however, viruses cannot be completely inactivated; as a rule, this is only possible by means of the body's own defences. • The viruses attach themselves to the cell membranes via specific receptors **(= adsorption)**. Viruses enter the cells by means of **endocytosis**. The virus coat opens, with the result that viral nucleic acid and enzymes are liberated **(= uncoating)**. This is followed by **transcription** of viral nucleic acid to mRNA, the formation of enzymes (= early-phase proteins) and structural proteins (= late-phase proteins) as well as nucleic acids for virus multiplication **(= replication)**. After maturation, the viruses are released from the host cells by exosomes. • **Virostatics** can therefore have the following *points of attack*: (*1.*) prevention of viral attachment to the host cells, (*2.*) inhibition of penetration, (*3.*) inhibition of uncoating, (*4.*) inhibition of nucleic acid synthesis, (*5.*) inhibition of protein synthesis, and (*6.*) prevention of virus liberation. (s. tab. 40.5)

Due to their various modes of action and viral targets, some first and second generation virostatics have also been employed for treating hepatitis viruses. Thus, various virostatics are indicated in infections with **secondary hepatotropic viruses** (s. pp 112, 464):

| | |
|---|---|
| **Aciclovir** | **HSV, VZV (EBV)** |
| **Amantadine** | **Influenza A, B** |
| **Didanosine** | **HIV** |
| **Famciclovir** | **HSV** |
| **Foscarnet** | **HSV, CMV, HIV** |
| **Ganciclovir** | **CMV, HSV, VZV (EBV)** |
| **Vidarabine** | **HSV, VZV (EBV)** |
| **Zidovudine** | **HIV** |

Virostatics are not indicated in *acute* viral hepatitis induced by **primary hepatotropic viruses.** Their application is, however, recommended in *chronic* hepatitis B and C and B/D. Interferon is the first choice in this connection. It is also used (as early as possible) in *acute HCV infection*. In infections with hepatotropic viruses, the following virostatics have already been introduced or are under discussion:

| | |
|---|---|
| **1. Aciclovir** | **9. Interferon α, β** |
| **2. Adefovir** | **10. Lamivudine** |
| **3. Amantadine** | **11. L-dT** |
| **4. Emtricitabine** | **12. Lobucavir** |
| **5. Entecavir** | **13. Ribavirin** |
| **6. Famciclovir** | **14. Tenofir** |
| **7. Foscarnet** | **15. Vidarabine** |
| **8. Ganciclovir** | *etc.* |

### 5.1.1 Interferon

Interferons (IFN) were discovered in England by A. Isaacs et al. in 1957. (39) They are low molecular weight glycoproteins acting as cytokines (so-called intercellular mediators) with clear species-specific effects. **Interferon type I** includes the subtypes IFN-α and IFN-β. They are formed by nearly all cells, whereby *IFN-α* is mainly produced by monocytes and B-lymphocytes, and *IFN-β* mainly by fibroblasts. Both subtypes bind to the same receptor at the target cells and are taken up in the hepa-

tocytes by endocytosis. Prior to degradation, IFN activates many genes, thus causing a broad spectrum of proteins to be synthesized. This explains its multiple biological effects. The antiviral effect of IFN-α is evident in all the important steps of virus replication. However, the various cell types form different IFN-α subtypes; so far, more than 30 subtypes are known. IFN-α and IFN-β have a half-life of (only) 3−4 hours.

**Interferon type II** includes IFN-γ, which is probably only produced by T lymphocytes and natural killer cells. IFN-γ is of no importance for the therapy of viral hepatitis. (36) (s. p. 702!) • Recently, *IFN-ω* was isolated, but its biological role is not yet understood.

**Recombinant IFN** is produced from a clone of E. coli, which carries a plasmide that possesses a gene for IFN$_{\alpha 2b}$. The molecular weight amounts to 19,200 daltons. It has a high level of purity (>99%). If antibodies against recombinant IFN occur, natural IFN may prove useful. Recombinant interferons differ in only one single amino-acid position:

|  | Position 23 | Position 34 |
|---|---|---|
| IFN-α$_{2a}$ | lysine | histidine |
| IFN-α$_{2b}$ | arginine | histidine |
| IFN-α$_{2c}$ | histidine | arginine |

**Lymphoblastoid IFN-α** also exists; this is a mixture of natural IFN-α subtypes with different structures of the carbohydrate chains. • Furthermore, a **consensus IFN-α** has been developed; this is a genetically modified IFN-α, which has the properties of various IFN-α subtypes. Thus its biological activity is increased (by ca. 30% in chronic hepatitis C, probably due to better receptor affinity).

**Pegylated IFN:** The optimization of biological IFN effects has been achieved by pegylated IFN. The term "pegylation" denotes covalent linkage of polyethylglycol (PEG) to IFN. Thus IFN is protected from proteolysis, and its half-life is extended approx. tenfold (to about 40 hours). Therefore, this "depot interferon" has an improved efficacy due to prolonged persistence in the body. (35, 37, 38, 41, 45)

|  | Peginterferon alpha-2a (40 kDa) | Peginterferon alpha-2b (12 kDa) |
|---|---|---|
| Volume of distribution (units) | 8−12 l | 0.99 l |
| Clearance (units) | 94 ml/h | 22.0 ml/h |
| Absorption half-life | 50 h | 4.6 h |
| Elimination half-life | 80 h | ~40 h |
| Time to maximum concentration (T$_{max}$) | 72−96 h | 15−44 h |
| Peak-to-trough ratio | 1.5 | >10 |

The interferons display multiple **biological modes of action.** Each of these effects (or their sum) contributes

to therapeutic efficacy. It is still unclear which actions or mechanisms assume a central role in the treatment of chronic viral hepatitis. (40, 42−45) (s. tab. 40.6)

1. **Antiviral effects**
   • Reduction in cellular uptake of viruses
   • Inhibition of intracellular processing of viruses
   • Reduction in viral mRNA synthesis
   • Reduction in protein synthesis
   • Induction of ribonuclease
2. **Immunostimulation**
   • Induction of substances inhibiting cell division and reducing oncogene expression
     − cytokines
     − complement factors (B, C$_2$)
     − nuclear proteins
   • Increase in the activity of
     − macrophages and natural killer cells
     − cytotoxic T lymphocytes
   • Hypothalamus-mediated fever
3. **Increased expression of membrane proteins**
   • HLA classes I, II − antigens
   • β$_2$-microglobulin
   • Fc-receptor
4. **Antineoplastic effect**
   • Inhibition of cell division
   • Decrease in oncogene expression
   • Direct cytotoxicity
5. **Inhibition of fibrosis**

*Tab. 40.6:* Biological modes of action of interferons

The principles and results of **interferon treatment** in chronic viral hepatitis B and C have been discussed in detail. (s. pp 702, 707)

### 5.1.2 Nucleoside analogues

**Nucleosides** (e. g. adenosine, cytidine, guanosine, pyrimidine, thymidine, uridine) consist of a nitrogenous purine or pyrimidine base linked to a 5-carbon sugar (ribose or deoxyribose). **Nucleotides** (adenine, cytosine, guanine, thymine, uracil), the phosphate esters of nucleotides, form the basis of RNA and DNA. As infectious viral nucleic acids, they are capable of penetrating the cells and using available enzyme systems for replication.

As modified nucleoside components, the **nucleoside analogues** inhibit the replication of viral nucleic acids. Therefore, they belong to the group of virostatics. They are phosphorylated by means of cellular or viral kinases, thus becoming biologically active. As regards their clinical application as virostatics, it must be ensured that endogenous DNA synthesis is not inhibited along with viral nucleic acid synthesis. Otherwise, severe mitochondrial lesions with lactic acidoses and irreversible liver damage may occur, possibly with a fatal outcome, as was the case with fialuridine used in chronic hepatitis B (R. McKenzie et al., 1995).

Many of these nucleoside analogues have already been used clinically as **virostatics** against secondary he-

patotropic viruses, influenza A or HIV infection. (s. p. 853). The development of nucleoside analogues is of great importance for the treatment of chronic hepatitis B and C or D. Their virostatic efficacy can be studied in chronic hepatitis B using standardized in-vitro systems and animal experiments. (50) In hepatitis C, no such models exist, so that efficacy studies are only possible in infected patients. Several new developments have already been incorporated into clinical studies in hepatology. They are generally used in combination with interferon; in some cases, two nucleoside analogues may be used together. (45, 50, 52, 55)

(*1.*) **Famciclovir:** After absorption, this guanine derivative is converted to its active form *penciclovir*. The biologically active metabolite penciclovir triphosphate, which effects the inhibition of viral DNA polymerase, is only formed in the infected liver cell. The dosage is 3 × 500 mg/day. • After discontinuation of this substance, the previous findings usually reappear, i.e. it is only effective as an ongoing treatment. It is used therapeutically in combination with IFN. (47) (s. p. 705)

(*2.*) **Lamivudine:** This is a cytosine(cytidine)-nucleoside analogue. Its effect is based on the inhibition of reverse transcriptase in HIV and of DNA polymerase in HBV. The daily oral dosage is 1 (−3) × 100 mg/day. After discontinuation of lamivudine, the previous findings recur; here, too, efficacy only exists with continued therapy. A combination with famciclovir seems promising. Its clinical application is mainly in combination with IFN. Long-term monotherapy over several years may be necessary. (48, 54) (s. p. 704)

(*3.*) **Lobucavir:** This guanosine derivative has proved very effective against HBV. The dosage is 1−4 × 200 mg/day. After discontinuation of the one-month therapy, values returned to their initial levels. A combination with IFN is also recommended for this substance, and indeed has a very good action profile.

(*4.*) **Aciclovir:** After oral application, only about 20% of the applied dose of this guanosine derivative is absorbed. Aciclovir is mainly eliminated via the kidneys (ca. 85% of the dose within 48 hours). Its half-life, which is approx. 3 hours, depends on renal function. The substance is employed especially in HSV and VZV infections. This agent inhibits DNA polymerase (i.e. replication) and effects a chain break. As a monotherapy in HBV infection, aciclovir only shows moderate efficacy. Side effects are rare.

(*5.*) **Ganciclovir:** This is a guanosine derivative exhibiting a good action profile in HBV, EBV, CMV and VZV infection. Ganciclovir triphosphate inhibits virus replication. The half-life is about 4 hours. Elimination is via the kidneys. Only a minor fraction of this substance is absorbed after oral administration; application (e.g. in CMV infection) is usually intravenous (10 mg/kg BW/day). It has severe toxic side effects. Ganciclovir was

given successfully as early as 1989 in chronic hepatitis B. Subsequently, good results were achieved in combination with IFN.

(*6.*) **Ribavirin:** This guanosine analogue was first used experimentally by O. Reichard et al. (1991) and in chronic hepatitis C by J. Andersson et al. (1991). It is rapidly absorbed and distributed in the body, but is excreted slowly (half-life 79 hours). The bioavailability is 45−65%. As a monotherapy, it only leads to a decrease in transaminases and a slight improvement in histological activity. Ribavirin may not exhibit a direct antiviral effect, but can trigger a favourable response to interferon. When combined with IFN, ribavirin proved far more efficacious in chronic hepatitis C (immunomodulation?) without any increase in the typical side effects of IFN. (49, 51, 53) (s. p. 707)

(*7.*) **Amantadine:** The antiviral efficacy of amantadine (1-adamantanamine) was reported for the first time by W. L. Davies et al. in 1964. The mode of action consists in preventing uncoating and viral maturation (i.e. inhibiting the release of the nucleic acids that have already penetrated the host cell). The active substance is almost completely absorbed following oral administration. It is eliminated unchanged via the kidney. The half-life is about 15 hours. So far, it has only been indicated to combat influenza virus type A. (s. p. 708)

## 5.2 Immunosuppressants

Immunosuppressants are substances that suppress the immune response. Inhibition or neutralization of the major part of the body's defence system is essential in (*1.*) organ transplantation and (*2.*) autoimmune diseases. The following are considered to be some of the most important immunosuppressants:

| | |
|---|---|
| 1. **Antilymphocytic globulin** | 6. **Glucocorticoids** |
| 2. **Anti-CD 3 antibodies** | 7. **Methotrexate** |
| 3. **Azathioprine** | 8. **Sirolimus** |
| 4. **Cyclophosphamide** | 9. **Tacrolimus** |
| 5. **Cyclosporine A** | |

### 5.2.1 Glucocorticoids

The immunosuppressive effect of glucocorticoids is based on the reduced formation of interleukins 2 and 6 with inhibition of T lymphocyte proliferation and on a decrease in IL-2 release. The glucocorticoids are therefore effective at a very early phase of the immune response. • At the same time, phospholipase $A_2$, and thus prostaglandin synthesis, is inhibited, and leucocyte migration is reduced (= anti-inflammatory effect). (60) The clinical use of glucocorticoids is indicated in (*1.*) autoimmune hepatitis, (*2.*) immunocholangitis, (*3.*) PBC with a progressive course, (*4.*) florid alcohol-induced hepatitis or progressive alcoholic liver disease with evi-

dence of antihistone B2, and (*5.*) drug-induced idiosyncrasy of the immunological type. In the diseases mentioned under points (*4.*) and (*5.*), the use of glucocorticoids should be reviewed critically.

### 5.2.2 Azathioprine

The effect of azathioprine is based on inhibition of T lymphocyte proliferation and differentiation of activated B and T cells. This results in a change in interleukin expression. Azathioprine suppressed CD 28-dependent Rac-1 activation, resulting in suppression of bcl-x expression and a consecutive induction of T cell apoptosis. These results have important implications for the development of novel substances showing higher affinity to Rac-1 with more specific therapy in autoimmune diseases and organ transplantation. (66) Azathioprine is converted in the hepatocytes to 6-mercaptopurine, the actual active agent. The half-life is 5 hours. It can take several weeks until a steady state is reached in the blood, which explains the delayed effect of azathioprine (3−6 months). It is assumed that (due to genetic determination?) the imidazole residue of azathioprine is capable of binding sulphhydryl groups, resulting in an additional antimetabolic effect. (56) Pharmacological differences are further suggested by a report stating that treatment failure with azathioprine in autoimmune hepatitis was successfully overcome by subsequent treatment with 6-mercaptopurine. (63) A short time after the introduction of azathioprine, results of comparative studies with azathioprine and 6-mercaptopurine in CAH (probably autoimmune hepatitis) were reported. (61) • Azathioprine is used clinically in autoimmune hepatitis, immunocholangitis and progressive PBC. Combined use with prednisolone yields even better results. (63) These two substances administered at a low maintenance dosage can ensure remission for many years. (60) Maintenance of remission achieved with azathioprine following discontinuation of prednisolone has likewise been reported. Hepatological side effects include bone-marrow depression, allergic reactions, greater susceptibility to infection, cholestasis, destructive cholangitis, VOD and nodular regenerative hyperplasia. (s. pp 650, 685)

### 5.2.3 Cyclosporine A

This active substance suppresses the release of interleukin 1 from monocytes and the synthesis of interleukins 2, 3 and 4 as well as of TNF-α from T helper cells; T cell proliferation, macrophage stimulation and B cell activation are inhibited. Even at an early stage of the immune reaction, this leads to the suppression of both humoral and cellular immune responses. The body's bacterial defence is still not significantly influenced, as the phagocytic activity of the RES is barely inhibited by cyclosporine. Bioavailability is about 35% following oral application; it is almost completely metabolized in the body and eliminated predominantly via the bile. Clin-

ically, its main indication is the prevention of transplant rejection. (57, 62, 64) Occasionally, it has also been used in liver diseases, particularly in autoimmune hepatitis and PBC. (65) As in the case of azathioprine, cholestasis also constitutes a major hepatological side effect when using cyclosporine. Canalicular damage demonstrated in animal experiments could be prevented by S-adenosyl-L-methionine. Cyclosporine may cause elevated as well as reduced blood values in combination with many other medicaments. (68) (s. pp 650, 686)

### 5.2.4 Tacrolimus

Tacrolimus was introduced for clinical use in 1989 as a new, well-tolerated immunosuppressive substance that can be administered orally or intravenously. Its immunosuppressive effect is based on the inhibition of the lymphokinin synthesis of interleukins 2 and 3, interferon-γ and TNF-α as well as a reduction in interleukin-2 receptor expression. Tacrolimus leads to inhibition of T cell activation, the formation of cytotoxic T lymphocytes, the induction of specific T helper cells and T helper cell-dependent B cell proliferation. Its bioavailability is about 20%. A number of studies have meanwhile been published reporting the superiority of tacrolimus over cyclosporine. (58, 62) Experimentally, tacrolimus has been found to effect a decrease in free radicals, cytokines, tumour necrosis factor and neutrophilic infiltration in liver tissue. A possible increase in blood values (hitherto) occurring with about 20 drugs and a fall in blood values with numerous other drugs must be considered. Tacrolimus may cause manifestation of diabetes, or even trigger it. Initially only intended as an immunosuppressant against graft rejection (59), tacrolimus has meanwhile also been used successfully in PSC and autoimmune hepatitis. (67) (s. p. 686)

### 5.2.5 Cyclophosphamide

Cyclophosphamide is a prodrug which is converted into active metabolites in the liver. Urotoxic side effects must be anticipated; they can be suppressed by the additional administration of sodium-2 mercaptoethanesulphonate. • This alkylating substance has a strong immunosuppressive effect; therefore, it is occasionally used to prevent graft rejection or (at a low dosage) in autoimmune hepatitis. (s. p. 686)

### 5.2.6 Methotrexate

This folic acid antagonist belongs to the group of antimetabolites which suppress endogenous substances (metabolites) and trigger the formation of functionally incompetent macromolecules. Because of their largely non-specific effect, all rapidly dividing cells are adversely affected and toxically damaged. At a low dosage, methotrexate has been used in autoimmune diseases. (s. pp 650, 658, 686)

## 5.3 Immunostimulants

Immunostimulants are defined as substances which stimulate immunological responses and improve a weakened immune system. They include interferon, thymus factor, interleukins, extracts of microorganisms, chemically defined substances (e. g. levamisole, selenium, zinc) and plant-derived substances (extracts from Phyllanthus, Bupleurum, Glycyrrhiza, Schizandra, etc.). (s. pp 705, 868)

### 5.3.1 Selenium

Discovered by J. J. Berzelius as early as 1817, selenium was only recognized as being an essential trace element for humans in 1957. So far, glutathione peroxidase (G. C. Mills, 1957) and 5-deiodase (D. Behne et al., 1990) have been defined as selenium-containing enzymes. The daily requirement ranges from 20 to 100 µg, which is met mainly by animal protein; in the case of a lactovegetarian diet and a simultaneously increased need (e. g. due to liver cirrhosis or malabsorption), cellular selenium deficiency may occur. (73) Of the 13 selenium proteins known so far, only 2 glutathione peroxidases have been closely defined: one membrane-bound and one cytosol-bound enzyme. They are components of an antioxidative system in that they catalyze the reduction in hydrogen peroxide, organic hydroperoxides and fatty acid hydroperoxides. Further biochemical effects include: stimulation of the immune system (increased activity of the natural killer cells, stimulation of IFNγ synthesis, enhanced capability to phagocytize) (72), hepatoprotection (73, 80), detoxication of heavy metals, regulation of lipid peroxidation (scavenger of free radicals), inhibition of carcinogenesis and tumour growth (73, 80), etc. (s. pp 50, 51, 787) • *Sodium selenite* seems to be most appropriate for infections. (s. p. 304)

### 5.3.2 Zinc

Zinc is an essential trace element, 98% of which is deposited in the intracellular space. The various organs differ significantly in their zinc concentration. The total body content amounts to $1.5-4.0$ g. The daily zinc requirement ranges between 10 and 15 mg. A high content of certain amino acids (alanine, cysteine, glycine, histidine) greatly facilitates the intestinal absorption of zinc, whereas phytate-containing pulses and cereals as well as chronic alcohol abuse impair its absorption to a considerable extent. (106) Zinc is readily excreted and hardly accumulates in the body. All in all, there are many factors leading to relative or absolute zinc deficiency. (s. p. 50) (s. tab. 3.15 ) • Zinc is an essential component of about 200 enzymes. It plays a major role in the metabolism of carbohydrates, proteins, lipids, vitamin A and alcohol as well as influencing DNA and RNA synthesis and stimulating the immune system. (110) It activates ornithine carbamoyltransferase, alkaline phosphatase, δ-ALA synthetase and carboanhy-

drase, and especially superoxide dismutase. Zinc metabolism primarily occurs in the liver. It is largely governed by hormones (e.g. glucagon, insulin, glucocorticoids, ACTH, STH, sex hormones) and regulated by interleukins 1 and 4 as well as TNF. Its close relationship with the immune system thus becomes evident. (76, 78) Among other things, zinc influences thymulin, DNA and RNA polymerase (= gene expression in cell differentiation and proliferation) and the mediator functions in the immune response. (75) Understandably, zinc deficiency in liver cirrhosis or alcoholic liver diseases may well contribute to the patient's susceptibility to infections or febrile conditions (e. g. spontaneous bacterial peritonitis) and possibly even the induction of carcinogenesis. • The multiple biochemical roles of over 200 zinc-containing enzymes explain the wide spectrum of manifestations associated with zinc deficiency in hepatology. This is of great importance for the pathogenesis of hepatic encephalopathy and the therapeutic use of zinc. (69, 70) (s. pp 90, 269, 278, 787)

### 5.3.3 Thymosin

Of the group of thymosins, a mixture of various thymus hormones (or factors), fraction 5 has been well defined. It is already used, for example, for the synthetic manufacture of **thymosin-α**. Further thymus factors include *thymulin* and *thymostimulin* (G. M. Mutchnick et al., 1991). • Thymus factors effect the maturation of thymus T cells, which migrate to the lymphatic system as immune cells. The clinical use of thymosin-α is indicated in impaired immune defence with a decreased count or reduced function of T lymphocytes. (74) Clear effects on HBV DNA and on transaminases were demonstrated in chronic hepatitis B. (71) • In combination with IFN, good results were also obtained in chronic hepatitis C. (79) In a recent study, the use of thymosin as monotherapy in chronic hepatitis C did not prove to have any beneficial effect. Generally, good tolerance was recorded for this drug. (77) (s. p. 705)

## 5.4 Ursodeoxycholic acid

The secondary bile acid *7-keto-lithocholic acid* is transported from the intestinal tract via the portal vein to the liver, where it is converted to **ursodeoxycholic acid** (UDCA) by bacterial enzyme action. (s. pp 36, 705) (s. fig. 3.3) • The *molecular formula* of UDCA is identical to that of CDCA ($C_{24}H_4O_4$); however, it has the hydroxyl group at the $C_7$ atom in the β-position and not in the α-position like chenodeoxycholic acid. The tertiary bile acid UDCA thus constitutes the 7β-epimer of the secondary bile acid CDCA. This changes the steric arrangement: the molecule possesses a *higher polarity* and is thus less able to form micelles. UDCA is hydrophilic and only slightly lipophilic, and therefore practically non-toxic to the organism. With its *molecular weight* of 392.6, it constitutes $0.5-1.0$ $(-5.0)$% of

human bile. Following oral administration, UDCA is passively absorbed in the jejunum and in the proximal portion of the ileum and, through active transport, in the distal ileum; in addition, approx. 20% of the UDCA can be absorbed in the colon. In portal blood, UDCA is transported bound to protein and conjugated in the liver with taurine (to a small extent also with glycine). These conjugates reach the bile. The *half-life* is 3.5−5.8 days. Like its breakdown product isoursodeoxycholic acid, UDCA is excreted predominantly in faeces and to a lesser degree in urine. (83, 86, 87, 99, 102)

Functioning as detergents, **hydrophobic (lipophilic) bile acids** (cholic acid, chenodeoxycholic acid, deoxycholic acid, lithocholic acid) exert toxic effects on the biomembranes of liver cells and mitochondria. At the same time, these bile acids display an immunosuppressive effect and influence the humoral and cell-mediated defence (e.g. inhibition of monocytes). As in the case of PBC, hydrophobic bile acids also induce an excessive expression of MHC-I and MHC-II molecules from hepatocytes and biliary cells.

**Modes of action:** The mechanisms of UDCA and its effects in cholestatic liver diseases are not yet fully understood − even though a number of different effects have been demonstrated. These include (*1.*) hepatoprotective (92, 97, 98), (*2.*) cytoprotective (89), and (*3.*) biliary-metabolic effects (84, 93, 104, 105), as well as (*4.*) an influence on the immune system. In ligature of the bile duct in rats, UDCA was found to reduce the occurrence of histological changes and biliary cirrhosis as well as of portal hypertension. (98) (s. tab. 40.7)

1. Inhibition of the enteral absorption of hydrophobic bile acids
2. Induction of bicarbonate hypercholeresis
   − increase in bile flow (hypercholeresis)
   − increase in the cholehepatic circulation of UDC (= cholehepatic shunt) (s. p. 36)
3. Incorporation into the lipid membranes of liver cells and mitochondria, preventing loss of phospholipids and cholesterol
   − stabilization of membranes
   − improvement of bile acid transport
   − amelioration of immunological membrane functions
4. Influence on calcium-mediated intracellular signal transfer
5. Interaction with the glucocorticoid receptor
6. Influence on protein kinase C
7. Reduction in MHC-I and MHC-II molecule overproduction (= decrease in T lymphocyte toxicity)
8. Inhibition of interleukins 1, 2, 4 and 6, TNF-α and immunoglobulin formation
9. Synergistic effect with IFN-α

*Tab. 40.7:* Biochemical and pharmacological modes of action of ursodeoxycholic acid

**Contraindications:** The following contraindications should be observed: acute cholecystitis, acute cholangitis, obstruction of the cystic duct and common bile duct as well as frequent biliary colic.

**Indications:** The indications for the clinical use of UDCA are either already well-documented, empirically

proven or pharmacologically justified. (91, 94, 96, 100−102) • Practically *no side effects* are to be expected. From the therapeutic viewpoint, it is possible to achieve an improvement in the clinical symptoms (fatigue, pruritus, gastrointestinal symptoms, steatorrhoea), especially in cholestasis with decreased values of AP, LAP, γ-GT and bilirubin. (95, 96) • There is a similar improvement in further laboratory parameters (transaminases, GDH, IgM, cholesterol, etc.) together with an amelioration of histological alterations. (82) Special attention should be paid when administering UDCA in cirrhosis with ascites. (s. pp 233, 241, 651, 658, 686) (s. tabs. 13.10; 40.8)

**Viral hepatitis**
Acute viral hepatitis (88)
Chronic hepatitis (82, 101)
**Autoimmune diseases**
1. Autoimmune cholangitis
2. Autoimmune hepatitis
3. Overlap syndrome
4. Primary biliary cholangitis (85, 94, 100)
5. Primary sclerosing cholangitis (90, 103)
**Cholestatic liver diseases**
1. Alcoholic liver disease with cholestasis
2. Chemically induced cholestasis
3. Cholestasis with complete enteral feeding
4. Drug-induced cholestasis
5. Secondary sclerosing cholangitis
**Genetically determined cholestasis**
1. Alagille's syndrome
2. Byler's syndrome
3. Cholestasis of pregnancy
4. Disturbances of the steroid ring
   − 7α-hydroxylase deficiency
   − 4δ-3-oxosteroid-5β-reductase deficiency
   − 3β-hydroxysteroid-5δ-dehydrogenase
5. Mucoviscidosis
6. Recurrent benign cholestasis
**Organ transplantation**
1. After liver transplantation (81)
2. Refractory graft vs. host reaction

*Tab. 40.8:* Demonstrated, empirically confirmed or pharmacologically justified indications for the therapeutic use of ursodeoxycholic acid (with some references)

## 5.5 Lactulose

### 5.5.1 Chemistry

▶ Lactulose does not occur in nature, nor is it present in breast milk or fresh cow's milk. Small amounts of lactulose are, however, found in heated dairy products, especially in condensed milk (an average of 660 mg, up to a maximum of 940 mg, per 100 ml). • The initial substance for the synthetic manufacture of lactulose is **lactose.** This disaccharide consists of D-glucose and D-galactose, interlinked through a β-1-4-glycoside bond. • **Lactulose** was manufactured for the first time in 1929 as a keto-analogue of lactose (E. Montgomery et al.). As a disaccharide, it is composed of D-galactose and D-fructose. The **molecular formula** is $C_{12}H_{22}H_{11}$, with a **molecular weight** of 342.3. Lactulose has a high **degree of sweetness** (0.48−0.62, compared with 1.0 for sucrose). The **pH value** ranges between 3.4 and 4.0. (107)

## 5.5.2 Pharmacokinetics

▶ Lactulose can be neither absorbed nor broken down by enzymatic or bacterial action in the small intestine; after 1−2 hours, it reaches the colon unchanged. Lactase activity in the intestinal mucosa is not influenced by lactulose. Following oral intake of lactulose, approx. 0.5−1.0% is taken up by the intestinal mucosa through **passive diffusion** and completely excreted unaltered in the urine. However, its absorption is increased by intestinal disease or damage to the intestinal mucosa following cytotoxic chemotherapy. With simultaneous oral ingestion of hyperosmotic solutions, elevated lactulose levels are likewise detectable in the urine. The amount of lactulose thus excreted provides clues to the degree of damage possibly caused to the intestinal mucosa. After oral administration of 20−25 ml lactulose, there is only a slight rise in the **blood sugar level** of 1−12 mg%; therefore, no clinically relevant aggravation of diabetes need be feared with lactulose therapy, nor are any systemic effects evident. • Lactulose is not demonstrable in the stool; this suggests that a complete **breakdown** takes place in the colon due to saccharolytic bacteria. The following bacteria have proved most effective for lactulose catabolism: Lactobazillus species, Bifidobacterium, Clostridium perfringens and the Bacteroides species. An amount of up to 80 ml lactulose can be broken down per day by bacterial enzyme action under physiological conditions. Long-term treatment with lactulose stimulates the formation of bacterial β-galactosidase, whereby higher bacterial metabolization rates of lactulose are achieved. (107) The main metabolites include **lactic acid,** resulting from anaerobic fermentation, and **pyruvic acid**, resulting from aerobic metabolism − with subsequent formation of other organic acids (formic acid, succinic acid, butyric acid, caproic acid, acetic acid, etc.). This leads to a **fall in the pH value** in the colon (dose-dependent) to 5−6. The pH value is not in the desired therapeutic acid range until an **increase in osmotic pressure** with an evacuation frequency of 2−3 times/day has been achieved at the respective lactulose dosage. • Degradation of lactulose in the colon with enhanced formation of organic acids results in an **inhibition of growth** of gram-negative proteolytic microorganisms which are responsible for the formation of endotoxins. There is also promoted growth of saccharolytic bacteria, creating bifidus flora typical of breast-fed babies (F. PETUELY, 1957, 1986; F. MEYERHOFER et al., 1959). (106, 110, 112, 114)

## 5.5.3 Pharmacology

"Wrong idea, good results (the lactulose story)" (U.P. HAEMMERLI et al., 1969); "Lactulose works, but why?" (K.A. HUBEL, 1973); "In several aspects lactulose is an unusual drug"; "Lactulose is a fascinating hybrid of a nutrient and a drug" (J. BIRCHER et al., 1988); "Lactulose is a many splendored thing ... with many other beneficial actions in its bag of tricks" (H.O. CONN, 1992). (s. fig. 40.1)

Unchanged lactulose is pharmacologically inert. Its multiple effects are only evident after breakdown by bacterial enzymes in the colon. (107) • The ability to **break down** lactulose varies greatly from one bacterial species to another, and even from strain to strain, depending on their enzyme endowment. Therefore, the quantity and the predominant type of organic acids formed on breakdown depend on the lactulose dose and the enzyme endowment of the saccharolytic bacteria. The total acid content of the colon is also influenced by individual factors, such as the absorption rate into the colon mucosa or the buffering caused by secreted bicar-

bonates, and possibly also by retroactive effects of the lactulose metabolites on the intestinal bacteria with potential changes in their metabolism. • The organic acids and the bacterial formation of gas as well as the increase in osmotic pressure account for the **laxative effect** (F. MAYERHOFER et al., 1959). This action occurs within 8 hours of lactulose administration. With a rise in the bacterial count of more than 50%, there is also (1−2 days after lactulose application) a rise in the stool mass and thus an additional acceleration of defaecation. • The **formation of ammonia** in the intestine is due to the breakdown of proteins or amino acids, nucleic acids and biogenic amines. The intestinal formation of ammonia is inhibited by intraluminal acidosis and promoted by alkalosis. Independently of the intestinal flora, ammonia is also formed in the intestinal mucosa through glutamine uptake and the release of ammonia, alanine and glutaminic acid. This metabolic $NH_3$ production with hyperammonaemia was also demonstrable in microbe-free and hepatectomized experimental animals. With an intestinal pH value of <6, non-ionized ammonia ($NH_3$) diffuses from the blood to the intestine, while the diffusion of non-ionized ammonia from the intestine into the bloodstream is simultaneously decreased. This results in an elevated excretion of ammonium cations ($NH_4^+$) in faeces and a **reduction in hyperammonaemia**. The rapid onset of effect on hyperammonaemia following lactulose enemas can also be explained by the influence on non-ionic diffusion. A further mechanism underlying the lactulose-induced decrease in hyperammonaemia may be based on the fact that lactulose constitutes a valuable carbon and energy source for intestinal bacteria. Bacterial growth is thereby promoted and a substantial quantity of nitrogen is included in the protein synthesis of bacteria, which leads to a measurable consumption of ammonia. A fall in the colonic ammonia level may also be the result of a marked reduction in proteolytic intestinal bacteria by lactulose. (108, 111, 116) • The therapeutic efficacy of lactulose in the treatment of **hepatic encephalopathy** was demonstrated by J. BIRCHER et al. in 1966. Numerous publications dealing with this indication have appeared. (s. p. 279) Such favourable experience has been further supported by recent studies. (108, 109, 113, 115) • The efficacy of lactulose in **endotoxinaemia** demonstrated by D. SCEVOLA et al. (1979) was later confirmed in various publications and also recently demonstrated anew. (114) Different explanations for this anti-endotoxin effect of lactulose have been put forward: (*1.*) increased removal of endotoxins due to higher evacuation frequency, (*2.*) blocking of endotoxin receptors by lactulose, and (*3.*) influence on the number and metabolic performance of gram-negative intestinal bacteria. (s. fig. 40.1)

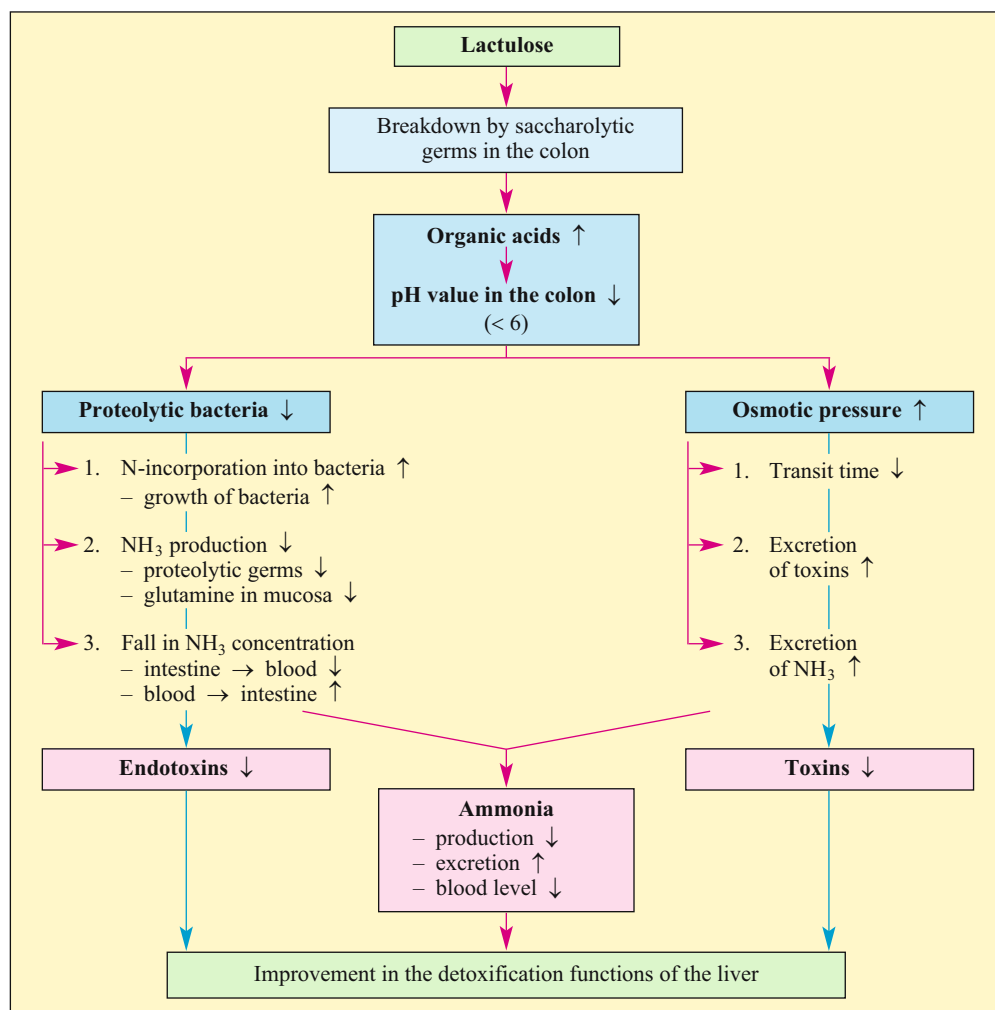
A **reduction in the cholesterol level** due to lactulose was observed by N. EBNER in 1973 and confirmed by D. CONTE et al. in 1977. Lactulose can also be used in hepatogenic disturbances of lipid metabolism. • **Translocation** of


*Fig. 40.1:* Reduction in the blood ammonia levels with a corresponding improvement in the detoxification functions of the liver as a result of multifactorial influence exerted by lactulose on ammonia metabolism

gram-negative bacteria to the mesenterial lymph nodes was significantly suppressed in experimental obstructive jaundice under lactulose treatment compared to the reference group without lactulose (114). Furthermore, galactosaemia-induced liver damage and bacterial conveyance could be prevented by lactulose. (110)

▶ A therapeutic drop in the pH value to < 6 is generally achieved when *evacuation occurs 2−3 times per day*. In order to guarantee this condition, respective quantities of lactulose should be administered in 2 (−3) daily doses. • In principle, evacuation frequency should be *"no less than 2 and no more than 4 times per day"*. With this regimen, no major side effects need to be feared.

### 5.5.4 Indications

The multiple modes of action of lactulose, which are based on an interplay of several effects, require a sufficiently acidic pH value in the colon.

Lactulose is administered as long-term therapy. The indications are derived from its modes of action. (s. tab. 40.9)

1. Reducing or normalizing hyperammonaemia in hepatic encephalopathy
2. Eliminating endotoxinaemia
3. Prophylactic use in cirrhosis (and other chronic liver diseases)
4. Decreasing susceptibility to infections in cirrhosis by inhibiting the translocation of intestinal bacteria
5. Reducing the cholesterol level and influencing lipid metabolic disturbances in primary biliary cholangitis (and other liver diseases accompanied by hyperlipidaemia)
6. Improving the absorption of calcium in malabsorption

*Tab. 40.9:* Indications for the therapeutic use of lactulose

## 5.6 Branched-chain amino acids

The cirrhosis patient is in a *vicious circle* regarding protein metabolism: cirrhosis → hepatic encephalopathy → protein restriction → malnutrition → catabolism →. Thus, prolonged protein restriction and catabolism may considerably worsen the prognosis of cirrhosis. • In this hazardous situation, the dietary and therapeutic use of branched-chain amino acids (BCAA), i.e. valine, leucine and isoleucine, is a logical therapeutic intervention.

The **urea cycle** is the most important process in biological ammonia detoxication. (s. pp 57, 266) (s. figs. 3.12, 3.13) • It is directly linked with **amino-acid metabolism** and thus also with $NH_2$ donors and precursors through specific amino acids and transamination processes. Here, the major transamination processes are those involving glutamate and oxalacetate as well as α-ketoglutarate and aspartate.

▶ The **ammonia hypothesis** postulates that a high ammonia concentration in the tissue inevitably leads to a clear increase in glutamine. This results in a marked intracellular **decrease in glutamate** (and α-ketoglutarate). This glutamate pool can be refilled by a more intensive **degradation of BCAA** as $NH_2$ donors. At the same time, transamination effects the **formation of branched-chain keto-analogues** of the respective amino acids. • Succinyl CoA is also facultatively involved, providing **α-ketoglutarate** via the citric acid cycle; this is the starting substrate of glutamate prior to transamination. These reactions occur mainly in the muscles. (s. fig. 40.2)

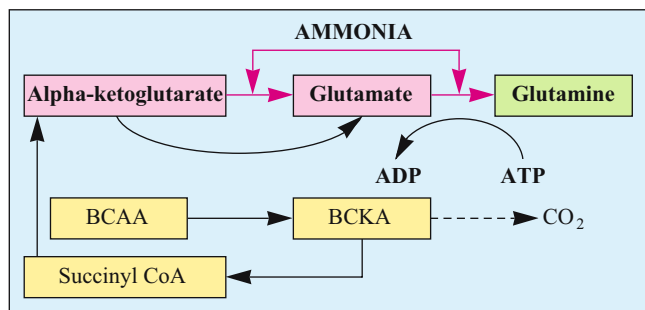

**Fig. 40.2:** Indirect influence of ammonia on the metabolism of branched-chain amino acids (so-called ammonia hypothesis) (according to E. HOLM, 1986) (BCAA = branched-chain amino acids, BCKA = branched-chain keto acids)

▶ **Branched-chain amino acids** apparently stimulate the urea cycle. Carbamoylphosphate synthetase, which channels ammonia into the urea cycle, is induced by ornithine and N-acetylglutamate as a cofactor of urea synthesis. Here, BCAA follow **two modes of action:** (*1.*) they stimulate the synthesis of N-acetylglutamate via synthetase formed from glutamate and acetyl CoA, and (*2.*) they inhibit ornithine-keto acid transferase, which is the enzyme responsible for ornithine degradation, leading to an increase in ornithine concentration. • **Ammonia detoxication is thus stimulated by two regulatory mechanisms.** (s. fig. 40.2)

▶ As a rule, cirrhosis patients show reduced plasma BCAA levels and unchanged BCAA concentrations in the brain, whereas methionine and aromatic amino acids (AAA) (phenylalanine, tyrosine, tryptophan) are elevated in the plasma and brain. (s. p. 280) • The **fall in BCAA levels** is attributable to its increased degradation, which, in turn, is caused or aggravated by hyperinsulinaemia.

Methionine and AAA compete with BCAA for the same transport system at the **blood-brain barrier.** Lowered BCAA levels in the blood therefore favour the passage of elevated methionine and AAA concentrations. The influx of these amino acids is increased by concomitant hyperammonaemia. Ammonia crosses the blood-brain barrier freely. In the astrocytes of the brain, BCAA effect an increase in glutamate by transamination with α-ketoglutarate. Glutamine formation rises, permitting the removal of ammonia from the brain. Glial swelling could be reduced in animal experiments. • **Anabolic protein metabolism** in the muscles is responsible for (*1.*) reduction in muscle protein breakdown products which contribute to the formation of ammonia, and (*2.*) higher amounts of ammonia being taken up by the musculature and converted via glutamate to glutamine, which is harmless. • Hyperammonaemia in liver cirrhosis cannot be influenced by **keto-analogue amino acids,** which are N-free precursors of protein synthesis. However, the keto-analogue of leucine can inhibit the breakdown of muscle protein, which means that favourable effects might still be achieved by using BCKA in decompensated cirrhosis − without any discernible impact on the ammonia level itself. (117, 120, 129)

The use of branched-chain amino acids is based on the following **modes of action** (s. tab. 40.10):

1. Compensation of the amino-acid imbalance
2. Restoration of the competitive transport mechanisms at the blood-brain barrier
3. Stimulation of glutamine synthesis in the brain, muscle and liver (= transitory ammonia detoxication)
4. Inhibition of ornithine breakdown in the liver with a favourable effect on urea synthesis (= definitive ammonia detoxication)
5. Anabolic and anticatabolic effects, especially in muscles
6. Stimulation of the HGF, favouring liver regeneration

**Tab. 40.10:** Modes of action of branched-chain amino acids

The **indication** for administering BCAA in patients with hepatic encephalopathy to compensate amino-acid imbalance was proposed by J. E. FISCHER et al. in 1974, and implemented parenterally. However, oral application of BCAA for an adequate treatment period also has *beneficial effects* on cirrhosis and HE: (*1.*) improvement in protein tolerance and the nutritional condition, (*2.*) improvement in cerebral functions (118, 122), probably due to an amelioration of liver function, (*3.*) stimulation of ammonia detoxification with a positive nitrogen balance (118), (*4.*) reduction in or normalization of AAA levels, and (*5.*) promotion of glutamine synthesis with a favourable effect on the cells of the immune system and on renal function. • By means of BCAA, it was possible to prolong the survival time and delay the occurrence of liver failure in rats with $CCl_4$-induced cirrhosis. (123, 126) • However, there are diverging results, which need further clarification. In principle, the use of BCAA is considered to be a necessary form of supplementary treatment for catabolic metabolism in cirrhosis (124, 125, 127, 128, 130−132), in (also latent) HE and after curative resection of hepatocellular carcinoma. (121) (s. p. 280)

## 5.7 Amino acids of the urea cycle

As early as 1932, H. A. KREBS and K. HENSELEIT discovered in their investigation of the amino acids that *ornithine*, even in small amounts, was capable of increasing urea synthesis from (toxic) ammonia. Otherwise, only *arginine* had a slight effect in this respect. (138) The following table shows which of the **amino acids involved in the urea cycle** are available for therapeutic purposes:

| | |
|---|---|
| Arginine<br>Ornithine aspartate (OA)<br>= *available* | Arginine aspartate<br>Arginine malate<br>Aspartic acid<br>Citrulline |
| Arginine + citrulline<br>+ ornithine<br>= *available* | Ornithine<br>Ornithine α-ketoglutarate<br>= *not available at present* |

The ammonia-reducing effect of the amino acids involved in the urea cycle has been strikingly well demonstrated in a variety of **experimental studies** by several research groups. In most of these studies, ornithine aspartate was used, although arginine, ornithine and ornithine α-ketoglutarate have also been investigated. (134, 137, 141, quot. 139) • The greatest effect on ammonia reduction was achieved with **ornithine aspartate,** the combination of these two amino acids being more effective than the administration of either substance alone. The above results were confirmed in experimental studies by K. ZICHA et al. (1968) and G. HERMANN (1972). In healthy dogs, the increased ammonia levels due to ammonia overload were lowered to normal by ornithine aspartate; in dogs with Eck's fistula, the occurrence of toxic ammonia levels could be prevented (C.E. GROSSI et al., 1967). • Further experimental studies revealed that the liver content of ornithine, citrulline, arginine, glutamate and urea rose following exposure to ammonium chloride in rats. The urea synthesis rate exceeded the norm by 50%, while glutamate concentration doubled as a result of α-ketoglutaric acid, which increased to the highest possible limit. With simultaneous administration of *arginine* or *ornithine*, hepatic ornithine concentration increased considerably, and urea synthesis rose by 80−85%. • In healthy volunteers, administration of *ornithine α-ketoglutarate* led to elevated renal excretion of urea and ornithine α-ketoglutarate, i.e. a clear stimulation of urea synthesis was attained.

▶ Since the **clinical studies** of L. ZIEVE et al. in 1960, the use of these amino acids or their salts has been indicated in hyperammonaemia. (146) Thus, following protein overload in alcoholic cirrhosis patients, a reduction in ammonia levels was achieved by administering 60 g ornithine α-ketoglutarate. (135, 140) • *Since the first clinical use of* **ornithine aspartate** *more than 30 years ago (1968), a series of studies has been published.* (136, 142−145) This ammonia-reducing substance is the stable salt of L-ornithine and L-aspartic acid with the *empirical formula* $C_9H_{19}N_3O_6$ and a *molecular weight* of 265.3. *Bioavailability* is 82.2 ± 28.0%. The substance is rapidly absorbed, with subsequent splitting into its two component amino acids. Its *half-life* is 40 minutes.

The **biomolecular modes of action** of ornithine have been the subject of several experimental investigations. Ornithine activates the enzymes carbamylphosphate synthetase and ornithine carbamyl transferase, which are necessary for the liver-specific process of **urea synthesis** (133, 139); this occurs mainly in the *periportal hepatocytes* (= definitive ammonia detoxification). Glutamine synthesis (binding of ammonia to glutamate) takes place predominantly in the *perivenous hepatocytes* (= transitory ammonia detoxification). Large amounts of glutamate are necessary for this. Aspartate, ornithine

(via α-ketoglutarate), glutamate and other dicarboxylates are taken up almost exclusively by the perivenous hepatocytes responsible for glutamine synthesis. In addition, aspartate and dicarboxylates are considered to be activators of glutamine synthesis, a process which is disturbed in cirrhosis patients. (s. pp 57, 266) (s. figs. 3.12, 3.13)

**Aspartic acid** is not only involved in the urea cycle, but following oxidative deamination to α-ketoglutarate, it is also a component of the citric acid cycle. An increased quantity of energy is thus made available in the form of ATP for the energy-consuming urea cycle. The energy cycle is additionally stimulated by transamination of aspartic acid to oxalacetate. The increased channelling of aspartic acid into the urea cycle facilitates the release of fumaric acid, which is also a substrate of the citric acid cycle, and thus further enhances the formation of ATP. Moreover, aspartic acid binds the ammonia which is present in the musculature; as a result, asparagine is formed, and free toxic ammonia is bound. • Aspartic acid is a glucoplastic amino acid and an important initial substrate for pyrimidine synthesis in liver cell regeneration. Following condensation with carbamylphosphate and the formation of the intermediate product L-dihydro-orotic acid, orotic acid, the central product in the biosynthesis of pyrimidine nucleotides, is formed by oxidation.

There are several biochemical and clinical **modes of action** associated with ornithine aspartate. (s. tab. 40.11)

| |

**Tab. 40.11:** Modes of action of ornithine aspartate

The various modes of action provide the basis for the following **therapeutic indications** of ornithine aspartate:

| |
|---|
| 1. Hepatic encephalopathy<br>  − with improvement in the mental condition and psychometric test results<br>2. Relief of $NH_3$ intoxication symptoms<br>  − e. g. fatigue, weakness |

## 5.8 D-penicillamine

D-penicillamine is a **non-physiological amino acid.** It is a dimethyl derivative of cysteine, which is a structural component of many proteins. Metabolically, penicillamine is relatively stable. In addition to the amino group ($-NH_2$) and the carboxyl group ($-COOH$), it contains a sulphhydryl group ($-SH$) as a further reactive centre. The underlying biochemical **modes of action** are:

1. Chelate formation with heavy metals
2. Exchange reactions with disulphides
   − with low molecular weight substances
   − with proteins
3. Binding with aldehyde
   − to pyridoxal phosphate
   − to aldehyde groups in collagen and other proteins

Penicillamine may effect **chelate formation** with the heavy metals copper, lead, zinc, gold and mercury. This complex formation is accompanied by simultaneous reduction processes, e. g. copper is reduced to copper-1-ion. From the biochemical viewpoint, an influence on **collagen synthesis** is also conceivable, as the amino-oxydase involved in the formation of collagen contains copper, so that this enzyme is inactivated through the binding of copper to penicillamine. To my knowledge, this process has not yet been confirmed in vivo. • The **mesenchyma suppression effect** of penicillamine with a decrease in the formation of connective tissue is based on the inhibition of the cross-linkage between fibre protein precursors and hydroxyproline synthesis. However, it appears that the process of hepatic fibrosis is not influenced. • Of relevance is the reaction with macro-globulins, which is accompanied by the breaking of the disulphide (S-S) bridges through exchange reactions; this leads to depolymerization. An example of the binding of penicillamine to an aldehyde group is its binding to pyridoxal phosphate − a coenzyme which is formed in the body from vitamin $B_6$. Equally important is the reaction of penicillamine with the aldehyde groups of tropocollagen, which causes the formation of thiazoli-dine, thus preventing synthesis of insoluble collagen. (150) • Intestinal **absorption** is rapid and relatively high. The *half-life* is 3−4 hours. The greater part of the orally applied substance is eliminated within 24 hours. In particular, diseases with high hepatic copper concentrations are an indication for penicillamine. • *Side effects* occur frequently; the use of vitamin $B_6$ may be necessary.

The principal **indications** for penicillamine are:

1. Wilson's disease (149) (s. p. 615)
2. Indian childhood cirrhosis (147) (s. p. 616)
3. Primary biliary cholangitis (148) (s. p. 650)
4. Heavy metal poisoning

## 5.9 Somatostatin

Somatostatin was first isolated from the *hypothalamus* of sheep for use as a growth hormone-inhibiting factor in 1973 (P. Brazeau et al.). In the same year, its synthetic production was also reported (H. D. Croy et al., 1973). The *molecular weight* is 1,638. The *empirical formula* of this substance, which is composed of 14 amino acids, is $C_{76}H_{106}N_{18}O_{19}S_2$. To my knowledge, somatostatin was used *clinically* for the first time in 1974 in a patient with acromegaly (S. S. C. Yen et al.). • Since 1979, somatostatin has been recommended for **oesophageal variceal bleeding** (L. Thulin et al.). Its plasma half-life is 1−2 minutes; the substance is broken down by endopeptidases

and aminopeptidases, with a renal excretion rate of about 80%. • The following **organ-specific effects** are worth mentioning: (*1.*) inhibition of endocrine and exocrine functions (in the area of the pancreas, stomach and small intestine − especially inhibition of insulin and glucagon release) and (*2.*) inhibition of the blood supply to the gastric mucosa and splanchnic vessels.

In **oesophageal variceal bleeding,** somatostatin is recommended immediately after emergency admission to hospital at the following dosage: an i.v. bolus injection of 250 (−500) μg and subsequently 250 μg per hour (possibly with 2-minute bolus injections). In this way, sclerotherapy or ligation is technically facilitated and the effectiveness of the therapy improved; fewer blood products are needed. No major side effects have occurred at this dosage. (152, 154) The bolus injection rapidly effects a reduction in portal venous and intravaricose pressure as well as a decrease in the blood flow in the azygous vein. (151, 153) It is worth noting that intestinal blood is eliminated more slowly and virtually unchanged, since somatostatin inhibits the release of digestive enzymes and prolongs the intestinal transit time. Continued passage of tarry stool may at first be erroneously interpreted as an effect of somatostatin − unless systemic problems or a fall in Hb actually suggest further bleeding. (s. p. 360)

## 5.10 Terlipressin

Terlipressin, chemical name N-α-triglycyl-8-lysine-vasopressin, consists of 12 amino acids. The *molecular weight* is 1,377.5, and the *empirical formula* is $C_{52}H_{74}N_{16}O_{15}S_2 \cdot C_2H_4O_2 \cdot 5H_2O$. Through hydrolytic removal of the glycyl residues, the vasoconstrictor hormone *lysine-vasopressin* is slowly released as an active substance. Peak concentrations are obtained after 120 minutes. The breakdown of lysine-vasopressin into inactive metabolites, effected by hepatic and renal endopeptidases and exopeptidases, is almost total, so that only about 1% is excreted in the urine. • The *plasma half-life* is 12 minutes, the elimination time is 40−180 minutes. The effect persists for 4−5 hours. The *vasoconstriction* is particularly intensive in the splanchnic system; as a result, arterial blood flow is reduced, and portal hypertension is lowered (by up to 35% with 1 mg terlipressin). (155, 158, 161) The smooth muscles of the oesophageal sphincter are contracted with consecutive compression of the existing varices. At the same time, increased peristalsis occurs, leading to a more rapid evacuation of intestinal blood and of ammonia formed by intestinal bacteria. • The *renal blood flow* is elevated in hypovolaemia. The elevated WHVP and HVPG become reduced and hepatic arterial blood flow increases.

The following dosage is recommended for acute **oesophageal variceal bleeding:** 1−2 mg terlipressin as an i.v. bolus (if possible in the ambulance or upon emergency admission) followed by 1 mg as an i.v. bolus every 4−6 hours for a total period of 2−3 days. Terlipressin reduces the elevated blood levels of renin and aldosterone and increases the GFR. The combined use of vasoconstrictor therapy with local mechanical haemostasis gives the best results − and a higher chance of survival. The side effects are slight. (157, 159, 160, 162) (s. p. 360) • Application is recommended in the case of the *hepatorenal syndrome.* (156)

## 5.11 S-adenosyl-L-methionine

S-adenosyl-L-methionine (SAMe) is present in nearly all **body cells.** About 30% of hepatic SAMe is localized in the mitochondria. It is formed from methionine and ATP by SAMe synthetase (G. L. CANTONI, 1952). Transport from the cytosol to the mitochondria takes place via a specific phospholipid carrier system in the biomembranes. (164, 172) • Metabolically, S-adenosyl-L-methionine is an important initial substrate for numerous **synthesis pathways** (164, 167):

1. **Transmethylation:** The transfer of methyl groups is of great relevance for phospholipid synthesis in the biomembranes and for the synthesis of hormones, nucleic acids, proteins, porphyrins, etc. (164)

2. **Transsulphuration:** The involvement of SAMe leads to the formation of glutathione, cysteine, etc. These substances play an important metabolic role in detoxification processes and in the elimination of reactive oxygen intermediates.

3. **Aminopropylation:** The transfer of decarboxylated SAMe is crucial to the synthesis of polyamines (spermine, spermidine, putrescine). Together with ornithine decarboxylase, SAMe determines the synthesis rate of polyamines, which are essential for cell regeneration. At 30−60 minutes, the half-life of SAMe decarboxylase is very short and thus readily adaptable to various metabolic situations.

▶ In **experiments,** SAMe was found to prevent lipid peroxidation and to normalize the reduced glycogen content of hepatocytes in liver damage. In further studies, its cytoprotective effect was also confirmed. (163, 166−171, 173, 177−181) This protective effect likewise applied to preneoplastic cell damage. The results concerning the prevention of cholestasis were impressive. • In cirrhosis or severe liver disease, there is a reduction in SAMe synthetase, glutathione, cysteine and phospholipid methyltransferase (together with a simultaneous deficiency in phosphatidylcholine formation, accompanied by disturbed membrane fluidity and decreased activity of $Na^+/K^+$-ATPase and $Ca^{2+}$-ATPase).

*The pharmacological effects and therapeutic uses of SAMe in hepatology are discussed in a detailed review.* (169) • The impressive outcome of various experiments led to numerous **clinical studies,** which, however, also included negative results. (165, 169, 174−176) On the whole, there was a significant decrease in bilirubin, bile acids, alkaline phosphatase and transaminases. Pruritus, a frequent symptom in cholestasis, also showed regression.

S-adenosyl-L-methionine is an interesting substance which deserves further clinical investigation. The recommended *dosage* is 800 mg/day with intravenous administration or 1,200 mg/day orally. No major *side effects* have been noted. The studies available so far suggest the following *indications*:

1. Alcoholic liver disease, especially in cholestasis (s. p. 537)
2. Drug-induced cholestasis (s. p. 554)
3. Chemically induced cholestasis (s. p. 572)
4. Recurrent intrahepatic cholestasis (s. p. 233)
5. Recurrent intrahepatic cholestasis of pregnancy (s. p. 233)
6. Gilbert-Meulengracht syndrome (s. p. 221)
7. Compensated liver cirrhosis (s. p. 741)

## 5.12 Haemarginate

The requirements for successfully treating clinically manifest acute porphyria are: (*1.*) elimination of the causative factor(s), (*2.*) use of supportive therapeutic measures (fluid and electrolyte balance, analgesics, anticonvulsants, antihypertensive agents, antiemetics, antiarrhythmics), (*3.*) i.v. glucose infusion (approx. 400 g/day), and (*4.*) haemarginate. (s. p. 607)

**Haemarginate** is produced from erythrocyte concentrate. It compensates the loss of the intracellular haem balance, which regulates haem synthesis. In this way, the overproduction of porphyrin precursors is reduced. Haemarginate is relatively stable; following i.v. administration, it is bound to haemopexin and albumin, and thus made available to the liver cells. (185) • *Dosage* is 3 mg/kg BW/day, administered per daily i.v. infusion (for about 15 minutes) exclusively in 0.9% NaCl solution (100 ml). Haemarginate is stabilized by arginine and contains 96 vol.% ethanol (1,000 mg/ ampoule) as well as propyleneglycol (4,000 mg/ampoule). It is degraded into bilirubin and excreted via the bile. The application period depends on the degree of severity of acute porphyria; as a rule, it extends over 3−5 days. With successful use of haemarginate, the excessive elimination of PBG and ALA is restored to normal, as is the excretion of uroporphyrinogen and coproporphyrin. These values should be monitored in the urine under haemarginate therapy. (182−184) • *Side effects* may appear in the form of phlebitis. This is, however, rare when haemarginate is administered intravenously into large veins. Minor, clinically insignificant effects on blood coagulation have only seldom been observed.

*Important:* Haemarginate treatment should be initiated as early as possible before any neuronal damage, which may be irreversible, occurs.

## 5.13 Phytotherapeutics

Plant extracts have been used in the treatment of liver diseases for over 2,000 years. • So far, more than 170 plant-derived substances from some 55 plant families have been well documented regarding their **hepatoprotective efficacy.** (187) Recently, the Rosmarinus species (186) and Salvia miltiorrhiza (189) were added to this list as antifibrinogenetic agents. • In controlled **clinical studies,** many of these active substances were found to be effective in various liver diseases. Some of them are already listed in the pharmacopoeia. • *Two points* should be made here: (*1.*) in the plant kingdom, there are other substances with specific agents which would act on liver structures or against liver diseases, but have not yet been recognized as such; (*2.*) more sophisticated biochemical/biomolecular procedures now allow more exact characterization and a more precise description of known and previously unknown active substances, so that their targeted therapeutic use may be made possible. (188)

Phytotherapeutics are defined by law as substances derived from plants, plant parts or plant components in a processed or unprocessed form and used medicinally. As substances, phytogenic preparations are treated in the same way as synthetic chemical compounds or substances of other origin. Phytopharmaceuticals must likewise comply with the usual safety standards, such as quality, harmlessness and efficacy. (s. p. 553)

Phytotherapeutic agents are used as *primary preparations* (e. g. tinctures) or as a concentration of various *active substance fractions* and as *pure substances.* Monoextracts are complicated mixtures of chemical substances. They contain primary active agents, secondary active agents and inert accompanying substances. The **main active agents** wholly or predominantly determine the therapeutic properties of phytopharmaceuticals. **Secondary active agents** present in addition to the main active agent(s) may attenuate, potentiate or modify the effects of the main active agent. The overall therapeutic effect generally results from the synergy of several constituents. **Accompanying substances** include cellulose, lignin and starch as well as various forms of sugar, protein and fat. • The active constituents of plants essentially depend on climate, location and other exogenous factors. Therefore, isolating the main active agent is a prerequisite for clarifying its composition, synthesis and pharmacosynthetic modification. Should an active substance be unknown or not well-documented, a quantitatively predominant substance (or several substances) amenable to analysis is then defined as the **key substance.** This is to ensure that a certain phytopharmaceutical preparation is offered at a standardized quality. According to the legal requirements, the key substances may also be defined as so-called *"other scientifically proven material".*

> Pharmaceuticals of plant origin also form part of rational drug therapy in science-oriented medicine. They are used in the treatment of certain defined diseases and complaints. The more carefully the various pharmacological characteristics of phytogenic remedies are elucidated, the more reliably their clinical effects can be evaluated (e. g. digitalis, rauwolfia, hyoscyamine, senna). • *This is also true of the phytotherapeutic preparations used in hepatology.*

### 5.13.1  Essential phospholipids

> ► Essential phospholipids (EPL) are isolated from the **soya bean.** This plant was mentioned in the books of Pen Ts'ao Kong Mu (during the reign of Emperor Sheng Nung, 2838 BC). It was one of the five "holy cereals" considered essential for human life. • Today, about 800 soya bean species are known. Depending on the species, location and extraction method, the seeds contain 35−40% proteins, 20−30% carbohydrates, 5−10% accompanying substances (amines, vitamins, triterpene saponins, glycopeptides, lectin, flavonoids, xanthines, etc.) and 12−18% crude fats. The crude oil contains 90−95% fatty acid glycerides, predominantly unsaturated fatty acids (oleic acid, linoleic acid). Refining crude oil yields 30−45% phosphatides (soya lecithin). The phosphatides contain 15−20% phosphatidylcholine ("lecithin"), which represents an important constituent of cell membranes and is also involved in lipid metabolism in the liver (H. EIKERMANN, 1939). *(Detailed account: 190)*

Essential phospholipids are a highly purified phosphatidylcholine fraction containing essential (unsaturated) fatty acids, especially linoleic acid (about 70%), in the

$C_1$ and $C_2$ positions. The main active ingredient in EPL is 1,2 dilinoleoylphosphatidylcholine (DLPC) (40−52% of the phosphatidylcholine molecules). Standardization is performed with reference to 3-sn-phosphatidylcholine (73−79%). In the literature, the designation PPC (polyenylphosphatidylcholine) is also used; this is intended to emphasize the special fatty acid composition. DLPC has a high bioavailability and an affinity for cell membranes. The phosphatidylcholines constitute a typical lipid bilayer and are thus the main structural component of cellular and subcellular membranes. Moreover, the proportion of phosphatidylcholines with highly unsaturated (essential) fatty acids is a decisive factor in determining membrane fluidity and thus also the biological membrane functions (see figure 40.3 regarding the multiple functions of phospholipids). Endogenous phospholipids are substituted by EPL, which may be administered by the oral route or, in a highly purified form, by the intravenous route. (205, 206, 222) (s. p. 27) (s. fig. 2.19)

EPL administration has protective, curative and/or regenerative effects on the biomembranes of hepatocytes and sinus endothelia following damage to the cell membrane through toxic, inflammatory, allergic, metabolic or immunological reactions. The cytoprotective effect of EPL has been demonstrated in 17 in-vitro and 104 in-vivo experiments including 29 different models and 7 different animal species. They were conducted using EPL together with various chemicals (191, 214, 225), alcohol (192, 194, 196, 208, 210−212, 217−219), narcotic drugs, cytostatics, ionizing rays, etc. (s. tab. 40.12) These experiments clearly demonstrated the notable **hepatoprotective** and **curative effects** of EPL in vivo. Remarkably good results were also obtained with EPL as an antifibrogenic agent. (191, 207−209, 213) The earlier EPL was given, the more pronounced the effects were. Inhibition of lipid peroxidation in the liver membranes was likewise verified. In animal experiments, it could be demonstrated that PPC increases SAMe and GSH levels in alcohol-induced hepatic oxidative stress. (193) Similarly, it was possible to diminish the antiapoptotic action against ethanol-induced hepatocyte apoptosis. (215) In a further study, the alcohol-induced increase in peroxinitrite hepatotoxicity and the concomitant production of oxide and superoxide could be prevented by PPC. (194) Furthermore, it has been shown that PPC activates enzymes such as triglyceride lipase, which is responsible for triglyceride degradation in the liver. (197) In addition, dilinoleoylphosphatidylcholine, which is the main active ingredient in PPC, diminishes the activity of acylcoenzyme A: cholesterol acyltransferase, an enzyme that leads to the storage of cholesterol in the liver. (216) • Based on these pharmacological and clinical data, PPC would appear to be the drug of choice for significantly reducing or abolishing fatty liver of different origin, e.g. due to alcohol or obesity, even if the causing noxa cannot be eliminated, as is the case with diabetes-associated

| Intoxications due to chemical substances | | | | Intoxication due to drugs | | | |

*Tab. 40.12:* Cytoprotective effects of EPL in in-vivo investigations (104 experiments, 29 different models, 7 different animal species) (status 1988: E. Kuntz; status 2000: K.-J. Gundermann)

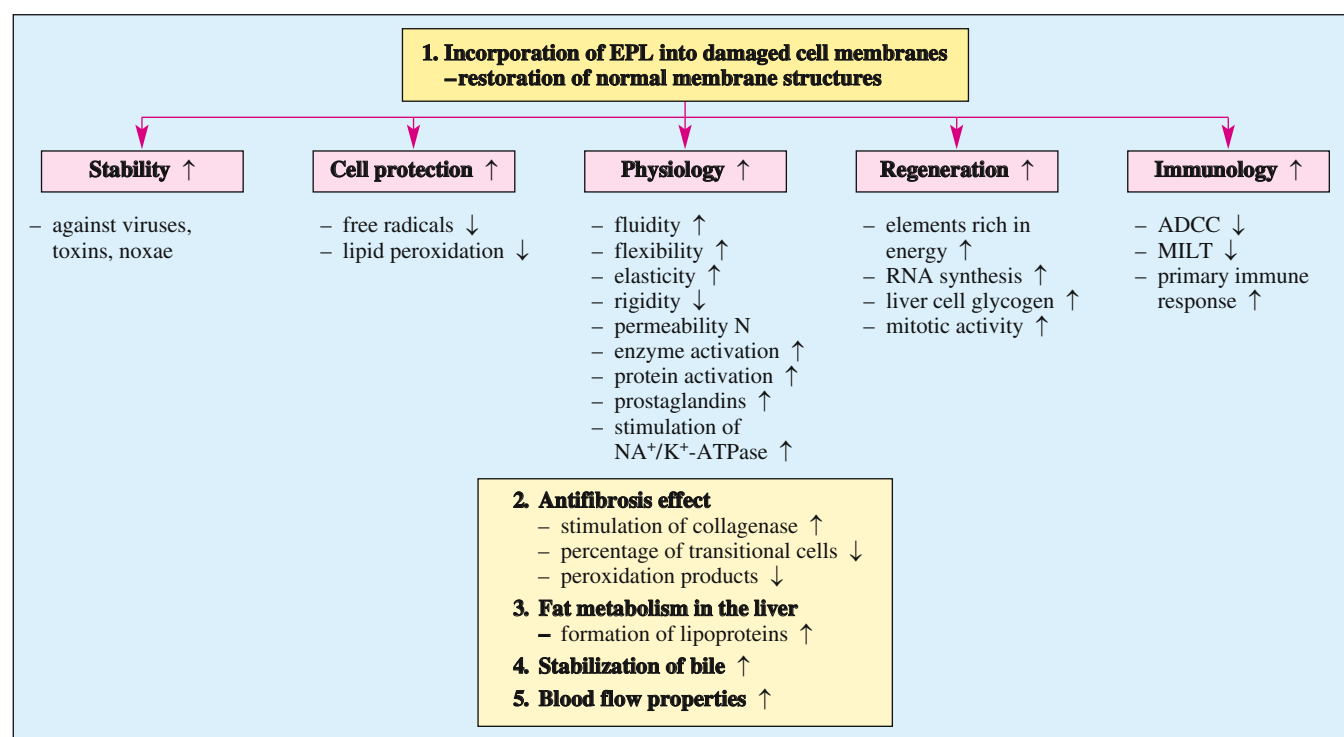

*Fig. 40.3:* Putative and demonstrated hepatic modes of action of EPL in vitro and in vivo. (ADCC = antibody-dependent cell-mediated cytotoxicity, MILT = mitogen-induced lymphocytotoxicity, N = normal)

steatosis. (199, 201, 203) The **regenerative effect** of EPL on experimentally induced liver cell damage was confirmed by biochemical and histological findings. (200) (for further details, see 190, 206) (s. tab. 40.12) (s. fig. 40.3)

These results were confirmed in further studies. (195, 221, 223, 224, 226) It was also discovered that EPL can have an inhibitory effect on alcoholic fibrogenesis in baboons. (209, 212) The **clinical studies** which were available up to 1988 (190) have meanwhile been supplemented by other investigations. (198, 202, 220)

In **severe liver insufficiency,** we were able to effect a life-saving reversal in 7 out of 10 seemingly hopeless cases by the first ever intravenous application of PPC (3,000 mg/day). (204) • A European multicentre double-blind study showed that EPL significantly increased the rate of IFN-α responders among patients with **chronic hepatitis C** as well as reducing the relapse rate. (220)

The modes of action of EPL suggest the following **indications:** curative, protective/curative and curative/regenerative therapy (*1.*) in toxic liver damage and fatty liver,

(2.) in acute viral hepatitis, acute intoxication, liver insufficiency, and (3.) as a supportive flanking therapy in chronic viral hepatitis and cirrhosis.

### 5.13.2 Silymarin

The name "sillybon" was given by ancient Greek writers − and later by Theophrastus (372−287 BC) − to a thistle species, without its being defined more closely. In "De Materia Medica" by Dioscorides (about 50 AD), the plant later called milk thistle is described as a medical remedy for the bites of poisonous snakes. In his book "Historia Naturalis", Plinius the Elder (23−79 AD) was the first to mention the choleretic effect of milk thistle. The extract was recommended as a liver remedy by H. Brunfels (1434) and P. A. Mathiolus (1590), and also in the herbals of H. Bock (1560) and A. Lonicerus (1564). • As a result of the investigations of F. Mayer et al. (1949) and O. Eichler et al. (1949), the year 1949 can be regarded as the "hour of birth" of silymarin for liver treatment. *(Detailed account: 227)*

▶ Silymarin is a mixture of three chemically related *flavanolignoids*; it is obtained by extraction from the seeds of the milk thistle (Silybum marianum Gaertn. or Carduus marianus [L]). These flavanolignoids include: (1.) *silibinin*, (2.) *silidianin*, and (3.) *silicristin*. **Silibinin** is the main active constituent. Its molecular weight is 482.5, the empirical formula is $C_{25}H_{22}O_{10}$. • The *major pharmacokinetic characteristics* are rapid absorption and a calculated absorbed fraction of 23−47%. Peak plasma concentrations are achieved after 1−2 hr. In plasma, 90−95% of silymarin is bound to protein. The half-life is 6.3 hr. Because of the relatively high molecular weight, >90% is excreted via the bile. About 10% of the administered dose enters the enterohepatic circulation. With repeated administration, steady state elimination is achieved from the second day; thus there is no accumulation of silibinin. • *Silicristin* displays pharmacokinetic properties similar to those of silibinin, yet with a lower biliary excretion rate (4−10%). No further information is available on the second minor component *silidianin* (and *isosilibinin*). (228, 230, 241−243, 247, 260, 262, 264) *(Detailed account: 227)*

▶ In addition to an array of general **pharmacological findings** in vivo or in isolated organs, specific hepatology-related results have been obtained. A number of studies provided evidence of different membrane effects; experimental cholestasis was prevented or reduced, and the release of histamine or serotonin from mast cells was diminished. Silymarin inhibits the different cytochrome P-450 enzymes to a varying extent. (228, 230, 242, 243, 250, 260, 262, 264) Evidence of **membranotropia** and **hepatoprotection** is of major relevance: respective positive effects have been shown in more than 30 different model studies in over 120 investigations. (232−236, 238−240, 246, 249, 254, 255, 258, 259, 261, 265, 267) • The efficacy of silymarin as an **antioxidant** (so-called *radical scavenger*) was confirmed in recent studies. (229, 237, 251, 253, 255, 257, 266) Furthermore, an **antifibrosis effect** (231, 244, 248, 252) and the inhibition of β-glucuronidase (336) have been demonstrated. The modes of action of silymarin are based on several cellular targets. (s. tab. 40.13)

The **clinical studies** (approximately 120) available up to 1988 (227) have meanwhile been supplemented by further investigations. (236, 242, 246, 256, 263) Silymarin did not prove beneficial to patients with PBC.

The **combination** of *essential phospholipids* and *silymarin* is of special clinical interest because of the cellular targets and modes of action of these two drugs. (268−273) (s. fig. 40.3) (s. tab. 40.13) In patients with chronic hepatitis, a combined *EPL-silymarin substance* was applied with success (269). Thus, the available results of clinical studies suggest the following **indications:**

**Silibinin (intravenous)**
- Amanita poisoning

**Silymarin (oral)**
- Toxic liver damage
  - alcohol toxicity
  - drug toxicity
  - chemical toxicity
- Supportive therapy
  - chronic hepatitis
  - liver cirrhosis

1. **Protection of biological membranes from noxae**
   - Inhibition of toxin uptake
   - Stabilization of biological membranes
     - influence on phospholipid turnover
     - biochemical interactions with membranes
     - decrease in enzyme induction
     - inhibition of phosphodiesterase
2. **Support of cellular detoxication mechanisms**
   - Stimulation of superoxide dismutase
   - Maintenance of the glutathione pool (GSH) of hepatocytes
3. **Antioxidative effect**
   - Interactions with free radicals
   - Reduction in lipid peroxidation
     - inhibition of lipoxygenase
     - decrease in malondialdehyde
     - diminution of glutathione consumption
4. **Inhibition of fibrogenesis**
5. **Increase in protein biosynthesis**
6. **Inhibition of cholesterol synthesis**
   - fall in microsomal hydroxylmethylglutaryl-CoA reductase

***Tab. 40.13:*** Cellular tackling points and modes of action of silymarin

### 5.13.3 Glycyrrhiza glabra

Glycirrhizin was used for the first time in hepatology in 1977 by H. Suzuki et al., who achieved good results in patients with chronic hepatitis. The main constituents isolated from the roots of Glycyrrhiza glabra are triterpene saponins, including glycyrrhizin (5−20%), and triterpene sapogenins. Glycyrrhizin is a conjugate of 1 molecule of glycyrrhetinic acid with 2 molecules of glucuronic acid. It is metabolized by β-glucuronidase, predominantly in the intestine (by bacteria) and to a lesser extent in the liver (by lysosomes). The half-life is 3−5 hours, in chronic liver disease 4−10 hours. The following modes of action are postulated: (1.) it acts as a radical scavenger, (2.) it decreases cell-membrane permeability, and (3.) it prevents membrane penetration by viral particles. (276) The antiviral cytoprotective and immunomodulatory effects are based on these modes of action. Although its previously known pharmacological

effects were not considered to be of any consequence for hepatology, glyzyrrhizin has meanwhile surprisingly proved its worth as a hepatoprotective compound. The agent induces interferon formation and, in this way, also has an antiviral effect. Good therapeutic results were recorded in several clinical studies on chronic hepatitis B, NANB and C and for prophylactic use in transfusion hepatitis (with administration both before and after blood transfusions) as well as in subacute viral liver failure (200−600 mg/day). Glycyrrhizin inhibited HAV replication and improved the immunological identification of HBsAg; HBeAg-positive patients showed more rapid seroconversion. (275, 277) A mixture of glycyrrhizin (40 mg) + cysteine (20 mg) + glycine (400 mg) has also been used as therapy. • With long-term administration, **pseudoaldosteronism** may appear, which can be eliminated by spironolactone (e.g. 50 mg/day).

### 5.13.4 Colchicine

▶ Colchicine is an alkaloid obtained from the *autumn crocus* (Colchicum autumnale). It is a nitrogen-containing, tricyclic compound with a tropolone structure. The results of the pharmacokinetic studies available so far are summarized in a review. (289) Colchicine inhibits the function of the microtubuli (280) and acts as a toxin on cells, mitoses and capillaries. (279, 284, 287, 290) Albumin synthesis is apparently only slightly affected. (282) In existing iron overload, further iron uptake is greatly increased by colchicine. Trimethylcolchicinic acid proved less toxic. (279) The antifibrotic effect of colchicine is probably based on a reduction in collagen secretion and an increase in collagenase activity with elevated collagen breakdown. (286) In existing liver disease, the pharmacokinetics of colchicine is influenced. (288, 289) A potential antilipid peroxidative effect was observed in experimentally induced acetaminophen liver damage. (284)

The results obtained from the *clinical use* of colchicine are controversial. Good results in the prevention of cirrhosis in chronic hepatitis B and, when combined with UDCA, in primary biliary cholangitis are counterbalanced by unfavourable results in chronic hepatitis (283, 291), primary biliary cholangitis (281) and primary sclerosing cholangitis (285) as well as in alcoholic hepatitis. • A beneficial effect of colchicine on hepatic fibrogenesis should be the subject of further debate. (s. pp 650, 658, 743)

### 5.13.5 Betaine

Betaine is a quarternary ammonium compound. This substance is widely found in nature; it was first isolated from *sugar beet* (Beta vulgaris). • Like choline and methionine, betaine belongs to the group of *lipotropic substances*. Choline plays a major role in the mobilization of neutral fats in the liver, using them to form transportable phospholipids with neutral fats. In order to be able to give up its methyl group, choline requires betaine. Thus it assumes an important function in the transmethylation cycle of lipid metabolism, particularly since it is also essential for the resynthesis of methionine. Within the therapeutic dosage range, betaine is in no way toxic.

### 5.13.6 Cynara scolymus

*Cynarine* is the main active agent of artichoke extract. It is a cinnamic acid derivative; the substitution pattern of its aromatic rings is similar to that of dopamine. Caffeic acid is also regarded as a major active substance. It has not yet been clarified to which constituents the known *modes of action* are attributable: (*1.*) increase in choleresis, (*2.*) inhibition of cholesterol biosynthesis, (*3.*) hepatoprotection due to antioxidative effects, and (*4.*) activation of the urea cycle.

### 5.13.7 Bupleurum falcatum

An extract of *Bupleurum falcatum* with the active agent saiko has for a long time been used in hepatobiliary diseases in Eastern Asia. The substance is commercially available in China under the name Sho-Saiko-To. The active components are attributed to the saiko-saponins (M. YAMAMOTO et al., 1981, 1985). Inhibition of fibrogenesis was demonstrated in animal experiments. (292−294) A good effect was achieved in chronic hepatitis in several clinical studies. Significantly more rapid HBeAg elimination was attained in children with chronic hepatitis B. (295) (s. pp 553, 705)

### 5.13.8 Phyllanthus amarus

Extracts from Phyllanthus amarus and Phyllanthus niruri have been used in India for more than 20 years in acute viral hepatitis, apparently with success. Compared with essential phospholipids, Ph. niruri was equally effective in improving laboratory values, while Ph. amarus proved to be even more efficacious. Phyllanthus extracts inhibit HBV reduplication (298, 299) and DNA polymerase in HBV and WHV infection (300), whereas this effect was not verified in DHV hepatitis. (297) HBsAg carriers also exhibited a loss of HBsAg in 50% of cases and a significant rise in anti-HBs titres. (296) These good results contrast with a number of unfavourable experiences, which may be attributable to the fact that the Phyllanthus species contain varying amounts of active substances in different countries. This was also believed to explain the better efficacy of Phyllanthus urinaria compared to Ph. amarus and Ph. niruri.

### 5.13.9 Schizandra chinensis

The hepatoprotective efficacy of Schizandra chinensis is based on its lignoids Gomisines A, C, N, Wuweizisu C and Schisanthesin D. (302) A rapid decrease in transaminases was verified in chronic viral hepatitis (189 patients). (308) Hepatoprotective and anticarcinogenic effects were demonstrated in experimental studies. (301, 303−307)

### 5.13.10 Catechin

The active substance (+)-catechin is the main component of the plant *Uncaria gambir*. In the systematic chemical nomenclature,

this natural substance is called (+)-cyanidanol-3. Pure (+)-cate-chin is considered completely non-toxic. Catechin is readily absorbed and rapidly degraded in the liver. So far, 11 metabolites have been identified. Because of its low molecular weight, catechin is mainly eliminated via the kidney. • The following *modes of action* have been demonstrated: (*1.*) increase in ATP concentration in the liver and (*2.*) inhibition of lipid peroxidation. This is the basis of the marked hepatoprotective effect. It was used clinically as an adjuvant in acute viral hepatitis, chronic hepatitis and toxic (also alcohol toxic) liver damage. The results reported seemed promising. • Although catechin was regarded as totally non-toxic on the basis of experimental studies, major (unexplained) **side effects** including haemolytic anaemia, idiosyncratic reactions and even deaths occurred (K.A. NEFTEL et al., 1980; N. BRATTIG et al., 1981). • The preparation, which had already been introduced in many countries, was thereupon **withdrawn from the market.**

# 6 Surgical therapy

Even in antiquity, liver injuries were considered to be fatal due to the uncontrollable bleeding. Proof of an enemy's death was not furnished until his liver could be presented. (s. p. 5) As far as we know, CELSUS (30 BC−50 AD) gave the first, remarkable description of *liver surgery*, which, due to the high volume of blood, was carried out using a cautery knife. • Surgical treatment techniques for liver diseases were not included in textbooks on hepatology until 1965. The two-volume book by F. TH. FRERICHS (1861) (s. fig. 1.19), the textbook by H. EPPINGER (1937) (s. fig. 5.1) and the two-volume book by I. MAGYAR (1961) *contained no descriptions of liver surgery* − apart from the treatment of echinococcus cysts − although extensive liver or portal vein system surgery had been carried out since the second half of the 19th century.

Since the first surgical treatment of refractory ascites by **hepatopexy** (C.T. BILLROTH, 1894) and of bleeding oesophageal varices using **resection of the short gastric veins** (G. BANTI, 1894), vast numbers of surgical techniques have been developed in order to manage both of these emergency situations.

*The attempt to compile a **systematic list** of all procedures is bound to be incomplete despite thorough investigations. However, it is worth the effort to include the ingenious − and seemingly logical − surgical methods of our worthy predecessors, so that their approaches to the operative management of ascites or bleeding oesophageal varices are not forgotten. (s. tabs. 16.19 and 19.7!)*

► An important prerequisite for liver surgery was knowledge of the **vascular system,** which was first described by F. GLISSON in 1654 (s. fig. 1.16) and again by R. REX in 1888, and which is known in detail today. • For the **segmental classification** of the liver, the system according to C. COUINAUD (1954) and A. PRIESCHING (1986), using the branches of the portal vein as orientation, gained prevalence. The caudate lobe is designated as segment I. Segment IV is situated on the right side of the falciform ligament (it is exclusively oriented to venous drainage via the intermediate hepatic vein). This sets limits for surgical techniques, and the haematogenous

route of liver metastases is also taken into account. • Hjortsjö's concept (C.H. HJORTSJÖ, 1948) referring to the division of the anterior segment into two vertical subsegments could be confirmed by recent investigations. (332) (s. p. 16 (s. figs. 2.5, 40.4)

► During the past 30 years, the surgical treatment of liver diseases or injuries has made enormous **progress** due to the introduction of more sophisticated techniques, newly developed instruments and anaesthetic procedures as well as better management of intraoperative haemodynamics. These options regarding superior liver surgery have only been made possible by the introduction of modern imaging procedures, endoscopic techniques and angiography. As with the use of laparoscopy, these examination methods guarantee far more exact presurgical staging than was conceivable in the past. • Since the introduction of **TIPS,** shunt and block surgery have lost some of their importance, both in terms of elective indications and the emergency treatment of complications observed in portal hypertension. In an era of well-managed liver transplantation (which in the meantime is performed at a large number of centres), TIPS and shunt surgery serve to bridge the time gap until a favourable date for transplantation has been found. • It should be noted that an appropriate **shunt operation** guarantees a more stable situation than TIPS, especially in the long term. Indeed, shunt surgery, rehabilitated by C.E. ZÖCKLER et al. (1985), is experiencing a revival in many places.

## 6.1 Ascites in portal hypertension

Even though conservative therapy proves efficacious in 85−90% of ascites cases, 5−15% are unresponsive to such treatment. • These patients can be treated successfully using invasive or surgical measures, since the prognosis for ascites which is really refractory is poor. However, in each case, surgical options have to be carefully considered, taking into account all individual facts and deciding about indications with respect to (*1.*) peritoneovenous shunt, (*2.*) TIPS, or (*3.*) liver transplantation. • The first two methods contribute to recompensation and help to bridge the time gap until liver transplantation can be carried out, whereby the liver function should be maintained as effectively as possible. • After **peritoneovenous shunt** (s. p. 311) (s. figs. 16.12−16.14) (s. tabs. 16.14−16.18) or **TIPS** (309, 310, 313) (s. pp 259, 314, 362) (s. fig. 16.15), a subsequent transplantation no longer poses a problem.

## 6.2 Bleeding in portal hypertension

The causal spectrum of upper or lower gastrointestinal bleeding is extremely broad. (s. tab. 19.4) (s. pp 348, 366) The most common sources of bleeding in portal hypertension are varices of the oesophagus and stomach (s. pp 254, 352), portal hypertensive gastropathy or intestinal vasculopathy (s. p. 257), and intestinal varices. (s. p. 256) It is particularly the unexpected and massive variceal bleeding which is life-threatening and which requires intensive care, i.e. a combination of medication and mechanical measures. Of greatest importance are drugs to reduce portal vein pressure, sclerotherapy or variceal ligation, and (if necessary) balloon tamponade. (s. pp 358−359) • Whether or not surgical techniques are indicated is determined after definitive haemostasis

and should be based on a critical evaluation of individual risk factors and the respective liver status. However, surgical treatment is needed for variceal bleeding which lasts longer than 2 days (requiring a daily supply of >4 units of blood) and which could not be stopped despite all conservative measures; this also applies to early relapse bleeding. • From a haemodynamic point of view, **TIPS,** which is a non-surgical connection between the hepatic and portal vein, represents a *portacaval side-to-side shunt*. This results in a sustained decrease in portal vein pressure. Relapse bleeding is reduced to $10-20\%$. Such an approach does not complicate subsequent liver transplantation. TIPS is thought to be the ideal technique for **bridging** the time gap before liver transplantation can be carried out. $(310-312)$

### 6.2.1 Shunt operation

The importance of surgical treatment for oesophageal or gastric variceal bleeding is still controversial. Nevertheless, according to the findings to date, shunt surgery with a relapse bleeding risk of $5 (-10)\%$ is deemed to be the best **prophylaxis against bleeding,** so that >50% of Child A and B patients reach their fifth postoperative year. In the only comparative prospective study carried out so far, the small-calibre, portacaval H-graft prosthetic shunt proved to be superior to TIPS in all relevant aspects. (311) • Good **selection criteria** are: (*1.*) Child A and B patients, (*2.*) liver volume between $1,000-2,500$ ml (as a close correlation to the $O_2$ consumption of the liver), (*3.*) portal vein perfusion of $10-30\%$ of the total hepatic blood flow (for a distal splenorenal shunt of >30%) in sequential scintigraphy or duplex Doppler sonography, (*4.*) selective pananiography to check whether the arteries and veins have a sufficient length and lumen, and (*5.*) use of a shunt technique which does not harm liver function and at the same time facilitates subsequent liver transplantation. The most efficient techniques have proved to be the **distal splenorenal shunt** (particularly in high portal vein residual perfusion) using the same procedure as with splenopancreatic disconnection and gastric transection (319), and the small-calibre **mesocaval interpositional prosthetic shunt** (especially in cases of decreased portal vein blood flow). Chylous ascites was observed as a rare complication of a distal splenorenal shunt. If, for surgical reasons, these methods cannot be applied, the portacaval side-to-side shunt using a small-calibre stent is now recommended when there is no possibility of liver transplantation. (316) The partial portacaval shunt is preferred to the direct shunt. (315) The **survival rate** after 5 and 10 years is reported to be $75-80\%$ and $65-70\%$, respectively. • The outcome of shunt surgery is determined by the **preoperative liver function** and the arterial compensation capacity (which still cannot be measured exactly). The preoperative portal vein pressure is obviously not a risk factor during surgery or postoperatively. (314, 317, 318, 320) • Treatment of multiple arterioportal fistulas by shunt surgery should be mentioned as a **rarity** here. (s. p. 363!) (s. tab. 19.7)

### 6.2.2 Block surgery

Block surgery prevents the portal blood from flowing to the oesophagus and thus intervenes directly at the site of bleeding. However, it does not reduce portal hypertension – portal vein residual perfusion is not decreased. • The numerous methods or modifications may be differentiated into **three groups**: (*1.*) simple block operations, in which the oesophagus is divided close to the cardia and re-anastomosed, (*2.*) extended block operations, which comprise additional skeletization of the stomach in order to avoid fundus variceal bleeding, and (*3.*) the Sugiura method, which also includes splenectomy in addition to gastric devascularization and oesophageal section. (314) • Block operations are only indicated

when TIPS or shunt surgery could not be carried out or were unsuccessful. Devascularization procedures are worth considering as emergency interventions. (s. p. 363)

## 6.3 Liver resection

▶ The first liver resection in the form of a lobectomy was carried out on a dog by G. Zambeccari as early as 1680. The first resection in humans (removal of an adenoma) was also performed in Italy, but the outcome was fatal (A. Lius, 1886). The first successful resection of a large, benign, pedicled lobular constriction was carried out by C. v. Langenbuch (Germany) in 1888, while successful resections were performed in the USA by W. W. Keen as from 1892.

### 6.3.1 Basic principles

**Definition:** A liver resection is defined as the surgical removal of tissue components of the liver in order to eliminate a localized disease process. • The left hepatic lobe (segment I–IV) contains 40% and the right lobe (segment V–VIII) contains 60% of the total liver mass. (s. fig. 40.4) Removal of >80% of a healthy liver is (in principle) fatal. • Hyperplasia of the remaining liver can be expected, while regeneration of the resected portion of the liver is also possible.

**Functional reserve:** The method of choice and the extent of the resection depend upon the residual function of the remaining liver tissue. As a rule, it is relatively easy to determine the loss of tissue caused by surgical intervention, but this is not equivalent to the functional loss: on the one hand, the tumourous or diseased tissue which has been removed had no function and therefore cannot be evaluated as a functional loss; on the other hand, the neighbouring tissue, which was displaced by the growth process, might indeed experience functional recovery after tumour resection. It should be noted that healthy liver tissue usually has to be removed due to the necessity of allowing a safety margin. This is especially true when keeping to the respective segmental boundaries. Evaluation of the remaining functional reserve is extremely difficult in a diffusely diseased liver. This is above all true in cirrhosis; here, it is first of all necessary to determine the *Child Pugh stage*. (s. tab. 35.6) Several *laboratory parameters* (e.g. ChE, GEC, ICG, aminopyrin $^{14}C$ test) (339, 340) as well as CT volumetry or $^{99m}Tc$ GSA (339) – and, in the future, *virtual liver surgery* (336) – are suitable for assessing preoperative liver function and its postoperative functional reserve (even though functional values cannot be directly related to the functional hepatocyte mass). (321, 333, 334)

▶ **Parenchyma setting:** When incisions are made in the parenchyma, all structures within the tissue (arteries, portal veins, hepatic veins, bile ducts) must remain intact. Apart from the well-established method called "finger fracture" (W. Anschütz, 1903), ultrasonic cutters, water beam dissectors or laser scalpels are used

nowadays in order to distinguish between hepatic parenchyma and vascular structures. • **Haemostasis** can be achieved by surgical techniques and electrocoagulation, infrared coagulation, argon beamer or fibrin glue. • The insertion of **drainage tubes** allows the removal of postoperative lymph, gall, residual haematomas and (possibly) oozing blood. Even if these surgical methods are carefully managed, it is not possible to avoid such fluid discharge completely. • The post-resection **methylene blue test** helps to reduce the postoperative biliary leakage rate. (335) (s. pp 780, 798!)

### 6.3.2 Classification and indications

**Left hemihepatectomy:** This procedure includes segments II, III and IV, i.e. the left liver lobe is removed. • In *extended left hemihepatectomy*, segment V or VIII is also resected. (s. fig. 40.4)

**Right hemihepatectomy:** This procedure was successfully carried out for the first time by W. WENDEL (Germany) in 1911 in order to remove a large adenoma. • The technique involves the resection of segments V, VI, VII and VIII, i.e. right liver lobe is removed. • *Extended right hemihepatectomy* also includes segment IV (left middle segment). (s. fig. 40.4)

**Lobectomy:** In left lobectomy, segments II and III are removed, while in right lobectomy, segments IV−VIII are resected (whereby the right and left halves of the liver are incorrectly called "lobes"). (s. fig. 40.4)

**Segmentectomy:** This surgical technique involves the removal of a single liver segment or a combination of segments. Both marginal and central segments may be involved. Another surgical option includes going beyond the boundaries of the segments, such as removal of segment V and the lower half of segment IV. • Resection of segment VIII is the most difficult procedure; usually, segment VII is removed at the same time, since the venous blood flow is interrupted in any case. • Segmentectomy IV divides the liver into two parts as far as the vena cava. The cava/gall-bladder line serves as orientation. • **Left lateral segment resection** involves segments II and III (also known as left lobectomy, see above). • **Segment I** cannot be assigned to either of the two halves of the liver. Its boundaries are difficult to determine; in general, the anterior boundary is defined by the hilar ramification of the portal vein structures, while the posterior boundary line is deemed to be the vena cava. Segment I varies in size, and sometimes it is nothing more than a thin layer of tissue. • As a rule, it is possible to define the segmental boundaries by targeted puncture of the portal vein branches to show colour contrast in the respective segment and also by intrasurgical sonography. (326) (s. fig. 40.4)

**Dorsocranial resection,** a special technique with simultaneous hepato-atrial anastomosis, may be indicated in the Budd-Chiari syndrome (G. BANSKY et al., 1986; S. MEYER et al., 1988). (s. p. 830)

A wide spectrum of *focal lesions* of varying sizes provides the **indication** for liver resection (323, 325, 328, 330, 331, 333, 337):

1. Benign liver tumour
2. Congenital malformations
3. Focal bile-duct processes
4. Granuloma (tuberculosis, actinomycosis, *etc.*)
5. Liver metastasis
6. Malignant liver tumour
7. Parasitic foci
8. Traumatic liver injury

### 6.3.3 Regeneration

In 1879 H. TILLMANNS first reported the phenomenon of liver regeneration following a large resection in an ani-

***Fig. 40.4:*** Representation of the liver segments (acc. to C. COUI-NAUD, 1954) (ULS = upper liver surface, LLS = lower liver surface). (327) Left liver lobe: I−IV (segment I corresponds to the caudate lobe and can only be delimited at the LLS; segment IV is actually located to the right of the falciform ligament). Segment IV is subdivided into an apical part (IVa) and a caudal part (quadrate lobe) (IVb). Right hepatic lobe: segments V−VIII. (1 = inferior vena cava; 2, 3 = falciform ligament) (s. figs. 2.1, 2.5)

mal experiment. This observation was confirmed in 1931 by animal experiments, in which restoration of the liver was demonstrated following two-third resection in the rat. (329) • It has meanwhile been shown that liver regeneration begins directly after resection with a cascade of biochemical and molecular mechanisms. It becomes measurable three to four weeks later. Numerous examinations revealed that the remaining liver reaches its initial, normal size again within 3−6 months. (324) Even in chronic hepatitis or cirrhosis, the liver demonstrates its regenerative capacity after extensive resection, albeit more slowly and to a lesser extent than a liver with healthy parenchyma. • Regeneration appears

to depend on (*1.*) regeneration-stimulating factors in the portal blood after resection (e.g. endotoxin) and (*2.*) the quantity (and quality or special characteristics?) of the portal blood flow. • Regulatory factors of growth can be divided into: (*1.*) *mitogens* (which stimulate synthesis of DNA and mitosis of hepatocytes), such as EGF, TGFα, HGF and FGF; (*2.*) *inhibitors*, such as TGFβ, HPI and some interleukins; (*3.*) *co-mitogens* (which enhance the effect of mitogens and reduce the effect of inhibitors), such as insulin and glucagon ("goodies of the liver"), TNFα, IL 1, IL 6 and hormones. The genetically steered interplay of numerous factors in separate phases of development leads to a closely controlled regeneration process. What is important for the result is the relationship between liver mass and body mass. (322, 338, 341) (s. p. 402!) • Regeneration did not occur in a portacaval end-to-side shunt under experimental conditions. Liver cirrhosis induced in animal experiments proved to have regenerative capacity, an observation which was confirmed by clinical findings. It is assumed that in resection-related regeneration, "other" mechanisms (apart from age) are set in motion than in cirrhosis-related regenerative processes. (342) The type and extent of the cirrhosis also seem to be important factors with regard to resection-stimulated regeneration in residual cirrhosis.

Complete regeneration of the right liver lobe occurred in two women following right lobectomy; surprisingly, the regenerated right lobe showed exactly the same external shape as the original one. (428, 448) This led to the well-founded assumption that there is both (*1.*) resection-stimulated hyperplasia of the remaining liver and (*2.*) regeneration of its resected part. The causes of these two developments are still unclear, as is the varying capacity of a cirrhotic liver to regenerate. Several different methods of elucidating the regenerative processes have been suggested. (322) (s. pp 5!, 402)

## 6.4 Liver injuries

> Liver injuries, particularly caused by weapons and accidents, have been known ever since the dawn of mankind. There are numerous reports dating from antiquity and later centuries of liver injuries and surgical attempts to heal them. • About 1600, F. HILDANUS reported an excision of a prolapsed part of the liver after trauma − the patient survived. In 1716 G. BERTA succeeded in treating a prolapsed and severely injured liver in a madman who had cut open his belly with a knife. • Laparotomy has been used since 1886 to manage liver injuries; mortality rates were 60% (L. EDLER, 1887), 81% (F. TERRIER, 1896) and 44% (B. T. TILTUN, 1905).

The following **classification** is used to assess liver injury (H. BOCKHORN et al., 1982):

| | | |
|---|---|---|
| Type | Ia: | Superficial parenchymal lesions |
| | Ib: | Deep liver ruptures |
| | Ic: | Visible parenchymal destruction, with or without bile-duct injury |
| Type | II: | Additional injuries of the porta hepatis (bile ducts, portal vein, hepatic artery) |
| Type | III: | Injuries of the portal vein hilum |
| Type | IV: | Liver injuries combined with lesions of the vena cava |

Whereas penetrating injuries are less common today, the number of blunt injuries has increased, frequently accompanied by liver rupture. A liver injury is involved in up to 40% of patients with blunt abdominal trauma. Conservative treatment is recommended as far as possible in order to avoid unnecessary laparotomy. (353) The overall mortality rates were 11.8% and 16.8%, respectively. (345, 347) In many cases, the urgency of the situation does not allow the requisite examinations (e.g. US, CT (350, 352), angiography, laparoscopy) to be made − an emergency operation has to be performed. Such an operation must even be done under shock if the patient does not respond directly to conservative methods.

The **surgical treatment** chosen depends on the type of injury, but also on the patient's condition at the time. Some 40−65% of all deaths are due to exsanguination, while 35−60% are caused by postoperative organ failure. Intra-abdominal formation of abscesses is deemed to be the most common complication. (344, 349) Based on the findings available, the following **surgical methods** are used: (*1.*) drainage, (*2.*) superficial suture with drainage, (*3.*) haemostasis by means of transcatheter arterial embolization (346, 348), fibrin glue, infrared coagulator or electrocoagulation, (*4.*) anastomosis techniques (e. g. intracaval shunt), (*5.*) hepatorrhaphy, (*6.*) resection techniques (e. g. debridement, segmentectomy), etc. (343, 344, 349, 351) An overall mortality rate of 10.5% was reported in 1,000 consecutive liver injuries.

# 7 Liver transplantation

> The first liver transplantation was carried out on a dog by C.S. WELCH et al. in 1955. (425) • After a five-year period of experimental preparations, T.E. STARZL et al. were able to carry out the first orthotopic liver transplantation for extrahepatic biliary atresia on a 3-year-old boy in Denver (USA) on **1ˢᵗ March 1963**; however, the boy bled to death during the operation. Another four transplant recipients lived 6−23 days. (414) • In 1968 R.Y. CALNE et al. began carrying out liver transplantations in Cambridge (England). In Germany, A. GÜTGEMANN et al. started performing liver transplantations in 1968, followed by R. PICHLMAYR et al. in 1979. While surgical techniques were constantly undergoing improvement, the problem of organ rejection could not be solved by the substances used at that time (cyclophosphamide, antilymphocytic globulin, azathioprine).

It was not until the introduction of cyclosporine A (R. Y. CALNE et al., 1979) and the combination of cyclosporine A + prednisolone (T. E. STARZL et al., 1980) that the ultimate breakthrough was achieved. In 1983, liver transplantation was recognized as an important option for patients in the final stage of chronic liver disease. • By 1993, a total of 26,500 liver transplantations were reported to have been carried out worldwide (R. BELLE et al., 1993). Under the auspices of Eurotransplant, more than 21,000 liver transplantations had been performed by the end of 1995. Due to the rapidly rising number of centres (about 300 worldwide), the *total number of liver transplantations was thought to have reached about 80,000 worldwide by the end of 2000.* • In Germany, the number of liver transplantations rose from 502 in 1992 to 779 in 2004. • The 1-, 5- and 10-year survival rates amount to >90%, >80% and >75%, respectively. However, the demand for liver transplantation (LT) is far greater than the supply of donor organs. This lack has **practical consequences**: (*1.*) on the indication for LT, (*2.*) on the development of more sophisticated liver-support devices for bridging a life-threatening situation and for avoiding LT should the diseased liver meanwhile become restored (s. p. 384), (*3.*) on the search for alternative transplantation techniques (e. g. split-liver, APOLT, LDLT) for optimizing the use of cadaveric livers, and (*4.*) on the mortality rate among those patients who are waiting for a suitable organ. • The waiting period currently lies between 6−12 or even 12−18 months.

Potential indications for **liver transplantation** are given in almost any kind of life-threatening liver disease (*1.*) which has taken a progressive and irreversible course or (*2.*) in which a period of time has to be bridged between the patient's irresponsiveness to treatment and the probable reversibility of the diseased liver. The motivation and compliance of the patient are prerequisites for LT.

## 7.1 Indications

If the indication for LT is given, the case should be registered with a liver transplantation centre. The patient is then checked regarding the indication, and all contraindications should be excluded. Subsequent to phase-1 and phase-2 evaluation, the patient is added to the waiting list. Principally, only those patients will be selected for LT (*1.*) who have a realistic chance of surviving the perioperative phase and (*2.*) whose chances of survival are considerably better following LT. Children of <1 year can also be successfully transplanted. (359, 375, 418) The spectrum of **indications** for liver transplantation has widened enormously due to more sophisticated presurgical diagnosis, more exact evaluation of risk factors, better management of intraoperative techniques and supplementary measures, improvement in immunosuppressive agents and more qualified aftercare. The indic-

ations may be grouped into **eight main categories**, subdivided into *frequent* and *rare*. In addition, differentiation is made between *safe, possible* and *limited* indications for liver transplantation. (s. tab. 40.14)

The indication for LT depends on (*1.*) **type of liver disease** and (*2.*) **stage of disease,** i. e. at what point LT is carried out during the course of disease. It should be noted that the preparations necessary for LT should commence as from stage Child B. • Eurotransplant assigns the status **"high urgent"** only to patients suffering from acute liver failure or acute transplant failure following LT. Patients suffering from acute deterioration of an existing liver disease are not included in this category. High urgent registrations undergo meticulous examination by Eurotransplant. In such cases, the waiting period is 6−30 hours. Important parameters regarding an indication for LT in acute liver failure include: (*1.*) advancing encephalopathy, (*2.*) atrophy of the liver (daily US!), (*3.*) development of an ascites, (*4.*) decrease in the transaminases and Quick's value, and (*5.*) progressive renal insufficiency. In order to bridge the time until a transplant is available, the use of a liver-support device can be most helpful. (s. pp 384−386)

**Three indication categories** are differentiated according to the overall condition of the patient, respective liver function, the effects of the liver disease on other organs, and existing risk factors:

(*1.*) **Elective indication:** The general condition is stable and the nutritional state is still good or can be improved; liver function is decreasing, but still sufficient; bilirubin is constantly rising; there are as yet no severe extrahepatic complications (e. g. encephalopathy, ascites, hepatorenal or hepatopulmonary syndrome).

(*2.*) **Late indication:** The general condition is poor and the nutritional state is considerably reduced; liver function is severely compromised and shows increasing deterioration; there are complications and additional risk factors.

(*3.*) **Emergency indication:** Failure of vital functions; severe complications are observed (HE stages II−IV, kidney insufficiency, respiratory insufficiency). • This situation may develop either (*1.*) as the final phase of a long-standing, preexisting liver disease or in abrupt manner, or (*2.*) as a high urgent indication in acute liver failure (361, 362, 370, 408, 417) or acute liver transplant failure.

**Time of indication:** Determining the best time for LT is very important, but it is also difficult. Although Child-Pugh classification is used as a standard in liver cirrhosis, it has not proved to be a valuable tool regarding the timing of LT. • Important **criteria** for determining the best time of indication are: (*1.*) *type of liver disease*, including its natural course and risks due to complications, (*2.*) *subjective drop in performance of the patient*, and (*3.*) progressive deterioration of certain *laboratory parameters*. In this context, a slow but steady decrease in GPT and GOT to subnormal values points to severe and irreparable loss of parenchyma. Deterioration of endogenous functional values also suggests that the final phase is imminent. This is likewise confirmed by the fact that the results of exogenous function tests worsen. Such tests are easy to carry out, do not entail side effects, cause little inconvenience and are highly reliable, particularly in combination. (s. tab. 40.15) The ICG and the aminopyrine ^{14}C breath test have proved to be valuable transplant control measures. (369)

It is important not to miss the right moment for LT. A long waiting period with conservative therapy generally leads to an increase in intraoperative risks as well as a

| 1. **Cirrhosis** | 5. **Hepatic tumours** | Haemophilia |
|---|---|---|

1. **Cirrhosis**
   Alcoholic cirrhosis
   Autoimmune hepatitis
   Cryptogenic cirrhosis
   HBV and HDV
   HCV

2. **Cholestatic diseases**
   Alagille syndrome
   Bile-duct atresia
   Bile-duct papillomatosis
   Biliary cirrhosis after cholangitis
   Biliary cirrhosis after PBC
   Biliary cirrhosis after PSC
   Caroli's disease (410)
   Cholangiodysplasia
   Cholestatic sarcoidosis
   Graft-versus-host disease

3. **Acute liver failure**
   Acute episode of a chronic liver disease
   Fatty liver of pregnancy
   Fulminant viral hepatitis (371)
   HELLP syndrome
   Intoxications, poisoning (361)
   Postoperative, posttraumatic

4. **Mycosis**
   Candidiasis
   Coccidiodomycosis

5. **Hepatic tumours**
   Benign tumours
   Cystic liver (383, 401)
   − echinococcosis (382)
   − focal nodular hyperplasia
   Sarcoidosis

   Malignant tumours
   − selected biliary carcinomas
   − selected gall-bladder carcinomas
   − selected hepatic carcinomas
   − selected metastases

6. **Vascular diseases**
   Budd-Chiari syndrome
   Haemangiomatosis
   Veno-occlusive disease

7. **Metabolic diseases**

**I. Liver disease**
1. Type: primary hepatocellular
   primary biliary
2. Natural course

**II. Subjective deterioration in condition**

**III. Changes in laboratory values**
1. *Enzymatic activity*
   • GPT, GOT — < 10 U/l
2. *Endogenous function values*
   • Albumins — < 3 g/dl
   • Quick's value — < 40%
   • Cholinesterase — < 1,000 U/l
   • Bilirubin — > 5 mg/dl
3. *Exogenous function values*
   • Indocyanine green — > 5 min.
   • Galactose elimination capacity — < 5 mg
   • MEGX
   • Aminopyrine $^{14}$C
4. *Biliary function*
   • Alkaline phosphatase — > 1,500 U/l

**Tab. 40.15:** Important criteria in timing liver transplantation

decrease in postoperative survival time. Any complications further worsen the prognosis and put LT into the "late indication" category. (354) • In addition to rising bilirubin and AP values, the consequences of impaired bile flow (e.g. undernourishment and malnutrition, catabolism, osteoporosis, malabsorption, hypercholesterolaemia and pruritus) are prognostically relevant in primary biliary diseases − while liver function tests still show good values in most cases.

Liver transplantation has the following aims: (*1*.) improvement in life expectancy and (*2*.) improvement in the quality of life.

## 7.2 Contraindications

As the management of liver transplantation has improved, absolute and relative contraindications have been established. Relative contraindications may question the success of LT in some cases. Obesity leads to an increased rate of postoperative complications, but it does not influence the survival rate. (396, 403) (s. tab. 40.16) • Contraindications should also be considered in urgent LT due to acute liver failure − possibly accompanied by necrotizing pancreatitis, septic shock and problems with assisted respiration. • Visceral inversion is not deemed to be a contraindication: a successful LT was indeed carried out under such conditions by G. B. KLINTMALM et al. in 1993.

## 7.3 Preoperative diagnostics

**Clinical examination** prior to LT comprises: (*1*.) meticulous anamnesis including all previous findings, (*2*.) thorough internal examination, (*3*.) psychosocial and psychiatric assessment, and (*4*.) broad spectrum of laboratory parameters. *The medical "work-up" prior to LT takes about 10−12 days.*

*Tab. 40.16:* Absolute and relative contraindications for liver transplantation. (The relative contraindications should be determined for each individual case)

**Specific laboratory parameters** comprise: (*1.*) blood group and antibodies, (*2.*) HLA typing, (*3.*) hepatitis serology, including HCV RNA (by PCR) and HBV DNA, (*4.*) serology, including HSV I and II, EBV, CMV, HIV and varicella, (*5.*) coagulation status, (*6.*) thyroid function, (*7.*) renal function, and (*8.*) immunology, including ANA, AMA, SMA, anti-LKM and anti-SLA.

**Technical examinations** comprise: (*1.*) thoracic X-ray, (*2.*) ECG, (*3.*) echocardiography, (*4.*) pulmonary function, (*5.*) gastroscopy, (*6.*) EEG, (*7.*) US and colour-encoded duplex sonography of the abdomen, (*8.*) radiology (including CT and angiography of the coeliac trunk) and right renal arteriography (to exclude high right kidney) as well as MRI cholangiography. With regard to postoperative osteoporosis, bone densitometry is recommended prior to LT. (367)

This **extensive programme** is, on the one hand, essential for preoperative diagnostics and the documentation of initial findings, while on the other hand, postoperative changes in the findings can be evaluated more easily. • The **indication** for LT is determined by an interdisciplinary team. If possible, both assessment and registration of cirrhosis patients should be carried out during Child B as soon as progressive deterioration is observed. • When preoperative diagnostics have been completed, patients grouped in the elective category may spend the **waiting period** at home. However, even if the findings are constant, there is always a risk of acute and unforeseeable complications.

Previous **shunt operations** and **TIPS** need to be removed in order to guarantee that the transplanted liver is sufficiently supplied with portovenous blood. In these cases, the portal system is checked preoperatively for thromboses by means of colour-encoded duplex sonography and X-ray techniques. In any case, the confluence of superior mesenteric vein and splenic vein must be free. (391) • The main advantage of portacaval end-to-side anastomosis is its low thrombosis rate of <5%; in addition, there is no need for a distal shunt ligature. In shunts distal to the hilus (mesocaval, distal splenorenal), no preparation of the liver hilus is required; however, in 10% of cases, these shunts show portal vein thrombosis (in TIPS, up to 15%). • Usually, all surgical shunts are disconnected or ligated before the liver transplantation is completed in order to

avoid a steal effect. • Although portal vein thrombosis, previous operations in the liver hilus and portosystemic shunt surgery are (sometimes considerable) obstacles to liver transplantation, they are not regarded as contraindications. When there is isolated or partial portal vein thrombosis, a connection to the portal vein can often be restored by thrombectomy or bypass techniques; the survival rate is similar to that in patients with a primary open portal vein. Nevertheless, the conditions for a successful LT are more favourable if there is no portal vein thrombosis and the liver hilus does not require special preparatory measures.

## 7.4 Preparation of patients

(*1.*) During the waiting period, it is important to maintain or even improve the patient's **nutritional status.** Protein tolerance can be monitored by using simple *psychometric tests.* A protein intake of 1.0−1.5 g/kg BW/day would be ideal. Supplementation by *branched-chain amino acids* may be helpful. The *calorie supply* has to be adjusted to the optimal requirement of the patient. (s. pp 741, 850, 861)

(*2.*) The daily food intake should be spread over **five meals.** However, it is almost impossible to achieve an optimum supply of water-soluble and fat-soluble **vitamins.** Administration of multivitamin preparations is therefore recommended. **Sodium chloride** intake should not exceed 7−8 g/day. (s. pp 278, 730, 734, 741)

(*3.*) Depending on the patient's condition, regular **muscle training** should be carried out daily if possible in order to improve anabolism as well as urea and glutamine metabolism in the muscles. (s. pp 650, 732)

(*4.*) The administration of **lactulose** over an extended period of time (dosage aim = 2−3 stools per day) is recommended. (858) • It is advisable to use a combination with *metronidazole* or with *non-absorbable antibiotics* (e. g. paramomycine) preoperatively in order to suppress the gram-negative intestinal flora and thus also the formation of endotoxins. If necessary, **antimycotics** may be administered in addition.

(*5.*) *Latent encephalopathy,* detectable by psychometric tests (s. p. 202), is frequent; experience has shown that it can rapidly become manifest. Of the urea-cycle amino acids suitable for therapy, **ornithine aspartate** has proved the most successful − also as an i.v. infusion in the postoperative phase. (s. pp 279, 733)

(*6.*) The relevant literature also recommends **vaccination** against pneumococcus and influenza as well as hepatitis B (unless there is already immunity).

## 7.5 Surgical aspects

### Compatibility of blood groups

Interestingly, compatibility within the **blood group system** has proved to be the decisive factor in liver transplantation to date. • Although the *HLA system* is usually determined (for retrospective evaluation), it is of minor importance according to present knowledge. This is also true of so-called *"cross-matching"* between

patient serum and donor lymphocytes. No other compatibilities between recipient and donor (apart from body weight, height and thorax size) are known to be required.

## Quality of a donor liver

*The quality of the donor liver is of crucial importance for successful LT. First of all, careful and proper* **organ retrieval** *by a qualified team is an important prerequisite. Most centres now have such a designated multi-organ retrieval team.* • Any information pertaining to the donor (e.g. clinical results, anamnesis, laboratory values, current medication, further findings) is listed in the **donor protocol.** Of equal importance in the evaluation of a donor liver are the circumstances leading to the donor's death (cause of death, intensive care measures, etc.). • Using more suitable **preservation solutions** (Ringer's lactate, University of Wisconsin solution), the conservation time of donor livers could be prolonged to 15−20 hours. Great emphasis is being placed on achieving further improvements in this area. • During removal by the surgeon, the **donor liver** is assessed macroscopically and by palpation. This requires considerable experience, particularly since no other criteria for assessing the quality of the donor organ are available. (424) The **transplant** should be almost identical to the recipient's organ in terms of size, weight and vascular diameter (portal vein, superior/inferior vena cava). • The use of *size-reduced transplants* is being further developed as a possible method for the future.

## Types of transplantation

Normally, **orthotopic liver transplantation** (OLT) is used; in this technique, the donor liver is implanted at the site where the recipient's organ has been removed. The average survival rate is >90% after 1 year and >80% after 5 years. (s. p. 387)

A modified procedure, so-called **orthotopic segment liver transplantation** (OSLT), has proved successful (H. Bismuth et al., 1984); this involves implanting parts of an adult liver, i.e. segments II and III or I−IV depending on the size of the recipient's organ, into a young recipient ("reduced size").

In **split liver transplantation** (SLT) (R. Pichlmayr et al., 1989), it is possible to transplant segments V−VIII, which are left over in OSLT, into an adult. (400) This means that two recipients can be supplied with one donor organ. The surgical splitting of the donor liver subjects the organ to considerable stress, and therefore its quality has to meet particularly high standards. (366, 426)

In **living donation** (LDLT) (R. W. Strong et al., 1990), segments II and III are taken from a parent and transplanted into the child. (416) The surgical risk for the living donor, which was quite high at the beginning, has been reduced considerably in the meantime to about 0.24%. The survival chance of the recipient is 27−92%. To date, more than 3000 transplantations of this kind have been carried out worldwide. The technique has now been generally established for children. About 5% of all LT patients are also suitable for an LDLT. Therefore, the possibility of such an LDLT should be discussed in all those cases where the waiting time for a regular LT would prove to be a problem. More than 75% of the donors are free from complications. In LDLT involving adults, the volume of the donor organ should be equivalent to approx. 1% of the body weight of the recipient. The respective size of the transplant, which is usually taken from the right lobe, is determined by means of CT volumetry. • After LDLT, bile leaks (7−10%) and biliary strictures (16−20%) frequently appear. In such suspected complications, ERC is recommended. (364, 376, 383, 392, 395, 411)

In **heterotopic liver transplantation** (HLT), the donor liver is transplanted as an auxiliary (additional) organ into the right upper abdomen, but the recipient retains the diseased liver (K. Absolon et al., 1965; J. G. Fortner et al., 1970). This technique is not easy to carry out in terms of surgical requirements; it involves the so-called piggyback method and is used particularly for young patients suffering from acute liver failure. (s. p. 387)

**Auxiliary partial orthotopic liver transplantation** (APOLT) was introduced by G. Gubernatis et al. in 1991. In this procedure, segments II and III of the diseased liver are removed, while segments II−IV (or sometimes only segments II and III) of the donor organ are transplanted. The bile duct is reconstructed as a biliodigestive anastomosis. Full reversibility of the existing liver disease is a precondition for the surgical concept of APOLT. (408, 417) (s. p. 387)

The importance of an adequate supply of **zinc** is now accepted. In most cases, however, there is already a deficiency of this important trace element (unless previous medication has remedied the situation). Due to the scale of the operation, there is a considerable loss of zinc, which usually cannot be balanced even by intravenous substitution. Experience has shown that pronounced and extremely detrimental *zincuria* may be kept in check by i.v. application of **potassium canrenoate.** (s. p. 787!)

**Venous bypass:** Insertion of a combined venovenous and portovenous bypass reduces the negative effects of the anhepatic operative phase (lasting 30−120 minutes) by interrupting the blood flow in the portal vein and inferior vena cava. This measure allows greater haemodynamic stability during the anhepatic phase.

**Biliary anastomosis:** Reconstruction of the biliary flow is achieved by side-to-side anastomosis of the two choledochal stumps or, when primary bile-duct disease is present in the recipient, by anastomosis using a jejunum sling in the Roux-en-Y technique.

**Duration of the operation:** The duration of the operation varies greatly owing to the widely differing conditions during surgery. On average, it takes 5−10 hours. • The blood loss also differs considerably: 6−15 units of blood are normally substituted, but this quantity may be much higher in some cases. The number of units of blood can be reduced by administering *aprotinin*, which inhibits fibrinolysis after reperfusion.

## 7.6 Postoperative features

The postoperative phase is characterized by **three important objectives:** (*1.*) monitoring the functional condition of the transplanted liver, (*2.*) adjustment of immunosuppression, and (*3.*) early detection and treatment of complications.

**Early postoperative phase:** Extubation is carried out as soon as possible with subsequent regular breathing exercises and optimal infusion therapy. This takes into account all problems arising from such extensive surgery, e. g. lactate-free volume replacement, stability of circulation and coagulation, pain therapy, electrolytes, zinc, vitamins, acid-base balance, energy carriers. Loss of protein is substituted by fresh-frozen plasma and albumin. The onset of bile production and a decrease in lactate values are initial signs that the transplant is functioning well. In addition, factor V and thromboplastin time generally increase. Occasionally, ascites can occur. (365) From 7th day, the transaminases fall steadily. Antibiotic prophylaxis, which began during surgery, is usually discontinued on 2nd or 3rd day. Oral and bodily hygiene as well as monitoring of infection are also part of the intensive-care programme. Special surveillance protocols have been carefully designed for this purpose.

### Immunosuppression

Both the induction and adjustment of immunosuppression also follow established protocols, which can, however, be executed in various ways. In the meantime, new immunosuppressants are in use (tacrolimus, sirolimus, mycophenolate mofetile, brequinar, leflunomide, etc.). Cyclosporine and tacrolimus include a calcineurine inhibitor. Initially, the patients receive *triple therapy*: tacrolimus (or cyclosporine) + prednisolone + mycophenolate, occasionally with interleukin-2 receptor antagonist (e. g. basiliximab, diclizumab). • After 3 months, the patient is given *dual therapy*, generally with tacrolimus (or cyclosporine) + prednisolone or with tacrolimus + mycophenolate; after a further 6 months, the patient is put on *monotherapy* with tacrolimus (or cyclosporine). During dual therapy, the dosage of prednisolone is reduced slowly until the drug is ultimately discontinued (except in cases with AIH as an underlying disease). (405) • In patients with HCC, immunosuppression based on rapamycin appears to be more efficacious, since it appears to have an antitumourigenic effect. • The monitoring of tacrolimus (or cyclosporine) is carried out at regular intervals using the respective values in the blood. • Long-term follow-up is performed by the family doctor or internal specialist and, at certain intervals, by the outpatient department of the transplantation centre. (372) • The **toxicity** of immunosuppressive agents is the main cause of complications (e.g. hypertension, kidney damage and even kidney failure, severe headaches, altered blood values, nervousness, trembling, peripheral paraesthesia, increase in liver enzymes). Such toxicity-related complications may also be due to **interactions** between cyclosporine and other drugs. Differential diagnosis of transplant rejection may prove difficult.

**Tolerance:** Donor cells have sometimes been detected in the blood of liver transplant recipients. This chimerism may influence the immune system of the host with development of tolerance to donor tissue. (406, 423) That would mean that a donor liver might, in some cases, be spontaneously accepted. As a result, it is possible to stop the administration of immunosuppressants. • Usually, after 5-year survival of a primary graft, one third of all patients are able to cease immunotherapy.

### Complications

Major complications following LT include: (*1.*) non-function of primary graft (1st–2nd day), (*2.*) infection (3rd–14th day, and longer), and (*3.*) rejection (5th–10th day). The clinical features of these complications are similar:

> liver = large, firm, tender on pressure
> fever
> leucocytosis
> jaundice

Such findings require immediate and extensive examination: US, Doppler sonography, CT, HIDA scintigraphy and cholangiography. • Further complications are (*1.*) afterbleeding (10–15%), (*2.*) portal vein thrombosis (up to 2.2%) or hepatic vein occlusion, (*3.*) hepatic artery thrombosis or stenosis, (*4.*) pleural effusion, and (*5.*) subcapsular necrosis (due to the disproportionate size of donor and recipient liver). Stenosing of the suprahepatic vena cava is a particularly dangerous condition, which can lead to ALF. • The most frequent complication affects the biliary system in the form of leaks or strictures (up to 50% of cases). They can be diagnosed with the help of T-drain radiology or ERC. (389)

### Infection

One of the major problems following LT and immunosuppression are infections. During the early postoperative phase, the danger of **bacterial** or **fungal infection** is particularly great due to high-dosage immunosuppression and intensive medical care at a time when the patient's physical condition is considerably impaired. Monitoring of infection, accompanied by optimal hygiene and prophylactic measures, is required as well as (possibly) immediate treatment with antibiotics. In order to avoid translocation of gram-negative microorganisms, decontamination of the intestinal tract, already initiated in the preoperative phase, is often continued; in addition, the use of an antimycotic agent is recommended (e. g. against candidiasis or coccidioidomycosis). (377, 380, 404, 421) • **Viral infections** are most frequent 2–4 months after LT. A particular danger, both in adults and children, may come from new infection with or reactivation of CMV (412, 422), EBV, herpes-6 virus, varicella-zoster or Listeria monocytogenes. (386) CMV infection is associated with a higher rate of rejection. Early diagnosis (by PCR) and early treatment (e. g. intravenous ganciclovir) are required. Of the various viral infections, especially condylomas

caused by papilloma viruses are to be feared in the long term, since a high percentage of them can develop into squamous-cell carcinoma. A new form of treatment with *imiquimod* may prove to be effective.

### Transplant rejection

**Hyperacute form:** Transplant rejection may occur as an antibody-related **complication** within a short period of time after LT. This rare event is caused by donor antigens coming into contact with preformed antibodies in the recipient, which results in damage to the endothelial cells of the arteries with vascular occlusion. The outcome is necrosis of the transplant.

**Acute form:** This condition appears within the first 1−3 postoperative weeks. Some 40−60% of patients have one or even several rejection reactions of varying intensity, accompanied by discomfort, fever, exhaustion and, occasionally, mild jaundice. Early diagnosis is only possible by detecting an increase in liver enzymes, particularly GDH; the diagnosis is confirmed histologically. Percutaneous biopsy should be carried out with antibiotic protection. (385) Histology reveals the presence of large lymphocytes, plasma cells, macrophages and granulocytes in the portal fields in this type of cellular reaction. The interlobular bile ducts are damaged, and there is subsequent cholestasis. It is possible to observe adherence of lymphocytes to the venous and arterial endothelium, resulting in subendothelial inflammation (= **endothelialitis**). (s. fig. 40.5) • *Therapy* is based on prednisolone (500 mg i.v. for 3 days). In cases showing no reaction, the dosage of tacrolimus should be increased, and, occasionally, mycophenolate (2 x 1g/day) or rapamycin can be added. In non-responders, therapy with OKT3 is recommended (after histology has shown persistent rejection). Thus, an acute rejection does not pose a risk for long-term prognosis. In most cases, drug therapy is successful and without morphological residues. (357) • *Retransplantation* is seldom necessary.

***Fig. 40.5:*** Acute rejection: portal/periportal inflammation and portovenous endothelialitis (↓) (HE)

**Chronic form:** This condition is no longer observed very often (< 5%). It usually sets in 1−9 months after LT and

***Fig. 40.6:*** Chronic rejection: stenosing foamy cell arteriopathy

is characterized by progressive cholestasis. This form may develop after repeated acute attacks or develop insidiously from the beginning. There is a ductopenic reaction, whereby the interlobular bile ducts are infiltrated and destroyed by mononuclear cells; ultimately, the bile ducts disappear. Duct loss can be calculated from the ratio of the number of hepatic arteries to the number of bile ducts within a portal field (normal = > 0.7), whereby 20 portal fields should be examined. At the same time, obliterating arteritis develops, with fibrinoid wall necrosis and deposition of foam cells within the intima. (393) The result is portal and periportal fibrosis. (s. fig. 40.6) Differential diagnosis is difficult and may require repeated biopsies. Chronic rejection can be graded histologically in a mild, moderate or severe form. *Therapy* with tacrolimus halted progression in some cases. Tacrolimus and mycophenolate may generally bring about a reduction in the chronic rejection response. Should the treatment fail, the only alternative is *retransplantation*. In this case, an elective indication for retransplantation is given, since liver functions remain intact for a relatively long time. • In acute and chronic rejection accompanied by an increase in alkaline phosphatase, *ursodeoxycholic acid* should be used as supportive therapy. • With regard to unclarified **complicative situations,** it is essential to determine the level of immunosuppressants in the blood (underdosage? toxicity?). Subsequently, US and colour-encoded duplex sonography as well as CT or MRI are indicated. Radiology-dependent interventions may be required.

*Retransplantation* is required in 5−10% of patients. The main indications are primary graft failure, hepatic arterial thrombosis and chronic rejection. • Results of retransplantation are not so satisfactory as with the first LT: the survival rate is shorter and mortality (usually due to sepsis) is mostly within 6 months. Nevertheless, the prognosis is improving steadily. (407)

### Relapse of the underlying disease

Some 25% of hepatocellular and up to 70% of cholangiocellular **carcinomas** are subject to relapse within 12

months. Tumour relapse is caused by the presence of undetected extrahepatic metastases, which find their way back into the transplanted liver, and on the suppressed state of the immune system. According to some observations, the probability of relapse depends on the stage of the primary tumour. For this reason, only (selected) early tumour stages are a possible indication for LT. • Reinfection of the transplant occurs in 80−100% of cases due to **hepatitis B** from extrahepatic reservoirs, most likely in the early postoperative (low-defence) stage. Of these cases, about 15% follow a fulminant course, about 15% show persistent hepatitis, 5% reach chronic carrier stage, and 20−25% develop fibrosing cholestatic hepatitis with a high rate of viral replication and an unfavourable course. (360) In some patients with severe reinfection, cirrhosis can develop within a few years. **HDV infection** may lead to a similar outcome. With such a negative outlook, it is important to consider every possibility of avoiding reinfection. The prophylaxis is based on HBIG (10,000 IU intraoperatively and then daily) + lamivudine until HBsAg has disappeared from the serum. In this way, the risk of reinfection can be reduced to 10−20%. (s. p. 709) Should reinfection nevertheless occur (renewed evidence of HBsAg), new nucleoside analogues (e. g. adefovir, entecavir, tenofir) are available under certain conditions. (355) • In **hepatitis C,** the transplant is reinfected in 90−100% of cases, although only about half the patients display HCV antibodies when immunosuppressives are administered. HCV replication occurs already in the first week after LT. The infection follows a mild course both in terms of clinical findings and morphology; fulminant or cholestatic courses are rare. In 10−30% of patients, chronic hepatitis, or even cirrhosis, appears. Nevertheless, in view of the great effort involved in performing an LT, the use of peg IFNα with ribavirin, and occasionally in combination with amantadine, must be considered. (s. p. 708) (363, 373, 377, 390, 397, 407, 409, 422) • **HGV infection** (generally a result of numerous blood transfusions!) is of no clinical significance. (378) • **Alcoholic liver disease** is followed by relapse within 2 years in about 20% of cases. (368, 399, 415) • Relapses have been observed following **primary biliary cholangitis** (384, 420) or **primary sclerosing cholangitis** (< 5%) (374, 381, 387), **autoimmune hepatitis** (despite immunosuppression in 10−30%) (356, 392) subsequent to **BCS** (without anticoagulant in 100%), or **non-alcoholic steatohepatitis.** (394)

## 7.7 Aftercare and rehabilitation

LT patients require 7−10 days in an intensive care unit and about 3 weeks in a normal ward of the hospital. The patient is usually fully rehabilitated after 6 months. Subsequent to inpatient treatment, *follow-up therapy* is carried out at a **rehabilitation clinic** which is specialized in hepatology. Generally, this stationary rehabilitation phase lasts 4−6 weeks and includes various **tasks** and **objectives**. (s. tab. 40.17)

1. Step-by-step reorientation of the individual patient from the clinical atmosphere to the more "normal" daily routine in a rehabilitation centre. Medical follow-ups, including monitoring of the immunosuppressive adjustment.
2. Gradual social and cultural reintegration within the rehabilitation community.
3. Detailed information for the patient regarding personal hygiene, nutrition, lifestyle, significance of aftercare, recognizing complaints or abnormalities, etc.
4. Improvement in the patient's nutritional state.
5. General physiotherapeutic measures; targeted training of the muscle groups atrophied to a varying extent in the individual patient.
6. Psychotherapeutic support (particularly in how to handle the fear of complications), opportunities for psychosocial care, discussion of questions relating to the patient's occupation, etc.

**Tab. 40.17:** Tasks and objectives of aftercare and rehabilitation in specialized clinics

**Risk of infection:** Patients are subject to a high risk of infection at public events, when using public transport, and particularly during waves of influenza. Interdigital mycosis also presents an infection risk. A further problem can derive from indoor plants (beware of fungal spores in potting compost!). Domestic animals similarly constitute a risk factor; it is of particular importance that no new pets should be introduced. Towels and bed linen must be changed regularly. Shower water, which is usually heated to 60 °C in the boiler, should be run for an extended period 2−3 times a week in order to prevent legionellosis. Vaccinations with live vaccines should be avoided. Intake of tap water and non-pasteurized milk is forbidden as these liquids have a high bacteria count. Lettuce and vegetables need to be washed several times and with particular care. Fruit that is difficult to clean (raspberries, etc.) should not be eaten; preference is to be given to fruit which can be peeled. Raw steak tartare must not be consumed. • These numerous recommendations and warnings are not designed to create hysteria, but to help minimize the risk of infection at a realistic and, for the patient, comprehensible level.

**Nutrition:** The patient's diet should comply with the basic principles of physiological nutrition. It is recommended to take three main and two minor meals per day. Foodstuffs causing flatulence and containing poorly digestible fats (e. g. lard) should be avoided. It is important to consider the influence of glucocorticoids on appetite as well as their metabolic side effects (e. g. restriction of sodium chloride, loss of potassium).

**Medical aftercare:** This comprises adjusting and monitoring *immunosuppressants*, providing the patient with all necessary information as well as recognizing and

controlling side effects. • Occasionally, *pleural effusion* has to be monitored and, if necessary, aspirated. *Ascites,* often evident as a local accumulation of fluid in the abdomen, may still be present. • Sometimes, *wound care,* treatment of postoperative wound complications or removal of a T-drainage, generally after 6 weeks, may still be required. • The *renal function* needs to be monitored carefully, even if there is no obvious progressive renal damage. • The *vascular system* (portal vein, inferior vena cava, hepatic artery) has to be checked by colour-encoded duplex sonography for the occurrence of thromboses, stenoses or aneurysms. Bile leakage or stenoses may appear in the *bile ducts.* • In 60−80% of patients, *hypertension* can be anticipated due to treatment with cyclosporin. In 20−30% of cases (more often with tacrolimus than with cyclosporine), *diabetes mellitus* or *hypercholesterolaemia* develops.

> If this wide spectrum of sophisticated rehabilitation measures is carried out with great care − and with success − fewer problems will arise in the aftercare of outpatients when they return to their normal daily routine. The *length of stay* at a specialized clinic should be tailored to the patient's individual needs; on average, this lasts 4−6 weeks. In view of the high costs involved in LT and the great inconvenience to which the patient is subjected, the rehabilitation phase assumes an essential role; follow-up therapy is thus both necessary and recommended for achieving long-term survival and improved quality of life with reintegration into the work process.

Inpatient monitoring is succeeded by **outpatient control protocols.** The check-ups are carried out by the family doctor or internist in close cooperation with the transplantation centre. • The 1-year survival rate after liver transplantation is generally 80−95%. The 5-year survival rate varies depending on the underlying disease, e. g. 70−80% in cirrhotic patients, 45−50% in acute liver failure, and 35% in malignancies. (379, 388) About two-thirds of the patients begin working again despite a long phase of being unable to work due to chronic liver disease. Most liver transplant recipients are very satisfied with their newly acquired quality of life. (398, 399)

# 8 Sociomedical aspects

*Health awareness* on the part of the individual as well as *preventive* and *rehabilitative medicine* in general are exerting more and more influence on developments in the medical world − and thus also on hepatology. These changes in medical practice are an inevitable and characteristic feature of a modern society. • Consequently, physicians will need to devote more attention to *"prevention"* in the healthy person in order to keep the curative phase of any illness as short as possible. And to an increasing degree, they will also have to undertake

"rehabilitation" of the patient in order to reduce to a tolerable minimum any periods in which the individual is unable to perform efficiently and is also unfit for work. (s. fig. 40.7)

*Fig. 40.7:* Combination of prevention and rehabilitation in health awareness

## 8.1 Health awareness

▶ This term subsumes all factors which reduce potential damage to health. These include protective measures promoted by the state, various authorized institutions and associations as well as by industry, science and the medical professions. Above all, however, every individual should assume personal responsibility for maintaining his or her state of health through appropriate behaviour. • *The media must also accept a vital role in this context!*

---

**Health awareness with regard to hepatology**

- Healthy diet and normal body weight
- Hygiene concerning drinking water and food
- Physical/muscular fitness
- No alcohol abuse
  No medication abuse
  No drugs
- Avoidance of occupation-related damage
- Prevention of infections by observance of basic hygiene

---

## 8.2 Preventive medicine

These are health measures which are carried out by individuals of their own accord, sponsored by the state, accepted by medical insurance companies and organizationally feasible; they enable the monitoring and preservation of health as well as the early recognition of diseases.

## 8.3 Rehabilitation

Rehabilitation is designed to reintegrate people with physical or mental impairment into both their professional and personal environment. It comprises aftercare with a social component in the sense that society is called upon to help, and thus it is a communal undertaking. Rehabilitative measures should start as early as possible during the curative phase. Once the disease has consolidated and as soon as the prognosis offers a realistic perspective, the physician should address the question of rehabilitation. The necessity for rehabilitation depends on the severity of the symptoms and/or the psychosocial problems involved.

The indications for **medical rehabilitation** are subject to strict legal stipulations. First of all, an expertise including a detailed medical evaluation is required from a physician. In rehabilitation centres specialized in hepatology, all necessary interdisciplinary diagnostic and therapeutic measures are applied. It is important that the rehabilitee cooperates actively.

Measures necessary for **occupational rehabilitation** are initiated at the same time. These include options for

vocational retraining and additional qualifications, redesigning the workplace to fit the needs of the handicapped person, reintegration into the work process, personal support, etc. Occupational rehabilitation also depends on the rehabilitee being adequately motivated. Furthermore, it is important to evaluate individual vocational preferences and prospects of success. Job-related psychological and aptitude tests together with measures aimed at finding a suitable job must be carried out before a final decision can be made.

## 8.4 Capacity for work

A positive and negative profile of a patient's capacity for performing certain tasks should be compiled on the basis of the respective disease phase. For the rehabilitation process, it is important to assess the remaining capacity of the individual in combination with any personal strengths. In addition, liver function and potential health risks have to be considered. The medical evaluation of the patient's capacity for work forms the basis for the respective sociolegal decision. It should be noted, however, that the medical expertise and the legal decision are independent of each other − such legal terms as *"incapacity for work"* or *"inability to practise the learned profession"* must be avoided in the medical report. • A patient's capacity for work also includes *fitness to drive a vehicle* (e. g. in cases of encephalopathy) or *fitness for public service* (e. g. in the educational or judicial sector). In severe cases of advanced liver disease, evaluation is not difficult. However, this is not so easy in less severe cases (e. g. diffuse fibrosis, lack of complicative developments) or low-grade to moderate inflammatory processes. Objectivation of the findings is only possible by extensive diagnostic clarification of the function and morphology of the liver − as well as of other affected organs.

The physician's assessment of a patient's capacity for work takes into account the individual factors in a certain type of liver disease and thus forms the basis for determining (*1.*) **unfitness for work,** (*2.*) **inability to practise the learned profession** and (*3.*) **inability to earn** within the sociolegal framework of the country concerned. This involves reviewing the overall situation in a concrete manner, i. e. whether there is a workplace available that is appropriate to the patient's capacity for

work. Pension allowances paid due to inability to practise the learned profession are generally lower than those paid due to unfitness for work. Assessment of the inability to earn does not depend on whether the person has recently worked or on current job prospects. It should be noted that clearly defined standards of assessment are required under pension law. Concerning accident insurance, severe disability and social compensation, the principle of abstract damage assessment applies. The inability to practise the learned profession as well as the inability to earn must be permanent. All indications for rehabilitation must be checked carefully and with regard to the relevant conditions. **Unfitness for public service** is a term generally used for civil servants, but it also applies to soldiers and persons doing community work.

The hepatological diagnosis should be as accurate as possible, so that the physician is able to assess the (positive and negative) capacity profile. In this connection, the insured person is not obliged to tolerate **invasive examinations** (e.g. laparoscopy, percutaneous liver biopsy). However, the risk of underestimating the reduction in earning capacity can be detrimental for the individual. Moreover, the possibility of *further deterioration of a disease* is not included in an assessment; thus a follow-up report may be required after a certain period of time.

The original International Classification of Impairment, Disability and Handicap (ICIDH) has been revised as the International Classification of Functioning (ICF). This new classification requires a precise description of the disease-related impairments of the individual patient. Subjective complaints should be considered although they cannot, of course, be evaluated objectively. Aggravations must be treated with caution. Objective assessment can be based on enzymatic and mesenchymal activity (s. tabs. 5.15; 5.22), serological or immunological findings (s. tabs. 5.17; 5.20), and liver function tests (s. tab. 5.14). Ultrasound, occasionally colour-encoded Doppler sonography, or even CT give an impression of the morphological structure of the liver, especially in cases where patients refused to have a biopsy. The assessment programe should also contain psychometric tests. (s. pp 202−206) (s. fig. 5.2)

The term **reduction in earning capacity** is used in civil law to assess claims payments. It denotes the difference between the income earned before the accident happened and afterwards, i.e. the actual and proven pecuniary loss is determined.

The term (severe) **disability** was defined by the World Health Organisation (WHO) in 1980. It contains guidelines for protecting severely disabled persons by law. The principle of abstract damage assessment applies when determining the degree of disability. A small part of the labour market should be kept open for severely disabled persons.

The above statements can only serve as general criteria for the physician's evaluation of patients suffering from liver disease. More detailed information is usually available from the insurance provider. Thus it is desirable that medical practitioners cooperate closely with sociomedical specialists, so that it is possible to deal directly with any application for compensation, disability pension, etc.

Although there are **guidelines** for evaluating the reduction in earning capacity (REC), the actual degree of disability (DOD) may be assessed differently depending on the existing disease. In the individual case, the physician may propose percentage values concerning the disability which are higher or lower than the recommended rate.
• The assessment of chronic hepatitis B and C is of great importance (H. SELMAIR et al., 1998), and it should be made according to the aetiological-morphological nomenclature. (s. pp 693−695) (s. tab. 40.18)

| | |
|---|---|
| Functional hyperbilirubinaemia | 0−10% |
| Acute viral hepatitis | 100% |
| Asymptomatic HBsAg carrier status | 0% |
| Chronic active hepatitis | |
| − low inflammatory activity | 20−30% |
| − moderate inflammatory activity | 30−40% |
| − severe inflammatory activity | 50−>70% |
| − fibrosis (low → severe) | 20−60% |
| Scarred liver without complications (depending on the functional reduction) | 20−40% |
| Cirrhosis, compensated | |
| − inactive (stable) | 40% |
| − moderately active | 50% |
| − distinctly active | 60−100% |
| with severe functional reduction | 80−100% |
| with shunt surgery | 60−100% |
| Cirrhosis, decompensated | 80−100% |
| Fatty liver | 0−10% |
| − with hepatitis (low → severe) | 20−100% |
| Fatty cirrhosis | 40−100% |
| Chronic cholangitis | 20−100% |
| Liver transplantation | 100% |
| (after consolidation lasting 2 years with 100% DOD/REC, and later on no less than 60%) | |
| Liver lobe resection | > 50% |
| Tumour resection | 100% |
| Primary liver cell carcinoma (within the first 5 years of consolidation, the REC remains at 100%) | 100% |

***Tab. 40.18:*** Guidelines for assessing the reduction in earning capacity (REC) and the degree of disability (DOD) in liver diseases. (If the hepatological picture cannot be classified in relation to a diagnosis shown in the above table, it should be described and classified according to its functional disturbances in line with the above diagnoses)

Altogether, *three criteria* are important in the assessment of a liver disease:

1. its effects on the patient's capacity for work
2. its connection with a specific damaging event
3. its rehabilitation potential

Medical evaluations are simply opinions of an advisory nature; they have to be assessed by administrative and legal experts before a final decision can be made. • The physician, however, is responsible for the medical determination of a disease and the resulting diagnosis of *unfitness for work*.

## 8.5 Self-help groups

In most countries, there are self-help groups for liver patients. Participation in such self-help groups is generally beneficial. They are highly valued for their constant availability and their counselling competence. The patient can remain anonymous and all counselling is confidential. This useful service is offered free of charge. Self-help groups provide the participants with information on all important topics (including the latest developments) by means of printed material, special meetings and reports in the media; in addition, they facilitate a mutual exchange of experience among the patients.

The wish and the hope expressed by a Babylonian haruspex (a diviner whose predictions are based on inspecting the entrails of sacrificed animals) in the following sentence, which he inscribed as a repeating stereotype on a clay model of a sheep's liver (ca. 2000 BC) (s. fig. 1.1) (s. p. 2), is dedicated to all patients suffering from liver disease and also to all users of *"Hepatology − Principles and Practice"*:

**"May your liver be smooth"**

*"In the heart the physician grows,*
*from God he proceeds ...*
*The highest ground of all remedies is love."*

Theophrastus Bombastus von Hohenheim,
called PARACELSUS (1493−1541)

# Index

# Abbreviations

| Abbreviation: | Meaning: |
|---|---|

**A**

| | |
|---|---|
| AA | Amino acid |
| AAA | Aromatic amino acid |
| AAT | $\alpha_1$-antitrypsin |
| ABT | Aminopyrine breath test |
| AcCoA | Acetyl coenzyme A |
| ACE | Angiotensin-converting enzyme |
| ACTH | Adrenocorticotropic hormone |
| ADH | Antidiuretic hormone |
| ADH | Alcohol dehydrogenase |
| ADP | Adenosine diphosphate |
| ADR | Adverse drug reaction |
| ADT | Placebo (**a**ny − what you **d**esire − **t**hing) |
| AE | Anion exchanger |
| AFP | $\alpha_1$-foetoprotein |
| Ag | Antigen |
| AHA | Antibody histone (2B)-A |
| AIC | Autoimmune cholangitis |
| AIH | Autoimmune hepatitis |
| AIP | Acute intermittent porphyria |
| ALA | $\delta$-aminolaevulinic acid |
| ALAD | $\delta$-aminolaevulinic acid-dehydratase |
| ALD | Aldolase |
| ALDH | Aldehyde dehydrogenase |
| ALF | Acute liver failure |
| ALG | Antilymphocytic globulin |
| ALL | Acute lymphatic leukaemia |
| ALT | Alanine aminotransferase (= GPT) |
| AMA | Antimitochondrial antibody |
| AML | Acute myelogenous leukaemia |
| AMP | Adenosine monophosphate |
| ANA | Antinuclear antibody |
| ANCA | Antinuclear cytoplasmic antibody |
| ANF | Atrial natiuretic factor |
| AP | Alkaline phosphatase |
| APOLT | Auxiliary partial orthotopic liver transplantation |
| APTT | Activated partial thromboplastin time |
| APUD | Amine precursor uptake and decarboxylation cells |
| ARA-AMP | Adenine arabinoside monophosphate |
| ARP | Anti-ribosomal P antibody |
| ASA | Acetylsalicylic acid |
| ASGPR | Asialoglycoprotein receptor |
| ASH | Alcoholic steatohepatitis |
| AST | Aspartate aminotransferase (= GOT) |
| AT III | Antithrombin III |
| ATP | Adenosine triphosphate |
| ATPase | Adenosine triphosphatase |
| AWS | Alcohol withdrawal syndrome |

**B**

| | |
|---|---|
| BAC | Blood alcohol concentration |
| BAL | Bioartificial liver device |
| BBB | Blood-brain barrier |
| BCAA | Branched-chain amino acid |
| BCS | Budd-Chiari syndrome |
| BELS | Berlin extracorporeal liver support |
| BICAP | Bipolar circumactive probe |
| BLSS | Bioartificial liver support system |
| BMI | Body mass index |
| BRIC | Benign recurrent intrahepatic cholestasis |

| | |
|---|---|
| BSEP | Bile salt export pump |
| BSR | Blood sedimentation rate (= ESR) |
| BUN | Blood urea nitrogen |
| BW | Body weight |

**C**

| | |
|---|---|
| CAGE | Alcoholism test |
| CAH | Chronic active hepatitis |
| CAM | Cell adhesion molecule |
| cAMP | Cyclic adenosine monophosphate |
| CBAT | Canalicular bile acid transporter |
| CBG | Corticosteroid-binding globulin |
| CC | Cystadenocarcinoma |
| CCC | Cholangiocellular carcinoma |
| CDCA | Chenodeoxycholic acid |
| CDK | Cyclin-dependent kinase |
| CDT | Carbohydrate-deficient transferrin |
| CEA | Carcinoembryonic antigen |
| CEDS | Colour-encoded Doppler sonography |
| CEP | Congenital erythropoietic porphyria |
| CESD | Cholesterolester storage disease |
| CET | Caffeine elimination test |
| CETP | Cholesterolester transfer protein |
| CF | Cystic fibrosis |
| CFR | Complement fixation reaction |
| CFT | Complement fixation test |
| CFTR | Cystic fibrosis transmembrane regulator |
| cGMP | Cyclic guanosine-3', 5'-monophosphate |
| CH | Cavernous haemangioma |
| ChE | Cholinesterase |
| CHBV | Crane hepatitis B virus |
| CHP | Chronic hepatic porphyria |
| CIBD | Chronic inflammatory bowel disease |
| CLH | Chronic lobular hepatitis |
| CLL | Chronic lymphatic leukaemia |
| CM | Contrast medium |
| CML | Chronic myeloid leukaemia |
| CMV | Cytomegalovirus |
| CNDC | Chronic non-suppurative destructive cholangitis |
| CNS | Central nervous system |
| CO | Cardiac output (vol./min) |
| CPH | Chronic persistent hepatitis |
| CREST | Calcinosis-Raynaud-esophagus-sclerodactyly-telangiectasia syndrome |
| CRP | C-reactive protein |
| CSF | Cerebrospinal fluid |
| CSH | Chronic septal hepatitis |
| CSI | Cholesterol saturation index |
| CT | Computer tomography |
| CTAP | CT arterioportography |
| CTL | Cytotoxic T lymphocyte |
| CVP | Central venous pressure |
| CYP | Cytochrome P-450 |

**D**

| | |
|---|---|
| DBP | Vitamin D-binding protein |
| DCP | Des-gamma-carboxy prothrombin |
| DCP | Divalent cation transporter |
| DDT | Dichlorodiphenyltrichloroethane |
| DHBV | Duck hepatitis virus |

| | |
|---|---|
| DIC | Disseminated intravascular coagulation |
| DLPC | Dilinoleoylphosphadidylcholine |
| DNA | Deoxyribonucleic acid |
| DOD | Degree of disability |
| DRQ | DeRitis quotient |
| DSA | Digital subtraction angiography |

**E**

| | |
|---|---|
| EBV | Epstein-Barr virus |
| EC | Elimination capacity |
| ECLP | Extracorporeal liver perfusion |
| ECM | Extracellular matrix |
| ECP | Erythropoietic coproporphyria |
| ECS | Extracellular space |
| EDRF | Endothelium-derived relaxing factor |
| EDTA | Ethylenediaminetetraacetic acid |
| EEG | Electroencephalography |
| EEP | Endogenous evoked potentials |
| EGF | Epidermal growth factor |
| EHP | Erythrohepatic porphyria |
| EHT | Electrohydrothermic probe |
| EIA | Enzyme immunoassay |
| ELAD | Extracorporeal liver assist device |
| ELISA | Enzyme-linked immunosorbent assay |
| EPL | Essential phospholipids |
| EPP | Erythropoietic protoporphyria |
| ER | Endoplasmic reticulum |
| ERC | Endoscopic retrograde cholangiography |
| ET | Endothelin |
| EUS | Endoscopic ultrasound |

**F**

| | |
|---|---|
| FA | Fatty acid |
| FBP | Folate-binding protein |
| FENa | Fractional sodium excretion |
| FFA | Free fatty acid |
| FFP | Fresh frozen plasma |
| FGF | Fibroblast growth factor |
| FHCC | Fibrolamellar hepatocellular carcinoma |
| FHF | Fulminant hepatic failure (= ALF) |
| FHVP | Free hepatic venous pressure |
| FIA | Fluorescence immunoassay |
| FM | Fibrin monomer |
| FNB | Fine needle biopsy |
| FNH | Focal nodular hyperplasia |

**G**

| | |
|---|---|
| GABA | Gamma-aminobutyric acid |
| GBV | GB-Virus |
| GDH | Glutamate dehydrogenase |
| GEC | Galactose elimination capacity |
| GFR | Glomerular filtration rate |
| GGT | Gamma-glutamyl transpeptitase |
| GHRF | Growth hormone-releasing factor |
| GOT | Glutamic oxaloacetic transaminase (= AST) |
| GPT | Glutamic pyruvic transaminase (= ALT) |
| GSH | Reduced glutathione |
| GSHV | Ground squirrel hepatitis virus |
| GSSG | Oxidized glutathione |
| GVHD | Graft-versus-host disease |

**H**

| | |
|---|---|
| HAI | Hepatitis activity index |
| HAV | Hepatitis-A virus |
| HBDH | $\alpha$-Hydroxybutyrate dehydrogenase |
| HBIG | Hepatitis-B immunoglobulin |

| | |
|---|---|
| HBP | Hepatic binding protein |
| HBSS | Hepatobiliary sequence scintigraphy |
| HBV | Hepatitis-B virus |
| HCC | Hepatocellular carcinoma |
| HCP | Hereditary coproporphyria |
| HCV | Hepatitis-C virus |
| HDL | High-density lipoprotein |
| HDV | Hepatitis-D virus |
| HE | Hepatic encephalopathy |
| HEP | Hepatoerythropoietic porphyria |
| HES | Hydroethyl starch |
| HEV | Hepatitis-E virus |
| hFABP | Hepatic fatty acid-binding protein |
| HGBV | Hepatitis-GB virus |
| HGF | Hepatocyte growth factor |
| HGV | Hepatitis-G virus |
| HHBV | Heron hepatitis B virus |
| HHC | Hereditary haemochromatosis |
| HIV | Human immunodeficiency virus |
| HL | Half-life |
| HLA | Human leucocyte antigen |
| HLT | Heterotopic liver transplantation |
| HMG-CoA | Hydroxymethylglutaryl-CoA |
| HMV | Heart minute volume |
| HPI | Hepatic proliferation inhibitor |
| HPLC | High-pressure liquid chromatography |
| HPS | Hepatopulmonary syndrome |
| HRGP | Histidine-rich glycoprotein |
| HRQL | Health-related quality of live |
| HRS | Hepatorenal syndrome |
| HSS | Hepatic stimulatory substance |
| HSV | Herpes simplex virus |
| HTL | Hepatic triglyceride lipase |
| HVF | Hepatocyte volume fraction |
| HVPG | Hepatic vein pressure gradient |

**I**

| | |
|---|---|
| IBC | Iron-binding capacity |
| IBP | Iron-binding protein |
| ICAM | Intercellular adhesion molecule |
| ICDH | Isocitrate dehydrogenase |
| ICG | Indocyanine green |
| ICP | Intracranial pressure |
| ICS | Intracellular space |
| ICU | Intensive care unit |
| IDL | Intermediate density lipoprotein |
| IDUS | Intraductal ultrasound |
| IFN | Interferon |
| IFT | Immunofluorescence test |
| IGF | Insulin-like growth factor |
| IHAT | Indirect haemagglutination test |
| IL | Interleukin |
| INR | International normalization ratio |
| IOUS | Intraoperative ultrasound |
| IRF | Iron regulation factor |
| ISC | Iron saturation capacity |
| IU | International unit |

**K**

| | |
|---|---|
| KB | Ketone bodies |
| kDa | Kilo-Dalton |
| KKS | Kallikrein-kinin system |

**L**

| | |
|---|---|
| LAM | Lamivudine |
| LAP | Laparoscopy |
| LAP | Liver active protein |

| | |
|---|---|
| LAP | Leucine aminopeptidase |
| LASER | Light amplification by stimulated emission of radiation |
| LB | Liver biopsy |
| LCAT | Lecithin-cholesterol acyl transferase |
| LCT | Lipiodol-computer tomography |
| LD | Lethal dose |
| LDH | Lactate dehydrogenase |
| LDL | Low-density lipoprotein |
| LDLT | Living donor liver transplantation |
| LE | Lupus erythematosus |
| LFA | Lymphocyte function antigen |
| LFT | Liver function test |
| LIP | Liver inhibitor protein |
| LITT | Laser-induced thermotherapy |
| LKM | Liver-kidney microsomal antigen |
| LMA | Liver membrane autoantibody |
| LPA | Liver-pancreas antibody |
| LPL | Lipoprotein lipase |
| LP X | Lipoprotein-X |
| LR | Liver resection |
| LSP | Liver-specific protein |
| LT | Liver transplantation |
| LTC | Laparoscopic transhepatic cholangiography |
| LTT | Line-tracing test |
| LTT | Lymphocyte transformation test |
| LWW | Liver wet weight |

### M

| | |
|---|---|
| MALT | Munich alcoholism test |
| MALT | Mucous membrane associated lymphoid tissue |
| MAO | Monoamine oxidase |
| MARS | Molecular adsorbend recirculatory system |
| MAST | Michigan alcoholism screening test |
| mAST | Mitochondrial aspartate aminotransferase (= m-GOT) |
| MBq | Megabecquerel |
| MCL | Midclavicular line |
| MCT | Medium-chain triglyceride |
| MCV | Mean corpuscular volume |
| MEGX | Monoethylglycinexylidide test |
| MELS | Modular extracorporeal liver support |
| MEOS | Microsomal ethanol-oxidizing system |
| MFH | Malignant fibrous histiocytoma |
| mGOT | Mitochondrial glutamic-oxalacetic transaminase (= mAST) |
| MHC | Major histocompatibility complex |
| MIGET | Multiple inert gas elimination technique |
| MMP | Matrix metalloproteinase |
| MOAT | Multi-organic anion transporter |
| MPS | Mononuclear phagocyte system |
| MRC | Magnetic resonance cholangiography |
| MRI | Magnetic resonance imaging (= MRT) |
| mRNA | Messenger RNA |
| MRP | Multi-drug resistance-associated protein |
| MT | Metallothionein |
| MTP | Microsomal triglyceride transfer protein |

### N

| | |
|---|---|
| NAD | Nicotinamide adenine dinucleotide |
| NADP | Nicotinamide adenine dinucleotide phosphate |
| NAFLD | Non-alcoholic fatty liver disease |
| NASH | Non-alcoholic steatohepatitis |
| NCT | Number-connection test |
| nDNA | Nuclear DNA |
| NHL | Non-Hodgkin lymphoma |
| NLCT | Number-letter combination test |
| NO | Nitrous oxide |

| | |
|---|---|
| NRH | Nodular regenerative hyperplasia |
| NSAR | Non-steroidal antirheumatics |
| NU | 5'-Nucleotidase |

### O

| | |
|---|---|
| OA | Ornithine aspartate |
| OATP | Natrium-independent transport system for organic anions |
| OCT | Ornithine carbamoyltransferase |
| OGTT | Oral glucose tolerance test |
| OLS | Overlap syndrome |
| OLT | Orthotopic liver transplantation |
| ORF | Open reading frame |

### P

| | |
|---|---|
| PAF | Platelet-activating factor |
| PAH | Para-aminohippuric acid |
| PAI | Percutaneous acetic acid injection |
| PAIR | Punction/Aspiration/Injection/Re-Aspiration |
| pANCA | Perinuclear antineutrophilic cytoplasmic antibody |
| PAP | Pulmonary artery pressure |
| PAS | Para-aminosalicylic acid |
| PAS | Periodic acid-Schiff reaction |
| PBC | Primary biliary cirrhosis |
| PBG | Porphobilinogen |
| PCB | Polychlorinated biphenyl |
| PCNA | Proliferating cell nuclear antigen |
| PCO$_2$ | Partial pressure carbon dioxide |
| PCP | Pentachlorophenol |
| PCR | Polymerase chain reaction |
| PCT | Porphyria cutanea tarda |
| PCWP | Pulmonary capillary wedge pressure |
| PDGF | Platelet-derived growth factor |
| PDR | Plasma disappearance rate |
| PEEP | Positive end-expiratory pressure |
| PELAM | Platelet endothelial cell adhesion molecule |
| PEI | Percutaneous ethanol injection |
| PEM | Protein-energy malnutrition |
| PET | Positron emission tomography |
| PG | Prostaglandin |
| PHI | Phosphohexose isomerase |
| Pi | Protease inhibitor |
| P III-P | Procollagen-III-peptide |
| PMN | Polymorphonuclear neutrophilic leucocytes |
| PPC | Polyenylphosphatidylcholine |
| PPH | Primary pulmonary hypertension |
| PPSB | Prothrombin complex (prothrombin, proconvertin, Stuart factor, antihaemophilic factor B) |
| PSC | Primary sclerosing cholangitis |
| PSE | Portosystemic encephalopathy |
| PT | Prothrombin time (= Quick) |
| PTC | Percutaneous transhepatic cholangiography |
| PTH | Parathormone |
| PTP | Percutaneous transhepatic portography |
| PTT | Partial thromboplastin time |
| PVC | Polyvinyl chloride |
| PVS | Peritoneovenous shunt |

### Q

| | |
|---|---|
| QOL | Quality of life |

### R

| | |
|---|---|
| RAAS | Renin-angiotensin-aldosterone system |
| RAST | Radio-allergo-sorbent test |
| RBP | Retinol-binding protein |

| | | | | |
|---|---|---|---|---|
| RCE | Reduction in earning capacity | | TIPS | Transjugular intrahepatic portosystemic shunt |
| REE | Resting energy expenditure | | TNF | Tumour necrosis factor |
| RER | Rough endoplasmic reticulum | | TNM | Malignant tumour classification system (tumour, node, metastasis) |
| RES | Reticuloendothelial system | | | |
| RFTA | Radiofrequency thermal ablation | | tPA | Tissue plasminogen activator |
| RHS | Reticulohistiocytic system | | TPT | Thromboplastin time |
| RIA | Radioimmunoassay | | TRH | Thyreotropin-releasing hormone |
| RIBA | Recombinant immunoblot assay | | tRNA | Transfer RNA |
| RNA | Ribonucleic acid | | TSH | Thyroid-stimulating hormone |
| RNF | Renal natriuretic factor | | TT | Thrombin time |
| ROI | Reactive oxygen intermediates | | TTR | Transthyretin |
| rRNA | Ribosomal RNA | | TUDCA | Tauro-ursodeoxycholic acid |
| RT-PCR | Reverse transcription-polymerase chain reaction | | TVC | Transvenous cholangiography |

**S**

| | |
|---|---|
| SAMe | S-adenosylmethionine |
| SBP | Spontaneous bacterial peritonitis |
| SDH | Sorbitol dehydrogenase |
| SeHCAT | Selenohomotaurocholic acid test |
| SEP | Somatosensory evoked potentials |
| SER | Smooth endoplasmic reticulum |
| SLA | Soluble liver cell antigen |
| SLT | Split liver transplantation |
| SMA | Smooth muscle antibody |
| SOD | Superoxide dismutase |
| SOL | Space-occupying lesion |
| SPECT | Single-photon emission computer tomography |
| SQUID | Superconducting quantum-interference device |
| SSC | Secondary sclerosing cholangitis |
| STD | Sexually transmitted disease |
| STH | Somatotropic hormone |
| STP | Standard temperature (0 °C) and pressure (760 mg Hg) |
| SVR | Sustained viral response |

**U**

| | |
|---|---|
| UDCA | Ursodeoxycholic acid |
| UDP | Uridine diphosphate |
| UES | Undifferentiated embryonal sarcoma |
| uPA | Urokinase plasminogen activator |
| US | Ultrasound |
| UTP | Uridine triphosphate |
| UV | Ultraviolet |
| UW | University of Wisconsin solution |

**V**

| | |
|---|---|
| VBDS | Vanishing bile duct syndrome |
| VC | Vinyl chloride |
| VCAM | Vascular cell adhesion molecule |
| VEGF | Vascular endothelial growth factor |
| VEP | Visually evoked potentials |
| VIP | Vasoactive intestinal polypeptide |
| VLDL | Very low-density lipoprotein |
| VOD | Veno-occlusive disease |
| VZV | Varicella-zoster virus |

**T**

| | |
|---|---|
| TAC | Transarterial chemotherapy |
| TACE | Transarterial chemoembolization |
| TAE | Transarterial embolization |
| TBG | Thyroxine-binding globulin |
| TCDD | Dioxin |
| TGF | Transforming growth factor |
| TIBC | Total iron-binding capacity |
| TIMP | Tissue inhibitor metalloproteinase |

**W**

| | |
|---|---|
| WAIS | Wechsler adult intelligence scale |
| WHV | Woodchuck hepatitis virus |
| WHVP | Wedged hepatic venous pressure |
| WNV | West Nile virus |

**Y**

| | |
|---|---|
| YF | Yellow fever |
