# Dedications

I have dedicated the **German edition** of the book "Praktische Hepatologie" (1998) to:

my unforgettable son *Hans-Dieter*

whose knowledge and manual skill I have always admired,

whose critical as well as creative ideas for our joint book were so valuable,

who did not live to see the completion of this, our work as a co-author

*dedicated in love and gratitude*

The 1st **English edition** of the book "Hepatology · Principles and Practice" (2002) is dedicated − also at my son's request − to:

Dr. med. Dr. rer. nat. *Herbert Falk* (Freiburg)

the most generous patron of hepatological research and further education,

the initiator of worldwide, international hepatology

*dedicated in admiration and friendship*
The 2nd **English edition** of the book "Hepatology · Principles and Practice" (2006) is dedicated to:

Prof. Dr. med. *Heribert Thaler* (Vienna)

who has united the histopathologic and clinical aspects of hepatology in such an excellent manner,

of whom I have learned so much in many years of friendship

*dedicated in esteem and cordiality*

V
# Authors

**Prof. Dr. med. Dr. med. h. c. Erwin Kuntz**
The author spent the first 16 years of his clinical career at the Medical University Hospital in Giessen (6 years as senior physician). Then followed 20 years as head physician at the Internal Department of the Academic Hospital in Schwäbisch Hall and at the Internal Department of the Academic Hospital in Wetzlar. For 45 years, he has taken an active part in the postgraduate education of physicians; he has been an organizer of numerous scientific congresses. He has received more than 20 national and international awards and honorary memberships as well as the Honorary Doctorate of the University of Debrecen/Hungary, the "Great Merit Cross of the Federal Republic of Germany" and the "Great Merit Cross of the Republic of Italy".

**Prof. Dr. med. Hans-Dieter Kuntz**
The co-author was certified as a specialist in internal medicine at the Academic Hospital in Duisburg. In 1980, he obtained the qualification of gastroenterology and became senior physician at the Department of Gastroenterology/Hepatology of the University Hospital in Bochum. As from 1989, he was head physician at the Department of Internal Medicine and Gastroenterology at Augusta Academic Hospital in Bochum. His many activities included the postgraduate education of physicians for 17 years. He was granted honorary membership of the Society of Gastroenterology of Uruguay (1993) and became a Fellow of the European Board of Gastroenterology (EUMS) (1996).

# Preface to the second edition

Originally, it was the intention of both my son and me that the German edition of "Praktische Hepatologie" should be followed by an English translation. After Hans-Dieter's premature death due to a serious illness, I made it my aim to complete an English-language version of the textbook by myself, knowing that this would have been his great wish. The memory of my dear son was an inspiration to me in my efforts at all times.

It was a great sense of achievement for both author and publisher that the first edition (2002) was sold out within such a short period and that a reprint was necessary. This fact, supported by the positive response shown directly by readers and reviewers, was the main motivation to prepare a second edition.

A decision was made to keep the well-established division of hepatology into six specialist areas; once again, forty chapters were used. Each chapter has been revised and updated with regard to content and language. At the beginning, there is a detailed table of contents and, at the end, a list of references. Like its predecessor, the second edition contains a visually comprehensive arrangement of the text into sections, incorporating various script sizes and types as well as 306 tables in half-tone colouring; significant conclusions are set in coloured boxes. A big, black dot is inserted whenever the following sentence represents a semantic leap from the preceding statement. (For further details regarding the structural concept of the chapters, see preface to 1st edition, page VII, paragraph 2.)

Altogether, about 7,000 references have been cited, of which some 1,500 have been replaced by more recent papers, including many from 2005. The Vancouver-style layout has been used again, since it proved to be clear and easy to read. (For further details regarding the extensive bibliography, see preface to 1st edition, page VII, paragraph 3.)

Every effort has been made to maintain and improve the concept of citing, whenever possible, the first-time authors of syndromes, clinical entities, morphological or clinical findings, imaging or endoscopic techniques and conservative or surgical measures. (For further details, see preface to 1st edition, page VII, paragraph 4.)

The number of coloured figures has been increased by 97 to a total of 477; developments in printing techniques make possible an even more colourful presentation with brilliant reproduction. All the figures are integrated in the text-flow. In this way, a hepatological atlas has been created, leading from "seeing" to "understanding", thereby facilitating diagnostic and therapeutic "acting".

My special thanks for their friendly assistance and helpful advice go to the pathologists Prof. Dr. H.-P. Fischer (Bonn) and Prof. Dr. G. Korb (Weiden), the radiologist Prof. Dr. K. Rauber (Wetzlar), the hepatologist Prof. Dr. J. Eisenburg (Munich), the virologist Prof. Dr. G. Berencsi (Budapest), the immunologist Prof. Dr. W. Storch (Weinheim) and the gastroenterologist Dr. G. Schmidt (Kreuztal). (In addition, numerous colleagues offered their support in preparing the first edition; they are named in the preface to 1st edition − see page VII, paragraphs 5 and 6.)

The abbreviations or symbols frequently used in the text are listed in the preface to the first edition (see page VIII).

All my personal thoughts and emotional feelings, which were written down in the first edition, are unchanged. This applies also to the two quotations from PARACELSUS at the beginning and end of the book. But, above all, how extremely happy and proud I would have been if my son Hans-Dieter could have joined me as co-author in achieving our common aim.

It is my sincere wish that this textbook will not only promote interest in the field of hepatology, but also deepen understanding of pathophysiological and morphological changes regarding liver as well as supporting successful application of the various diagnostic and therapeutic possibilities.

Finally, I should like to express my gratitude to the employees at Springer Publishing House (Heidelberg) for their professional help in completing this book, especially to Hinrich Küster, senior editor, and Meike Seeker, project manager, who gave their encouragement and kind support at all times.

Wetzlar, October 2005                    Erwin Kuntz

# Foreword to the second edition

The first edition of "Hepatology: Principles and Practice" by Erwin Kuntz, which appeared in 2002, was rapidly sold out. This was not astonishing since the textbook offered a comprehensive, lucid and scholarly presentation of liver disease. Informative figures and tables made reading a pleasure. The second edition has now been revised and updated to 2005 by Erwin Kuntz. Once again, the author, a distinguished hepatologist, has produced an encyclopedic masterpiece of hepatology. The book combines a complete scientific and historical discussion of the many aspects of hepatology together with the wise insight of a physician who has enormous practical experience in caring for patients with liver disease.

The second edition has been enlarged to more than 900 pages, a change necessitated by the enormous increase in our understanding of liver disease. The number of references that are cited now stands at 7,000; references are given in full and in alphabetical order, a feature that will prove most helpful to physicians engaged in teaching and research. The judicious use of color for figures and tables made the first edition extremely attractive to the reader. This practice is continued in the second edition which contains a further 97 figures and 30 tables, making a total of 477 figures and 306 tables. A special feature is the quality of the superb laparoscopic and histological pictures. Indeed, the colored figures are of such superior quality that they can be scanned directly for computer-based presentations. The histological illustrations are especially valuable as the number of autopsies and liver biopsies continues to decline worldwide. Moreover, these illustrations have been integrated perfectly into the text. The publishers, true to their long tradition, have done justice to the quality of this work in every way. The book is not only a true handbook of liver disease, but also a hepatological atlas.

Like its predecessor, the second edition also comprises 40 chapters. At the beginning of each chapter, there is a complete table of contents, which, together with the general index, makes it possible for the reader to find specific topics easily. The first chapter "History of Hepatology" is an indication of the depth and breadth of the knowledge which the author brings to the current edition. This chapter contains a richness of historical illustrations depicting the birth of knowledge of this multifaceted organ. The following chapters of the book show the profound knowledge and interest of Erwin Kuntz in the multiple spectra of hepatology. Each topic shows the evolution of our knowledge and acknowledges by name the individuals who contributed to our present knowledge. In this way, hepatology is not only discussed as a contemporary branch of internal medicine, but also related to the pioneering achievements of our ancestors, who deserve our full respect and recognition. The historical emphasis is global, rather than European. Throughout the book, detailed histological depictions of hepatic pathology have been fused with scientific aspects and clinical procedures. All forms of treatment have been updated, so that this work can be used as a manual of therapy which will be highly useful to both practitioners and teachers.

As Charles S. Lieber, New York, wrote three years ago in his foreword to the first edition, such a textbook could not have appeared at a better time. This statement applies to the second edition in the year 2005. Great progress has been made in hepatology with regard to diagnostics and therapy, and consequently, the number of publications dealing with, for example, the treatment of viral hepatitis has grown immensely. Likewise, there is much new information on the pathogenesis of autoimmune liver diseases and so-called overlap syndromes. Thus it is essential that the current body of knowledge is presented in an intensive and accurate form.

It is a pleasure to know Prof. Dr. Erwin Kuntz personally. His enthusiasm for hepatology is contagious and can be sensed in every chapter. To be shown his enormous private library and pictorial archive is a moving experience. This impressive collection contains important papers and original monographs of authors from past and present and provides the data base for this fascinating textbook.

We would like to wish this new edition from Erwin Kuntz the same resounding success which was enjoyed by the first edition. We are convinced that the book will not only find its place in every medical library, but also be consulted repeatedly by scientists and physicians who seek to understand how we can use its contents to improve the care of our patients with liver disease.

# Preface to the first edition

It is a wonderful experience for a father to work with his son on an enormous number of lectures, seminars, courses, congresses and publications over a period of many years. For a total of 35 (overlapping) years we were both active as clinicians in the field of hepatology. From this experience arose our wish to co-author a book on this fascinating subject. We were greatly encouraged in this project by friends and colleagues. • The joint work, supported by an extensive personal archive, a large number of clinical, endoscopic and morphological illustrations, and documentation of imaging technique findings, is intended to serve as a *teaching manual*, a *textbook*, and a *reference book* − for use in the doctor's surgery, in daily clinical practice, and in the specialist fields associated with hepatology.

After weighing up the various approaches and objectives of the book, the *concept* of subdividing the subject matter into 40 self-contained chapters presented itself. We set value on: − a systematic structure of the chapters, − a coherent presentation of facts and evidence, − a visually comprehensible arrangement of the text into sections, incorporating various script sizes and types, − half-tone colouring of tables and conclusions considered to be of exceptional importance, − consistent cross-referencing of figures, tables and text between different chapters, and the incorporation within the text of 276 tables, 380 figures, and numerous boxed texts (all in colour). • A big, black dot is inserted whenever the following sentence represents a mental leap from the preceding statement, which enables a more structured approach. • Our constant aim was to improve the readability and clarity of the book.

Each chapter has an extensive *bibliography*. We used a modified Vancouver-style layout, which we consider clear and easy to read. Authors' names (all authors are listed in full in the chapter bibliography) appear in semi-bold type and are ordered alphabetically for easy reference. As far as possible, we subdivided more extensive chapter bibliographies thematically. A total of 7,300 *publications* up to 2001 are cited. This detailed bibliography is intended to assist the interested reader in exploring specific areas in more depth. • We have therefore included both historical references and those older publications which we consider of particular significance or interest − there is always the danger, in hepatology as well as in other fields, that such works might regrettably become victims of our fast-moving times. There is certainly a subjective influence in this selection, and in this context any additions or corrections to the bibliography will be gratefully received.

A further conceptual concern was to cite, whenever possible, the *first authors* of publications on syndromes, clinical research, laboratory parameters, imaging or endoscopic techniques, morphological findings of special interest, and conservative, invasive and surgical procedures (and to correct previous information given in the literature). In the past, the creative or innovative ideas of these inaugurators have often led directly to significant progress or have served as a new starting point for subsequent, ground-breaking developments. Despite arduous research, it has not always been possible to attribute work correctly to the first author(s). Yet, the notable achievements of earlier physicians, clinicians and scientists deserve to be remembered with respect! In this connection, further information or corrections will be welcomed.

The extensive selection of *colour illustrations* incorporated into the text covers a wide range of clinical and morphological findings in hepatology: it is designed to lead from *"seeing"* to *"understanding"*, thereby facilitating diagnostic and therapeutic *"acting"*. Although we had collected an extensive picture archive of our own over a period of more than 30 years of clinical practice, we were nevertheless able to complement this and close any gaps thanks to numerous illustrations and impressive findings generously made available to us by colleagues. My special thanks for their friendly assistance go to the pathologists Prof. Dr. H.-P. Fischer (Bonn) and Prof. Dr. O. Klinge (Kassel), and to the radiologists Prof. Dr. K. Rauber (Wetzlar) and Prof. Dr. R. Heckemann (Bochum). Some very valuable documentations of findings could be used by courtesy of Prof. Dr. J. Eisenburg (Munich), Prof. Dr. K.-M. Müller (Bochum), Prof. Dr. G. Piekarski (Bonn), Prof. Dr. H. Thaler (Vienna), Prof. Dr. G. Volkheimer (Berlin), Prof. Dr. O. Vorländer (Berlin), and Prof. Dr. W. Wermke (Berlin).

We repeatedly enlisted the *helpful advice* of friends and colleagues to supplement or confirm our own interpretations. Our opinions not infrequently diverged (and in the field of hepatology, this can only be an advantage) and personal opinions were modified or confirmed. The contacts arising from these discussions have been immensely rewarding to me. Here I should like to express my special thanks to: Prof. Dr. G. Berencsi (Budapest), Prof. Dr. R. Klein (Tuebingen), Prof. Dr. H. K. Seitz (Heidelberg) and Prof. Dr. W. Storch (Weinheim). • Very many thanks for advisory support also go to: Prof. Dr. H.-R. Duncker (Institute of Anatomy, Univ. of Giessen), Priv. Doz. Dr. Marietta Horster (Institute of Classics and Ancient History, Univ. of Cologne) and Prof. Dr.

N. Katz (Institute of Biochemistry, Univ. of Giessen). • Receiving such varied and kind assistance and advice has filled me with gratitude and encouragement during the years spent compiling this book.

In preparing the book my thoughts and my loving gratitude have constantly been with *my son*, *Hans-Dieter*, whose death was so sudden and incomprehensible to us all. I have tried to represent his inspirations and detailed ideas as well as incorporating his particular clinical insights. This volume is thus our joint life's work. He will always be remembered as an example to us all.

At the beginning and end of the book I have purposely cited two quotations from Paracelsus which have always made a deep impression on me. • In the course of such intensive engagement with the history of hepatology, one is repeatedly filled with respect and admiration for how our forebears, solely through sight, hearing and touch, and an ingenuity of methods − and through logical deduction − drew medical conclusions, recognized correlations and established an astounding body of theoretical and practical knowledge. Many of these empirical findings were subsequently confirmed − some (still) remain "empirical", without, however, having been disproved. *"Empiricism, Intuition and Logic"* (R. Gross, Cologne, 1988) will always be the leitmotif of the physician! • The considerable and fascinating developments in hepatology, especially those of the last ten years, remain a central theme. • The current stage of this development may well become known as the 4th (biomolecular) epoch of hepatology, as I have proposed in the first chapter of our book.

Finally, my thanks to the employees at *Springer* for the speedy completion of this book and especially to Jörg Engelbrecht and Dr. Dorothee Guth for their encouragement and kind support at all times.

Wetzlar, July 2001                                    Erwin Kuntz

Frequently used *abbreviations* and *symbols* in the textbook are listed in alphabetical order below:

| s. fig. | see figure | ca. | circa | a.-v. | arterio-venous |
| s. figs. | see figures | e. g. | exempli gratia, for example | N.B. | nota bene, important |
| s. p. | see page | etc. | et cetera, and so on | i. m. | intramuscular |
| s. pp | see pages | i.e. | id est, that is | i. v. | intravenous |
| s. tab. | see table | quot. | quoted, quotation | s. c. | subcutaneous |
| s. tabs. | see tables | vs | versus | v. v. | vice versa, conversely |

As regards the *half-tone colouring* and colour intensity, blue is used − as far as possible − for normal findings, classification, causes, indications, therapy regimen, etc., red applies to pathological findings, contraindications, complications, side effects, etc., yellow to methods, test procedures, etc., and grey to historical details.

Medical and technical terms, orthography and hyphenation in this textbook are based on: (*1.*) P. Procter (editor): Cambridge International Dictionary of English (Cambridge Univ. Press) 1999, 3rd edition; (*2.*) J. Crowther (editor): Oxford Advanced Learner's Dictionary (Oxford Univ. Press), 1999, 5th edition; (*3.*) J. Dorland, W. A. Dressler (editor): Dictionary of Clinical Medicine (Chapman & Hall, London, et al.), 1996.

# Foreword to the first edition

The textbook "Hepatology. Principles and Practice" by Erwin Kuntz and Hans-Dieter Kuntz will undoubtedly become an international landmark. It reflects the scholarship, encyclopedic knowledge of the authors and the outstanding craftsmanship of the publishers. Professor Erwin Kuntz's stature was not only well established in Germany and the rest of Europe but his fame had crossed the Atlantic and I have known of him for many years. I also had the privilege of getting acquainted with him personally at an international meeting on phospholipids in Cologne in 1989 where I had the pleasure of enjoying both his intellectual and his broad humanistic qualities.

The book is not only an unusual combination of an extremely thorough textbook of all aspects of hepatology, including important pathogenic mechanisms and their clinical application, but it also has a very didactic approach which effectively highlights most points while not neglecting those details the academician or practitioner may want to find for needed clarification. It synthesizes more than 30 years of practical experience in clinical hepatology. Accordingly, it can be used as a teaching manual for students, postgraduate clinicians and practitioners, as a textbook for internists, gastroenterologists and hepatologists, as well as a reference book for teachers, scientists and authors. The original text has been revised and updated to 2000/2001. The bibliography now consists of about 7,300 papers and the number of colored figures has been increased to 380. It is a distillate of hundreds of personal publications and presentations and thousands of literature references of classic and contemporary scholars. The information is presented in such a way that it makes the facts very accessible and the chore of retrieval becomes a pleasure. The very vivid display of information gives unique insights providing a very rational approach to the practice of hepatology. This volume brilliantly achieves the basic aim of its authors, which is to guide the user from "seeing" to "understanding" and finally to "acting".

The book could have come at no better time. There is real blossoming of hepatology worldwide and its importance has increased logarithmically with the availability of transplantation and the pandemic of hepatitis C, with effective treatments finally evolving. Diagnostic procedures have also gained much greater sophistication and "interventional" hepatology is now finally on the rise. Being familiar with German, I had the pleasure of enjoying the original textbook but felt envious that this opus was limited to those fluent in that language. I am delighted to see that this work will now be shared worldwide in an English edition which has been thoroughly updated, with the most recent concepts and therapies reported and carefully assessed. Its comprehensive yet crisp and clear presentation will open the gates of hepatology to all health professionals. Last but not least, this work represents the highly humanistic qualities of its authors and is obviously an act of life time love, with abundant citations not only to our modern masters, but also giving proper credit to those who preceded them. Hippocrates already stated that the liver was the site of the soul; it is obvious that both Erwin Kuntz and his son, Hans-Dieter, have put their souls in this opus.

Charles S. Lieber M.D., M.A.C.P.
Professor of Medicine and Pathology
Mount Sinai School of Medicine
Director, Alcohol Research Center &
Section of Liver Disease & Nutrition
Bronx VA Medical Center
New York, USA

# Contents

*"... because the liver is a source of many diseases, and is a noble organ that serves many organs, almost all of them: so it suffers, it is not a small suffering, but a great and manifold one"*

Theophrastus Bombastus von Hohenheim, known as PARACELSUS (1493−1541)

(Liber tertius paramiri, de morbis ex Tartaro. St. Gallen, 1531)

# 1  History of Hepatology

# 1 History of Hepatology

## Hepatology from ancient to modern times

Over the millennia, the conception of the liver has been subject to more remarkable change than that of almost any other organ. • In antiquity, mantic, religious and speculative thinking combined with anatomical and physiological observations resulted in a most imposing body of knowledge concerning the liver. • The features and disease processes of the liver were described more accurately than in the case of any other organ, and modern medicine has repeatedly afforded resounding confirmation of those ancient observations.

> It may therefore be both interesting and instructive to trace the roots of our present knowledge of hepatology back to antiquity and to commemorate with admiration and respect the tireless spirit of medical and scientific research in this area.

## 1 Liver research in antiquity

> Even in primeval times, the liver must have been well-known as the most powerful and most blood-rich organ of the animal body. Varied and important processes were attributed to this impressive part of the entrails − it was even regarded as the "seat of life". • The Indo-Germanic word "lîp" meant both liver and life, and there are obvious similarities between the English "liver-live/life" (Old English: "lifer-līf") and the German "Leber-Leben". In Old High German, the liver was termed "leb(a)ra". The Hebrew "kábe(r), kábe(d)" (or "cheber") is the probable root of the Greek word "hepar".

### 1.1 Hepatoscopy

Evidently, priests and fortune-tellers at that time became interested primarily in the liver and thus great mantic-religious significance was attributed to this organ. *For the Babylonians and Assyrians, the* **inspection of entrails,** *in reality* **inspection of the liver,** *was the most important method of foretelling events.* This "hepatoscopy" was based on the premise that the god to whom the sacrifice was offered would show his pleasure by revealing the future through variations in the appearance of the sacrificial animal's liver.

The sacrificial priests of Mesopotamia had acquired a precise knowledge of the size, colour and external structure of the animal liver, especially that of the sheep −

the most commonly used sacrificial animal. They assigned specific names to the individual parts of the liver and gall bladder and to their different variations in form and appearance, reflecting similarities to everyday objects such as mountains, rivers, roads, nose, ear, tooth, hand, finger, etc. Hepatoscopy was carried out in accordance with stipulated ceremonial rites and in the face of an image of a god. It was limited to assessing the outer appearance of the liver; the organ itself was not dissected.

The Babylonian sacrificial priests taught the art of hepatoscopy systematically, using specially devised **models of the liver.** These models also served as topographical aids for the mantic interpretation of variations in the appearance of the animal liver. The no doubt oldest clay model of a sheep's liver is from a Babylonian temple and dates from ca. 2000 BC. (s. fig. 1.1) Clearly recognizable on the concave surface are 2 lobes: the coniform gall bladder with the cystic duct and the caudate lobe with the pyramidal process and the smaller papillary process (→). Carved lines divide the lower surface into approximately 40 small, rectangular fields, which contain cuneiform inscriptions of sacral symbols and mantic readings, one of the recurrent themes being *"May your liver be smooth".* • Many of the rectangles show small holes, presumably used to insert tiny wooden pins according to the variations in form observed in the animal liver. Such a topographical fixation of findings facilitated a more accurate prophecy.

***Fig. 1.1:*** Babylonian terracotta model of a sheep's liver with papillary process ( ↓ ), ca. 2000 BC (British Museum, London) (11)

Sumerian culture has also yielded artefacts concerned with hepatoscopy. More than 30 such clay models of the liver with cuneiform inscriptions dating from the 17th

*Fig. 1.2:* Sumerian clay model of the liver, 1700−1600 BC (excavations of Mari) (17)

century BC were found during the excavations of Mari. (17) (s. fig. 1.2)

Further clay models with cuneiform inscriptions dating from the 13th−12th century BC were also unearthed during the excavations of Bogazköy (1933/34). (9) (s. fig. 1.3)

*Fig. 1.3:* Sumerian clay model of the liver, ca. 1260 BC (excavations of Bogazköy) (9)

The art of hepatoscopy spread from Mesopotamia to Greece, where it received widespread acceptance, as evidenced by various illustrations and accounts of the inspection of entrails. Euripides (Elektra, 826−829) described hepatoscopy as follows: *"Aigisthos took the entrails in his hands and inspected them. Now the liver had no head, while the portal vein and nearby gall bladder revealed threatening events to the one who was observing it."* • Hepatoscopy was applied not only in political decision-making, but also in foretelling the medical prognoses and life events of prominent persons. Babylonian hepatoscopy was also referred to in the Old Testament (Ezekiel 21, v. 21): *"For the king of Babylon stood at the parting of the way, at the head of the two ways, to use*

*divination: he made his arrows bright, he consulted with images and he looked at the liver."*

A red-figured illustration on a Greek bellied amphora by Euthymides shows an animal liver being presented to a Greek hoplite before his departure to do battle in the Theban War. (14) (s. fig. 1.4)

*Fig. 1.4:* Red-figured illustration of inspection of the liver on a Greek bellied amphora (14)

The same motif of liver inspection with soldiers departing for battle appears in black on an Attic neck amphora (2) (s. fig. 1.5) as well as on an amphora of pan-Athenian form. (18) (s. fig. 1.6)

*Fig. 1.5:* Black-figured illustration of inspection of the liver on an Attic neck amphora (2)

The Etruscans also appear to have adopted hepatoscopy from the Babylonians and Assyrians. Etruscan fortune-tellers were particularly renowned and served so to speak as teachers of the Romans both in augury and in religious rites. Thus the Etruscans virtually held sole rights to carry out the inspection of the liver (Livius 1, 56, 5). M. T. Cicero (106−43 BC) always referred to the haruspices as "etrusci". Liver models such as that of a sheep's liver cast in bronze (3rd−2nd century BC) and a clay liver model (2nd century BC) (6) have survived from the Etruscan civilization. Circular and radial carved

3

**Fig. 1.6:** Black-figured illustration of inspection of the liver on an Attic amphora of pan-Athenian form (18)

lines can be seen on the former model, forming approximately 40 small subdivisions containing Etruscan symbols and names of gods. In addition, a pear-shaped gall bladder, the pyramidal process and the papillary process are mounted on the flat, stylized depiction of the visceral face of the animal liver. (s. figs. 1.7, 1.8, 1.9)

**Fig. 1.7:** Etruscan model of a sheep's liver in bronze, 300−200 BC (Museo Civico, Piacenza) (6)

**Fig. 1.8:** Etruscan model of a sheep's liver in bronze, 300−200 BC, showing inscriptions (Museo Civico, Piacenza) (6)

Such liver inspections are also depicted on burial urns, vases and hand mirrors. The bearded, winged figure of

**Fig. 1.9:** Etruscan clay model of a liver, ca. 200 BC (excavations of Falerii) (6)

the sacrificial priest KALCHAS, son of Thestor, is shown inspecting an animal liver on an Etruscan bronze mirror. • HOMER once said about him: "He knew what *is*, what *has been*, and what *will be*." (s. fig. 1.10)

**Fig. 1.10:** Etruscan hand mirror in bronze, 500−400 BC: KALCHAS (son of Thestor of Mykene), the most famous of the sacrificial priests, inspects the animal liver with large caudate process; on the table are the trachea and lungs of the sacrificial animal (6)

In addition to the *pyramidal process*, the left and right lobes of the liver (pars hostilis and pars familiaris, respectively) were differentiated. Predictions pertaining to the questioner were derived largely from the appearance of the *pars familiaris*, whereas those concerning his opponent were derived from the *pars hostilis*. On the basis of the presence or absence of specific individual features in the sacrificial liver, favourable and unfavourable influences were defined and weighed up, thereby allowing pronouncement of the final prediction. If the edge of the liver fell towards the right, the imminent recovery of the sick person was assured; furthermore, the questioner would live or survive if the gall bladder was long.

Numerous predictions based on hepatoscopy have proved to be of **historical interest**: the victory of the

emperor Augustus in the naval battle of Actium (31 BC) was predicted by the haruspices on the basis of an enlarged, double gall bladder; by contrast, the absence of a pyramidal process gave advance warning of the death of the consul Marcus Marcellus in the battle against Hannibal (208 BC); this ominous portent also foretold the emperor Caligula his imminent murder (41 AD) and the emperor Claudius his death by poisoning (54 AD) without, however, being able to prevent these assassinations.

> From the Babylonian and Assyrian civilizations to the fall of the Roman Empire − for more than 2,000 years − hepatoscopy was firmly established in the human belief system. It frequently influenced the lives and determined the major decisions of important people, and thus also affected the fate of entire nations and civilizations.

## 1.2 Mythological-speculative medicine

### 1.2.1 Liver as the seat of inner emotions

The Egyptian Papyrus Ebers (ca. 1550 BC) is one of the oldest known medical documents. It contains the first descriptions of the liver in a speculative medical sense and regards it as the seat of inner emotions: *"Four vessels lead to the liver, supplying it with air and water, and, being overfilled with blood, influence the occurrence of all sorts of illness";* or: *"The wrath of the heart results from ebullition of parts of the liver and rectum."*

The Babylonians' medical concept of the liver, based on detailed knowledge of hepatoscopy, was likewise purely speculative. For them, the liver was the seat of emotions, feelings, desires and sexual potency.

Further references to the liver as the seat of emotional life are found in the Old Testament, for example in the lamentations of Jeremiah (Lamentations 2, 11): *"Mine eyes do fail with tears, my bowels are troubled, my liver is poured upon the earth because of the misery of the daughter of my people ..."*

The Greeks similarly perceived the liver as the seat of feelings and rage as well as of the soul. In his "Timaios", Platon (427−347 BC) described the liver as the location of the "desiring soul", which he subordinated to the "rational soul" of the head. (3) Horatius designated the liver as the organ of love (10), whereas Juvenalis saw it as the seat of anger. (12)

► The significance of the liver (and bile) in emotional life is reflected to the present day in the form of **familiar quotations** such as: *„eine Laus über die Leber gelaufen"* (German) (literally: a louse has crawled over his liver; meaning: something is biting him); *„frei von der Leber weg reden"* (German) (literally: to speak straight from the liver; meaning: to speak one's mind); *„sich gelb und grün ärgern"* (German) (literally: to be yellow and green with anger; meaning: to be black with anger); *„die Galle hochkommen lassen"* (German) (literally: it rouses my bile; meaning: it makes me angry or indignant). The possession of "liver spots" (German: „Leberflecken") was attributed to the immoral tendencies of the bearer.

### 1.2.2 Liver and mythology

Mythology dominated the Greeks' medical concept of the liver. Hesiod (8th century BC) and Aischylos (525−456 BC) wrote of **Prometheus**, who was fastened to a rock in the Caucasus mountains by the gods: As a punishment for his having brought back the gift of fire to the mortals, he was chained to a rock, and an eagle came each day (or every second day) to eat away at his liver, which regenerated itself each night (4) − **the first record of the regenerative capacity of the liver!** Such a fate also befell **Tityos**, the son of Gaea, on whose liver two vultures fed in the underworld (s. fig. 1.11) (Odyssey 11, 576−578): *"And I saw Tityos, son of magnificent Gaea, lying on the ground. Over nine roods he stretched, and two vultures sat, one on either side, and tore his liver, plunging their beaks into his bowels, nor could he beat them free. For he had offered violence to Leto, the glorious wife of Zeus."*

**Fig. 1.11:** Vultures devour the liver of Tityos in the underworld; the liver regenerated itself each night

The position of the liver in the right upper abdomen and its close proximity to the diaphragm are described by Homer, and a stab wound in the liver was regarded as a fatal injury. Only when one had taken possession of an enemy's liver was the latter deemed truly dead. Thus Hecuba, craving revenge for her dead son Hektor, demanded the liver of Achilles (Iliad 24, 212). This conception is illustrated throughout the epic (Iliad 11, 579; 13, 412; 17, 349) and particularly in the twentieth stanza (Iliad 20, 469): *"... but he smote him upon the liver with his sword, and forth his life slipped, and the dark blood welling therefrom filled his bosom; and darkness enfolded his eyes as he swooned."*

## 1.3 Natural-philosophical medicine

During the 5ᵗʰ and 6ᵗʰ centuries BC, "logos" began to supersede "mythos" in liver research, as in other fields. • Thus DIOGENES OF APOLLONIA (ca. 430 BC) described a symmetrical vascular supply system, in which the spleen and liver were regarded as a paired double organ. He named the major blood vessel leading from the liver to the right axilla and hand *"hepatitis"* and that which connected the spleen with the left hand *"splenitis"*. Bleeding of the vein running from the right arm to the royal *("basilikos")* inner organ was the recommended treatment for liver disease; this vein is still known as basilic vein even today.

EMPEDOKLES OF AGRIGENT (490−430 BC) viewed the liver as the central organ of both the vascular system and nutrition. The liver was generally accepted as being the site of *biligenesis*, although PHILOLAOS OF CROTON postulated extrahepatic bile production. ANAXAGORAS OF KLAZOMENAE (500−428 BC) believed bile to be the cause of numerous illnesses.

## 1.4 Corpus Hippocraticum

▶ The Hippocratic manuscripts were written not only by HIPPOCRATES (460−377 BC), but by numerous physicians living at different periods of time; they were subsequently compiled into the Corpus Hippocraticum. The medical opinions − including those dealing with the liver − thus often diverge significantly from one another. Common to all Hippocratic physicians, however, is the *"Doctrine of the Fluids"* (cardinal humours), which underlies all their medical postulations. Good health depended on the harmonious mixing, circulation and effects (**"eucrasia"**) of the 4 fluids − blood, yellow bile (choler), mucous and black bile (melancholy) − while a preponderance of or qualitative change in one of the fluids (**"dyscrasia"**) led to illness. Treatment consisted in restoring the "life-balance" (**"diaita"**, i.e. Greek for "dietetics").

The **liver** was held to derive from the transformation of liquid blood into a solid, rigid mass. It comprised 5 lobes, with the gall bladder lying over the 4ᵗʰ lobe. The conception of the sacrificial priests regarding the anatomy of the liver, while known to the Hippocratic physicians, was not further developed medically, yet the few technical terms deriving from these sacrificial priests were subsequently adopted. In accordance with the doctrine of DIOGENES, the vein of the liver was designated *"hepatitis phleps"*; it roughly corresponds to the superior vena cava with its extension to the vein of the right arm. The liver was viewed as the central point of the entire venous system; the intrahepatic branches of a blood vessel were described, and the course of a vein from the navel to the liver(!) was determined. The excretion of bile into the intestine and into the urine was also known.

The Hippocratic physicians used **abdominal palpation** to diagnose a liver disease and already recognized as **symptoms** jaundice, dropsy, decolourized and foul-smelling stools, fever, itching, rumbling of the intestine and upper abdominal pain. Liver pain was believed to derive directly from a folding over of the hepatic lobe. Jaundice, according to their interpretation, resulted from the inundation of the body with bile due to dyscrasia. Dropsy was regarded as a consequence of a melting of the liver. To this excellent collection of symptoms was added the observation that dark stools (tarry stools!) presaged imminent death. Echinococcal infection of the liver was also mentioned. • Indeed, one impressive conclusion was that the consumption of *raw ox liver soaked in honey* was the correct **treatment** for liver disease and night blindness. A liver abscess was to be opened with a red-hot knife (= cautery).

## 1.5 Aristoteles of Stagira

A new epoch in liver research was heralded by the establishment of a comparative approach to anatomy and physiology by ARISTOTELES OF STAGIRA (384−322 BC). He described the extrahepatic bile ducts for the first time and disputed the Hippocratic concept that bile was one of the cardinal fluids of the body and that it caused disease. Bile seemed to him to be an irrelevant secretion. He was the first to distinguish between the hepatic arteries and veins with their open intrahepatic endings and also differentiated the portal vein within the venous system; he introduced the term aorta. ARISTOTELES regarded the task of the liver to be the digestion of food ("pepsis") and the cleansing of the blood, the latter function being supplemented by the lungs. • The liver and lungs were thus conceived as being complementary excretory organs of the body. The functioning of the liver was considered decisive for a person's life span.

## 1.6 Alexandrian School of Medicine

HEROPHILUS OF CHALCEDON (ca. 330−250 BC) already distinguished two hepatic lobes. Although he still believed that the venous vessels originated from the liver, he was the first to describe the portal vein system and to recognize its significance as the draining site of all resorbent intestinal veins.

ERASISTRATUS OF KEOS (ca. 300−250 BC) coined the term *"parenchyma"* (i.e. poured out beside) for liver tissue, based on the belief that it was formed by coagulation of the blood released from the hepatic vessels. For him, however, liver parenchyma was a completely useless structure. He also described for the first time the *"choledochos"*, which he believed absorbed the redundant and rather harmful bile (transported into the liver with the portal vein blood) from the intrahepatic bile ducts, and conducted it away. This separation of bile from blood in the liver was allegedly effected by the different viscosities of the two fluids and the different diameters of the adjacent (!) intrahepatic bile ducts and blood vessels. Stoppage of the bile flow would lead to jaundice (obstructive icterus!) and inflammation of the liver. He attributed the dropsy commonly associated with liver disease to a hardening of the liver, which he termed *"skirros"*: this compressed the intrahepatic vessels, diverting the flow of the watery fluid into the abdomen. Based on this surmise, he rejected the practice of

puncturing an ascites (= paracentesis) as being an unnecessary and non-causal therapeutic measure (!).

## 1.7 Roman Medicine

In the eight volumes of *"De medicina"*, which have been preserved to the present, A. C. CELSUS (ca. 30 BC−50 AD) reviews the entire field of medicine of that time and introduces precise Latin terminology. He supplied an impressive description of liver surgery, which − because of the organ's richness in blood − was already being performed using red-hot ("cautery") knives (!). He termed dropsy *"ascites"* and linked it not only to liver disorders, but also to diseases of the spleen and generally bad health (carcinoma?); he regarded paracentesis to be a good measure. Reflecting the idea of the liver as the "royal" organ, he named jaundice *"morbus regius"*: the diet prescribed for liver patients was so complicated that only royalty could afford such a costly therapy. He recommended bed rest and "psychotherapy" for the treatment of jaundice: *"One should have a good bed in a tasteful room, seek relaxation and good humour, and take heart from the comforting pleasure which will relieve the soul."*

Based on the Corpus Hippocraticum, PLINIUS THE ELDER (23−79 AD) recommended treating liver diseases by means of wolf's liver with honey or by means of donkey's liver with parsley and honey. • Treatment of liver diseases based on the use of poultices and laxatives, which is still known in modern times, dates back to the recommendations of CAELIUS AURELIANUS (5th century AD). He also described the discolouration of urine associated with jaundice.

RUFUS OF EPHESUS (1st−2nd century AD) differentiated the portal vein system and the veins and arteries of the liver. He also regarded yellow bile as a waste product and black bile as the dark sediment of the blood. He even distinguished between febrile and obstructive icterus. He deduced that the term *"icterus"*, already used at that time for jaundice, derived from the bright yellow eyes of the pine marten (iktis). The skin colour of the jaundiced patient was also compared to a yellow stone (ikterios lithos) and to a yellowish-green lizard as well as to a yellow bird called the golden oriole (ikteros), the sighting of which by a jaundiced patient would effect a cure while at the same time killing the bird (as documented about 50 years earlier by PLINIUS THE ELDER [see above]: Nat. Hist. 30, 93). (1, 7, 15, 16)

## 1.8 Galenos of Pergamon

The body of medical knowledge that had accumulated since the 5th century BC and which was in places completely contradictory was now compiled by GALENOS OF PERGAMON (131−201 AD) into an immense work, supplemented and corrected by a wealth of his own investigations. GALENOS (s. fig. 1.12) thus created a phenomenal, self-contained medical system that enjoyed dogmatic validity for over 1,500 years.

▶ GALENOS described the anatomy of the **liver** in greater detail than had ever been done before. In addition to separating the hepatic arteries from the veins, he recognized both the ramifications of the intrahepatic vessels and the capillary junctions of the portal vein system and hepatic veins. The conception of the liver as the origin of the venous system was retained. Liver parenchyma was held to derive from the solidification of blood under the influence of body heat. Having detected no morphological differentiations, GALENOS described the fine structure of the liver as "simple". The organ was thought to be a vegetative centre controlled by the brain via the liver nerve (vagus) − a view previously put forward by PLATON in his "Timaios". He also adopted to a great extent the Platonic doctrine regarding the "trinity of the soul", according to which the "psyche epithymetike" was to be found in the liver. The nutritive, or vegetative, liver was said to be superior to all the other abdominal organs: the essential life forces ("dynameis physikai") likewise originated here. The excretory organs − spleen, gall bladder and kidneys − were allegedly responsible for cleansing the liver. The metabolism of the liver was thus described as being directed by **4 vegetative forces:** the *attracting force* drew the nutrient fluids from the intestine, the *retaining force* held the chylus in the liver vessels, the *transforming force* mediated the transformation of the nutrient substances into blood, and the *expelling force* propelled the blood through the hepatic veins to the other body organs. Thus the gall bladder *attracted* bile from the liver via extremely fine intrahepatic bile ducts with minute openings which terminated (!) in the liver; the *retaining* force facilitated the accumulation of bile in the gall bladder, and the *expelling* force drove it into the intestine. The liver was considered the source of heat generation which warmed the stomach like a saucepan, making it the site of the first "pepsis". The nutrient fluids thus generated flowed into the mesenteric and portal veins, where they were thought to undergo a second "pepsis". The parenchyma allegedly produced blood from the transformed and by now blood-like chylus.

***Fig. 1.12:*** GALENOS OF PERGAMON (131−201 AD) (129−199 AD?) (Medical Academy Paris; photo by René Jacques, Paris)

▶ GALENOS was the first to ligature the liver veins of live animals in the interests of liver research. He held the opinion that further biological reactions must occur in the liver parenchyma. He also recognized the peristalsis-stimulating effect of yellow bile (!). Following the older description of RUFUS OF EPHESUS, GALENOS differentiated various **forms of icterus** in a way almost identical to modern thinking: (*1.*) icterus could occur as a result of inflammation, hardening or compression of the choledochus, (*2.*) icterus could develop at the crisis of a feverish illness, (*3.*) obstruction of the excretion of bile from the liver could cause jaundice, and (*4.*) icterus could result from the transformation of blood into bile, e.g. after a poisonous animal bite. These ideas are almost identical to the modern pathogenic concepts of mechanically, toxically or haemolytically induced icterus.

GALENOS' morphological and pathophysiological conceptions based on animal experiments served as unchallenged dogma for over 1,000 years. *He may justifiably be regarded as the founder of scientifically orientated hepatology.*

## 2 Liver research in the Middle Ages

Liver research in the following centuries was generally stagnant and bereft of new ideas. It is true that Arabian medicine led by RHAZES (865−926) underwent a revival and that AVICENNA (980−1037) supplied a compendium on the art of Galenic and Arabian medicine in his 5-volume *"Canon medicinae"* − nevertheless, Arabian medicine did not contribute any new morphological or physiological findings to the body of knowledge regarding the liver.

**Anatomia Mundini:** It is not known in which way the famous anatomists of that time − HEROPHILOS and ERASISTRATOS (s. p. 6) as well as GALENOS (s. p. 7) − obtained their knowledge about the human body. All previous descriptions regarding the anatomy of the liver were recorded in 1316 by MONDINO DE LUZZI (Bologna) in his *"Anatomia Mundini"*. This work is based on autopsies which he carried out for the very first time in public in 1306 and 1315. This unprecedented textbook of anatomy served as a canon for almost two centuries. (s. fig. 1.13)

**LEONARDO DA VINCI** (1452−1519) can be regarded as the greatest universal genius in the history of mankind. In the field of hepatology, he studied the portal vein system, the intrahepatic vessels and the bile-duct system in an excellent manner. He did not publish his first-rate observations, which therefore remained unknown for a long time.

**PARACELSUS:** The bitter attacks by Theophrastus Bombastus of Hohenheim, known as PARACELSUS (1493−1541), against the doctrines of GALENOS and AVICENNA heralded the end of the first epoch of liver research (ca. 2000 BC − ca. 1500 AD). PARACELSUS also initiated the era of iatric chemistry. He regarded the liver as the site of chemical and material transformations, particularly the processing of nutrient and metabolic "mercurial"

*Fig. 1.13:* The visceral surface of the multiple-lobed liver (A), with the gall bladder (B), portal vein (D), bile duct, bile system (C, E) ("Anatomia Mundini", 1316) (MONDINO DE LUZZI, Bologna)

substances. The emphasis was no longer on the "digestio" but on the "separatio" of substances inside the liver. (s. fig. 1.14)

*Fig. 1.14:* PARACELSUS (1493−1541) (Jan van Scorel, Louvre Museum, Paris; colour photo by Laniepce, Paris)

In his book *"De origine morborum ex tartaro"* (1531), PARACELSUS described the role of the liver as follows:

*"... because the liver is a source of many diseases, and is a noble organ that serves many organs, almost all of them: so it suffers, it is not a small suffering, but a great and manifold one."*

**VESALIUS**: An anatomical and historical demarcation line between the ancient and the more modern and scientific doctrine was drawn in 1543 with the publication of *"De corporis humani fabrica libri septem"* by A. VESALIUS (1514−1564), who thus became the founder of contemporary anatomical science. He introduced a uniform Latin nomenclature. (19) Supported by careful investigations, the morphology of the liver and its blood vessels was presented in exact detail for the first time in the seventh book. (s. fig. 1.15) The previously held belief that the liver comprised 4 or 5 distinct lobes was discredited, and the Galenic dogma that the liver is the origin of the venous system was rejected. He did, however, adopt the Galenic concepts of liver function. He recognized the foetal connection between the portal vein and the inferior vena cava (1561), subsequently termed the *ductus venosus Vesalii*, and not *"Arantii"*. (Note: G. C. ARANZI did not discover the D. venosus until 1564.) (15: vol. I/p. 67!)

*Fig. 1.15:* Illustration of the human visceral liver surface by A. VESALIUS, 1543 (19)

**Blood circulation:** With the new doctrine of the blood circulatory system by W. HARVEY (1578−1657), the old hepatological theory collapsed. The arteries were now regarded as nutrition-bearing vessels. The liver was no longer deemed the site of blood production, but was integrated in the venous arm of the blood circulatory system. It was seen as a point of collection and storage for chylus and nutrients (1628).

**GLISSON**: In 1654 F. GLISSON (1597−1677) published the first comprehensive monograph on the liver, which was to serve as an authoritative research work of reference for the next two centuries. (8) The inner structure of the liver, characterized by its intrahepatic vascular vessels, the differentiation of liver segments (!) through the large branches of the portal vein, the terminal regions of the blood capillaries and bile capillaries as functional pathways and the dynamics of the bile flow were all described in *"Anatomia hepatis"*. (s. fig. 1.16) "Glisson's capsule" was recognized as branching, tree-like intrahepatic connective tissue. The portal vessels, which are surrounded by connective tissue, are termed portal trias ("Glisson's triangle"). (1659) GLISSON found nerves only in the liver capsule, and not in the parenchyma. The role of the liver parenchyma was regarded as that of separating the bile from the blood by mechanisms of "affinity". • The *innervation of the liver* was described by TH. WILLIS (1621−1675).

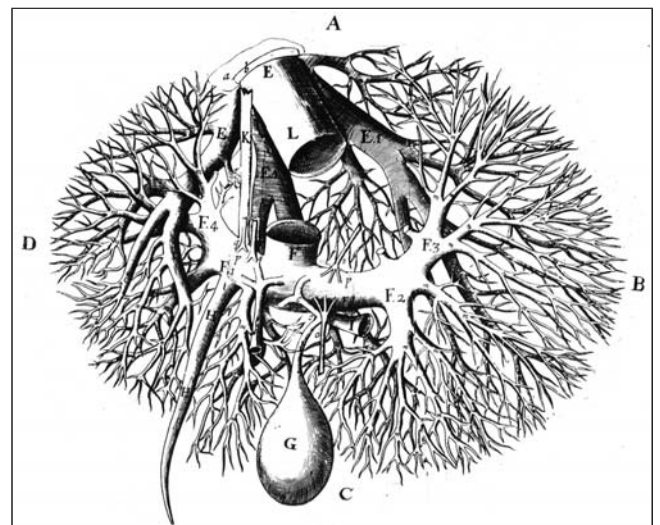

*Fig. 1.16:* Illustration of the blood and bile vessels of the liver by F. GLISSON, 1654 (A: dorsal region, B: right aspect, C: ventral region, D: left aspect, E: hepatic veins, H: umbilical vein, K: duct of ARANTIUS, G: gall bladder, I: bile duct, F: portal vein) (8) (Univ. Library, Freiburg)

**Liver parenchyma,** now at the forefront of research, was described in the pig by J. J. WEPFER (1664) as consisting of a gland comprising innumerable liver "lobules". M. MALPIGHI (1666) discovered the grapelike "out-budding" structure of the parenchyma into "lobuli" and "glandulosi acini". He defined the latter as the smallest functional unit of the organ, with each acinus having a branch of an afferent and an efferent vein as well as a bile-duct terminus. M. F. X. BICHAT (1771−1802) considered the liver parenchyma to be a special tissue in terms of function and morphology. He suspected that the liver had far more capabilities than had previously been assumed.

**Bile** began to assume increasing importance in theories on the processes of metabolism: it was defined as an alkaline secretion and the paramount digestive fluid by J. B. VAN HELMONT (1579−1644). J. JASOLINUS (1654) made a distinction between gall-bladder bile and liver bile, which was subsequently confirmed by J. BOHN (1697) as well as by H. BOERHAAVE (1708), who also recognized the role of bile in the digestion of fats. M. MALPIGHI had already established the thickening of bile in the gall bladder as early as 1687. In 1710 A. BORELLI described the enterohepatic circulation of bile through the portal vein system. The ligation of the hepatic artery by M. MALPIGHI and J. BOHN, and of the portal vein by H. BOER-HAAVE, led to the conclusion that the liver, rather than the gall bladder, was the organ of biligenesis.

**Lymphatic vessels:** With the discovery of the intestinal lymphatic vessels by C. ASELLI (1622), of the thoracic duct by J. PECQET (1651), of the separate nature of the chylus vessels and lymphatic systems by T. BARTHOLIN (1653) and of the exact description of the hepatic lymph vessels by O. RUDBEK (1653), the liver came to be regarded as an "excretory organ" which removed bile and other aqueous fluid (T. BARTHOLIN: *"lympha"*) from the blood. PECQET recognized that nutrients reach the thoracic duct via the lacteal ducts and are then fed into the venous system before the right heart.

**Connective tissue:** It appears that J. WALEUS (1640) was the first to describe connective tissue in the liver, namely in the area surrounding the vessels. • M. MALPIGHI (who is considered the founder of microscopic anatomy) detected connective tissue between the acini in 1666.

No doubt the most significant milestone text in the field of liver research was *"Elementa physiologiae corporis humani"* published in 1764 by **ALBRECHT VON HALLER** (1708−1777). (s. fig. 1.17) A comprehensive picture of 18th century **hepatology** was given in *volume 6* of this immense encyclopaedia, which was to form the indispensable basis of liver research up to modern times. All previous findings and conclusions dating back to antiquity were critically reviewed; dogmatic and speculative hypotheses and outmoded results were rejected and sound findings, mostly proven in experiments of his own, confirmed to yield a balanced, all-embracing account of the field of hepatology.

# 3  Liver research up to modern times

In subsequent years, a series of landmark findings substantially furthered the science of hepatology. The use of the microscope brought greater insight into the morphology of liver diseases. As a result of refined methods of chemical investigations, the liver was recognized as a *"chemical laboratory"* and as the *"site of intermediary metabolism"*. (5, 15, 20)

*Fig. 1.17:* ALBRECHT VON HALLER (1708−1777)
(Nat. Library Bern; photo by Boissonnas, Geneva)

1757  Proof of crystallization of bile acid compounds by P. RAMSAY.

1775  Discovery of bile cholesterol by B. G. F. CONRADI (published in 1783) − apparently postdating the earlier description of this substance by F. P. L. POULLETIER DE LA SALLE.

1789  First mention of the green or yellow "bile pigments" by A. F. FOURCROY.

1796  S. TH. SÖMMERING defined the total mass of the liver lobule as "acinus" on the grounds that it was composed solely of vessels (cf. M. MALPIGHI, 1666).

1815  C. B. ROSE confirmed a decrease of urea concentration in the urine in chronic liver disease and postulated the synthesis of urea in the liver.

1816  M. E. CHEVREUL reconfirmed the presence of cholesterol in both bile and gallstones (1824) and termed this compound "cholesterol".

1817  F. MAGENDIE postulated the detoxifying function of the liver.

1824  L. GMELIN described cholic acid (= glycocholic acid) as well as the bile pigments "brown bile" and "green bile" arising from oxidation processes. Inauguration of "Gmelin's test". Bile acid chemistry begins.

1826 Proof of cholic acid and taurin in the bile by F. Tiede-mann and L. Gmelin.

1828 F. Wöhler demonstrated the artificial synthesis of urea from ammonia.

1833 Description of the hexagonal architecture of the liver lobule and of the anastomoses of the fine bile capillaries by F. Kiernan. (s. fig. 1.18)

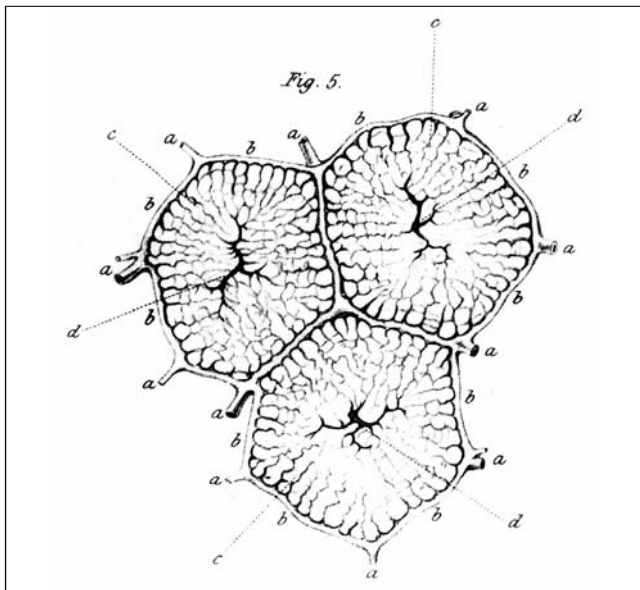

**Fig. 1.18:** Illustration of liver lobules and vessels by F. Kiernan, 1833 (a, b: interlobular veins, c: intralobular vein plexus, d: intralobular branch of the central hepatic vein) (13)

1837 Discovery of the liver cell by J. E. Purkinje, later by J. Henle (1838), also by F. Dujardin and G. Verger, but probably already discovered at an earlier time by M. Dutrochet (1824).

1839 Description of the intralobular connective tissue by E. Hallmann.

1840 The "green bile" described by L. Gmelin is designated "biliverdin" by J. J. Berzelius.

1841 J. Henle describes the bile canaliculi in the liver lobules as simple, unwalled intracellular spaces.

1842 J. Liebig postulated the liver's role in intermediary metabolism; bile production was described as one part of protein and carbohydrate metabolism, and the synthesis of urea in the liver was accepted.

1844 J. Müller localized the site of bile synthesis in the liver

1847 R. Virchow described „Hämatoidin" and the extrahepatic synthesis of bile pigments from haematoidin in old haematomas (s. Galenos: "blood turns to bile").

1848 Detection of 2 paired bile acids by A. Strecker: the taurin-containing cholic acid and the glycine-containing cholic acid, respectively designated taurocholic and glycocholic acid by C. G. Lehmann in 1854.

1848 Description of the bile microcapillaries in peripheral hepatic lobules by J. Gerlach.

1848 Sugar synthesis (= glycogen) in the liver identified by C. Bernard and C. L. Barresvil.

1854 Description of hepatocellular trabeculae by J. Gerlach.

1855 F. Führer and H. Ludwig postulated the synthesis of urea from erythrocytes.

1857 C. Bernard was the first to demonstrate glycogen in the liver. • He became the *founder of modern liver physiology.*

1858 Publication of „*Klinik der Leberkrankheiten*" (s. fig. 1.19) by F. Th. Frerichs (1819−1885). • He became the *founder of modern liver pathology.* (s. fig. 1.20)

**Fig. 1.19:** Front page of the outstanding textbook „Klinik der Leberkrankheiten" by F. Th. Frerichs (1819−1885): 2 volumes (1st ed. 1858, 2nd ed. 1861) Verlag Vieweg, Braunschweig/Germany; 416 and 549 pages, respectively. (s. fig. 5.1). **(Property of H. Eppinger! − Purchased from his estate)** *(Personal possession)*

1863 The "brown bile" (described by L. Gmelin) is termed "bilirubin" by G. Städeler (originally termed "bilirubrin" in 1844 by E. A. Platner).

1866 E. Hering proposed that the bile capillaries were bounded solely by liver cells and that the parenchyma had a structure of little plates rather than a trabecular form.

1868 M. Jaffé isolated "urobilin" from urine (corresponding to stercobilin in the stool).

1869 E. Ponfick first described the Kupffer cells and their phagocytic activity, which was more extensively documented by J. Peszke in 1874 and by K.W. von Kupffer in 1876.

1870 First description of the enterohepatic bile circulation by M. Schiff.

1871 B. Maly demonstrated the hydrolytic conversion of bilirubin to urobilin in the intestine.

1871 Detection of stercobilin by C. Vanlair and V. Masius.

1880 First blind hepatic biopsy performed by P. Ehrlich.

1882 W. von Schröder demonstrates ureagenesis in the liver.

1890 Confirmation of the existence of perivascular lymphatic vessels by J. Disse ("Disse's space"), which had already been proposed by Th. MacGillavry in 1864.

1890 Demonstration of the blood supply to the liver through the portal vein according to the double-flow principle by F. Glenard.

1891 Description of the lattice fibres and their demarcation by elastic fibre and collagenous connective tissue by A. Oppel.

1892 S. Minot coined the term "sinusoid" to describe the blood capillaries leading in a radial fashion to the central vein of the lobule.

1893 Demonstration of "meat intoxication" following an experimental shunt operation by J. Pawlov.

1903 M. Vidal performed the first portal shunt surgery on a human subject.

1903 W. Schlesinger described the detection of urobilin in urine. In the same year, O. Neubauer found that Ehrlich's reagent (dimethylaminoazobenzaldehyde) together with urobilinogen results in reddening.

► For further historical details, see the respective chapters!

*The above selection of pioneering work links up with modern hepatology, which has developed from biochemistry, histology and histochemistry − and is based on biomolecular and microstructural research methods.*

The current **4th epoch** of liver research may later be known as **"biomolecular hepatology".** *Not only examination techniques based on biochemistry, histology and imaging, but also the therapy of liver disease will increasingly be determined by biomolecular research.*

# 2  Morphology of the Liver

# 2 Morphology of the Liver

## 1 General anatomy of the liver

*The liver is the largest solid organ in the body.* • The **weight** of a normal liver comprises about 1/18 of the newborn child's body weight (approx. 5%) and about 1/50 of the adult's body weight (2.3−3%), varying in men from 1,500−1,800 g and in women from 1,300−1,500 g. The relatively larger weight in infancy is mainly due to an enlargement of the left lobe. The weight of the liver relative to body weight decreases from 3% to 2% with age. With regard to **size,** the liver is on average 25−30 cm in width, 12−20 cm in length and 6−10 cm in thickness. The **surface** is smooth and shiny. The **colour** of the liver is brownish red. The lobular structure can be seen distinctly upon close inspection. The **position** is intraperitoneal (with the exception of the area nuda and the gall-bladder bed). Due to the suction of the lung, the position of the liver is directly dependent on the position of the diaphragm; the respiratory displacement of the liver amounts to approx. 3 cm. (s. fig. 4.3!)

### 1.1 Topography

The topography of the liver is characterized by the (smaller) *left lobe* and the (about six times larger) *right lobe*, which are separated by the (translucent) *falciform ligament*. This peritoneal duplicature splits dorsad into a right and left coronary ligament of liver; both terminate in the triangular ligament. (s. figs. 2.1, 2, 5; 16.4) • The *round ligament* (= lig. teres) is a remnant of the umbilical vein of the foetus. It runs in the free edge of the falciform ligament (during the time of foetal development, it actually joins the left branch of the portal vein) and is often coated by drop-shaped mesenteric fat tissue. The *ligamentum venosum* is a slender remnant of the duct of Arantii in the foetus. (s. p. 9!) • On the inferior liver surface − separated by the portal vein − are the *quadrate lobe* (lying anteriorly between the gall bladder and round ligament) and the *caudate lobe* with papillary tubercle and caudate process (lying posteriorly along the inferior vena cava in front of the hepatic porta). This *hilum of the liver* in the centre of the inferior liver surface consists of the proper hepatic artery, portal vein, common hepatic duct, lymph vessels, and hepatic nerve plexus. These are held together by the perivascular fibrous capsule. (s. fig. 2.1)

With its convex **diaphragmatic surface,** the liver, which faces forwards and upwards, abuts the arch of the diaphragm and the anterior abdominal wall. It bears a flat cardiac impression. This diaphragmatic surface is differ-

entiated into the *pars libera* (covered with peritoneum) and the *pars affixa*. • The **visceral surface** inclines both backwards and downwards. The superior and inferior surfaces form together the sharp liver margin (*margo inferior*). The inferior surface may show impressions caused by adjacent organs (gaster, colon, kidney, duodenum, gall bladder) and the posterior surface shows a *fissure* for the ligamentum venosum. (s. fig. 2.1)

*Fig. 2.1:* Views of the liver: anterior, posterior, inferior. (LL = left lobe, RL = right lobe, D = diaphragm, GB = gall bladder, FLV = fissure for ligamentum venosum, RL = round ligament (= lig. teres), IVC = inferior vena cava, FL = falciform ligament)

### 1.2 Form and variants

The **shape** of the liver resembles largely that of a pyramid lying at a slant with its base towards the right side of the body. The exterior form can vary greatly. (s. p. 2)

► In the first instance, *genetic factors* are responsible for **variations in form**. Additional *internal causative factors* worthy of mention include changes due to portal vein thrombosis, haemocongestion, cardiac cirrhosis, thesaurismosis, fibrosis and atrophy. *External causative factors* include impression effects caused by pillar of diaphragm, costal arch, xiphoid process and wearing tight belts or laced corsets. (38) In addition, chronic coughing may lead to mostly parallel furrows on the convexity of the right lobe. (32) • *Zahn's furrows* can appear on the right surface of the liver; they generally run sagittally and are caused by hypertrophic columns as a result of chronic lung emphysema and also (more rarely) congenital factors. (s. fig. 2.2) • The posterior surface of the liver occasionally has furrows, known as *rima coeci Halleri*. A branch of the portal vein always extends beneath their bed (J. HYRTL, 1873). • A tongue-shaped projection of the right (or more rarely the left) lobe of liver adjacent to the gall bladder is known as *Riedel's lobe* (B. M. K. L. RIEDEL, 1888). This condition may be congenital or arise due to the traction of a gall bladder enlarged by stones. Riedel's lobe is more frequent in women. It is not deemed to be a true accessory lobe. • *Fissures* (also called "simian cleft") (s. figs. 2.3; 31.20) − which may give rise to a hepar succenturiatum (= accessory lobe) (12) or hepar lobatum − are without clinical significance. • An interposition of intestinal loops (generally transverse colon) between liver and diaphragm is termed *Chilaiditi syndrome*. It is the result of hepatoptosis. • A **relaxation of diaphragm** due to congenital muscular aplasia in the region of the right diaphragm leads to displacement of the right liver lobe into the right thoracic space. (71)

**Fig. 2.2:** Zahn's furrow: diagonal craniocaudal impression of a hypertrophic diaphragm contour. Along the bottom of the furrow, there is a capsular fibrosis

**Accessory lobe:** This anatomical abnormality is rare and without clinical significance. Up to 16 accessory lobes have been reported in a single patient. They are usually located on the inferior surface of the liver. (s. fig. 2.4) Therefore they are generally detected only during the course of imaging examinations, surgery or autopsy.

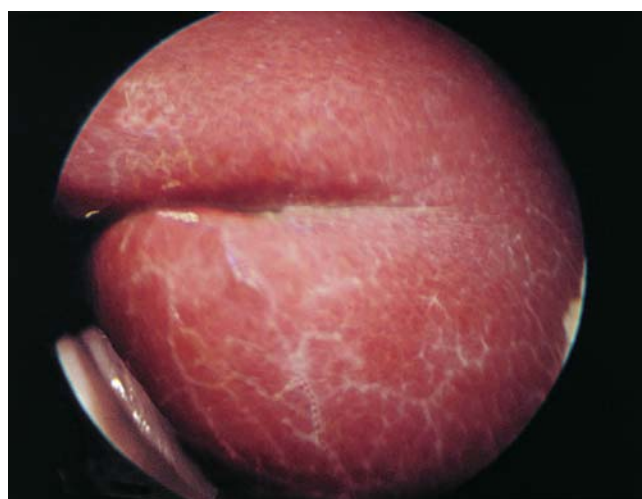

**Fig. 2.3:** Reticular fibrosis of the liver surface in chronic persistent hepatitis B with a so-called "simian cleft" (s. fig. 31.20)

**Fig. 2.4:** Accessory lobe on the inferior surface of the right lobe of liver. Here shown in chronic hepatitis B

Often an accessory lobe may contain its own blood, bile and lymph vessels. (12, 39)

**Lobar atrophy:** Atrophy may develop as a result of disturbances in the portal blood supply or biliary drainage of a lobe. It is generally possible to differentiate between the two aetiologies with the help of scintigraphic methods. • Likewise, lobar atrophy (the left liver lobe is most frequently affected) may develop following necrosing processes of the parenchyma, such as those caused by acute virus hepatitis (s. figs. 21.13; 22.16), intoxications and chemoembolization, or in cases of severe inanition as well as in marked cirrhosis (s. figs. 35.1, 35.14). Compensatory hypertrophy of the opposite lobe is usually witnessed. (17, 18, 79)

**Lobar agenesis:** In most cases, agenesis affects the right lobe. This very rare abnormality is mostly associated with other congenital malformations, especially of the biliary system. The unaffected liver lobe will generally develop compensatory hypertrophy. (22, 40, 49)

15

## 1.3 Segmental subdivisions

The boundaries regarding physiological topography are marked by the distribution pattern of the portal vein, the hepatic artery and the bile ducts, or according to the origin of the three large hepatic veins. The result is a clear and precise subdivision of the liver in the sense of a functional lobulation into 12 segments (3 main segments, each with 4 subsegments) (28) or 9 segments, respectively. The essential findings are based on the investigations of C.H. HJORTSJÖ (1948, 1951), C. COUINAUD (1954, 1957), S.C. GUPTA et al. (1977, 1981), H. BISMUTH (1982), and A. PRIESCHING (1986). (s. figs. 2.5; 40.4) • *Rex-Cantlie's line* (H. REX, 1889; J. CANTLIE, 1898), running from inferior vena cava to gall bladder, forms the boundary between the two portal distribution areas and thus between the right lobe (right portal vein) and the left lobe (left portal vein) of liver (so-called *double-flow principle of the portal vein*). Additionally, however, the left part of the right lobe of liver (segment II 1−4, the so-called *"centre of the liver"*) is supplied by both branches of the portal vein. Consequently, segment II 3 (equivalent to segment IV) would correspond to the quadrate lobe, II 2 to the caudate process, and segment II 1,2 (or I) to the caudate lobe. (s. figs. 2.5; 40.4)

***Fig. 2.5:*** Segmentation of the liver. • **a:** *Left lobe* (I, 1−4): 4 segments; "centre of the liver" (II): quadrate lobe (II, 3): caudate lobe (II, 1,2) and caudate process (II, 2); *right lobe* (III, 1−4): 4 segments. • Rex-Cantlie's line (===) as functional division between both liver lobes runs between II 2,4 and II 1,3. Topographically, the liver lobes are separated by the falciform ligament (⎯⎯) between I 1,3 and II 1,3. • **b:** The liver can be divided into 9 segments (I−IX) according to the ramifications of the portal veins. Segments II/III, I/IV, V/VIII and VI/VII are also combined into double segments

The "portal segments" and the "hepatovenous segments" are, however, subject to considerable individual variations with respect to their size and the position of their boundaries. This point must always be considered in cases of hepatectomy. For this reason there is, as yet, no general agreement about the designation of the segments. (16, 28, 70)

# 2 Structure and histology of the liver

Structurally and histologically, the liver can be divided into **four tissue systems:** (*1.*) intrahepatic vascular system, (*2.*) stroma, (*3.*) sinusoidal cells, and (*4.*) hepatocytes.

## 2.1 Intrahepatic vascular system

### 2.1.1 Hepatic artery

The **common hepatic artery** is a branch of the coeliac trunk (= Haller's tripod), from which the splenic artery, the phrenic artery and the left gastric artery emerge. In about 18% of cases there is a second hepatic artery leading out of the left gastric artery and in about 10% of cases there is a second hepatic artery leading out of the superior mesenteric artery. The common hepatic artery extends into the proper hepatic artery. Prior to this point, the gastroduodenal artery and the right gastric artery branch off. The course and the ramification of the hepatic artery are "normal" only in about 55% of cases! (61) These frequent vessel abnormalities are of great importance in surgery. • The pressure in the hepatic artery amounts to 100 mm Hg, with a pressure-dependent autoregulation of the blood flow (increase of pressure = decrease of blood flow, and vice versa).

In the porta hepatis, the **proper hepatic artery** divides into the *right branch* (from which the cystic artery emerges) and the *left branch* (from which a "middle hepatic artery" occasionally emerges). The branches of the hepatic artery run close to the portal veins and may even (rarely) coil round them in places. An arterial sphincter is located prior to the further division of the hepatic artery into smaller branches. • There are anastomoses between the arterial branches and the hepatic vein. By way of an arteriolar sphincter (46), the *interlobular arteries* branch into *intralobular arterioles*, supplying the lobules of the liver with arterial blood. The arterial blood enters the sinusoids either through terminal branches or through arterioportal anastomoses and mixes with the portal blood. The pressure in the hepatic arterioles is 30−40 mm Hg. (36, 46, 61)

The blood of the hepatic artery supplies **five regions** of the liver: (*1.*) peribiliary vascular plexus as the greatest arteriolar compartment, (*2.*) interstitium of the portal

fields, (*3.*) vasa vasorum of the portal vein, (*4.*) vasa vasorum of the hepatic vein, and (*5.*) liver capsule.

▶ **Hepatic blood flow** amounts to ca. 1,200 ml/min in women and ca. 1,800 ml/min in men, depending on the physiological conditions. Of this blood, 70−75% are supplied by the portal vein and 20−25% by the hepatic vein. The oxygen supply is secured by the hepatic artery at 20 vol. % and the portal vein at 16−17 vol. %. • The **blood content** is equivalent to 25−30% of liver weight. The liver blood volume accounts for 10−15% of the total blood content of the body − an extremely high proportion.

▶ **Oxygen consumption** of the liver amounts to 6 ml/minute/100 g wet weight. The acino-peripheral region (zone 1) has the best supply of oxygen (mainly aerobic metabolism), whereas the centroacinar region (zone 3) has the most oxygen-deficient blood (mainly anaerobic metabolism). A decrease in liver blood supply generally occurs whilst standing, during sleep, when fasting, and in old age. Oxygen extraction in the liver amounts to approx. 40%; any additional requirement of oxygen is (initially) met by a considerable increase in oxygen extraction of up to 95%. The regulation of the blood flow in the sinusoids is influenced in different ways: (*1.*) neural factors (adrenergic and dopaminergic receptors), (*2.*) anatomical mechanisms, and (*3.*) vasoactive substances (e.g. endothelin, CO, NO, adenosine).

### 2.1.2 Portal vein

The portal vein is formed posterior to the pancreatic isthmus by coalescence of the superior mesenteric vein and splenic vein. The inferior mesenteric vein enters at a point not far from this junction. The portal vein then runs through the hepatoduodenal ligament and absorbs venous blood from the ventricular coronary vein. • At the porta hepatis, the portal vein divides into the *right branch* (which takes in the cystic vein as well as one or two veins from the caudate lobe) and the *left branch*, into which flow the paraumbilical veins, extending through the round ligament, and the ventroflexal ramus, emerging from the left sagittal fossa. (s. fig. 2.6) • The branches of the portal vein extend (by further branching and reduction in the lumen) into the portal tracts. Here they merge with the *interlobular veins*, which generally divide into two *conductor veins* (= venulae interlobulares). The conductor veins divide into *distributor veins* and continue as Y-shaped *terminal branches* (= venulae afferentes). The portal blood passes through the periportal limiting plate of hepatocytes, entering the **sinusoids** through venous inlets. This means that the blood of the portal vein flows only into the sinusoids. Terminal branches of the arteries join up with the sinusoids separately. The outflow of sinusoidal mixed blood (75% from the portal vein, 25% from the hepatic artery) occurs via venous capillaries in the *central hepatic vein* (or *terminal hepatic vein*). The venous blood from the capillaries of

the portal tract flows off either through the distributor veins or directly into the sinusoids. The difference in pressure between portal veins and hepatic veins is more important for the sinusoidal supply of blood than are the respective absolute values. (36) • These radicular portal veins, originating in the portal fields, are thus also described as the *"inner root of the portal veins"* (H. ELIAS et al., 1949).

***Fig. 2.6:*** Diagram of the portal vein: p.v. = portal vein, r.b. = right branch, l.b. = left branch; c.v. = cystic vein; u.v. = umbilical vein; r.g.v. = right gastric vein, l.g.v. = left gastric vein; sp.v. ○ = splenic vein, s.g.v. = short gastric veins, l.g-e. v. = left gastro-epiploic vein; ● = gastrocolic trunc; r.g-e.v. = right gastro-epiploic vein, pd.v. = pancreaticoduodenal vein, m.c.v. = middle colic vein; ▲ = superior mesenteric vein, r.c.v. = right colic vein, ic.v. = ileocolic vein, j.v. = jejunal veins, i.v. = ileal veins; △ = inferior mesenteric vein, l.c.v. = left colic vein, s.v. = sigmoid veins

### 2.1.3 Hepatic vein

The hepatic vein emerges from the *central hepatic vein* in the centre of the lobule. It runs at an acute angle into the *sublobular vein*. From the confluence of the sublobular veins, *collecting veins* are formed which fuse to form 5 *trunk veins*: the right and left superior hepatic vein as well as the right, left and intermediate hepatic vein (the latter two forming a common trunk in 60−70% of cases). The hepatic veins progress intersegmentally; they receive branches from adjacent segments. This group of superior hepatic veins drains into the *inferior vena cava* at the posterior surface of the liver below the diaphragm. • By contrast, the group of inferior hepatic veins (= accessory hepatic veins) is very varied in terms of number, diameter and draining sites.

17

## 2.1.4 Biliary system

The *bile canaliculus* is formed as a bile capillary by means of a groove-like canal in the intercellular space, bounded by 2 adjacent liver cells. The bile canaliculi have no walls of their own, but are surrounded by a special zone of the cell membrane (so-called *pericanalicular ectoplasm*). Their diameter amounts to $0.5 - 1.0$ μm. They are interconnected and form an extensive polygonal network. The surface area of the bile capillaries is increased by *microvilli*, which show great functionally determined variability. The canalicular membrane constitutes 10% of the total plasma membrane in the hepatocytes. Similar to the pericanalicular ectoplasm, the hepatocytes contain contractile microfilaments and other components of the cytoskeleton. These canaliculi are supplied with carrier proteins and enzymes to control bile secretion. (2, 34)

The canaliculi continue into an ampulla-like extension known as *Hering's canal* (E. HERING, 1866). This area can be regarded equally as the end point of the canaliculi and the beginning of the ductules, hence the term *intermediate ductule* is used (M. CLARA, 1930). From here the bile ducts have their own wall of cuboidal epithelial cells. They are $7 - 20$ μm in diameter. Their designation as *preductules* has been generally adopted. (57) Because of their extreme proneness to damage, the preductules are described as the "Achilles' heel of the liver" (L. ASCHOFF, 1932).

The preductules merge either with the *cholangioles* (M. CLARA, 1934) or the *biliferous ductules* (H. ELIAS, 1949) or the perilobular ductules, respectively. Morphologically, it is generally not possible to distinguish between preductules and ductules. Thus both structures are subsumed under the term "cholangioles" or "terminal bile ducts". The ductules are followed by the *interlobular bile ducts* with a diameter of >50 μm. They run through the connective tissue wedges of the portal tracts (= Glisson's triangles). These interlobular bile ducts ($15 - 100$ μm) anastomose with each other. The larger septal ($100 - 400$ μm) and segmental ($0.4 - 0.8$ mm increasing to $1.0 - 1.5$ mm) bile ducts continue into the *right* and *left hepatic duct*, which unite at the hepatic porta to form the *common hepatic duct*. The latter confluences directly afterwards with the cystic duct, thus forming the *common bile duct* (= ductus choledochus). (34, 51, 78)

## 2.1.5 Lymph vessels

The liver forms more *lymph* than any other organ of the body ($0.4 - 0.6$ mg/kg BW/min). Lymph capillaries take up lymph from **Disse's space** (J. DISSE, 1890) and thereafter from **Mall's space** (F. P. MALL, 1906), which lies between the limiting plate and the portal connective tissue. Disse's space is also considered to be the main source of lymph. In addition, lymph capillaries commence in the adventitia of sublobular veins and run close to the hepatic veins as far as the paracaval lymph nodes. Lymph vessels possess valves which permit the lymph to flow only in one direction. Lymphatic vessels are present in all portal fields. They are found exclusively in the perivascular connective tissue and in the capsule of the liver. (s. fig. 16.4) • Drainage is effected by the *hepatic lymph nodes* in the area of the porta hepatis. Lymph reaches the *thoracic duct* via large valved lymphatic trunks and interconnected lymph nodes. Thus it enters the systemic circulation. (19, 67)

## 2.2 Stroma of the liver

The term **stroma** comprises the interstitial connective tissue of an organ. • In the liver, **four types of tissue structure** are differentiated: (*1.*) capsule of the liver, (*2.*) perivascular connective tissue, (*3.*) Glisson's portal tract, and (*4.*) reticular network.

► This **extracellular matrix** (ECM) is a dynamic concentration of complex macromolecules. Besides mechanical functions, the components of ECM also have important physiological tasks; therefore they have bidirectional contacts with the liver cells. These *matrix components* include: collagens, elastin, glycosaminoglycanes, proteoglycanes, and glycoproteins. In the liver, there are mainly collagens I, III (= large fibrils), IV (= net structure), and V, VI (= small fibrils). The Ito cells are deemed the main producers of ECM. The biosynthesis of collagen comprises the intermediate steps of pre- and procollagen. The half-life of liver collagen amounts to approx. 30 days. The *degradation of collagen* occurs through matrix-metalloproteinases, which are mainly formed in the Ito cells. During the degradation process, hydroxyproline develops, which in turn is either oxidized in the liver into $CO_2$ and $H_2O$ (ca. 75%) or excreted in the urine (ca. 25%). Thus the *excretion rate of hydroxyproline* in the urine is an indicator for collagen metabolism. The adhesive glycoproteins (e. g. fibronectin, laminin), which are also called *nectins*, are responsible for the connection between ECM and liver cells. The numerous heterogeneous components of the ECM are closely interwoven and communicate bidirectionally with the liver cells by means of special substances, so-called *integrins*.

### 2.2.1 Capsule of the liver

The capsule of the liver (A. von HALLER, 1764) is $43 - 76$ μm thick. It consists of the endothelial coating (= serosa) and a network of collagenous and elastic fibres. The capsule and the falciform ligament contain sensitive phrenicoabdominal branches of the phrenic nerve, which vary in extent (algesia or shoulder pain may thus accompany liver biopsy). Moreover, blood and lymph vessels as well as rudimentary bile ducts (which may become enlarged in the case of portal hypertension, ascites or cholestasis) are present in the capsule. The small blood vessels of the capsule anastomose with branches of the portal vein, yet not with the hepatic veins. The inner surface of the capsule is intimately connected to

the liver parenchyma, particularly in the area of the interlobular connective tissue.

## 2.2.2 Perivascular connective tissue

The perivascular fibrous capsule (F. Glisson, 1654) commences in the hepatic porta as a tree-like branching framework of connective tissue surrounding the interlobular vessels. It also surrounds the central hepatic vein and its small tributaries, which are joined to the parenchyma by radial fibres as well as being established in the portal tracts. This prevents a suction-induced collapse of the venous vessels as a result of respiration-dependent negative pressure in the pleural cavity. The perivascular connective tissue, known as *Glisson's capsule*, extends fine secondary trabeculae into the parenchyma. They contain the intralobular biliary, lymphatic and blood capillaries.

## 2.2.3 Lattice fibre network

The reticular network consists mainly of *lattice fibres* (O. Oppel, 1891) which lie on the hepatic cell plates and serve as a mechanical support for the sinusoids and also as a directrix in hepatocyte regeneration. The microvilli of the hepatic cells extend through this lattice fibre network into **Disse's space** (J. Disse, 1890). In general, this space is not visible in vivo, and thus the sinusoid wall appears to abut directly onto the hepatocytes. However, it constitutes about one third of the entire extracellular space in the liver, which itself accounts for $15-20\%$ of the liver volume and $2-4\%$ of the liver parenchyma. It is via Disse's space that the exchange of different substances between liver and blood takes place. The width of Disse's space varies between $0.2-1.0$ μm, depending upon the resorptive and secretory capacity of the hepatocytes. Fluid, protein and particles up to 100 nm may, however, enter this perisinusoidal space (increasingly in hypoxia) and be drained off. The space itself lies between the trabeculae and the sinusoids. It is thought to be connected to Mall's space, but no direct connection from Mall's space into the lymph vessels within the periportal region has so far been demonstrated. (s. figs. 2.7−2.9)

***Fig. 2.7:*** Reticular fibre network with central hepatic vein (CHV) (Gomori's reticulin stain)

***Fig. 2.8:*** Spatial relationship of sinusoid and hepatic cells: hepatocytes (H) in the form of boundary lamella (BL), cell nucleus (CN), canaliculus (BC), Disse's space (D), endothelial cells (E), sieve plate (SP), Kupffer cell (K), Ito cell (I). The cellular interchange area is increased by microvilli (modified from D. Sasse, 1986)

***Fig. 2.9:*** Liver cell and sinusoidal cells with organelles and polarized membrane compartments: hepatocytes (H), sinusoids (S), Disse's space (D), erythrocytes (ER), endothelial cells (E), Kupffer cells (K), Ito cells (I), microvilli (MV), canaliculus (BC), nucleolus (N), tight junctions (tj), cell nucleus (CN), mitochondria (M), smooth endoplasmic reticulum (SER), rough endoplasmic reticulum (RER), Golgi apparatus (GA), lysosomes (L), peroxisomes (P), ribosomes (R), microfilaments (MF) (modified from L. Cossel) (s. figs. 2.16−2.18)

## 2.2.4 Portal tract

In the *portal tract* (= Glisson's triangle, portal field) (F. Glisson, 1659), the perivascular connective tissue with its enclosed (and protected) radicles of the portal veins, the hepatic arterioles, bile ducts, lymph vessels and nerve fibres terminates in the connective tissue covering of the

perivascular fibrous capsule. Any lymphocytic infiltrations as well as occasional isolated histiocytic or monocytic forms which are embedded in this area are considered to be physiological. The continuous line of hepatocytes immediately bordering the portal tract is designated *limiting plate*. (s. figs. 2.8, 2.10, 2.12)

## 2.3 Sinusoidal cells

Four different *mesenchymal cell types* are subsumed under the term **sinusoidal cells:** (*1*.) endothelial cells, (*2*.) Kupffer cells, (*3*.) Ito cells, and (*4*.) PIT cells.

Although the sinusoidal cells (31 million/mg liver) make up only a relatively small proportion of the liver volume (6.3%), they constitute 30−40% of the total cell number. The total surface area of their plasma membranes is 26.5% of the total membrane surface of all liver cells. (3, 5, 23, 27, 44, 52, 56, 59) (s. figs. 2.8, 2.9)

### 2.3.1 Endothelial cells

Endothelial cells constitute the greatest proportion (70%) of the sinusoidal cells. These are flat cells, the nuclei of which camber the cell body. With their slim nuclear branches, they are in loose connection with both the neighbouring endothelial cells and the microvilli of the hepatocytes. They are located on a fine layer of extracellular matrix. Their proportion of the total cell number is 15−20%, but they make up only 2.8% of the liver volume. They form a continuous lining of the **sinusoids** which, however, possesses numerous intercellular spaces (0.1−0.5 μm) (S. Minot, 1892). The sinusoids (with a total surface area of 400 m$^2$) are 4−15 μm wide and 350−500 μm long. Here portal blood combines with arterial blood. The entry and exit of blood is controlled by sinusoidal sphincters. (36) Compared to the capillaries of other organs, sinusoids show fundamental structural differences. They are interspersed with **pores** which have a basic diameter of 0.1 μm, actively variable in width. When grouped together, such pores are known as *sieve plate*. (s. fig. 2.8) There are also larger pores (0.5 μm), so-called *fenestrae*. The smaller pores, the fenestrae and the intercellular spaces are essential for the process of filtering the components of the blood; they have scavenger functions (55) and regulate the exchange of fluid and material between the blood in the sinusoids and the hepatocytes. In addition, they are of great importance for the balance of lipids, cholesterol, and vitamin A. Endothelial cells also form and secrete cytokines (e.g. II 1, 6, IF, α-TNF), matrix components (e.g. collagens, fibronectin) and growth factors (e.g. HGF, IGF, FGF) as well as vasoactive substances (e.g. NO, endothelin). (52, 55, 76) • The cells themselves can be damaged or even completely destroyed by the effect of toxins, alcohol, hypoxia, viruses or increased pressure in the sinusoids. In this case, the hepatocytes are completely "naked" and exposed to all attacks. The endothelial cells are stabilized by a network of lattice fibres. • Because of their structural and functional characteristics, the endothelial cells, Disse's space and the so-called vascular hepatocyte pole are subsumed under the term *"perisinusoidal functional unit"*. (45)

### 2.3.2 Kupffer cells

The stellate cells initially determined by K. W. von Kupffer (1876) by means of the gold chloride method were actually Ito cells located in Disse's space. It was not until 1898 and 1899 that the sinus macrophages were described by von Kupffer again − though at this point not sufficiently differentiated from the gold-reactive fat-storing cells.

Kupffer cells (K. W. von Kupffer, 1876) constitute about 25% of the sinusoidal cells. They make up 8−12% of the total liver cells and 2.1% of the liver volume. Their total number/mg of liver amounts to 31,000, the half-life being 12.4 days. They probably derive from monocytes and are released by stem cells in the bone marrow. Thus they belong to the mononuclear phagocytosis system (MPS) (R. van Furth et al., 1970). Kupffer cells can multiply by mitosis. Their villiform surface (fuzzy coat) and irregular, mostly star-shaped form led to the designation "stellate cells". They are randomly distributed in the sinusendothelium, but occur 3−4 times more frequently in the periportal region than in the perivenous zone. They connect with adjacent cells or spaces by means of ramifications and through pores. Their cytoplasm contains numerous organelles. Charged Kupffer cells may be flushed out with sinusoidal blood. • *Phagocytosis* can be seen as the most important function of Kupffer cells. Apart from the cells at the base of the pulmonary vascular bed, they have the greatest intravascular phagocytic capacity. Further functions include (*1*.) *pinocytosis*, (*2*.) discharge of *signal substances* (e.g. cytokines, growth factors, erythropoietin, eicosanoids) or proteins and/or enzymes, and (*3*.) *clearance* of toxins, antigens, antigen-antibody complexes and purines. The phagocytosis and clearance of Kupffer cells is reduced through alcohol and drugs (e.g. mitomycin, α-methyldopa). (27, 56, 59, 65, 72) (s. p. 65) (s. figs. 2.8, 2.9)

### 2.3.3 Ito cells

Ito cells (T. Ito, 1951) are also known as fat-storing cells, hepatic stellate cells or lipocytes. These long-lived cells, 5−10 μm in size with long thin strands, lie in Disse's space (s. figs. 2.8, 2.9) and contain numerous cytoplasmic fat droplets as well as an abundance of vitamin A (= retinol ester). The retinol esters of the chylomicrons are absorbed by the hepatocytes and hydrolyzed into retinol. The latter is either passed to the blood by means of RBP or transported to Ito cells and stored. In the fat droplets of Ito cells, about 75% of the liver retinoids are present in the form of retinol esters. These fat droplets are characteristic of Ito cells; they represent vacuolized

cisterns of RBP. Ito cells constitute about 3−8% of the total liver cell number and 1.4% of the volume of the liver, occurring in a proportion of one Ito cell to 12−20 liver cells. Zone 3 of the acinus has the highest number. Ito cells are involved in the regulation of the width of the sinusendothelium, the microvascular tone and the regeneration of cells. They contain numerous filaments and organelles for protein synthesis, but cannot them-selves produce RBP. Moreover, they are capable of transformation into myofibroblasts. Ito cells are able to synthesize and secrete collagen types I, III and IV, fibro-nectin, laminin, or other substances. Unlike fibroblasts, Ito cells can express desmin. Hence Ito cells may play an important part in fibrogenesis, particularly in patho-logical intralobular fibrosis. (4, 7, 14, 27, 59, 62, 73)

### 2.3.4 PIT cells

PIT cells were first demonstrated in the sinusoidal wall in rats (E. WITTE et al., 1970). Later on, these lymphocytes with large granules and rod-cored vesicles were also found in the human liver, particularly in the sinusoids and in Disse's space. Due to their pseudopodia, they are variable. The proportion of PIT cells to Kupffer cells is 2:10. They are natural killer cells and destroy tumour cells or foreign cells as well as necrosed cells. It is not clear whether they have any additional "endocrine" function. Because of the strongly polarized distribution of their granulae, they could justifiably be classified as APUD cells. (6, 26, 27, 59, 68, 75)

### 2.4 Hepatocytes

▶ Hepatocytes were discovered by M. H. DUTROCHET, who recognized "cellules vesiculaires agglomerées" in liver tissue in 1824. This **first description** was confirmed and expanded by F. KIERNAN (1833), J. HENLE (1836) and J. E. PUR-KINJE (1837); they also discovered the liver cell nucleus.

Hepatocytes are **polygonal epithelial cells** with six or more faces corresponding to their individual position in the overall cell structure. The plate-like, overlapping hepato-cyte formations build a three-dimensional system. With the reduction in weight of the liver from 3% to 2% relative to body weight with age, there is also a decrease in the absolute number of hepatocytes. The usual life span of hepatocytes is at least 150−200 days; they perish as so-called *oncocytes* ("moulting"). This *programmed death* of the old hepatocytes is designated **apoptosis**. As yet, there is no reliable information available regarding the normal life span of human hepatocytes. It is determined on the one hand by genetic factors and on the other hand by ex-ogenous factors, which differ in nature and scope of influ-ence. In rats, a life span of 191 to 453 days was established for hepatocytes.

| | |
|---|---|
| Proportion of liver volume | 80% |
| Proportion of total cell number | 60−65% |
| Number of liver cells | 300 billion |
| Number of hepatocytes per g of liver | 171 million |
| Diameter of hepatocytes | 20−40 μm |
| Proportion of hyaloplasm in cell volume | 51% |
| Lifespan of hepatocytes | 150 (−200) days |
| Mitosis rate per 10,000−20,000 liver cells | 1 |
| Membrane surface of hepatocytes and organelles (s. p. 26) | 33,000 m$^2$ |

Hepatocytes show a varying content of carrier, receptor and channel proteins. They have a clearly contoured cell membrane which is divided into 3 compartments de-fined by morphological and functional **cellular polariza-tion.** (*1*.) About 37% of the external area of the hepato-cyte membrane is *sinusoidal surface,* the absorptive and secretory function of which is increased sixfold by nu-merous microvilli; they lie in Disse's space. Some even protrude through the fenestrae into the sinusoids and thereby have direct contact with the blood. On the sinusoidal membrane, there are invaginations with ves-icles underneath. (*2*.) About 12% of the outer hepato-cyte membrane consist of canaliculi, termed *canalicular surface.* This area is the secretory pole of the cell. (*3*.) The remaining 50% of the external hepatocyte mem-brane constitute the smooth **intercellular fissure,** which is connected with Disse's space. This fissure is sealed from the canaliculi by *tight junctions* (= zonula oc-cludens), allowing only an exchange of water and ca-tions to take place. The adjacent adhesion areas of the neighbouring hepatocytes, the *intermediate junctions* (= zonula adhaerens) and the *desmosomes* (= macula ad-haerens), are sealed by membrane proteins. These last two connecting structures are known collectively as ad-hering junctions. Actually, they contain *gap junctions* (= maculae communicantes) which form tube-like connec-tions between adjacent hepatocytes and so facilitate the intercellular exchange. When cell death occurs, the gap junctions of neighbouring cells, as dynamic structures, close down in order to prevent the progression of cell death. (s. figs. 2.8−2.10, 2.16)

***Fig. 2.10:*** Normal hepatic tissue. H = hepatocytes, P = portal vein, BD = bile duct, HA = hepatic arteriole (s. fig. 2.16)

Three **zonal areas** can also be differentiated in hepatocytes based on ultrastructural and functional differences (8, 30, 33, 35): (*1.*) *vascular zone* (supranuclear), (*2.*) *lateral zone*, and (*3.*) *biliary zone* (adjacent to the bile capillaries). • They each have a different stock of *organelles.* (s. p. 26)

## 2.5  Biliary epithelial cells

Biliary epithelial cells are organ-typical. They constitute some 3.5% of all hepatic cells. Depending on the size of the biliary ducts in which they are located, they show distinct histological and histochemical variations. In comparison with hepatocytes, biliary epithelial cells contain fewer mitochondria and less ER; there is a complete absence of cytochrome P 450. They are rich in cytoskeleton and contain Golgi apparatus and vesicles. The round-to-oval nuclei lie in the basal cytoplasm. These biliary cells probably play a role in biligenesis. (63) The epithelial cells of the intermediate ductules are also regarded as stem cells for the liver parenchyma.

## 2.6  Nervous system

The hepatic nerves consist of fibres of the sympathetic ganglia $Th_7-Th_{10}$, the vagus and the right phrenic nerve. At the porta hepatis, they form one plexus around the hepatic artery and another plexus around the portal vein plus biliary duct. With the vessels, the nerves reach the liver and "terminate" in the portal fields, where they regulate biliary and vascular structures. Also in the perisinusoidal space, there is a fine nerval network which is in direct contact with hepatocytes and Ito cells. The nerves contain adrenergic (aminergic), cholinergic and peptidergic fibres; the function of peptidergic innervation is unknown. This most finely ramified hepatic nervous system influences haemodynamics, the metabolism of hepatic cells, and the motility of the biliary ducts. The liver parenchyma itself is not sensitive to pain as it contains no sensory nerves. The liver capsule and the falciform ligament are innervated by sensitive phrenicoabdominal branches of the phrenic nerve. (1, 5, 64) • A transplanted and therefore *denervated liver* shows that innervation is not essential for the function of the organ. This remarkable phenomenon cannot yet be explained.

# 3  Hepatic lobules and acinus

▶ The term **parenchyma** referring to the liver tissue was coined by Erasistratos. The **liver lobules** were first described in the pig in 1664 by J. J. Wepfer (using microscopic techniques) while the lobular structure was confirmed by M. Malpighi in 1666. The term **acinus** was coined by S. Th. Sömmering in 1796. • However, it was F. Kiernan (1833) who first gave a classic definition of the lobule in pig liver ("hepatic lobule"). Today, such anatomical clarity can only be found in the livers of the camel, polar bear and seal. (s. fig. 1.18)

Kiernan´s description of the acinus provided the basis for subsequent definitions, such as *"biliary lobule"* (Ch. Sabourin, 1888), *"portal unit"* (F.P. Mall, 1906), *"hepaton"* (R. Rössle, 1930) and *"synergid of the liver"* (H. Siegmund, 1943). In 1848 J. Gerlach had recognized that liver cells were arranged in bands (columns). • Not until a hundred years later did H. Elias (1949) describe the arrangement of liver cells in the form of plates as muralium simplex or lamina hepatis, with internal cavities (= lacunae). (10) (s. fig. 2.11) • E.H. Bloch (1970) considered the "single sinusoidal unit" to be a functional unit of the liver, the main component of which is a sinusoid lying sandwich-like between the hepatocyte trabeculae. • T. Matsumoto et al. (1979) suggest an angioarchitectural concept. The portal corner region with septal ramifications is seen as the basic structure of the primary hepatic lobule. In the parenchyma, vascular septa are postulated, i.e. terminal ramifications of the portal vein which join up with the sinusoids directly. (In 1997, W. Ektaksin et al. described them as inlet venules.) (s. fig. 2.12)

| | |
|---|---|
| Total number of hepatic lobules | 1.0−1.5 million |
| Depth of hepatic lobules | 1.5−2.0 mm |
| Diameter of hepatic lobules | 1.0−1.3 mm |

***Fig. 2.11:*** Diagram of the traditional ("classic") hepatic lobule according to the lobular structure (F. Kiernan, 1833) (s. fig. 1.18) and as stereogram (H. Elias, 1949): the liver cell columns run radially from the limiting plate to the central vein (10) (s. fig. 2.16)

***Fig. 2.12:*** Hepatic lobules with central vein ( ↑ ) and Glisson's triangles (G). Slight distortion of the lobular architecture

## 3.1  Central vein lobule

The classic central vein lobule accords with the traditional description of *lobular structure* (F. Kiernan, 1833; H. Eppinger, 1937; H. Elias, 1949). The hepatic lobule

resembles a hexagon with portal tracts at the corners. It consists of radially arranged columns (or plates) of 15−25 liver cells placed between the limiting lamellae and the central vein, the axis of which they are also aligned with. This particular arrangement of the hepatocyte plates does not occur until after birth and is due to the suction effect of the right ventricle. The lobule is limited by the surrounding periportal fields. The hollow spaces between the liver cell plates form a labyrinth, in which the sinusoids and Disse's space are located. The *limiting plate* (W.H. Harris, 1942) or *limiting lamella* (H. Elias, 1949) consists of smaller, basophilic and glycogen-free liver cells with a nucleus which is richer in chromatin. As a unicellular liver plate, it lies perpendicular to the remaining liver cell plates. It is penetrated only by capillaries. As it is limited on the periportal side by Mall's space, it can only be reached by peripheral sinusoidal blood on the lobular side. Due to its optimal blood supply, the limiting plate proves itself to be a particularly resistant layer of liver cells. It constitutes a dividing wall between parenchyma and mesenchyma. This lobular structure thus shifts the periportal fields with the supplying branches of the hepatic artery and portal vein to the periphery and the central vein to the centre of the lobule, which results in centripetal blood flow. The bile flows centrifugally towards the periphery. (s. figs. 1.18; 2.11−2.13)

## 3.2 Portal vein lobule

The portal vein lobule was first recognized in the description of the "portal unit" given by F.P. Mall (1906). It resembles a hexagon. The periportal field constitutes the axis at the centre while the central veins form the limiting points. (s. fig. 2.13) The glandular character of the liver is the main criterion of differentiation of the portal vein lobule. Thus the direction of blood flow is from the centre towards the periphery (centrifugal) and the direction of bile flow from the periphery towards the centre (centripetal). It could also be demonstrated that the lobule periphery is enclosed by basket-like ramifications of the portal vein (= *corbicula portalis*). (77) This further emphasizes the significance of the hepatic lobule.

## 3.3 Liver acinus

The functional and microcirculatory hepatic unit forms the basis for assessing the hepatic acinus (A. M. Rappaport, 1954). (41−43) The portal vascular bundle, with the terminal branches of the hepatic artery and portal vein diverging fan-shaped after penetrating the lobules, is at the centre of the *acinar structure*. These vessels represent the central axis for the circular blood supply of the related liver parenchyma. This area is roughly the shape of a rhombus, the outer angles of which are formed by the two *central veins* of the adjacent lobules while the diagonal

corresponds to the (arterial and portal) *terminal vessels*. The central vein at the periphery of the acinus, to which the sinusoids extend radially, drains off the venous blood; it is generally known as the *terminal hepatic venule* (= terminal hepatic vein). (s. p. 17) The liver acinus also serves as *secretory unit* for the transport of bile. In the acinus, the blood flow occurs centrifugally and the flow of bile centripetally. Three or more acini together form a so-called complex acinus. • This zonal model has been modified according to more recent findings, so that zones 1 to 3 do not surround the terminal afferent vessels in an onion-like way, but are now arranged in circular form around the vessels. (29) (s. figs. 2.13−2.15)

***Fig. 2.13:*** Diagram of the classic hepatic lobule (I), the portal vein lobule (II) and the hepatic acinus (III): CV = central vein (●), P = portal tract (▶). Flow direction: venous blood (= blue arrow), arterial blood (= red arrow) and bile (= green arrow), with the microcirculatory acinus zones 1, 2, 3. • (cf. W. Ekataksin et al., 1992: the microvascular unit is regarded as an area in which all liver cells receive blood from a common terminal vessel)

The zones of the acinus differ in their blood supply corresponding to the distance of the hepatic cells from the periportal field and from the terminal blood vessels, respectively. **Zone 1** has the best supply of oxygen and substrates; it comprises the (lobule-peripheral) parenchyma adjacent to the limiting lamella. Toxins are most damaging in zone 1. **Zone 2** corresponds to the inter-

mediate area with a reduced supply of blood. **Zone 3,** which has the poorest blood supply, is located near the central vein, i.e. at the end of the microcirculatory system of the liver. Having the lowest oxygen supply, this area has the least resistance to damaging influences, particularly with regard to oxygen deficiency, and it has the lowest regenerative capacity. It has also been postulated that the two halves of zone 2 can be added to zones 1 and 3, respectively, because zone 2 has no separate functional boundaries of its own. (15) • **Zones A, B, C** form concentric circles round the periportal field, which have a similarly decreasing quality of blood supply. Thus zone C1 is better supplied than, for example, C3, A2 or A3, i.e. the optimal blood supply is not dependent on proximity to the periportal field, but on proximity to the terminal distributory branches of the blood vessels or to the limiting lamella. (s. figs. 2.13−2.15)

**Fig. 2.15:** Diagram of the liver lobule and the acinus arranged like a clover leaf around the portal field according to the acinar structure (modified from D. Sasse, 1986): central hepatic vein (CV) or terminal hepatic vein, periportal field (P). Circulatory and metabolically different zones: zone 1 (periportal), zone 2 (intermediate), zone 3 (perivenous)

**Fig. 2.14:** Diagram of the functional (microcirculatory) liver unit ("simple acinus") (A. M. Rappaport, 1960, 1963): terminal hepatic vein (thV), periportal field (P), zones of different blood supply A, B, C and 1, 2, 3. Zone 1 (afferent zone): zone richest in $O_2$, nutrients and hormones. Zone 3 (efferent zone): zone poorest in $O_2$, nutrients and hormones, but enriched with $CO_2$ and metabolites from zones 1 and 2. (Direction of blood flow is from 1 to 3 and from A to C)

In correspondence with the oxygen gradient in zones 1 to 3 and A to C, there is a metabolic and enzymatic "zoning" of the hepatocytes. W. Eger had already described "functional zones" in 1954. (9) They have subsequently undergone reclassification as acini, although they were initially considered to be part of the lobular structure. This chemomorphology of the acinus is designated the **metabolic heterogeneity** of hepatocytes (K. Jungermann et al., 1978). (13, 15, 24, 25, 29, 31, 37, 66) Thus different metabolic processes are found in the periportal region (zone 1) and in the perivenous area (zone 3). Additionally, zones 1 to 3 are equipped with a very varied

stock of enzymes, which does not, however, remain constant. There is also an **ultrastructural heterogeneity.** In zone 1, Kupffer cells, microvilli, mitochondria, lysosomes and the Golgi structures are more numerous than in zone 3, and the lumen of the bile capillaries is larger. (35) By contrast, there is less smooth endoplasmic reticulum in zone 1 than in zone 3 (15,700 $\mu m^3$ against 21,600 $\mu m^3$ per cell). (33) The fenestration of the sinus-endothelium increases continuously from zone 1 to zone 3. (21) • Enzyme content and metabolic capacity of the hepatocytes depend on the *microcirculatory variability* (caused endogenously or exogenously) and can vary considerably in the individual acinus areas.

Strong arguments have, however, been put forward against metabolic heterogeneity, at least against the concept of rigid zoning. The columns of the hepatocytes in the separate zones proved to be variable with regard to staining characteristics as well as enzyme content. (31) Surprisingly, it could be unequivocally shown that a clear cellular multiplication occurs in the peripheral, i.e. in the periportal, zone and that the hepatocytes formed here are displaced towards the central vein. The hepatocytes migrate through all three zones at a speed of 1.44 $\mu m$/day, which is 0.32% of the diameter of the acinus. (80) From this it can be established that hepatocytes adopt the respective zonal differentiation during their migration from zone 1 to zone 3 and that the individual hepatocyte also receives the complement of enzymes typical for the respective zones during its spatial displacement. • With regard to their *metabolic capacities*, hepatocytes are thus pluripotent: their zonal position, the variability of microcirculation and their ability to migrate interzonally may possibly decide which metabolic functions are fulfilled directly and which are "deferred" from zone to zone.

The morphological unit is the **liver lobule.** With regard to the histological evaluation of a liver biopsy specimen, the use of this *lobular structure* is imperative to pathologist and clinician alike.

On the basis of the acinar concept, the **liver acinus** can be seen as a *"structural + microcirculatory + functional unit"*, which is nevertheless subject to the blood flow and the variability of the same.

# 4 Subcellular structures

Liver cells comprise the cell nucleus (= *karyoplasm*) and the cell body (= *cytoplasm*). Hepatocytes and sinusoidal cells have various types of *organelles* in their eosinophilic cytoplasm such as endoplasmic reticulum, Golgi apparatus, lysosomes, mitochondria, peroxisomes, ribosomes, centrioles and kinetosomes. Numerous and diverse metabolic processes take place with their help. Almost all cytoplasmic structures of liver cells are continuously renewed (up to twice daily). (20, 27, 30, 33, 35, 46−48, 50, 53, 58, 59, 69, 74) (s. figs. 2.9, 2.16−2.18) (s. tab. 2.1)

**Fig. 2.16:** Hepatocytes (H) in the form of cellular trabeculae with biliary capillaries (BC), cell nucleus (CN) and nucleolus (N); sinusoids (S) with leucocyte (L), endothelial cell (E) and erythrocytes (ER); Disse's space (D); × 1,980 (s. figs. 2.10−2.12)

## 4.1 Cytoplasm

The cytoplasm of the cell is designated *hyaloplasm* in electron microscopy and *cytosol* in biochemistry. It constitutes about 51% of the cell volume and shows a microtubular lattice. (s. fig. 2.17) Basophilia, caused by ribonucleic acid, is the histochemical index for increased functional activity of the hepatocytes. The smooth endo-

**Fig. 2.17:** Hyaloplasm of the hepatocyte: glycogen granules (G), mitochondria (M), rough endoplasmic reticulum with ribosomes (R); edge of the cell nucleus (CN); × 32,000 (s. fig. 2.9)

plasmic reticulum is responsible for the pale eosinophilic colouring of the cytoplasm. Together with the cell membrane, the hyaloplasm is also involved in the formation of microvilli, pseudopodia, etc. • The watery solution of the hyaloplasm contains a mixture of molecular components. Of these, the proteins with about 10,000 different forms (15−20% of the weight, 10 billion protein molecules) are by far the most important. Further, glycogen granula in high numbers as well as pigments and lipid droplets can be found. Water loss from the hepatocytes gives rise to so-called *dark liver cells* (= shrinkage, with catabolic signal); conversely, water retention gives rise to so-called *hydropic liver cells* (= swelling, with anabolic signal). Indeed, the latter term cannot really be defined as such since numerous changes in the cells are involved.

## 4.2 Cell nucleus

The nucleus of the liver cell has 1 or 2 nucleoli. (s. fig. 2.18) Its proportion of the cell volume is 6%. About 20−25% of liver cells have 2 nuclei, presumably as a sign of increased cell activity. Number, size, nuclear pattern or nuclear changes are very varied due to diverse influences (e.g. age, nutrition, physiological "moulting") − above all in pathological processes. About 10−44% of the nuclei are diploid, 55−80% are tetraploid and 5−6% are octoploid. Increasing polyploidy is deemed a precancerous phase. The nucleus has a bilaminar "nuclear membrane" (D. W. FAWCETT, 1955). The inner nuclear

membrane is connected to the heterochromatin, while the outer layer is joined via membrane eversions to the endoplasmic reticulum. Between the two membranes is the $20-70$ nm wide perinuclear cavity, which is connected to the spatial system of the endoplasmic reticulum. • The inner structure of the nucleus is non-homogeneous due to granules and the thread-like form of the chromatin; the latter constitutes the main component of the nucleus. This comprises chromosomes which contain genetic information in the form of DNA (deoxyribonucleic acid). With approx. $3 \times 10^9$ nucleotides per nuclei, this information is incredibly tightly packed. The DNA is firmly attached to histones (nucleosomes). RNA transcription occurs in the interphase nucleus, and DNA is reduplicated prior to cell division. In the

metabolically activated nucleus, RNA substances are concentrated in the nucleolus, in which the ribosomes are synthesized. It is chiefly the non-activated, non-despiralized chromatin in the form of heterochromatin which is deposited in the nuclear periphery, so that a dark nuclear capsule can be differentiated. Number and size of the nucleoli are dependent upon various influences. The exchange of substances and the transfer of genetic or metabolic information between nucleus and cytoplasm occur predominantly through (*1.*) diffusion, (*2.*) cell membrane pores (diameter ca. 10 nm), and (*3.*) pinocytosis.

### 4.3 Organelles

Various tiny structures, so-called organelles, are embedded in the cytoplasm where they make numerous cell functions possible. (s. fig. 2.9) (s. tab. 2.1) • The enzyme-rich **mitochondria** have an outer and an inner membrane, with the latter forming creases (cristae). The outer membrane is relatively permeable for small molecules. However, the inner membrane (which surrounds the matrix) must use specific transport proteins to enable protons, calcium, phosphate and so on to pass. Energy-rich substrates are transformed into ATP in the mitochondria. The enzymes which are responsible for fatty-acid degradation and the citric-acid cycle can be found in the matrix. The inner membrane also contains the enzymes of the so-called respiratory cycle. An enormous number of energy-providing reactions and metabolic processes take effect at this site. They have a round-to-oval shape with a diameter of about 1 μm. There are $1,400-2,200$ mitochondria per liver cell ($18-22\%$ of the liver cell volume). They generally lie in

***Fig. 2.18:*** Nucleus, nucleolus and hyaloplasm of the liver cell (20): cell nucleus (CN), marginal nucleolus (N), electron-dense dark nuclear capsule (DC), undulating nuclear membrane with (partial) fusion of the two membranes (NM), endoplasmic reticulum (ER), mitochondria (M); $\times$ 14,600

| | Membrane surface in proportion to the total hepatocyte membrane surface | Proportion of the hepatocyte cell volume | Number per hepatocyte | Function |
|---|---|---|---|---|
| 1. Rough endoplasmic reticulum (RER) | 35% | 9% | 1 | Synthesis of proteins, glucose-6-phosphatase, triglycerides, coagulant factors, *etc.* |
| 2. Smooth endoplasmic reticulum (SER) | 16% | 6% | 1 | Biotransformation; synthesis of steroid hormones, phospholipids, bilirubin conjugation, cholesterol, bile acids, glucose metabolism, *etc.* |
| 3. Golgi apparatus | 7% | | | |
| 4. Mitochondria | 39% | $18-22\%$ | $1,700-2,200$ | Protein secretion, haem synthesis, transport and degradation functions, cellular energy generation (ATP), oxidative phosphorylation, urea synthesis, gluconeogenesis, liponeogenesis, ketogenesis, β-oxidation of fatty acids, citric acid cycle, respiratory chain, *etc.* |
| 5. Lysosomes | 0.4% | 1% | $200-300$ | Degradation of "foreign" macromolecules in the cell by means of hydrolytic enzymes, deposition of copper, ferritin, lipofuscin, bile pigment, *etc.* |
| 6. Peroxisomes (microbodies) | 0.4% | 1% | $400-1,000$ | Oxidative degradation processes by means of peroxidases, catalase, xanthine oxidase, degradation of long-chain fatty acids, antioxidative function, *etc.* |

***Tab. 2.1:*** Numerical and functional summary of the most important organelles (adapted from B. ALBERTS et al., 1983) (s. figs. 2.9, 2.17)

the vicinity of the rough ER and are able to move within the cell. Multiplication occurs through division. Their half-life is 9−10 days. (s. figs. 2.17, 2.18) • The **endoplasmic reticulum** (= about 20% of the liver cell volume) consists of a smooth (SER) (40%) and a rough (RER) (60%) portion. The rough surface is due to ribosomes (9−10 million/liver cell); it is also known as ergastoplasm (identical to the basophilic granulae). (s. fig. 2.17) • The SER contains microsomes. It forms tubules and vesicles as well as being the site of the cytochrome P 450 systems. • The *Golgi complex* is generally found between the cell nucleus and the canaliculus and consists of 4 to 6 cisternae. This membrane system, which is formed from lamellar vesicles, communicates with the smooth ER. It is primarily concerned with the intracellular transport of various substances, but also with processes of degradation and excretion. • The **lysosomes** (200−300/liver cell) lie predominantly close to the canaliculus. They are organelles for the digestion and storage of cellular and noncellular (also exogenous) material. They contain hydrolytic enzymes, mainly proteases (= lysosomal enzymes) and acid phosphatase. • The **peroxisomes** (= microbodies) are enzyme-rich and oxidative-reactive structures. They are round to oval in shape and 0.2−1.0 μm in size. The liver cell contains 400−1,000 peroxisomes; their function is still not fully understood. (47)

## 4.4 Membrane

Hepatocytes, like the essential organelles, are surrounded by membranes which differ in their function and structure. The membrane of the hepatocytes consists of lipids (52−54%), proteins (44−46%) and carbohydrates (2−4%). The latter are structural, antenna-like docking points for tissue-specific receptors. (s. fig. 2.19) The membrane surface area of $3 \times 10^5$ million liver cells and their organelles is 33,000 m$^2$, i.e. *a surface area that is 5 times larger than that of a football field* (inner membrane surface area = 24,000 m$^2$). The basolateral (sinusoidal) proportion of the hepatocyte membrane amounts to approx. 85%, the apical (canalicular) proportion to approx. 15%. The membranes consist of a double layer (bilayer) of choline phospholipids, into which cholesterol, proteins, glycolipids and glycoproteins are incorporated with "systematic variability". This specific structure makes possible the enormous number of membrane-related functions. The hydrophilic parts of the phospholipid molecules form the outer and inner boundaries of the membrane, while the hydrophobic parts are directed towards its interior. The bilayer membrane is a liquid crystalline system (= *fluidity of the membrane*) allowing lateral movement (= *lateral diffusion*) of the proteins and phospholipids deposited in this area. In addition, the phospholipids can change position between the layers (= *flip-flop*). (74) The side of the sinusoidal cell turned towards the hepatic lacuna carries numerous microvilli, increasing the surface area

of the cell membrane. (50) The form and number of the microvilli not only depend upon the functional condition of the liver cell, but also upon damaging effects. • The hepatocyte membrane has multiple and existential *functions* such as (*1.*) mechanical and chemical protection, (*2.*) demarcation of neighbouring cells, (*3.*) link with the extracellular matrix, (*4.*) contact and interaction with neighbouring cells, (*5.*) signal exchange between intra- and extracellular space, (*6.*) transport mechanisms, (*7.*) enzymatic reactions, (*8.*) anchoring of the cytoskeleton.

*Fig. 2.19:* Diagram of the plasma membrane showing its integral proteins (fluid mosaic model) (adapted from S. J. Singer et al., 1972 and H. Knüfermann, 1976). • 1: external aqueous milieu, 2: internal aqueous milieu, 3: fracture plane of the apolar membrane layer, 4: externally orientated intrinsic protein (ectoprotein), 5: internally orientated intrinsic protein (endoprotein), 6: external extrinsic protein, 7: internal intrinsic protein, 8, 9: membrane-penetrating proteins with hydrophobic interactions in the inside of the membrane (P = polar region), 10: membrane pervaded by glycoprotein with sugar residues (■), 11: lateral diffusion (A) and flip-flop (B), 12: hydrophilic region (A) and hydrophobic region (B) of the bilayer membrane

## 4.5 Cytoskeleton

The cytoskeleton, made up of protein fibres, consists of dynamic structures with the ability to adapt their form rapidly to any respective requirements. It is important for the overall organization of the cell (e. g. transport processes, organelle movement, cell polarity, and cell division). It comprises the following *components:* (*1.*) actin filaments, (*2.*) microtubules, and (*3.*) intermediate filaments. (11) (s. fig. 2.9)

Thread-like **actin filaments** (microfilaments) spread through the hepatocytes creating a three-dimensional network and ensuring both form and stability of the cell. They also guarantee the shape of the microvilli and fenestrae as well as supporting the mechanical functions of the canaliculi. In addition, they influence the viscosity of the cytoplasm. Cytochalasin A depolymerizes

actin with lumen enlargement of the canaliculi, thus causing cholestasis; in this way phalloidin both stabilizes and inhibits the bile flow (M.J. PHILIPPS et al., 1987). • The tube-like **microtubules** consisting of tubulin also form a network within the cell. They serve the targeted transport of subcellular substrates or organelles, and they are important for the mitotic mechanisms involved in cell division. • The **intermediate filaments** also have a tubular structure and, in addition to their stabilizing functions, probably serve the intracellular transport of materials, too. • **Microtrabeculae** have also been postulated (possibly as a special form of actin filaments), forming a three-dimensional cytoplasmic meshwork, in which enzymes may also be deposited. The microtrabeculae form a dynamic lattice and in this way are connected with all organelles, microtubules and filaments as well as with the nuclear and cellular membranes. Various "motor proteins" produce a diverse range of motilities at the cellular and subcellular level. • This gives rise to the **cytoplast,** the vital functional unit of the liver cell.

# 5 Stem cells

Stem cells are **progenitor cells** which are not yet specifically formed. They can multiply almost infinitely and form nearly all 210 tissue types in the human being. Depending on their derivation, they are defined as follows: (1.) **embryonal** (= taken from the inner cell mass of the blastocysts), (2.) **foetal** (= isolated from 5−9 week-old abortive foetuses, and (3.) **adult** (= taken from the tissue of adults or children by means of biopsy or from the umbilical cord of newborns. Adult stem cells are limited in number and life span; they do, however, have a broader development potential than so far assumed. They have also been found in the liver. The transformation of stem cells from the bone marrow into hepatocytes has been carried out successfully. • **Liver stem cells** (7−15 µm) can develop both primary cell types of the liver, (1.) mature hepatocytes and (2.) biliary epithelial cells. These stem cells are deemed to be genuine liver stem cells, and not merely derived from the activation of immature oval cells in the liver. (54, 59, 60, 81) (s. fig. 2.20)

# 3 Biochemistry and Functions of the Liver

# 3 Biochemistry and Functions of the Liver

## 1 Metabolic functions of the liver

▶ The morphological and functional integrity of the liver is vital to the health of the human organism. This essentially depends upon constant maintenance of the numerous biochemical functions of the liver and the diverse metabolic processes occurring in the hepatocytes and sinusoidal cells.

The liver ensures that approximately 70 partial functions within 12 major metabolic areas proceed either continuously or in biological (e.g. circadian) rhythms, or vary according to specific requirements. (s. tab. 3.1)

1. Bilirubin metabolism
2. Porphyrin metabolism
3. Bile acid metabolism
4. Amino acid and protein metabolism
5. Carbohydrate metabolism
6. Lipid and lipoprotein metabolism
7. Hormone metabolism
8. Vitamin metabolism
9. Trace elements and the liver
10. Biotransformation and detoxification function
11. Alcohol degradation
12. Acid-base balance

▶ *About 500 separate biochemical processes occur in one single liver cell!*

*Tab. 3.1:* Essential biochemical metabolic functions of the liver

**Metabolic processes** utilize a variety of differing and contrasting biochemical routes to enable synthesis of degradation and activation or deactivation of substances; in addition, they facilitate cellular uptake and excretory mechanisms. Moreover, there are various links between different metabolic pathways and functional processes. Intermediate chemical products generated in the course of metabolic reactions may be taken up by other pathways or cycles. Substrates are shifted between subcellular structures, and the metabolic end-products of one process are often used as the original substrate for new syntheses.

A general picture of the intricate complexity of various cycles, biochemical pathways and metabolic reactions within the liver has been excellently presented in **two posters.** (27)*

2. *Reutter, W., Geilen, Ch., Baum, O.*: Metabolic pathways in the liver cell. (6th Ed., 1998)

## 2 Regulatory metabolic mechanisms

The intricate network of biochemical reactions occurring within the restricted volume of the liver cell requires subtly controlled metabolic regulatory mechanisms. (28) These occur on **four levels:** (*1.*) at the molecular level, (*2.*) within the organelles, (*3.*) at the cellular level, and (*4.*) at the organ level.

(*1.*) *Regulation* may occur at the **molecular level** for example:
- through negative feedback, whereby the end-product of a metabolic reaction inhibits the activity of the enzyme which determines the speed of reaction. This affords a rapid adaptation of specific chemical reactions in response to alterations in metabolic conditions;
- through changes in the actions of activators and inhibitors;
- through modulation of enzyme activities;
- through changes in the rate of enzyme synthesis or degradation.

(*2.*) *Regulation* can take place within the **organelles** for example:
- Protein synthesis occurs in the ribosomes of the rough endoplasmic reticulum − by contrast, the process of protein degradation occurs in the lysosomes.
- Fatty acids are synthesized in the smooth endoplasmic reticulum, but they are broken down in the mitochondria.

(*3.*) *Regulation* may be effected at the **cellular level** for example:
- Hepatocytes display *metabolic heterogeneity* according to their zonal location within the acinus. (42) (s. p. 24) Specific chemical processes thus proceed exclusively or predominantly in the hepatocytes of the periportal or the perivenous zones. The zonally segregated reactions may also be regulated separately. It seems that, under certain conditions, metabolic processes are also "shifted" from one zone of the acinus to another.
- Hepatocytes interact closely with the sinusoidal cells and Kupffer cells (e.g. in the breakdown of erythrocytes and the degradation of pyrimidine nucleotides).
- Hepatocytes and sinusoidal cells are influenced by vegetative nerve fibre endings in Disse's space.

(*4.*) *Regulation* of metabolic processes may be achieved through biochemical interactions at the **organ level** for example:
- between the liver and the musculature
- between the liver and the kidneys

- between the liver and the endocrine system
- between the liver and the intestine

**Zonal heterogeneity**

Although hepatocytes appear to be relatively uniform under the light microscope, they display structural heterogeneity when viewed under an electronic microscope and functional heterogeneity on a metabolic level. (s. p. 24) This heterogeneous zoning provides optimum control and prevents futile cycles. However, the zones have no clear-cut boundaries, and merge freely with each other. (10, 28, 42−44, 46) (s. tab. 3.2)

| Periportal zone (zone 1) | | Perivenous zone (zone 3) | |
|---|---|---|---|
| Hepatocytes | smaller | Hepatocytes | larger |
| Mitochondria | larger | Mitochondria | smaller |
| Golgi membrane | ↑ | Golgi membrane | ↓ |
| Golgi glycogen | ↑ | Golgi glycogen | ↓ |

***Tab. 3.2:*** Morphological heterogeneity of liver cells and organelles as well as metabolic heterogeneity of hepatocytes according to their respective zonal location in the acinus (s. pp 23, 24)

Bile acids are channelled from the sinusoids periportally via transport systems with low affinity and high capacity, and in the perivenous area via transport systems with high affinity and low capacity. The bile acids are therefore excreted with decreasing concentration from the periportal to the perivenous area.

Intrahepatic biliary epithelium also plays a contributory role in functional heterogeneity. The absorption and secretory processes along the bile ducts fulfill different functions. Such cholangiocytic heterogeneity can also be detected in various reactions to different forms of damage. (46)

In addition to the regulatory mechanisms listed above, metabolic processes may be altered at the cellular and subcellular levels by further **influencing factors** such as hormones, vitamins, trace elements and the autonomic nervous system. • *The liver requires ca. 340 kcal/day in order to carry out all its functions adequately.*

# 3 Bilirubin metabolism of the liver

▶ The complete structure of bilirubin was described as an open tetrapyrrole derivative of haem by H. FISCHER in 1935.

Bilirubin is an organic anion. It is mainly (ca. 80 %) derived from the degradation of ageing erythrocytes in the spleen, liver (hepatocytes, Kupffer cells), kidneys and bone marrow. Approximately 36.2 mg bilirubin are produced from 1 g haemoglobin. The daily output of bilirubin is 250−350 mg (3.8 ± 0.6 mg/kg BW).

The oxidation of **haem**, a complex consisting of iron and protoporphyrin which is derived from haemoglobin, is effected by haem oxygenase to produce **biliverdin IX**α. This is converted to **bilirubin IX**α by biliverdin reductase. The reaction speed of this process is governed by the haem oxygenase. This enzyme complex contains the inducible cytochrome P 450, which accelerates bilirubin production when the haemoglobin level is elevated. A small proportion of bilirubin (20−30%) is produced from the degradation of other metalloporphyrins. (s. fig. 3.1)

Bilirubin − an apolar, water-insoluble lipophile substance − is potentially toxic. It is bound to serum albumin and transported to the sinusoidal membrane of the liver cell as a **bilirubin-albumin complex**. (s. fig. 3.1) The binding capacity of albumin is exceeded only at a serum bilirubin concentration of >4−5 mg/dl. In the case of decreased albumin binding (e. g. in acidosis) or oversaturated binding capacity, there is a danger of toxic cell damage due to the diffusion of unbound bilirubin into the cells (in some cases accompanied by kernicterus). Neonates and premature babies are at particular risk because of their immature blood-cerebrospinal fluid barrier. Albumin-bound bilirubin can function as an antioxidant to intercept free radicals and/or O$_2$ radicals. (93) (s. tab. 3.25)

The precursory peak or **shunt bilirubin** (10−20%) is formed during the first 3 days of life from the breakdown of erythrocyte precursors in the bone marrow. A smaller proportion originates from haemoproteins in the liver. In increased erythropoiesis or in dyserythropoiesis, the proportion of precursory bilirubin is raised. • Albumin is bound to the sinusoidal surface of the cell membrane (by a specific receptor?), and detachment of bilirubin follows. Subsequently, nonspecific membrane glycoproteins mediate the active **bilirubin uptake** (even against a concentration gradient) into the liver cell. • **Binding of the bilirubin** to the Y protein (= ligandin, identical to glutathione-S transferase) is effected in the

cytosol of the liver cell, preventing both movement of bilirubin from the cytosol into the cellular organelles and its diffusion back into the bloodstream. With a higher bilirubin concentration and a saturation of the Y protein, bilirubin is bound to the Z protein (= fatty

acid-binding protein). It has a lower affinity with, but a larger capacity for bilirubin than ligandin. (5, 20, 84)

The **conjugation** of bilirubin occurs in the SER, mediated by microsomal enzymes: bilirubin is esterified with glucuronic acid through the action of UDP-glucuronyltransferase (localized in the q 37 area of chromosome 2) to produce monoglucuronide. The subsequent diglucuronidation takes place in the RER. (s. fig. 3.1) The conjugation converts **indirectly reacting** (lipophilic, unconjugated, water-insoluble, primary) bilirubin to **directly reacting** (water-soluble, conjugated, secondary) bilirubin, which is consequently eliminated via the bile and urine. The conjugated form of bilirubin is normally present in the blood in $3-10\%$ of the total serum bilirubin. A small amount of bilirubin is covalently bound to protein, a proportion of which reaches the serum as **δ-bilirubin** (half-life in serum is 14 days). • The *intracellular transport* of bilirubin is effected via the microtubules of the Golgi apparatus and also by means of passive diffusion processes in the cytosol.

Active **excretion** occurs in the canaliculi at the canalicular membrane, albeit independently of bile acids, by means of nonspecific transport proteins (mainly by MOAT), but is independent of bile acids; during this process bilirubin is found in 100-fold concentrations. Various substances compete with the bilirubin excretory process for this nonspecific carrier system. Bilirubin is transported together with cholesterol, bile acids and phospholipids in mixed micelles or vesicles. Bilirubin diglucuronide is discharged into the intestine together with the bile. Absorption is neither possible from the gall bladder nor from the intestine; in general, no enterohepatic reabsorption of bilirubin takes place. The glucuronic acid moieties are released by the action of β-glucuronidase from enteric bacteria, and bilirubin is converted into colourless, stereoisomeric **urobilinogen** by bacterial reductases. Oxidation of urobilinogen gives rise to **urobilin** and **stercobilin,** which, together with their degradation products, are responsible for the brown colour of the stools. A portion of the urobilinogen (ca. 1%) is reabsorbed, transported through the portal vein back to the liver and re-excreted via the bile (= *enterohepatic circulation*). A small proportion of the urobilinogen in the blood is eliminated from the body in the urine ($1.0-3.5$ mg/day; $1.7-5.9$ µmol/day). Some $70-470$ µmol ($40-280$ mg) stercobilin are excreted in the stools daily. (s. figs. 3.1; 5.3) *(see chapter 12)*

# 4 Porphyrin metabolism of the liver

**Porphyrins** represent the prosthetic groups of haemoproteins (haemoglobin, myoglobin, cytochromes, oxygenases, catalases, peroxidases, etc.). The chemical parent compound of the porphyrins is the tetranuclear pyrrolic dye, porphin. • The capacity for **haem synthesis** is common to almost all cells, but is especially important

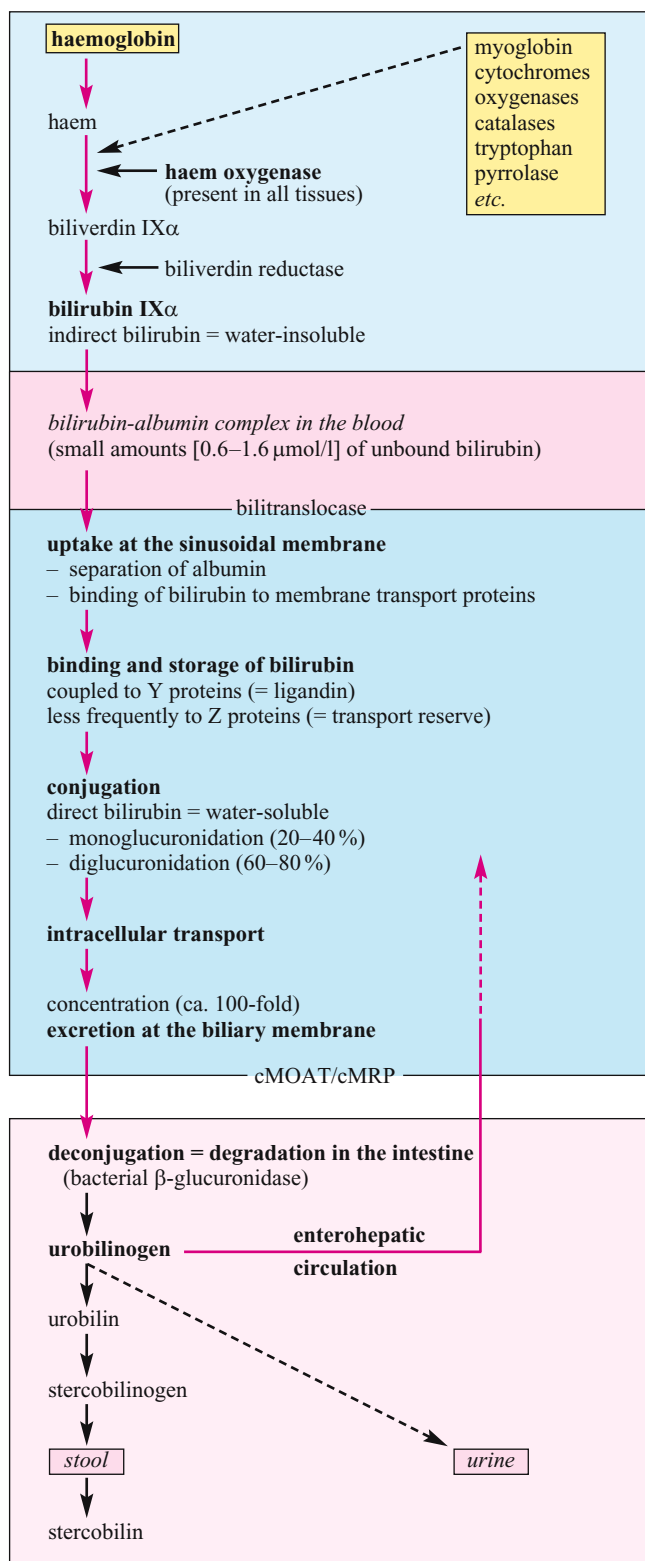

*Fig. 3.1:* Diagram showing bilirubin metabolism

in the erythrocyte precursors for the synthesis of haemoglobin and in the hepatocytes for the synthesis of hepatic haemoproteins. Haem synthesis mainly takes place in the bone marrow (80−85%) and in the liver (ca. 15%). Two-thirds of the haem synthesized in the liver are required for the formation of cytochrome P 450. Daily production of haem amounts to ca. 300 mg (0.7−1.6 µmol/kg BW), of which only 1% is excreted unused in the urine and stools. The action of oxygen gives rise to the strongly red-fluorescing ($\lambda_{max}$ = 366 nm) porphyrins. (s. fig. 7.10) • Haem synthesis begins in the mitochondria, then progresses through a series of cytosolic reactions before being completed again in the mitochondria. (s. fig. 3.2) The porphyrinogens represent colourless intermediate products. Each step in this process is enzymatically controlled. • The **regulation** of haem synthesis is highly efficient, whereby 3 enzymes play key roles: (*1*.) δ-aminolaevulinic acid synthase, (*2*.) uroporphyrinogen synthase, and (*3*.) ferrochelatase. The most crucial enzyme is δ-aminolaevulinic acid synthase, whose activity is subject to negative feedback control by the end-product haem − i.e. haem controls its own rate of synthesis. Porphyrins are irreversible oxidation products. With the exception of protoporphyrin, they are not utilized for other purposes, but are excreted. Under pathological conditions, they are stored in cells. Some intermediate products are eliminated in the stool (e.g. protoporphyrin IX) and others in the urine (e.g. coproporphyrin III, uroporphyrin I). (s. tab. 3.3) • Important **inducers** of δ-aminolaevulinic acid synthase include: barbiturates,

sulphonamides, oestrogens, androgens, alcohol and fasting. (*see chapter 31.15*)

| | µmol/24-hour urine |
|---|---|
| δ-aminolaevulinic acid | 1.9−49.0 |
| porphobilinogen | 0.5−  7.5 |

# 5  Bile acid metabolism of the liver

## 5.1  Biosynthesis of bile acids

> The complete structure of the bile acids was elucidated by H. WIELAND in 1932.

▶ The **primary bile acids** are formed in the hepatocytes as liver-specific degradation products of cholesterol due to the action of microsomal, peroxisomal and mitochondrial enzymes; they are linked to cytosolic proteins. The initial enzyme in the biosynthesis, **cholesterol-7α-hydroxylase**, is also the rate-determining one. This enzyme, a cytochrome P 450 mixed-function oxidase, is localized in the SER. Its enzymatic activity is regulated by a *negative feedback* mechanism, in which bile acids re-enter the liver after passage through the entero-hepatic circulation. After a possible second hydroxylation, the enzymatic removal of side chains as well as the introduction of a carboxylic group take place in the mitochondria. (s. fig. 3.3) • Two primary bile acids are thus synthesized. Twice as much cholic acid (1 mmol) as chenodeoxycholic acid is produced (1 mmol corresponds to 0.4 g free bile acid). The two bile acids represent 60−90% of the total bile acid production:

1. **Cholic acid** (ca. 40%)
   (3α-,7α-,12α-trihydroxy-5β-cholanic acid)

2. **Chenodeoxycholic acid** (ca. 40%)
   (3α-,7α-dihydroxy-5β-cholanic acid)

Biosynthesis of the two primary bile acids is followed by conjugation of their carboxylic group with the amino group of either glycine or taurine, mediated by a cytoplasmic enzyme. By means of this conjugation, the primary bile acids, which initially are barely water-soluble, become anions and are thus rendered hydrophilic. In this way **four conjugated bile acids** are formed:

**Fig. 3.2:** Diagram showing porphyrin metabolism with haem synthesis in the liver (0.7−1.4 µmol/kg body weight per day = ca. 10−20% of total haem synthesis) (s. tab. 3.3)

| | |
|---|---|
| 1. Glycocholic acid | 24% |
| 2. Taurocholic acid | 12% |
| 3. Glycochenodeoxycholic acid | 24% |
| 4. Taurochenodeoxycholic acid | 12% |
| = ca. 72% conjugated primary bile acids | |

| | |
|---|---|
| 1. Glycodeoxycholic acid | 16% |
| 2. Taurodeoxycholic acid | 8% |
| 3. Glycolithocholic acid | 0.7% |
| 4. Taurolithocholic acid | 0.3% |
| = ca. 25% conjugated secondary bile acids | |

▶ The **secondary bile acids** result from the activity of anaerobic intestinal microorganisms in the ileum, caecum and colon. (s. fig. 3.3) • *Deconjugation*, with the subsequent release of free bile acids, is a prerequisite for these reactions. This is followed by 7α-dehydroxylation of cholic acid and chenodeoxycholic acid to yield deoxycholic acid and lithocholic acid, respectively. 7α-dehydrogenation and oxidation of chenodeoxycholic acid also yield ketolithocholic acid:

| |
|---|
| 1. **Deoxycholic acid** <br> *(3α-,12α-dihydroxy-5β-cholanic acid)* |
| 2. **Lithocholic acid** <br> *(3α-hydroxy-5β-cholanic acid)* |
| 3. **Ketolithocholic acid** <br> *(3α-hydroxy-7keto-5β-cholanic acid)* |

▶ The **tertiary bile acids** are formed in the liver as well as in the gut. (s. fig. 3.3) • Intestinally absorbed lithocholic acid is enzymatically converted to sulpholithocholic acid in the liver. Ketolithocholic acid is transformed to (hypercholeretic) ursodeoxycholic acid in both the intestine and the liver. When passing through the canaliculi, UDC is partly reabsorbed by epithelial cells and returned to the liver via the blood circulation (= *cholehepatic shunt*). (41) The latter is chemically and structurally identical to chenodeoxycholic acid, of which it is deemed to be the 7β-epimer:

| |
|---|
| 1. **Sulpholithocholic acid** <br> *(3-sulphohydroxy-5β-cholanic acid)* |
| 2. **Ursodeoxycholic acid** (2−5%) <br> *(3α-,7β-dihydroxy-5β-cholanic acid)* |

The bile acids may be further modified by **enzymatic reactions.** The enzymes involved have been found in the liver, intestine and kidney. By their action, conjugated and unconjugated primary or secondary bile acids may become bound to sulphuric acid, glucuronic acid or glucose. A further improvement in water-solubility can be obtained by **sulphation** or **glucuronidation**.

**Regulation of the biosynthesis** of bile acids is predominantly achieved through feedback by the respective daily loss quota. Further regulations are effected by HMG-CoA reductase and 7α-hydroxylase, which are themselves chiefly adjusted by ursodeoxycholic acid. (s. fig 3.3) With advancing age, bile acid synthesis in the liver decreases and excretion of cholesterol in the bile increases. • *The terms "bile acids" and "bile salts" are interchangeable.*

*Fig. 3.3:* Biosynthesis of bile acids

The secondary bile acids become partially (30−50%) absorbed in the intestine and, following reconjugation with glycine or taurine in the liver, are excreted into the canaliculi. The bile thus contains a mixture of primary and secondary bile acids. Deoxycholic acid as a secondary bile acid is likewise an "end-product"; it enters the enterohepatic circulation without further modification. • Conjugation of the secondary bile acids in the liver yields the following **four conjugated bile acids:**

## 5.2 Enterohepatic circulation of bile acids

▶ **Bile acid production** amounts to 400−500 mg/day (ca. 1 mmol). Excretion in the stool is of a similar order; accordingly, renewed synthesis of bile acids is determined by the daily loss. Excretion in the urine lies below 0.5 mg/day (8 μmol/day) − this small amount may be disregarded.

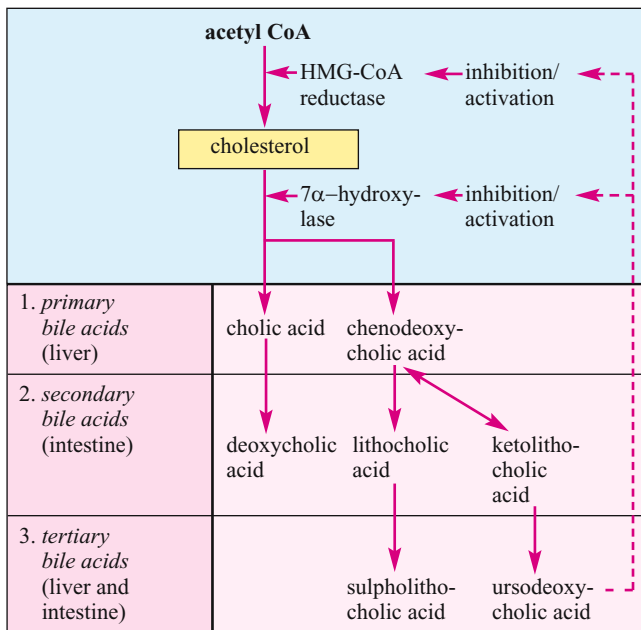
▶ The body's **bile acid pool** (2−5 g, 5−10 mmol) is held constant by the balance between the rates of synthesis and excretion. This pool is brought into circulation 3−10 times/day by biliary secretion of the bile acids into the intestine at a rate of 12−24 g/day (30−60 mmol/day). As a general rule, the pool circulates 2(−3) times per meal. Approximately 95% of the intestinal bile acids are reabsorbed. The hourly uptake of bile acids by the liver is in the order of 450 μmol (180 mg).

Circulation of the bile acids is guaranteed by several **metabolic pump systems** in such a way that they are also transported against a concentration gradient. (3, 11, 15, 19, 23, 30, 37, 50, 56, 59, 70, 81, 92, 94, 100)

(*1.*) **Bile acid uptake** at the *sinusoidal membrane surface* is achieved actively by several $Na^+$-dependent (NTCP) as well as $Na^+$-independent (OATP) carrier proteins and passively by facilitated "biological" diffusion or free "physical" diffusion processes.

(*2.*) **Bile acid release** occurs at the *biliary membrane surface* in the canaliculi either actively, facilitated by ATP-driven carrier glycoproteins such as MRP2 (also called cMRP or MOAT) and BSEP (identical to cBAT), or by exocytosis of intracellularly derived mixed vesicles, or with the help of a potential-dependent membrane carrier.

(*3.*) **Bile acid uptake** at the *mucosal surface* of the enterocytes proceeds actively either through $Na^+$-dependent carrier systems in the ileum or by free diffusion in the ileum and colon.

The gall bladder and upper small intestine serve as **mechanical stores** with the ability to drive the circulation of the bile pool by peristaltic action. • The bile acids become bound chiefly to albumin or HDL for **transport in the blood.** Incorporation into HDL is effected by apolipoproteins $A_1$ and $A_2$. • **Uptake into the hepatocytes** is mediated by a membrane-specific transport system, which comprises polypeptides and glycoproteins with strong affinities for bile acids. This influx process is predominantly an active transport mechanism against an electrochemical gradient. Energy is supplied by $Na^+/K^+$-ATPase. • **Intracellular transport** of bile acids to the biliary pole of the hepatocytes follows after their binding to cytosolic proteins: "free" bile acids would be damaging to subcellular structures because of their amphiphilic nature and detergent activity. As in the case of bilirubin, vesicles of the endoplasmic reticulum and of the Golgi apparatus as well as of the cytoskeleton are involved in transcellular transport.


All bile acid transport systems possess a high **reserve capacity,** the potential of which greatly exceeds the normal maximum secretion level. Bile acid cross-over from the enterohepatic into the peripheral circulation arises only in the case of massive disturbances in secretion (e.g. in cholestasis). The approx. 1% proportion of bile acids present in the peripheral system remains constant, both pre- and post-prandially. The first-pass elimination of bile acids from the portal blood reaches 70−90%, depending on their type and conjugation status. The bile acids have a half-life of 2−3 days.

## 5.3 Functions of bile acids

The essential **functions of bile acids** are found in cholesterol metabolism, digestion and resorption of fats in the intestine, and regulation of bile flow. (s. tab. 3.4)

Conjugated bile acids have amphiphilic properties in that all their hydrophilic groups lie on one side of the molecule and their hydrophobic (lipophilic) groups on the opposite side. This explains their capacity for **micelle formation.** Owing to their internally orientated hydrophobic groups, such bile acid micelles are able to take up water-insoluble compounds (cholesterol, triglycerides, fat-soluble vitamins, etc.) and then keep them in "solution" in the aqueous milieu by means of their outwardly orientated hydrophilic groups. On attaining a critical size, the disk shape of the micelle is transformed

into a bubble-like structure (= vesicle, liposome). The micelle may also serve as an excretory mechanism for heavy metals such as copper and mercury.

---

1. **Cholesterol metabolism**
   a. reduction in excess cholesterol
      − through degradation of cholesterol to bile acids
      − by solubilization of cholesterol in the bile
   b. regulation of cholesterol synthesis in the liver and intestine
   c. regulation of cholesterol output into the bile
      − $3\alpha$-,$7\alpha$-bile acids inhibit secretion
      − $3\alpha$-,$12\alpha$-bile acids increase secretion
2. **Digestion and resorption of dietary fats**
   a. by formation of micelles
   b. by stabilization and activation of enzymes (e.g. pancreatic lipase, phospholipase $A_2$, pancreatic cholesterol esterase)
3. **Effects on the bile flow due to osmotic water movement**
4. **Effects on bile secretion**
   a. monohydroxy bile acids function cholestatically
   b. dihydroxy and trihydroxy bile acids have a choleretical effect
5. **Emulsification of fat-soluble vitamins**
6. **Stimulation of intestinal motility**

*Tab. 3.4:* Functions of bile acids

---

## 5.4 Composition and secretion of bile

**Primary bile,** already containing various compounds (= solutes) collected during transcellular transport, is formed by osmotic filtration at the canalicular membrane of the hepatocytes. It is yellow to orange in colour. Paracellular incorporation of further solutes into the bile occurs via the intercellular gap and the tight junctions. The **canalicular bile flow** comprises two fractions:

(*1.*) The **bile acid-dependent fraction** (250 ml) is formed chiefly in the periportal acinus. (s. tab 3.2) There is a linear relationship between bile acid excretion and bile flow. Osmotic filtration of water and inorganic ions is proportionally elevated (dependent upon bile salt concentration). Other secretory mechanisms or pump systems may also be activated by bile acids.

(*2.*) The **bile acid-independent fraction** (200 ml) is to be found in the absence or near absence of bile acids. This fraction is formed chiefly in the perivenous acinus. (s. tab. 3.2) However, $Na^+/K^+$-ATPase, glutathione and an active bicarbonate transporter also play an important role. Likewise, the prostaglandins $A_1$, E and $E_2$ stimulate the production of this fraction.

The bile acid uptake capacity at the sinusoidal membrane is 8−10 times higher than the secretion rate at the canalicular membrane. Approximately 450 ml **canalicular bile** are formed daily, each fraction constituting half of this total. Secretion of bile into the canaliculi is further assisted by microfilaments. In the case of loss of microfilament function, the canaliculi become broadened and immobile, thereby also inhibiting the bile flow.

This volume of secretion is supplemented in the ductules by ca. 150 ml **ductular bile,** resulting in a daily production of ca. 600 ml. Bile formation is lower at night than during the day. The most important constituents of the so-called *liver bile* are the bile acids, phospholipids, proteins, cholesterol and bilirubin. The term **bile lipids** includes cholesterol, bile salts and phospholipids. The manner in which cholesterol is excreted into the gall bladder is not yet known, nor have any cholesterol-specific transport systems been detected. Cholesterol is primarily broken down into bile acids. (see above) (s. tab. 3.5)

| | | | |
|---|---|---|---|
| Bile acids (bile salts) (3−45 mM) | | 67% | |
| Phospholipids (150−800 mg/dl) | | 22% | |
| Protein, IgA, IgM, glutathione | | 5% | |
| Cholesterol (80−200 mg/dl) | | 4% | |
| Bilirubin (1−2 mM) | | 0.3% | |
| Electrolytes ($Na^+$, $K^+$, $Ca^{++}$, $HCO_3^-$) | | | |
| Water | 90−95% | pH | 6.2−8.5 |
| Solutes | 5−10% | Spec. gravity | 0.995−1.008 |

**Tab. 3.5:** Composition of ductular bile (so-called liver bile)

# 6 Amino acid and protein metabolism of the liver

The body contains approx. 14,000 g protein in total. There is a 24-hour turnover of 600−700 g of the amino acid pool. The musculature has the highest absolute rate of protein synthesis. The protein synthesized here is retained for exclusive use in the muscles. In relation to its weight, the liver generates more protein than the musculature. The synthesis rate in the liver amounts to 120 g/day, whereby 70−80% of these proteins are released by the hepatocytes, so that only 20−30% remain available for their own use. Plasma protein turnover is 25 g/day, that of the total tissue protein approx. 150 g/day. Amino acid turnover and protein synthesis proceed rapidly and continuously.

## 6.1 Biochemistry of amino acids

Human protein metabolism is essentially dependent on 20 amino acids. These amino acids lend themselves to various **classification criteria,** which also give hints regarding their *biochemical functions* (s. tab. 3.6):

1. according to their **metabolic characteristics** into ketogenic and glucogenic amino acids;
2. according to their **chemical structure** into α-, β- and γ-amino acids;
3. according to their **configuration** into D- and L-amino acids;
4. according to their **isoelectric point** into neutral, acidic and basic amino acids as well as amphoteric amino acids;
5. according to the **polarity** of their side chains into polar amino acids (with neutral + hydrophilic side chains) and nonpolar amino acids (with neutral + hydrophobic side chains) as well as those carrying basic + hydrophilic side groups (e. g. aspartate, glutamate) or those carrying basic + hydrophobic side groups (e. g. arginine, histidine, lysine);
6. according to their **biosynthesis** in the human organism into 8 essential, 10 non-essential and 2 semi-essential amino acids.

**Essential amino acids** are indispensable in that the body is incapable of replacing them simply by using its own synthesizing facilities: they must either be supplied in adequate quantities from outside or generated by degradation of body proteins. • **Non-essential amino acids** are synthesized in the liver, muscles, kidneys and intestine. Only the synthesis of arginine from ornithine and the hydroxylation of phenylalanine to tyrosine are liver-specific reactions.

The division between **branched-chain amino acids** (isoleucine, leucine, valine) and the group of **aromatic amino acids** (methionine, phenylalanine, tryptophan, tyrosine) is of clinical relevance. (s. tab. 3.6) (s. fig. 3.4)

The **amino acid pool** (600−700 g) is distributed among the musculature (80%), the liver (15%) and the plasma (5%). The proportion of free amino acids merely amounts to about 0.5% of the total amino acids contained in the body proteins. Of this amount, 300−500 g are used daily for protein synthesis, and approx. 2 g are used for the synthesis of other N-containing compounds (e. g. purines, porphyrins, pyrimidines); a further 120−130 g are degraded per day. • This daily amino acid consumption is replaced from *three sources*, so that the amino acid pool is maintained at a constant level: (*1.*) 70−100 g should be contained in the diet, (*2.*) 300−500 g derive from protein degradation, and (*3.*) 30−40 g are replenished from the biosynthesis of non-essential amino acids. The essential amino acids released by proteolysis are utilized as rapidly and completely as possible in the neosynthesis of proteins (= *recycling of essential amino acids*).

The **degradation** of essential amino acids proceeds primarily in the liver − only the three branched-chain amino acids (isoleucine, leucine, valine) are broken down almost exclusively in the muscles. Non-essential amino acids can be degraded in the liver and muscles (but also in other organs). This is effected mainly by transamination and oxidative deamination. (16) • The *C-skeleton,* an intermediate product in amino acid degradation, is used for energy production in the citric acid cycle. *Ketoplastic amino acids* serve to produce energy while *glucoplastic amino acids* guarantee gluconeogenesis. (s. fig. 3.4)

The **amino group** is excreted to a minor extent as ammonia. Because of its toxicity, ammonia must be rapidly converted into a nontoxic derivative. This is achieved by the binding of ammonia either to α-ketoglutarate or to a $PO_4$ ion to produce glutamate or carbamylphosphate, respectively. Both compounds are subsequently channelled into the urea cycle. A third alternative metabolic pathway is the coupling of ammonia to glutamate to yield glutaminic acid, which is then eliminated in the urine. The *"temporary ammonia detoxification"* takes place in both the liver and the musculature as well as in other organs. The *"definitive ammonia detoxification"* is, however, a liver-specific reaction in the urea cycle. (s. p. 57)

| Amino acids | essential AA | semi-essential AA | non-essential AA | BCAA | AAA | polar AA | ketogenic AA | glucogenic AA |
|---|---|---|---|---|---|---|---|---|
| Alanine | | | + | | | + | | + |
| Arginine | | + | | | | | | + |
| Asparagine | | | + | | | + | | |

| Valine | + | | | + | | + | | + |

*Tab. 3.6:* Classification of the 20 important (essential and non-essential) amino acids (AA = amino acid; BCAA = branched-chain amino acid; AAA = aromatic amino acid)

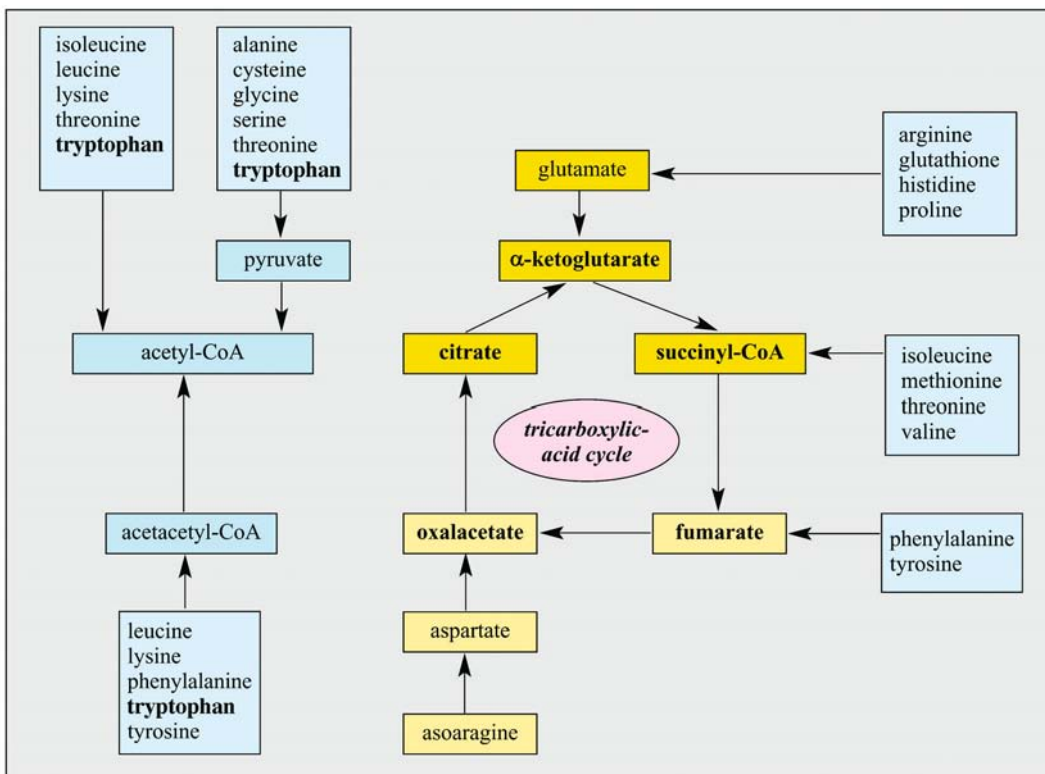

*Fig. 3.4:* Transfer of carbon skeletons from the amino acids into the tricarboxylic-acid cycle via intermediates (G. REHNER, H. DANIEL, 1999)

Dietary protein deficiency, especially a lack of essential amino acids, has a long-term effect on regulatory mechanisms. **Tryptophan** plays a significant role here. Tryptophan deficiency leads to decreased protein synthesis, which is reversible solely by dietary supplementation of tryptophan even during inanition. The tryptophan effect occurs rapidly following the stimulation of nuclear RNA synthesis. (89) (s. fig. 3.4)

The **glucose-alanine cycle** between the liver and the musculature is particularly significant. In muscle tissue, ammonia is generated during the degradation of amino acids (particularly the branched-chain amino acids). The transfer of ammonia to pyruvate yields alanine, which is then transported through the bloodstream to

the liver. Here, the C-skeleton of alanine is liberated for use in glucose synthesis via pyruvate, while the amino-N of alanine is incorporated as ammonia into the urea cycle. Glucose is released from the liver back to the muscle tissue. Up to 60−70% of the alanine released from the muscles are derived from glucose.

The **regulation** of amino acid metabolism is achieved by feedback mechanisms. The varying concentrations of amino acids in the portal blood are balanced in the liver, whereby there is a negative feedback in relation to the amino acid output of the intestine. The degradation and synthesis of amino acids (and consequently also of proteins) are kept constant. A circadian rhythm operates in this instance. Only the branched-chain amino acids pass through the liver unmetabolized, irrespective of their concentration in the portal blood. • The synthesis of amino acids and proteins is regulated by various *hormones*: glucagon inhibits protein synthesis, while stimulation is effected by insulin, somatotrophin, TSH and glucocorticoids. Protein synthesis in the hepatocytes is also controlled by colloid osmotic pressure.

## 6.2  Protein synthesis and catabolism

Hepatic **protein synthesis** proceeds via the subcellular stages of gene transcription (in the nucleus) and gene translation (in the cytoplasm). The DNA is transcribed into various types of RNA by the action of the different DNA-dependent RNA polymerases I (A), II (B) and III (C). RNA polymerase I is responsible for the transcription of ribosomal RNA, RNA polymerase II mediates the transcription of messenger RNA, and RNA polymerase III forms transcriptal RNA. These three different RNA types move out of the nucleus into the cytoplasm. Here the **ribosomes** acquire the genetic information needed for protein synthesis via mRNA, and tRNA transports the activated amino acids to the ribosomes, which are themselves activated (and if necessary replicated) by rRNA. (s. figs. 2.9, 2.17; 3.5)

Proteins destined for secretion from the liver cell collect as "bound polysomes" on the endoplasmic reticulum, which is thus recognizable as *rough endoplasmic reticulum* (RER). From here the proteins are transported to the Golgi apparatus, where they are either stored or "processed", but are also available for secretion. (s. p. 27)

More than 100 plasma proteins are synthesized in the liver cell, the majority being **glycoproteins.** About 15 of the glycoproteins (including C-reactive protein, fibrinogen, haptoglobin, ceruloplasmin and $\alpha_1$-antichymotrypsin, $\alpha_1$-antitrypsin, $\alpha_2$-macroglobulin) belong to the *acute-phase-reaction* group.

Numerous **transport proteins,** including prealbumin (= transthyretin), albumin (72), ceruloplasmin, haemopexin, haptoglobin, retinol-binding globulin, thyroxine-

binding globulin, transcobalamin, transcortin and transferrin are synthesized in the liver.

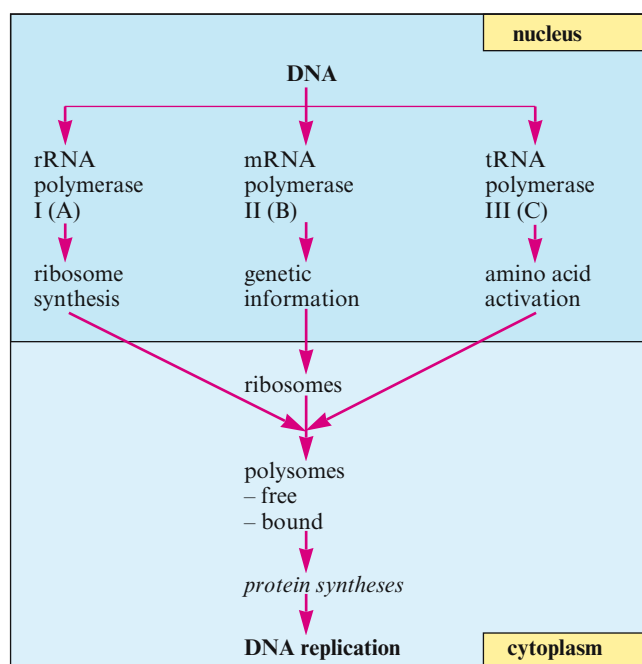

*Fig. 3.5:* Diagram showing protein synthesis in the liver cell by means of transcription (in the nucleus) and translation (in the cytoplasm)

# 7  Carbohydrate metabolism of the liver

The liver is of central significance for the regulation of carbohydrate metabolism and the maintenance of the physiological glucose concentration within narrow limits. A person weighing 70 kg has a carbohydrate reserve of approx. 2,500 kcal. There is an intermittent dietary uptake of carbohydrates which, after resorption in the intestine, are transported primarily to the liver. The liver can take up about 87% of the glucose delivered by the portal blood. When required, the liver is able to release glucose from its stored carbohydrate reserves to compensate for any deficiency and maintain the normal blood sugar value. The adjustment of blood sugar concentration, which is responsible for all intermediary metabolic processes, is regulated by the interplay between insulin and its hormonal antagonists, such as glucagon and adrenalin. Thyroxine, glucocorticoids and STH are also involved in this regulatory system. (s. fig. 3.6) • Moreover, the liver fulfils functions in the pentose-phosphate cycle as well as in the metabolism of galactose, fructose and sorbitol. • Thus the liver contributes in four different ways to the maintenance of **glucose homoeostasis** within the context of carbohydrate metabolism: (*1.*) glycogenesis, (*2.*) glycogenolysis, (*3.*) gluconeogenesis, and (*4.*) glucolysis. • *The liver therefore functions as a glucostate* (K. JUNGERMANN, 1986).
**Fig. 3.6:** Regulation of carbohydrate metabolism in the liver and musculature as well as its relationship to protein and fat metabolism

## 7.1 Glycogenesis and glycogenolysis

The postprandial glycogen content of the liver is $65-80$ g/kg liver wet weight ($= 5-8\%$ of total liver weight). This reserve is sufficient to maintain glucose homoeostasis in the organism for up to 10 hours or, in conjunction with gluconeogenesis, up to 20 hours. In periods of fasting, the glycogen content sinks to 0.1%, but rises to >10% when a high-carbohydrate diet is consumed. Some $250-350$ g glycogen are stored in the muscles, but this is solely for utilization by the muscle tissue. The total amount of glycogen in the body is $400-500$ g. Glucose, fructose and galactose are available as initial basic substances. Fructose and galactose are converted to glucose in the liver and may then be channelled into glycogenesis. The metabolization of fructose is insulin-dependent, whereas that of galactose is insulin-independent.

▶ The **uptake** of glucose by the perivenous hepatocytes is effected in relation to its respective concentration and carried out by insulin-independent glucose transporter isoform (GLUT 2, and possibly GLUT 1). Nothing is known about the function of GLUT 1, which is present in the perivenous scavenger cells. It is mainly found in centroacinar hepatocytes and has a high glucose affinity at low capacity. GLUT 4 can be found on adipocytes and skeletal muscle cells. • In the first instance, the liver allows most of the incoming glucose to pass through to the peripheral organs for utilization; it is only the returning 3-carbon moieties which are subsequently incorporated into glycogen (= **glucose paradox**) (J. D. MCGARRY et al., 1987). Glucose is converted by glucokinase to glucose-6 phosphate and glucose-1 phosphate. This leads to the synthesis of UDP glucose (= *activated glucose*), from which **glycogen** is formed. Once glycogen has reached saturation level, the remaining glucose is broken down into lactate. When lactate is transported via the blood stream, it is taken up together with alanine by the periportal hepatocytes, which are then able to form glycogen by means of gluconeogenesis.

▶ In **hypoglycaemia**, a protein phosphorylase is activated by glucagon and adrenalin via cyclic AMP. As a result, glycogenesis is inhibited and **glycogenolysis** is stimulated: glycogen is converted by glycogen phosphorylase to glucose-1 phosphate, which is then converted to glucose-6 phosphate. This leads to the release of **free glucose**. • *Glucose-6 phosphate is therefore the key activator in glucose metabolism.*

## 7.2 Gluconeogenesis and glucolysis

The extracellular **glucose pool** is 110 mmol ($= 20$ g) in a volume of 28 litres, giving a concentration of 5 mmol/l. (s. fig. 3.7) • *Glucose* is able to cross the plasma membranes freely and enter the liver cells independently of insulin. It is capable of taking part in metabolism only after phosphorylation (by hexokinase or glucokinase). • Glucokinase activity is regulated according to the blood sugar level in the portal vein. The physiological glucose concentration is thus maintained within a range of 2.5 mmol/l ($= 45$ mg/dl) to 7.77 mmol/l ($= 140$ mg/dl). Glycogenolysis in the liver releases glucose at a rate of 26 mmol/hr in the resting state. This is supplemented by 13 mmol/hr from gluconeogenesis. These 39 mmol are released hourly into the extracellular glucose pool. The CNS receives 20 mmol/hr, i. e. more than twice as much as the muscles (9.4 mmol/hr) and the erythrocytes (8.3 mmol/hr). The glucose entering intermediary metabolism serves as an energy source, but is also incorporated into the pentose-phosphate cycle and glycogen synthesis. A total of 38 mmol/hr (6.8 g) glucose are consumed, and 39 mmol ($= 7.0$ g) are simultaneously liberated. Glucose, as glucose-6 phosphate, may be channelled into various metabolic pathways, e. g. into the pentose-phosphate cycle, into glycolysis with pyruvate and/or lactate as end-products, or into the citrate cycle with degradation into $CO_2$, $H_2O$ and energy (ATP). Aerobic glycolysis produces 38 mol ATP.

**Gluconeogenesis** is activated when the glycogen reserves are exhausted. There are three alternative substrates available in the liver cells for glucose synthesis:

1. *Lactate* (60%)
   = from anaerobic glycolysis
2. *Amino acids*, mainly alanine (30%)
   = from proteolysis
3. *Glycerol* (10%)
   = from lipolysis in the fatty tissue

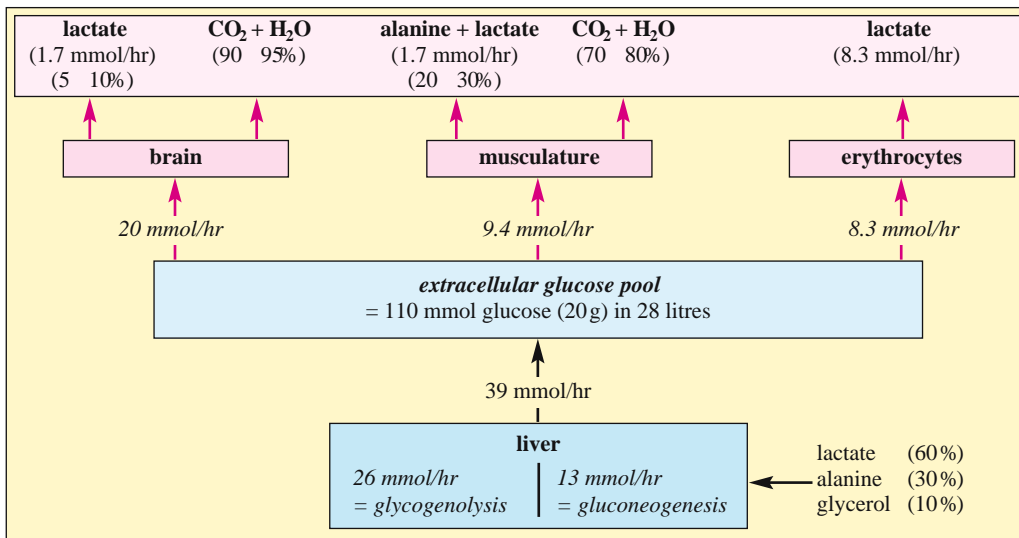
Gluconeogenesis enables the liver to produce at least 240 g glucose per day. This amount can be used up by erythrocytes and the nervous system in 2 days of fasting. Most of the amino acids required for gluconeogenesis during fasting originate from the degradation of proteins in muscle tissue and visceral organs (including the liver). Fatty acids are no longer available for gluconeogenesis because the acetyl residues which are produced


**Fig. 3.7:** Diagram showing glucose metabolism (fasting state)

in their β-oxidation are completely metabolized in the citrate cycle. Gluconeogenesis is an energy-rich process which is increased in the short term by glucagon, adrenaline and acetyl-CoA or in the long term by glucocorticosteroids, but it is inhibited by insulin. The key enzymes of glycolysis are activated by insulin, and a catabolic metabolism is converted to an anabolic one. The hormone amyline, a peptide made up of 37 amino acids, is secreted by β-cells together with insulin. Although it raises glucose levels slightly, it considerably increases the lactate level, which is then used in gluconeogenesis. (77)

**Ketogenesis** is an important metabolic function in the liver. It is the result of an increase in lipolysis in the fatty tissue, with a rise in fatty acids. Insulin inhibits ketogenesis, whereas it is accelerated by fasting as well as by glucagons and insulin deficiency. Ketones (acetacetate, 3-hydroxybutyrate, acetone) are synthesized by means of β-oxidation from acetyl-CoA, assuming the production of this substance exceeds the amount required by the hepatocytes (and glucose metabolism is simultaneously reduced). The liver itself does not require any ketones: acetone is expired, whereas 3-hydroxybutyrate and acetacetate serve as a source of energy. Ketonaemia can lead to metabolic acidosis and electrolyte shifts.

# 8 Lipid metabolism of the liver

Fats and fat-like compounds of varying chemical structures are classified as **lipids**. They have a low molecular weight and are insoluble in water. The original substance in fat biosynthesis is acetyl-CoA (so-called activated acetic acid). On the basis of chemical criteria, they may be divided into *simple lipids* (glycerides, cholesterol, cholesterol esters, bile acids) and *complex lipids*. (s. tab. 3.7)

The liver has a variety of **functions** in lipid metabolism: (*1.*) uptake, oxidation and transformation of free fatty acids, (*2.*) synthesis of plasma lipoproteins, (*3.*) trans-

formation of lipoproteins, (*4.*) catabolization of LDL, VDL and chylomicron remnants, and (*5.*) secretion of enzymes for lipoprotein metabolism.

| Simple lipids | | |
|---|---|---|
| cholesterol esters | (ca. 225 mg/dl) | 32.7% |
| free cholesterol | (ca. 65 mg/dl) | 9.0% |
| triglycerides | (ca. 170 mg/dl) | 24.0% |
| free fatty acids | | 1.0% |
| bile acids | | 0.3% |
| **Complex lipids** | | |
| glycerophospholipids | (ca. 200 mg/dl) | 29.0% |
| sphingolipids | | 4.0% |

**Tab. 3.7:** Distribution of simple and complex lipids in the plasma

## 8.1 Classification of lipoproteins

**Lipoproteins** are macromolecules comprising proteins (= apolipoproteins, apoproteins) and lipids. They transport water-insoluble lipids in the blood, with the exception of the albumin-bound free fatty acids. Only short-chain fatty acids are dissolved in plasma. The lipoproteins are formed in the liver and in the mucosa of the small intestine. (14)

Lipoprotein **characteristics** depends on the varying proportions of protein and lipid present. Lipids are of lower density (<0.9 g/ml) than proteins (>1.28 g/ml), giving a range of lipoprotein densities from 0.9 to 1.21 g/ml. • Lipoprotein **classification** is made according to the respective densities as determined by ultracentrifugation or according to their electrophoretic migration.

**Chylomicrons** are synthesized from exogenously derived triglycerides with *long-chain fatty acids* ($C_{16}-C_{20}$) after their cleavage and re-esterification in the intestinal mucosa. The *medium-chain fatty acids* ($C_{10}-C_{14}$) and the *short-chain fatty acids* ($C_4-C_8$) are transported through the portal vein directly to the liver. Chylomicrons have a particle size of up to 1,000 nm and consist of 98% lipids and 0.5−2.5% proteins. Their density is <0.95 g/ml. The function of the chylomicrons is the transport of exogenous triglycerides in the lymph and blood. Their contents are released to the tissues via the capillaries (by the action of hepatic triglyceride lipase and lipoprotein lipase). They are taken up by the liver as cholesterol-rich "remnants" and degraded in the lysosomes. (s. fig. 3.8)

**Very low density lipoproteins (VLDL)** are synthesized in the liver cell at the contact area of the smooth and rough endoplasmic reticulum and, to a very minor degree, in the mucosa of the small intestine. They have a particle size of $30-80$ nm and consist of 90% lipids and $8-13$% proteins. Their density is $<1.006$ g/ml. The predominant apolipoproteins are B, C III, and E. They are designated as pre-beta lipoproteins on the basis of their electrophoretic migration. The main function of VLDL is the transport of triglycerides of endogenous origin. (s. fig. 3.8)

**Low density lipoproteins (LDL$_2$)** are formed from VLDL in the plasma (by the action of lipoprotein lipase) via *intermediate density lipoproteins* (LDL$_1$ or IDL). If no VLDL is secreted, there is no synthesis of LDL. Insulin and oestrogen increase VLDL secretion. They display a particle size of ca. 20 nm and consist of 75% lipids and $20-30$% proteins. They have densities of $<1.063$ g/ml. The predominant apolipoproteins are A I and A II. According to their electrophoretic migration, they are classified as beta-lipoproteins. The function of LDL is the transport of cholesterol and cholesterol esters. Cell surface LDL receptors take up LDL-bound cholesterol ($50-60$%) according to cellular requirements. In the event of increased LDL availability, scavenger cells (e.g. macrophages) can also act to clear away cholesterol, independently of the LDL receptors. (s. fig. 3.8)

**High density lipoproteins (HDL$_{2,3}$)** are formed in the liver and small intestine. A minor proportion of the HDL appears to derive from triglyceride-rich lipoproteins in the plasma. HDL have a particle size of $5-15$ nm and appear initially as disk-shaped bodies which, after uptake of lipids and lipoproteins, develop in the blood to spherically shaped molecules. They comprise ca. 50% lipids and $45-55$% proteins. Their density is $<1.21$ g/ml. They are designated

$\alpha_1$-lipoproteins based on their electrophoretic migration. HDL transports cholesterol esters derived from the action of lecithin-cholesterol-acetyl transferase (LCAT). They are further differentiated into HDL$_{2a}$, HDL$_{2b}$ and HDL$_3$ on the basis of their varying densities and protein moiety. (29) (s. fig. 3.8)

► The mechanism of **oxidative energy generation** in the liver is mainly the result of *fatty-acid degeneration*. This process begins when the fatty acids are activated. It is followed by β-oxidation (= constant splitting of 2 carbon units until the carbon chain has been completely broken down) in the mitochondria. The acetyl-CoA which is produced can be channelled into the citrate cycle by means of oxaloacetation or used in other biosyntheses. Beta-oxidation of the fatty acids produces (apart from $H_2O$ and $CO_2$) a total of 44 mol ATP from 1 mol of a $C_6$-fatty acid (by comparison, one molecule of glucose produces "only" 32 mol ATP). Another, albeit insignificant, means of fatty-acid degeneration is possible with the aid of α- or φ-oxidation. Peroxisomes are also involved in β-oxidation. The latter produces acetyl-CoA, which is subsequently oxidized to $CO_2$ in the citrate cycle. • *Amino acids* (e.g. alanine, isoleucine, leucine, serine) may provide a further source of energy via pyruvate or acetyl-CoA.

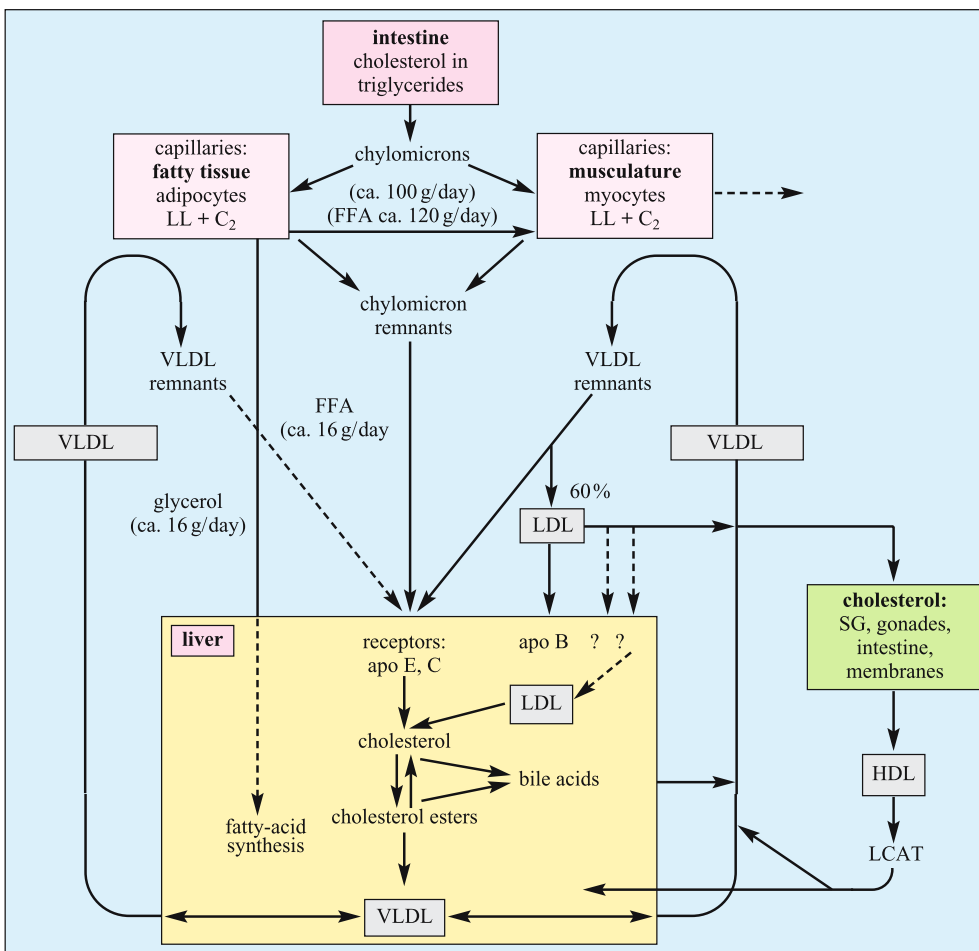

*Fig. 3.8:* Diagram showing the metabolic exchange of lipids between intestine, fatty tissue, musculature and liver (FFA = free fatty acids, LL = lipoprotein lipase, $C_2$ = apoprotein, SG = suprarenal gland)

Energy can likewise be generated by means of *fructose* and *ethanol oxidation*. The partial pressure of oxygen falls from 13 % (centroacinar) to 6 % (perivenous) due to progressive oxygen consumption. Thus it is here that hypoxic cell damage can most frequently be expected.

**Fatty-acid synthesis** is primarily carried out by means of acetyl-CoA cocarboxylase from acetyl-CoA in the cell plasma. In each case, the synthesized fatty acid can be extended by attaching acetyl residues (the opposite can be achieved using β-oxidation). (s. fig. 3.9)

**Lipogenesis**, the synthesis of lipids from carbohydrate via acetyl-CoA, occurs almost exclusively in the liver cells and the fatty tissue. (s. fig. 3.9) • According to *lipid topogenesis* (4), the enzymes involved in triglyceride and phospholipid synthesis are localized on the cytoplasmic surface of the endoplasmic reticulum. The level of hepatic synthesis is regulated primarily by the *insulin-glucagon quotient*, as described by R. H. UNGER in 1971.

## 8.2 Regulation of lipoproteins

▶ Up to now, 13 different **apolipoproteins** are known to be necessary for the maintenance of physiological lipid metabolism (e. g. A I-IV, B 100, C I-III, E). As a result, there is a great variety in terms of their biochemistry and function. Apolipoproteins are synthesized predominantly in the rough endoplasmic reticulum. A further form of classification and regulation of apolipoprotein types is possible according to 4 density groups, or 7 groups if $HDL_{2a}$, $HDL_{2b}$ and $HDL_3$ are included.

The liver synthesizes two enzymes involved in intraplasmic lipid metabolism: *hepatic triglyceride lipase* (HTL) and *lecithin-cholesterol-acyltransferase* (LCAT). • The liver is further involved in the modification of circulatory lipoproteins as the site of synthesis for *cholesterol-ester transfer protein* (CETP). • Free fatty acids are in general potentially toxic to the liver cell. Therefore they are immobilized by being bound to the intrinsic *hepatic fatty acid-binding protein* (hFABP) in the cytosol. The activity of this protein is stimulated by oestrogens and inhibited by testosterone. • Peripheral *lipoprotein lipase* (LPL), which is required for the regulation of lipid metabolism, is synthesized in the endothelial cells (mainly in the fatty tissue and musculature).

**Triglycerides** consist of glycerol and three long-chain fatty acids (ca. 45 % oleic acid, ca. 26 % palmitic acid, ca. 16 % linolic acid). The correct biochemical term is triacylglycerol. They contain 9.5 kcal/g. The total fat content in a person of standard weight provides an energy reservoir of approx. 110,000 kcal. Triglycerides are synthesized from fatty acids and glycerol in lipocytes and hepatocytes. They carry no electrostatic charge and are thus designated *neutral fats*. The liver synthesizes approx. 57 mmol (= 50 g) triglycerides, which are released as VLDL bodies. There is normally no storage in the hepatocytes. VLDL triglycerides are transported to the white fatty tissue, where they are enzymatically split to allow storage of the resulting fatty acids as triglycerides in the adipocytes.

Degradation of triglycerides stored in the fatty tissue is effected by means of lipase and hormone activity (catecholamines, ACTH, glucagon). (s. fig. 3.9)

**Phospholipids** are a heterogeneous group of lipids. They mainly consist of phosphatidylcholine (ca. 67 %), sphingomyelin (ca. 21 %), lysolecithin (ca. 7 %), and phosphatidylethanolamine (ca. 4 %). Each of these constituents has a separate fatty-acid composition. (s. fig. 3.9)

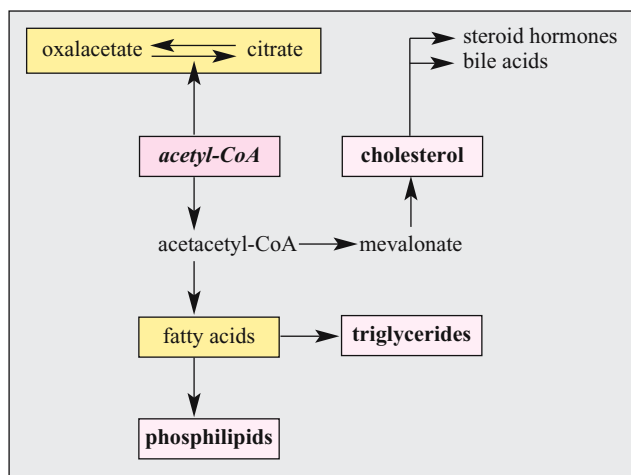

*Fig. 3.9:* Acetyl-CoA (activated acetic acid) as an original substance for biosynthesizing fats

**Free fatty acids**, whose levels are generally raised by insulin or alcohol, influence the rate of VLDL synthesis and hence the concentration of triglycerides. About 16 g glycerol, which are mainly utilized in the liver, are released daily by lipolysis, and about 120 g free fatty acids are made available for generating energy in the heart and skeletal musculature (75 %) as well as in the liver itself (25 %). These free fatty acids are bound in the plasma to albumin (50 %) and lipoproteins (50 %). Their extremely short plasma half-life of approx. 2 minutes emphasizes their high metabolic activity. • Fatty acids are present in the plasma in *saturated* (no double bond) and *unsaturated* (various numbers of double bonds) forms. • **Essential fatty acids** cannot be synthesized by the body, which means they must be obtained from food intake. The most important ones are multiple unsaturated fatty acids such as *linolic acid* ($C_{18}$-fatty acid, 2 double bonds), *linolenic acid* ($C_{18}$-fatty acid, 3 double bonds), and *arachidonic acid* ($C_{20}$-fatty acid, 4 double bonds). Their prime function is to act as precursors for the synthesis of eicosanoids. (s. fig. 3.10)

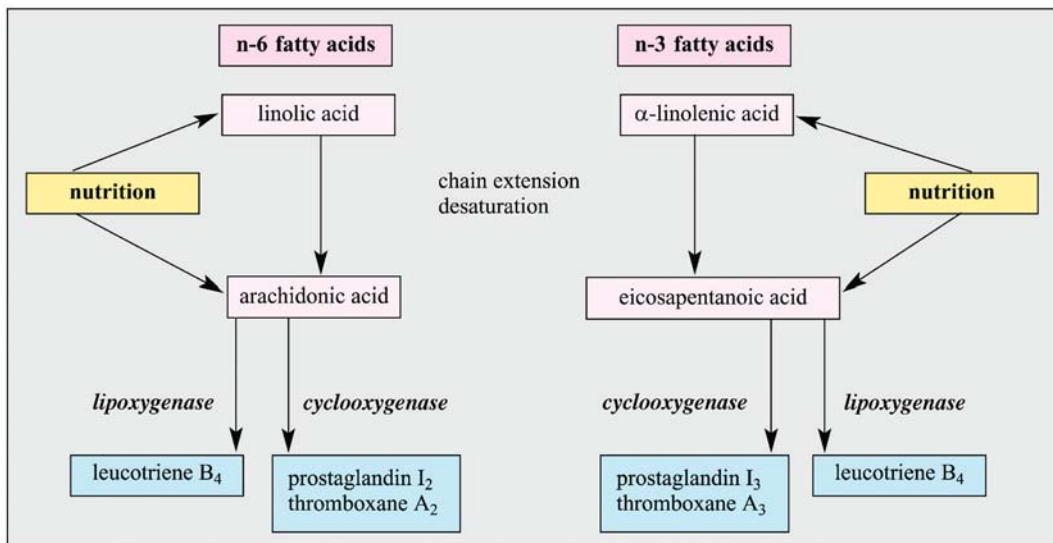
▶ Arachidonic acid is of particular importance, being the initial compound for **eicosanoid biosynthesis.** Prostaglandins, prostacyclins and thromboxanes are synthesized from the eicosanoids via the *cyclo-oxygenase pathway*. • The important mediators of inflammation − such as leukotrienes and leukotetraenes − are synthesized via the *lipoxygenase pathway*. (s. fig. 3.10)


*Fig. 3.10:* Synthesis of eicosanoids (leucotriene $B_4$, $B_5$, prostaglandin $I_2$, $I_3$, and thromboxane $A_2$, $A_3$) from n-3 and n-6 fatty acids

## 8.3 Cholesterol metabolism

Cholesterol is formed in the liver (85%) and intestine (12%) − this constitutes 97% of the body's cholesterol synthesis of 3.2 mmol/day (= 1.25 g/day). Serum cholesterol is esterized to an extent of 70−80% with fatty acids (ca. 53% linolic acid, ca 23% oleic acid, ca 12% palmitic acid). The cholesterol pool (distributed in the liver, plasma and erythrocytes) is 5.16 mmol/day (= 2.0 g/day). Homocysteine stimulates the production of cholesterol in the liver cells as well as its subsequent secretion. Cholesterol may be removed from the pool by being channelled into the bile or, as VLDL and HDL particles, into the plasma. The key enzyme in the synthesis of cholesterol is *hydroxy-methyl-glutaryl-CoA reductase* (HGM-CoA reductase), which has a half-life of only 3 hours. Cholesterol is produced via the intermediate stages of mevalonate, squalene and lanosterol. • *Cholesterol esters* are formed in the plasma by the linking of a lecithin fatty acid to free cholesterol (by means of LCAT) with the simultaneous release of lysolecithin. (s. figs. 3.8, 3.9) (s. tab. 3.8)

| Cholesterol supply / day | Cholesterol consumption / day |
|---|---|
| 1. From the diet:<br>  = 300−400 mg<br>2. From endogenous synthesis:<br>  − liver        1,000 mg<br>  − intestine      200 mg<br>  − tissue        50 mg<br>3. From intestinal reabsorption:<br>  = 300−500 mg | 1. Incorporation into VLDL,<br>  HDL: = 1,000 mg<br>2. Biochemical degradation:<br>  − bile acids     350 mg<br>  − hormones      50 mg<br>  − vitamin $D_3$     10 mg<br>3. Excretion:<br>  − intestine     500 mg<br>  − skin       100 mg |

*Tab. 3.8:* Cholesterol balance (supply/consumption per day) under normal conditions

▶ Endogenous consumption, degradation and elimination of cholesterol are kept in balance metabolically by dietary intake, endogenous synthesis and intestinal reabsorption. Cholesterol is an important substance for the structure and function of biomembranes. Moreover, it is the initial substrate for the biosynthesis of bile acids, vitamin $D_3$ and steroid hormones. (s. tab. 3.8)

# 9 Hormone metabolism and the liver

In minute amounts, **hormones** engender specific biochemical *"primary reactions"* through cellular metabolic processes, which subsequently trigger *"secondary reactions"* through physiological processes.

Hormone **synthesis** takes place in special cells or tissues either in the form of precursors with storage potential (= **prohormones**) or in the form of stored or continuously secreted substances in an active state (= **hormones**). Synthesis, release and activation of the hormones are under the strict control of a regulatory system, which itself responds according to a variety of endogenous and exogenous stimuli.

**Inactivation** of the hormones occurs mainly due to enzymes (in the kidney, plasma and target cell) and in the liver as a result of proteolytic or redox reactions. The liver contributes to the maintenance of **hormonal homoeostasis**. Liver diseases may thus affect the hormone regulation in different ways, giving rise to various and sometimes long-lasting disorders.

In the endocrine system the **signal substances** are called *hormones*, in the nervous system they are known as *neurotransmitters*, and in the immune system *cytokines*. • Signals transferred through the hormones may be endocrinal, neuroendocrinal, paracrinal (= signal transfer to adjacent cells), and autocrinal (= signal transfer within the individual cell itself). • *Receptors*, which are able to *detect* and *bind* a substance (e.g. hormones), are required to transmit signals for special cellular activity, including that of hormones. All substances which specifically bind with receptors are termed *ligands*. Both glycoprotein and peptide hormones, for example, are bound to receptors on the cell membrane, whereas steroid and thyroid hormones bind with cytoplasmic or nuclear receptors.

## 9.1 Classification of hormones

Proteohormones, steroid hormones and peptide hormones may be differentiated on the basis of their **chemical structure**. • Hormones may be classified as *neurosecretory* (e. g. hypothalamus), *glandular* (endocrine glands) or *aglandular* according to their **source tissue**. Aglandular hormones are also known as tissue hormones: they are synthesized in special cells located in specific organs. • Hormones may be differentiated according to their **transport characteristics** into unbound hormones and hormones which are coupled to a carrier protein. • A further classification is based on their **principal functions**. (s. tab. 3.9)

1. **Water-salt balance-regulating hormones**
   − renin, angiotensin, aldosterone, *etc.*
   − mineralocorticoids
   − atrial natriuretic peptides
   − vasopressin
2. **Effector hormones**
   − catecholamines (adrenalin, noradrenalin, dopamine)
   − insulin, glucagon
3. **Personality-differentiating hormones**
   − ACTH, STH, TSH, TRH, FSH, LH, PL, MSH
   − thyroxine ($T_4$), triiodothyronine ($T_3$)
   − androgens, oestrogens, gestagens, progesterones
   − glucocorticoids
4. **Calcium phosphate metabolism-regulating hormones**
   − parathormones, 1,25 dihydroxycholecalciferol, calcitonin
5. **Gastrointestinal hormones**
   − bombesin, cholecystokinin-pancreozymin, enterogastrones, gastrin, GIP, motilin, neurotensin, secretin, somatomedin, somatostatin, substance P, VIP

*Tab. 3.9:* Classification of hormones according to their principal biological functions

## 9.2 Effector hormones and the liver

The so-called effector hormones (insulin, glucagon, catecholamines) evoke an extremely fast response. Within a short time, a rapid and lasting redirection of the metabolism can be attained. Catecholamines are degraded in the liver and, following sulphation or glucuronidation, are eliminated as metabolites in either the bile or urine.

*Insulin* stimulates glucose uptake in both the musculature and the fatty tissue. Structural modification of STH, with a concomitant enhancement of its activity, is effected by insulin. The storage of amino acids in the muscles is also increased. (s. tab. 3.10)

| Criteria | Insulin | Glucagon, Catecholamines |
|---|---|---|
| **Anabolism** Glycogenesis Lipogenesis Protein synthesis Glycolysis | Increased | Inhibited |
| **Catabolism** Glycogenolysis Lipolysis Proteolysis Ketogenesis | Inhibited | Increased |
| **Gluconeogenesis** | Inhibited | Increased |

*Tab. 3.10:* Metabolic effects of insulin and contra-insulin hormones (glucagon, catecholamines) in the liver

*Glucagon* stimulates the adenylate cyclase system in the liver and thereby the formation of cAMP, which gives rise to important metabolic changes. (s. tab. 3.10) • Furthermore, there is a consequent decline in cholesterol synthesis, improvement in alanine membrane transport, activation of the enzymes of the urea cycle and stimulation of amino acid degradation.

## 9.3 Steroid hormones and the liver

Glucocorticoids, androgens, oestrogens and gestagens belong to the group of biologically active steroid hormones. The biogenesis of all steroid hormones involves the key compound cholesterol. (s. tab. 3.11)

**Glucocorticoids**
1. Increase in gluconeogenesis
2. Increase in protein synthesis
3. Regulation of amino acid metabolism
   − increase in amino acid degradation in muscle tissue
   − increase in amino acid uptake by the liver
4. Improved efficiency of urea synthesis
5. Inhibition of phagocytic activity of Kupffer cells

**Androgens**
1. Increase in haem synthesis
2. Stimulation of specific protein syntheses
3. Increased activity of cytochrome P 450
4. Decrease in hFABP

**Oestrogens**
1. Increase in hFABP
2. Increase in δ-aminolaevulinic acid with decrease in porphyrin decarboxylase
3. Increase in protein synthesis
4. Stimulation of phagocytic activity of Kupffer cells
5. Inhibition of cytochrome P 450 subtypes
6. Increase in lithogenicity of the bile
   − increase in cholesterol excretion
   − decrease in bile acid excretion
   − decrease in secretion of bile

**Progesterone**
1. Induction of haem synthesis
2. Limited stimulation of protein synthesis
3. Substrate-dependent (inhibitory or stimulatory) regulation of the cytochrome P 450 complex

*Tab. 3.11:* Significant effects of steroid hormones in the liver

Likewise, elimination of the steroid hormones occurs almost exclusively via the liver (after glucuronidation and sulphation) into the bile or urine. They are only excreted in a free form in minute amounts via the urine, intestine or skin. There are numerous important interactions between the liver and steroid hormones.

## 9.4 Thyroid hormones and the liver

Conversion of 70% of the total $T_4$ (thyroxine) to $T_3$ (3,5,3-triiodothyronine) occurs in the liver: 20% of the $T_4$ input are catabolized in the liver cells, and the remaining 10% are directed into various metabolic pathways. Approximately 30% of the $T_4$ and 50% of the $T_3$ are stored in the hepatocytes due to binding

to specific proteins. The more active hormone $T_3$ is involved in numerous metabolic reactions in the liver. (s. tab. 3.12)

1. Increase in protein synthesis
2. Increase in gluconeogenesis
3. Increase in ketogenesis
4. Increase in amino acid uptake
5. Regulation of bile acid metabolism
   − increase in bile acid synthesis
   − increase in biliary cholesterol excretion
   − increase in bile flow
6. Increased turnover of vitamin K-dependent clotting factors
7. Increase in size and number of mitochondria
8. Hypertrophy of the smooth endoplasmic reticulum

*Tab. 3.12:* Metabolic effects of $T_3$ in the liver

# 10 Vitamin metabolism and the liver

## 10.1 Classification of vitamins

**Vitamins** are vital (= *vita*) and mainly nitrogenous (= *amines*) substances of low-molecular weight. As a rule, they must be present in the diet as "essential" components. Only a few vitamins (e. g. A, K, $B_1$, $B_5$, $B_{12}$, folic acid, biotin) are formed in the intestine by bacteria. Plants constitute the main source of exogenous vitamin supply. In a biochemical context, the principal biocatalytic effect of vitamins consists in substituting cofactors of enzymes which have undergone metabolic degradation.

**Water-soluble vitamins** are readily absorbed under physiological conditions. They are transported to the intra- and extracellular fluid and act as coenzymes in a number of enzyme reactions in protein, nucleinic acid and energy metabolism. They are readily excreted via the kidney. (s. tab. 3.13)

**Fat-soluble vitamins** require the simultaneous presence of lipids and bile acids for their absorption. In order to be transported to the liver, they are bound to lipoproteins of the chylomicrons. Fat-soluble vitamins are stored in the liver or fatty tissue, often in large amounts and for prolonged periods of time. From there they become available to the intermediary metabolism for complex tasks. Vitamins A and D are secreted from the liver cells by means of carrier proteins. By undergoing biotransformation, fat-soluble vitamins become metabolically inactive as well as water-soluble and are thus capable of being excreted. (s. tab. 3.13)

## 10.2 Mechanisms of vitamin action

Vitamins are involved in a variety of ways in almost all processes of the intermediary metabolism taking place in the liver. An understanding of the major mechanisms of action provides insight into the possibilities of disturbance and the occurrence of symptomatological dysfunctions in liver diseases.

### 10.2.1 Fat-soluble vitamins

**Vitamin A:** Both vitamin $A_1$ (= *retinol*) and $A_2$ (= *3-dehydroretinol*) occur in nature. Like their derivatives, they are classed under the umbrella term *axerophtol*. The major provitamin is *β-carotin*. Vitamin A is stored as a lipoglycoprotein complex in the fat-storing cells of the liver. It is released when necessary by being coupled with a retinol-binding protein (RBP) and is then transported to the cells which require vitamin A. In the case of zinc deficiency the rate of RBP synthesis is markedly increased, and as a result serum retinol concentration is reduced. Retinol deficiency can be compensated by zinc substitution. The daily requirement is approx. 1 mg. (7, 36)

*Biological actions:*
− involvement in the synthesis of glycoproteins, glycolipids and proteoglycane
− stabilization of the cellular and subcellular membranes
− involvement in the production of steroid hormones

**Vitamin D:** *Calciferol* is taken up from the food as vitamins $D_2$ (= *ergocalciferol*) and $D_3$ (= *cholecalciferol*). In skin exposed to UV radiation, vitamin $D_2$ is formed from the provitamin ergosterol, and vitamin $D_3$ from the provitamin 7-dehydrocholesterol. 25-hydroxycholecalciferol (= *calcidiol*) is formed in the liver, 1,25-dihydroxycholecalciferol (= *calcitriol*) is produced in the kidney. The synthesis rate in the liver is controlled through the respective cholecalciferol concentration. Transport in serum is effected by a D-binding protein (DBP) identical to Gc-globulin. Oestrogen and pregnancy are known to cause an increase in DBP. (6)

*Biological actions:*
− involvement and control in regulating intra- and extracellular calcium concentrations

**Vitamin E:** *Tocopherol* is the umbrella term for all derivatives of the tocoltrienol and tocotrienol type that are similar in their mode of action. Of these derivatives, α-tocopherol is the most effective. Only a small part of the vitamin E supply is absorbed (20−40%), the process being facilitated by the presence of nutritional lipids, bile and pancreatic secretion, and medium-chain triglycerides. No transport protein for vitamin E is known.

*Biological actions:*
− protection of vitamin A and β-carotin
− protection of unsaturated fatty acids in biomembrane phospholipids (= antioxidant towards oxygen and hydroxyl radicals)
− influence on cholesterol metabolism
− influence on nucleinic acid metabolism

**Vitamin K:** Vitamin $K_1$ (= *phylloquinone*), of plant origin, and vitamin $K_2$ (= *menaquinone*), synthesized by bacteria, are naturally occurring vitamins. Vitamin K is the only fat-soluble vitamin acting as a coenzyme. Furthermore, synthetic K vitamins exist ($K_3$−$K_7$); of these, $K_3$ (= *menadione*) and $K_4$ (= *menadiol*) are the most significant. The vitamin is stored in the liver only in small quantities. About 50% of the daily requirement is covered by intestinal bacterial synthesis. No intermediary degradation of vitamins $K_1$ and $K_2$ is known. The synthetic menadione ($K_3$) and its derivatives are converted into $K_2$ in the microsomal fraction of the liver cells. Vitamin $K_3$ competes with the excretion of bilirubin in the biotransformation process; depending on the dosage, it may have toxic effects. Parenteral application of $K_1$ and $K_2$ in patients with cirrhosis may cause a paradoxical fall in the clotting factors with an increase in toxic metabolites and additional liver damage (G. MANDEL et al., 1980).

*Biological actions:*
− stimulation of the production and secretion of the coagulation factors II, VII, IX and X as well as of the two inhibitors, protein C and protein S
− influence on bone mineral metabolism via osteocalcin

**Vitamin F:** Essential fatty acids (e. g. unsaturated *linoleic acid, linolenic acid, arachidonic acid*) are also known collectively as vitamin

F. They belong to the group of vitamin-like agents. Exogenous supply is necessary.

*Biological actions:*
− constituent of phospholipids in all biomembranes
− constituent of prostaglandin precursors
− influence on the mitochondrial metabolism

### 10.2.2 Water-soluble vitamins

**Vitamin B$_1$:** Vitamin B$_1$ was discovered in 1926 by JANSEN and DONATH, who synthesized it in its crystalline form from rice bran. It was initially called *aneurine* due to its antipolyneuropathic effect. Because it contains sulphur, WINDAUS correctly renamed it *thiamine* in 1932, a term by which it is still known today. The structure of this vitamin was described by WILLIAMS and GREWE in 1936. It is made up of pyrimidine and thiazole. Thiamine occurs in nature as free thiamine and in the form of thiamine monophosphate, diphosphate and triphosphate. A maximum amount of $8-15$ mg is absorbed daily in the proximal portion of the small intestine. In the case of oversupply, thiamine is neither stored nor intestinally absorbed. A regular intake, with a daily requirement of about 1 mg, is necessary. The major coenzyme is thiamine pyrophosphate (TPP). Thiamine deficiency may be caused by malnutrition, impaired absorption, alcoholism, antithiamines or a lack of magnesium. • Magnesium is an important cofactor for the coenzyme thiamine pyrophosphate.

*Biological actions:*
− as cocarboxylase it is crucial to carbohydrate metabolism and the citric acid cycle
− involvement in the pentose phosphate cycle
− involvement in the formation of acetylcholine

**Vitamin B$_2$:** Vitamin B$_2$ is also termed *riboflavin* or *lactoflavin*. Vitamin B$_2$ was isolated from eggs by KUHN and GYÖRGY in 1933 (= ovoflavin) and from whey (= lactoflavin) by ELLINGER and KOCHARA in the same year. After being found in animal organs and plants (= hepatoflavin), it became known as riboflavin. Its structure was described by KUHN and KARRER in 1935. The riboflavin coenzymes, such as flavine mononucleotide (FMN) and flavine adenine dinucleotide (FAD), are taken up with food, converted into riboflavin and absorbed in the intestine. However, they are reconverted in the form of FMN and FAD in tissue cells, mainly hepatocytes. Virtually no storage of vitamin B$_2$ takes place.

*Biological actions:*
− involvement in the transformation of amino acids into keto acids
− involvement in the breakdown of saturated fatty acids by β-oxidation
− involvement in the synthesis of long-chain fatty acids
− influence on the inactivation of biogenic amines to imines and subsequently to ammonia
− component of xanthine oxidase, glutathione reductase, aldehyde dehydrogenase, microsomal flavoprotein monooxygenase, and membrane-related NADPH granulocyte oxidase

**Vitamin B$_5$:** *Niacin* (= nicotinic acid) and *niacinamide* (= nicotinamide) are supplied in the diet and converted in the body into the coenzymes nicotinamide-adenine dinucleotide (NAD) and nicotinamide-adenine dinucleotide phosphate (NADP). These coenzymes are important in tissue respiration. Nicotinic acid can also be formed from tryptophan via kynolin acid.

*Biological actions:*
− component of the electron carriers NAD$^+$/NADH and NADP$^+$/NADPH (thus it acts as a coenzyme for several oxidoreductases)
− histamine antagonist

**Vitamin B$_6$:** Three substances are classed under the term *pyridoxine* or *adermine: pyridoxol, pyridoxal* and *pyridoxamine*. Pyridoxine was isolated by various study groups in 1938. Its structure was described by FOLKERS and KUHN in 1939. Pyridoxal and pyridoxamine were discovered by SNELL in 1942. Pyridoxal phosphate and pyridoxamine phosphate are biologically active substances. • Intestinal absorption of B$_6$ is dose-dependent and not limited. In alcoholism, a deficiency of vitamin B$_6$ is encountered in $20-30\%$ of cases, whereas the respective percentage is $50-70\%$ in alcoholic cirrhosis. Vitamin B$_6$ is an important coenzyme for transaminases, which transfer amino groups from amino acids to keto acids. In this way, biochemical pathways between the citric acid cycle and carbohydrate and amino acid metabolisms are created. (104)

*Biological actions:*
− coenzyme for numerous enzymes
− influence on the metabolism of steroid hormones
− activation of δ-aminolaevulinic acid synthase
− involvement in lipid metabolism
− involvement in the synthesis and metabolism of amino acids
− involvement in the formation of nicotinamide from tryptophan
− involvement in serotonin synthesis

**Vitamin B$_{12}$:** This vitamin was isolated for the first time in 1948 by FOLKERS and SMITH. Its structure was described by various study groups in 1955. Substances with a central cobalt atom in a modified porphyrin ring are called *cobalamins*. The major forms are: cyanocobalamin (B$_{12}$), hydroxocobalamin (B$_{12a}$), aquacobalamin (B$_{12b}$), nitrosocobalamin (B$_{12c}$), and methylcobalamin. The coenzyme of vitamin B$_{12}$ is 5-desoxyadenosylcobalamin. Its "gastric intrinsic factor vitamin B$_{12}$ complex" is absorbed in the lower ileum, from where it passes into the portal vein. The transcobalamins I, II and III are available as transport proteins. Transcobalamin II constitutes the principal extracellular transport protein, whereas the transcobalamins I and III are considered intracellular storage proteins. In the cells, the coenzyme is mainly found; in the plasma, methylcobalamin predominates. Approximately 1 mg (of the body's total content of $2-5$ mg) is stored in the liver. Vitamin B$_{12}$ excreted in the bile is reabsorbed ($70\%$) and channelled into the enterohepatic circulation.

*Biological actions:*
− involvement as a coenzyme in amino acid and nucleinic acid metabolism

| Water-soluble vitamins | Fat-soluble vitamins | Acting as a coenzyme | Not acting as a coenzyme | Vitamin-like agents |
|---|---|---|---|---|
| B$_1$ | A | B$_1$ | A | Essential fatty acids (F) |
| B$_2$ | D | B$_2$ | C | Carnitine (T) |
| B$_6$ | E | B$_6$ | D | Bioflavonoids (P) |
| B$_{12}$ | K | B$_{12}$ | E | Inosite |
| | | K | | |
| Biotin (H) | | Biotin (H) | | |
| Pantothenic acid | | Pantothenic acid | | |
| Niacin (PP) | | Niacin (PP) | | |
| Folic acid (M) | | Folic acid (M) | | |
| | | Ubiquinone (Q) | | |

*Tab. 3.13:* Classification of vitamins and vitamin-like agents

- involvement in DNA and protein synthesis
- conversion of methylmalonyl-CoA into succinyl-CoA for lipid and porphyrin synthesis

**Vitamin M:** Vitamin M is also called pteroylglutaminic acid or *folic acid*. It was isolated from yeast extract by WILLS in 1930. Its structure was described by ANGIER in 1946. Folic acid is made up of pteridine + p-aminobenzoic acid + glutamic acid. There are several known derivatives, called *folates*, which are capable of mutual restructuring. The coenzyme *tetrahydrofolic acid*, which plays a role in many biochemical reactions, is formed with the help of $B_{12}$. Around 50% of total body folate are stored in the liver. A folate-binding protein (FBP) is available for transport. Folate undergoes enterohepatic circulation. The release of folate from the liver cells is stimulated by alcohol, which increases urine excretion. Folate deficiency (e. g. in the case of alcohol abuse) is accompanied by the development of macrocytosis.

*Biological actions:*
- influence on the intermediary metabolism of homocysteine, histidine and serine
- promotion of the biosynthesis of nucleinic acids
- involvement as a coenzyme in porphyrin synthesis

**Vitamin H:** In the liver, *biotin* participates as a prosthetic group in carboxylases and transcarboxylases. It is found in the free form as well as covalently linked with protein.

*Biological actions:*
- involvement in fatty acid synthesis
- involvement in gluconeogenesis
- effect on amino acid metabolism
- involvement in the urea cycle
- promotion of purine synthesis
- promotion of transfer-RNA synthesis

**Vitamin C:** *Ascorbic acid* is the most important redox substance of cell metabolism. The body content probably amounts to about $2-5$ g, the major part being stored in the liver and muscles. Intestinal absorption ($80-90\%$) is an active, sodium-dependent process. The transport of ascorbic acid in the blood probably takes place as an ascorbic acid-albumin complex. Cellular uptake is stimulated by insulin.

*Biological actions:*
- influence on the hydroxylation of proline and lysine residues in collagen synthesis
- promotion of the synthesis of noradrenaline from dopamine
- involvement in the hydroxylation of steroid hormones
- incorporation of iron into ferritin
- sulphate donor in the sulphation of proteoglycanes
- antioxidant effect

**Vitamin T:** *Carnitine* is a trimethylbetaine encountered in nearly all tissues, above all in the musculature.

*Biological actions:*
- involvement in fatty acid transport
- involvement in mitochondrial fatty acid oxidation
- involvement in transmethylation
- influence on the effect of thyroxine

# 11 Trace elements and the liver

**Trace elements** are micronutritive elements occurring in minute, species-specific quantities (<0.01% of body mass or $<10^{-6}$ g/g BW). These inorganic bioelements are subdivided into essential and non-essential (accidental) trace elements. (s. tab. 3.14)

The results of investigations available so far have demonstrated that the liver assumes a central role in preserving the **homoeostasis** of trace elements. Liver diseases may also lead to persistent disturbances in the metabolism of trace elements which are of clinical significance and may require therapeutic steps. (57, 66)

**Essential trace elements** are vital substances, the deficiency of which leads to specific abnormalities of the structural or biochemical type. These disorders can be prevented or eliminated by supplementation of the respective element. They are important components of enzymes, chromoproteins or hormones. In humans, 15 trace elements are recognized as "essential". (s. tab. 3.14)

| Essential | | Non-essential | |
|---|---|---|---|
| Chloride | Cl | Aluminium | Al |
| Chromium | Cr | Barium | Ba |
| Cobalt | Co | Bismuth | Bi |
| Copper | Cu | Cadmium | Cd |
| Fluorine | F | Caesium | Cs |
| Iodine | I | Gold | Au |
| Iron | Fe | Lead | Pb |
| Manganese | Mn | Silver | Ag |
| Molybdenum | Mo | Titanium | Ti |
| Nickel | Ni | | |
| Selenium | Se | | |
| Silicon | Si | | |
| Tin | Sn | | |
| Vanadium | V | | |
| Zinc | Zn | | |

*Tab. 3.14:* Essential and non-essential trace elements in the human body

▶ For many of these elements, the mechanisms of intestinal absorption, transport in the blood, intracellular uptake, especially by the liver cells, and the question of their storage or elimination are still not fully understood. • It should be considered that trace elements may also have **toxic effects** if given in overdosage or in the case of increased accumulation in the body due to insufficient excretion.

## 11.1 Iron

Of the body's daily iron uptake, $1-2$ mg are absorbed in the duodenum and proximal jejunum. Resorption is pH-dependent; $Fe^{3+}$ is insoluble at a pH value of >4. Vitamin C enhances iron resorption (= reduction of iron and formation of a soluble iron-ascorbat chelate). DCT 1 (= divalent cation transporter) serves as a mucosa transporter and also supports mucosal transport of zinc, copper, cobalt etc. Iron facilitates $O_2$ transport and the transfer of electrons.

In the intracellular space, iron is stored as both ferritin (ca. 47%) and haemosiderin (ca. 12%) as well as in the form of an iron-transit pool (ca. 27%). (21) Iron metabolism is of utmost importance for the organism and is characterized by the following **values:**

**Total body iron content:** $4-5$ g ($0.07-0.09$ mol)
(men: 50 mg/kg BW, women: 35 mg/kg BW)
- $60-65\%$ in haemoglobin (ca. 2.5 g)
- $10\%$ in myoglobin (ca. 0.5 g)
- $20-30\%$ as depot iron (ca. 1.0 g)
  (bone marrow, liver, spleen)
- $5\%$ in enzymes
  (e. g. cytochrome, catalase, peroxidase, enolase, succinate dehydrogenase, certain hydroxylases, and ribonucleotide reductase)

**Transferrin** is mainly synthesized in the hepatocytes. There are about 20 known variants. Iron is transported by transferrin (approx. 30% of transferrin is saturated with iron). With the help of a membrane receptor, the iron-transferrin complex is taken up and released in the liver cell, where it is immediately bound (because of its toxicity) to ferritin. The liver cells take up iron predominantly from transferrin, to a lesser degree also from haptoglobin, haemopexin, lactoferrin and circulating ferrin. Transferrin, which is mainly formed in the hepatocytes, may also bind and transport, in decreasing order, chromium, copper, manganese, cobalt, cadmium, zinc and nickel. The half-life of transferrin is $1-2$ hours, which is very short in view of its total blood concentration of $3-4$ mg. Approximately 0.4 g ferritin iron is stored in the liver. In the case of transferrin deficiency, its bacteriostatic and fungistatic effects are also reduced. Transferrin without iron saturation is known as **apotransferrin**. (31, 66, 67)

**Lactoferrin** can only be distinguished from transferrin immunologically. It is also an iron transport protein which, however, is formed in granulocytes and glandular epithelia.

**Haemopexin** is a protein which is formed in the hepatocytes. It facilitates the intracellular transport of both haem and iron while preventing the loss of haem-Fe via the kidneys. With increasing diminution of the synthesis capacity of the liver, there is a corresponding decrease in the serum level of haemopexin.

**Ferritin** neutralizes the intracellular toxicity of iron and effects its water-solubility. It is formed in the RES (as well as at the polysomes of the liver cells) and degraded in the lysosomes. The serum ferritin value corresponds to the total amount of mobilizable depot iron in the body. (31, 66, 67)

**Haemosiderin** is also an iron-protein complex, assumed to be formed from ferritin. In the case of iron overload in the body, more haemosiderin than ferritin is formed, which is then stored in the intracellular space. Haemosiderin can be demonstrated biochemically using the Berlin blue reaction. *(see chapters 5.5.2 and 31.17)*

## 11.2 Copper

The body's total content of copper is calculated to be $80-150$ mg ($1.5-2.35$ mmol). Of this amount, $10-15\%$

are found in the liver. In the liver cells, copper is encountered in the cytoplasm, nucleus, mitochondria and microsomes. The daily copper requirement in the diet is $3-5$ mg. Copper is excreted at $2-4\%$ in the urine and at 80% in the bile; consequently, the serum level of copper is increased in cholestasis. Copper levels can also be raised by the influence of oestrogens as well as by an increased oral intake of zinc. • **Ceruloplasmin** is an α-globulin and belongs to the acute phase protein group. It is able to reoxidize iron and can therefore be termed ferrioxidase; it also facilitates the transfer of iron into transferrin. For transport in the blood, 95% are bound to ceruloplasmin, whereas 5% are bound to albumin or free amino acids. (13, 26, 66, 102) *(see chapters 5.6.5 and 31.16)*

*Biological actions:*

The biological effect of copper consists in activating copper-dependent enzymes needed for several cellular metabolic actions:
- oxidation of $Fe^2$ to $Fe^3$
- cross-linkage of collagen and elastic fibres
- metabolism of catecholamines (by monoamine oxidase)
- metabolism of keratin and pigment (by tyrosinase)
- conversion of superoxide radicals into $O_2$ and $H_2O_2$ (by zinc-copper superoxide dismutase)
- involvement in the intracellular respiratory chain (by mitochondrial cytochrome C-oxidase)
- activation of phosphatases

## 11.3 Zinc

The normal zinc content of the body amounts to $20-30$ mmol ($1.3-2.0$ g). The daily dietary requirement is $10-15$ mg. In the blood, zinc is bound to $\alpha_2$-macroglobulin, albumin or amino acids, and a small amount is also bound to transferrin. Zinc is crucial to a variety of enzyme reactions. This applies especially to the liver. More and more attention has therefore been paid to the role of zinc in liver disease in recent years. Six enzyme groups (hydrolases, isomerases, ligases, lyases, oxidoreductases and transferases) with a total of 35 **zinc metalloenzymes** are listed. (98) • *Almost 200 enzyme reactions in the body are zinc-dependent!*

Zinc assumes a special role in the intrahepatic formation of retinol-binding protein, which is essential for the release of vitamin A into the blood. Zinc deficiency results in a decrease in RBP. Furthermore, as a part of ADH, zinc is crucial for alcohol degradation in the hepatocytes and for enzyme activation in the detoxification of ammonia in the urea cycle. (s. fig. 3.12!)

The metabolism of zinc is influenced by hormones, stress situations, lipopolysaccharides, toxins, oxygen radicals, lipid peroxidations, etc. This may lead to fluctuations in the zinc concentration, mainly due to the induction of **metallothioneine** (MT), which is a transport and intracellular depot protein. One third of this protein consists of cysteine, which binds zinc, copper, cadmium, cobalt and mercury. This protects the body from toxic heavy metal

ions (e. g. cadmium and mercury). The induction of MT thus also leads to increased (yet reversible) binding of zinc, which feigns zinc deficiency. It cannot be excluded that altered zinc distribution might eventually result in lower zinc levels in the body. This can be caused by various factors. (66, 76, 98) (s. tab. 3.15)

*Biological actions:*
- influence on carbohydrate, protein and lipid metabolism
- influence on alcohol metabolism
- influence on epithelial differentiation
- stabilization of biological membranes
- receptor binding of insulin
- influence on the production of testosterone
- influence on the metabolism of vitamin A
- influence on the immune system
- influence on blood formation
- influence on the urea cycle

1. **Increased zinc requirement**
   - Infections, burns, stress situations
   - Pregnancy
   - Surgical procedures
   - Tumour disease
2. **Insufficient alimentary supply of zinc**
   - Abuse of laxatives
   - Alcoholism
   - Nutrition poor in zinc
3. **Reduced intestinal absorption**
   - Colitis, Crohn's disease
   - Inhibition of absorption by starch, phosphate and calcium as well as by phytic acid (in the case of a vegetarian diet)
   - Intestinal bypass
   - Sprue, pancreatic insufficiency
   - Wilson's disease
4. **Altered zinc distribution**
   - Acute and chronic hepatitis
   - Alcoholic liver disease
   - Autoimmune diseases
   - Inflammatory processes, infections
   - Liver cirrhosis
   - Malignant diseases
   - Pharmacons (glucocorticoids, contraceptives, antimetabolites, chelate formers)
5. **Increased zinc excretion**
   - Alcoholism
   - Diabetes mellitus
   - Diarrhoea
   - Liver cirrhosis, alcoholic liver diseases
   - Pharmacons
   - Renal diseases, diuretics
   - Severe hepatitis
   - Surgical procedures

*Tab. 3.15:* Aetiology of absolute and relative zinc deficiency

## 11.4 Selenium

Selenium is taken up in the body in both an inorganic and organic form. The body's selenium amounts to $10-15$ mg or $0.12-0.19$ mmol ($= 5$ mmol/kg wet weight). The estimated daily requirement is $20-100$ µg. The serum concentration (normal: $50-120$ µg/l) is regulated through renal elimination (normal: $10-50$ µg/l).

Inorganic selenium is bound to VLDL and LDL, while organic selenium is bound to amino acids. (63, 66, 101) • Selenium deficiency occurs particularly in alcoholism and liver cirrhosis. This may set up a vicious circle leading to further liver cell necrosis. Selenium is incorporated into cysteine and thus becomes an essential component of both glutathione peroxidase and phospho-lipid-hydroxyperoxide-glutathione peroxidase. These enzymes play an important role as radical scavengers in the prevention of lipid peroxidation in the area of the biomembranes. Selenium is deemed to have a protective effect in fulminant hepatitis and an inhibitory effect on the formation and growth of malignant tumours. • *5-deiodase* is a further selenium-containing enzyme involved in the formation of triiodothyronine. (s. p. 857)

## 11.5 Manganese

The liver contains 24 µmol/kg BW, which is equivalent to approximately 10% of the body's manganese depot ($0.2-0.36$ mmol). It is bound to transferrin for transport in the blood. (66)

Acetyl-CoA decarboxylase, alkaline phosphatase, aminopeptidases, arginase, carboxypeptidase A, enolase, glucokinase, hyaluronidase, mevalonatekinase, pyruvate decarboxylase and superoxide dismutase are regarded as manganese metalloenzymes or manganese-dependent enzymes. • Thus the formation of glucose from lactate, the synthesis of triglycerides and the formation of cholesterol are positively affected, and the synthesis of mucopolysaccharides is promoted. Superoxide dismutase is important for the elimination of superoxide-anion radicals ($O_2^-$) through the formation of $H_2O$ and $O_2$.

## 11.6 Chromium

The chromium content of the liver amounts to 1 µmol/kg BW, which corresponds to 1% of the body's total quantity of ca. 100 µmol. Chromium is bound to transferrin and α-globulin for transport in the blood. (65)

► The **biological effect** of chromium is based on the binding of insulin with the cell membrane (together with nicotinic acid and glutathione), where it is at the same time partly responsible for insulin activity. In chromium deficiency (e. g. due to stress), glucose tolerance is reduced. In diabetics requiring insulin, the urinary loss of chromium is increased. The *linkage* of chromium + nicotinic acid + glutathione is called the **glucose tolerance factor.** An increase in blood sugar leads to an augmented formation of this factor in the liver cells – insofar as this is still possible with limited liver function. Chromium has a stimulating effect on RNA synthesis. It is involved in lipoprotein metabolism.

## 11.7 Cobalt

Inorganic cobalt is transported in the blood by albumin and transferrin; it is taken up by the liver. The serum concentration amounts to $1.9-7.6$ mmol/l. An increased value is a sign of liver cell necrosis (e. g. acute hepatitis). Its biological significance is attributed to its position as a central atom in vitamin $B_{12}$ and its involvement in the release of renin and erythropoietin.

# 12 Biotransformation and detoxification

The **elimination** of endogenous and exogenous substances from the body is necessary if they: (*1.*) do not serve the production of energy, (*2.*) are not needed for the maintenance of structure, or (*3.*) cannot be stored without causing harm. • Therefore *gaseous substances* are excreted via the lungs and *water-soluble substances* are excreted via the kidney or (through bile) in the faeces. However, *fat-soluble foreign substances* cannot be excreted in an unchanged state.

Exogenous and endogenous substances which may cause damage to the body must be broken down and/or detoxified and made water-soluble, so that they are capable of being excreted in the stool or urine. This especially applies to lipophilic or corpuscular substances which cannot be excreted and may therefore accumulate in the body at potentially toxic levels. • *The liver is the central organ for the degradation and/or detoxification of superfluous and harmful substances as well as their excretion from the body.*

Of the twelve metabolic functions shown in table 3.1, both the biotransformation and the detoxifying function are of major relevance. Disturbance of one or several of the other metabolic fields may be hazardous and is often associated with complications − any breakdown of the detoxifying function, however, leads to cell necrosis and liver failure, and thus death.

## 12.1 Foreign compounds (xenobiotics)

The term **xenobiotics** comprises on the one hand substances which trigger defence mechanisms in the organism and on the other hand exogenous substances which contaminate or burden and thus damage the ecological systems of the organism itself or the environment. Xenobiotics are therefore substrates which may also be defined as potentially hepatotoxic substances. (s. tab. 3.16)

1. Alcohol
2. Chemicals
3. Drugs
4. Heavy metals
5. Endogenous toxic metabolic products
6. Toxins:   a. plant toxins
             b. animal toxins
             c. bacterial toxins

***Tab. 3.16:*** Xenobiotics or potentially hepatotoxic substances

▶ Xenobiotics may be present in *water-soluble* (hydrophilic) or in *fat-soluble* (lipophilic) form. However, they are also taken up in the body as *gaseous* substances and *corpuscular-insoluble* substrates (e. g. heavy metals). Any xenobiotics reaching the liver must be rendered inactive and harmless, i. e. capable of being excreted. (61)

*Hydrophilic xenobiotics* enter the cell at the sinusoidal side of the hepatocyte membrane by means of transport systems using carrier proteins. These carrier proteins exhibit no or only low substrate specificity, so that various endogenous and also exogenous substances can be transported through the cell membrane. Competition between these substances for carrier proteins may lead to the mutual inhibition of the transport mechanism.

*Lipophilic xenobiotics* are superior in number (about 70−80%). Because of their high solubility in fats − thus also in the phospholipid double layer of the cellular and subcellular membranes − these substances rapidly (and without hindrance) reach the liver cells and organelles according to the laws of nonionic diffusion.

## 12.2 Metabolization of xenobiotics

The detoxifying function of the liver was established by F. Magendie as early as 1817. For the conversion of endogenous and exogenous toxic substances, the term **detoxification** was introduced. Later, however, a **change of metabolization** was demonstrated, meaning not only that foreign substances are detoxified by the liver, but that atoxic substances may become toxic after undergoing metabolization in the liver (*"toxication"*), e. g. the insecticide parathion, or the conversion of $CCl_4$ into highly reactive radicals, or the carcinogenicity of benzpyrene, aflatoxin and nitrosamine. As a result of dysregulation of cellular metabolic processes, toxic metabolites may also be produced (*"biotoxometabolites"*) which are not normally metabolites of the parent compound. • Furthermore, it was noted that some therapeutically active substances were converted in the liver into inactive metabolites (*"inactivation"*) and some inactive medical substances, such as prodrugs (e. g. cyclophosphamide), into active metabolites (*"activation"*). Moreover, during their liver passage, active substances were found to be weakened or even potentiated in their activity (*"change of activity"*). (s. fig. 3.11)

Based on the individual variability in the behaviour of the liver cell towards foreign substances and drugs, the thesis was put forward that both the effectiveness as well as the side-effects of medicaments are genetically determined (A. G. Motulsky, 1957). As a result, the term **pharmacogenetics** (F. Vogel, 1959) was introduced to define clinically relevant, hereditary differences in the effects of drugs which lead to abnormal reactions in patients (due to genetic polymorphism). (17, 22, 99, 103)

Moreover, major *influences on the metabolism* of xenobiotics in the liver due to nutritional factors as well as through interactions with chemicals and alcohol have been reported. Distinct age and gender-related differences have also been noted. (s. tab. 3.18) • *The glucuro-*

*nidation capacity of the liver can be reliably measured by means of* **4-methylumbelliferone** (H.-D. Kuntz, 1983). (52−55)

Any foreign substances in the gastrointestinal tract − even in high concentrations − are directly transported to the liver because of its topographic position and functional role. At the same time, several (superfluous and occasionally harmful) substances also travel to the liver via the haematogenous system. • *The liver is constantly required to clear such substances from the body.*

## 12.3 Mechanisms of metabolic detoxification

Due to the multiplicity of substances to be eliminated, both *substrate-specific* and *substrate-nonspecific* elimination mechanisms are necessary. The liver is thus capable of eliminating a maximum number of foreign substances with little biomolecular effort. By means of its nonspecific elimination systems, the liver is generally able to cope metabolically with the daily variety of foreign substances as well as with "newly formed" ones. (s. tab. 3.17)

1. **Biotransformation**
   − 2-phase reaction
   − enzyme adaptation
2. **Ammonia detoxification and bicarbonate neutralization**
   − urea cycle / glutamine cycle
   − bicarbonate neutralization
3. **Alcohol degradation**
4. **Reticuloendothelial system (RES)**
5. **Radical scavengers and antioxidants**

*Tab. 3.17:* Important (substrate-specific and substrate-nonspecific) mechanisms of metabolic clearance

If these elimination systems are overburdened or their functions are disturbed, the extent to which the metabolism can be relieved of unnecessary or harmful substances may be more or less limited. This leads to accumulation and eventually produces toxic effects of substances which, in normal quantities, would be well tolerated and readily eliminated.

## 12.4 Biotransformation

The term **biotransformation** is defined as biochemical changes in a substance through autometabolic processes. In this way, lipophilic substances can be converted into water-soluble (= excretable) metabolites in the liver.

▶ Such *lipid-soluble, non-excretable substances* − if subject to glomerular filtration − are almost completely reabsorbed from the primary urine by renal tubules, with the result that they are hardly ever excreted via the kidney. This might involve the danger of accumulations of lipophilic xenobiotics in the body, especially in fatty tissue. Therefore hydrophilization of these substances (with the associated feature of being excretable in the bile or urine) is required.

The enzyme systems involved in biotransformation are largely **substrate-nonspecific**. Therefore, they are not only able to convert exogenous or endogenous lipophilic substances into water-soluble metabolites, but also to intervene in the metabolism of endogenous substances (e. g. bile acids, hormones). These enzymes are mainly localized **structure-bound** in the biomembranes or found **non-structure-bound** as soluble enzymes. About 5% of the total protein reserves of the liver are needed for the biotransformation of enzymes.

This biotransformation process takes place principally in the liver, i.e. in the *smooth endoplasmic reticulum*, partly also in the *mitochondria*. The kidneys, lungs, intestine, muscles, spleen and skin are involved to a lesser degree in biotransformation. Through hydrolysis and reduction, the intestinal flora may also play a role in this metabolic process. • Biotransformation is limited by the hepatic blood flow (= *flow-limited elimination*) and by the capacity of microsomal enzyme systems (= *capacity-limited elimination*). (80, 95)

### 12.4.1 2-phase reaction

Biotransformation of xenobiotics takes place in two phases. In **phase I** (= *functionalization reactions*), reactive groups are either activated or inserted into the substance molecule, thus providing the lipophilic molecule with a functional hydrophilic group. (In phase II, a hydrophilic residue is added to this group; transferases hereby catalyze the conjugation with an endogenous substance.) • Phase I effects the insertion of reactive (polar) groups (such as $-OH$, $-COOH$, $-SH$, $-NH_2$) by means of four chemical processes: oxidation, reduction, hydrolysis, and hydration.

**Oxidation reactions** (or hydroxylation) by *oxidases* (= removal of hydrogen or electrons) and *dioxygenases* (= insertion of the 2 atoms of the oxygen molecule into the foreign substance) as well as by *monooxygenases* (= insertion of one oxygen atom into the foreign substance and reduction in the other oxygen atom to $H_2O$) are of great significance in biotransformation. • Here the conversion of xenobiotics may be accomplished via various enzymatic pathways by means of *oxidation*: (*1.*) aromatic amines, (*2.*) aliphatic chains, (*3.*) alcohol and aldehydes, (*4.*) oxidative N-desalkylation, (*5.*) oxidative O-desalkylation, (*6.*) oxidative desamination, (*7.*) S-oxidation, (*8.*) N-oxidation, and (*9.*) S-O-exchange.

**Cytochrome P 450:** The drug-metabolizing enzymes responsible for the breakdown of xenobiotics (B. B. Brodie, 1967) exhibit mainly oxidative properties. In particular, the microsomal mixed-function monooxygenases are worth mentioning. They contain the haemprotein cytochrome P 450 consisting of a complex of various isoenzymes. The name cytochrome P 450 signifies that reduced cytochrome has a carbon-monoxide difference spectrum with 450 nm maximum absorption (R.W. Esta-brook et al., 1975). CYP enzymes can be detected in the smooth ER as well as after high-speed centrifugation in the microsomal fraction. The highest levels of CYP activity are seen in centroacinar zone 3 and the lowest in periportal zone 1. Biliary epithelia, endothelial cells and Kupffer cells contain no cytochrome P 450. Up to

now, 57 functional CYP genes and 33 pseudogenes arranged into 18 families and 42 subfamilies have been found, including 1A1, 1A2, 2A6, 2A7, 1B1, 2B1, 2B4, 2B6, 2B7, 2C3, 2C6−2C9, 2C11, 2C18, 2C19, 2D1, 2D6, 2E1, 3A1, 3A4, 3A5, 3E1, 4A1, 4B1, 5A1 and others (= number of the enzyme group, letter of the enzyme subgroup, number of the respective enzyme species). Cytochrome P 450 enzymes are ubiquitous. They are found in bacteria, plants and animals. The approximately 500 known cytochrome P 450 genes have developed from a common gene, which probably originated 3−3.5 billion years ago. (71) • Furthermore, a *flavoprotein* (= hydrogen transfer agent) and an *NADPH-cytochrome-C reductase* (= hydrogen donor) exist. One oxygen atom is needed for the oxidation of the respective substrate, the second oxygen atom serves the oxidation of hydrogen to water. The high degree of hereditary biochemical individuality in biotransformation is achieved through these diverse oxidative reactions. (105)

The range of microsomal enzymes includes *epoxide hydratase*. This is required for the degradation of epoxides, which may originate as aliphatic or aromatic decomposition products from the metabolism of foreign substances. The precursors of these biotoxometabolites are hydroperoxides, formed, for example, from arachidonic acid by means of lipoxygenase activity. Epoxides are capable of provoking toxic, mutagenic, antigenic, carcinogenic and other effects (= *chemical lesion*).

**Reduction:** Phase I can also be accomplished by means of reductions. The reductive enzymes are localized both in the microsomes and the cytosol. They trigger the enzymatic transformation of ketones, aldehydes, sulphoxides, nitro- and azo-linkages, etc. The intestinal flora also contributes to the reductive metabolism of foreign substances.

**Hydrolyses:** They are of minor significance. Here amidases and glycosidases are important enzymes. Intestinal bacteria with hydrolytic activity split mainly phase II metabolites in the large intestine, with the result that absorbable catabolites then enter the enterohepatic circulation.

> Through the metabolic stages of phase I alone, substances can be made water-soluble and thus capable of being excreted via the kidney.

In **phase II** (= *conjugation reactions*), the foreign substance molecule or a metabolite formed in phase I conjugates with an endogenous substance by means of specific transferases. The resulting, mostly acidic conjugation products are highly hydrophilic and are therefore readily excreted in the urine and/or bile. Most of these conjugates are biologically inactive and thus in the true sense of the word "detoxicated". Some conjugates can be rehydrolized to the initial substance and then reabsorbed in the intestine. • Phase II, with its enzyme reactions, occurs (like phase I) in the endoplasmic reticulum. For the conjugation process, various substances can be used as *endogenous ligands:*

| **Endogenous ligands** |
| --- |
| 1. Activated glucuronic acid<br>   (by glucuronosyl transferase)<br>2. Activated sulphuric acid<br>   (by sulphotransferase or thiosulphate-S transferase)<br>3. Activated acetic acid<br>   (by N-acetyl transferase)<br>4. Amino acids (glycine, glutamine, taurine)<br>   (by transacylase)<br>5. S-adenosyl methionine<br>   (by transmethylase)<br>6. Mercapturic acid derivatives<br>   (by glutathione-S transferase) |

> Phase II is adequate for biotransformation if the initial substance possesses a group with binding ability, i.e. phase I is no longer needed for the activation or insertion of a reactive group.

> Sometimes neither phase I nor phase II is required for the elimination of a foreign substance: the given substance is firstly taken up by the liver cells due to its low lipophilicity, but can nevertheless be excreted adequately via the kidneys despite its low hydrophilicity.

### 12.4.2 Enzyme adaptation

In the course of evolution and during the short life-span of every human being, it was − and still is − necessary for the performance of enzyme systems involved in biotransformation to adapt permanently to the requirements of life. This enzyme adaptation is achieved by **four mechanisms:**

| |
| --- |
| 1. Enzyme induction<br>2. Enzyme inhibition<br>3. Activation of an inactive enzyme<br>4. Reduction in enzyme breakdown |

Changes in the enzyme activities involved in biotransformation may be caused by various **factors**. These can be both non-variable and variable in nature with individually different modes of influence. (s. tab. 3.18) (s. fig. 3.11)

| *Variable factors* | *Non-variable factors* |
| --- | --- |
| 1. Protein content of<br>   nutrition<br>2. Pharmacons<br>3. Chemicals<br>4. Alcohol<br>5. Constituents of<br>   tobacco smoke<br>6. Heavy metals<br>7. Pregnancy<br>8. Diseases, *etc.* | 1. Genetics<br>2. Gender<br>3. Age |

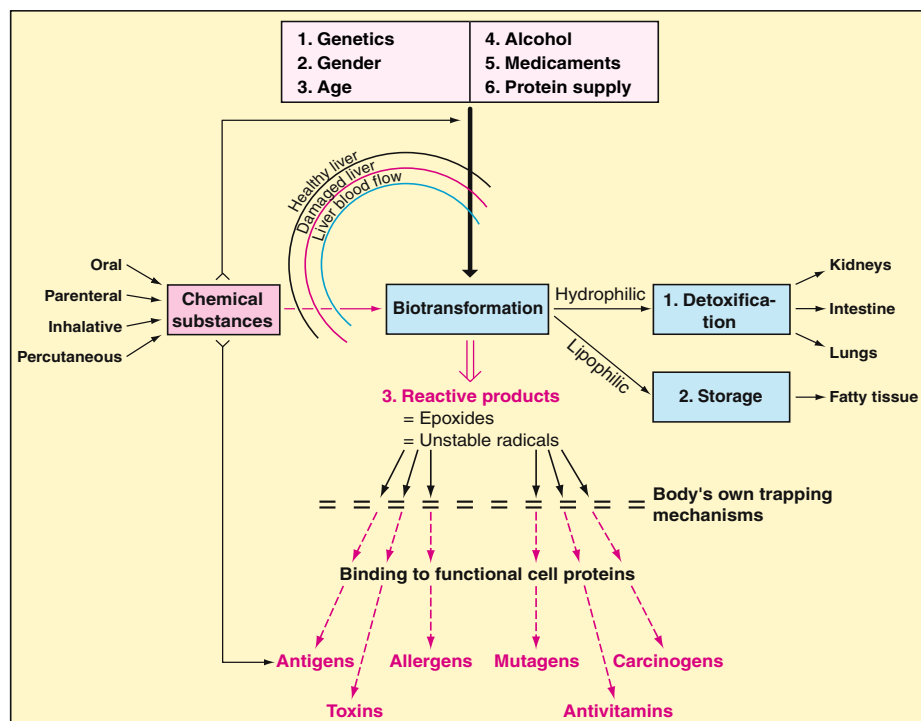
***Tab. 3.18:*** Variable and non-variable factors influencing the biochemical mechanisms involved in the metabolism of foreign substances


***Fig. 3.11:*** Diagram showing the biotransformation of foreign substances and their influencing factors as well as the development of reactive products and biotoxometabolites

**Enzyme induction** is of the greatest importance. Xenobiotics may lead to an increase in biotransformation enzymes. Various foreign substances induce different enzyme systems, resulting in various types of enzyme inductions. (105) Initially, enzyme induction can only be detected by means of electron microscopy. In more intensive and longer-lasting induction, proliferation of the *smooth endoplasmic reticulum* (SER) becomes more clearly visible microscopically. (s. figs. 2.9; 21.2) This is accompanied by a rise in γ-GT in serum, as this enzyme is formed there and produced in higher amounts corresponding to the increased proliferation of the SER. (s. p. 98)

▶ *Viewed from this angle, a rise in γ-GT is a "physiological" process, i. e. a criterion for increased enzyme induction or a sign of adaptation to the requisite (and accomplished) enhancement in biotransformation performance.*

▶ *Membrane hyperplasia:* The proliferation rate of the SER may have developed to such an extent that cell volume grows by up to 50%; this can increase the weight of the liver and cause hepatomegaly. *(see chapter 11)*

In response to enzyme induction, various **metabolic processes** may occur:

(*1*.) Biotransformation or degradation capacity is increased, and thus the plasma half-life is shortened. This is achieved by endogenous active substances (e. g. steroid hormones), essential substances (e. g. vitamin D) and foreign substances (especially drugs) as well as by changes in the enzyme inducer.

(*2*.) With lower activity of the catabolites towards the initial substance, the effect is weakened; with higher activity of the metabolite, the effect is potentiated.

(*3*.) As a result of the activation of foreign substances, adverse effects or chronic toxicity − even cancerogenicity − may occur.

(*4*.) Owing to their chemical binding to cellular proteins, metabolites of foreign substances may be unexpectedly converted into **biotoxometabolites**. These *chemical lesions* constitute irreversible changes to essential cell components. The main cause of cellular biotoxication are free radicals or epoxides, such as are produced in the course of oxidative and reductive metabolic processes. A lack of radical scavengers (catalase, superoxide dismutase, glutathione, vitamins C and E, etc.) and an overload or disturbance regarding the respective detoxification pathways may lead to a dangerous increase in such biotoxometabolites. This involves the danger of the unpredictable appearance of allergens, antigens, carcinogens, mutagens or toxins, and possibly antivitamins. (s. fig. 3.11)

**Alcohol** plays an important role in the metabolism of foreign substances and is responsible for numerous interactions with drugs. A special type of cytochrome P 450 (P 450 II E 1) is induced by the chronic intake of alcohol. This subtype may influence other drug-metabolizing enzyme systems and possibly account for the carcinogenicity of dimethylnitrosamine in the gastrointestinal tract.

**Enzyme inhibition** may be triggered by a number of foreign substances. Such a process, in turn, results in an inhibition of biotransformation and thus in a prolongation of the effects of drugs and xenobiotics as well as of the inhibitor. A reduction in enzyme activity occurs in response to an inhibition of synthesis or an increase in breakdown induced by foreign substances. It can likewise be conditioned by the fact that several substances are competing for the enzyme-binding site. In administering drugs to elderly people, it should be considered that cytochrome P 450-dependent enzyme reactions get slower with age, thus making dose adjustments necessary.

The major **types** of enzyme inducers are: (*1.*) phenobarbital (*2.*) methylcholanthrene, and (*3.*) anabolic steroid. (s. tab. 3.19)

| Effect of induction | Phenobarbital type | Methylcholanthrene type |
|---|---|---|
| Microsomal proteins | ++ | (+) |
| Cytochrome P 450 | ++ | ++ |
| Cytochrome P 448 | (+) | ++ |
| NADPH cytochrome-C reductase | ++ | ∅ |
| NADPH-cytochrome P 450 reductase | ++ | ∅ |
| Glucuronyl transferase | (+) | ++ |
| Steroid metabolism | accelerated | ∅ |
| Acceleration of metabolism | by several active substances | by only few active substances |
| Bile secretion | ++ | ∅ |
| Liver weight | ++ | (+) |
| Onset of effect | after 2−3 days | after 12−24 hours |

**Tab. 3.19:** Effects of enzyme inducers of the phenobarbital and methylcholanthrene types (+ = increased, (+) = slightly increased, ∅ = not increased or not accelerated)

▶ The knowledge of biotransformation currently available raises the following issue, which up to now may not have been given the attention it deserves: owing to the considerable *individual variability* of drug metabolization (= *pharmacogenetics*) with multiple influencing factors, it might be problematic in **clinical studies** to administer the same drug dosage to all study participants and to obtain comparable equivalent results for the drug under study. • *Both the therapeutic efficacy and side effects of a drug may vary greatly in different patients, even with similar plasma concentrations.* • This might further explain the potential divergency of clinical study results − and possibly also the potential "inefficacy" of a drug or an "adverse drug reaction".

# 13 Ammonia detoxification and bicarbonate neutralization

## 13.1 Urea cycle

▶ As early as 1815, C. B. Rose had assumed the synthesis of urea to be localized in the liver. (s. p. 10) In 1858 A. Heynsius observed that the concentration of urea was higher in the liver than in all other organs. In 1868 E. Stadelmann found patients with liver disease to have markedly increased blood levels of ammonia compared with normal individuals.

**Ammonia:** $NH_3$ is a colourless gas. It is freely soluble in water, whereby ammonium is formed. Ammonia develops in the liver following degradation of protein, amino acids, nucleinic acids and biogenic amines, and in the kidney by tubular hydrolysis of glutamine.

**Ammonium:** $NH_4^+$ is free $NH_3$ dissolved in water. It is defined as the sum of free $NH_3$ and ionized $NH_4^+$, which is in a pH-dependent dissociation balance with $NH_3$, i. e. alkalosis shifts the balance towards free ammonia. With a normal blood pH value of 7.4, more than 90% of the ammonium are available as $NH_4^+$.

The **formation of ammonium** is a continuous metabolic process. The highest amount of about 4 g/day (= 0.23 mol/day) is formed in the *colon*, a lower production of ammonium takes place in the *small intestine* from glutamine. Furthermore, 20% of the urea formed in the intestine are rehydrolyzed to ammonium. A total of 300−500 mmol ammonia are produced daily in the intestinal tract; thus the concentration of $NH_4^+$ is 5−10 times higher in the portal vein than in the peripheral blood. • The *liver* produces a higher amount of $NH_4^+$ from the degradation of protein and amino acids which, however, is directly detoxified in the urea cycle. • A considerable amount of ammonia is also formed in *muscle*, depending on muscular action. • In the *kidneys*, 30−40 mmol ammonium are produced daily by the tubular hydrolysis of glutamine (with the help of glutaminase) and passed into the blood. In potassium deficiency and alkalosis, the renal formation of ammonia is markedly increased. • *Helicobacter pylori* also produces ammonium: this pathogen carries urease molecules on its surface. These split the urea, which is amply formed in the contents of the stomach, into ammonium and hydrogen carbonate. Depending on the number of pathogens and the amount of urea, large concentrations of ammonium accumulate. As a result, the gastric acid is neutralized in its microenvironment by helicobacter, so that the pathogen gains time to penetrate the mucosa. (s. pp 62, 266)

▶ With the degradation of *100 g protein, 20 g ammonia* are formed. It is freely diffusible and thus toxic. Therefore it must be rapidly dissolved in water and converted into nondiffusible ammonium. The higher intracellular concentration of protons causes $NH_4^+$ to accumulate in the cell. (s. fig. 3.15)

An increase in freely diffusible, and thus toxic, ammonia may be due to a dissociation imbalance with ammonium as well as inadequate detoxification of $NH_3$ and $NH_4^+$. The question of the toxicity of ammonia, especially **neurotoxicity**, has not been fully ex-

*Fig. 3.12:* Diagram showing the ammonia detoxification process in the urea cycle (= ornithine cycle) (H. A. KREBS, K. HENSELEIT, 1932) (A. L. LEHNINGER, 1979)
plained with regard to its pathogenesis. Proposed potential **causes** include: (*1.*) damage to the mitochondria, (*2.*) disturbance or insufficiency of major liver cell functions, (*3.*) increase in the permeability of the blood-liquor barrier, and (*4.*) dysregulation of neurotransmitters and their receptors.

The **detoxification of ammonium** must be balanced with the formation of ammonium in order to avoid toxic concentrations in the peripheral blood. The urinary elimination rate is $20-40$ mmol/day (= 1.9 g). • The detoxification of ammonium takes place in the liver-specific urea cycle. The skeletal muscles and the brain are involved in ammonium detoxification via the glutamine cycle.

The *urea cycle*, also called *ornithine cycle*, was first described by H. A. KREBS and K. HENSELEIT in 1932. (quot. 51) The principle of ammonia detoxification in the urea cycle is based on the conversion of ammonium and bicarbonate in the mitochondria under ATP consumption into carbamoyl phosphate (by means of carbamoyl phosphate synthetase). It enters the urea cycle, which is localized mainly − yet with a low affinity for ammonium − in the periportal zone of the liver lobule. In the urea cycle alone, about two thirds of the amino nitrogen of ammonia are irretrievably lost to the organism (= *definitive ammonia detoxification*). (s. fig. 3.12)

With increasing dysfunction of the liver, the enzymes responsible for the urea cycle display a marked loss of activity. Some of these enzymes are zinc-dependent (s. fig. 3.12); a decrease in enzyme activity is therefore evident in zinc deficiency. (s. tab. 3.15)

The remaining third of the ammonia is trapped by the peripheral hepatocytes (= scavenger cells) due to their high affinity. By means of glutamine synthetase, glutamine is formed as a nontoxic transport form of ammonia. At the same time, it also serves to activate the urea cycle (= *temporary ammonia detoxification*). (s. fig. 3.13)

▶ **Urea cycle:** *Carbamoyl phosphate synthetase* is of decisive importance in the detoxification process. However, it requires a relatively high concentration of $NH_4^+$. An increase in enzyme activity (and thus in urea synthesis) is not only rapidly achieved by an elevation in $NH_4^+$, but also by ATP and *ornithine*. N-acetylglutamate serves as a further enzyme activator, becoming active within one hour. In the long term (within $3-7$ days), glucocorticoids and glucagon cause an increase in carbamoyl phosphate synthetase activity. • From the hepatocyte cytosol, $NH_4^+$ travels to the mitochondria, where it is enzymatically restructured into carbamoyl phosphate. $NH_4^+$ may also be formed in the mitochondria through glutamine splitting. The mitochondrial linkage of *carbamoyl phosphate* and ornithine leads, by means of ornithine carbamoyl transferase, to the formation of *citrullin*. This reaches the cytosol and combines, under ATP consumption, with aspartate (by means of argininosuccinate synthetase) to form *argininosuccinate*. The latter is split (by means of argininosuccinate lyase) into arginine and fumarate. *Fumarate* enters the citric acid cycle. *Arginine* is split (by means of arginase) into ornithine and *urea* − a reaction reported by A. KOSSEL and H. D. DAKIN as early as 1904. (quot. 51) *Ornithine* again reaches the mitochondria to be reincorporated in the cycle. (s. fig. 3.12)

*Fig. 3.13:* Diagram showing the urea and glutamine cycle in the liver acinus

As a rule, 2 mol bicarbonate are required for the synthesis of 1 mol urea. The amount of urea eliminated in the urine is approximately 500 mmol/day (ca. 30 g). Normally, only about 25% of the capacity of the urea cycle are used. It is therefore virtually impossible for hyperammonaemia to be a sequela to isolated $NH_4^+$ hyperproduction alone. • In patients with liver cirrhosis, the capacity for urea synthesis is reduced by approximately 80%, i.e. there is a considerable decrease in ammonia detoxification in the periportal field, predominantly due to a function loss on the part of the perivenous scavenger cells.

Alkalosis and hypokalaemia (possibly caused by secondary hyperaldosteronism or use of diuretics) shift the dissociation constant towards free, toxic $NH_3$. By contrast, ammonia is considered − in a process resembling a vicious circle − to be a secondary stimulus for aldosterone production. • Thiazide diuretics in particular put an overload on the detoxification capacity of the scavenger cells. This is because of an insufficient supply of bicarbonate for carbamoyl phosphate synthetase reaction due to diuretic-induced inhibition of the mitochondrial carboanhydrase.

## 13.2 Glutamine cycle

▶ In **glutamine synthesis**, glutamate is initially formed by the binding of $NH_4^+$ to α-ketoglutaric acid, which is converted into glutamine through ATP-dependent amidation by means of glutamine synthetase. This synthetase is found in the microsomes and mitochondria of the hepatocytes as well as of the muscle and brain cells. Glutamine synthesis is not a liver-specific process. *Glutamine constitutes the non-toxic transport form of $NH_4^+$ between the tissues.* Glutamine synthesis and glutamate transport take place in the *perivenous* zone, whereas the glutaminase reaction occurs in the *periportal* zone (= **intercellular glutamine cycle**).

The *glutamine cycle* and the urea cycle are economically sequenced. The *urea cycle* localized in the periportal field requires a high concentration of $NH_4^+$, which is likewise available in the sinusoidal blood of that area. Through the glutaminase reaction, which is also localized in the periportal field, an additional amount of $NH_4^+$ is released by glutamine splitting for stimulation of urea synthesis (= high capacity with low affinity). • By contrast, glutamine synthetase shows a high affinity for $NH_4^+$, so that even small amounts of ammonium, which have escaped the urea cycle, are "temporarily" detoxified by the *glutamine synthesis* taking place in the perivenous blood (= low capacity with high affinity). Only approximately 8% of the perivenous hepatocytes are needed for fixation of residual ammonia. (s. fig. 3.13)

The glutamine formed in the *liver* is released into the systemic circulation. Through arterial blood, the *brain* is also supplied with ammonium (approximately 10% of the plasma concentration). Detoxification is effected via glutamine synthesis. The glutamine formed in the brain enters the blood circulation. In the *muscles*, ammonium

is also converted into glutamine through the pathway of glutamine synthesis and passed into the blood. Glutamine travels from the blood to the *kidneys*, where it is split into glutamate and ammonia by glutaminase. $NH_3$ is excreted in the urine. Glutamine is also released into the *small intestine*, where it serves as the main source of energy for mucosal cells. The ammonia liberated by splitting is transported as $NH_4^+$ through the portal vein to the liver for detoxification. (s. fig. 3.14) • $NH_4^+$ is rapidly converted into a *nontoxic form*. This is done by (*1.*) transfer to a ketonic acid with formation of a corresponding amino acid, (*2.*) formation of carbamoyl phosphate, and (*3.*) formation of the acid amide of glutaminic acid (= *temporary ammonia detoxification*). The nitrogen from the acid amide group of glutamine remains in the metabolism for various syntheses. This group of acid amides is therefore called the *ammonium storage group*.

*Fig. 3.14:* Schematic diagram showing ammonium metabolism and the organs which are involved via the blood circulation (blue = glutamine, red = $NH_4^+$, green = urea)

## 13.3 Bicarbonate neutralization

A high amount of bicarbonate is constantly being produced in the body. Degradation of 100 g protein yields approximately 1 mol bicarbonate (= 61 g). Bicarbonate neutralization takes place via the urea cycle too, as the synthesis of 1 mol urea requires 2 mol bicarbonate. Besides the lungs and kidneys, the liver therefore also plays an important role in acid-base metabolism and is partly responsible for pH homoeostasis.

The pH value in the portal vein drops in the case of increased urea synthesis. This decrease corresponds to the consumption of $HCO_3^-$. At the same time, intra- and extrahepatic glutamine synthesis is reduced. When the pH value falls in the blood, corresponding amounts of bicarbonate must be made available for the compensation of *metabolic acidosis*. This amount of $HCO_3^-$ is then not available for urea synthesis, which results in a curbing of the urea cycle. Additionally, the glutaminase

| 100 g protein | 1,000 mmol $NH_4^+$ 40  960 | 1,000 mmol $HCO_3^-$ 960  40 | 20 mmol $H_2SO_4$ 20 |
|---|---|---|---|
| Liver | 40 Glutamine | 480 Urea | 20  $SO_4^{--}$ + 40  $CO_2$ |
| Urine | 40 $NH_4^+$ | 480 Urea | |
| Acidosis | ↑ ↑ ↑ | ↓ | |
| Alkalosis | ↑ | ↓ | |

| *Acidosis* | Periportal | | Perivenous | |
|---|---|---|---|---|
| | • Urea synthesis | ↓ | • Glutamine synthesis | ↑ |
| | • Glutamine degradation | ↓ | = Liver: glutamine-producing | |
| | • Consumption of $HCO_3^-$ | ↓ | | |
| *Alkalosis* | • Urea synthesis | ↑ | • Glutamine synthesis | ↓ |
| | • Glutamine degradation | ↑ | = Liver: glutamine-consuming | |
| | • Consumption of $HCO_3^-$ | ↑ | | |

***Fig. 3.15:*** Tabular survey of catabolites of 100 g protein and their hepatic and renal metabolic pathways including excretion in the urine under normal metabolic-acidosic and metabolic-alkalotic conditions. (If no other units are specified, the data are in mmol)

reaction is reduced, and there is a decline in the intramitochondrial production of bicarbonate as a result of decreased carbonic anhydrase activity, with a further curbing of the urea cycle. Simultaneously, an increase is observed in hepatic glutamine synthesis, and (by augmentation of the pH-regulated glutamine degradation in the kidneys) the definitive urinary elimination of surplus $NH_4^+$ is achieved (= *renal ammoniogenesis*) − without simultaneously influencing the acid-base metabolism. • The rise in the blood pH value is followed by an increase in urea synthesis: in *metabolic alkalosis*, the uptake of $NH_4^+$ and $HCO_3^-$ by the mitochondria is enhanced with an elevated consumption of bicarbonate for increased urea synthesis. In the mitochondria, $CO_2$ is converted spontaneously or by carbonic anhydrase into H-ions and bicarbonate.

Thus the **bicarbonate buffer** in the liver with its components $CO_2$ and $HCO_3^-$ is also used for maintaining pH homoeostasis. The various cellular and subcellular compartments can only keep their own specific pH values constant provided the pH value of the extracellular space is not subject to major fluctuations. A constant balance between the formation and excretion of $CO_2$ and $HCO_3^-$ must therefore be guaranteed. • **Bicarbonate neutralization** takes place, energy-driven and irreversibly, in the urea cycle. In this context, $HCO_3^-$ is considered to be a relatively strong base, whereas $NH_4^+$ is regarded as a weak acid.

The following mean metabolic values apply to the **degradation of 100 g protein**: ca. 1,000 mmol $NH_4^+$, ca. 1,000 mmol $HCO_3^-$, 20 mmol $SO_4^{--}$ and 3 mol $CO_2$ (0.5 mol $CO_2$/day are additionally formed in urea synthesis and sulphuric acid neutralization). Some 40 mmol $HCO_3^-$ are buffered by 20 mmol $H_2SO_4$. • The amounts of 960 mmol $NH_4^+$ and 960 mmol $HCO_3^-$ give a total of 480 mmol urea reaching the kidneys. Furthermore, 40 mmol $NH_4^+$ are transferred as *glutamine* from the liver to the kidneys, where they are again split to give 40 mmol $NH_4^+$. (s. fig. 3.15)

The **acid-base metabolism** is influenced by the pH- and $HCO_3^-$-regulated switchover of ammonium detoxification from urea to glutamine formation. In acidosis, bicarbonate is conserved by curbing hepatic urea synthesis; in alkalosis, however, bicarbonate is consumed by enhancing hepatic urea synthesis. (1, 34, 35)

# 14 Alcohol uptake and degradation

**Alcohol** is the designation for hydrocarbons in which the H-atoms are substituted by one or several hydroxyl groups (−OH).

According to the **number of OH groups**, a subdivision is made into 6 alcohol types: 1-valent (= alcohols), 2-valent (= glycols), 3-valent (= glycerins), 4-valent (= erythritols), 5-valent (= pentitols), and 6-valent (= hexitols).

According to the **binding type of the OH group**, a distinction is drawn between primary (−$CH_2$−OH), secondary (=CH−OH) and tertiary (≡C−OH) alcohols.

The **nomenclature** follows two principles: (*1.*) the ending "ol" is added to the name of the paraffin hydrocarbon (e. g. methanol), or (*2.*) the name of the corresponding alkyl group is placed before the word alcohol (e. g. methyl alcohol).

The term "alcohol" which is generally applied in medicine corresponds to the chemical compound ethanol or ethyl alcohol. Its empirical formula is $C_2H_5OH$ or $CH_3−CH_2−OH$, respectively.

## 14.1 Endogenous alcohol synthesis

Alcohol may be formed in the body in three ways and therefore a cellular alcohol-metabolizing system has evolved in the course of phylogenesis:

1. Under physiological conditions, alcohol may be formed in **intermediary metabolism** as an intermediate product, e. g. in pyruvate decarboxylation and threonine degradation. Here minimal amounts of alcohol may arise (blood alcohol concentration of about 0.0009−0.001‰).

2. Some **intestinal bacteria** (e. g. Escherichia coli, salmonellae, and especially gram-negative pathogens) are also equipped with a fermentation capacity and produce small amounts of alcohol. No alcohol is detectable in

the stool, however. *Blood normally contains minute quantities of alcohol (on average 0.02−0.03‰).*

3. Endogenous intestinal fermentation may occur in the case of an excessive intake of carbohydrates in the diet (e. g. fruit juices, farinaceous food, raw fruit and vegetables), in the presence of certain **intestinal fungi** (e. g. *Candida species* [C. albicans, C. tropicalis, C. stellatoidea, C. glabrata, C. parapsilosis, C. guilliermondii, C. kefyr, C. robusta, etc.] as well as *Saccharomyces cerevisiae* and some types of *Torulopsis* and *Trichosporae*). *In this way, amounts of alcohol corresponding to a blood alcohol level of 0.15−0.30‰ may be produced.*

## 14.2 Exogenous alcohol uptake

Exogenous alcohol uptake in the body may occur in three ways:

1. **Oral** consumption of alcohol in various forms:
− alcoholic beverages
− alcoholic home remedies
− alcohol contained in drugs
− alcohol contained in food (e. g. kephir, bread)
− alcohol-"free" fruit juices are allowed to have an alcohol content of up to 0.5% by volume due to fermentation in the bottle
− alcohol-"free" beers have an alcohol content of up to 0.4% by volume
− alcohol produced from fruit, e. g. intestinal fermentation of the durian (*Durio Zibethinus*).

Too little attention has been paid to the alcohol content of **drugs,** or the respective content has generally been considered negligible. In this context, we found the following relevant data: In the 1993 „Rote Liste"*, 902 drugs had an alcohol content of 5% to >81% by volume; the corresponding figure for 1996 was 854 out of 11,714 preparations (= 7.3%).

* „Rote Liste" (= "Red List": German Pharmaceutical Directory)

| Red List | 1993 | 1996 | | 1993 | 1996 |
|---|---|---|---|---|---|
| −10% in volume | = 147 | 114 | 51−60% in volume | = 121 | 161 |
| 11−20% in volume | = 166 | 196 | 61−70% in volume | = 72 | 90 |
| 21−30% in volume | = 121 | 127 | 71−80% in volume | = 3 | 6 |
| 31−40% in volume | = 126 | 130 | >81% in volume | = 10 | 10 |
| 41−50% in volume | = 133 | 147 | no data | = 3 | − |

It is astonishing − and actually irresponsible − that 15 (out of 89) "liver therapeutics" given in the 1994 „Rote Liste" and 14 (out of 95) given in the 1997 „Rote Liste" have an alcohol content of 25−66% in volume. • *Alcoholics who have "dried out" should pay particular attention to this point!*

2. **Inhalation** of alcohol vapour.
3. **Percutaneous** uptake through the skin is possible − such as when using cosmetics, after-shave, gloss paints and alcohol compresses − especially in cases involving an increased resorption capacity of the epidermis.

## 14.3 Alcohol absorption

Only small amounts of alcohol are absorbed by the oral mucosa. About 20 to 30% are absorbed in the stomach and 70 to 80% in the duodenum and the upper section of the small intestine. The extent and speed of absorption are influenced by various factors. (75) (s. tab. 3.20)

Due to a number of **influencing factors,** the amounts of alcohol absorbed per time unit vary greatly in the individual case. Thus the rate of hepatocyte exposure to alcohol is also influenced. Furthermore, different absorption rates occur depending on the mental state (e. g. balanced mood, aggressive excitation, exhaustion accompanied by resignation) and the physical condition (e. g. resting, carrying out heavy work).

| Increased gastric ADH activity and/or inhibition of absorption |
|---|
| 1. Full stomach |
| 2. Kind of food |
|    − rich in proteins, rich in fats |
|    − rich in fibre |
| 3. Slow drinking |
| 4. Low alcohol concentration |
| 5. Pyloric stenosis |

| Reduced gastric ADH activity and/or acceleration of absorption |
|---|
| 1. Empty stomach |
| 2. Kind of alcoholic beverage |
|    − sweet or hot |
|    − containing $CO_2$ |
| 3. Rapid drinking |
| 4. High alcohol concentration |
| 5. Gastric resection |

**Tab. 3.20:** Factors influencing the absorption of alcohol

**Absorption of alcohol** in the gastrointestinal tract takes place much more rapidly than its degradation. As a result, accumulation of alcohol, even at toxic levels, may readily occur. Alcohol is rapidly and completely absorbed in the upper gastrointestinal tract and transported to the liver through the portal vein. Thereafter, alcohol dissolves in the body fluids and is distributed to all organs depending on their water content. On average, the body's water content amounts to 65%, the average water content of blood being 83%. When a diffusion balance has been achieved between the blood and the tissues (after about 45−90 minutes), the alcohol concentration in the blood is 1.27 times higher than in the body tissues. Five minutes after its uptake, it is already detectable in the blood. Maximum concentrations are reached after 30−60 minutes. In the case of obese people, blood alcohol levels are considerably higher than in persons of normal weight.

## 14.4 Biochemical parameters of alcohol uptake

The **caloric value** of alcohol is 7.1 cal/g (= 29.7 kJ). In the case of alcoholic beverages with calorie-containing ingredients, it is necessary to add the calories for carbohydrates (4.0 cal/g) and, if applicable, for protein (4.0 cal/g) as well as for fat (9.0 cal/g).

Biochemical quantities are always based on pure alcohol in grams. (s. tab. 3.21) The **alcohol amount** ingested in grams (A) is calculated from the volume % of the drink multiplied by the specific weight of the alcohol (0.8):

vol. % x 0.8 = amount of alcohol contained in grams/100 ml alcoholic beverage

**Example:** Beer with 5 % volume alcohol contains 5 grams, i.e. 50 grams alcohol/litre. As alcohol is lighter than water, this is multiplied by 0.8. Therefore 50 x 0.8 = 40 grams alcohol/litre.

Conversely, alcohol volume percentage (vol. %) can also be calculated from the alcohol-gram content per litre (s. tab. 3.21):

alcohol grams/litre x 1.25 = vol. %

**Example:** 40 g alcohol/litre x 1.25 = beverage contains 5 vol. %.

| Beverage | Alcohol content (vol. % per beverage) | Alcohol content (grams/litre per beverage) |
|---|---|---|
| export, pils, weissbier | 4−6 | 32.0−48.0 |
| bockbier, doppelbock | 6−9 | 48.0−72.0 |
| apple wine | 4−6 | 32.0−64.0 |
| sparkling wine | 5−12 | 76.0−96.0 |
| champagne | 5−12 | 76.0−96.0 |
| white wine | 9−12.5 | 72.0−100.0 |
| red wine | 9.5−12.5 | 76.0−100.0 |
| sherry, vermouth | 17−20 | 136.0−160.0 |
| advocaat, cherry brandy | 20−25 | 160.0−200.0 |
| herbal liqueur | 30−37 | 240.0−296.0 |
| corn schnapps, double-corn schnapps | 32−38 | 256.0−304.0 |
| calvados, gin, brandy | 38−40 | 304.0−320.0 |
| whisky, aquavit, cognac, fruit schnapps | 40−44 | 320.0−352.0 |
| vodka, rum | 40−55 | 320.0−440.0 |
| balm spirit | 79 | 632.0 |

***Tab. 3.21:*** Alkohol content in vol. % and grams per litre for a variety of beverages

The **blood alcohol concentration** (BAC) is the balance between absorbed and eliminated amounts of alcohol. Fatty tissue takes up little alcohol and is incapable of degrading it. Here the various factors influencing absorption are not considered. (s. tab. 3.20) The BAC is calculated using *Widmark's formula* (E. M. P. WIDMARK, 1922):

$$A = c \times p \times r$$

whereby *A* represents the amount of alcohol (in g), *c* the blood alcohol concentration (in ‰), *p* the body weight (in kg), and *r* a reduction factor of 0.7 for men and 0.6 for women.

The **alcohol level** (‰) is given in grams of ethanol per 1,000 ml blood and is calculated on the basis of the formula:

$$c = \frac{A}{p \times r}$$

**Example:** One glass of beer of 0.2 l and with 5% alcohol in volume contains 8 g pure alcohol. In the case of a man weighing 70 kg this corresponds to a ratio of 8:49 (70 x 0.7) = 0.16‰.

## 14.5 Alcohol degradation

The capacity to degrade alcohol is, to a high degree, genetically determined. Approximately 90% are degraded by the liver. A small percentage (<10%) is also metabolized in the stomach by means of gastric alcohol dehydrogenase. The ADH activity of the gastric mucosa is reduced in women, in old age, following administration of cimetidine and after gastric resection as well as in cases of chronic alcohol abuse (more markedly so in women than in men). Up to 8% are eliminated unchanged via the lungs and the skin, whereas around 1% is excreted in the urine. Some 10−15% are degraded enzymatically by the gastric mucosa and around 80% by the liver. Alcohol elimination increases considerably in the case of chronic alcohol consumption.

The metabolization rate of alcohol amounts to $1.9-3.2$ mmol $\times$ kg$^{-1}$ $\times$ hr$^{-1}$, i.e. $88-146$ mg alcohol/kg BW/hr, for a single intake in a healthy organism; the maximum degradation capacity is about 240 g alcohol/24 hr. Following completed absorption and diffusion balance between blood and tissues, alcohol is degraded in a linear manner at a constant reaction speed. The maximum degradation of alcohol in men with a body weight of 70 kg is calculated to be 168 g within 24 hours, the corresponding value for women being 143 g. At a rough estimate, $0.7-1$ g alcohol/hr is broken down per 10 kg BW, meaning that the blood alcohol level is reduced by $0.10-0.15$‰ per hour. In the case of protein deficiency ($<20-25$ g protein/day), the degradation capacity is reduced by 28−49%. This is demonstrated in fasting (36 hours) with a 43% decrease in the degradation rate, which is attributable to the associated increase in fatty acid oxidation. (9, 75, 87, 96)

The **lethal concentration** is generally 3.5−4.0‰ (although, in individual cases, people have survived higher concentrations). The **lethal dose** is 2.5−3.5 g/kg BW when alcohol ingestion occurs over a period of $1-2$ hours (e. g. in a drinking bet) or $300-800$ g alcohol in total, depending on the individual case. (s. fig. 28.5)

The **consumption of oxygen** for alcohol degradation in the liver is very high: approximately 75% (in alcohol

intoxication 85% and more) of the hepatocyte $O_2$-uptake is used for the oxidative metabolization of alcohol. Therefore the hepatocytes are in a state of relative hypoxia. This may lead to a severe disturbance in many physiological processes of intermediary metabolism. The period of oxygen-consuming alcohol degradation is thus associated with increased vulnerability of the liver cell to further damaging factors.

A total of **three enzyme systems**, which can be differentiated by column chromatography, are available in the liver cells for alcohol degradation. These enzyme systems differ with regard to hepatocellular localization and biochemical properties. (s. tab. 3.22)

1. Alcohol dehydrogenase (ADH)
2. Microsomal ethanol-oxidizing system (MEOS)
3. Catalase

| Criteria | ADH | MEOS | Catalase |
|---|---|---|---|
| Intracellular localization | Cytosol | Endoplasmic reticulum | Peroxisomes |
| Cofactor pH optimum | NAD 11 | NADPH; $O_2$ 6.9−7.5 | $H_2O_2$ 5.5 |
| Substrate specificity − Methanol − Ethanol − Propanol − Butanol − Pentol | ++ +++ ++++ ++++ ++++ | ++ ++++ +++ ++ + | ++++ ++++ (+) ∅ ∅ |
| Increase in enzyme activity following chronic consumption of alcohol | ∅ | ++++ (♂ > ♀) | ∅ |

**Tab. 3.22:** Localization-related and biochemical differences of the three enzyme systems responsible for alcohol degradation

1. **Alcohol dehydrogenase** (ADH) is of great relevance for alcohol degradation. It is not available before the 3rd year of life and is localized in the cytosol of the hepatocyte, predominantly in the centre of the liver lobule. ADH is a zinc-dependent enzyme; in cases of *zinc deficiency* (as caused by alcohol abuse in particular), there is a loss of activity with further diminution of alcohol metabolization. So far, five isoenzymes ($ADH_{1-5}$) with additional subgroups have been identified; in the meantime, another gastric ADH isoenzyme has been detected in the gastric mucosal cells. The activity of gastric ADH depends, for example, on gender, age, drug intake and potential colonization with Helicobacter pylori. • An "atypical $ADH_{2.2}$" (with 3 to 6 times higher activity) occurs in Europeans in 5−20% of cases, the respective frequency for East Asians (e. g. Japanese, Chinese, Koreans) being 80−98%. The increased occurrence of the *"flushing syndrome"* in these races is based on this

"atypical ADH" and on a genetic reduction in the $ALDH_1$ isoenzyme. (s. tab. 3.23) (s. p. 64) (9, 60, 78)

ADH 4 and ADH 5 can only rarely be demonstrated. Both possess a low affinity with alcohol; they are therefore of no importance for degradation purposes. ADH 4 is only found in the gastric mucosa. It is to be noted that cimetidine and ranitidine inhibit the ADH of the liver and the gastric mucosa, thus elevating the blood alcohol level. This is, however, not the case with famotidine. • In patients with liver disease, ADH activity is reduced − and therefore alcohol degradation as well.

ADH also oxygenates methanol into toxic formaldehyde. Consequently, ethanol should be administered in order to inhibit the breakdown of methanol in cases of methanol intoxication.

| Class | Allele | Localization |
|---|---|---|
| I | ADH 1 ADH 2.1 ADH 2.2 ADH 2.3 ADH 3.1 ADH 3.2 | liver, stomach liver, stomach liver, stomach liver, stomach liver, stomach liver, stomach |
| II | ADH 4 | liver, stomach |
| III | ADH 5 | liver, stomach |
| IV | | stomach |

**Tab. 3.23:** Isoenzymes of ADH in the liver and in gastric mucosa

*Saturation of the enzyme ADH* is already achieved at a blood alcohol concentration of 0.5‰ with full enzyme activity occurring at 0.2−0.5‰. Thus a maximum rate of alcohol degradation is reached at these relatively low concentrations. • There is no *induction of the enzyme ADH* following chronic alcohol consumption. Higher alcohol concentrations as well as protein deficiency, sexual hormones, thyroidal hormones, etc. may even cause a decrease in ADH activity.

ADH catalyzes the oxidation process in the cytosol of the hepatocyte, forming a complex of ethanol, ADH and $NAD^+$. The reaction consists in transferring the hydrogen from the ethanol molecule to $NAD^+$ with parallel formation of acetaldehyde.

$$CH_3-CH_2-OH + NAD^+ \longrightarrow CH_3-CHO + NADH + H^+$$
In a subsequent, and likewise NAD-dependent reaction, the highly toxic acetaldehyde is converted to acetic acid in the mitochondria by way of aldehyde dehydrogenase (ALDH). The resulting NADH is then reoxidized. (60, 78) (s. fig. 3.16)

$$CH_3-CHO + NAD^+ + H_2O \longrightarrow CH_3-COOH + NADH + H^+$$
*Fig. 3.16:* Diagram showing alcohol degradation in the liver cell by means of alcohol dehydrogenase (ADH), catalase and the microsomal-ethanol oxidizing system (MEOS) as well as by aldehyde dehydrogenase (ALDH)

The speed of alcohol degradation by ADH is determined by the **reoxidation rate** of NADH to NAD. The metabolization of 1 mol alcohol yields 2 mol NAD + H$^+$. This leads to a massive shift in the redox status of the liver cell in favour of reduction. Alcohol degradation would cease if NADH were not continuously reoxidized. Thus the degradation of alcohol is limited by all NADH-oxidizing processes taking place in the hepatocyte. The reoxidation of NADH, i.e. the removal of alcohol hydrogen, occurs through the oxidation of hydrogen to water in the mitochondrial respiratory chain, whereby energy is produced. An inhibition of the respiratory chain by specific inhibitors almost completely stops the degradation of alcohol. Acetic acid is released into the blood, where it is converted to acetyl CoA in the extrahepatic tissues. It is included in the citric acid and fatty acid cycles as well as in cholesterol synthesis, or is oxidized to $CO_2$. • *Acetic acid is the final product of alcohol degradation.* (s. fig. 3.16)

Alcohol hydrogen is transferred via the *malate-aspartate cycle* from the cytosol to the *mitochondrial respiratory chain*. The passage of 1 mol-reducing equivalents is effected by transporting 1 mol malate and 1 mol glutamate into the mitochondria and simultaneously removing 1 mol α-ketoglutarate and 1 mol aspartate from the mitochondria. In this way, cytosol hydrogen enters the respiratory chain, which is functionally embedded in the citric acid cycle.

2. The **microsomal ethanol-oxidizing system** (MEOS) (C. S. LIEBER, L. M. DeCARLI, 1968, 1970) is the second enzyme system involved in alcohol degradation (10 − 20%). It is localized in the endoplasmic reticulum, predominantly in perivenous hepatocytes. Men show a higher MEOS activity than women. Many other factors (nutrition, age) may also influence this activity. With regard to its localization and its mixed-function oxidation system of cytochrome P 450 and cytochrome P 450 reductase, it corresponds to the biotransformation system for the breakdown of foreign substances. **CYP 2E1** is a relatively alcohol-specific isoenzyme. It can also break down especially large quantities of alcohol into hepatotoxic acetaldehyde. Further isoenzymes are 1A2, 2A6, 2B6, 2D6, and 3A4. • MEOS is usually localized in centroacinar hepatocytes where there is already minimal $O_2$ partial pressure. As a consequence, the large amount of $O_2$ required to break down the alcohol will trigger alcohol-toxic liver damage in the centre of the lobule. As a cofactor, MEOS requires molecular oxygen in addition to NADPH. Moreover, it contains phospholipids, whose role is not known as yet. Normally, alcohol degradation via MEOS only plays a minor role because of the lower substrate affinity involved. MEOS becomes increasingly active, however, in the case of regular alcohol consumption and higher alcohol levels in the blood (>0.5‰). (s. fig. 3.16)

$$CH_3–CH_2–OH + NADPH + H^+ + O_2$$
$$\longrightarrow CH_3–CHO + NADP^+ + 2 H_2O$$
The MEOS is induced by chronic alcohol consumption, so that both the degradation of alcohol as well as the metabolization of foreign substances (and drugs) are accelerated with regular alcohol ingestion; some industrial solvents and carcinogens are also more highly activated. This is only possible, however, if no alcohol is present in the body during the uptake of foreign substances because that would result in a competitive inhibitory effect. Thus alcohol consumers have an increased metabolization capacity for foreign substances when sober (= *higher dose tolerance*), which is due to increased induction of the MEOS, whereas the breakdown of foreign substances is slowed down under alcohol consumption (= *higher dose sensitivity*). Enzyme induction only sets in after 2 − 3 days of alcohol intake, even in the case of higher concentrations, and persists for up to 3 weeks after discontinuing consumption. Thus ADH and the MEOS metabolize alcohol to acetaldehyde: both enzyme systems have their own specific reaction and activity. For alcohol oxidation, the MEOS does not require ADH either in an obligatory or in a facultative sense. Accelerated metabolization of foreign material due to increased MEOS activity may also lead to the formation of *biotoxometabolites*. (s. p. 55) (s. figs. 3.11, 3.16)

3. **Catalase** (D. KEILIN et al., 1945) is localized in the peroxisomes; alcohol is oxidized via intermediate steps to xanthine by means of xanthine oxidase. This releases $H_2O_2$, which is deactivated with the help of glutathione and then split into oxygen and water. By way of this peroxidase reaction, alcohol can also be degraded to acetaldehyde. (12) However, in the case of chronic alcohol consumption, glutathione is bound to acetaldehyde with the result that the released $H_2O_2$ can intensify lipid oxidation. (s. fig. 3.16)

$$CH_3-CH_2-OH + H_2O_2 \longrightarrow CH_3-CHO + 2H_2O$$

**Catalase activity** only occurs in higher alcohol concentrations (>1‰), with alcohol acting as a hydrogen donor. With chronic alcohol intake, catalase shows no changes in activity. The reaction time is determined by the amount of the $H_2O_2$ available. Oxidative alcohol degradation by catalase (approx. 2%) is of little importance under physiological conditions. It differs greatly from ADH and the MEOS. (s. tab. 3.22)

All three oxidative pathways of alcohol degradation lead to the formation of **acetaldehyde** within the cytosol of hepatocytes, preferably in the perivenous area. But around 20% of Kupffer cells are also damaged by the acetaldehyde. These then release highly reactive cytotoxins into the extracellular space, which may lead to endotoxinaemia. The oxidation of alcohol to form acetaldehyde and its reduction to an acetate require NAD as a cofactor, which is then reduced to NADH. Permanent overloading of the system shifts the NAD/NADH ratio towards NADH, i. e. hepatic redox status. • This is the major cause of numerous hepatocellular *metabolic disorders* such as (*1*.) reduced activity of the tricarboxylic cycle, (*2*.) reduced fatty acid oxidation, (*3*.) reduced gluconeogenesis, (*4*.) increased triglycerine synthesis, and (*5*.) lactic acidosis. • Acetaldehyde is a reactive molecule which can give rise to numerous *biochemical effects*:

− covalent bond with phospholipids and proteins
− alkaloid-like complex formation consisting of biogenic amines
− release of prostaglandins
− separation of pyridoxal-6-phosphate from the protein bond
− peroxidation of lipids
− binding to cellular membranes
− stimulation of collagen synthesis in Ito cells
− inhibition of fatty acid oxidation
− inhibition of lipoprotein secretion from the liver cell
− immunogenic effectiveness
− membrane damaged by lipid peroxidation
− suppression of oxidative phosphorylation
− shift in redox status (NAD/NADH)
− deactivation of glutathione
− diminished leukocytic defence mechanisms

Toxic acetaldehyde resulting from alcohol oxidation is almost completely oxidized to acetate in the liver cell by **aldehyde dehydrogenase** (ALDH). For this purpose, various NAD-dependent ALDH isoenzymes are available. Isoenzyme II is bound to the mitochondrial matrix, while isoenzymes I, III and IV are found in the cytosol as well as in the microsomes and, to a lesser degree, in the mitochondria. They also exhibit biochemical differences. Acetaldehyde can be oxidized either by ALDH or by xan-

thine oxidase during the formation of acetate from $H_2O_2$, with the potential appearance of lipid peroxidations. Following chronic intake of alcohol, the activity of mitochondrial ALDH is reduced with an increase in acetaldehyde, partly due to diminished NADH reoxidation in the mitochondria. A genetically determined $ALDH_2$ deficiency, first discovered in the Japanese with an incidence of about 50% (H. W. GOEDDE et al., 1979), is considered to be a further cause of alcohol intolerance in the form of catecholamine-induced vasodilation with potential dysphoric symptoms (*"flushing syndrome"*) (s. p. 62). Increased production of acetaldehyde may also be attributed to microsomal enzyme induction of the MEOS. (s. fig. 3.16)

▶ Increased acetaldehyde concentrations in the liver cell lead to severe morphological damage, especially in the mitochondria and the cytoskeleton, and to increased lipid peroxidations.

# 15 Reticuloendothelial system

▶ As early as 1893, M. PAVLOV had established in his clinical investigations that the liver had an antitoxic function: following a ligature of the portal vein, the blood was led past the liver, which resulted in toxication symptoms in the form of fever and nephritis. • *In 1924 the term "reticuloendothelial system" (RES) was coined by L. A. ASCHOFF.* He used this term to describe a widely distributed cellular functional system in the organism, composed of sessile and circulating macrophages of mesenchymal origin. These cells had a marked phagocytic capability for particulate material. The RES was demonstrable in the liver in particular. • Thus 30 years after the first observation made by PAVLOV, the significance of the liver as an important defence system was confirmed.

## 15.1 Systematics and nomenclature

The macrophages stored in the *reticuloendothelial system* are found in the CNS as microglia, and in the spleen, lymph nodes, thymus, tonsils and bone marrow in the form of reticulum cells. They occur as sinus wall cells in the spleen and bone marrow, but mainly in the liver in the form of sinusendothelial, Kupffer, Ito and PIT cells. (s. p. 20) About 90% of the total RES are localized in the liver.

*Microphages* develop from eosinophilic and neutrophilic granulocytes; they are capable of phagocytizing small particles (especially bacteria).

The *monocytary system* is localized in the connective tissue of nearly all organs. It consists of sessile histiocytes and mobile macrophages. Both cellular types may originate from blood monocytes, which are also part of this system.

▶ Based on morphological and functional criteria, it was suggested that the term "reticuloendothelial system" should be replaced by the designation **"reticulohistiocytary system" (RHS)** or the term **"mononuclear-phagocytizing system" (MPS)** (H. L. LANGEVOORD et al., 1970). This designation has not been widely accepted, however, so that the term **"reticuloendothelial system" (RES)** is still mainly used.

## 15.2 Functions of the hepatic RES

The total blood flow from the vessels of the splanchnic bed through the portal vein as well as the chyle and lymph flow through the thoracic duct must pass the liver. The same applies to the systemic blood flow. Therefore, the liver is indeed the central organ for checking the blood for foreign particles and substances as well as for endogenous substances which must be eliminated for physiological reasons. For these vital functions, the RES cells are provided with special **capabilities** (2, 48, 64, 69, 73, 85, 86, 88, 91):

1. Marked capability for phagocytosis
2. Marked capability for pinocytosis
3. Release of signal substances (cytokines, eicosanoids)
4. Endotoxin clearance
5. Abundance of enzymes
6. Capability for storing substances
7. Synthesis of the platelet-activating factor (PAF)
8. Synthesis of matrix components
   (collagenase, fibronectin, proteoglycans)

**1. Filter function:** The sinusendothelial cells are equipped with numerous pores of various diameters, depending on their different functions. Larger molecules and particles are hereby filtered out and kept away from the liver parenchyma.

**2. Phagocytosis function:** Owing to the favourable localization of the Kupffer and sinusendothelial cells in the sinusoidal blood flow, they are able to phagocytize any foreign colloidal or particulate substrates, endogenous macromolecules, altered erythrocytes, autologous altered protein, tumour cells, tissue particles, immune complexes, bacteria, fungi, etc. For this purpose, Kupffer cells are equipped with a special surface-ciliated border and stellate branches which act as mechanical trapping mechanisms. Moreover, they carry specific receptors for carbohydrate components as well as for the Fc part of the IgG molecule and for complement $C_3$. They also possess lysosomal enzymes, yet in much lower amounts than do the sinusendothelial cells. The degradation of bilirubin and haemoglobin as well as the transport of iron take place in Kupffer cells. The intensity of hepatic phagocytosis shows a reverse correlation with the rate of blood flow in the liver, which is of clinical significance. Tumour cells, which are intensively phagocytized by Kupffer cells, provoke liver metastases to a lesser extent than do less phagocytized tumour cells. Exogenous structures are submitted to very intensive phagocytosis by the RES − as are higher molecular weight foreign proteins.

**3. Metabolization of foreign substances:** Sinusendothelial cells are also capable of endocytosis and, by virtue of their extensive enzyme equipment, in a perfect position to metabolize different kinds of foreign substances. They are endowed with a good stock of acid phosphatase, acid DNase, β-N-acetylglucosaminidase, β-glucuronidase, arylsulphatase (A, B), cholesterol esterase, collagenases, etc.

**4. Clearance function:** Sinusendothelial cells assume a clearance function with respect to *connective-tissue macromolecules* (e. g. mucopolysaccharides) through endocytosis and enzymatic breakdown. The clearance of bigger molecules takes place more rapidly than that of smaller ones. Mucopolysaccharides (e. g. components of coagulation, of blood groups and of immune substances) are constantly produced in the intermediary metabolism. It is imperative to clear such substances from the blood. The biosynthesis of mucopolysaccharides in the endoplasmic reticulum is stimulated by androgens and STH, and is inhibited by glucocorticoids. • The RES plays a special role in the breakdown of polypeptide- and polysaccharide-containing *fibrinolysis activators* (e. g. tissue plasminogen activator). Insufficient breakdown of these substances is a major cause of impaired hepatogenic haemostasis. • Its capacity to remove *antigens* from the blood circulation means that the liver is the central organ for nonspecific defence processes. Bacteria, viruses and macromolecules, which generally pass from the gastrointestinal tract through the portal vein into the sinusoidal blood, may function as antigens. Likewise, immune complexes are taken up and eliminated by the RES. However, hepatocytes are also able to eliminate antigens and immune complexes by means of their IgG-Fc and $C_3$ receptors. Although the phagocytosis capacity of Kupffer cells is 14 times higher than that of hepatocytes, the liver nevertheless contains twice as many hepatocytes as Kupffer cells. RES cells and hepatocytes jointly form a strong barrier against antigens and immune complexes. The liver indirectly participates in humoral and cellular immune reactions by means of this phagocytosis of antigenic substances. (64, 82, 88)

**5. Elimination of endotoxins:** Bacterial lipopolysaccharides moving from the intestine through the portal vein to the liver are detoxified in the RES (especially by Kupffer cells) under physiological conditions. Hepatocytes are also capable of taking up and detoxicating endotoxins. In the case of reduced clearance function of the RES and augmented formation of endotoxins or their increased influx into the bloodstream, endotoxinaemia with secondary liver cell damage may occur. (69)

**6. Metabolization of lipoproteins:** The hepatic RES assumes an important role in the clearance of cholesterol esters and lipoproteins. The uptake of lipoproteins by Kupffer cells is 3−4 times higher than by liver cells, even though the absolute uptake capacity of liver cells is naturally much higher due to their being twice as numerous. The hepatic endothelial cells bind to their surface chylomicrons, VLDL, LDL and HDL, all of which contain apolipoprotein E. These cells also exhibit lipase and cholesterol esterase activity. Under pathological conditions, Kupffer cells may take up cholesterol esters in amounts high enough for conversion into so-called *foam cells*. Blockage of the hepatic RES leads to a decline in lipoprotein clearance, potentially resulting in hyperlipoproteinaemia. Moreover, Ito cells are able to store lipids.

**Influence on the RES:** The activity of the RES may be intensified by **opsonins** (A. E. WRIGHT et al., 1903). Opsonins are endogenous substances which can attach themselves to bacteria, fungi, foreign bodies, immune complexes, etc. and thus promote their phagocytosis. Fibronectin (so-called "molecular adhesive"), which is formed in liver cells (and possibly also in RES cells), is a major opsonin. The group of opsonins further comprises the immunoglobulins G, M, $C_{3b}$ and $C_5$. Glucans, zymosan and oestrogens also enhance the activity of the RES, whereas higher concentrations of alcohol, glucocorticoids and endotoxins cause an inhibition in the activity of the RES.

**Production of signal substances:** Kupffer cells also secrete substances influencing the metabolism of liver cells. The synthesis of **acute phase proteins** is stimulated accordingly. In this connection, it is particularly worth mentioning the *antiproteases*, which are able to interrupt proteolytic reaction cascades. Such reactions are triggered in inflammatory processes or tissue lesions by *proteases* formed in the liver. • Potential overactivity of these reaction cascades is prevented by the antiproteases produced by Kupffer cells. Thus the liver itself is capable of controlling these reactive processes. The ideal localization and morphology of hepatic RES cells facilitate optimum functional interplay.

This cooperation not only takes place between the sinusoidal cells, but also with the hepatocytes: (*1.*) endothelial and Kupffer cells complement each other through various mechanisms of endocytosis and different pathways of enzymatic clearance; (*2.*) as a double barrier, they protect the liver cells both from toxic and undesired substances, even to the extent of "self-sacrifice"; (*3.*) they intervene in the metabolism of liver cells with self-produced substances; (*4.*) they send "signal substances" like cytokines (e. g. interferons) and eicosanoids (e. g. leukotrienes) to the liver cells for independent control of biochemical and biomolecular reaction cascades.

Hepatic RES is of great relevance both under physiological and pathological conditions. In the past 10 years, an array of experimental results yielding further knowledge of the RES have become available – yet, many questions remain unanswered or are under discussion. Moreover, there are hardly any procedures for measuring RES functions in a clinical setting. Nevertheless, the RES might offer various possibilities for targeted therapeutic approaches.

# 16 Radicals and antioxidants

## 16.1 Definition

$H_2O_2$ is produced by superoxide dismutase or peroxisomal oxidases. It is, in fact, not a radical. However, due to its immense ability to penetrate biological membranes, $H_2O_2$ is able to have a direct damaging effect on many biological systems. It is above all a precursor of hydroxyl radical. $H_2O_2$ is reduced by catalase and glutathione-peroxidase activity.

**Radicals** and **reactive oxygen intermediates** (ROI), or activated oxygen species, are atomic or molecular substrates formed during the reduction of oxygen in the body. In their outer molecular surface, they carry one or several unpaired electrons. Consequently, they are highly reactive – but also short-lived. Their half-life ranges between $10^{-9}$ (HO$^{\bullet}$) and 10 seconds. The small amounts of incidentally released superoxides are usually inactivated by high concentrations of protective enzymes (SOD, glutathione peroxidase, catalase) contained in the mitochondrion. Superoxide anion radicals are one of the chief sources of oxygen toxicity. They are mainly formed in the electron transport chain of the mitochondria and endoplasmic reticulum. As so-called free radicals, they are available in a chemically free form. As unstable, highly reactive molecules, radicals are able to capture an electron from adjacent stable molecules in order to stabilize their own atomic structure. The adjacent molecule concerned is thus turned into a radical itself: the process starts anew and a chain reaction (e.g. lipid peroxidation) sets in. This chain reaction is only interrupted when the radical encounters another radical or when it is rendered harmless by an antioxidant. Hydroxyl radical (HO$^{\bullet}$), which is produced by water hydrolysis, is the most reactive of all free oxygen radicals. It can react with almost every organic molecule. In their capacity as prooxidants, the reactive oxygen intermediates are both free radicals and non-radical molecules. Several types of radicals are of relevance in biological systems. (s. tab. 3.24)

| | |

| LO$^{\bullet}$ | fatty acid alkoxyl radical |
| LOO$^{\bullet}$ | fatty acid peroxyl radical |

**Tab. 3.24:** Radicals and reactive oxygen species

## 16.2 Formation and importance of free radicals

Mitochondria constitute the main source with regard to oxygen concentration in the cell. This especially applies to the respiratory chain in the inner mitochondrial membrane. Moreover, the additional formation of cellular oxygen takes place through the transport of electrons in the nuclear membranes and microsomes. Eosinophilic

granulocytes are likewise considered to be active in forming oxygen radicals. Cytochrome P 450 also yields reactive oxygen intermediates. The presence of oxygen in virtually all cellular structures thus enables the ubiquitous formation of oxygen radicals. • Exogenous sources of free radicals include UV radiation, X-rays, tobacco smoke, organic solvents, pesticides, etc. (s. tab. 3.24) (24, 32, 33, 40, 62)

$$\text{Haber-Weiss reaction: } O_2^{\bullet} + H_2O_2 \longrightarrow OH^{\bullet} + OH + O_2$$

$$\text{Fenton reaction: } Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^{\bullet} + OH^-$$
All oxygen-reducing metabolic processes are accompanied by the formation of reactive oxygen intermediates. As this term implies, they exhibit high reactivity. Their formation is therefore a prerequisite for a variety of specific cellular metabolic processes. This applies especially to biomolecular reactions relating to phagocytosis and biotransformation, the metabolism of arachidonic acid, collagen, iron, purine, neurotransmitters and histamine, the blood coagulation system, enzymatic activities of flavoproteins, iron-sulphur proteins, quinones, etc. In many reactions, 1 or 2 oxygen atoms are inserted into the carbon skeleton of metabolic intermediates by way of mono- or bioxygenases. This process is catalyzed by a reductant. The catalytic enzyme activity of oxygenases is probably influenced by reactive oxygen intermediates.

The view is held that the **origin of life** in the universe ca. 3.5 billion years ago is attributable to the formation of radicals: amino acids and nucleotides may have been formed from simple reduced components of the primitive atmosphere, assuming free radicals were generated through solar radiation (D. HARMANN, 1986).

## 16.3 Balance between formation and inactivation

The *biological necessity* regarding the presence of reactive oxygen intermediates to ensure the smooth course of multiple biomolecular metabolic processes is undisputed. The prerequisite is, however, that the concentration of both prooxidants and free radicals is kept (under physiological conditions) within the required cellular "normal range" by a subtle coupling mechanism between formation and inactivation. This is accomplished by morphologically and functionally intact biological membranes and by a physiological inactivation system of enzymatic and non-enzymatic mechanisms (= *antioxidants*). These antioxidants are either formed endogenously or are supplied by an exogenous route. The *antioxidative capacity* is the total of all endogenous and exogenous defence mechanisms; this process guarantees the oxidative balance.

Maintaining a physiological equilibrium (= concentration) of cell-formed reactive oxygen intermediates by means of highly sensitive regulation mechanisms is a fundamental process of biomolecular homoeostasis.

## 16.4 Scavengers and antioxidants

**Scavengers** are substances which bind and eliminate free radicals at the *right* moment, in the *right* concentration, with *high* selectivity and with a *stoichiometric* reaction.

**Antioxidants** are substances which keep oxygen radicals or "reactive oxygen intermediates" (ROI) under control by means of subtle time- and concentration-specific inactivation. This can be the result of enzymatic or non-enzymatic processes. The most important antioxidants in this respect are catalase, superoxide dismutase and glutathione peroxidase as well as DNA repair enzymes (such as DNA glycosylases, endonucleases and DNA ligases) in close cooperation with p 53.

Antioxidants were already used by the Egyptians for the **preservation of corpses** of high-ranking persons (E. E. CROSS et al., 1987). • The use of scavengers (e. g. 2-mercaptoethylamine) has also been reported to **prolong the lives** of mammals by up to 30% (E. L. SCHNEIDER et al., 1985).

It was not until thirty years after the copper-containing protein erythrocuprein was discovered (T. MANN, D. KEILING, 1939) that its enzymatic nature was proved. At that time, this protein was shown to convert superoxide radicals into molecular oxygen and $H_2O_2$ (J.M. McCORD, 1969; I. FRIDOVICH, 1969); it was FRIDOVICH who coined the term *superoxide dismutase* (SOD). This presumably most important of antioxidants accelerates the conversion of superoxide radicals 10,000 times more effectively than spontaneous dismutation.

$$1. \quad O_2^{\bullet} + O_2^{\bullet} + 2H^+ \xrightarrow{\text{SOD}} H_2O_2 + O_2$$

$$2. \quad \text{Catalase reaction: } H_2O_2 + H_2O_2 \longrightarrow 2H_2O + O_2$$
Antioxidants participate in various reaction steps in the elimination of reactive oxygen species. Such intervention is possible due to their varying chemical structures and capabilities. So far, a number of different substances have been recognized as more or less potent antioxidants. (s. tab. 3.25). In addition, the following drugs may also act as scavengers: *indomethacin, acetylsalicylic acid, penicillamine* and *allopurinol* (which blocks the xanthine oxidase reaction and prevents the formation of $O_2^{\bullet}$ and $H_2O_2$) as well as *deferoxamine* (which inhibits hydroxyl radicals in Fenton's reaction). Antioxidants have a synergistic effect in that they display a mutual reinforcing action, but they cannot replace each other. Thus hydro-

gen superoxide is eliminated by catalase and the reduction in organic peroxides is catalyzed by glutathione peroxidase through *reduced glutathione* (= GSH). (8, 33, 47, 83, 90, 91, 93)

$$3. \quad 2\,GSH + H_2O_2 \longrightarrow GSSG + H_2O + H_2O$$
To ensure a physiological balance between the formation and the inactivation of free radicals − or reactive oxygen species − numerous substrates (such as enzymes, vitamins, provitamins, trace elements, transport proteins, amino acids) must always be available in adequate quantities and in an active form.

| Endogenous antioxidants | Exogenous antioxidants |

## 16.5 Pathophysiology

Depending on the metabolic status within the various compartments of the cell, fluctuations in the concentration of radicals or reactive oxygen species may occur.

Continued **reduction** or cessation in the formation of oxygen radicals (especially in the area of the mitochondria, nuclear membranes or microsomes) is eventually fatal to the cell. • An uncontrolled *increase* in the cellular formation of superoxide dismutase (as is found in mental disease, trisomy 21, etc.) may also entail dangerous disturbances in the cellular oxygen balance. • Moreover, a *change* in the physicochemical properties of superoxide dismutase under pathological conditions, which may lead to reduced enzyme activity and altered cell compartments, is being discussed as a further influencing factor.

An **increase** in free radicals or reactive oxygen species is encountered in various diseases or metabolic disorders. This may lead to changes in cell metabolism and/or enhanced nonspecific reactions, and even cell death.

▶ The augmented formation of free radicals as well as their reduced inactivation are discussed as *pathogenetic factors*, e.g. irradiation, sunburn, autoimmune diseases, collagenoses, inflammatory (especially bacterial and vi-

ral) processes, operations, severe traumatization, myocardial ischaemia, intestinal ischaemia, colitis, haemoglobinopathies, atherosclerosis, haemorrhagic shock, cerebrovascular insult, Parkinson's disease, cataractogenesis, retrolental fibroplasia, chemical intoxication (e.g. $CCl_4$, smog, paraquat, adriamycin) and carcinogenesis − as well as the body's process of ageing, which is due among other things to extreme physical activity, alcohol abuse and smoking. So-called **free radical diseases** are directly or indirectly caused by oxidative stress.

▶ Moreover, the occurrence of fluorescing *pigments* in the form of lipofuscin, ceroid and porphyrin (as found in Wilson's disease, haemochromatosis, Dubin-Johnson-Sprinz syndrome, porphyria cutanea tarda and abuse of analgesics − as well as pigmentation in old age) is a reliable sign of excessive free-radical formation in the cell.

From the biomolecular viewpoint, increased concentrations of radicals lead to hazardous biological reactions, e.g. (*1.*) lipid peroxidation, (*2.*) oxidation of SH- and $NH_2$-groups in proteins, and (*3.*) hydroxylation of nucleic acids with modification of DNA. • Radicals cause oxidative changes and damage by withdrawing electrons from other molecules. • **Oxidative stress** *is defined as an imbalance between free-radical formation and antioxidative capacity.* Oxidative stress causes oxidation of mitochondrial NAD(P)H and produces ROS in the mitochondria. This increases free $CA^{++}$ levels in the mitochondria and activates the serine proteases, which can kill the cell. Direct damage to the hepatocytes by ROS may trigger so-called inflammatory factors and cause more cellular damage. • Low GSH levels in hepatocytes render them particularly vulnerable to oxidative stress. (18, 33, 40, 79, 97) (s. p. 401)

## 16.6 Lipid peroxidation

In lipid peroxidation, unsaturated fatty acids are peroxidized in the biological membranes of cells and their organelles. This leads to chain breaks in fatty acids with insertion of hydrophilic groups and cis-trans-isomerization. Membrane-bound proteins are damaged. Lipid radicals (L˙) are transformed into unstable lipid-peroxy radicals (L00˙). • Lipid peroxidation markers include *malondialdehyde* and *4-hydroxynonenal*. (18, 38, 79, 97) (s. figs. 2.19; 21.12)

Further sequelae to lipid peroxidation include inhibition of membrane-bound, phospholipid-dependent sodium-potassium ATPase and calcium ATPase with changes in the electrolyte milieu, especially calcium overloading of the cell with subsequent further cell damage and cell death as well as inhibition of adenylate cyclase. This results in loss of function in the mitochondria and microsomes. Damage to the DNA leads to enzyme defects or impaired enzyme synthesis, which triggers further metabolic changes. This also causes a cellular overload with calcium and subsequent activation of

proteases, which in turn affect other enzyme systems in such a way that indeed further radicals are produced instead of the usual degradation products being formed. (s. fig. 21.12)

The data currently available on the formation of radicals and antioxidants have also contributed to clarifying various pathophysiological relationships in the field of hepatology. The hazardous interplay between the increased formation of free radicals, the occurrence of lipid peroxidation and cell damage − in the sense of a vicious circle − has provided a better understanding not only of the mechanisms causing toxic and inflammatory damage to liver cells, but also of cell death.

# 17 Cellular transport processes

The functioning of a cell (hepatocytes included) depends essentially on the orderly and targeted transport of molecules. This applies equally to absorption into the cell, intracellular transport, and discharge from the cell, whereby individual substances may either remain unaltered or undergo biochemical changes. The most important substances required by liver cells are water, electrolytes, trace elements, proteins, lipids, carbohydrates, bile salts, and bilirubin. The structure of the **cell membrane** and its functional capacities are key factors in these transport processes. (5, 15, 23, 26, 30, 37, 39, 45, 49, 50, 58, 59, 67, 68, 70, 74, 102, 106) (s. p. 27) (s. fig. 2.19)

**Cellular transport** primarily occurs with the help of (*1.*) ionic channels, (*2.*) carrier proteins, (*3.*) pumps, and (*4.*) vesicles. These transport processes may be in the form of active, passive or vesicular mechanisms.

## 17.1 Passive transport

Passive transport through the cell membrane rarely requires any form of energy. It takes place along electrochemical gradients through either free or facilitated diffusion.

**Free diffusion:** This process is the simplest form of transport through the cell membrane. It is, however, only possible for small molecules (e. g. water, urea, and dissolved gases such as oxygen, carbon dioxide, ammonia). Molecules are transported from areas of high concentration to areas of low concentration until equilibrium is achieved. No energy is required here. This process is not exposed to any form of competitive inhibition.

**Facilitated diffusion:** Large molecules (e. g. glucose, protein, organic ions) cannot diffuse across the cell membrane barrier unaided. Mechanisms in the form of channels or transport proteins (= carriers) are therefore required to enable molecules to penetrate the impermeable

membrane when entering and leaving the cell. These mechanisms sometimes require energy and may be exposed to competitive inhibition. Each of the *ion channels* contains a channel protein with water-filled pores through which the molecules can diffuse. A selection filter distinguishes between the individual ions such as $Ca^{++}$, $Na^+$, $K^+$, and $Cl^-$. These ion channels can alter their permeability by opening or closing. There are also water channels. • *Transport proteins* are part of the cell membrane (ectoproteins, endoproteins, membrane-penetrating proteins). (s. fig. 2.19) They facilitate the substrate-specific passage through the membrane. In order to carry out this function, they are activated by physical, chemical or hormonal stimulants. However, these carriers can also be blocked by inhibitors. If the carrier system becomes overloaded, its transport capacity is reduced and the process slows down. Individual substances are bound to specific transport proteins during their passage through the membrane.

| Uniporter | | Transport of 1 substance in one direction |
|---|---|---|
| **Cotransporter** | *Symporter* | Transport of 2−3 substances stoichiometrically in one direction (= positive plus-coupling) |
| | *Antiporter* | Transport of 2−3 substances in the opposite direction (= negative plus-coupling) |

## 17.2 Active transport

Active transport through the cell membrane always requires energy. This is derived from splitting ATP. Transport takes place against an electrochemical gradient, i. e. in an "uphill" movement. • *Primary active transport* occurs when ATP splitting is directly linked to the transport process (as is the case with $Na^+/K^+$-ATPase). This can involve three different ATPase groups (known as P-, V- and F-ATPases). (58) The $Na^+/K^+$-ATPase consists of an essential ion pump which is found in all body cells. It acts as an antiporter. With each pump cycle 2 $K^+$ are transferred into the cell and 3 $Na^+$ are removed. This transport process uses up 30−70 % of the cell's energy capacity and is subject to competitive inhibition. It can be activated and displays substrate specificity as well as saturation kinetics. • *Secondary active transport* occurs when ATP splitting is part of another reaction (e. g. $Na^+/glucose$ transport in intestinal mucosa) instead of being directly coupled with the transport process. • *Pumps* ensure active transport; the proteins involved are likewise ATPases, which split ATP hydrolytically on the inner side of the membrane. Each pump has a separate function, e. g. ion pumps, peptide pumps and pharmaceutical pumps.

## 17.3 Vesicular transport

Vesicular transport denotes the transport of macromolecules inside hepatocytes in the form of vesicles en-

cased in a membrane. There are four forms of absorption and release: (*1*.) exocytosis, (*2*.) endocytosis, (*3*.) transcytosis, and (*4*.) diacytosis. (19, 25)

**Exocytosis:** Macromolecules are transferred from cytoplasmic secretory vesicles to the extracellular space; for this purpose the vesicles fuse with the cell membrane. After its contents have been released into the extracellular space, the vesicle frees itself from the external cell membrane and returns to the cytoplasm for the next transport sequence (= recycling). This process requires energy and is $Ca^{++}$-dependent. Exocytosis can be triggered by an external stimulus. This is then called *controlled exocytosis*. If there is no external stimulus, it is known as *constitutive exocytosis*.

**Endocytosis:** The term endocytosis denotes the *internalization* (= encasing) of molecules inside vesicles. This can take place in the form of *pinocytosis* (= fluid-phase endocytosis), whereby the molecules remain in a detached state with no membrane binding. It can also occur in the form of adsorptive endocytosis, whereby the molecules are bound to membrane receptors by a ligand and the whole complex is transported into the cell.

**Transcytosis:** In this process, the vesicles are moved from one cell pole to another without their contents changing.

**Diacytosis:** In this process, a part of the intact and internalized ligand receptor complex returns to the cell surface.

These vascular transport mechanisms within the hepatocytes require an intact cytoskeleton. This is because the transport of the membrane-encased vesicle keeps close to the cytoskeleton structures.

Motor proteins (e. g. microtubular kinesin, cytoplasmic dynein) move the vesicles. This requires energy from ATP. Vesicular transport also involves other cytoplasmic factors and is influenced by other effects (e. g. $Ca^{++}$, cAMP, C-protein kinases).

# Diagnostics in Liver Diseases

## 4 Clinical findings

# 4 Clinical findings

## 1 Elements of liver diagnostics

In the case of a disease, the basic requirement for systematic and appropriate therapy is the diagnosis. (34)

▶ When translated, the Greek word **"diagnosis"** means *"decision"*, *"differentiation"* or *"assessment"*. • A disease is identified by the information gained from the patients themselves *(= auto-anamnesis)* or their personal environment (= *external anamnesis*) as well as from diverse examination results (= *findings*).

> The term **diagnosis** includes the nosological and systematic designation of a clinical picture and the sum total of the results, which provide a basis for medical action and therapeutic success.
>
> The term **diagnostics** covers all measures aimed at identifying the development of a disease and ultimately producing a diagnosis.

A diagnosis should be *rational* (= *in terms of intellect*), that is to say logical and targeted. At the same time, however, the way it is arrived at must be *efficient and economical* (= *expedient*), i.e. financially viable (cost effective for the health service) as well as acceptable in terms of the strain it puts on the patient. • For this reason, economical and efficient diagnostics is by definition rational.

> *A rational diagnostic procedure is always economical and efficient when carried out at the hospital or in the doctor's surgery − even though it may be more expensive in individual cases. • Economical and efficient diagnostics must never become irrational!*

These two basic requirements for rational and economical diagnostics are likewise true for detailed diagnosis (19) − even if a **detailed diagnosis** understandably entails greater reflection and higher costs. With a detailed diagnosis, however, particularly an **early diagnosis**, the therapeutic measures applied can be better targeted, more appropriate and indeed more successful − and ultimately less cost-intensive. (s. fig. 4.1)

▶ Each diagnostic step and each detailed diagnosis presents certain **difficulties** in terms of methodology and theory:

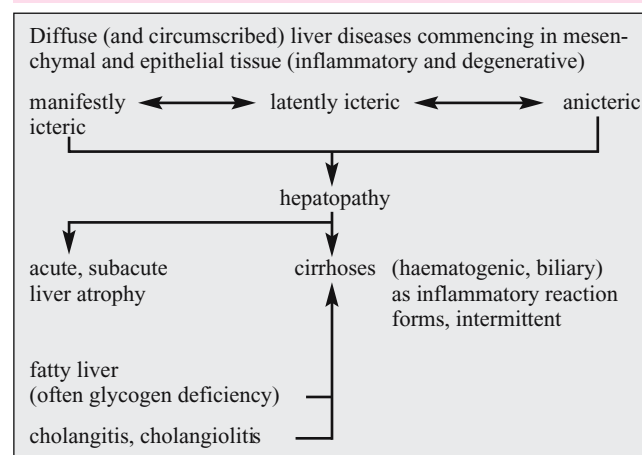
1. Emergency therapy may be urgently required **prior to** diagnosis.
2. Diagnostics may be **limited:**
   a. because examination techniques are (still) insufficiently developed,
   b. because of inadequate equipment for examination purposes,
   c. because they are refused by the patient.
3. All too often there is, unfortunately, a tendency to apply examination techniques on a broad and cost-intensive scale, and indeed "irrationally".

▶ In 1979 J. E. HARDISON drew up a *list of arguments* that are used to explain this kind of behaviour in medical practice, which are equally applicable today (14):

1. the excuse that "everything has been done";
2. the excuse that if something is not done immediately, it will never be done at all;
3. the excuse that more has to be undertaken under inpatient conditions than at the doctor's surgery;
4. the academic excuse − as if there were such a thing as an academic or a non-academic diagnosis;
5. the father-mother excuse: "If it were my father or mother, I would do it like that";
6. the precluding excuse: "Well, perhaps we'll find something we never even thought of";
7. the legal excuse: "If we don't carry out the examination, we could be sued".

**Fig. 4.1:** Elements of diagnostics

In his book „Funktionelle Pathologie" (1932) (p. 392), GUSTAV VON BERGMANN coined the term **hepatopathy,** since more detailed liver diagnostics was not possible at that time:



> ### 1ˢᵗ hepatological principle
>
> The term "hepatopathy", coined by GUSTAV VON BERGMANN in 1932, and the expression "liver parenchymal damage", which has also been employed occasionally, should only be used to describe the so-called "pre-diagnostic stage" of liver disease.

In suspected "hepatopathy", the preliminary steps towards reaching a **diagnosis** and ultimately the **detailed diagnosis**, whether at the doctor's surgery or at the hospital bedside, should proceed rationally and economically by means of step-by-step systematic examination.

The impressive, almost "99%" certainty of present-day liver diagnostics is the outcome of the coordination of all available examination techniques that have meanwhile been perfected − in conjunction with the further development of sensitive and specific procedures.

## 1.1 Diagnostic targets

The seven main diagnostic questions (s. tab. 4.1) can be answered in nearly all cases using four sets of examinations (s. fig. 4.2) − provided all the necessary diagnostic channels can be applied. By repeatedly reviewing the activity and the function of the liver, it is possible to make reliable statements on the course of the disease, the success of therapy and the prognosis.

▶ In this context, **check lists** simplify and accelerate the examination procedure. It is most important that no key factors are forgotten and nothing is undertaken unnecessarily. (19) (s. figs. 4.21; 5.2) • In addition, a **step-by-step programme** subdivided into minimum, necessary and maximum requirements (s. tab. 5.23) together with logically constructed **flow diagrams** (s. figs. 9.4; 13.7; 16.10, 16.16; 19.12; 22.9−12) facilitate the required rational and economical *"step-by-step diagnostics"*.

---

*2nd hepatological principle*

It is not **"what is done"** in terms of numerous examinations and chemical laboratory parameters that is decisive, but the clinical **interpretation** of the findings and the clinical consequences derived therefrom.

---

## 1.2 Diagnostic pillars

The target of a detailed diagnosis is generally achieved using various and mutually complementary examination techniques. Diagnostic methods in liver disease are founded on four diagnostic pillars, which are applied stepwise and nearly always provide the basis for an exact and detailed diagnosis. Complex or invasive techniques are only used when they are clearly indicated. (19) (s. fig. 4.2)

If the various examination procedures are inadequately coordinated and the results improperly interpreted, it is all too easy to obtain "false-positive" or "false-negative" results.

1. **Determining liver damage**
   - primary liver disease
   - secondary (reactive) liver disease

2. **Classifying liver disease**
   - diffuse
   - localized

3. **Differential diagnosis of jaundice**
   - prehepatic
   - posthepatic
   - intrahepatic

4. **Determining the type and aetiology of liver disease**
   - hepatitis
   - cholestasis
   - fibrosis
   - cirrhosi s
   - focal lesions
   - tumours
   - infections
   - parasitic
   - vascular
   - immunologic
   - metabolic
   - toxic
   - geneti c
   - *etc.*

5. **Determining the stage of disease**
   - prodromal
   - acute
   - chronic
   - cure d
   - compensated
   - decompensated

6. **Determining the activity**
   - enzymatic activity
   - mesenchymal activity
   - immunological activity
   - histological activity

7. **Testing the liver function**

**Statements concerning**

1. **Course of the disease**
   - regressive
   - stationary
   - progressive

2. **Success of therapy**

3. **Prognosis**

*Tab. 4.1:* Diagnostic targets and other relevant aspects in liver diseases

*Fig. 4.2:* Diagnostic pillars for detailed diagnosis in liver diseases

This is summed up in the third hepatological principle:

---

*3rd hepatological principle*

In the diagnosis and assessment of liver disease, the clinical, laboratory and ultrasound findings must always be interpreted integratively and simultaneously, together with the histology and any additional imaging procedures (insofar as these are indicated).

---

▶ A *detailed diagnosis* should be the ultimate aim, so that in each case:
(*1.*) the cause of the liver disease is identified and perhaps eliminated by successful therapy;
(*2.*) the therapeutic possibilities for the treatment of liver disease can be applied more specifically and hence lead to greater success;
(*3.*) both the effect and efficacy of therapeutic measures can be statistically evaluated in those patients who are clinically comparable.

---

*The hepatological issues in question, differential diagnostic considerations and possible therapeutic outcome determine the scope of the diagnostic measures undertaken. This calls for systematization and rationalization.*

---

## 1.3 Diagnostic accuracy

Even with normal bioptic histology, it is possible to detect liver damage with an adequate degree of probability by means of laboratory parameters. • By contrast, even pathological liver biopsy findings can be accompanied by normal laboratory values. In individual cases, this can mean that a liver disease is "mute" under chemical laboratory conditions, but at the same time histologically "false-normal". Combining the clinical and chemical laboratory findings with the results of sonography and morphology makes it possible to achieve a hepatological diagnosis or detailed diagnosis of almost "99%" certainty.

▶ The **specificity** and **accuracy** of individual laboratory parameters used to be assessed almost solely on the basis of morphological findings. • Today, exact procedures are available for hepatological detailed diagnosis which provide excellent sensitivity and specificity (especially in the fields of serology and immunology). But they have by no means ousted the histological examination of the liver. On the contrary, **histology** has gained enormously in significance, particularly due to more advanced methods and a better interpretation of results. The same is true of **electron microscopic** assessment of hepatocellular organelles and biological membranes, which constitute the morphological substrate for the many functions of the liver. Hence the **visionary target** of *"organelle pathology"* and *"organelle diagnostics"* has proved feasible.

In reviewing the accuracy of diagnostic procedures in 520 of our own patients with different liver diseases, varying results (depending on the severity of the disease) were found. (s. tab. 4.2)

| Clinical findings | 30% |
|---|---|
| Laboratory parameters | 81−96% |
| Ultrasonography | 60−75% |
| Histology | 82−95% |
| Laparoscopy | 78−88% |
| Laparoscopy + histology | 97% |

**Tab. 4.2:** Accuracy of diagnostic procedures in various liver diseases (E. KUNTZ, 1987) (s. tab. 5.11)

---

*4th hepatological principle*

Up to now, no single examination method exists (be it a clinical, laboratory chemical, morphological or imaging procedure) which, in itself, allows a global statement to be made regarding a particular type of liver disease or liver dysfunction.

---

# 2 Clinical findings

At the forefront of liver diagnostics are the tried and tested methods of *anamnesis*, *inspection*, *palpation* and *percussion* or even *auscultation*. These specific medical examinations can be regarded as a safety net in daily routine diagnostics. Within the scope of the many examinations that take place at the doctor's surgery, these basic medical skills help to filter out patients with "suspected hepatopathy". Ascertaining the clinical findings is deemed to be the *1st diagnostic pillar* and, as such, constitutes the commencement of any diagnostic procedures focused on the liver. (s. fig. 4.2)

## 2.1 Anamnesis

The anamnesis is of particular significance for the clinical findings − and is usually the first step towards establishing a diagnosis.

Determining whether there has been any history of hepatobiliary disease in the *family* and establishing the geographic and ethnic origin of the patient are key anamnestic factors. • It must be ascertained whether the *disease* has occurred suddenly, developed gradually, or simply not been noticed up to now. • It is also important to determine whether this is a *primary* or *secondary* liver disorder (the latter is a concomitant reaction which has occurred during a systemic illness or other organic disease). The anamnestic search for the cause of the infection in the patient takes into account viral, bacterial, parasitic and mycotic diseases. *(see chapters 22−26)* (s. tab. 4.1)

Anamnestic evidence of *alcoholism* or *drug abuse* and also personal questions relating to *sexual habits* should be handled with extreme care and sensitivity. Once one has gained the patient's trust, it is considerably easier to obtain the relevant details. • It is essential to establish whether the patient has been exposed to any *foreign sub-*

*stances* (medicines, herbal remedies, aphrodisiacs, chemicals). This can be done with the aid of the **check list** which we have been using for many years. (s. tab. 29.7) *(see chapters 29 and 30)*

It is mainly "targeted" **questioning** which sheds light on the possibility of liver disease.

> ▶ *"Targeted"* (i.e. specific) **questions** are most likely to lead to the *"target"*:
> − previous diseases of the liver or biliary tract (colic, jaundice)?
> − previous operations?
> − previous blood transfusions (blood products)?
> − particular eating habits?
> − metabolic diseases (diabetes, gout, hyperlipid-aemia, etc.)?
> − consumption of alcohol?
> − intake of medicaments?
> − occupation- or hobby-related liver noxae?
> − drug abuse?
> − journeys abroad?
> − sexual habits?
> − hereditary liver diseases?

Another group of anamnestic findings is based on the patient's subjective **complaints**. However, patients suffering from liver disorders frequently fail to recognize symptoms.

> ▶ **Complaints:**
> • Fatigue (*"pain of the liver"*), decline in performance and productivity, weariness, affective lability, nervousness, sleeping disorders, lack of concentration
> = *such as can be witnessed in many harassed people today as "neurasthenic syndrome".*
> • Abdominal pain, repletion, flatulence, nausea, loss of appetite, indigestion, food intolerance, loss of weight
> = *such as are found in various abdominal diseases.*
> • Epigastric pain, nausea, vomiting, intolerance regarding fatty foods or smoking and alcohol, pruritus, constipation, meteorism
> = *such as occur in cholecystopathy.*
> • Stenocardia, vertigo, tachycardia, hypotonia, circulatory disorders
> = *such as are found in cardiovascular diseases.*
> • Fever, arthralgia, myalgia, muscle cramps
> = *such as are often witnessed in infectious diseases.*
> • Impotence, amenorrhoea, nosebleeds, bleeding gums, tendency to haematoma, night blindness
> = *which can also lead to a wrong diagnostic conclusion.*

This wide range of very different subjective ailments makes it clear that there are no typical symptoms and

that it is not possible to draw any conclusions on the basis of such complaints as to the severity of the liver disease. Here the constellation of the symptoms and findings (as well as the time when they first appeared and their duration) can provide more information than is available from merely one symptom or finding.

The most frequent, yet **non-specific complaints** mentioned by liver patients are fatigue, languor, repletion, flatulence, epigastric pressure, lack of appetite, nausea, various forms of intolerance, pruritus and impotence. • *Information* on dark-coloured urine, discoloured stools, haematemesis, cutaneous haemorrhages or tarry stools can be a very important sign of hepatobiliary disease. (s. fig. 4.21)

## 2.2 Palpation

### 2.2.1 Palpation of the liver

> *"One good feel of the liver is worth any two liver function tests"* (F. M. HANGER, jr., 1971).

Determining the liver size is considered to be the *"simplest"* and *"cheapest"* liver function test and, chronologically speaking, it is also the *"first"*. (s. fig. 4.3) (9, 21, 26−29, 31, 32, 35−37)

> Every enlarged liver, as well as every hard liver, must be considered pathological − until counter-evidence is produced by laboratory values and ultrasonography and, if necessary, by means of histology or laparoscopy.

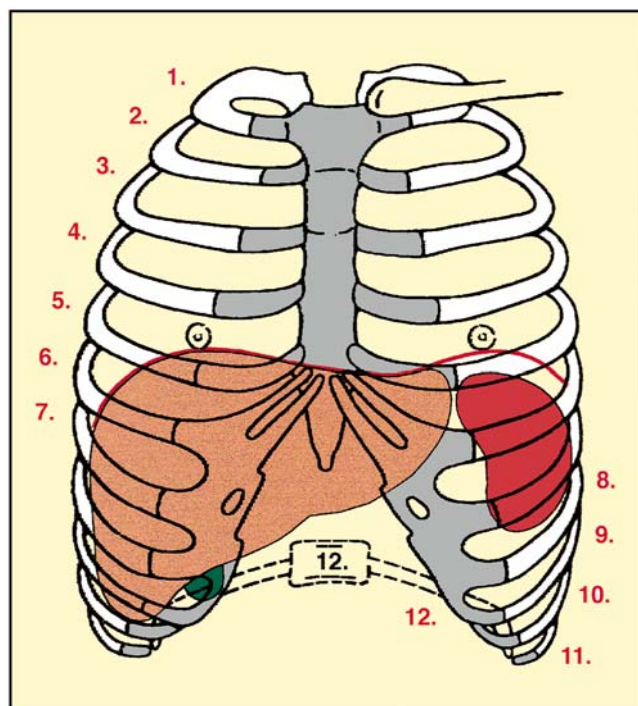


**Fig. 4.3:** The contours of the liver (brown) and spleen (red) as well as the gall bladder (green) in the right and left hypochondrium (costae verae 1−7; costae spuriae 8−10; costae fluctuantes 11−12)

**Sliding palpation:** Liver size, consistency and surface as well as tenderness on pressure can be determined by sliding palpation. The lower edge of the liver is perceptible by touch at the costal arch in the mid-clavicular line. It crosses the epigastrium and ends at the left costal arch on the level of the parasternal line. Under palpation, the liver edge was felt to be deeper than shown by the scan, and only in 60% of all cases did palpation of the liver edge correlate with the scan. (32)

**Bimanual ventral palpation:** The finger tips of both hands are pressed in 1−2 cm, flat and parallel to each other below the costal arch. Upon deep inspiration, the size of the liver can be determined by the caudal shift of the liver margin. (s. fig. 4.4)

***Fig. 4.4:*** Palpation of the liver: bimanual ventral palpation (Gilbert´s technique)

**Bimanual ventrodorsal palpation:** The palpating right hand presses deep into the right costal arch during the expiratory phase and moves upwards during the inspiratory phase − taking the skin and tissue layers with it. Because it moves downwards on inspiration, the liver can be better felt by the left hand when pressing up from behind in a ventral direction. (s. fig. 4.5)

**Hepatomegaly** can easily be mimicked under palpation by phrenoptosis in lung emphysema, ptosis of the liver, asthenic habitus and also by an enlarged Riedel's lobe. • It is very difficult to state the extent of liver enlargement exactly in terms of "finger breadths" below the costal arch: when 120 "finger breadths" were compared, they were found to range from 1.3 to 2.4 cm. (31) *(see chapter 11)*

**Liver atrophy** can be assumed when the edge of the liver is elevated due to meteorism or in Chilaiditi syndrome. • However, the liver may also shrink or no longer be palpable as a result of increasing liver atrophy in acute

***Fig. 4.5:*** Palpation of the liver: bimanual ventrodorsal palpation (Chauffard´s technique)

viral hepatitis or liver cirrhosis. For this reason, a diminished liver can be a more severe condition (generally with a poorer prognosis) than an enlarged liver (e.g. fatty liver).

During palpation, the **liver surface** proves to be smooth, humped or roughly noduled. The consistency of the liver is perceptible as soft, firm or hard. It is important to point out that the firmer the liver, the larger it appears to the palpating hand.

In a normal liver, the **liver edge** feels relatively sharp and insensitive to pain; the surface is smooth and the consistency is soft. In liver cirrhosis, the edge of the liver is sharp and hard; the consistency is firm. In acute hepatitis, the edge of the liver, which tends to be rounded, and the clearly enlarged liver are painful under pressure. • *Hepatomegaly*, caused for example by a fatty liver, displays a rounded liver edge with little or no sensitivity to pressure, whereas in congestive liver, the blunt liver edge proves to be very painful on palpation. • There is admittedly a slight chance of confusing the edge of the liver with *tendinous inscriptions*, but the latter are not displaced in relation to the skin and tissue layers during respiration.

**Pain on palpation** mainly points to capsular tension as a result of an enlarged liver (acute viral hepatitis, fatty liver, congested liver). In general, the metastatic liver is likewise painful. *Liver abscesses* may cause (frequently severe) pain on tapping. The liver parenchyma itself is insensitive to pain, although pain receptors are found

sporadically in the walls of the portal and arterial vessels or in interlobular connective tissue.

### 2.2.2 Palpation of the spleen

Palpation of the spleen should always accompany palpation of the liver. It is carried out with the patient in a semidextral recumbent position, the knees bent and the arms lying flat at the sides of the body. Normally, the spleen is not palpable.

**Splenomegaly** is perceptible by touch at the costal arch in the inspiratory phase. This can be accomplished in particular during ventrodorsal palpation when the physician's right hand works from the back towards the (not too deeply) palpating left hand. An enlarged spleen is easily perceptible due to its "downward and inward" movement (in contrast to the left lobe of liver). • *Sensitivity to pressure* of the enlarged spleen points to an inflammation. *(see chapter 11)*

The following **technique** can also be used to detect an enlargement of the spleen: the examining physician, standing to the left of the patient (who is positioned as described above), palpates with the finger tips of the left hand below the costal arch in order to detect the enlarged spleen during the inspiratory phase.

## 2.3 Percussion

### 2.3.1 Percussion of the liver

Percussion also enables the size of the liver to be established; hepatic dullness (in cm) is determined by the localization of the so-called liver-lung margin and the lower liver edge, as measured on the right mid-clavicular line (MCL). During this procedure, the lower lung margin is subjected to light percussion, whereas the upper margin, i.e. lung-liver margin, is determined by heavy percussion. This gives the superficial dullness, i.e. *absolute liver dullness*, which is usually deemed to represent the *size of the liver*. Experience shows that the rounded top of the liver can be assumed to be about 5 cm higher than revealed by percussion. The size of the liver seems to be smaller with percussion than with ultrasound. Determining the liver size upwards is, however, of no genuine clinical significance, since hepatomegaly develops "downwards" in the area of least resistance. • Percussible determination of the **normal liver size** has produced mean values of $10-12$ cm ($9 \pm 2$ cm in women, $11 \pm 2$ cm in men) (E. Hafter, 1962; J. Naftalis et al., 1963; H. A. Kühn et al., 1979). (7, 21, 26−29, 31, 35−37)

Once the percussion technique has been mastered, the **relative liver dullness** can also be more closely defined within the area of superficial dullness as a zone with a resonance on percussion resembling that of the thigh, i.e. the cranial part of the liver covered by the lung. This is the only way of determining the true size of the liver "upwards". • The size of the **left lobe of liver** is determined by percussion above *Traube's space*, which is narrowed in terms of percussion from the right due to an increase in size of the left lobe of liver.

Another way to determine the liver size, or the lower liver edge, is by **scratch auscultation**: The stethoscope is placed on the epigastrium, i.e. above the liver; the finger tip strokes ("scratches") the mid-clavicular line in a cranial to caudal direction at intervals of approx. 1 cm parallel to the presumed edge of the liver; when the liver margin is crossed, the scratching noise in the stethoscope fades and finally disappears. However, this technique is not deemed to be reliable. (18, 42)

### 2.3.2 Percussion of the spleen

Percussion of the spleen is difficult and is carried out by tapping gently at various points on the anterior axillary line. The upper spleen margin lies about $10-15$ cm above the left costal arch. The **absolute splenic dullness** (so-called spleen width) is about 6 to 7 cm; it lies between $9^{th}$ and $11^{th}$ rib. The splenic width established by percussion corresponds to the anterior lower two thirds of the spleen, i.e. adjacent to the thoracic wall. The upper third of the spleen is covered by the lung. When the spleen is subjected to percussion, variations in the shape of the thorax, diaphragm status and intestinal loops are evident (cf. liver percussion).

### 2.3.3 Ascites

Ascites can be recognized by the wide protuberance of the abdomen with moderate bulging of the abdominal flanks and spreading of the navel. Examination by percussion produces *tympanic intestinal resonance* in the upper area and typical *dullness in the flanks*. Small ascites (about 1 litre) may be determined in the *knee-elbow position*, whereby dullness is detected in the lower abdominal region. In this connection, the *fluctuation wave* is an impressive sign: a short hard surge of the fluid swell against the palpating hand is virtually conclusive here. *(see chapter 16)*

### 2.3.4 Meteorism

Meteorism presents as a pointed arching of the abdomen at navel level. This condition is likewise associated with tympanic resonance; however, the dullness in the flanks is missing.

> ▶ It would be a tremendous loss if palpation and percussion of the liver and spleen were inadequately learned, inappropriately performed and no longer mastered as a basic examination technique for interpretative purposes on account of ultrasound methods.

## 2.4 Inspection

> *"Even though you read and learn so much, your learning does not mean that you know; let your eyes be your professors."* (Theophrastus Bombastus von Hohenheim, known as **Paracelsus**)

Hardly any other organ of the body causes such a wide variety of externally discernible changes to the skin and mucosa as the diseased liver. Inspection of the body can give diagnostic clues regarding the presence of a liver disease or special maladies of the liver. Inspection of the liver-diseased patient can produce a number of findings concerning the whole body and the skin as well as the mucosa, nails and eyes. These signs are summarized under the term **skin stigmata in liver diseases** (German: *Leber-Haut-Zeichen"*; H. KALK, 1955, 1957) (3, 16, 17, 25) (s. tab. 4.3):

**Tab. 4.3:** Skin stigmata in liver diseases (check list: s. fig. 4.21)

### 2.4.1 Chvostek's body type

The habitus described by F. CHVOSTEK (1922) is frequently found in alcohol-related cirrhosis. In the male, it is characterized by the absence of secondary hair on the chest and abdomen as well as of axillary hair, and by a horizontal, female-like boundary of the pubes and a lengthening of the distance between xiphoid process and navel. *"Abdominal baldness"* (which means *effemination* with changes in the pattern of body hair) is a typical finding. The incidence is given as approx. 70%. These changes are often accompanied by thick hair-covering of the head growing down onto the forehead, and bushy eyebrows. • In women suffering from alcoholic cirrhosis, the pubic and axillary hair may also be largely absent, and the mammae may be atrophic.

### 2.4.2 Facies cirrhotica

Patients with liver cirrhosis often show typical facial skin stigmata: the colour is a pallid yellowish grey, mostly with patchy pigmentation due to the greater deposition of melanin. Spider naevi and reticular telangiectases are found. The skin frequently appears shrivelled, wrinkled and prematurely aged.

### 2.4.3 Parotid enlargement

Parotid enlargement is occasionally found in cirrhotic patients, especially in alcohol-related cirrhosis (M. SPOSITO, 1942). An enlarged parotid is not painful. (11, 48)

### 2.4.4 Hair changes

Apart from the *hypotrichosis* of primary and secondary pubic hair, already described in Chvostek's body type, cirrhosis patients occasionally show an absence of frizziness in pubic hair. • In kwashiorkor, the hair becomes light in colour and straggly and loses its frizzy appearance with simultaneous hypotrichosis.

Localized *hypertrichosis* is found in Chvostek's body type in the form of noticeably bushy eyebrows. It is also, however, found in porphyria cutanea tarda in the area around the zygomatic arch and lateral to the eyes, as well as on the forearm and lower leg, mostly in the form of short, compact hairs.

► Hypertrichosis (particularly of the lanugo type) is also described as **paraneoplastic syndrome**, above all in cases of carcinoma of the intestinal tract or the digestive organs (*Herzberg-Potjan-Gebauer syndrome*, 1969).

### 2.4.5 Jaundice

In the case of increased serum bilirubin levels of 1.8−2.0 mg/dl, diffusion is effected through the blood capillaries, and bilirubin accumulates in the connective tissue, mainly in elastin. (s. p. 100) In its subsiding phase, jaundice is therefore still visible for longer periods even when serum bilirubin values are normal. • Initially, *scleral icterus* develops, which is easily recognizable in daylight when serum bilirubin values are >2 mg/dl. This subicterus is likewise witnessed in the conjunctiva and occasionally on the oral mucosa at the boundary between the soft and hard palate as well as on the periumbilical abdominal skin. (33, 41) • In fully developed *jaundice*, colours range from straw-coloured yellow through bright yellow to greyish yellow as well as reddish yellow and greenish yellow. Icteric discoloration of the skin is frequently darker in the upper than in the lower part of the body. *(see chapter 12)*

**Verdin icterus** is deemed to be the prototype of obstructive jaundice, particularly in long-standing courses of the disease; **melas icterus** displays a greyish green hue; **rubin icterus** (rust-coloured) is mainly seen as a sign of hepatocellular jaundice, whereas **flavine icterus** is more likely to occur in cases of haemolysis (TH. BRUGSCH, 1930). Such systematization of the icteric forms in terms of pathogenesis is unreliable and obsolete, since the differences in colour mainly correlate with the duration of the jaundice and the level of serum bilirubin.

### 2.4.6 Spider naevus

The term spider naevus (Latin: naevus araneus) is also known as liver star, liver spider, vascular spider or spider naevi. (17, 20, 25, 30)

► These arterial telangiectases were observed in liver disease by V. HANOT and A. GILBERT in 1890, by A. GILBERT and M.C. HERRSCHER in 1903 and by F. PARKES-WEBER in 1904. Such spiders were first described in pregnant women by D. CORBET in 1914. Spiders evident in liver disease were the focus of renewed attention in the nineteen-thirties (J. STEINMANN, 1935; N. FIESSINGER, 1936; H. EPPINGER, 1937).

*Fig. 4.6:* Spider naevus in liver cirrhosis in the ventral side of the left shoulder

Spider naevi consist of a central arterial vessel, about the size of a pinhead, from which minute, steadily narrowing capillaries, similar to a spider's legs, lead off radially. A passage into the veins, however, cannot be discerned. The central artery winds its way upwards out of the subcutis with an ampulla-like dilatation directly under the epidermis. From the morphological point of view, the course of the vessel can be divided into five sections (G. A. MARTINI, 1964). The central arterial telangiectasis, often button-like and occasionally even clearly protruding, can be seen to pulsate. Spiders occur as solitary or multiple stigmata. (s. fig. 4.6) • The size of the areola of spiders ranges from just a few millimetres up to 2 cm, sometimes even more. When pressed with a glass spatula, the radiating areola disappears and the small pulsating central vessel remains visible, but also disappears if more pressure is applied. Removing the pressure leads to a swift filling of the central vessel and the peripheral vascular areola. Occasionally, the spider has a narrow white marginal rim. • The most common sites are on the nose, forehead, zygomatic arch, neck, throat, shoulders, chest and back as well as the extensor sides of the arms and dorsum of the hand. Hence this localization of the spider naevi corresponds to the area of influence of the superior vena cava, the region of the excitation erythema, the projection fields of the trigeminus core region as well as the phrenic dermatomes ($C_3$ and $C_4$) and the neighbouring dermatomes ($C_5$ to $C_8$).

It would appear that the spider naevi occur as segmental reflexes, depending on visceral affections. This would explain why they "blossom" and reoccur when the liver condition deteriorates, and fade when the liver condition improves. The occurrence and rapid appearance of fresh spiders can be considered as an unfavourable sign, such as is observed, for example, in serious virus hepatitis or in the development of primary liver cell carcinoma.

**Aetiopathogenesis:** W. B. BEAN (1942) assumed the cause of spiders was increased oestrogen blood levels. Other aetiopathogenic factors include the activation of vasoactive ferritin, vasoactive histamine or bradykinin as well as endotoxins. Consequently, the al-

tered haemodynamics in chronic liver disease in the sense of a hyperdynamic circulation would also affect the dermatome areas, specified above as preferred sites. • Spider naevi are found not only in liver disease, but also in pregnancy, collagen disorders, hyperthyroidism as a paraneoplastic symptom, lead poisoning, vitamin deficiency conditions as well as following the intake of oestrogen or similar hormone preparations.

### 2.4.7 Palmar/plantar erythema

*Palmar erythema* (erythema palmare symmetricum, "liver palms"), frequently observed (in some 75% of cases) in chronic liver disease, was initially described by H. J. CHALMERS in 1899. It becomes manifest as diffuse or patchy reddening of the palms up to the start of the wrist joint; it is particularly evident on the balls of the small finger and thumb as well as on the finger tips and finger joints. The affected area is clearly outlined against the rest of the hand surface. The centre of the palm is generally free of erythema. The hands are warm − corresponding to the vasodilatation and increased circulation. In liver patients, palmar erythema varies in its intensity: during sporadic deterioration in the course of the disease, it can be more pronounced, and when the liver findings improve, it can fade. (s. fig. 4.7) • Occasionally, the soles of the feet are also affected and show *plantar erythema*. (16)

*Fig. 4.7:* Palmar erythema in liver cirrhosis

**Morphology:** No morphological changes of the cutis are witnessed. The blood capillaries are irregularly distributed and of differing length; however, they meander greatly in their path with arch-shaped dilatation of the final loop. The blood flow is rapid and jerky.

**Differential diagnosis:** Palmar erythema is also found in pregnancy, in hyperthyroidism, collagen diseases, endocarditis, long-standing feverish conditions, tuberculosis, diabetes mellitus, malignant tumours, chronic polyarthritis and in cases of malnutrition − as well as in healthy people.

**Aetiopathogenesis:** As with spider naevi, the capillary dilatation causing palmar erythema is attributed to an increased oestrogen content of the blood, a rise in bile acids or endotoxins and an activation of vasodilating substances with more numerous arteriovenous shunts and a hypercirculatory syndrome. Portal hypertension is seen as an important codeterminant. • The "blossoming" of spider naevi and palmar erythema is also observed in the phenomenon of *haemodynamic-related resistance to diuretics.*

*Incomplete spider naevi* can develop within a palmar erythema: they have no central artery. The combination of these two liver skin stigmata is frequently found in decompensated liver cirrhosis and in highly active chronic hepatitis.

### 2.4.8 Telangiectases

Apart from spider naevi, reticular telangiectases are frequently witnessed, particularly in alcoholic liver disease. They appear as tiny, bluish red vessels, in general symmetrically positioned on the cheeks, but also on the nose, forehead and neck. Those parts of the skin that are exposed to light are predominantly affected. The arterial and venous capillary loops are dilated.

### 2.4.9 White nails

White nails is the term used to describe a light pink/silvery-white enlargement of the nail lunula. (40) Ultimately, the entire nail plate is coloured a diffuse lacklustre white, except for a narrow, normal-coloured rim. The lunula of the thumb, the colour of which resembles frosted glass, can also spread and eventually take up the entire nail. The nails frequently have *longitudinal grooves*. Fully developed white nails actually look as though they have been coated with mother-of-pearl nail varnish. Usually white nails only occur after long-standing liver cirrhosis (10 to 20 years); they are hence considered to be a late sign. The cause of the whitish discoloration is attributed to air bubbles in the nail due to a disorder in the metabolism of keratin. White nails are often combined with "paper money skin". (3, 25, 40) (s. fig. 4.8)

***Fig. 4.8:*** White nails and paper money skin in liver cirrhosis

### 2.4.10 Muehrke's nail lines

These are white lines running across the nail plate parallel to the lunula. They were first observed by C.R. MUEHRKE (1956). Instead of being contained in the actual nail, the lines are set in the nail bed. This is thought to be caused by severe (< 2.2 g/dl) prolonged hypalbuminaemia, especially in cases of cirrhosis or nephrotic syndrome. This finding is, however, relatively rare. (24)

### 2.4.11 Paper money skin

The skin of the chronic liver patient often resembles so-called *parchment skin*: it appears prematurely aged, shrivelled, wrinkled, dry and atrophic − mostly greyish yellow in colour. (s. figs. 4.8, 4.18; 20.1) In contrast, partially atrophic, slightly reddened skin areas that have the appearance of a fading exanthema can occasionally be seen. Within these areas of the skin, there are fine, linear telangiectases, scattered at random, resembling delicate fibres. For this reason, the term *paper money skin* was coined (W.B. BEAN, 1945). These changes are mostly found around the neck down to the chest area, on the cheeks, behind the ears and on the surface of the hands and fingers. Exposure to sun and wind renders the appearance of paper money skin more pronounced. It is frequently combined with spider naevi.

### 2.4.12 White spots on the skin

Liver-disease patients often display white spots on the skin, which are the size of a lentil (sometimes as large as 0.5−1.0 cm in diameter). They can be detected chiefly in the area of the arms, on the back and on the buttocks. Upon cooling of the skin, white spots appear or become more pronounced, so that a cold-related vasocontraction is assumed to be the causative factor. In the predilection area of the spider naevi, the white spotting of the skin can be deemed a preliminary stage of liver star: within the round white spot, a central red dot is formed, from which the typical spider naevus develops with a white areola.

**Vitiligo:** Vitiligo (caused by functional failure of the melanocytes) sometimes occurs in primary biliary cirrhosis or autoimmune hepatitis.

### 2.4.13 Smooth red tongue

A *smooth red tongue*, first described by H. KALK (1955) (16), is raspberry-coloured. It is moist and more or less atrophic. There is no coating of the tongue, nor can any independent capillary changes or venous stasis be detected. The red colour is often in contrast to the yellowish or greyish yellow skin colouring. The tongue changes mainly develop parallel to the course of the cirrhosis: upon clinical improvement, the raspberry shade changes into the normal reddish grey colour of the tongue, which regains its coating. These changes of the tongue occur relatively rapidly as the condition improves or deteriorates. In cases with significant hepatic dysfunction, the smooth red tongue generally remains unchanged. Its cause is assumed to be metabolic cell dysfunction or hyperergic-allergic phenomena. (15) • There is often *angular cheilosis* with rhagades (perlèche, angulus infectiosus), such as can be witnessed in vitamin $B_2$ deficiency, diabetes mellitus, iron deficiency, infections, etc. (s. fig. 4.9)

**Fig. 4.9:** Smooth red tongue with angular cheilosis in liver cirrhosis

### 2.4.14 Liver tongue

A so-called congested tongue or "liver tongue" (R. PANNHORST et al., 1957) is voluminous due to the accumulation of fluid and displays tooth marks at the edges. It often has a deep median vertical groove and several small furrows or fissures. Corresponding to its occurrence with (or due to) portal hypertension, it is bluish purple in colour and its undersurface displays greatly distended veins. (15)

### 2.4.15 Lacquered lips

A smooth red tongue is often combined with a peculiar reddish colouring and smoothness of the lips, known as lacquered lips. They are also one of the late signs of cirrhosis, mainly with a necrotic course of the disease.

### 2.4.16 Gynaecomastia

In cases of gynaecomastia, the male mammary gland is enlarged. Within the increased volume of the breast, a firm, circumscribed and relatively well-defined tissue mass can be felt, which is usually sensitive to pressure. Apart from the enlargement of the mammary gland, which causes the patient mental as well as physical distress, spontaneous and sometimes sharp pain occurs. Occasionally, a serous or milk-like secretion is discernible. Gynaecomastia can also be unilateral. It occurs most frequently in alcoholic cirrhosis. (s. fig. 4.10)

The **cause** of gynaecomastia is generally attributed to inadequate inactivation of oestrogen or decreased production of testosterone (e. g. due to a lack of zinc in chronic alcoholism). Also of causative significance are the increased prolactin plasma level and a greater degree of response on the part of the mammary gland tissue. (3, 6, 8, 25, 45) • Gynaecomastia is also found as a persistent pubertal condition and in adiposity. It is always important to exclude other causes such as testicular tumours, hypogonadism, corticoadrenal tumours, bronchial carcinoma, etc. • Gynaecomastia can also occur as a result of treatment with *spironolactone*, which is often indicated in cirrhosis patients − however, when the medicament is no longer taken, this finding is reversible.

### 2.4.17 Dupuytren's contracture

The term Dupuytren's contracture (F. PLATTER, 1614; G. DUPUYTREN, 1832) denotes a hardening of the palmar fas-

**Fig. 4.10:** Gynaecomastia in liver cirrhosis

cia in the connective tissue, with firm band-like connections extending as far as the periosteum and even into the outermost skin layers. The preferred site is the distal ulnar quadrant of the flat of the hand. Severe flexion contractures, especially of the 4th and 5th fingers, ultimately develop. (s. fig. 4.11)

**Fig. 4.11:** Dupuytren's contracture in liver cirrhosis

Whereas Dupuytren's contracture is only found in about 2% of the population, it is detectable in about 30% of all cirrhosis patients, mainly bilaterally. Men are affected in 90% of cases and thus far more often than women. The disease generally commences unilaterally. Men are frequently affected in their younger years, whereas in women, the disease commences later and takes a more rapid course. There is a greater tendency towards recurrence of the disease after surgery than after radiological treatment. In cirrhosis patients, contracture occurs predominantly in combination with palmar erythema. There also seems to be a correlation between contracture and spider naevi. (2, 4, 12, 23)

At present, there are only hypothetical explanations for the **cause** of the contracture and its correlation with liver cirrhosis. A genetic factor probably plays a part, possibly also in combination with genuine epilepsy. Its more frequent incidence in alcoholic cirrhosis points to a disorder in collagen metabolism as a pathogenic factor.

Evidently, the platelet-derived growth factor (PDGF) which is produced, causes the connective tissue to proliferate and contract. PDGF stimulates the formation of prostaglandin E., which likewise changes the fibroblast contractility. (39)

### 2.4.18 Pigmentation and striae

Patients suffering from **liver cirrhosis** frequently display a brownish discoloration of the skin, predominantly due to the deposition of melanin.

In **haemochromatosis**, a pronounced brownish pigmentation is found due to the deposition of haemosiderin and melanin in the skin (= *bronze diabetes*), particularly in the lines of the palm. (s. fig. 4.12) Other predilection sites with distinctive slate-grey pigmentation are the axillae and the inguinal or lumbar region. Occasionally, a brownish ring-shaped discoloration is seen on the proximal fraction of the nail plate.

***Fig. 4.12:*** Pigmentation of the lines of the palm in haemochromatosis (left) − in comparison with a normal hand

**Wilson's disease** is occasionally accompanied by an argyric-like discoloration of the *skin* (greyish brown to bluish grey). The fingernails often display skyblue-coloured lunulae (A.G. Bearn et al., 1958). (46)

**Primary amyloidosis** can cause the skin to turn reddish brown. • In **Gaucher's disease**, greyish brown pigmentation can develop, similar to chloasma uterinum. This symmetric pigmentation sometimes extends upwards from the foot to the knee. • In **kwashiorkor**, dark red blotches are sometimes found in the inguinal and periumbilical area. • In **hamartoma** of the liver, a greyish brown skin pigmentation of the acanthosis nigricans type has been described. In the axillae, the skin is thickened and its texture has a greater consistency; it is also more fissured. • **Juvenile cirrhosis** (= lupoid hepatitis) often produces dark purple stripes on the hips, gluteal region and thighs of the young women affected. These striae run parallel to the tension lines of the skin. They can fade due to skin atrophy and loss of pigmentation.

Where the skin is exposed to sunlight, **porphyria cutanea tarda** displays a greyish brown, maculate or even patch-

like area of pigmentation, resulting from the deposition of melanin. The skin can be changed in the same way as in sclerodermatitis. Because of the photosensitivity of the skin, sporadic subepidermal blisters or pimples with encrusted skin lesions are formed, as a result of which the skin injures easily. The scars take the form of whitish, irregularly circumscribed blotches. (s. fig. 4.13) Periorbitally deposited melanin pigment is a typical feature.

***Fig. 4.13:*** Back of the hand in porphyria cutanea tarda

**Butterfly sign:** Hypopigmentation in the form of butterfly-shaped areas of skin on the back, located on either side of the spine, are sometimes seen in patients with cholestatic jaundice. (43)

### 2.4.19 Inflammatory erythematous stigmata

**Erythema diffusum hepaticum** can be observed in patients suffering from acute liver insufficiency. It is manifested as diffuse plate-shaped erythema of the face, extending up to the hair line. Occasionally, it can also be detected in the region of the jugulum and sternum. Minute red dots are frequently observed within the erythema. These become more prominent as the erythema fades away. Should reddish-coloured telangiectases occur in this area, the picture of paper money skin emerges. (s. figs. 4.8, 4.19)

**Exanthemas** are observed as prodromal skin symptoms in acute viral hepatitis (5−20% of cases). They can be manifested as urticaria, scarlatinoid or morbilliform exanthemas as well as varicella and erythematous multiform rashes.

**Acrodermatitis papulosa eruptiva infantum** (*Gianotti-Crosti syndrome*) can occur in children with acute viral hepatitis B. This is a lichenoid-papuloid skin rash on the face and limbs, which breaks out suddenly. These skin stigmata generally take 2−8 weeks to disappear.(s. p. 430)

### 2.4.20 Xanthelasmas and xanthomas

**Xanthelasmas** can be found at the corners of the eye or periorbitally, above all in cases of biliary cirrhosis due to primary biliary cholangitis (CDNC). (1) They display

a yellow, reddish yellow to brownish yellow colouring and are sharply circumscribed, sometimes as large as a fingernail, sometimes arranged in stripes. They can be flat (*xanthelasma planum*) or, due to cholesterol deposits, appear as raised bulges or tubers (*xanthelasma tuberosum*). (s. fig. 4.14)

*Fig. 4.14:* Xanthelasmas in biliary cirrhosis as a result of primary biliary cholangitis

**Xanthomas** (*xanthoma tuberosum*) display a straw-like yellow through to greyish yellow hue. These are round, well circumscribed, plaque-like raised or papuloid deposits in the skin, which predominantly occur on the extensor sides of the extremities, the elbow and knee area, the external ear, parts of the buttocks and back, occasionally also on the hands and soles of the feet. They can appear in cholestatic liver diseases, particularly in biliary cirrhosis as a result of CDNC. Their occurrence depends on the lipid and cholesterol content of the blood. (1) These changes are considered to be late symptoms. (s. p. 235) (s. figs. 4.15, 4.16)

*Fig. 4.15:* Xanthoma on the elbow in biliary cirrhosis as a result of primary biliary cholangitis

### 2.4.21 Scratch marks

Fully developed *pruritus* is found above all in cases of cholestasis and biliary cirrhosis due to CDNC as well as

*Fig. 4.16:* Multiple xanthomas in chronic cholestasis due to congenital biliary tract atresia

in liver hamartomas. The cause of this often unbearable itching is attributed to bile acids, in particular unconjugated chenodeoxycholic acid. The pruritus is mainly experienced on the extremities and trunk, which is also where the *effects of scratching* are found in the form of stripe-like excoriations, blood-encrusted skin lesions, dot-like erosions, secondary papuloid dermatitis, lichenification and bacterial superinfected scratch wounds. There may still be some visible signs of scarring and pigmentation. (s. p. 235) (s. fig. 13.3)

### 2.4.22 Eye changes

**Scleral icterus** occurs from a serum bilirubin level of $1.6-1.8$ mg/dl upwards. At the same time, the conjunctiva is icterially discoloured. Jaundice is based on the affinity of the elastic fibres for bilirubin.

**Kayser-Fleischer corneal ring** (B. KAYSER, 1902; B. FLEISCHER, 1903) occurs in Wilson's disease. It has also been observed in alcoholic liver disease. (47) Deposits of copper compounds form a brownish green corneal ring of $1-3$ mm in width near the limbus. It can be identified at an early stage by slit-lamp examination. (s. fig. 4.17) • Individual radiating, greenish brown **sunflower cataracts** are sporadically detectable in Wilson's disease.

*Fig. 4.17:* Kayser-Fleischer corneal ring in Wilson's disease

**Pingueculae** present as wedge-shaped, yellowish deposits on both sides of the pupilla and are observed in Gaucher's disease. • **Retraction of the eyelid** (Darlrymple's sign) and **infrequent blinking** (Stellwag's sign), such as in hyperthyroidism, are also found in cirrhosis patients.

### 2.4.23 Drumstick fingers

Drumstick fingers can be observed in chronic liver patients with a hepatopulmonary syndrome. *(see chapter 18)* These changes are due to an increased blood supply to the distal phalanges and the opening of arteriovenous anastomoses with relative hypoxia of the tissue as well as a more extensive formation of connective tissue between the nail and the bone. • The exaggerated convexity found in **hour-glass nails** can be a preliminary stage of drumstick fingers. Occasionally, a combined occurrence of finger clubbing and white nails can be observed (= *hypertrophic osteoarthropathy*). (s. fig. 4.18) (s. p. 336)

*Fig. 4.18:* Drumstick fingers and hour-glass nails in liver cirrhosis (and moderate paper money skin: s. figs. 4.5; 20.1)

### 2.4.24 Testicular atrophy

Considerable endocrine disorders may be present at times in cirrhosis patients. Progressive testicular atrophy with impotence and eunuchoidism (hypogonadism, "abdominal baldness", Chvostek's habitus) can occur. Fully developed testicular atrophy appears regularly in haemochromatosis.

### 2.4.25 Cutaneous and mucosal haemorrhages

Cutaneous and mucosal haemorrhages can occur in both liver insufficiency and liver cirrhosis. They appear as *petechiae* (pinpoint-sized capillary haemorrhagic foci), *purpurae* (small maculae) (s. fig. 20.2) or *vibices* (streak-like markings) as well as more extensive *ecchymoses* (circumscribed haemorrhagic foci >3 mm in size) and *suggillations* (areas of coin-sized haemorrhagic foci) (s. figs. 4.19; 20.1) or as *suffusions* (confluent haemorrhagic foci, generally without sharp circumscription). The haemorrhages are spontaneous or occur as a result of skin punctures or traumatism. Causative factors include greater fragility of the vessels, defective anchoring

of the smallest subcutaneous vessels, increased hydrostatic pressure when standing, and coagulaopathy.

*Fig. 4.19:* Cutaneous haemorrhages (confluent and streak-like) on the lower part and wrist of the left arm in a patient with cirrhosis

### 2.4.26 Vein dilatation

Clearly *recognizable veins* in the chest and abdominal area in approx. 40% of cases are a visible sign of portal hypertension with collateral veins. (s. fig. 4.20)

*Fig. 4.20:* Vein dilatation and tortuosity in the abdominal wall of a cirrhotic patient suffering from ascites and jaundice

**Caput Medusae:** Excessive forms of vein dilatation can develop in the abdominal skin, such as *vein convolutions* or *Medusa's head* (M. A. SEVERINO, 1632); the latter is also known as *Cruveilhier's sign* (J. CRUVEILHIER, 1829). It develops in portal hypertension, with the result that after the obstructed umbilical vein has been reopened, collaterals are formed over the paraumbilical veins (so-called Sappey's veins). Subsequently, visible venectasiae radiate out from the navel, like the snakes on the head of the gorgon Medusa. • A similar venectasia can also be seen in the area of the epigastric and superficial thoracic veins (*Cruveilhier-von Baumgarten syndrome*). (s. fig. 7.4) • Caput Medusae is also formed as a result of a persistent and malformed umbilical vein with hypoplasia as well as in thrombosis of the intrahepatic branches of the portal vein. It even occurs in children and juveniles (*Cruveilhier-von Baumgarten disease*). With caput Medusae, the umbilical vein remains open or is reopened, or the paraumbilical veins are dilated without change in the blood pressure. • Thus a prehepatic block (portal vein or splenic vein thrombosis) can never cause a caput Medusae because it never affects the umbilical vein. (s. p. 256) (s. fig. 14.13)

### 2.4.27 Hepatic foetor

There can be a pronounced increase in methionine and its derivatives in acute liver failure or in serious cases of cirrhosis. From these substances, mercaptans are formed in the colon (e. g. methandiol, ethandiol, dimethyldisulphide). The cause of the *sweetish aromatic smell* of the expiratory air ("fresh-raw liver") known as hepatic foetor (F. UMBER, 1926; L. SCHIFF, 1946) is deemed to be volatile *dimethylsulphide*. (38) Its concentration does not correlate with the degree of encephalopathy or hepatic insufficiency, but with the intensity of the portosystemic shunts. *Trimethylamine* is also suspected of being a causative factor. (22) (s. pp 267, 379)

### 2.5 Auscultation

Although auscultation of the abdomen is less important, this method of examination should be performed in certain diagnostic situations. Vascular sounds can occur in the form of arterial bruit or venous hum.

**1. Arterial bruit:** A systolic rushing sound synchronized with the heart beat indicates increased arterial blood flow. This often barely audible sound is easier to discern if one listens for arterial bruit and feels the patient's pulse at the same time. • It is sometimes heard where aneurysm or stenosis is present in large arteries (e. g. coeliac artery, hepatic artery) as well as in arteriovenous malformations, highly vascularized liver tumours, pronounced acute alcohol hepatitis, 1−2 days after liver biopsy resulting from temporary arteriovenous fistula, or in twisted arteries in cirrhosis. It is seldom found in healthy persons. (10, 13, 44)

**2. Venous hum:** LAENNEC (1819) was the first to describe the sound which one could hear coming from the veins of patients with cirrhosis. In France this sound phenomenon was termed "bruit de diable" (BOUILLAUD, 1835). The German term "Nonnensausen" is believed to have been introduced by von MERING (1901) in his textbook on internal medicine. It is derived from the noise made by a children's humming-top and is therefore best translated as "humming-top murmur". • Pronounced portal collateral circulation may cause a constant rushing sound due to increased blood flow. This hum mainly occurs between the navel and xiphoid. It is heard frequently and distinctly in Cruveilhier-von Baumgarten syndrome as well as in venous convolutions on the surface of the abdomen and in the centre of the (extremely rare) caput Medusae. The noise increases when the patient inhales or is in a standing position. (5)

**3. Friction rub:** A respiratory friction sound above the liver is an indication of perihepatitis. This inflammation of the liver occurs in tumours, liver abscesses or bacterial perihepatitis (e. g. *Fitz-Hugh-Curtis syndrome*) and, in rare cases, temporarily after a liver biopsy. • Perisplenic rubbing is occasionally discernible after splenic infarction. When pressure is applied to the stethoscope, the rubbing sound increases.

# 3 Liver check list

A *liver check list* provides a swift and clear method of ensuring that all important **clinical findings** can be "ticked off" in the patient's file. This list comprises the 10 most important subjective ailments, the 12 most important liver skin stigmata and the 9 most important clinical findings. *One glance is enough to review the total findings of the liver patient; moreover, documentation itself involves a minimum of time and effort.* Over the years, such a check list has proved its value in numerous practitioners' surgeries and outpatient departments. It ensures that nothing is "forgotten" or "overlooked" and (particularly during the first check-up) enables a very simple, yet extensive, documentation of hepatologic findings to be drawn up. (s. fig. 4.21 on the next page!)

# Diagnostics in Liver Diseases

## 5 Laboratory diagnostics

# 5 Laboratory diagnostics

## 1 Four epochs of laboratory liver diagnostics

**First epoch**

▶ In the 2 volumes of the classical textbook of hepatology by F. Th. Frerichs „Klinik der Leberkrankheiten" ("Clinical aspects of liver diseases"; 1858, 1861), there is no mention of laboratory diagnostics. (s. figs. 1.19, 1.20) • According to our knowledge, laboratory diagnostics was first presented in 1923 by G. Lepehne in his book „Die Leberfunktionsprüfungen, ihre Ergebnisse und ihre Methodik" ("Liver function tests, their results and methods"). This monograph initiated the **1st epoch of biochemical liver diagnostics.** The laboratory field was again addressed by H. Eppinger in 1937 in his textbook „Die Leberkrankheiten" ("Liver diseases") consisting of 52 pages; enzyme tests, however, were not mentioned. (s. fig. 5.1)

*Fig. 5.1:* H. Eppinger (1879−1946): „Die Leberkrankheiten" ("Liver diseases"), publisher J. Springer, Wien, 1937, 801 pages *(private property)* (s. fig. 1.19)

**Second epoch**

▶ The introduction of alkaline phosphatase (1933), cholinesterase (1938), aldolase (1954), transaminases (1955), γ-GT (1961) and GDH (1962) into liver diagnostics marked the onset of the **2nd epoch,** the **era of enzymochemistry.** • The resulting understanding with regard to the biochemistry of the liver appeared so fascinating to the hepatologists of that time that enzyme diagnostics was classified as *"biochemical biopsy"* (F. Wroblewski et al., 1956). • In his monograph „Leberfunktionsproben" ("Liver function tests"), H. Schaefer (1951) listed 171 liver tests, including alkaline phosphatase and cholinesterase. An up-to-date presentation of biochemical diagnostics was given by I. Magyar (1961) in his textbook „Erkrankungen der Leber und der Gallenwege" ("Diseases of the liver and biliary tract"). Up to that time, ca. 200 "liver tests" were known.

**Third epoch**

▶ The discovery of the Australian antigen by B. S. Blumberg et al. (1965) using serological techniques can be considered as the onset of the **3rd epoch** of laboratory liver diagnostics. With the advent of modern techniques in **serology and immunology,** liver diagnostics has improved tremendously.

**Fourth epoch**

▶ The fourth epoch of liver research is based on biomolecular and microstructural methods. This **4th epoch** may some day become known as **biomolecular hepatology.** (s. p. 12!)

## 2 Difficulties of laboratory liver diagnostics

In order to evaluate the results of biochemical tests within a hepatological context in an adequate manner, one has to be aware of some *fundamental issues*:

(*1.*) Owing to the liver's large functional reserve capacity as well as to its outstanding regenerative ability, morphological damage may evade biochemical detection, i.e. the damage may remain "biochemically silent".

(*2.*) A great number of liver tests are nonspecific, and their results are pathological in other diseases as well. It is therefore necessary to consider the specificity, sensitivity and clinical validity of the respective tests when setting up the diagnostic procedure.

(*3.*) In a variety of liver diseases, it often happens that only certain partial functions or cellular structures are impaired; this impairment can differ widely in intensity and extent in the individual patient. Therefore, when applying only a few biochemical tests, pathological changes may well be overlooked. For the detection of hepatocellular damage or disorders of hepatic functions, a variety of examination methods will have to be employed in order to provide a comprehensive assessment derived from the various single findings.

(*4.*) With increasing duration of liver or biliary tract diseases, but also with the simultaneous appearance of complications, biochemical findings become more and more ambiguous and misleading.

In order to give due consideration to these facts and reduce the uncertainties of liver diagnostics, a large number of function tests with a multitude of modifications were developed. However, the application of such **"batteries of tests"** or **"liver test arrays"** as well as **"shotgun investigations"** did not only result in unnecessary discomfort for patients and staff alike, but also in the uneconomical use of laboratory testing. Furthermore, these tests failed to improve liver diagnostics.

# 3 Prerequisites for correct laboratory findings

We usually assume that laboratory findings are correct. However, we tend to overlook the wide range of factors which might influence the measured value considerably. • *Therefore, it is absolutely essential to ensure the reliability of laboratory findings.*

During *(1.) sample collection, (2.) sample transport, (3.) sample preparation*, and *(4.) sample processing* (including *storage*), laboratory findings may be exposed to a multitude of influencing factors, thus allowing serious mistakes to occur. (1)

In order to obtain accurate laboratory values, **three steps** are necessary, each requiring continuous monitoring and control: (*1.*) preanalytical phase, (*2.*) analysis, and (*3.*) analytical assessment.

## 3.1 Preanalytical phase

The most frequent mistakes leading to an incorrect laboratory value occur during the preanalytical phase − since there is no "quality management" at this point, as there is in the later phase of analysis and analytical assessment.

**Influencing factors:** Factors affecting haemanalysis values are as follows:

(*1.*) *Food intake:* An empty stomach strictly means no consumption of food or alcohol (and preferably of nicotine as well) 10−12 hours prior to blood collection. (1)

(*2.*) *Time of day:* The most favourable time to take the blood sample is between 7 and 9 o'clock in the morning. (8)

(*3.*) *Body position:* The blood sample should be taken when the patient is in a sitting or lying position − following a 10-minute resting period. (1)

(*4.*) *Physical activity:* No previous physical strain.

(*5.*) *Drugs:* Medication must be reported to the laboratory; it should only be administered after the blood sample is taken.

(*6.*) *Further possible influencing factors:* Body weight, temperature, circadian rhythms, climate and altitude as well as various diagnostic examinations. (1, 2, 7, 8)

**Blood sample collection:** It is important to take the blood sample under standardized conditions (1, 3, 7):

(*1.*) Venous stasis with 40−50 (max. 60) mm Hg.

(*2.*) No pumping of the fist.

(*3.*) If possible, syringe with needle No. 1 − downward insertion of the needle at an angle of approximately 30°.

(*4.*) Gentle aspiration, blood collection at a slow and constant rate; if the blood flow stops, syringe should be slightly rotated.

(*5.*) Stasis of the vein should not exceed 2 to 3 minutes.

(*6.*) Respective instructions regarding the collection of different types of samples (serum, plasma, citrated and EDTA blood) have to be observed.

(*7.*) *After removing the needle, do not bend the arm but elevate it* − this will empty the vein and avoid bleeding as well as preventing haematoma.

**Haemolysis:** Haemolysis has a negative influence on the reliability of certain laboratory values, such as an *elevation* of LDH, GOT, GPT and potassium as well as a *decline* of alkaline phosphatase, γ-GT and bilirubin. (6) Haemolysis has to be avoided in all cases. In artificially induced haemolysis, haptoglobin is normal; however, in intravasal haemolysis, it is reduced or hardly detectable. • **Colour reactions** such as bilirubinaemia, hyperlipidaemia and discoloration of serum by medication or i.v. diagnostic substances can also distort laboratory values. (1, 4)

**Specimen identification:** The sample must not be dispatched until it has been labelled correctly and the appropriate form for specimen identification has been enclosed. Mistakes made during identification (mismatching of names or samples) can be the source of considerable misjudgements or delays and may also cause grave errors with possible legal consequences.

**Specimen transport:** The sample must reach the laboratory in the shortest time possible and the mode of transport should not alter laboratory findings in any way. Precise regulations have therefore been established for transportation. When mailing samples, the results may alter within the course of 2 days by as much as 10%. (1, 7)

**Specimen stability:** The stability of a sample is of relevance for the preanalytical phase as well as for phases 2 and 3 (analysis and analytical assessment), which are performed exclusively in the laboratory. (5) As a rule, when stored in a refrigerator (4°C) in closed containers, only a minor loss of *serum enzyme activity* is to be expected after 3−5 days, which will increase slightly at room temperature (20−25°C). (s. tab. 5.1) • The *substrates* necessary for biochemical liver diagnostics generally remain stable for several days under identical conditions (exception: ammonia with a maximum of 2 hours). (s. tab. 5.1)

| Loss of enzyme activity | 4°C | 20−25°C |
|---|---|---|
| Alkaline phosphatase | 0% | (10%) |
| Cholinesterase | 0% | ( 0%) |
| GDH | 5% | (15%) |
| GOT | 8% | (12%) |
| GPT | 10% | (17%) |
| γ-GT | 0% | ( 0%) |
| LAP | 0% | ( 0%) |
| LDH | 8% | ( 2%) |
| **Stability of substrates** | **4°C** | **20−25°C** |
| Ammonia (in hours!) | 2 | (−) |
| Autoimmune antibodies | 14 | ( 5) |
| Cholesterol | 6 | ( 6) |
| Copper | 14 | (14) |
| Electrophoresis | 6 | ( 6) |
| Hepatitis serology | 14 | ( 5) |
| Immunoglobulins | 7 | ( 3) |
| Iron | 7 | ( 4) |
| Neutral fats | 3 | (−) |
| Potassium | 14 | (14) |
| Protein | 6 | ( 6) |
| Sodium | 14 | (14) |

***Tab. 5.1:*** Loss of enzyme activity (in %); stability of substrates (in days) during storage of serum in a refrigerator (4°C) and at room temperature (20−25°C)

**Scope of duties:** The following tasks are a mandatory part of the *preanalytical phase*; they require strict observation in order to obtain reliable laboratory values:

1. Adequate preparation of the patient
2. Standardized collection of the blood sample
3. Knowledge of influencing factors
4. Correct labelling (sample + accompanying form)
5. Transportation of the sample
6. Storage of the sample

## 3.2 Analytical phase and assessment

During the phase of **analysis** (phase 2), substrates are determined using reliable (standardized) methods. During the phase of **analytical assessment** (phase 3), the performance (= reliability) of the methods is assessed. • **Criteria for reliability** are (*1.*) *precision,* (*2.*) *accuracy,* (*3.*) *specificity and sensitivity,* and (*4.*) *upper and lower limits of detection.* In addition, (*5.*) the *plausibility* of a finding is also assessed. • **Standard values for quality control** demonstrate the degree of seriousness of having wrong findings and simultaneously limit the respective maximum error value. In clinical chemistry, **precision** (= exactness of measured values or congruence of repeated measurements) and **accuracy** (= deviation from nominal values) are imperative. Measuring values for the various biochemical parameters are specified at different levels.

# 4 Selection criteria for liver tests

▶ After the introduction of modern biochemical techniques (such as enzyme diagnostics, serology and immunology) into hepatology, only a few of the numerous liver function tests have prevailed. Hepatic diagnostics has been "streamlined" and completely redeveloped. Only the determination of bilirubin, serum iron and urinary bile pigments has remained from the first epoch.

**Assessment scale:** At this point, it is necessary to make use of a selection of biochemical tests in order to obtain a reliable, differentiated and also economical liver diagnostic schedule. (9–11) • *Such tests should complement one another in their diagnostic informativeness, but at the same time they should overlap as little as possible.* • For the selection of biochemical tests in liver diagnostics, various **criteria** are applied as an assessment scale. (s. tab. 5.2)

| I. | 1. Specificity | II. | 1. Costs involved |
|---|---|---|---|
| | 2. Sensitivity | | 2. Practicability |
| | 3. Clinical reliability | | 3. Inconvenience to the patient |
| | | | 4. Influencing factors |

**Tab. 5.2:** Selection criteria used as an assessment scale for biochemical hepatic tests

**Morphological lesions:** Hepatocytes and biliary capillaries respond to damage with structural disorders of their membranes and organelles. Electron microscopic differentiation of these lesions may yield additional diagnostic possibilities *("pathology of organelles")*. (14) • Depending on the nature and intensity of the damage as well as the duration of exposure, *morphological lesions* appear in various forms and also in combination:

| | |
|---|---|
| • **inflammatory** | • **proliferative** |
| • **necrotizing** | • **accumulative** |
| • **degenerative** | • **fibrogenic** |

These forms of morphological damage lead to the appearance of certain **biochemical disorders** of varying intensity and in several combinations. (s. tab. 5.3)

1. **Disorders of hepatocellular integrity**
   - GPT (ALT), GOT (AST), GDH, LDH, γ-GT
   - Iron
   - Zinc
   - Vitamin $B_{12}$

2. **Excretory disorders**
   - Bilirubin
   - Bile pigments (in urine)
   - Bile acids
   - AP, LAP, 5′-NU, γ-GT
   - Copper
   - Cholesterol
   - Indocyanine green test (ICG)
   - Bengal rose test

3. **Disorders of synthesis capacity**
   - Cholinesterase (ChE)
   - Clotting factors
   - Antithrombin III (AT III)
   - Albumin
   - LP-X, LCAT, lipoprotein
   - $α_1$-foetoprotein (AFP)
   - Transport proteins
   - Glycoproteins
   - Binding and carrier proteins

4. **Disorders of metabolic performance**
   - Ammonia
   - Galactose test (GEC)
   - Free phenols (in serum and urine)

5. **Disorders of biotransformation**
   - Bilirubin glucuronization
   - Aminopyrine $^{14}C$ breath test
   - Caffeine elimination test (CET)
   - 4-Methylumbelliferone test

6. **Disorders of hepatic blood perfusion**
   - Indocyanine green test (ICG)

7. **Elevation of mesenchymal reactions**
   - γ-globulins
   - Immunoglobulins A, G, M
   - Copper
   - Procollagen-III-peptide (P-III-P)

8. **Changes in serology and immunology**
   - Virus serology
   - Autoantibody
   - Tumour marker
   - Lymphocyte transformation
   - Leucocyte migration

**Tab. 5.3:** Most common biochemical reactions and dysfunctions of the liver together with related laboratory parameters

**Liver-function tests:** There is no single biochemical method which provides a global statement on the hepatic

function itself. (s. p. 107) Here the term **liver-function tests** should be limited to those tests *which make possible the assessment of a specific liver function!* • Thus the elevation of indicator enzymes (GPT, GOT, GDH), which point to a disorder of hepatocellular integrity, cannot be designated as a test of liver function any more than, for example, the elevation of alkaline phosphatase can be described as an indicator of biliary diseases. • *With these liver-function tests, only a small number of the various hepatic functions are recorded. The common (endogenous and exogenous) function tests can, in general, merely indicate a disorder of a certain partial hepatic function.*

---

*5th hepatological principle*

Rational and reliable liver diagnostics requires the simultaneous application of certain liver tests for ascertaining important parameters of cellular integrity and essential liver functions. In some cases, they have to be complemented by further specific tests.

---

**Liver check list:** On the basis of their biochemical or biomolecular classification, essential laboratory results are systematically classed in 5 groups in a liver check list. (13) (s. fig. 5.2) (see also fig. 4.21!)

**Graduated programme:** This check list facilitates a rational and step-by-step diagnosis as well as a detailed biochemical classification and interpretation of findings. Depending on the diagnostic issue, only single specific parameters are applied and possibly complemented "stepwise" in the form of a graduated programme (= algorithm). (12, 13) (s. tab. 5.23)

▶ Both the decline in enzyme activity and the change in measured values of substrates are comparatively low during storage in a refrigerator. (s. tab. 5.1) The patient's serum should therefore be stored for $3-4$ days in order to determine the additional values required *("step-by-step")* without inconvenience and loss of time to the patient, without additional demands on the staff and without extra material costs.

# 5 Assessment of hepatocellular integrity

## 5.1 Enzyme diagnostics

**Enzymes:** As high-molecular proteins, enzymes are essential components of cellular ultrastructures. Enzymes are synthesized on demand, following the same mechanism as other proteins. Within the human organism, more than 1,000 enzymes are known, although only 50 have been utilized for diagnostic purposes so far. • As biocatalysts, enzymes facilitate biochemical processes in a specific direction and at an appropriate pace without undergoing modifications themselves. Due to their protein structure, they possess a high substrate specificity, thereby allowing a multitude of simultaneous metabolic processes to take place. In order to be effective, some enzymes rely on cofactors, prosthetic groups or coenzymes. The nomenclature of enzymes is derived from the reaction they catalyze, or their specific substrate, by adding the suffix "-ase". Historic denotations for enzymes also exist.

According to international standards, they are divided into **6 major categories:** *(1.) oxidoreductases, (2.) transferases, (3.) hydrolases, (4.) lyases, (5.) isomerases*, and *(6.) ligases*. Each enzyme is characterized by an **EC number** (= Enzyme Commission), which is further subdivided by means of points. (s. tab. 5.4)

| Check list of biochemical findings | | | | | Name | | | | Date | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| **Hepatocellular damage** | | | | **Cholestasis** | | | | **Hepatic function** | | | | **Mesenchymal activity** | | | | **Immunology** | | |
| | ∅ | + | ++ | | ∅ | + | ++ | | ∅ | + | ++ | | ∅ | + | ++ | | ∅ | + | ++ |

***Fig. 5.2:*** List of essential biochemical findings and the respective "hepatic diagnostic evaluation" (2nd diagnostic pillar; s. fig. 4.2) according to their principal biochemical or biomolecular classification (s. fig. 4.21) (s. tab. 5.23)

| 1. Glutamic pyruvic transaminase (= Alanine aminotransferase) | GPT ALT | 2.6.1.2 | +++ |
|---|---|---|---|
| 2. Glutamic oxaloacetic transaminase (= Aspartate aminotransferase) | GOT AST | 2.6.1.1 | + |
| 3. Glutamate dehydrogenase | GDH | 1.4.1.3 | ++ |
| 4. Gamma-glutamyl transferase | γ-GT | 2.3.2.2 | ++ |
| 5. Lactate dehydrogenase | LDH | 1.1.1.27 | + |
| 6. Cholinesterase | ChE | 3.1.1.8 | +++ |
| 7. Phosphohexoisomerase | PHI | 5.3.1.9 | + |
| 1. Alkaline phosphatase | AP | 3.1.3.1 | +++ |
| 2. Leucine arylamidase (= Leucine aminopeptidase) | LAP | 3.4.11.1 | ++ |
| 3. Gamma glutamyl transferase | γ-GT | 2.3.2.2 | ++ |
| 4. 5′-Nucleotidase | 5′-NU | 3.1.3.5 | ++ |

*Tab. 5.4:* Seven essential hepatocellular and four biliary diagnostic enzymes together with their respective terminology, abbreviations, EC code and specificity $(+ \rightarrow +++)$

| Indicator enzymes | GPT, GOT, GDH, LDH |
|---|---|
| Secretory enzymes | ChE |
| Excretory enzymes | AP, LAP, γ-GT, 5′-NU |
| **Unilocular** | |
| Cytoplasm | GPT, LDH |
| Mitochondria | GDH |
| Endoplasmic reticulum | γ-GT, ChE |
| **Bilocular** | |
| Cytoplasm | cGOT  (20%) |
| Mitochondria | mGOT (80%) |
| Periportal (zone 1) | GPT, LDH, AP |
| Pericentral (zone 3) | GDH, ADH |
| Zones 1−3 | GOT |

| half-life | in hours | half-life | in days |
|---|---|---|---|
| LDH$_5$ | 10 ± 2 | γ-GT | 3−4 |
| GOT | 13 ± 1 | AP | 3−7 |
| GDH | 16 ± 2 | ChE | < 10 |
| GPT | 47 ± 10 | LAP | < 10 |

*Tab. 5.5:* Schematic differentiation of hepatocellular enzymes according to their type and preferred localization within the liver cell or the liver lobule as well as their half-life

**Hepatobiliary enzymes:** Each organ possesses a typical quantitative and, to some extent, qualitative distribution of enzymes resulting in a cellular profile of enzymes, which is termed the **enzyme pattern.** Thus within the hepatocytes and the biliary ducts, the liver also possesses a characteristic distribution of enzymes with gradually varying specificity. This specificity of essential hepatobiliary enzymes is of importance for the diagnosis of hepatobiliary diseases. (26) (s. tab. 5.4)

▶ The (ubiquitous) enzyme **phosphohexoisomerase** (PHI) is also found within hepatocytes. Elevated activity is observed in malignancies, and thus this enzyme can be used to monitor the course and therapy of these diseases. Particularly in metastasizing liver cell carcinoma, PHI exhibits the most reliable elevation of enzymes, as compared to GOT and GPT (84%: 50%: 30%) (M.K. SCHWARTZ, 1973). • Although both (mitochondrial) **ornithine carbamoyltransferase** (OCT) and (cytoplasmic) **sorbitol dehydrogenase** (SDH) possess a high hepatocellular specificity, they play no part in diagnostics. Likewise, the assessment of **isocitrate dehydrogenase** (ICDH) as a marker of centroacinar necrosis (17), **aldolase** (ALD) and **alcohol dehydrogenase** (ADH) is unnecessary during the course of enzyme diagnostics in hepatobiliary diseases.

**Classification:** The classification of the hepatobiliary enzymes essential for enzyme diagnostics is based on their characteristic nature − i. e. *excretory, secretory* and *indicator enzymes.* (s. tab. 5.5) They are located predominantly within the liver cells and the biliary ducts as well as within the hepatic lobules. The speed of **enzyme elimination** does not depend on the blood enzyme levels, but follows an exponential curve. This allows the computation of the **half-life** of enzymes within the plasma, which is not influenced either by gender or age and is a typical enzyme characteristic. The velocity of enzyme elimination is largely constant. (s. tab. 5.5) However, in chronic diseases of the liver, it is known, for example, that GPT is usually eliminated faster than GOT despite its longer half-life.

**Normal levels:** Under normal conditions and during physiological "moulting", hepatocytes leak minor quantities of enzymes, which are detectable in the serum as "normal values". Due to inflow (= enzyme secretion from the liver cell) and outflow (= enzyme elimination), these values are kept largely constant within a normal range.

**Elevation of enzyme values:** The liver contains approx. 400 U GPT/g protein and 500 U GOT/g protein. In increased permeability of or damage to the liver cell membrane − referred to as low-grade disorders of cellular integrity − cytoplasmic enzymes (GPT, GOT, γ-GT, LDH) enter the plasma. Only during cellular necrosis − resulting in the destruction of mitochondria and the endoplasmic reticulum − do localized enzymes (GDH, γ-GT, GOT) enter the bloodstream. These enzymes then become elevated to levels which are considered to be pathological. One gram of liver tissue contains approx. 171 million hepatocytes. (s. p. 21) *Damage to the cellular membranes of only 1 gram of liver parenchyma (with a normal wet weight of the liver of ca. 1,500 g) results in an increase in the serum enzyme activity of GPT to pathological levels. With corresponding liver cell necrosis, GOT and GDH respond in the same fashion with a measurable increase in activity. If the liver loses only $^1/_{1000}$ of its cell enzymes, there is a rise in the respective enzyme activity in the serum by a factor of 2.* The enzyme content in the hepatocytes can be up to 10,000 times higher than in the serum. Hence there is a genuine correlation between the nature and intensity of hepatocellular damage and the increase in activity of free cytoplasmic as well as bound mitochondrial enzymes.

**Enzyme distortion:** A shift in the normal enzyme pattern is termed enzyme distortion. It is possible to derive various kinds of *information* from the prevailing enzyme pattern:

1. The less distorted the enzyme pattern within the serum, the more profound is the underlying necrotic hepatocellular damage, i. e. the enzyme profile within the serum corresponds to that within the hepatocytes: LDL > GOT > GPT > GDH.

2. The more distorted the enzyme pattern, the more chronic is the course of the disease.

3. The severity and type of cell damage (inflammatory or necrotizing) are determined by the relation between enzymes localized in the cytoplasm and the mitochondria.

4. The level of enzyme values supplies information on the extent of the hepatic parenchymal damage.

5. The relative half-life of enzymes is indicative of the duration of the disease (acute, chronic).

6. The relation between cholinesterase and indicator enzymes gives insight into the stage of a chronic liver disease.

The cell-integrity enzymes GPT (ALT), GOT (AST) and GLDH cannot be regarded as *liver-function tests* (LFT) because they are not markers of a specific liver function. (s. p. 107) Therefore the term "LFT" is a *misnomer* and should not be used for these enzymes!

**Enzyme ratios:** In hepatocellular damage, the serum GPT value generally exceeds the GOT value, the so-called *inflammatory type.* Only during cellular necrosis with associated destruction of mitochondria does the GOT activity exceed that of GPT, because the mitochondrial portion of GOT then leaks into the serum. This constitutes the basis for the **DeRitis ratio** (F. DeRitis et al., 1956). The course of disease is more severe (i. e. more necrotic) and the respective prognosis more serious if the GOT/GPT ratio exceeds 1, the so-called *necrotizing type.* In chronic active hepatitis C, a value of >1 correlates closely with the extent of fibrosis and the development of cirrhosis. (33) This ratio may be >2 in alcoholic or malignant liver diseases and it may be >4 in fulminant hepatitis. • In hepatological diagnostics, further **ratios** can be applied as additional parameters. (s. tabs. 5.6, 5.7)

**Transaminases:** The transaminases catalyze the reversible transformation of α-ketoacids into amino acids. Most frequently, the 2 transaminases GPT (= *glutamic pyruvic transaminase*) (or ALT = *alamine transaminase*) and GOT (= *glutamic oxaloacetic transaminase*) (or AST = *aspartate transaminase*) are used for enzyme diagnostics (F. DeRitis et al., 1955; F. Wroblewski et al., 1955). (s. tab. 5.4) While GOT is distributed evenly, the GPT concentration continuously decreases from periportal to pericentral in the acinus. These are considered to be the basic parameters in the diagnosis and follow-up of hepatocellular disease. If the cause of elevated transaminases remains unclear, the indication for liver biopsy is given. (28, 30, 31, 34)

▶ *Generally, the elevation of transaminases is a reliable marker of hepatocellular damage.* (19−21, 23, 24, 28, 32, 34)

| GOT/GPT ratio (= DeRitis ratio) | |
| --- | --- |
| 1. Inflammatory type | GOT < GPT = <1 |
| 2. Necrotizing type | GOT > GPT = >1 |
|   − in severe alcoholic or | |
|     malignant liver disease | GOT > GPT = >2 |

| γ-GT/GOT ratio | |
| --- | --- |
| 1. Acute viral hepatitis | = <1 |
| 2. Toxic hepatitis | = <2 |
|   Chronic persistent hepatitis | |
| 3. Chronic hepatitis | = 2−3 |
|   Acute alcoholic hepatitis | |
|   Cirrhosis | |
| 4. Alcoholic cirrhosis | = 3−6 |
|   Acute obstructive jaundice | |
| 5. Biliary cirrhosis | = >6 |
|   Chronic obstructive jaundice | |
| 6. Liver carcinoma | = >12 |
|   Liver metastases | |

| (GPT + GOT)/GDH ratio | |
| --- | --- |
| 1. Severe toxic/inflammatory damage | = <10 |
|   of perivenous parenchyma | |
| 2. Hepatic metastases | = <10 |
| 3. Obstructive jaundice | = <20 |
|   Necrotic episode in acute hepatitis | |
|   Acute intoxication, liver carcinoma | |
| 4. Biliary cirrhosis | = 20−30 |
| 5. Acute episode in chronic hepatitis | = 30−40 |
|   or in liver cirrhosis | |
| 6. Cholestasis | = 30−50 |
| 7. Acute viral hepatitis | = >50 |
|   Acute alcoholic hepatitis | |

**Tab. 5.6:** Enzyme ratios (using optimized tests) as additional "cheap" and "fast" enzyme parameters of differential diagnosis of liver diseases (13, 18, 33)

| LDH/GOT ratio | |
| --- | --- |
| 1. Haemolytic jaundice | = > 12 |
| 2. Hepatocellular jaundice | = < 12 |

| GPT/GDH ratio | |
| --- | --- |
| 1. Obstructive jaundice | = < 10 |
| 2. Hepatocellular jaundice | = > 10 |

**Tab. 5.7:** Enzyme ratios as additional support for the differential diagnosis of hyperbilirubinaemia

**Extrahepatic causes** of increased transaminases include: (*1.*) cardiac infarction, (*2.*) severe tachycardia, (*3.*) muscular diseases, (*4.*) pulmonary embolism, (*5.*) hypo-/hyperthyreosis, (*6.*) coeliac disease, (*7.*) heatstroke, (*8.*) hyperthermia, (*9.*) excessive physical exercise, (*10.*) long-term fasting, (*11.*) above-average protein intake, (*12.*) haemolysis, (*13.*) postprandial and (*14.*) long-term venous stasis.

**Macroenzymes** are characterized by a high molecular weight and therefore have a delayed clearance. For this reason, they cause false-positive increases of certain liver cell enzymes. *Type 1 macroenzymes* result from the formation of antigen-antibody complexes, using GPT, GOT, γGT and AP. *Type 2 macroenzymes*, result from oligomerization, using γGT, AP, LAP and 5′-NU.

In unresolved elevation of the transaminases (possibly also of other hepatobiliary enzymes), percutaneous liver biopsy will supply a normal result in up to 10% of cases. (20) This *"histological normality"* is, however, not necessarily representative of the entire liver! (s. p. 160) (s. figs. 7.8; 8.3) *Any histological findings should be limited exclusively to the individual biopsy punch. Consequently, the localized findings obtained by the pathologist should not be automatically related by the hepatologist to the liver as a whole.*

### 5.1.1 GPT (ALT)

GPT possesses a sensitivity of 83%, with a specificity of 84% relating to nonhepatic diseases and 97.8% relating to healthy subjects. • According to our own investigations, elevation of GPT as a **"screening enzyme"** was demonstrated in 81% of 520 patients with very different liver diseases. (13) (s. tabs. 4.2; 5.11)

► *Elevated GPT is the most sensitive indicator of hepatocellular damage. An exclusive rise in GPT is, as a rule, of hepatocellular origin.*

However, it is not possible to detect the cause of hepatocellular damage, nor to differentiate primary liver disease from a secondary hepatic reaction (e. g. in various inflammatory processes). Moreover, the chronicity of a liver disease, or its respective stage, cannot be determined by virtue of elevated GPT values. • Serum GPT may also be increased due to obesity, extreme physical strain, persisting tachycardia, hyperthyroidism, long-term fasting, excessive protein intake and blood collection. Slightly elevated GPT values may occur in the second trimester of pregnancy. (15) In the absence of clinical findings, a continuous elevation of GPT (and also of GOT) is found with the appearance of macroenzyme-1 immune complexes.

Determination of GPT has proved to be a reliable marker for the follow-up of a precisely diagnosed inflammatory liver disease and the so-called asymptomatic HBsAg-carrier state as well as for the screening of blood donors. In extensive hepatocellular damage, the elevation of GPT is accompanied by a corresponding increase in the GOT value.

► *False-normal GPT* values are often found − despite the presence of liver damage − in: (*1.*) haemochromatosis, (*2.*) ileo-jejunal bypass, (*3.*) marked (e. g. alcohol-induced) deficiency of pyridoxal phosphate ($B_6$), (*4.*) severe loss of liver parenchyma, and (*5.*) during the terminal stages of liver disease with exhaustion and/or blockage of hepatocellular enzyme synthesis caused by toxins. (31) • In "healthy" persons, slightly elevated GPT values were detected in 0.5% of cases.

| Normal GPT value (37 °C) | |
| --- | --- |
| Women | 10−34 U/l |
| Men | 10−45 U/l |

### 5.1.2 GOT (AST)

The diagnostic sensitivity of GOT (71%) is significantly lower than that of GPT. This is understandable, since it is only the cytoplasmic portion of the GOT (20%) which will enter the blood if the liver cell membrane is damaged − a factor which arithmetically also reduces the sensitivity. The isolated elevation of GOT is not to be expected in liver diseases − except for false-normal GPT due to $B_6$ deficiency. GOT is mainly present in the heart and skeletal muscles, but is also found in the kidney, brain, pancreas and lung. Diseases of these organs are accompanied by respective increases in GOT. An elevation of GOT values may also occur as a result of haemolysis, strenuous physical exercise and prolonged venostasis during blood collection. Distinctly elevated levels were found in hypoxic hepatitis. (22, 35) As a rule, pregnancy shows a normal GOT value. (15) In hepatology, the main purpose of determining GOT is to complement GPT values. Beyond this, the GOT value can be applied for the determination of *enzyme ratios* as an additional parameter in the differential diagnosis of liver diseases. (s. tabs. 5.6, 5.7).

► Determination of **mitochondrial GOT** (mGOT = 80%) is recommended as an additional laboratory parameter for the detection of persistent **alcohol abuse**, particularly in those cases where GDH measurements are inconclusive. Mitochondrial GOT (mGOT) serves as a fatty acid-binding protein (FABP). This might help to explain the increased uptake of fatty acids in hepatocytes due to alcohol abuse.

► The **decline in transaminases** to "normal" levels − with a continued deterioration of the active liver disease − and sometimes even to (extremely) subnormal concentrations is a fatal sign. Excessive enzyme deprivation, with a simultaneous marked reduction in cholinesterase activity, is commonly regarded as a *final sign of laboratory chemistry, indicating the imminent death of the liver-diseased patient.*

Any determination of **elevated transaminases** requires remeasurement after 14 days (or earlier) because:

(*1.*) after normalization, there will be no further consequences (e. g. the condition was caused by a secondary hepatic reaction to an infection),
(*2.*) a marked increase is indicative of the development of acute viral hepatitis or progressive intoxication, both of which have to be clarified,
(*3.*) a persistent elevation requires further diagnostic steps for final differentiation of the active liver disease. (20, 28, 30, 32, 34, 101)

| Normal GOT value (37 °C) | |
| --- | --- |
| Women | 10−31 U/l |
| Men | 10−35 U/l |

### 5.1.3 Glutamate dehydrogenase (GDH)

GDH effects the oxidative deamination of glutamate. Extensive GDH activity is found only in the liver − it

is very low in the heart, kidney, brain, lung, and skeletal muscles. In hepatocytes, it is present as a mitochondrial enzyme. Therefore, it only enters the blood after extensive cellular damage with subsequent destruction of the mitochondria. Centrolobular (zone 3) GDH activity is 1.8 times higher than that found in the periphery of the liver lobule. This region represents the final stretch of the sinusoidal supply pathway. Hepatocytes located at this site are therefore particularly prone to hypoxia and toxins. (16) This results in a more pronounced elevation of GDH with a respective decline in the GPT + GOT/ GDH ratio. (27) (s. tab. 5.6) • GDH is unsuitable as a "screening enzyme" since the respective sensitivity is only 47%. In combination with GPT and GOT, it can, however, yield the most reliable assessment of hepatocyte integrity.

A marked **elevation of GDH** is found in stages of extensive alcohol-induced steatosis, in primary biliary cirrhosis, during the development of liver cell carcinoma due to cirrhosis (with an increase in activity comparable to that of γ-GT and AP), in benign obstructive jaundice (with a decline in elevated GDH and transaminase values after approx. one week even though there is simultaneous persistence of cholestasis enzymes) as well as in acute incomplete obstructive biliary flow. Regression of acute viral hepatitis or progression of a chronic inflammatory liver disease is indicated more reliably by GDH than by transaminases. • During *acute cholestasis,* possibly with loss of gallstones through the bile duct, GDH is markedly elevated. This clear rise in GDH is a reliable parameter for diagnosing biliary-induced colic on the right side, because kidney stones can now be ruled out. (13) • *Extremely high GDH values* (up to 1,000 U/l and higher) are found in severe toxic liver cell necrosis (as induced by halothane, amanita phalloides, etc.), during acute right heart failure, severe respiratory insufficiency, circulatory failure, immunological rejection after liver transplantation, and abrupt impairment of the hepatic circulation. (16)

| Normal GDH value (37°C) | |
|---|---|
| Women | < 5 U/l |
| Men | < 7 U/l |

### 5.1.4 Lactate dehydrogenase (LDH)

LDH is a cytoplasmic enzyme which catalyzes the oxidation of lactate into pyruvate. It consists of **5 isoenzymes.** As a ubiquitous enzyme and constituent of almost all tissues, LDH enters the blood circulation even in minor cell and tissue damage. The *isoenzymes $LDH_4$ and $LDH_5$* are predominantly located in the liver, cardiac muscle and malignant tissues. After severe damage of the liver parenchyma, these isoenzymes may become elevated. The half-life of $LDH_5$ is very short ($10 \pm 2$ hours).

A marked *elevation* of total serum LDH is most obvious in liver metastases and obstructive jaundice. This explains why a considerable increase in LDH activity, in particular that of isoenzymes 4 and 5, can be detected

in malignant ascites. An increase in LDH (in the absence of haemolysis) and low transaminase activity are reliable markers of hepatitis mononucleosa: this is due to virocytes secreting large quantities of LDH into the serum. • For the differential diagnosis of haemolytic and hepatocellular jaundice, the *LDH/GOT ratio* is helpful as an additional parameter. (s. tab. 5.7)

| Normal LDH value (37°C) | | | |
|---|---|---|---|
| Women | < 247 U/l | Men | < 248 U/l |

### 5.1.5 Gamma-glutamyl transferase (γ-GT)

Gamma-GT is found in the liver, bile ducts, kidney, pancreas, epididymis, heart, lung, small intestine, bone marrow, salivary glands, thymus, spleen, and brain. The kidney has the highest specific activity of γ-GT, with a concentration 25 times greater than that of the liver. The heterogeneity of γ-GT was described in 1965 (F. KOKOT et al.). Eleven isoenzymes are known today. (27)

Gamma-GT catalyzes the transfer of the glutamyl residues of various peptides. It is the key enzyme of the **glutamate cycle,** and it is also active in the regulation of **glutathione metabolism.** • Due to a strong enrichment in the endothelial cells and pericytes of the cerebral capillaries, γ-GT seems to exert an important **protective and detoxifying function** at the blood-brain barrier (e.g. metabolization of foreign substances via the mercapturic acid pathway).

There is *no γ-GT activity* in muscle, bone and erythrocytes. Despite high γ-GT activity in kidneys, nephropathies do not result in γ-GT elevations. During pregnancy, γ-GT activity is normal or the serum values may show a declining tendency from the second trimester onwards. • In the liver, γ-GT is found in the membranes of hepatocytes and bile duct epithelia. The periphery of the liver lobule has the highest γ-GT activity. Gamma-GT passes from the liver into the bile and is then excreted partly by the kidneys in the urine. (s. tabs. 5.4, 5.5)

**Elevation of γ-GT** was introduced into liver diagnostics by E. SZCZEKLIK et al. in 1961. Elevated values can be attributed to *two causes*: (*1*.) enhanced de-novo synthesis and (*2*.) damage to the liver cell membrane. • The enhanced de-novo synthesis occurs as a result of an induction of the biotransformation enzyme system by foreign, pharmaceutical or chemical substances as well as by cholestasis or bile acids. Three-fold (or higher) rises cannot as a rule be attributed to a sole induction. • Enhanced de-novo synthesis can also be triggered by augmented cellular regeneration, which leads to an increase in the activity of a foetal form of γ-GT. Thus elevated γ-GT can often still be detected during the phase of restoration after acute viral hepatitis even if other indicator enzymes have already returned to normal levels. The higher γ-GT level therefore does not only hint at persisting cellular damage, but is likewise indicative of the stage of regeneration and thus also of the (histologically) prevailing posthepatitic "vulnerable" phase. Likewise, enhanced regeneration

after cirrhosis can be accompanied by elevated γ-GT. (13, 25, 27, 28, 36)

▶ Enhancement of the γ-GT activity − without an associated increase in GPT − can usually be explained as *enhanced induction* or *cellular regeneration*. In both of these cases, this can be seen as a *"physiological" process of adaptation in order to fulfil a more demanding task*. (s. p. 55)

Even minor *hepatocellular damage* results in the release of membrane-bound γ-GT in connection with simultaneous leakage of GPT (the low concentration of the associated GOT portion is not yet detectable at this point). Gamma-GT is known to be a sensitive indicator of hepatocellular damage. Normal γ-GT excludes a liver disease in 90−95% of cases.

In *hepatobiliary diseases*, the sensitivity and specificity of γ-GT is 95%, since γ-GT is also located in cholangiocytes. In individuals with a healthy liver, the specificity is 74%, in overall healthy individuals it is 95%. • In cholestasis, the sensitivity of γ-GT is six times that of AP and nine times that of LAP. • Obstruction of bile flow can be the cause of isolated γ-GT elevation in fatty liver.

*Alcohol-induced liver damage* elevates γ-GT. The level of elevation depends on various endogenous (including genetic) and exogenous factors. Alcohol induction, such as can be measured by elevated γ-GT, only occurs after prolonged *regular* alcohol abuse and disappears only after *rigorous abstinence for several weeks*. Yet, γ-GT is not alcohol-specific. Some 20−30% of alcoholic patients even have normal γ-GT values.

▶ It is factually wrong and not justifiable to base the assessment of persistent alcohol abuse (particularly in cases involving legal decisions, e. g. drinking and driving) *solely* upon elevated γ-GT levels. • The "possibility" of an alcohol-induced γ-GT elevation has to be made "probable" in each individual case by applying further laboratory tests, by means of psychological testing and by ensuring that all other causes of γ-GT elevation have been ruled out.

*Elevation of γ-GT* is found in cholestasis, liver cirrhosis, viral hepatitis, fatty liver, porphyria, toxic liver damage, pancreatitis and pancreatic cancer, myocardial infarction, nephrotic syndrome, diabetes mellitus, right heart failure, obesity, nicotine abuse, and brain tumours. There is a good correlation of γ-GT with CEA in colon cancer, involving a metastatic spread to the liver − an increase in γ-GT in neoplastic disease is likewise supportive of the diagnosis of hepatic metastases.

A permanent rise in γ-GT due to liver cirrhosis suggests *primary liver cell carcinoma*. The sensitivity of isoenzyme II was very high at 90%; this parameter therefore proved to be more reliable for diagnosis and follow-up than AP isoenzyme-1, α$_1$-foetoprotein or α$_1$-antitrypsin. Isoenzyme-2 of gamma-GT is reported to be the best marker during the early stages of primary liver cell carcinoma. (36)

A **decline in γ-GT** to subnormal levels can be observed during oestrogen administration and from the second trimester of pregnancy onwards (15) as well as with excessive consumption of coffee. • In haemolysis, false-low values may be found.

**Normal values of γ-GT** may be the result of "cellular moulting" or due to regular but still individually differing inductions within the biotransformation process caused by toxins. (s. p. 55) Similarly, normal values of γ-GT in women may be brought about by hormonal action (e. g. decline in enzymatic activity through oestrogens).

| Normal γ-GT value (37°C) | |
|---|---|
| Women | < 40 U/l |
| Men | < 60 U/l |

## 5.2 Iron and ferritin

**Hepatocytes** are involved in iron metabolism in two ways: they are the site of transferrin synthesis, and they represent the most important site in the storage of iron in the form of ferritin or haemosiderin. Hence the level of iron in the serum depends on the ability of the hepatocyte to store iron and to synthesize transferrin. *(see chapters 3.11 and 31.17)*

The first observation of **hypersideraemia** in an icteric liver disease was made by A. WARBURG and H. A. KREBS (1927). In 1939 G. HEMMELER used the determination of serum iron to differentiate hepatocellular jaundice from obstructive jaundice, because the latter regularly reveals a normal iron value.

Structural hepatocellular damage causes iron to leave the cell and subsequently results in an increase in serum iron. After diffuse liver damage has worn off, the elevated serum iron level takes a relatively long time to return to normal. This leads to the conclusion that hepatocellular damage is terminated (detectable in the return of enzymatic activities to normal) before the hepatocyte regains the ability to store iron.

The **range of variation** in iron values primarily depends on age, gender and nutrition. In addition, there are distinct circadian variations: in the evening, the iron value is lower than in the morning. Day-to-day changes are also evident (varying RES activity?). • Considerable **interference factors** are possible during the collection of a blood sample: (*1.*) for the determination of iron, an iron-free needle has to be employed, (*2.*) any excessive venous stasis results in elevated iron values, (*3.*) contamination can also be caused by ferrous syringes, and (*4.*) haemolysis has to be avoided.

**Ferritin** shows a direct and quantitative correlation to the iron stored in the RES. It therefore represents a useful indicator of the total concentration of stored iron in the organism. The liver is the organ with the highest ferritin concentration. Thus ferritin levels below 15 µg/l are always an indicator of depletion of the iron depot − with or without associated anaemia. Ferritin is equally important for monitoring therapeutic measures concerning the restoration or reduction of the iron depot. The iron value de-

creases in severe liver diseases as well as in neoplasms, and there is no longer a correlation with the iron stored, whereas serum ferritin levels start to increase. (29) • For the differentiation of primary (idiopathic) haemochromatosis from the more frequent secondary haemosiderosis, the **deferoxamine test** has proved to be reliable.

> **Method:** After emptying the bladder, deferoxamine (one vial of 500 mg) is injected (i.m.) and urine is collected for exactly 6 hours with subsequent determination of iron excretion. Iron levels of >4 mg are considered to be characteristic of primary haemochromatosis, while iron levels of <2 mg are either regarded as normal or caused by secondary haemosiderosis. • This test can also be executed as follows: 10 mg/kg BW deferoxamine (i.m.) with urine collection for 24 hours, whereby haemochromatosis value is >10 mg iron and normal value is <2 mg.

*Elevated iron*, which usually corresponds to increased ferritin, is found *primarily* in idiopathic haemochromatosis and *secondarily* in acute viral hepatitis, liver cell necrosis and necrotic episodes, alcoholic liver diseases, porphyria cutanea tarda, oestrogen administration, etc.

*Reduced iron* is found in infections or chronic inflammations, in neoplasms as a *distributive disorder* (i.e. shift of the serum iron pool to the macrophages), or as *iron deficiency* (i.e. due to reduced iron intake or a decline in transferrin synthesis). Iron deficiency can also appear during liver cirrhosis due to occult bleeding.

| Normal iron value | |
|---|---|
| Women | 23−165 µg/dl |
| Men | 40−168 µg/dl |
| **Normal ferritin value** | |
| Women | 9−140 µg/l |
| Men | 18−360 µg/l |
| **Normal transferrin value** | |
| Women | 190−440 mg/dl |
| Men | 220−500 mg/dl |
| **Iron-transferrin saturation** | |
| 16−45% | |

## 5.3 Zinc

Zinc is an important trace element. *Zinc deficiency* or a disorder of *zinc distribution* plays an increasingly important role in hepatology: hypoproteinaemia, reduction in the urea synthesis or disturbance of cell-mediated immunity may be the result. (s. p. 50) (s. tab. 3.15)

The first description of zinc deficiency in a patient with alcoholic cirrhosis (B. L. VALLÉE et al., 1956) has meanwhile been confirmed by numerous investigations. In cases where zincuria is initially elevated and subsequently reduced, the decreased zinc levels may be used for diagnosis and at the same time indicate therapeutic substitution.

| Normal zinc value | |
|---|---|
| Serum | 0.6−1.2 mg/l |
| Urine | 0.15−0.8 mg/24 hr |

# 6 Disorders of excretion

Within a certain degree of hepatocellular damage, liver cell functions remain completely or widely intact; at least, no impaired partial functions are yet detectable under clinical conditions. As liver damage progresses, however, numerous cellular functions become increasingly affected, so that clinically relevant disorders become evident. Thus impairment of the hepatic excretory capacity can be taken as a criterion of parenchymal damage.

▶ There are basically two metabolic functions which are affected by **disorders of excretion,** both of which take place predominantly in the *smooth endoplasmic reticulum:*

(*1.*) **Endogenous clearance** excretes physiological metabolites in a timely manner and in quantitatively appropriate proportions (e.g. bilirubin, enzymes, bile pigments, bile acids).
(*2.*) **Exogenous clearance** eliminates ingested substances within a certain period of time and in a certain quantity (e.g. foreign substances used in diagnostics).

## 6.1 Bilirubin

Under normal conditions, 250−300 mg bilirubin are produced per day. Primary, albumin-bound, unconjugated and therefore water-insoluble bilirubin is conjugated in the liver to become water-soluble; it can now be eliminated by the kidneys. (s. p. 33)

The differentiation between **indirect bilirubin** (= primary, albumin-bound, water-insoluble/fat-soluble form) and **direct bilirubin** (= secondary, conjugated, water-soluble/fat-insoluble form) using diazobenzolsulfonic acid was introduced by A. A. HIJMANS VAN DEN BERGH (1918). Direct bilirubin can be detected "directly" by way of diazotization, while indirect serum bilirubin can only be determined after extraction with alcohol or in the presence of an accelerator (caffeine, sodium acetate) by way of the diazo reaction. (s. p. 34) • Direct bilirubin consists of two fractions: bilirubin monoglucuronide and bilirubin diglucuronide. Besides these water-soluble bilirubin fractions, serum also contains **delta bilirubin** as a third water-soluble form (half-life is 18 days). Thus together with indirect bilirubin, **total bilirubin** consists of 4 fractions. The serum level for indirect bilirubin is computed from the difference between total and direct bilirubin. In fact, there is no direct bilirubin, but a normal level of <0.3 mg/dl is "faked" when using conventional methods of detection. The excretory capacity of the liver regarding bilirubin is twice the physiologically required level. This is why the serum bilirubin level is only seen to be elevated after substantial disturbance of excretory hepatic functions (e.g. bilirubinuria is recognized earlier than bilirubinaemia). • In men, the concentration of total bilirubin may be slightly higher than in women, with a normal age-related peak between the ages of 20 and

25. The concentration of bilirubin is not influenced by pregnancy.

A *false-pathological elevation* of the bilirubin concentration can be induced by fasting (>24 hrs.), intense muscular activity, haemolysis and certain drugs (e.g. antibiotics, propranolol, methyldopa and oestrogen).

A *false-pathological decrease* of the bilirubin concentration can be induced by the displacement of bilirubin from albumin-binding sites due to pharmaceutical substances or xenobiotics. This leads to an increased migration of bilirubin into the tissue, causing the bilirubin concentration to decline. A decrease in the serum bilirubin value is also found in pregnancy. (15) Intensive exposure to sunlight similarly reduces the serum bilirubin concentration (up to 30% loss).

► **Hyperbilirubinaemia** is a clinical symptom. *Scleral icterus* becomes evident if bilirubin exceeds 1.6−1.8 mg/dl, while clinical *icterus* is diagnosed at levels of >2.5 mg/dl. (s. p. 80) Congenital (hereditary) hyperbilirubinaemias are primary disorders of bilirubin metabolism. Hyperbilirubinaemias are divided into pre-, intra- and posthepatic jaundice. • The diagnostic *sensitivity* and *specificity* of hyperbilirubinaemia for the detection of a liver disease is low. The *prognostic value* is equally low with certain exceptions, e.g. alcoholic hepatitis, primary biliary cirrhosis or mechanical obstruction of bile ducts. • Prehepatic (haemolytic) jaundice can be differentiated from hepatic jaundice using the LDH/GOT ratio in addition to other parameters. • Differential diagnosis of posthepatic (mechanical) and intrahepatic (hepatocellular) jaundice is facilitated by the GPT/GDH ratio. (s. tab. 5.7) • Mechanical jaundice is demonstrated in most cases either by a value of less than 20 in the GPT+GOT/GDH ratio or by a value of more than 6 in the γ-GT/GOT ratio. (s. tab. 5.6) *(see chapter 12)*

| Normal bilirubin value | | |
|---|---|---|
| Total bilirubin | <1.1 mg/dl | <18.8 μmol/l |
| Indirect bilirubin | 0.3−1.0 mg/dl | 5.0−17.0 μmol/l |

## 6.2 Bile pigments in the urine

The various bile pigments urobilinogen, urobilin and stercobilin (along with related polymers) are produced in the intestine. They are excreted predominantly in the faeces, while a minor portion (10−15%) is reabsorbed into the **enterohepatic circulation** by hepatocytes. Minor quantities of bile pigments (<2%) enter the main bloodstream to be excreted as water-soluble substances via the kidneys in the urine (1.0−3.5 mg/day). (s. p. 36) (s. fig. 5.3)

Under normal conditions, **bilirubin** is not detectable in the urine. Bilirubinuria may occur in hepatobiliary diseases, with bilirubin regularly appearing in its conjugated (water-soluble) form. Bilirubinuria may be identified prior to the detection of icterus. Jaundice without parallel bilirubinuria suggests unconjugated hyperbilirubinaemia.

The determination of **urobilinogen** based on the aldehyde reaction (which is non-specific for urobilinogen) was established by P. Ehrlich (1901). Excretion of urobilinogen in the urine is influenced by a number of factors. Since urobilinogenuria only occurs in relatively serious disorders of the hepatobiliary system, it is only of minor diagnostic relevance. • A *lack of urobilinogen* in the urine in the presence of jaundice points to complete obstructive jaundice. Even after total cessation of bile production due to severe liver disease or destruction of the intestinal flora, urobilinogen may also be absent. (s. fig. 5.3) (s. tab. 5.8)

*Fig. 5.3:* Enterohepatic circulation and excretion of bile pigments

**Bilirubinuria**
1. Hepatocellular damage with increased membrane permeability
2. Disorder of bilirubin excretion
3. Intrahepatic bile obstruction
4. Extrahepatic obstructive jaundice

**Prehepatic urobilinogenuria**
   = *severely overstrained functional hepatic capacity*
1. Significant elevation of bilirubin production (haemolysis, *etc.*)
2. Significant increase in intestinal urobilinogen production (ileus, enterocolitis, *etc.*)

**Hepatic urobilinogenuria**
   = *severely limited functional hepatic capacity*
1. Severe liver disease
2. Collateral hepatic circulation (cirrhosis, portal vein thrombosis, occlusion of hepatic vein, *etc.*)

*Tab. 5.8:* Causes of bilirubinuria and urobilinogenuria

**Urine test strips:** Commercially available urine test strips can reliably detect urobilinogenuria and bilirubinuria.

When performed as a routine screening test, the urine may occasionally reveal a positive reaction. *Bilirubinuria* and/or *urobilinogenuria* are attributable to various causes. (s. tab. 5.8)

## 6.3 Bile acids

The liver is the sole organ for the synthesis, conjugation, transport, excretion and reabsorption of bile acids. Therefore, bile acids assume a key role as a test of **endogenous hepatic function,** since they may suggest (*1.*) hepatocellular damage, (*2.*) excretory disorder of the liver, (*3.*) decrease in synthesis capacity, and (*4.*) existence of portosystemic shunts. The determination of bile acids can therefore be utilized as a test of endogenous hepatic function for the diagnosis and follow-up of liver diseases. Elevated values are accepted as a sensitive and early sign of **cholestasis** and thus constitute a precise liver-specific parameter. (37, 40, 83) *(see chapters 3.5 and 13)*

▶ Previous difficulties concerning the method of determination were overcome through the introduction of a reliable **enzymatic dye test,** with a specificity for 3-α-hydroxy groups and a precision of ±5−8%. There is no age-or gender-dependent range of variation. Half-life is 2−3 days.

The *sensitivity* of values determined 2 hours after food consumption seems to be higher than that after fasting. The fasting value is, however, preferred for the sake of reproducibility. In liver diseases, the postprandial increase in serum values can be several times higher than after fasting. In healthy individuals, however, fasting values are only exceeded by 50−70%. The elevation of bile acids in the serum is reflected by an increase in their excretion in the urine (normal < 8 µmol/day). The elevated level of bile acids returns to normal at a relatively slow pace.

The *specificity* of bile acid determination in liver diseases is high, particularly in those with a cholestatic component. The *sensitivity* has been determined as 89%. Congruence with liver histology was found to be 83% after fasting and 96% in postprandial patients. The sequence for *diagnostic accuracy* was determined as: bile acids (fasting) > ICG test > GPT > AP > bilirubin.

| **Normal bile acid value** | |
|---|---|
| Total bile acids | |
| − fasting | 1.0−6.0 µmol/l |
| − postprandial (2 hrs) | 6.0−9.0 µmol/l |

## 6.4 Enzymatic markers of cholestasis

The term "enzymatic markers of cholestasis" (or cholestasis-indicating enzymes) comprises alkaline phosphatase, leucine aminopeptidase (or leucine arylamidase) as well as 5′-nucleotidase and γ-glutamyl transferase. *(see chapter 13)*

### 6.4.1 Alkaline phosphatase (AP)

Alkaline phosphatase catalyzes the biochemical splitting of phosphoric acid ester. • AP (W. M. ROBERTS, 1933) is found in the liver, bone, kidney, intestine, lung and placenta. A *Regan isoenzyme* can be detected as an ectopic variation of placental AP in tumour patients (10−30% of cases). The AP of the liver is located in the cytoplasm and in the membranes, primarily at the biliary pole. Placental AP is also present in the liver. The AP of bile duct epithelia is not elevated in healthy individuals. The serum activity of AP is predominantly due to the isoenzymes of the liver and osteoblasts; only 14% are of renal origin. Half-life is 3−7 days.

The **increase in AP activity** is stimulated by bile acids. A rise in bile acids, which is considered to be the most sensitive and earliest marker of cholestasis, precedes any elevation in AP. The latter derives from enzyme synthesis with increased secretion into the blood. Under pathological conditions, bile duct AP is formed, which is a sensitive marker for hepatobiliary diseases, cholestasis and space-occupying lesions of the liver. The *sensitivity* is 80−100% in cholestatic diseases. AP activity is usually higher in obstructive jaundice and cholangitis than in intrahepatic obstructions, and it is highest in the "vanishing bile duct disease" or in complete obstruction. (13, 39, 41) (s. tabs. 5.9; 13.2−13.4)

1. Bone diseases with osteoblast activity (Paget's disease, rachitis, osteomalacia, bone tumours, aseptic bone necrosis, fracture healing)
2. Autoimmune vasculitis
   Polymyalgia rheumatica
   (*typical:* AP ↑↑ and blood sedimentation rate ↑↑↑)
3. Renal diseases (diabetic glomerular sclerosis, acute tubular necrosis, hypernephroid carcinoma)
4. Tumours, particularly bronchial carcinoma, M. Hodgkin
5. Hyperthyroidism
6. Congestive liver
7. Hyperparathyroidism
8. Leukaemia, lymphoma, multiple myeloma
9. Drugs, chemicals
10. Hyperphosphatasaemia
11. Intestinal ischaemia, coeliac disease
12. Hyperlipidaemia
13. Acromegaly
14. Cystadenoma of the pancreas
15. Sarcoidosis
    *etc.*

***Tab. 5.9:*** Differential diagnosis of elevated alkaline phosphatase (s. tabs. 13.2−13.4)

Elevated AP values are normally found in *periods of growth,* after *fractures* (= activity of osteoblasts and chondroblasts), during the last trimester of *pregnancy* (15), and in *healing processes* (= activation of fibroblasts). An *extremely fatty diet* can increase the isoenzyme of intestinal AP in persons of blood group B or 0. (Osteoporosis shows normal AP values!) • Augmented AP values can also be expected in *diverse diseases* such as congenital (42) or transitional

hyperphosphatasaemia, cardiac infarction, renal insufficiency, chronic obstructive pulmonary disease and pancreatopathy. AP is as a rule markedly increased in healthy women over 65 years. (s. tab. 5.9)

A **decrease in AP activity** is found in congenital hypophosphatasaemia, hypothyreosis, cachexia, haemolysis, pernicious anaemia and fulminant hepatitis due to Wilson's disease as well as in zinc and magnesium deficiency or after intake of oestrogen, clofibrate and anticoagulants. A decline in AP activity during the last trimester of pregnancy points to an impending miscarriage.

| Normal AP value (37 °C) | |
|---|---|
| Women | 55−105 U/l |
| Men | 40−130 U/l |
| Adolescents | 100−400 U/l |

### 6.4.2 Leucine arylamidase (LAP)

Leucine arylamidase (= leucine aminopeptidase) is a ubiquitous enzyme, mainly localized in the liver and bile ducts as well as in the pancreas, breast, intestine and kidney. During pregnancy (as from 2nd trimester), LAP increases. Arylamidases are predominantly localized in the cytoplasm, while aminopeptidases are found in the microsomes of hepatocytes. LAP splits aminoterminal amino acids off from peptides. High LAP activities are detectable in the epithelia of the bile ducts.

*Elevated LAP values* are found predominantly in biliary and cholestatic diseases − in accordance with AP. In liver diseases due to alcohol abuse, LAP values are exhibited both more frequently and with higher values than AP. In hepatitis mononucleosa, LAP is generally also more clearly elevated than AP. Significant increases in LAP are found in pancreatic and breast cancer as well as in collagenoses of the vascular type. LAP is not found in bone: there is no evidence of elevated LAP in bone diseases. Normal LAP in connection with an increase in AP consequently rules out hepatobiliary diseases and requires further investigation. In these cases, parallel determination of AP and LAP is advisable.

| Normal LAP value | |
|---|---|
| Women | 16−32 U/l |
| Men | 20−35 U/l |

### 6.4.3 5′-Nucleotidase (5′-NU)

5′-NU is membrane-bound and can be found in the liver, brain, heart, blood vessels, pancreas and intestine. It is not yet understood why this enzyme does not increase in bone disease, periods of growth or pregnancy. Even in hepatocellular damage (e.g. acute or chronic hepatitis), it is also normal or only slightly elevated. (38)

*Elevation of 5′-NU* is found in cholestasis, biliary diseases and liver tumours (in 80−90% of metastases). It not only precedes, but also persists longer than AP. The

value and accuracy of 5′-NU can be compared to those of LAP. Therefore 5′-NU, like LAP, can be utilized for the causal differentiation of elevated AP, particularly during pregnancy. However, determination of 5′-NU is rarely carried out due to the high expenditure and greater effort required for this method.

| Normal 5′-NU value |
|---|
| 3−26 U/l |

### 6.5 Copper

Copper, another endogenous substance excreted with bile, has received increasing attention in the last few years. It has important functions within the organism. (s. p. 50)

*Elevation* of serum copper is found in cholestasis, obstructive jaundice, primary biliary cholangitis, malignant tumours, kwashiorkor, exocrine pancreatic insufficiency, during the last trimenon of pregnancy and after administration of oestrogens. • A *decrease* in serum copper is typical of Wilson's disease. In some rare cases, it is caused by familial benign hypocupraemia and nutritional deficiency in neonates.

The simultaneous determination of serum iron allows the differentiation of various **iron-copper constellations,** which facilitates differential diagnosis. (s. tab. 5.10)

| Liver disease | Iron | Copper |
|---|---|---|
| Acute viral hepatitis, acute hepatic damage | ↑ | N |
| Mechanical jaundice<br>− early stage<br>− late stage | N<br>N | N<br>↑ |
| Chronic hepatitis, cirrhosis, scarred liver | N− ↑ | |
| Primary biliary cirrhosis | N | ↑ |
| Carcinoma | ↓ | ↑ |

| Men | 56−111 µg/dl |

### 6.6 Cholesterol

As early as 1862, A. Flint described **hypercholesterolaemia** in liver disease, particularly in cholestatic forms.

*Elevation* of cholesterol is found in fatty liver, particularly under diabetic metabolic conditions. A rather marked increase in cholesterol can be observed in all forms of cholestasis; differentiation between intra- or extrahepatic cholestasis, however, is not possible. This elevation of cholesterol in obstruction is due to an enhanced synthesis of cholesterol in hepatocytes and intestinal walls as well as to the retention of bile lipids. Marked elevations of cholesterol are detectable in primary biliary cirrhosis and in cholesterol storage disease. A pronounced increase in cholesterol is also found in Zieve's syndrome (L. ZIEVE, 1958).

*Decrease* in cholesterol synthesis is found in severe hepatic parenchymal damage, particularly in cirrhosis.

| Normal cholesterol value |
|:---:|
| $\leq$ 200 mg/dl |

# 7 Disorders of synthesis capacity

The more damage there is to the liver parenchyma, the more intense and varying are the disorders of synthesis capacity. This predominantly affects the synthesis of cholinesterase, coagulation factors, albumin, $\alpha_1$-foetoprotein and lipoproteins.

## 7.1 Cholinesterase (ChE)

Pseudocholinesterase (W. ANTOPOL et al., 1938) represents the total activity of roughly 18 genetically determined variants. It is synthesized in the ribosomes and/or in the rough endoplasmic reticulum. This is also the site of synthesis of the coagulation factors and albumin, thus indicating a close correlation between cholinesterase and these two partial functions. Cholinesterase is released as an inactive secretory enzyme into the bloodstream, where it is activated. Half-life is 10 days. Under physiological conditions, the activity of serum ChE is held constant within a normal range. During pregnancy (as from 2nd trimester), ChE activity declines.

A **decline** in ChE activity is found in a number of diseases and/or in connection with damaging effects. The reduction in enzymatic activity correlates with the restricted synthesis capacity of the hepatocytes. (44)

(*1*.) *Liver diseases:* severe acute (necrotic) hepatitis, chronic hepatitis, chronic alcoholic liver damage, liver cirrhosis, cardiac liver, liver abscess, liver tumours and liver metastases, toxic liver damage, etc. • A severe and, above all, constant reduction in ChE activity (e. g. < 500 U/l) is usually suggestive of an unfavourable prognosis and the foreseeable moment of "liver death".

(*2*.) *Medicaments:* cytostatic substances, contraceptives, streptokinase, parasympathicomimetics, glucocorticoids, etc. (1)

(*3*.) *Inflammatory processes:* enteritis, colitis, tuberculosis, trichinosis, polymyositis, infectious diseases, burns, irradiation, etc.
(*4*.) *Tumours:* carcinomas, Hodgkin's disease, leukoses
(*5*.) *Postoperative stress syndrome*
(*6*.) *Administration of albumin*
(*7*.) ChE activity is significantly reduced in malignant or tuberculous *pleural effusion* and *ascites*. (45)
(*8*.) *Diseases* such as hypothyreosis, malabsorption, kwashiorkor and pernicious anaemia also cause ChE to decline.

An **elevation** of ChE activity can be detected in fatty liver, obesity, diabetes mellitus, exudative enteropathy, nephrotic syndrome, hyperthyroidism, Meulengracht's icterus, chronic obstructive jaundice, etc. *Specificity* in liver diseases is 61%, and *sensitivity* is 49%. In cirrhosis, however, sensitivity is 88%; normal ChE therefore widely excludes cirrhosis. In connection with other hepatobiliary enzymes, ChE can be useful in the diagnosis and assessment of the course of liver disease. There is a very good correlation of ChE activity with coagulation factors in liver diseases; however, the correlation is less significant with albumin synthesis.

| Normal ChE value (37 °C) | | |
|:---|:---:|:---:|
| Women | 3,930−10,800 U/l | 3.92−10.8 U/l |
| Men | 4,620−11,500 U/l | 4.62−11.5 U/l |

### 7.1.1 Diagnostic accuracy using enzymes

Clinical and enzymatic data of 520 of our patients suffering from various liver diseases were evaluated to assess the diagnostic accuracy of each method. (s. tab. 4.2)
• *In the detection of "hepatopathy", application of 3−7 hepatobiliary enzymes yielded a sensitivity of 95−97%. (13) (s. tab. 5.11)*

| | |
|:---|---:|
| 1. GPT <br> (= *screening enzyme*) | = 81% |
| 2. GPT + γ-GT + ChE <br> (= *3-fold pattern*) | = 95% |
| 3. GPT + γ-GT + ChE + AP <br> (= *4-fold pattern*) | = 97% |
| 4. GPT + γ-GT + ChE + AP <br> + GOT + GDH <br> (= *6-fold pattern*) | = 97% |
| 5. GPT + γ-GT + ChE + AP <br> + GOT + GDH + LDH <br> (= *7-fold pattern*) | = 97% |

***Tab. 5.11:*** Diagnostic accuracy in the detection or exclusion of hepatopathy using 7 hepatobiliary enzymes in 520 patients suffering from various liver diseases (13)

**Threefold pattern:** GPT + γ-GT + ChE was successful as a hepatological check-up; the **fourfold pattern** (including AP) proved completely reliable. Individual cases

may require the inclusion of *GDH* (or *bile acids*). Utilization of enzyme ratios can further improve diagnostic accuracy. (s. tabs. 5.6, 5.7)

## 7.2 Coagulation factors

**Coagulation factors** I, II, V, VII, IX−XIII are synthesized in hepatocytes. To a minor extent, factor I is also synthesized in the intrahepatic RES, while factor VIII is formed exclusively in the RES. Formation of factors II, VII, IX and X as well as of the two inhibitor proteins C and S depends on vitamin K, the absence of which will cause the synthesis to decline. Factors I, V, XI, XII and XIII are formed without the mediation of vitamin K. • Proteolytic enzymes convert coagulation factors into active factors in the plasma. (s. tab. 5.12)

The following **inhibitors** are synthesized in the liver, independently of vitamin K: AT III, protein C inhibitor, $C_1$-esterase inhibitor, $\alpha_2$-macroglobulin, histidine-rich glycoprotein, etc.

▶ The coagulation factors become effective within a proteolytic **cascade system.** This cascade consists of an interconnected exogenous (extrinsic) and endogenous (intrinsic) coagulation system as well as an activating pathway. Coagulators and inhibitors are finely regulated by positive and negative feedback mechanisms to ensure **homoeostasis of haemostasis.** (s. fig. 19.1) Disorders affecting this system can lead to serious complications. (s. fig. 19.2) (s. tab. 5.13)

Coagulation factors are proteins with varying but usually short half-lives. (s. tab. 5.12) Their determination allows the assessment of hepatic function. However, the respective half-life has to be considered. Disorders of coagulation factors are therefore important functional parameters in hepatic diseases − both in severe acute and in chronic cases. • In liver diseases, there may be a lack of coagulation factors, which is predominantly and primarily caused by a disorder of the hepatocyte synthesis capacity. • This lack can also be due to other *causes*: (*1.*) accelerated catabolism, (*2.*) altered biosynthesis of inhibitors, (*3.*) production of "abnormal" factors, and (*4.*) increased demand due to intravasal coagulation.

### 7.2.1 Fibrinogen and factor VIII

In frequent cases, *fibrinogen* is initially elevated in liver diseases and only declines as a result of severely impaired synthesis or severe inflammatory processes (shortening of half-life). • *Factor VIII* shows an atypical reaction: its level is either normal or even slightly elevated in liver diseases, possibly due to enhanced RES activity. (s. tab. 5.13)

| Factor | Synonym | Site of synthesis hepato-cyte | RES/ extra-hepatic | Vitamin K depend-ency | Half-life |
|---|---|---|---|---|---|
| I | Fibrinogen (= substrate of thrombin) | + | + | ∅ | 4−6 days |
| II | Prothrombin (= zymogen of thrombin) | + | | + | 2−4 days |
| III | Thromboplastin (= activator of F VII) | | + | | |
| IV | Calcium$^{2+}$ | | | | |
| V | Proaccelerin (= cofactor of F II activator) | + | | ∅ | 12−15 hours |
| VI | Accelerin (= constituent of F II activator) | | | | |
| VII | Proconvertin (= trigger factor of the exogenous coagulation system) | + | | + | 2−5 hours |
| VIII C | AHG-A (= cofactor of F X activator) | | | | |
| VIII | v. Willebrand factor (= connecting endothelial cells/thrombocytes) | | + | ∅ | 10−18 hours |
| IX | Christmas factor (AHG-B) (= constituent of F X activator) | + | | + | 10−30 hours |
| X | Stuart-Prower factor (= constituent of F II activator) | + | | + | 20−42 hours |
| XI | Rosenthal factor (AHG-C) (= constituent of F IX activator) | + | | ∅ | 10−30 hours |
| XII | Hageman factor (= trigger factor of the endo-genous coagulation system) | + | | ∅ | 2−4 days |
| XIII | Laki-Lorand factor (= fibrin-stabilizing factor) | + | | ∅ | 4−6 days |
| XIV | Fletcher factor (= prekallikrein) | | | | |
| XV | Fitzgerald factor (= activator of F XII) | | | | |

*Tab. 5.12:* Classification and synonyms of coagulation factors, their site of synthesis, vitamin K dependency and half-life (as far as is known)

| **Antithrombin III** | (↓) | ↓↓ | N-↓↓ | N-↑ |

***Tab. 5.13:*** Changes of some parameters of the coagulation system in liver diseases (N = normal) (s. tabs. 19.1; 35.4)

## 7.2.2 Quick's value

Quick's value is referred to as a global test for the determination of thrombin formation (from prothrombin) and fibrin formation in the presence of fibrinogen, calcium$^{2+}$ and thromboplastin (= *thromboplastin time*). This simple test screens factors II, V, VII, IX and X (previously referred to as prothrombin complex). A decline in any of these factors extends the thromboplastin time, i. e. Quick's value (in %) will decline (A. J. QUICK et al., 1933). • Quick's value is rather insensitive, which is understandable in the light of the complexity of the coagulation system with the widely varying half-lives of its factors (2 hours to 4 days). Specificity also is low. In liver diseases, Quick's value (like ChE activity) is known to be a sensitive parameter of hepatocyte protein synthesis. It is extremely valuable in cases of acute hepatitis, intoxication or necrotic episodes for the diagnosis of an impending coagulative disorder. In addition, Quick's value is useful in the follow-up of chronic liver diseases and can be helpful in making prognostic inferences, particularly when combined with ChE. (s. tab. 5.13)

**Koller's test** (F. KOLLER, 1961) differentiates between a lack of coagulation factors due to hepatocellular damage or due to vitamin K deficiency. This test facilitates the differential diagnosis between hepatocellular and mechanical jaundice as well as between liver diseases and bile-duct diseases. The *advantages* are: simple to perform, hardly any side-effects, low in costs.

**Method:** Intravenous administration of 10 mg vitamin K in cases with a Quick's value of <70%. Diagnostically, a return to normal levels of >75% within 24 hours excludes liver disease, but favours vitamin K deficiency. A non-increase in the value indicates liver disease, since the synthesis of factors II, VII, IX and X does not depend on the administration of vitamin K.

**Colombi index** (in %) is the sum of factors II, V and VII (A. COLOMBI et al., 1967). The lower the index, the more serious is the liver disease (<150 = serious, <80 = very serious). With a Colombi index of <70, the prognosis of consumptive coagulopathy is poor. (s. fig. 19.2)

| Normal value | |
|---|---|
| Thrombin time | 16 − 24 sec |
| Quick's value | 70 − 100% |
| Fibrinogen | 180 − 350 mg/dl |

## 7.2.3 Antithrombin III (AT III)

Antithrombin III is formed in the hepatocytes as an $\alpha_2$-globulin. It serves as a physiological **inhibitor of serin proteases** in the coagulation system and thus inhibits activating factors IIa, IXa, Xa, XIa and XIIa. As the name implies, AT III is most effective as an inhibitor of thrombin. Half-life is 2−3 days.

A *reduction* in AT III activity (<70%) can no longer compensate coagulation processes when the activity of the procoagulator is normal or augmented: this increases the impending danger of thrombophilic diathesis (e. g. thrombosis of oesophageal varices with subsequent peptic ulceration). AT III is a specific marker of consumptive coagulopathy. Application of contraceptives causes AT III activity to decline (with genetic predisposition = approx. 1 : 5,000), which is paralleled by an increase in factors II, VII, IX, X and XII (= hypercoagulopathy).

An *elevation* of AT III activity (>120%) is found in cholestasis and obstructive jaundice. This leads to hypocoagulopathy with the danger of bleeding. (s. tab. 5.13)

| Normal AT III value | |
|---|---|
| Activity | 80−130% |
| Concentration | 0.74−1.26 U/l |
| | 220−350 mg/l |

## 7.3 Dysproteinaemia and hypoalbuminaemia

**Albumin** is synthesized in the liver cell. The rate of synthesis is 12−17 g/day (150−250 mg/kg BW), which can be enhanced 3−4 times due to a loss of albumin. The albumin pool of the organism is approx. 500 g. Half-life is 18−21 days. Albumin is determined as a part of serum electrophoresis either quantitatively (g/l or g/dl, respectively) or as a relative percentage (rel. %). Concentrations of globulins are also quantified in this way.

**Dysproteinaemia** is a quantitative or qualitative change in protein fractions in the pherogram. These changes predominantly occur together with increases or decreases in certain proteins, such as acute phase proteins, immunoglobulins, haemostasis parameters, prealbumin-transferrin group and antibodies. Dysproteinaemia can therefore be detected in a number of diseases. A direct diagnosis based on dysproteinaemia or on protein constellations is not possible. There is no hyperalbuminaemia per se (except in exsiccosis). However, *statements* can be made regarding: (*1.*) clarification of the stage of

activity of a disease, (*2.*) assessment of the course of a disease, and (*3.*) assignment to specific classes of diseases (e.g. gammopathies). (s. p. 110)

**Hypalbuminaemia:** For clinical evaluation of hypalbuminaemia, three *essential factors* have to be considered: (*1.*) the long half-life, which can conceal intermittent disorders of synthesis for approx. 2−3 weeks, (*2.*) the respective size of the plasma distribution space, which is inconsistent in liver diseases, and (*3.*) a certain depressing effect on albumin synthesis exerted by the enhanced formation of γ-globulins in the RES. Thus albumin is reduced in *cirrhosis* due to an elevated distribution volume in haemodilution, particularly in association with ascites. Since the half-life is also prolonged in cirrhosis, a reduction in the rate of synthesis by 50% only lowers the serum albumin by 20%. This has to be taken into account when assessing the albumin value in patients suffering from cirrhosis. The diminished synthesis of albumin coincides with the loss of liver parenchyma. A reduction in albumin by 10 g/l is equivalent to a loss of approx. 30 g protein. • Due to the long half-life of albumin, severe acute liver diseases exhibit a decline in albumin only during the later course. Hypalbuminaemia can also be expected in chronic liver diseases, liver tumours, autoimmune diseases, liver abscesses, infectious diseases of the liver, kwashiorkor, etc. Higher sensitivity is revealed by the *prealbumin* value in simultaneous and close correlation with galactose EC. The half-life is approx. 2 days and thus considerably shorter than that of albumin. (46) A reduction in albumin with a parallel elevation of β-globulin is found in cholestasis and primary biliary cirrhosis. Albumin can also decline during pregnancy or due to the intake of contraceptives.

| Normal albumin value | |
|---|---|
| 3.7 − 5.9 g/dl | 56 − 68 rel.% |
| **Normal prealbumin value** | |
| 25 − 45 mg/dl | |

## 7.4 Lipoprotein X (LP-X)

▶ LP-X was detected by D. SEIDEL et al. in 1969 during the course of a **cholestasis syndrome** as an abnormal lipoprotein with a low portion of protein (6%) as well as a high content of cholesterol (22%) and phospholipids (66%). The increase in the LDL fraction in cholestasis (G. B. PHILLIPPS, 1960) was linked to the appearance of LP-X. However, it probably imitates an increase in LDL. LP-X develops in the plasma during cholestasis as a result of the fact that lipoproteins, which are normally excreted with the bile, flow back into the blood and become transformed. *(see chapter 13)*

LP-X can be detected in *cholestasis* in 90% of patients. Its sensitivity is equivalent to the activities of AP, LAP and γ-GT; however, it is believed to possess a better correlation with liver histology. It cannot be used to differentiate between intra- and extrahepatic cholestasis.

Since the normalization of LP-X levels precedes the normalization of cholestasis enzymes, an earlier hint is given of a regressive course of cholestasis. In biliary cirrhosis caused by CDNC, LP-X is considerably elevated. (47)

## 7.5 α₁-foetoprotein (AFP)

▶ The oncofoetal antigen α$_1$-foetoprotein was described in 1963 (G. ABELEV et al.) before being detected in 1964 for the first time by Y. S. TATARINOV in a patient suffering from liver carcinoma. The glycoprotein AFP is formed in the **foetal liver** and is biochemically identical to the tumour AFP of hepatocytes. The (physiologically) elevated AFP in the neonate will slowly and steadily decline to reach normal adult levels by the 10$^{th}$ month.

In **normal hepatocytes** of the adult, AFP is not formed; minute quantities in the serum (as normal levels) result from cellular growth during the course of "moulting". There is no age- or gender-specific influence on AFP levels. Its half-life is 3−6 days.

**Elevation** of AFP is found predominantly in *primary liver cell carcinoma*: sensitivity can be as high as 90−95%, specificity is approx. 80%. The magnitude of this value correlates with the tumour volume (or the tumour AFP concentration) and with the extent of de-differentiation. After successful resection of the tumour, elevated AFP levels decline to normal levels in relation to their half-life. The persistence of elevated levels is indicative of the existence of tumour remnants. Values in excess of 180 µg/l suggest the existence of a primary liver cell carcinoma. Elevated levels should be re-assessed after 2−3 weeks. In 60% of cases, values exceed 100 µg/l, in 50% they exceed 1,000 µg/l, and in 40% even 10,000 µg/l; values of > 2,000 µg/l are virtually conclusive. Elevation is also found during acute necrotic episodes of chronic hepatitis B, whereby such cases frequently develop into cirrhosis and liver cell carcinoma. In a metastatic liver AFP is elevated in some 30% of cases, whereas in gastrointestinal tumours this value is approx. 20%. During regeneration, e.g. in cirrhosis, moderately increased AFP levels (ca. 25%) are detectable, just as occasional temporary elevations are found in liver diseases in general. (43)

The *determination* of AFP is indicated for (*1.*) regular supervision of high-risk groups (HBsAg-positive cirrhosis, haemochromatosis, alcoholic cirrhosis), with more frequent controls as the duration of high-risk disease increases, (*2.*) early diagnosis of primary liver cell carcinoma, (*3.*) monitoring the success of surgical interventions, and (*4.*) postoperative follow-up. *(see chapter 37)*

| Normal AFP value |
|---|
| < 10 µg/l |

# 8 Disorders of metabolism

## 8.1 Ammonia

Ammonia is formed in the cell or by bacteria during various de-amidization reactions of amino acids. A certain quantity (ca. 25%) of ammonia is produced in the intestine by bacteria or through enzymatic action in the intestinal mucosa during protein degradation. This mean value of *intestinal ammonia production* is elevated under normal conditions as a result of the increased consumption of meat or fish and reduced during a predominantly lacto-vegetarian protein diet. Production of ammonia is raised by physical work; a similar effect is possible in constipation.

The **determination of ammonia** in blood is carried out enzymatically, which is considered to be specific, precise and simple. (48) *Serious mistakes* can easily occur during the preanalytical phase of ammonia determination, making it imperative to comply with the "standardized" method of taking a blood sample. (s. p. 91) EDTA blood should be taken with the addition of sodium borate and L-serine. Furthermore, elevated serum $\gamma$-GT activity and increased thrombocytes cause the ammonia level to rise, as does cigarette smoking prior to blood collection. Even minor haemolysis (e.g. in the event of prolonged transport) will spoil the blood for ammonia determination, since the ammonia concentration of erythrocytes is three times that found in plasma. Besides these interfering factors, ammonia concentration is influenced by (*1.*) the metabolic performance of the urea cycle, (*2.*) the extrahepatic formation and elimination of ammonia, and (*3.*) the acid-base status.

Owing to the multitude of factors interfering with the ammonia concentration as well as to the multifactorial pathogenesis of hepatic encephalopathy (HE), it is understandable that there is no correlation between the levels of ammonia and the prevailing HE stage. Nevertheless, a *hyperammonia syndrome* is generally presumed if concentrations in the venous or arterial plasma reach $135-170$ µg/dl. A value of $>150$ µg/dl can be attributed to coma stage I. Here, the arterial ammonia level correlates better with HE than do the values found in venous blood. (s. pp 56, 266)

The **ammonia tolerance test** (C. VAN CAULAERT et al., 1932; E. KIRK, 1936) is carried out with the oral administration of $4-5$ g ammonium acetate or 3 g ammonium chloride. Normally, there is no significant elevation of ammonia levels after 30, 60 and 120 minutes. In hepatic cirrhosis and in portacaval anastomosis, there is a clear elevation with delayed normalization. (49)

| Normal ammonia value (plasma) | |
|---|---|
| Women | $19-65$ µmol/l |
| Men | $27-90$ µmol/l |

# 9 Diagnostics of liver functions

**Principle:** The principle behind the quantitative diagnosis of liver functions is to administer defined test sub-stances with known hepatic mechanisms of elimination with a view to gaining information on single hepatocellular processes for the assessment of certain *partial functions* of the liver. The administration of such substances should facilitate the assessment of liver metabolism, excretion and biotransformation as well as of hepatic perfusion. (13, 63, 68, 71, 80, 89) (s. tab. 5.14)

1. **Metabolic function**
   - Galactose elimination capacity
     (T. STENTAM, 1946; N. TYGSTRUP, 1963)
   - Antipyrine elimination
     (E. S. VESELL, 1968)
   - Ammonia tolerance test
     (C. VAN CAULAERT et al., 1932; E. KIRK, 1936)
   - Tryptophan tolerance test
     (M. RÖSSLE et al., 1983)
   - Methionine tolerance test
     (K. SCHREIER, H. SCHÖNSEE, 1952)
2. **Excretory function**
   - Indocyanine green test
     (L. J. FOX, 1957)
   - Aminopyrine $^{14}$C breath test
     (G. W. HEPNER, E. S. VESELL, 1975)
   - Bromsulfophthaleine
     (S. M. ROSENTHAL, E. C. WHITE, 1925)
   - Bengal rose test
     (G. V. TAPLIN, O. M. MEREDITH, 1958)
3. **Biotransformatory function**
   - Antipyrine clearance test
     (E. S. VESELL, 1968)
   - Caffeine elimination test (= demethylization)
     (E. RENNER et al., 1983)
   - 4-Methylumbelliferone (= glucuronization)
     (H.-D. KUNTZ, 1982)
4. **Hepatic perfusion**
   - Indocyanine green test
     (J. CAESAR et al., 1961)
   - Sorbitol clearance
     (G. MOLINO et al., 1986)

***Tab. 5.14:*** Test substances with various mechanisms of elimination and their applications for the assessment of partial functions of the liver

**Indications:** The application of direct tests of (quantitative) liver functions follows the indications listed below:

1. detection of previously unknown enzymatically inactive liver diseases
2. functional characterization of acute and chronic liver diseases
3. assessment of the course of chronic liver diseases
4. monitoring of recovery
5. specific issues
   - detection and extent of toxic damage
   - therapy trials
   - assessment of prognosis
   - indication for shunting
   - indication for transplantation

**Endogenous functional values** (e.g. albumin, cholinesterase, Quick's value, bile acids) as well as **exogenous test**

**substances** (e. g. galactose, indocyanine green, MEGX and aminopyrine $^{14}$C) allow the reliable clinical evaluation of "liver function". • The quantitative diagnostics of hepatic function cannot be obtained by any other method of assessment (as yet) − not even through imaging or through histology. It is, however, to be expected that in future a more reliable statement regarding metabolic liver function will be possible (e. g. by means of molecular genetics).

► For the **assessment of the course** of chronic liver diseases, valuable results are supplied by defined exogenous test substances, which can determine the prognosis of a disease or the right time for a surgical intervention. In the absence of enzymatic features, the course of chronic hepatitis, hepatic fibrosis or chronic toxic damage can best be determined with the aid of specific functional tests. The course of compensated cirrhosis can also be most reliably supervised using quantitative methods of assessment. • Endogenous and exogenous factors may have unpredictable effects on the results of liver function tests, which leads to an interindividual variation range in reference values. However, intraindividual reproducibility is good, making it possible to assess the progress of each patient more accurately.

## 9.1 Galactose elimination capacity (GEC)

> ► Galactose was introduced by R. BAUER in 1906 as a test substance for the assessment of hepatic function. We have presented the continuous **methodological development** of this liver function test up to the contemporary intravenous injection of galactose in excess substrate. (69)

The galactose test assesses the ability of the hepatocyte to convert galactose to glucose. A healthy liver possesses a capacity to metabolize 500−600 mg galactose per minute. Roughly 90% of parenterally administered galactose is metabolized in the liver − independently of hepatic perfusion. *Galactose elimination capacity* (GEC) correlates well with the "viable liver cell volume" (67) and is therefore referred to as a reliable measure of the metabolic function of the liver. Prior to determination of GEC, 24-hour alcohol abstinence is necessary. (50, 53, 55, 65, 67, 69, 71, 72, 75, 77, 82)

> **Method:** The principle of GEC involves the intravenous administration of galactose in excess substrate in order to assess the maximum rate of hepatic metabolization. This requires a galactose concentration of 0.5 g/kg BW (serum concentration of > 45 mg/dl for at least 45 minutes), which is injected within 4−5 minutes as a 40% pyrogen-free sterile galactose solution. The bladder has to be emptied immediately prior to the injection and subsequently the urine has to be collected for exactly 5 hours to assess the respective galactose excretion (in grams). Blood samples are taken from the fingertip (or from the cubital vein into an EDTA test tube) at 5, 25 and 45 minutes after injection. We have reported in detail on how to conduct this method as well as on the analysis of GEC. (67, 69)

The *advantages of GEC* are obvious: (*1.*) there is no interference with bilirubin, haemolysis or hyperlipid-

aemia, (*2.*) neither a disorder of hepatic excretion nor a change in perfusion will alter the result, (*3.*) there are generally no side effects, (*4.*) blood samples can be taken from the fingertip as well as from the vein, (*5.*) laboratory analysis is easy to perform, (*6.*) costs for the test are low, and (*7.*) quantitative assessment of the degree of severity of a liver disease is possible:

| Degree of severity of the decrease in function | |
|---|---|
| 6−7 mg/kg BW/min | = low |
| 5−6 mg/kg BW/min | = medium |
| 4−5 mg/kg BW/min | = high |
| < 4 mg/kg BW/min | = very high |

| Normal GEC value |
|---|
| > 7 mg galactose/kg BW/min |

## 9.2 Indocyanine green test (ICG)

Indocyanine green was introduced by J. CAESAR et al. in 1961 as a liver function test. • Anionic tricarbocyanine dye is referred to as an *ideal test substance*: (*1.*) it is tolerated very well; there have been no reports of any incidents so far, and even paravenous injection is tolerated; (*2.*) it is excreted unchanged by hepatocytes in the bile as there is no biotransformation − this is why ICG clearance is valid as a measure of hepatocellular uptake and transport processes; (*3.*) there is no interference with drugs (except rifamycin), haemolysis, bilirubin (up to approx. 4 mg/dl) or hyperlipidaemia; (*4.*) the substance is not subject to the enterohepatic circulation; (*5.*) the rapid elimination, which depends on hepatic perfusion ("flow-limited"), allows the calculation of the hepatic flow volume as a whole based on ICG clearance; (*6.*) the method is simple to perform.

The optimal *dosage* of ICG seems to be 0.5 mg (= 0.1 ml)/kg BW. Its half-life is $2.7 \pm 0.6$ minutes and its plasma disappearance rate (PDR) is $25.6 \pm 4.5\%$ (PDR is the elimination per minute as a percentage of the dosage). The injection of ICG has to be carried out quickly (within 10 seconds). Taking a new syringe and the other arm, blood samples are taken after 3, 6 and 9 minutes; the time for collecting the blood sample should not exceed 30 seconds. Samples have to be analyzed immediately. The absorption maximum is at 772 (or 805) nm in the spectral photometer. • According to the literature and in the light of our own experience, the *clinical significance* of the ICG test is to be rated very highly. There is a close correlation between the Child-Pugh classification of cirrhosis and both ICG and the aminopyrine breath test. The ICG test has also proved effective for assessing liver function in PBC as well as in the resected and/or transplanted liver. As yet, however, the high costs unfortunately prevent wider application. (54, 57, 61, 64, 68, 75, 89)

| Normal ICG value |
| --- |
| Half-life < 3.5 minutes |

## 9.3 Aminopyrine $^{14}$C breath test

Features of the test substance aminopyrine (dimethyl-aminopyrine) are: (*1.*) rapid and complete intestinal re-sorption, (*2.*) low protein binding, and (*3.*) almost exclusive metabolization by the liver. The aminopyrine test is known to be non-invasive, methodologically simple and quick to perform. Of importance is a resting period for the patient of at least 30 minutes prior to the intravenous administration of $^{14}$C-aminopyrine in a dosage of 1.5 µCi. Depending on the liver function, radiation exposure of the patient corresponds to $0.6-2.5$ mrem ($= 1-2$ thorax x-rays). The test is also influenced by numerous medicaments and alcohol as well as any alteration in the basal metabolic rate. The procedure finishes with a triple breath test at ten-minute intervals.

> **Principle:** After the test substance has been demethylated by the microsomal enzyme system of the SER (cytochrome P 450), the labelled carbon atoms are catabolized to $^{14}$CO$_2$. The velocity of demethylation can be measured by determining the $^{14}$CO$_2$ value in expired air. Catabolization of aminopyrine is enhanced with elevated activity of the cytochrome P 450 and reduced accordingly due to the loss of liver cell volume. The metabolization is independent of perfusion. Exposure to radiation is minimal.

A number of studies have demonstrated the value of the aminopyrine test. There is a close correlation with histology and prognosis of current liver diseases as well as with the estimation of the operative risk in patients suffering from cirrhosis. Accelerated aminopyrine dissimilation due to toxin-induced microsomal enzyme activation may reveal alcohol or drug abuse even without recognizable liver damage. (51, 60, 71, 75, 76, 83, 86)

| Normal value | |
| --- | --- |
| Oral | $> 7\%$ $^{14}$CO$_2$ within 2 hrs |
| Parenteral | $0.6-1$ mol $^{14}$CO$_2$ within 30 min |

## 9.4 Antipyrine test

Antipyrine is oxidized through biotransformation, independently of perfusion, predominantly in the microsomes, and is excreted after hydroxylation and conjugation. After oral administration (15 or 18 mg/kg BW, respectively), the metabolic clearance ability of the liver (metabolic capacity of the microsomal monooxygenase system) can be assessed by computation of the concentration curve and the plasma half-life (after 3 and 24 hours). The serum half-life and plasma clearance are significantly enhanced/decreased, depending on the reduction in liver function. There is a close correlation with the galactose elimination capacity as well as with Quick's value. ($58-60$, 74, 88)

## 9.5 Caffeine elimination test (CET)

Caffeine is completely absorbed within the intestine, and about 97% is metabolized selectively by the liver − relatively independently of perfusion − by way of microsomal demethylation (E. RENNER et al., 1984). After intravenous administration of 125 mg caffeine (with 125 mg sodium benzoicum) − equivalent to $1\frac{1}{2}$ cups of coffee − a plasma caffeine increase was detected in liver patients, corresponding to the limited demethylation capacity via paraxanthin. The prolongation of half-life and the limitation of plasma clearance (PC) were clearly altered in patients suffering from cirrhosis. The result can be influenced by age, smoking, contraceptives and numerous medicaments, etc. The test shows no side effects, it is cost-favourable and easy to carry out. (56, 70, 73, 81, 87)

| Normal CET value | |
| --- | --- |
| Half-life | $<4-6$ hrs |
| PC | $<2$ ml/kg BW/min |

## 9.6 Monoethylglycinexylidide test (MEGX)

Monoethylglycinexylidide is a metabolite of lidocaine. Cytochrome P 450-dependent metabolization is measured 15 and 30 minutes after i.v. application of lidocaine (1 mg/kg BW, for $2-3$ min) (M. OELLERICH et al., 1987, 1989). The blood sample is taken from the contralateral arm. The basic value (zero value) is subtracted from the MEGX value after 15 and 30 minutes. The MEGX test is influenced by numerous medicaments and substances, since lidocaine-metabolizing CYP 450 3A4 is subject to genetic polymorphism. Such disturbances together with multifarious side effects hinder wider clinical application. • Following liver transplantation, the primary transplant function was correctly predicted in about 85% of cases and primary transplant failure in about 66%. A further study with 69 transplant patients yielded a prognostic sensitivity of 73% and a specificity of 78%. In patients suffering from chronic hepatitis or cirrhosis, the MEGX test showed a good correlation with the severity of disease and proved to be a valuable prognostic criterion of assessment. (62, 84, 85) A comparison between the MEGX test and the aminopyrine or galactose test, however, showed a broad range of values in minor liver diseases ($46 \pm 23$ ng/ml) as well as in cirrhosis ($19 \pm 11$ ng/ml), whereby the aminopyrine test exhibited a better correlation with the increase in severity than did the MEGX test. (78) The metabolic capacity is considered to be sufficiently representative for the functional reserve of the liver. (52)

| Normal MEGX value | |
| --- | --- |
| | 15 min (µg/l): | 30 min (µg/l): |
| Women: | $25-60$ | $41-70$ |
| Men: | $42-90$ | $58-98$ |

## 9.7 Sorbitol clearance

The D-sorbitol test (G. MOLINO et al., 1986) is considered a reliable measure for blood flow in liver parenchyma, i.e. liver plasma flow. A 40-percent sorbitol solution is administered via perfusor i.v. within 3 hours (= 7.5 ml/hr or 50 mg sorbitol/min). There are no side effects. The test is cost-favourable, but time-consuming. • Between 120th and 180th minute urine is collected and blood samples are taken, the latter in 10-minute intervals. (66, 79)

## 9.8 Bengal rose $^{131}$iodine test

This method tests the excretory function of the liver (exogenous clearance), with no metabolization of the substance in the liver. In addition, this test might possibly reveal insufficient parenchymal storage. The Bengal rose test cannot be applied in the icteric patient. For clinical hepatology, this test is of minor importance.

## 9.9 Bromsulphalein test

Owing to various disadvantages and side effects, this test (S.M. RO-SENTHAL et al., 1925) is no longer available today − although it was a helpful diagnostic tool in the past.

# 10 Assessment of mesenchymal reaction

Elevation of indicator enzymes (particularly GPT, GOT and GDH) in the sense of hepatocellular damage is labelled **"enzymatic activity"**. • Quantitative changes of gamma globulins, immunoglobulins, serum copper and procollagen-III-peptide can be suggestive of the mesenchyma being involved in the liver disease. An enhancement of the mesenchymal reaction can be subsumed under the term **"mesenchymal activity"**.

> Any thorough detailed laboratory diagnosis should test and clinically interpret the enzymatic activity as well as the mesenchymal activity.

## 10.1 Gamma globulins

Chronic liver diseases are generally associated with an increase in γ-globulins, which is indicative of the effects of the chronic process on the liver mesenchyma. (100) Gamma globulins invariably possess features of antibodies and are therefore termed *immunoglobulins*.

**Synthesis:** Synthesis of γ-globulins occurs in the RES, plasma cells and lymph nodes. The sinusoids of the liver comprise an abundance of globulin-forming cells. Under normal conditions, however, the proportion of γ-globulins synthesized in these cells is low. The half-life of γ-globulins is between 5 and 23 days. The liver only degrades some 30% of γ-globulins. An elevation of γ-globulins predominantly depends on the chronicity of the liver disease.

**Cause of γ-globulinaemia:** Antibodies directed against tissue antigens, particularly against bacterial antigens of the intestinal tract, are believed to be the cause of γ-globulinaemia. Furthermore, toxins (particularly endotoxins) entering the reticuloendothelial system of the liver via the portal vein are essential causal factors. These substrates stimulate the globulin-forming cells, causing them to multiply and increase their synthesis: each cell will now produce a greater number of γ-globulins. Basically, the cause of polyclonal hypergammaglobulinaemia is the persistence of antigen stimulation due to deficient RES function as well as non-specific generalized immunological ("mesenchymal") hyperreactivity.

**Elevation:** An increase in γ-globulins is found during the late stage of acute or subacute diseases as well as in chronic inflammatory processes and malignomas. • Such an increase can thus be observed to a varying extent during the course of active viral hepatitis, in chronic persistent hepatitis, in chronic toxic or chronic inflammatory liver damage, and particularly in cirrhosis. A characteristic merger of the β- and γ-peaks (so-called "bridging" or "shoulder") can be found occasionally in cirrhosis. The increase in γ-globulins does not provide any diagnostic hints, but it is still useful for the assessment of the course of a liver disease. • It is noteworthy that γ-globulinaemia exerts a certain *depressor effect* on albumin synthesis. The administration of lactulose or paromomycin, for example, for enhanced intestinal detoxification can therefore serve as an initial therapy to minimize the formation and transport of intestinal toxins via the portal vein to the liver RES. (100)

| Normal γ-globulin value |
|---|
| 5.8 − 15.2 g/l |
| 9 − 19 rel.% |

## 10.2 Immunoglobulins

The **humoral** and **cellular immune systems** function jointly as an acquired defence against infection. Whether the humoral or the cellular defence system is predominantly used depends in the individual case on the nature of the pathogen or the foreign body, the reactivity of the organism and the mode of infection. The humoral immune response proceeds via the B-lymphocytes and plasma cells, while the cellular immune response is mediated via the T-lymphocytes. The haematopoetic stem cells mature into B-lymphocytes. These are further transformed to plasma cells, which in turn synthesize IgM, but they can also "switch" to produce IgA and IgG. (99)

In decreasing concentrations, **serum immunoglobulins** consist predominantly of IgG, IgA and IgM with their subclasses $G_{1-4}$, $A_{1-2}$ and $M_{1-2}$. Quantitative changes of immunoglobulins are only partially detected using electrophoresis: the γ-globulin fraction consists predominantly of IgG, while IgA and IgM are detectable in the β- or β/γ-fraction. Catabolization of IgG depends on the respective immunoglobulin concentration, while IgM and IgA are catabolized independently of the serum level. The half-life of IgG is 9−23 days, of IgA 6 days and of IgM 5 days.

There is no known immunoglobulin constellation which is found exclusively in liver diseases and which possesses real diagnostic value in itself. Except for the extent of the parenchymal damage, the course and prognosis of liver diseases are, however, clearly influenced by the intrahepatic mesenchymal reaction. Immunoglobulins thus make possible an assessment of "mesenchymal activity" in the persisting presence of antigen. In liver diseases, an inhomogeneous polyclonal gammopathy is regularly found, with certain immunoglobulin patterns being suggestive of certain liver diseases and courses. This **immunogram** (13) is a valuable tool in the follow-up of diffuse liver diseases and can be used for prognostication. (s. tab. 5.15)

In **acute viral hepatitis A,** there is a marked increase in IgM during the course of 6−8 weeks and a subsequent slight increase of IgG. As of the 2nd week of disease, the IgM level declines faster than the slightly elevated IgG level, with normalization of IgM after 4 weeks. A persistent elevation of IgM and IgG or a marked elevation of IgG is suggestive of persistent (protracted) hepatitis. • Apart from an increase of IgM, **acute viral hepatitis B** and **C** are associated with a stronger and earlier increase in IgG than in viral hepatitis A. Normalization of IgG and IgM values occurs more slowly than in hepatitis A. Normal values of IgG are mostly reached only after 6 months. There are no differences between the icteric and the anicteric form.

There is a marked elevation of IgM in **chronic persistent hepatitis** with normal or only slightly elevated IgA. A continuing rise in IgG would be suggestive of a progression to chronic active hepatitis.

**Chronic active hepatitis** is associated with a strong elevation of IgG with normal or slightly elevated IgM and IgA. Marked elevations of IgG and IgA − with a strong parallel rise in the blood sedimentation rate (BSR), in γ-globulin values and in total protein − are

found in autoimmune hepatitis. These considerable increases in IgG reflect the degree of mesenchymal inflammation with plasma cell infiltration, which is why this form is also referred to as the so-called *"hyper-γ-globulinaemic chronic hepatitis"*. Chronic inflammatory liver diseases are therefore characterized inter alia by marked IgG elevations and only minor IgM increases, even if histology has not yet detected the chronicity of the process. The elevation of IgM, along with IgG, is indicative of the infectious agent still being active within the organism. Cholestatic forms usually exhibit an elevation of IgG.

**Chronic steatohepatitis** reveals only slight elevations of IgA and IgG. A pronounced increase in IgA is usually suggestive of an alcoholic or drug-induced cause. Elevation of IgA and IgG are laboratory markers for the development of cirrhosis.

**Primary biliary cholangitis** or primary biliary cirrhosis are both characterized by strong elevations of IgM. Only occasionally (in 20−30% of cases) is there also an elevation of IgG in immunologically and clinically more active forms. IgA values only show a slight increase during the late course.

In **drug-induced liver damage,** a similar immunological mechanism is conceivable: the respective medicament acts as a hapten, and an endogenic protein turns into an autoantigen. In hypersensitivity reactions, IgE can increase.

**Liver cirrhosis** shows an elevation of all 3 classes of immunoglobulins, which is also the cause of the fusion of the β- and γ-fractions ("bridging"). *(see chapter 35)*

*Tab. 5.15:* Immunogram of various liver diseases (13)

## 10.3  Procollagen-III-peptide (P-III-P)

A **normal liver** contains roughly $7-9$ mg collagen per gram wet weight. Types I, II and IV are detectable in comparable concentrations. With increasing **fibrosis,** especially type I and type III collagen contents rise in the liver. In advanced stages of long-term disease, synthesis of type I prevails. • The chronic inflammatory process of a liver disease activates the connective tissue metabolism with significant elevation of monoamine oxidase and collagen peptidase serum levels. Of all the metabolites of collagen metabolism, the N-terminal propeptide of procollagen III exhibits the best correlation with fibrosis activity. The activity of proteoglycan and glycoprotein metabolisms (and therefore also of lysosomic enzymes) is detected most reliably with the N-acetyl-β-D-glucosaminidase. The lysosome release also reflects the **mesenchymal activity.** • Procollagen III is initially synthesized in parenchymal cells, Ito cells and fibroblasts; it is then secreted into the extracellular space. Here propeptides are split off, whereby the concentration of the separated P-III-P is used as a direct measure for the amount of collagen synthesized and deposited extracellularly. The collagen monomers formed are deposited as collagen fibrils in the connective tissue and some of the P-III-P is discharged into the blood. Further **fibrosis markers** are: P-I-CP, type IV collagen and prolylhydroxylase.

Procollagen-III-peptide was detected by H. ROHDE et al. in 1978. The results of P-III-P determination in liver diseases were presented by the same research group in 1979. P-III-P determination is less important for diagnosis, but it facilitates monitoring the course of a liver disease with respect to the current degree of fibrosis. This makes it possible to obtain information on the *activity* (= connective tissue formed per unit of time) and *reversibility* of liver fibrosis. Thus there is a good correlation between P-III-P concentrations and the histomorphometrically estimated fibrosis activities.

▶ Patients with chronic congestive liver or alcoholic cirrhosis exhibited distinctly elevated P-III-P values. In long-lasting, slightly active posthepatitic cirrhosis, P-III-P possesses only limited value, since type I collagen is predominantly elevated in these cirrhotic forms. Increasing levels of P-III-P are an early and sensitive marker of veno-occlusive diseases. In chronic hepatitis, P-III-P values are often elevated. Sensitivity is 94% for the differential diagnosis of chronic active and chronic persistent forms, whereby this value cannot substitute the histological result. The favourable response to cortisone treatment in chronic hepatitis was allegedly detectable at an earlier stage in the decline in P-III-P values than in the activity of transaminases. In the progression of primary biliary cholangitis, P-III-P may be a good and, in certain cases, an even better marker than histology. There were also marked elevations of P-III-P serum values in extrahepatic cholestasis and schistosomiasis. P-III-P elevations were likewise detectable in progressive drug-induced liver damage, chronic liver congestion, and enhanced mesenchymal activity in the progression of alcoholic fatty liver to chronic steatohepatitis. $(90-98)$

| Normal P-III-P value |
|---|
| $3-16$ µg/dl |
| $0.3-0.8$ U/ml |

# 11  Serological diagnostics of viral hepatitis

Numerous viruses are able to cause acute viral hepatitis. **Primary hepatotropic viruses** lead to a completely independent form. • **Secondary hepatotropic viruses** lead to systemic infection (with various organs being affected) as well as simultaneous and often predominant concomitant hepatitis. • **Tropical virus infections** may at times trigger inflammatory concomitant reactions of the liver. This requires differential diagnosis for epidemiological and clinical reasons as well as to comply with legal regulations *(= notifiable disease)*. (s. tab. 5.16)

**Primary hepatotropic viruses**

1. Hepatitis A virus
   − Picorna virus
2. Hepatitis B virus
   − Hepadna virus
3. Hepatitis C virus
   − Flaviviridae group
4. Hepatitis D virus
   − Delta viroid
5. Hepatitis E virus
   − Caliciviridae group
6. Hepatitis G virus
   − Flaviviridae group

   7. Molecular, partially identified
   − Hepatitis non-A, non-E virus
   − Hepatitis GBV (A−C)

**Secondary hepatotropic viruses**

1. Herpes viruses
   − Epstein-Barr virus
   − Herpes simplex viruses
   − Human herpes viruses
   − Varicella-Zoster virus
   − Cytomegalovirus
2. Enteroviruses
   − Coxsackie virus
   − Echovirus
3. Rubella virus
4. Paramyxoviruses
5. Adenoviruses

**Exotic hepatotropic viruses**

1. Togaviridae viruses
   a. Alpha viruses
      − Semliki Forest viruses
   b. Flavi viruses
      − Yellow fever virus
      − Dengue virus
      − Kyasanur Forest virus
2. Filo viruses
   − Marburg virus
   − Ebola virus
3. Bunya viruses
   − Hanta virus
   − Rift Valley fever
4. Arena viruses
   − Lassa virus

**Tab. 5.16:** Pathogens of acute viral hepatitis as independent or concomitant disease (s. tab. 23.1!)

## 11.1  Hepatitis A virus (HAV)

▶ The uncoated hepatitis A virus was discovered in the stools of afflicted patients with the help of immunoelectron microscopy by S. M. FINESTONE et al. in 1973. This RNA virus has a diameter of $27-32$ nm and belongs to the family of Picornaviridae. It is a spherical particle of icosahedral symmetry (= a polyhedron limited by 20 triangular faces). The RNA possesses functional and structural regions, encoding three enzymatically active peptides (P1 to P3) and four structural proteins (VP1 to VP4). Whereas VP1 to VP3 are easily recognizable from the outside, also for the immune system, VP4 is concealed on the inner side. The genome consists of positive, linear single-stranded RNA with 7,478 nucleotides. It possesses one open reading frame (ORF) with both a 5'NCR and a 3'NCR (non-coding region). The ORF translates a polyprotein, which is degraded into structural protein P1 as well as into non-structural proteins P2 and P3. From P1 and RNA, immature viral particles originate. With the help of the enzymatic degradation into the four capsid proteins VP1−VP4, mature viruses develop. (s. p. 418) (s. fig. 5.4)
*Fig. 5.4:* Structure of the hepatitis A virus. It consists of 60 capsomeres, which as a whole form the capsid

Virus RNA is infectious. HAV multiplies within the cytoplasm of hepatocytes. • Approximately 2 to 3 weeks after infection, the viruses appear in the stool, but disappear after 4 to 5 weeks, thereby terminating the infectivity. As of the 4th week, HAV antibodies (anti-HAV) of the IgM and IgG type appear in the serum as **serological markers.** (s. fig. 5.5) Acute hepatitis A has a high IgM titre, whereas an infection occurring several months earlier can be recognized by a high IgG titre. • Once the infection has been overcome, the elevated IgG titre remains for life. Immunity is permanent. Renewed rises in titre (= *booster effect*) are possible after recurrent HAV contacts. The HAV vaccine induces equal IgM and IgG immune responses. By means of quantitative determination of the total anti-HAV, it is possible, for example, to differentiate between passive immunization and (acute or past) HAV infection. HAV RNA can be detected with the help of hybridization tests, and HAV with the help of PCR. (101, 109, 119) *(see chapter 22.3!)*

*Fig. 5.5:* Scheme of the immune status during the course of acute viral hepatitis A

## 11.2 Hepatitis B virus (HBV)

▶ The hepatitis B virus is a coated, circular, double-stranded DNA molecule, with a (+) partial overlapping strand; the minus strand has a length of approx. 3.2 kilobases. This virus with a diameter of 42 nm is classified as a hepadnavirus of the orthohepadnavirus family. (s. p. 423) HBV is also referred to as **Dane particle** after its discoverer (D.S. DANE et al., 1970). (s. p. 414) It consists of a coat and a nucleocapsid. The **virus coat** is made up of the "s" (= antigen surface), which was discovered as a so-called Australia antigen by R.S. BLUMBERG et al. in 1965. (s. p. 414) It comprises a large (l), medium (m) and small (s) protein. The **nucleocapsid** with a diameter of 27 nm contains the "c" (= core) antigen and the "e" (= envelope) antigen, which is a protein subunit of the core. Thus four **open reading frames** S, C, P and X code for the viral proteins HBsAg, HBeAg and HBxAg as well as for DNA polymerase. Replication of the DNA is effected by reverse transcriptase. There are two regions called DR1 and DR2 (= direct repeat) as well as two regions called Enh1 and Enh2 (= enhancer of the replication). (s. fig. 5.6) *(see chapter 22.4!)*

*Fig. 5.6:* Scheme of genome organization of HBV: a (−) singular strand and a partial overlapping (+) strand with the direct repeat regions (DR 1, DR 2) and the replication enhancer regions (Enh 1, Enh 2); there are four open reading frames (ORF), namely S, P, X and C, with the coding areas for the different HBV proteins (S, pre S1, pre S2 for the three surface proteins s, m and l, P = DNA polymerase, X = X protein, pre C for the HBe antigen and C for the HBc antigen); the nucleocapsid HBc encircles the genome HBV

Besides the complete HBV, there are other DNA-free **HBs particles**, which are detectable in serum as so-called redundant surface material. These particles present as *spheres* or *tubules*. The spherical particles have a diameter of 22 nm, whereby the length of the tubules is variable. Both particles are non-infectious since they possess no precursor polypeptide to bind to the hepatocyte receptor. • The relation of infectious viruses to non-infectious particles is about 1 : 1,000. (s. p. 424) (s. fig. 5.9)

HBsAg particles all contain a common **determinant "a"**, which is coded by the S gene. Apart from that, there are four other distinguishable *subtypes* d, y, w and r, which seem to be of merely epidemiological significance. This

results in four constellations *adw, adr, ayw* and *ayr*, all of which are detected by the serological HBsAg test. (101−103, 106, 107, 114−116, 119) **HBsAg** is identical to the "Australian antigen", which was detected for the first time in 1965 (B.S. BLUMBERG et al.) (103). HBsAg can be demonstrated histochemically in the cytoplasm and on the membranes of the hepatocytes as well as in the serum. Hepatocytes containing HBsAg appear as **groundglass cells** in normal histology. (s. pp 396, 424) (s. fig. 5.7) • After an incubation period of 2 to 6 months, HBsAg appears as the earliest serological marker in the serum − about 2 to 5 weeks prior to the onset of clinical symptoms. Highest values are reached with the manifestation of the disease, followed by a gradual and steady decline to negativity within 3 to 6 months in a favourable course. This reduction in titre cannot be observed in cases with a tendency towards chronicity. HBsAg is neither carrier nor proof of infectivity and is not accepted as a "primary test" for acute HBV infections. HBsAg can be present without complete virus formation. In questionable or minor HBsAg positivity as well as in cases with suspected immunity complexes, an HBsAg-confirming test should be executed. In some 20−25% of cases of acute hepatitis B, HBsAg detection in the serum remains permanently negative. However, even in these patients, antibodies against HBsAg can appear. (s. fig. 5.8) (s. tabs. 5.17, 5.18)

**Fig. 5.7:** Ground-glass hepatocytes (see arrows) in chronic hepatitis B virus infection (s. figs. 22.7, 22.8)

**HBV mutants:** During the infection, HBV can mutate. Such HBV mutants may multiply and thus cause reinfection even in the presence of anti-HBs. There are, for example, pre-core mutants (which prevent HBeAg secretion), X gene mutants, pre-S/S gene mutants ("immune escape mutant") and YMDD mutants of the polymerase gene (especially during lamivudine therapy). (s. p. 425) • Despite successful B vaccination, mutated HBV strains have the potential for eliciting a virus B infection!

**HBeAg** (L.O. MAGNIUS et al., 1972) is detectable in serum together with HBsAg, or shortly afterwards. This condition is present in the nuclei of the hepatocytes and can

**Fig. 5.8:** Scheme of the immune status during the course of viral hepatitis B

be demonstrated by immunoelectron microscopy in the endoplasmic reticulum and cytosol. HBeAg is a subcomponent or a degradation product of HBcAg. It is a marker for replicating HBV, i.e. viraemia, and as such it is proof of infectivity. HBeAg normally disappears at the peak of the disease, generally prior to HBsAg turning negative. Persistence for more than 12 weeks indicates a transition to chronic hepatitis. With the appearance of HBV mutants, which do not form pre-C protein, no HBeAg is produced: disappearance of HBeAg with positive HBsAg is not to be interpreted as a favourable course with the infection being overcome, but as suspected formation of mutants.

**HBcAg** is also found in the nuclei of the hepatocytes, but it is not present in the serum in its free form. (s. p. 424) (s. fig. 22.8!)

**Anti-HBc** is the earliest immunological response to HBV antigens. Initially, there are high concentrations of IgM anti-HBc. This is known to be the most reliable marker of an acute HBV infection, since it is detectable even during the so-called serological gap (which is between the disappearance of HBsAg and the appearance of anti-HBs). (s. fig. 5.8) As the infection progresses, the IgM antibody level steadily declines and eventually disappears after 6 to 12 months, while IgG anti-HBc continues to be present. Persistent IgM titres suggest (*1.*) continuing presence of replicating HB viruses, (*2.*) impending transition to chronic hepatitis, and (*3.*) reactivation of the HBV infection. After HBV infection, IgG anti-HBc will persist and be detectable for a considerable period of time (for many years, possibly for life). Its determination is useful as a marker for the epidemic prevalence of HBV in a population − however, this is not the case with the determination of anti-HBs. • The positive detection of anti-HBc on its own allows various *interpretations*: (*1.*) anti-HBs has disappeared after an

infection long passed while IgG anti-HBc is still present, (*2.*) IgM anti-HBc has again appeared after reinfection, (*3.*) anti-HBc is already being produced, but HBsAg is forming immune complexes with anti-HBs, and (*4.*) there is a "smouldering" or "silent" hepatitis (e. g. in drug addicts, in cases of haemodialysis or in immuno-compromised patients). Although very small amounts of HBsAg are actually found in all cases, they are not detectable, with the result that anti-HBs remains subliminal and only anti-HBc appears. (102) Differential diagnosis between "late immunity" and "smouldering" hepatitis can generally be accomplished via HBV DNA determination (possibly PCR). • Infection with HBV through an exclusively anti-HBc-positive carrier (e. g. by blood transfusion) is possible.

**Anti-HBs** is formed after the disappearance of HBsAg and a subsequent "serological gap" of approx. 5 to 6 months following the infection. (s. fig. 5.8) This gap can be extended by several weeks if the appearance of anti-HBs is delayed. Sufficiently high titres of antibodies ensure immunity against HBV reinfection. Anti-HBs is detectable for many years. Some $10-15\%$ of patients do not form any antibodies and remain HBsAg carriers.

**Anti-HBe** develops with the disappearance of HBeAg in the serum. This serum conversion occurs roughly at the peak of the clinically manifest disease. Detection of anti-HBe is a favourable sign and suggests cessation of (clinically relevant) infectivity. Even this extremely short-lived HBV antibody may nevertheless be present for several years. (s. fig. 5.8)

**HBV DNA** is found in serum as long as there are replicating HB viruses. The sensitivity of *dot-blot hybridization* is in the range of 1 picogram HBV DNA (= 1 billion$^{th}$ of a gram, i. e. $3 \times 10^4$ to $3 \times 10^5$ virus particles). • Meanwhile, a most sensitive method for the qualitative detection of HBV DNA has been developed: in-vitro gene amplification, also known as *polymerase chain reaction (PCR)* (K. B. MULLISS, 1985). This technique allows the detection of 1 femtogram HBV DNA (= 1 trillion$^{th}$ of a gram, i. e. $3 \times 10^1$ to $3 \times 10^2$ HBV particles, approx. $10-100$ viruses/ml). Given this incredible sensitivity, it is doubtful whether such a minimal quantity of viruses has any clinical relevance. • *After all, with the PCR method it was possible to confirm the persistence of replicable HB viruses in 100% of HBeAg-positive patients, in 80% of individuals with anti-HBe and in 57% of "healthy" HBsAg carriers.* • The detection of HBV DNA as the most sensitive marker of virus replication and, as such, proof of infectivity has replaced the determination of DNA polymerase. In routine diagnostics, however, a quantitative test should be used. There are different procedures, e. g. membrane hybridization (dot-blot, slot-blot), branched DNA hybridization.

**HBV replication** occurs in hepatocytes and extrahepatic cells (i. e. in bone marrow, kidney, pancreas, thymus, spleen, lymph nodes and endothelial cells). Results of

the highly sensitive PCR should therefore be interpreted with caution in each individual case. (s. fig. 5.9)

*Fig. 5.9:* Scheme of HBV replication in hepatocytes (or in extrahepatic cells) with incomplete, non-infectious HBsAg particles in the serum in the form of spheres (x) and tubules (xx)

## 11.3 Hepatitis C virus (HCV)

▶ In 1989 molecular biological methods helped demonstrate a hepatitis C virus which was identified as the pathogen in 90% of hepatitis non-A-non-B (Q. L. CHOO et al.). (105) The same research group developed an anti-HCV test (G. KUO et al., 1989). This marker was positive in $70-92\%$ of patients with posttransfusion hepatitis and in $58-79\%$ of patients with sporadic NANB hepatitis. *(see chapter 22.5!)*

The enzyme immunoassay (EIA) of the *1$^{st}$ generation* determined antibodies against a non-structural protein (C 100) of the NS4 region with a sensitivity of 70%. • The *2$^{nd}$ generation* of the anti-HCV test is carried out with a mixture of core (C 22), NS 3 (C 33) and NS 4 (C 100) antigens. • The *3$^{rd}$ generation* possesses in addition the proteins of NS 5. The latter is best suited for the detection of RNA. This meanwhile established third generation test has achieved a significant improvement in the reliability of results. • In suspected HCV infection, an anti-HCV test is required. Anti-HCV titres were detected in $20-40\%$ of patients with acute hepatitis C at the onset of the disease; after 3 months, this was the case in $70-90\%$. In patients with extremely low HCV viraemia, anti-HCV may even be missing. Anti-HCV antibodies are also detectable in the urine and saliva. • Positive antibody titres were found with relatively high frequency in alcoholic cirrhosis, autoimmune hepatitis and PBC as well as in drug addicts. • A positive test does not reveal whether there is still an active infection or whether recovery has been reached. Over the years, anti-HCV can actually disappear from the serum. (s. p. 440)

A positive anti-HCV test should be confirmed by means of the **RT-PCR test** or quantitative **hybridization test**, e. g. branched-DNA hybridization, amplicor technique. With the help of these procedures, it is possible to detect HCV RNA within 1 week after infection. (104, 105, 108, 111, 113, 119, 121) (s. p. 440)

*Tab. 5.17:* Constellations of serological findings and their clinical interpretation during the course of HBV and HDV infection or HBV vaccination (* = immune complex) (107, 114−116, 119) (s. tab. 5.18)

## 11.4 Hepatitis D virus (HDV)

▶ Hepatitis delta virus is a viruoid from the plant kingdom. It requires a helper virus, such as HBV, for its replication. The hepadnavirus HBV delivers its coat protein for completing a pathogen, which then penetrates the hepatocytes. • Up to now, three genotypes of HDV are known. Compared to genotypes 2 and 3, genotype 1 more often leads to a severe or fulminant course as well as the development of HCC. (s. fig. 22.18!) *(see chapter 22.6!)*

**Serological diagnosis** is effected by means of the determination of HDAg and/or anti-HDAg, with parallel positive HBsAg. Acute infections as well as chronic diseases can be confirmed serologically using IgM and IgG anti-HDV. The detection of HDV RNA is possible using PCR. Infection with HDV can occur as coinfection or superinfection. • The *coinfection* is paralleled by positive IgM anti-HBc, HBeAg and HBV DNA as well as IgM anti-HDV. • The *superinfection* usually has the following constellation: predominantly positive IgG anti-HBc, anti-HBe and IgG anti-HD, usually with negative HBV DNA. • After an HDV infection has been cured, anti-HDV usually disappears from the serum, thus making recognition of a previous delta hepatitis virtually impossible. (107, 112, 119) (s. tabs. 5.17, 5.18) (s. fig. 22.18)

During the course of HBV or HDV infection, a multitude of serological findings can be witnessed. A clinical *interpretation of such serological constellations* is necessary for each single case, since this will yield an essential understanding of the stage and course of disease, infectivity, prognosis or serological cure. In single cases, un-

**Constellations of serological findings**

1. Early, presymptomatic phase of acute already infectious hepatitis B (= late incubation period)
2. Onset of manifestation phase
3. Acute hepatitis B
4. Subsiding hepatitis B; persisting infectivity
5. Recent hepatitis B infection; "diagnostic window"; low or no virus persistence or infectivity; probability of immunity to reinfection (development of anti-HBs can be delayed for a period of 4 to 6, or even 12 months)
6. Phase of convalescence/stage of recovery; immunity to reinfection; no infectivity
7. Previous infection; immunity; no sign of infectivity
8., 9. Previous hepatitis B infection with subclinical or chronic course; infectivity; reactivated chronic hepatitis B
10., 11. Chronic course of hepatitis B with varying activity; simultaneous infection with infectivity; high-risk situation (e. g. dialysis)
12., 13. "Healthy" HBV carrier status with varying infectivity; varying immune response; varying threshold of detectability of markers
14., 15. "Ill" HBV carrier status; infectivity; subsiding infection
16. Outcome of active immunization
17. Acute HBV/HDV coinfection
18. Chronic HBV infection with HDV superinfection
19. Subsiding HBV/HDV coinfection with negativity of HDV and persisting infectivity
20. Previous HBV infection long passed; immunity

*Tab. 5.18:* Serological markers allow differentiation of hepatitis B infection (s. fig. 5.9) (s. tab. 5.17)

equivocal interpretations can be further clarified by determining titre levels or IgM antibodies.

## 11.5 Hepatitis E virus (HEV)

Until recently, the entire virus group of NANB hepatitis was thought to be transmitted parenterally; in the meantime, however, an enterally transmitted hepatitis E virus has been identified. It is a single-stranded RNA virus with a diameter of 32−34 nm, which has so far been classified as a calicivirus. (120) According to virological investigations (E. V. KOONIN et al., 1992), it possesses great similarity with the RNA of rubella viruses (of the Togaviridae group). This could also explain the similar consequences of rubella viruses and HEV for both the pregnant woman and the embryo. The viral genome was isolated from the stool of patients, whereas the viral antigen was detected in the liver of infected chimpanzees. In a self-experiment, HEV was transmitted, inducing acute viral hepatitis E (A. CHAUHAN, 1993). Cultivation in cell cultures has not been possible. In the meantime, cloning and sequencing has been successfully performed and a test developed for the detection of *IgM* and *IgG anti-HEV.* (110, 118, 120) *(see chapter 22.7)*

## 11.6 Other hepatitis viruses

As is commonly known, it has been possible to isolate parenterally transmitted HCV and enterally transmitted HEV of the hepatitis non-A-non-B group. However, further types of viruses seem to exist. *The previous NANB group has proved to be a reservoir for several types of viruses (e.g. HFV, HGV, GBV).*

Thus a virus particle was detected which was provisionally labelled *virus F* **(HFV)**. • In a further case, another virus was differentiated as *virus G* **(HGV)**. • In 1992 the research group of G. BERENCSI discovered **yellow fever virus antibodies** in the serum of patients with transfusion hepatitis, although these Hungarian patients had never been in contact with yellow fever. The yellow fever-positive sera (following transfusion hepatitis) turned out to be negative with regard to all other hepatitis viruses. Such a hepatitis virus, cross-reacting with attenuated yellow fever viruses, seems to be the cause of further, still unknown, forms of posttransfusion hepatitis. (117) *(see chapter 22.8−13)*

# 12 Immunological diagnostics

Autoimmunity is essential in each individual − and normally it does exist. Natural autoreactive antibodies ensure **immunological homoeostasis.** The immune system is well-equipped to fulfil its tasks of distinguishing between endogenous and exogenous structures.

Invasion of the organism by infectious or exogenous agents triggers a multitude of cellular **defence reactions** which are intended to help eliminate the foreign agents. The different interactions between the defence reactions of the immune system and the foreign agent cause varying clinical symptoms as well as varying courses of disease.

Chronic liver disease, particularly that of viral origin, can therefore be caused by a **weakened immune system.** In contrast, auto-immune-induced chronic liver disease is attributable to an **over-reaction of the immune system:** the immune system has lost its ability to distinguish between substances of an endogenous and exogenous (or secondary modified endogenous) nature. This leads to immune reactions against endogenous structures and usually also to autoimmune hepatitis. The ability to differentiate exogenous from endogenous applies to both T and B lymphocytes. The balance between helper and suppressor T cells ensures the functional efficacy of the immune system. The maturation process of B lymphocytes into specific antibody-producing plasma cells is supported by helper T cells.

A disorder of this homoeostasis can induce the **production of autoantibodies** or the activation of auto-antigen-specific T lymphocytes. This leads to antigen-antibody reactions. These autoantibodies react with subcellular structures; they are only partly disease-specific and only organ-specific in single cases. There seems to be a certain genetic disposition for immunologically abnormal reactions or immune deficiencies. (230) • In certain liver diseases, such autoantibodies are found with a characteristic frequency or concentration as well as in certain combinations. This condition not only facilitates a differential diagnosis, but also leads to findings of therapeutical value. So far, no specific antibody could be determined as the cause of a liver disorder. However, autoantibodies play a pathogenic role in certain courses of disease. Most antibodies detected in hepatology can also be observed in other diseases without liver involvement. • *Antibodies are occasionally found at low titre levels and even in healthy (particularly elderly) individuals as well as in asymptomatic patients.*

▶ The **detection of autoantibodies** is facilitated by: (*1.*) immunofluorescence in tissue sections, (*2.*) immunodiffusion, (*3.*) counterelectrophoresis, (*4.*) enzyme immunoassay, (*5.*) radioimmunoassay, and (*6.*) immunoblotting.

The most important and most widely applied screening method regarding antibodies in the serum is **indirect immunofluorescence microscopy**. This is carried out on frozen sections of isolated cells or tissue which are incubated with diluted serum of patients. After further incubation with an antihuman antigen marked with a fluorescent dye, a microscopic examination is performed with the help of light of a given wave-length. Then, any fluorescent glow indicates where antihuman antigen has recognized autoantibodies, which are bound to cell or tissue antigens. The detection threshold lies at ca. 100 ng antibodies/ml serum.

**Circulating immune complexes** form in the presence of a quantitative excess of antigens (or antibodies) as small, still soluble particles, which are distributed by the blood in the body, and which penetrate vascular walls or tissues. Here they can initiate multiple damaging mechanisms and even so-called **immune complex dis-**

**eases.** In primary biliary cholangitis and primary sclerosing cholangitis, increased circulating immune complexes were observed. They can be detected by the *Raji-cell test* and the *C-1-q-binding assay.* • When positive, the determination of the **rheumatoid factor**, described for the first time by K. MEYER in *1922 in patients with liver cirrhosis*, may also suggest circulating immune complexes.

## 12.1 System of antibodies

The autoantibodies known in hepatology are classified in **two groups:** (*1.*) *nonorgan-specific antibodies* and (*2.*) *organ-specific antibodies.* Some can be characterized by additional subtypes, which allows a more detailed differential diagnosis (e.g. immunological mixed-forms, overlap with systemic collagenoses) as well as prognostic statements. (s. tab. 5.19) • *Of the more than 100 autoantibodies known to date, some have proved to be very useful for the diagnostic and prognostic assessment of various hepatobiliary diseases.*

---

**I. Nonorgan-specific antibodies**
1. *Antibodies against mitochondria (AMA)*
   *Subtypes:* anti-$M_1$ to anti-$M_9$
2. *Antibodies against nuclear antigens (ANA)*
   − Homogeneous     − Circular
   − Spotted          − Nuclear
   *Subtypes:*
   Anti-ds-DNA          Anti-Sm
   Anti-ss-DNA          Anti-SSA
   Antihistone          Anti-SSB
   Anti-Ul-nRNP        Anti-Scl-70
   Anticentromeres
   Human nuclear antigen (HNA), etc.
3. *Antibodies against histone-2B (IgA type) (AHA)*
4. *Antibodies against smooth muscles (SMA)*
   *Subtype:* Antiactin
5. *Antibodies against microsomes (LKM)*
   *Subtypes:* Anti-$LKM_{1-3}$
                Anti-$MFR_{1-2}$
6. *Antibodies against granulocytes (ANCA)*
   − cANCA = cytoplasmatic ANCA
   − pANCA = perinuclear ANCA
7. *Antibodies against the cytoskeleton:*
   *Subtypes:*
   Anti-intermediary filaments
   Antimicrofilaments
   Antimicrotubuli
8. *Antibodies against ribosomes*
9. *Antibodies against basal cells*
10. *Antibodies against reticulin*
11. *Antibodies against polyalbumin*

**II. Organ-specific antibodies**
1. *Antibodies against liver membrane antigens (LMA)*
2. *Antibodies against liver cytoplasm antigens (SLA)*
3. *Antibodies against biliary duct epithelia*
4. *Antibodies against biliary duct canaliculi*
5. *Antibodies against liver ribosomes*

**Tab. 5.19:** Autoantibodies and their subtypes in chronic hepatobiliary diseases

---

There are chronic autoimmune-associated liver diseases with and without cholestasis which are negative in virus serology. With the help of selected autoantibodies, a detailed laboratory diagnosis can be achieved. (124, 126, 129, 130, 133, 134) (s. tabs. 5.19−5.21; 33.1) *(see chapter 33)*

## 12.2 Antinuclear antibodies (ANA)

Evidently, ANA (first described by G.J. FRIOU et al. in 1957) belong to the natural autoantibodies which are continuously stimulated by a still unknown mechanism (possibly a persisting agent) in certain diseases. However, this antibody phenomenon is inconsistent and neither organ- nor disease-specific. ANA can be visualized by immunofluorescence in cryostat tissue sections of the rat liver and rat kidney as a *homogeneous* (s. fig. 5.10), *speckled* (s. fig. 5.11), circular or nuclear fluorescence pattern. This allows conclusions to be drawn as to the specificity of antinuclear antibodies and in some cases as to the nature of the underlying disease as well.

**Fig. 5.10:** Antinuclear antibodies (ANA) with homogeneous fluorescence pattern, here in chronic autoimmune hepatitis

**Fig. 5.11:** Antinuclear antibodies (ANA) with speckled fluorescence pattern, here in PBC

To a varying extent, ANA are detectable in chronic active hepatitis (CAH), in mixed forms of CAH/PBC and particularly in lupoid hepatitis (autoimmune hepatitis type I) (in 80−100%) as well as in oxyphenisatin-induced CAH. Clinically relevant titres start at a serum dilution of 1:80. Level of the titre, pattern of fluorescence and in particular interaction with the complement system are relevant for the pathogenic valence of ANA. The determination of ANA and SMA is indicated when autoimmune hepatitis is in question.

In the case of a positive reaction, further differentiation of antigen specificity should follow. In the case of a negative reaction together with sufficient clinical suspicion, immunological diagnostics must be extended to include antibodies against microsomes (LKM), ribosomes and the cytoskeleton. (s. tabs. 5.20; 33.1)

## 12.3 Liver membrane antibodies (LMA)

Heterogeneous autoantibodies of the IgG class against liver cell membrane were detected using immuno-fluorescence (W.B. Storch, 1973; U. Hopf et al., 1976). These antibodies are of no essential importance for clinical or differential diagnosis. In addition, their detection is a rather painstaking procedure (requiring hepatocytes of a perfused liver). • Likewise, **anti-LPS** has lost its importance, since it is an impure antigen fraction. • The *asialoglycoprotein receptor* has now been identified as an antigen of anti-LPS. Antibodies against these receptor proteins seem to correlate with the activity of chronic hepatitis.

## 12.4 Antibodies against smooth muscles (SMA)

Antibodies against smooth muscle antigens (SMA) were first detected by G.D. Johnson et al. in 1965. They are found in various viral and toxic forms of hepatitis as well as in PBC and PSC (40−70 % of cases). However, they are extremely heterogeneous. These antibodies react with structures of the cytoskeleton. Actin is the most important target antigen in liver diseases. SMA are not species-specific but organ-specific. The frequency of SMA does not increase with age. (s. fig. 5.12) In general, they have a low titre. They are best detected in the muscular layer of arteries and arterioles. High titres of antibodies of the IgG class and of the anti-actin subtype are found predominantly in autoimmune CAH (type I,

rarely type III) and in mixed forms of CAH/PBC (80% of cases). A high titre and sole occurrence is typical of SMA-positive CAH. (s. tabs. 5.20; 33.1)

*Fig. 5.12:* Antibodies against smooth muscles (SMA) in auto-immune chronic active hepatitis

## 12.5 Antibodies against liver-kidney microsomes (LKM)

Autoantibodies against liver-kidney microsomal antigen (LKM) − otherwise known as antigen against endoplasmic reticulum (AER) − were discovered in 1973 and termed LKM 1 by both M. Rizzetto et al. and W.B. Storch. (s. fig. 5.13) • In the meantime, 5 subtypes have been differentiated. Autoimmune hepatitis type II is classified as anti-LKM 1 subtype. The accepted target antigen is a membrane lipoprotein of the rough and smooth endoplasmic reticulum, in this context cytochrome P 450 2D6. This rarely detectable antibody is often found in high titres in younger patients with chronic aggressive hepatitis. (123) • LKM 2 antibodies have so far only been found in drug-related hepatitis caused by the diuretic agent tienyl acid (J.C. Homberg et

*Tab. 5.20:* Autoimmune-associated hepatobiliary diseases and their possible autoantibody constellations (s. tab. 33.1)

al., 1984). LKM 3 antibodies were found in chronic hepatitis D (O. CRIVELLI et al., 1983). (s. tabs. 5.20; 33.1)

***Fig. 5.13:*** Antibodies (type 1) against microsomes from liver and kidney (LKM) or against endoplasmic reticulum (AER). Antigenic substrate: kidney. Green fluorescence of the cytoplasm, particularly in the third segment of proximal tubules. The distal tubules are negative (40 x) (134)

## 12.6 Antibodies against mitochondria (AMA)

AMA are heterogeneous nonorgan-specific as well as organ-specific antibodies against antigens of the inner and outer mitochondrial membrane. They were discovered in 1965 (J. G. WALKER et al.). These antibodies are visualized in liver as well as in kidney tissue using immunofluorescence. (s. fig. 5.14) • Various research groups have meanwhile identified 9 different **AMA subtypes** associated with different diseases. These antibodies against subtypes have therefore achieved diagnostic and prognostic relevance. (s. tab. 5.21) The diagnosis of a PBC constellation showing a progressive tendency should give rise to more intensive therapeutic measures. (122, 126, 131)

***Fig. 5.14:*** Antibodies against mitochondria (AMA) in primary biliary cirrhosis (diffuse cytoplasmic fluorescence of renal tubuli with additional antibodies against nuclei)

In primary biliary cholangitis, AMA were found in $95-100\%$ of cases at high titres ($>1:100$). They usually

| AMA specificity | Incidence | Antigen specificity |
|---|---|---|
| anti-$M_1$ | syphilis (stage II) | iMM |
| anti-$M_2$ | primary biliary cholangitis (PBC) | iMM |
| anti-$M_3$ | pseudolupus | oMM |
| anti-$M_4$ | active PBC, CAH, AIH | miC |
| anti-$M_5$ | collagenoses | oMM |
| anti-$M_6$ | drug-induced CAH | oMM |
| anti-$M_7$ | cardiomyopathies, AIH | iMM |
| anti-$M_8$ | PBC: unfavourable prognosis | oMM |
| anti-$M_9$ | PBC: favourable prognosis | mcC |

1. **AMA+, anti-$M_2$+**
   - confirmation of diagnosis of PBC
2. **AMA+, anti-$M_2$+, anti-$M_9$+**
   - stages I and II, predominantly stationary course, favourable prognosis
3. **AMA+, anti-$M_2$+, anti-$M_8$+**
   - progressive course, unfavourable prognosis
4. **AMA+, anti-$M_2$+, anti-$M_4$+, anti-$M_8$+**
   - progressive course, cholestatic CAH, less favourable prognosis

***Tab. 5.21:*** Classification of AMA subtypes according to their presumed antigenic specificity and in relation to various diseases (iMM = interior mitochondrial membrane, oMM = outer mitochondrial membrane, miC = mitochondrial internal compartment, mcC = mitochondrial cytoplasmic compartment) • *In other studies, AMA profiles were not confirmed as prognostic parameters*

belong to the IgG class, and they are directed predominantly against the $M_2$ antigen of the inner mitochondrial membrane. (131) Pyruvate dehydrogenase (PDH), branched-chain ketoacid dehydrogenase (BCKD) and ketoglutarate dehydrogenase (KGD) have meanwhile been identified as autoantigens. AMA also appear in chronic inflammatory liver diseases, in particular in cholestatic forms. "Mixed-forms" of primary biliary cirrhosis and CAH always have to be considered. (s. tab. 5.20) • AMA of the subtype $M_5$ are detectable in collagenoses. • In hepatitis induced by iproniacid, AMA of the subtype $M_6$ were frequently found. Since iproniacid was taken off the market, $M_6$ antibodies have no longer been detected. • A significantly elevated AMA titre often presents an early sign of primary biliary cholangitis, long before clinical or laboratory symptoms become manifest. In the case of suspected PBC, subtypes (anti-$M_2$, anti-$M_9$, anti-$M_4$ and anti-$M_8$) should be differentiated when AMA are positive. (s. tabs. 5.21; 33.1)

## 12.7 Antibodies against soluble liver protein (SLA/LP)

These antibodies, detected by M. P. MANNS et al. in 1987, are targeted against soluble cytoplasmatic liver protein as the target protein (SLA). (128) They are likely to be the antibodies described earlier by P. A. BERG (1981), which are directed against a liver-pancreas antigen **(LP).** Anti-SLA-positive patients are always anti-LP-positive as well. They are neither species-specific nor organ-specific, but characteristic of the existence of an im-

munologic disorder. Its (re-)occurrence can also point to a new episode of disease. Anti-SLA or anti-LP are presumably antibodies against cytosol, as first described by W. B. Storch (1975). (133, 134) These antibodies may be an additional subgroup of AIH (type 3). (s. tab. 5.20) Other antibodies are generally detectable only in low titres and frequency. In about 25% of cases, merely SLA antibodies are present.

## 12.8 Antibodies against granulocytes (pANCA)

Perinuclear antineutrophilic cytoplasmatic antibodies (pANCA) react mainly with the target antigen myeloperoxidase, but also with other antigens. An atypical form of pANCA is xANCA, which does not react with myeloperoxidase. This is a combination of cANCA and pANCA, also described as "snowdrift pattern". The antibodies are seen as markers (75−85%) of primary sclerosing cholangitis as well as of colitis ulcerosa and panarteriitis nodosa. In Crohn's disease, pANCA are detectable in less than 10% of cases. pANCA are found in 25−30% of relatives. Their presence in AIH type 1 is helpful in differentiating pANCA-negative AIH type 2. (125, 126, 132) (s. fig. 5.15)

***Fig. 5.15:*** Antibodies against perinuclear antigens of granulocytes (pANCA). Antigenic substrate: granulocytes. Counter-staining with Evans blue. Green fluorescence of the perinuclear cytoplasm of the granulocytes, red colouring of the lymphocytes (100 x) (134)

## 12.9 Antihistone-2B

Antihistone antibodies of the IgA type are significantly correlated with PBC and AIH, occasionally with alcoholic liver diseases. The antihistone antibody is a nuclear antigen. (131) (s. tabs. 5.20; 33.1)

## 12.10 Anti-GOR

The anti-GOR antibody (S. Mishiro et al., 1990) is frequently detected in the early stage of viral hepatitis C. For more information about the *"term GOR"*, see page 679! (s. tab. 33.1) *(Personal information from S. Mishiro!)*.

In borderline cases, **immunological confirmation** is always required, even if only 10−15% of chronic liver diseases are of *autoimmune pathogenesis.* • Apart from that, liver diseases are quite frequently superimposed by immunological *epiphenomena*, just as there can be an overlap with *collagenoses.*

# 13 Biochemical algorithmic diagnostics

From a biochemical viewpoint, **three forms of activity** can be differentiated in hepatobiliary diseases: (*1.*) *enzymatic activity*, (*2.*) *mesenchymal activity*, and (*3.*) *serological and immunological activity.* (s. tab. 5.22)

1. **Enzymatic activity**
   - GPT ↑, GOT ↑, GDH ↑, γ-GT ↑
2. **Mesenchymal activity**
   - γ-globulins ↑
   - immunoglobulins A, G, M ↑
   - copper ↑
   - procollagen-III-peptide ↑
3. **Immunological activity**
   - hepatitis antigens/antibodies +
   - immunoglobulins A, G, M ↑
   - autoantibodies +
4. **Histological activity**

***Tab. 5.22:*** Four forms of activity of hepatobiliary diseases

These do not necessarily correlate with one another − in fact, they may even be present to a markedly different degree, or they may not be detectable at all. Such differentiated observations and interpretations of biochemical findings provide a better insight into the pathophysiological process and course of hepatobiliary diseases. Based on the morphological findings, the pathologist may add *histological activity* as a 4th form of activity with varying degrees of intensity.

► In the case of suspected hepatobiliary disease, **algorithmic biochemical diagnostics,** structured step-by-step, has proved to be efficient and economical for diagnosis or differential diagnosis. The biochemical mosaic becomes all the clearer, the more mutually complementary and separate puzzlestones are inserted. The confirmation of a hepatobiliary disease by means of clinical and biochemical (as well as sonographic) findings is equally possible in the doctor's surgery and under clinical conditions. During this procedure, biochemical parameters have to be utilized in a targeted manner *(and therefore economically)*, adapted according to the relevant issue and extended from a minimum programme into the programme required. Hereby, enzyme-screening schemes and enzyme ratios may be of additional diagnostic help. Only single cases require parameters taken from the maximum programme. (s. tab. 5.23)

| | Minimum | Necessary | Maximum |
|---|---|---|---|
| **1. Enzymatic activity** | GPT, γ-GT | → GOT, GDH | → LDH |
| **2. Synthesis capacity** | ChE, Quick's value | → albumin | → ammonia, galactose EC |
| **3. Excretion capacity** | AP, bile pigments in the urine | → bilirubin, LAP | → bile acids, iron, copper, cholesterol, indocyanine green, LP X |
| | | **Enzyme-screening scheme** **Enzyme ratios** | |
| **4. Mesenchymal activity** | γ-globulins | → immunoglobu-lins, A, G, M | → procollagen – III – peptide, copper |
| **5. Immunological activity** | HBs antigen, HBc antibody, HA antibody, AMA | → HBs antibody, ANA | → HBe antigen, HBe antibody, HBV DNA, HDV, HCV anti-body, SMA, LMA, α₁-foeto-protein *etc.* |

*Tab. 5.23:* Biochemical algorithmic programme for the diagnosis or differential diagnosis of hepatobiliary diseases (12, 13) (s. tabs. 5.6, 5.7, 5.11, 5.15, 5.17, 5.20, 5.21)

# Diagnostics in Liver Diseases

## 6 Sonography

# 6 Sonography

Ultrasonography is a routine examination measure in the diagnosis of hepatobiliary diseases.

*After years of experience with ultrasonography, a well-trained sonographer will produce highly reliable results in the field of liver imaging. • The method neither inconveniences nor harms the patient. Thus there is a broad range of indications for examination by ultrasonography in patients with hepatobiliary diseases. There are no contraindications. Specific diagnostic statements, however, are rarely possible.*

## 1 Physical principles

Mechanical oscillations of $>18,000$ Hz are referred to as ultrasound. In solid bodies, sound waves spread longitudinally as well as transversally; in fluids, gases or body tissue, however, waves only spread longitudinally. The average **velocity of sound conduction** (v) in tissues is approximately 1,500 m/sec.

|  | v (m/sec) | reflection |
|---|---|---|
| Air | 331 | 99.88% |
| Fat | 1,476 | 0.12% |
| Water | 1,496 | 0.00% |
| Muscle | 1,568 | 0.48% |
| Liver | 1,570 | 0.30% |
| Bone | 3,360 | 46.00% |

Ultrasonic waves are generated by a piezoelectric crystal and emitted via a sound-conductive medium. These waves are reflected, broken, dispersed and absorbed by boundary layers. The piezoelectric crystal also acts as a sound-wave receiver and registers the modified ultrasonic waves (= reciprocal piezoelectric effect). They are then converted into an electric signal and displayed by means of oscilloscopic imaging.

This will result in wavelengths of 0.1 to 1.5 mm in the **diagnostic frequency range** of 1 to 20 MHz. The 3.5 MHz range has proved suitable for abdominal sonography based on the B mode (= *brightness mode*). A 5 MHz transducer will increase the resolution (0.6 mm axially, 1.2 mm laterally) but will also decrease the depth of penetration of sound waves (10 cm). Resolution in tissues is approx. 1 mm towards the sound beam (= axial) and $2-6$ mm perpendicular to the axis of the sound beam (= lateral). Resolution thus depends on ultrasonic frequency and focus. An increase in ultrasonic frequency therefore produces higher resolution and greater penetration depth. • A **linear scanner** applies parallel sound waves, while a **sectorial scanner** emits waves of a focal or curved source. Both of these techniques rapidly produce images at a rate of 30/sec (= *real time*). This allows (*1*.) direct monitoring of internal physical motion and (*2*.) mobile handling of the transducer for **dynamic portrayal** and analysis of the image. In this way, the image can be frozen at any stage for documentation purposes, or the process of examination can be videotaped. (1)

## 2 General principles and echo types

The sonographic technique is based on *reflection*; it works by measuring and portraying differences of impedance. Differences in *acoustic characteristics* of structures and tissues are the basis of sonographic differentiation.

The product of sonic speed in the respective tissue, together with the specific tissue density, yields the **acoustic impedance** (= acoustic resistance). Each medium has its own value with regard to sonic resistance. The partition between two media of different acoustic impedance is termed **acoustic interface** (which should not be confused with the anatomical interface). The magnitude of difference of impedance determines the acoustic effectiveness of this interface. • Continuous technical development in grading the degrees of brightness of image points has made it possible to define the **different shades of grey** between the two extremes of reflection, black and white. Various organs, including the liver, exhibit characteristic shades of grey. Connective tissue, fat deposition, liquids, air or cellular infiltration will each alter the **grey scale.** This has considerably improved the differentiation of both the organs and the findings − thus a more exact diagnosis is guaranteed. (1)

Ultrasound impulses emitted into the body are reflected by interfaces, so that boundaries of organs are received as **contour echoes,** whereas internal heterogenicities of organs are received as **structure echoes.** Analysis of the echo structure is seen as a specific feature of ultrasonography. The sonic energy reflected by interfaces is visible on the screen in the form of bright spots. • As a rule, the echo represents an acoustic interface within a solid structure. Sonography can differentiate between various zones: (*1*.) **hyperechoic,** (*2*.) **isoechoic,** (*3*.) **hypoechoic,** and (*4*.) **echofree**. Echofree areas point to the absence of acoustic interfaces, which as a rule corresponds to a "liquid" consistency. (s. figs. 6.4, 6.11)

▶ *The terms "hypodense", "isodense" and "hyperdense" depict pathological changes observed in CT.* For physical reasons, they are reserved for CT examinations and should not be used in sonography. (s. p. 171)

## 3 Artefacts

Sonographic artefacts may at times impede the assessment considerably. (47) Artefacts are mainly associated with the method applied and hence can often be eliminated simply by changing the examination technique. The occurrence of artefacts is largely fostered by extensive differences in acoustic impedance within a particular substrate, especially in the abdomen. In some 5% of cases, artefacts render sonographic examination impossible. They may appear in **multiple forms:**

| | |
|---|---|
| 1. amplification artefacts | 5. mirror artefacts |
| 2. arched artefacts | 6. precursory artefacts |
| 3. artificial sedimentation | 7. repetitive echoes |
| 4. contour aberrations | 8. shadow zones |

# 4 Section planes

The ultrasonographic examination of the liver is performed on the basis of section planes. This investigation is best carried out by adhering to a well-established system. Movement, i.e. repositioning the transducer, should be reduced in favour of tilting and requiring the patient to breathe in deeply. (s. fig. 6.1)

*Fig. 6.1:* Section planes in the sonographic examination of the liver: longitudinal sections (I-IV), transverse section (V), subcostal section (VI), intercostal section (VII)

With the help of these different planes, it is possible to display numerous anatomical formations and structures. (s. tab. 6.1)

# 5 Examination of the liver

## 5.1 Normal findings

The assessment of the liver is based on knowledge of the sonographic anatomy as well as on external, internal and dynamic criteria. Evaluation of sonographic results must allow for the fact that normal findings vary with body height, body weight, shape of the thorax, habitus and age. (32–34, 81, 89) The normal liver parenchyma reveals equal or marginally higher echogenicity than the (right) renal parenchyma. (64) From the age of 60–65 onwards, the liver loses up to a third of its weight ("senile atrophy", F.Th. Frerichs, 1858). (s. tabs. 6.2, 6.3) (s. fig. 6.2)

Close to the **round ligament** of the liver, the lower liver margin is somewhat drawn in and rounded off. There is a circular to oval, precisely circumscribed hyperechoic

| 1. *Longitudinal sections I, II* | size, shape and internal structure as well as motility and compressibility of the left lobe of liver |
|---|---|
| 2. *Longitudinal sections III, IV* | size, shape and internal structure as well as motility and compressibility of the right lobe of liver; gall bladder, porta hepatis, portal vein, inferior vena cava, common hepatic duct |
| 3. *Transverse section V* | porta hepatis, falciform ligament, left lobe of liver |
| 4. *Subcostal section VI* | internal structure of the right lobe of liver with portal vein, portal vein branches and hepatic veins; gall bladder, intrahepatic bile ducts |
| 5. *Intercostal section VII* | right lobe of liver with subphrenic region |

*Tab. 6.1:* Sonographic diagram of hepatobiliary structures and formations using five section planes

*Fig. 6.2:* Normal liver with portal vein (VP), inferior vena cava (VC) and right branch of the portal vein (RHA). Subcostal plane: 1 = left branch of VP; 2 = right branch of hepatic vein; 3 = cranial diaphragm

change of structure, marking the border between the right and left lobe of liver. The higher the fatty tissue content of the round ligament of the liver, the more striking this normal finding appears to be. (s. p. 171!) Dorsal to this finding, a shadow zone may be generated by the absorption of sound waves due to connective tissue present at this site. • Likewise, the structure of the **falciform ligament** as shown by ultrasonography must be observed and correctly interpreted. (39) (s. figs. 6.3; 8.1!) • The *papillary process* of the caudate lobe (= segment I) may be misinterpreted as being a space-occupying proliferation. (43) • An enlarged *Riedel's lobe* shaped like a tongue (as a variation of the norm) may extend

as far as the pelvic region. • The sonographic definition of **liver segments** − particularly by means of laparoscopic sonography − has proved valuable for surgical procedures. (27, 37, 46, 80) (s. p. 138)

---

1. **External criteria**
   - Shape (dorsal and ventral contour)
   - Margin (inferior border of the liver)
   - Surface
   - Size (measuring of the right liver lobe in the MCL)
   - Position (e. g. downward displacement due to pulmonary emphysema)
2. **Internal criteria**
   - Circumscribed alterations
   - Internal structure
   - Sound conduction
   - Vascular structures
   - Anatomical segmentation
3. **Dynamic criteria**
   - Compressibility
   - Pain upon palpation
   - Respiration-related motility
   - Vascular pulsations

**Tab. 6.2:** Criteria for the sonographic examination of the liver

---

| | |
|---|---|
| **Size** | 12 ± 3 cm in the MCL (vertical) 9 ± 1 cm in depth |
| **Shape** | wedge-shaped |
| **Margin** | right ≤ 75°, left ≤ 45°, sharp-edged |
| **Surface** | smooth, slightly concave |
| **Contour** | dorsally and ventrally extended |
| **Internal structure** | fine homogeneous reflexes; somewhat more echogenic than the kidney parenchyma, slightly less echogenic than the pancreas; rather "dark" and "sharply contrasted"; the area of the caudate lobe is usually more hypoechoic |
| **Quadrate lobe** | 43 ± 8 mm |
| **Liver veins** | easily depictable as far as the periphery, < 6 mm, no wall echoes, lumen fluctuations during Valsalva's manoeuvre |
| **Portal vein** | mostly < 12 mm, ventral to the inferior vena cava, marked wall echoes, branching distribution from the porta hepatis, no respiratory modulation |
| **Hepatic artery** | branching with pulsations in the porta hepatis |
| **Bile ducts** | thin, bright reflex bands, mostly demonstrable (< 4 mm; < 50% of the accompanying portal vein branch) |
| **Ductus choledochus** | ≤ 7 mm; following cholecystectomy and in old age ≤ 11 mm |

**Tab. 6.3:** Normal ultrasound findings of the liver. (The liver is an organ rich in variation and thus the figures given should be seen merely as points of reference to be treated individually)

## 5.2 Indications

In the case of suspected liver or biliary diseases, US is always indicated. Sonography has become a routine examination technique. (56, 75) (s. tab. 6.4)

## 6 Diffuse liver diseases

*A normal sonographic finding does not necessarily rule out a diffuse liver disease (30% of cases). • The morphologically normal liver exhibits 20−25% false-positive ultrasonographic findings in terms of a diffuse liver disease. Indeed, in 35−40% of all ultrasound findings in the liver, results can be classified as diffuse parenchymal processes. Ultrasonography is no substitute for histology. • Neither subclassification nor aetiological classification of the various diffuse diseases of the liver is possible by means of ultrasonography. There are, however, criteria and constellations of findings which are typical of some forms of disease. (6, 36, 42, 58, 87, 92)*

The **increase in echogenicity** (i. e. increase in density) of a homogeneous, frequently coarsened structure with decreased sound conduction in the form of a "structurally dense liver" is a reliable indicator of a diffuse liver disease. This increase in intensity and frequency of echoes yields the image of a *"bright (white) liver"* (e. g. fatty liver, haemachromatosis). A diffuse liver disease can also be accompanied by a **decrease in echogenicity,** which is why the hypoechoic liver is known as a *"dark liver"* (e. g. acute liver congestion, acute viral hepatitis, amyloidosis). (s. fig. 6.4)

| Reflex density | Reflex distribution |
|---|---|
| 1. reduced | 1. even |
| 2. loose | 2. irregular |
| 3. moderately enhanced | 3. speckled |
| 4. clearly enhanced | 4. dotted |

*Fig. 6.4:* Structural changes in the hepatic parenchyma with regard to reflex density and reflex distribution

▶ In terms of ultrasonography, various liver diseases appear as diffuse changes in the parenchyma. They usually exhibit uncharacteristic findings. In cases where the diagnosis is uncertain, particularly after employing CT, liver biopsy (or laparoscopy) is then indicated:

| | |
|---|---|
| 1. acute hepatitis | 6. congestive liver |
| 2. chronic hepatitis | 7. systemic haematological diseases |
| 3. fatty liver | 8. liver cirrhosis |
| 4. metabolic diseases | 9. granulomatous liver diseases |
| 5. infectious diseases | 10. diffuse metastatic spread |

## 6.1 Congestive liver

The congestive liver is enlarged and tender upon pressure. The hepatic veins are dilated (normal diameter of the right hepatic vein is < 6 mm) and may be traced to the periphery. The inferior vena cava is widened and no longer exhibits the typical respiration-dependent double pulsation. Characteristic of the chronic congestive liver is the increase in echogenicity, so that during the progressive course of the disease, the findings can resemble those of a micronodular cirrhosis. *(see chapter 39.1)*

## 6.2 Fatty liver

The markedly enhanced echogenicity of the fatty liver ("bright liver" or "large white liver") is due to the high number of water/fat interfaces. (s. fig. 6.5) • False-positive findings occur in roughly 20% of cases. In decreasing hepatic steatosis (< 30%), the sensitivity of recognition is reduced accordingly. Sonographically, a fatty deposit is evidenced in > 20% of hepatocytes in about 90% of cases. There is a good correlation between ultrasonography and histological results, as there is between hypertriglyceridaemia and diabetes. The liver volume measured by ultrasonography is elevated, a fact which is also suggested by the rounded liver margin. The interior structure is inhomogeneously coarsened (in contrast to the kidney parenchyma), sound conduction continuously decreases dorsad, and hepatic veins are poorly imaged. In cases of pronounced fatty liver, the portal vein can be dilated as a result of portal hypertension. In 20−30% of cases involving a fatty liver, the sonographic findings are mistaken for liver fibrosis, haemochromatosis, micronodular cirrhosis, chronic hepatitis C, thesaurismoses and systemic diseases. However, an *acute fatty liver of pregnancy* usually produces a normal sonographic image. • Occasionally, the distribution of fat shows focal disorders. (s. figs. 8.2−8.4) A *focal accumulation of fat* in the liver appears as a hyperechoic area. In contrast, a *focal reduction of fat* within a fatty liver displays a hypoechoic area, primarily ventral to the hilus branching of the portal vein, often triangular in shape, but also with a rounded form. (64) (s. figs. 6.12, 6.13) *(see chapter 31.3)*
*Fig. 6.5:* Pronounced fatty liver (so-called enlarged white liver)

## 6.3 Liver cirrhosis

Sonographic findings in liver cirrhosis are polymorphic on account of the vastly differing individual hepatic structures (loss of parenchyma, regenerative nodes, connective tissue, fat depositions, compressed hepatic veins, etc.). (s. figs. 6.6, 6.7)

The size of the cirrhotic liver varies between hepatomegaly, normal finding and atrophy. The regular pro-

*Fig. 6.6:* Liver cirrhosis with ascites (longitudinal section): the left lobe of liver is rounded and plump; intrahepatic vessels are reduced. Irregular and inhomogeneous structure. Clear undulatory limitation (arrow) on the underside due to nodular transformation. Wide hypoechoic fringe due to ascites

portion of both liver lobes may have changed, resulting in an asymmetric enlargement or reduction of the liver. As a rule, ultrasonography shows the left lobe of liver to be affected to a greater extent and to be larger than the right lobe. The surface appears finely or roughly coarsened − particularly when applying a 5 or 10 MHz transducer. The contours can be seen as rounded edges and are frequently shaped like a bird's head. Echogenicity is increased with reduced sound conduction. The quadrate lobe (segment IV) often shows a reduced diameter (< 30 mm). Since the caudate lobe is less affected by this cirrhosis-related transformation due to its own special blood supply, it appears enlarged, it is strikingly hypoechoic and its contours are clearly delineated − a finding which always points to cirrhosis. Prominent arteries may represent the *"pseudo double-barrelled-gun" phenomenon.* (cf. fig. 6.8) • The Doppler perfusion index (DPI) is usually increased (E. LEEN et. al., 1993). In cases of pronounced cirrhosis, the sensitivity of sonography is 85−90% and it has a specificity of 80−95%. (2, 9, 16, 26, 34, 45, 59, 77, 79, 93, 105, 106) *(see chapter 35)*

## 6.4 Portal hypertension

Detection of portal hypertension *(see chapter 14)* is of crucial importance in the diagnosis of cirrhosis. The sensitivity is 76−80% and the specificity 100%. The following findings may be present: (*1.*) dilation of the portal vein (> 1.5 cm), (*2.*) calibre leap between the extra- and intrahepatic segments of the portal vein in the porta hepatis (so-called *portal vein amputation*), (*3.*) dilation of the splenic vein (> 1.5 cm), (*4.*) widening of the hep-

atic artery, (*5.*) splenomegaly with contact between the liver and spleen (s. p. 135), (*6.*) dilation and/or rigid calibre of the superior mesenteric vein, (*7.*) detection of collateral vessels, particularly in both the splenic and the hepatic porta as well as in the anterior wall of the stomach, (*8.*) thickening of the stomach wall to > 22 mm (73) and of the gall-bladder wall (74), and (*9.*) recanalization of the umbilical vein (s. fig. 6.7), which can be traced to the umbilical region (= *Cruveilhier-von Baumgarten syndrome*). (s. fig. 7.4) (23, 35, 93, 98)

*Fig. 6.7:* Alcohol-induced cirrhosis with recanalized umbilical vein (= hypoechoic band: see arrow); (PV = left branch of the portal vein; CPA = cockade of pyloric antrum) (s. fig. 14.12)

## 6.5 Portal vein thrombosis

Portal vein thrombosis *(see chapter 39.3.3)* with gradual or incomplete obstruction merely produces anastomoses and develops asymptomatically. After complete obstruction, ultrasonography will show paraportal, angiomatous anastomoses, predominantly in the porta hepatis (= *cavernous transformation*). (95) Splenomegaly is evidenced with a normal-sized liver. The portal vein is not detectable. • Colour Doppler sonography has become of paramount importance in portal vein system diagnostics.

## 6.6 Obstruction of hepatic veins

The Budd-Chiari syndrome *(see chapter 39.2.1)* as well as hepatic vein obstruction (type VOD) are discernible by the total absence of hepatic veins or by their diminished lumen. The residual lumen of a vein often shows hyperechoic thrombotic material. Sometimes membraneous webs of varying lengths consisting of hyperechoic structures with acoustic shadows are visible in the lumen of the inferior vena cava. The liver is enlarged. Due to its own venous drainage system, the caudate lobe (= segment I) is noticeably augmented (normal 6.8 ± 1.3 cm) and usually presents a hypoechoic structure. In most cases, ascites is also present. (40, 71, 95)

## 6.7 Jaundice

Diagnostic accuracy in differentiating between obstructive and nonobstructive jaundice *(see chapter 12)* can be achieved in up to 90% of cases. (s. tab. 12.1) • Ultrasonography will reveal the cause of an *obstruction* in 30−60% of patients and localize this occlusion in almost all cases. (s. fig. 25.8!) Ultrasound shows the congested intrahepatic bile ducts as resembling vessels which run parallel to the portal vein branches and are mostly found in a ventral position (so-called *"double-barrelled-gun phenomenon"*). (s. fig. 6.8) These congested bile ducts can also take on a *"lakeland plain"* pattern. (s. fig. 6.9) Close to the porta hepatis, dilated bile ducts may also appear in a radial pattern (so-called *"wheel-spoke phenomenon"*). An extrahepatic occlusion is generally easier to recognize if there is a change in the lumen of the common bile duct when Valsalva's manoeuvre is applied. (67)

*Fig. 6.9:* Blockage and dilation of the intrahepatic bile ducts ("lakeland plain") in obstructive jaundice

*Fig. 6.8:* Double-barrelled-gun phenomenon in obstructive jaundice (see arrow)

## 6.8 Ascites

Ascites *(see chapter 16)* can be successfully diagnosed even in small quantities (< 200 ml). Given a favourable location (preferred sites), it is even possible to detect fluid volumes of < 50 ml. • Such a preferred site of ascites is the so-called *Morrison's pouch*: the inferior surface of the right lobe is anterior to the colon, and posterior to the perirenal fatty tissue. It is separated from the latter by this peritoneal recess, where a small amount of ascitic fluid generally collects. Here it can be detected sonographically at an early stage. • Ascites coats abdominal organs, especially the liver and the spleen, and is shown as an echo-free fringe zone. (s. fig. 6.6) Occasionally, intestinal loops float freely in the ascitic fluid, revealing the mesenteric attachment (so-called *"sea-anemone phenomenon"*). In addition, concomitant pleural effusion may be visible as an echofree zone above the diaphragm. Similarly, pericardial effusion can appear as an echofree zone at the cardiac apex. As a result of adhesions, ascites is possibly discernible in honeycomb-like compartments of various shapes and sizes. (101)

# 7 Circumscribed liver diseases

*Focal changes* are detected by ultrasonography with a sensitivity of 60−95%. The frequency of focal hepatic lesions is 3 to 5% (up to 10%) of all ultrasonic scans. Sonography does not allow a distinction to be made between benign and malignant lesions. (19, 41, 55, 58, 61, 69, 72, 94, 99) • Focal changes in echogenicity give rise to an *inhomogeneous hepatic structure*. This can be caused by focal intrahepatic findings, vascular abnormalities, protrusions of the liver surface or circumscribed congestion of the bile ducts. The greater the difference in acoustic characteristics and the clearer the demarcation between focal changes and the surrounding liver parenchyma, the easier it becomes to detect such a focus by means of ultrasonography. Calcium-dense foci of a diameter of 3−5 mm, cystic formations of 5−8 mm and solid foci of 5−10 mm can therefore be identified. Such irregular permeation of the liver with different tissue structures will result in a homogeneously irregular image in ultrasonography, resembling a diffuse liver disease. • Detection of small foci close to the capsule is easier if a 5 MHz transducer is used.

## 7.1 Echofree lesions

Echofree lesions are: (*1.*) cysts, (*2.*) abscesses as well as necrotic colliquation of metastases, and (*3.*) fresh or re-

liquefied haematomas. (48, 85) • Caroli's syndrome (83), Osler's syndrome (95) and peliosis hepatis (54) may be assigned to this class as well. These echofree lesions exhibit distal sound amplification. (s. fig. 9.4)

**Cysts** *(see chapter 36.4.14)* are typically echofree, round, with a smooth, thin, limiting wall; they show a subsequent (dorsal) amplification of echo. Sizes of 0.5 cm and more can be clearly identified using ultrasound. The prevalence of (dysontogenetic) *congenital hepatic cysts* in the general population is $3-5\%$. They are mostly found in the right liver lobe, more frequently in women than in men, and are multiple in around 25% of cases. The cysts are usually $1-3$ cm in size. However, they develop at differing rates and can grow to as much as 20 cm in diameter. When they reach a certain size, the cysts can have suppression effects within the liver itself and also on adjacent organs. (s. figs. 6.10; 36.9) Bleeding into the cysts can cause internal sedimentary echoes in the cyst lumen. (11) • In autosomal dominant *polycystic liver disease* (96), varying numbers of different-sized cysts are found in the liver and in the kidneys, sometimes also in the pancreas and the spleen. The overall frequency is $0.5-0.8\%$. (s. figs. 8.6; 36.12) • *Hydatid cysts* often comprise daughter cysts with a doubling of the wall contour. The echo image may be extremely heterogeneous. The cyst walls are sometimes hyperechoic and thicker (with occasional calcification); they mostly show a smooth contour. (20, 52) A typical finding is the presence of smaller daughter cysts inside the mother cyst, e.g. honeycomb pattern in type II b or III. (s. figs. 25.15, 25.16) For purposes of sonographic classification, it has proved beneficial to have five categories. (30)

**Fig. 6.10:** Liver cyst. (C = cyst; HV = hepatic vein; VC = inferior vena cava; L = right lobe of liver; arrows = hyperechoic area below the cyst) (s. figs. 8.6; 36.9)

**Abscesses** *(see chapter 27)* display fine interior echoes, irregular shapes and blurred walls. There are repetitive echoes (so-called *"comet-tail phenomenon"*). Differentiation between an amoebic and pyogenic abscess is not possible with sonography. In the light of the multiple aspects of ultrasound findings regarding abscesses, a three-type classification system has been drawn up in line with the respective internal structures, which has been broken down further into types IIIb, IV and V. (38, 68, 91) (s. pp 175, 513) (s. figs. 6.11; 9.2; 25.1)

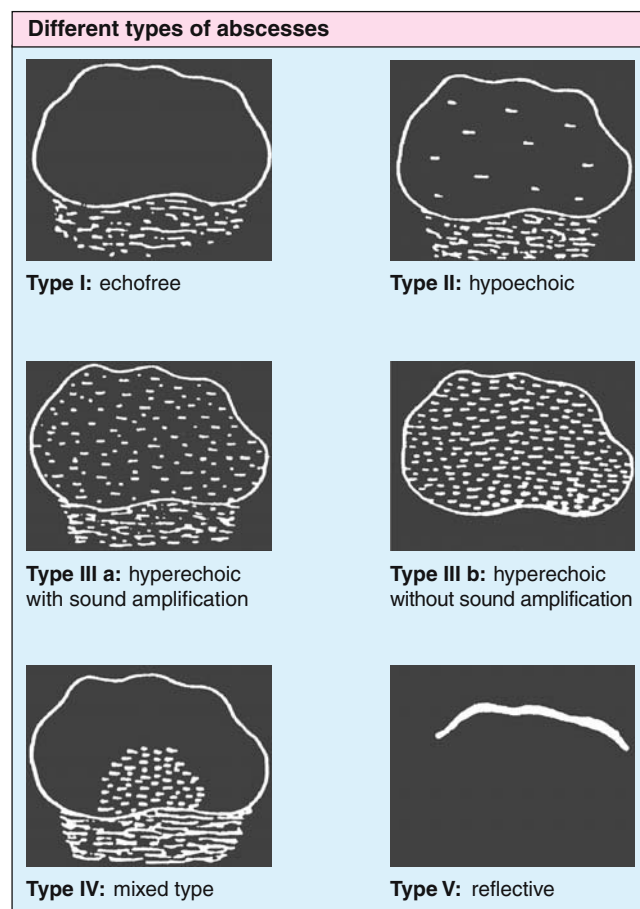

**Fig. 6.11:** Synoptic view of 5 different types of abscesses as shown by means of sonographic examination (38)

## 7.2 Hypoechoic lesions

The following lesions may be hypoechoic: (*1.*) metastases, (*2.*) liver cell carcinoma, (*3.*) adenomas, (*4.*) focal nodular hyperplasia, (*5.*) abscesses, (*6.*) haematomas, (*7.*) early liver infarction, (*8.*) foci showing reduced fatty infiltration, (*9.*) lymphomas, and (*10.*) lipomas. In individual cases, differentiation between a benign and a malignant structural defect may cause considerable difficulties. (59) (s. fig. 9.4)

**Adenomas** *(see chapter 36.4.1)* are encapsulated hypervascularized tumours. They have a smooth wall, are variable in size and are round to oval. As a rule, they are solitary (right more than left). They can be both hypoechoic as well as (more rarely) hyperechoic, possibly due to bleeding within the adenoma.

**Focal accumulation of fat** is predominantly found either near to the falciform ligament of the liver or to the por-

tal branches as well as in segment IV. It appears as an irregularly limited hyperechoic focus, which is often difficult to classify by differential diagnosis and can even be misinterpreted as being malignant. Blood vessels run normally. (31, 78, 97) (s. figs. 8.2−8.4) • **Focal reduction of fat** in a fatty liver (in alcohol abuse, diabetes mellitus, chemotherapy) is predominantly found close to the gall bladder or the caudate lobe. Mostly it has a triangular shape, and there is a vascular association. In rare cases, it shows a round shape. (13) (s. figs. 6.12, 6.13)

***Fig. 6.12:*** Focal reduction of fat in a fatty liver: hypoechoic, triangular shape (see arrow) near to the right branch of the portal vein (PV) and the gall bladder (GB); (VC = inferior vena cava)

***Fig. 6.13:*** Focal reduction of fat in a fatty liver: hypoechoic round shape (see arrows)

**Focal nodular hyperplasia** *(see chapter 36.4.2)* − as a benign hepatocellular tumour − is mostly hypoechoic. Occasionally, it can be differentiated as a protruding contour or a pediculate liver tumour. Compression of the surrounding liver tissue may be the cause of a visible "capsule", which actually has no anatomical structure of its own. At a size of > 3 cm, fibrous septa and arteries

can resemble a typical *wheelspoke structure*, often with a clearly visible central core. • The blood circulation within the tumour can be visualized by means of contrast medium: early arterial hyperperfusion is usually in evidence. As a hypervascularized lesion, FNH sometimes has afferent arteries, which may surround the lesion like a basket. (s. fig. 6.14)

***Fig. 6.14:*** FNH: Hypervascularized internal structure with hyperechoic star-shaped scar (= wheele-spoke pattern)

Macronodular **tuberculosis** (51), **granulomatosis** of the liver (60) and particularly **liver metastases** may likewise appear as focal liver diseases with differing echogenicity. **Haematomas** are initially hyperechoic, but turn hypoechoic when they liquefy within a few days, and even become echofree at a later stage. "Older" haematomas usually revert to being hyperechoic. (48, 85)

**Lymphadenopathy:** Enlarged abdominal lymph nodes are frequently detectable in acute viral hepatitis (A−D) and chronic hepatitis (B, C) − occasionally also in autoimmune hepatitis, primary biliary cirrhosis and primary sclerosing cholangitis. (12) Lymphadenopathy corresponds to the histological stage of chronic hepatitis C. (21) Sonographic determination of perihepatic lymphadenopathy predominantly in the hepatoduodenal ligament (57, 118) is not regarded as a pathognomonic sign of a underlying malignant disease.

## 7.3 Hyperechoic lesions

Hyperechoic lesions may be (*1.*) metastases, (*2.*) liver carcinoma, (*3.*) cholangiocarcinoma, (*4.*) haemangioma, (*5.*) hamartoma, (*6.*) nodular regenerative hyperplasia, (*7.*) old haematoma, (*8.*) focal fatty infiltration, (*9.*) echinococcus alveolaris, (*10.*) scarring, (*11.*) calcification (s. fig. 9.4), and (*12.*) aerobilia (s. fig. 32.6).

**Haemangioma** *(see chapter 36.4.4)* − the most common benign finding − is usually detected incidentally as a homogeneous and frequently circular focal lesion. It is

found in solitary or multiple (10−30%) form. The frequency is 8 times higher in women than in men. The preferred localization is close to the diaphragm or larger vessels. A haemangioma does not produce any biochemical variations from the norm. Occasionally, there is an afferent or efferent vessel. • The *typical haemangioma* (approx. 90%) has a diameter of 1−4 cm; it is uniformly hyperechoic (a white tumour like a "snowball"). It forms a clearly defined yet irregularly shaped ("lobulated") surface with a distal amplification of sound. It is often found close to a hepatic vein. It has no halo. A centripetal filling in a high-flow haemangioma (like the CT "iris diaphragm phenomenon") can be detected using echo contrast CHI. In a small number of cases (<0.5%) it may happen that a malignant tumour is hidden beneath the image of a haemangioma, and thus goes unnoticed. (50) (s. fig. 6.15) • The *atypical haemangioma* is indistinctly circumscribed and is usually larger than 4 cm. The inhomogeneous hyperechoic internal structure is caused by multiple acoustic interfaces (cavernous cavities of blood, bleedings, thrombosis, organized tissues, etc.). Large haemangiomas may exhibit the *"chameleon phenomenon"*: when the patient assumes a different position, they change their echogenicity. (100)

*Fig. 6.15:* Typical haemangioma: hyperechoic density like a white tumour ("snowball") near to a hepatic vein (= red-coloured) (s. figs. 8.5, 8.9; 36.6, 36.7)

**Nodular regenerative hyperplasia** *(see chapter 36.4.3)* is also deemed to be a benign hyperechoic structural deficiency. These multiple foci resemble grapes in their appearance and are found in the direct vicinity of vessels, possibly causing portal hypertension. Foci are 1−3 cm in size and may easily be confused with metastases.

**Echinococcus alveolaris** *(see chapter 25.2.3.2)* is a solid and irregularly shaped focus. Inside, small cysts can be differentiated. It exhibits infiltrating growth and can imitate a malignant process.

**Hepatocellular carcinoma** *(see chapter 37.3)* is five times more frequent in men than in women. Hypoechoic as well as hyperechoic structural defects are observed, with a variety of different sound qualities present in a single tumour. The carcinoma may appear as a solitary or

multiple phenomenon, at times also infiltrating diffusely. HCC can be differentiated from regeneration nodes by enhanced early-arterial perfusion of the contrast medium. However, there is a "chaotic" vascular pattern (as opposed to that witnessed in FNH). The rate of detection is 35−40% (<1 cm diameter of the tumour) and approx. 90% (>1−2 cm in size). When applying endoscopic or intraoperative ultrasonography (s. p. 138), the respective values are 86% and 98%! Most frequently, hepatocellular carcinoma develops in cases of liver cirrhosis (ca. 75%) or haemochromatosis (ca. 20%), which further complicates the diagnostic process with ultrasonography. (8, 22, 59, 76, 99, 100) (s. fig. 6.16)

*Fig. 6.16:* Hepatocellular carcinoma (subcostal section) with extended hypoechoic carcinoma (small arrows). Infiltration of the portal vein (intrahepatic) (large arrow) as a pathognomonic sign of liver cell carcinoma (→)

**Liver metastases** *(see chapter 37.10)* are depicted with extreme variability under ultrasonography. They mostly occur as multiple and less frequently as solitary tumours. The spread of multiple small metastases is the cause of a diffuse heterogeneous echoic pattern in large parts of the liver without any distinct focal findings. The *echoic pattern* of liver metastases varies between hypoechoic and hyperechoic − even within a single metastasis. This spectrum of variation depends largely on the vascularity and/or respective development of the tumour. Occult metastases can be detected by measuring the Doppler perfusion index (DPI). (49) Occasionally, there are separate hypoechoic and hyperechoic structural deficiencies with and without a halonated (hypoechoic) margin, possibly due to the varying age of the tumour with its intermittent metastatic spread. In some cases, signs of infiltration are found in the adjacent liver tissue,

biliary tract and vessels. The hypoechoic fringe embracing a more hyperechoic centre (the so-called "halo") is termed *"target phenomenon"*. By contrast, the *"bull's-eye phenomenon"* displays a hyperechoic fringe and a hypoechoic or echofree (i. e. liquid) centre due to central colliquation of a metastasis. (s. fig. 6.17) Calcified metastases (particularly of a mucinous colorectal carcinoma) are hyperechoic with sound extinction. (s. figs. 37.24, 37.25) Hyperechoic metastases are often found in rectal or colon carcinoma, while hypoechoic metastases are more often identified in mammary, pancreatic and bronchial carcinoma. • *There is no relation between the sonographic criteria of a metastasis and the localization or cell type of the primary tumour.*

*Fig. 6.17:* Liver metastasis (subcostal section): hypoechoic fringe (arrow); wide, more hyperechoic margin and hypoechoic central colliquation ("bull's-eye"). Structural inhomogeneity of the remaining hepatic segments

Humps on the surface of the liver, displacement or compression of intrahepatic vessels as well as bile ducts with cholestasis are all known to be important signs of a tumour. Central necrosis, bleeding, indistinct outlines and the formation of branches in the vicinity are signs of a high degree of malignancy or rapid tumourous growth. • The precision of detection regarding metastases by means of ultrasonography ranges from 44% to more than 90%, with sensitivity varying from 40−80% and specificity from 62−100%. Accuracy does not only depend on the size and location of metastases, but also on the type of the primary tumour. Metastases of 0.5 cm upwards are detectable by ultrasonography. Tumourous foci in the area of the left lobe of liver (as well as subphrenic or right-sided foci) are easily overlooked. Differential diagnosis between haemangioma or colorectal metastasis may be difficult. (4, 15, 56, 99, 100)

This synopsis of circumscribed structural defects clearly shows that solid focal alterations may be hypoechoic or hyperechoic as well as benign or malignant. • The value of ultrasonography is the actual detection and not the definite specific diagnosis of such focal findings!

The strategy generally applied in the diagnostic clarification in the case of suspected **"liver tumour"** is shown later in a **flow diagram.** (s. p. 196) (s. fig. 9.4)

# 8 Examination of the spleen

The spleen is hidden underneath the left costal arch. Examination of the normal spleen ($4 \times 7 \times 11$ cm) using ultrasonography (from the left side, through the intercostal window) is therefore quite difficult. The hump of the spleen may be covered by aeriferous lung segments in the phrenicocostal sinus. The weight of the spleen depends on its respective blood content as well as on the anatomy and gender of the individual; it varies from 120 to 200 g. The pole of the spleen has a length of up to 11 cm, and the spleen has a diameter of up to 5 cm. The echogenicity is fine and homogeneous; the pattern can be either looser or more dense than that of the liver. The normal spleen may show indentations or even flaps. Variable sectioning facilitates the determination of the size of the spleen in **splenomegaly.** (s. figs. 6.18; 11.1)

*Fig. 6.18:* Splenomegaly (S) in chronic myeloplastic leukaemia (length = 21 cm, depth = 7.4 cm)

The most useful parameter for the diagnosis of splenomegaly using sonography is a splenic width of $>5$ cm (80% accuracy) or $>7$ (100% sensitivity). The length of the spleen in splenomegaly ($>11$ cm) is used for diagnostic orientation. In long-standing splenomegaly,

the echo structure is coarsened. In liver cirrhosis, the spleen is as a rule significantly enlarged. *However, the absence of splenomegaly in individual cases excludes neither portal hypertension nor cirrhosis, since the release of pressure may have been effected via collateral vessels.* Patency of the splenic vein or the portal vein excludes thrombosis as a cause of splenomegaly. *(see chapter 11)*

# 9 Special sonographic techniques

## 9.1 Sonography-guided puncture

Liver changes of uncertain aetiology, whether of a diffuse or local nature, require histological clarification. This is particularly important if therapeutic consequences or prognostic statements are to be derived. For this purpose, the following possibilities exist: (*1*.) **fine-needle biopsy** with cytological or microbiological examination (3, 10, 24, 25, 82) or (*2*.) **thick-needle biopsy** with histological or histochemical evaluation. (8, 65, 102) For diagnostic and especially for therapeutic purposes, there is also (*3*.) **puncture** of lesions (cysts, abscesses) with the possible placement of a *drainage* and the application of antibiotic lavage as well as the *injection* of cytostatics or alcohol into the tumour region, or the injection of substances to promote the *sclerosing of cysts*. (s. tab. 7.3)

The external diameter of the customary **fine needle** is <1 mm. A *Chiba needle* is generally used, although this is only suitable for obtaining cytological material. Diagnostic assessment of the bioptic material requires special experience of cytology. • Using the *incisive biopsy cannula* (diameter ca. 1 mm), a narrow biopsy cylinder can be extracted, which is processed and assessed in the usual histological manner. As opposed to Chiba cytology, this bioptic method therefore allows a more reliable assessment of the benignancy or malignancy of a liver tumour.

---

**Method**

*There are three ways of proceeding:*

(*1*.) **Free puncture:** Puncture or biopsy needle and sound transducer are not connected mechanically.

(*2*.) **Linked puncture:** Biopsy is performed using *needle forceps* attached to the side of a sound transducer. The passage of the needle and the targeted focus are shown on a monitor using a sight line. The puncture path is at an angle (adjustable as required) to the propagation of sound, i.e. the sound follows a different path from the biopsy needle.

(*3*.) **Linked puncture with central perforation** of the linear sound transducer. Needle and sound follow the same route. The visibility of the needle is not as good as when the biopsy needle is introduced into the sound field from the side.

---

For the assessment of focal hepatic alterations, it is preferable to use needles with which one can obtain cytological as well as histological material in one session, namely with the help of fine-needle technology (e.g. Trucut bioptic gun, 21 G). A further development is to be seen in the self-activating vacuum needle, which, as a fine needle, ensures a high degree of accuracy in obtaining tissue for histological examination. Use of the Chiba needle, which was widespread in the past, now tends to be less common.

**Contraindications** include coagulation disorders, superficial hyperechoic foci (e.g. haemangioma), vascular aneurysm, portal hypertension, obstructive jaundice and hydatid cysts. Care should also be taken not to damage any unknown structures along the path of the biopsy needle.

Possible **complications** are (*1*.) bleeding, (*2*.) spread of tumour cells into the puncture channel (0.05%), (*3*.) mismanaged biopsy as well as possible injury or perforation of other organs, (*4*.) spread of infectious materials from abscesses, and (*5*.) bile peritonitis. The frequency of these complications is approximately 0.5% and the lethality approximately 0.08%. *Hepatic haematoma* resulting from puncture can be detected by ultrasonography provided it is large enough and subsequently monitored in the follow-up. (48, 85) Occurrence of pain in the region of the liver after puncturing is a strong indication for ultrasonography.

► Percutaneous "blind" biopsy, formerly used in Menghini's technique, is today considered obsolete; it has been replaced by **sonography-assisted liver biopsy.** As a consequence, the safety of biopsy has been significantly improved. (s. p. 149)

## 9.2 Limitations and complementary procedures

The results presented so far in the literature concerning the sensitivity and specificity of ultrasonography undoubtedly reflect the success of the respective investigators following **many years of experience.** *The accuracy of such results (given as a percentage) should, however, always be seen in relative terms, and any general statements made in this connection should be qualified to obtain a more realistic mean value.*

► Diagnostic expectations regarding ultrasonography in liver diseases are quite frequently exaggerated. Hence the **critical interpretation** of results is all too often neglected, and false-positive or false-negative conclusions are drawn all too hastily. Even when there is the slightest doubt regarding the interpretation of findings, the examination should be carried out again: **repeated investigations** will improve the accuracy.

► Under optimal conditions, **focal lesions** of a diameter of 5 mm upwards can be identified. Liver metastases at varying stages can only be detected in 50−60% of cases. • If the assessment of focal hepatic changes is not possible with ultrasonography − even after colour-encoded duplex sonography − the indication for **computer tomography** (CT) is given. Indeed, the new *spiral CT generation* with i.v. injection of contrast medium provides ex-

cellent vascular representation. The differentiation of focal and malignant as well as vascular alterations of the liver is thus achieved in a way previously not thought possible. (s. p. 173) • **Magnetic resonance imaging** (MRI) has gained increasing importance since the introduction of $T_2$ contrast medium (iron-[II, III]-oxides) as well as of *MRI angiography*; this imaging technique needs to be redefined from the hepatological point of view. (s. p. 177) • For the differential diagnosis of focal nodular hyperplasia versus adenoma, a **scintiscan** is indicated. (s. p. 194) • If diagnostic explanation has not been provided by means of these complementary examinations, the indication for **laparoscopy** with targeted biopsy (possibly with forceps biopsy) has to be considered. (s. p. 150)

## 9.3 Colour-encoded Doppler sonography

When reflected by mobile particles, sound waves undergo a shift of frequency proportional to the velocity of these particles (= *Doppler effect*).

1. Signs of liver cirrhosis
2. Diagnosis of portal hypertension (with detection of hepatofugal flow as well as the slowing down of blood flow in the portal vein)
3. Confirmation of collateral circulation (e. g. umbilical vein, veins of the gall-bladder wall) or flow reversal with centrifugal refluxes
4. Unclear splenomegaly
5. Suspected partial or complete thromboses of the splenic-portal vascular bed
6. Budd-Chiari syndrome or veno-occlusive disease
7. Vascular system in liver tumours, tumour compression
8. Diagnosis of focal hepatic lesions (low or high number of blood vessels)
9. Assessment of a portosystemic shunt
10. Gastrointestinal bleeding of unknown cause
11. Internal or external head of Medusa
12. Assessment of the portal vein system before and after liver transplantation
13. Variations or malformations in the portal vein system (or visceral arteries)
14. Suspected Cruveilhier-von Baumgarten syndrome
15. Suspected cavernous transformation (formation of multiple venous collaterals close to the hepatic porta)
16. Therapeutic assessment of the vascularization of liver tumours after surgical interventions, chemoembolization or parenteral chemotherapy

*Tab. 6.5:* Indications for colour-encoded Doppler sonography

The development of **Duplex sonography** is based upon the combination of conventional 2D grey-scale sonography with the 1D Doppler effect. This facilitates the one-dimensional determination of the direction, velocity and volume of flow. (18, 44, 66, 70, 88, 90, 103, 104, 106) • The introduction of **colour-encoded Doppler sonography** (CEDS) in 1987 can be attributed to a combination of 2D Doppler sonography with real-time grey-scale sonography. Both the volume and the direction of the blood flow are represented semiquantitatively by way of colour encoding (with different shades of brightness). The method is dependent upon the relationship between the vascular course and the transducer (red = blood flow towards the probe, blue = blood flow away from the probe). (5, 7, 28, 29, 62, 63, 84) (s. fig. 6.19) • The portal vein blood flow is centripetal and slightly pulsatile; the mean velocity of flow was measured as $15.2 \pm 2.6$ cm/sec, representing a flow volume of $693 \pm 235$ ml/min. (s. fig. 6.20)

*Fig. 6.19:* Portal vein (PV) and division into the right (RP) and left (LP) portal vein trunk (subcostal section)

*Fig. 6.20:* Portal vein flow depicted by means of spectral analysis (velocity of flow = 11cm/sec); hepatopetal flow is shown in red

The volume only increases slightly during expiration, but significantly after eating ($880 \pm 269$ ml/min). Portal hypertension can be most reliably determined by measuring the flow volume prior to and following a test meal. (53) • In the case of suspected pathological findings in the area of the splanchnic vessels, colour-encoded Doppler sonography is indicated. This investigation method will incorporate the portal vein system, hepatic veins, splenic vein,

superior mesenteric vein and coeliac artery as well as the arterial vascular system. (s. tab. 6.5) (s. figs. 6.14; 14.13; 35.12)

The use of signal amplification with the help of **ultrasound contrast medium** provides a considerably improved depiction of portohepatic vessels as well as the perfusion of hepatic tumours. • Microbubbles are used as a contrast medium. The echo signal is amplified by increased backscattering of ultrasound waves caused by the microbubbles. This technique is based on observations made by the cardiologist C.R. Joyner, jr. (1966). Up to now, the medium of choice has been a galactose solution (99.9%) suspended in palmitic acid, the latter being used to stabilize the microbubbles. It is administered as a bolus injection or intravenously. (17, 100)

Particularly *colour-power sonography* makes it easier to identify small and deeply-set vessels as well as poorly vascularized focal tumours reliably. The procedure does not replace CEDS, but serves to complement it. (14, 86)

The following **sonographic procedures** can be applied, depending on the specific tasks and objectives (s. tab. 6.6):

| |
|---|
| 1. Conventional sonography |
| 2. Doppler sonography |
|    − Duplex sonography |
|      (combination of 2D conventional sonography with 1D Doppler sonography) |
|    − colour-encoded sonography |
|      (combination of real-time grey-scale sonography with 2D colour-encoded real-time Doppler sonography) |
|    − Doppler-power sonography |
|    − contrast medium signal-enhanced Doppler sonography |
| 3. 3D Doppler sonography |

*Tab. 6.6:* Sonographic examination procedures

## 9.4 Endoscopic sonography

Endoscopic ultrasonography promises greater accuracy as it involves placing a specialized sound transducer directly on the liver by means of laparoscopy or surgery.

**Laparoscopic sonography:** As early as 1975, D. Look et al. showed the gall bladder, using the A-scan mode of ultrasonography via the laparoscope. In 1980 Y. Furukawa et al. described laparoscopic ultrasonography by employing the B-scan mode. Initially, optic lenses were employed, before being substituted later by linear probes. In 1989 F. Fornari et al. reported on the laparoscopic application of a rotating sectorial scanner. (108) Here a linear sound transducer (7 MHz) attached to a rigid shaft by means of a flexible segment produced optimum results. This routine has the advantage of a wider scope of motility and improved orientation inside the gas-filled abdomen − without significant additional inconvenience to the patient. • Laparoscopic ultrasonography not only detects intrahepatic foci − with the pos-

sibility of targeted biopsy − but it also allows better matching of a focal lesion with the respective segment as well as more reliable preoperative tumour staging. • This procedure is also of advantage for the intraoperative application of ultrasonography in the detailed search for intrahepatic foci as well as in the intraoperative depiction of segmental borders. (107−118)

**Intraductal ultrasonography:** IDUS involving flexible miniature ultrasound probes with a diameter of approximately 1.5−2 mm (7.5−20 MHz) will expand the diagnostic spectrum concerning pathological processes in the larger bile ducts. The choledochus can usually be examined up to the hepatic duct. The identification rate of malignant or benign findings is high (accuracy 92%, sensitivity 90%, and specificity 93%. (119−123)

# Diagnostics in Liver Diseases

## 7  Liver biopsy and laparoscopy

# 7 Liver biopsy and laparoscopy

## 1 Liver biopsy

Exceptions apart, it is impossible or nearly impossible to meet the essential target of a *detailed diagnosis* for hepatobiliary disease without additional histological sampling. Morphological diagnostics is based on **three examination methods,** the diagnostic relevance of which can be improved with a number of *additional techniques.* (s. tab. 7.1)

| Examination methods |

**Tab. 7.1:** Morphological examination methods and additional techniques for the clarification of hepatobiliary diseases

► *For this reason, the aim should always be a combination of clinical, laboratory, sonographic and morphological diagnostics.* This is important because morphological changes in the liver can remain concealed from clinical and laboratory detection − just as striking laboratory findings are not necessarily reflected in the bioptic material. • Moreover, *liver bioptic material is not always representative* of the underlying liver disease or the actual normality of the liver parenchyma − whereas an increase of GPT in the individual case always points to liver cell damage. • Even if sonography is deemed to be a routine examination in clarifying hepatobiliary diseases, *it cannot provide any histological statement.*

## 1.1 Historical development

► In cases of purulent echinococcus, puncture of the liver was carried out by Récamier as early as 1825 and by Stanley in 1833. In 1844, the diagnostic opportunities of liver biopsy were discussed in France by A. G. M. Vernois. • In his book "On diabetes" (1884), F. Th. Frerichs reported on the **first liver biopsy**, which was carried out by P. Ehrlich in Berlin in 1880. This publication included illustrations of the biopsy instruments used and the liver tissue removed. • In 1895 L. Lucatello reported on liver biopsy as a method of diagnosis, the cytomaterial being examined as smear or teased-out preparation. Using the thicker needle developed by F. Schupfer (1907), successful liver and spleen biopsies were carried out, so that the tissue cylinder could be assessed histologically as well. (140) A. Josefson (1920) also succeeded in performing liver biopsies in some cases. (73) A. Bingel (1923) (8) and J. Olivet (1926) (114) reported from the same hospital on systematically performed liver biopsies. • A **new aspiration method** with modified biopsy needles was presented by I. Silverman (1938, 1954) (144) as well as by P. Iversen and K. Roholm (1939). (67) Yet even this new technology failed to help liver biopsy achieve full recognition as a clinical method despite the fact that W. Kofler (1940) had termed liver biopsy "a useful and clinically important examination method" on the basis of over 100 specimens. (77) • The following years witnessed more publications on this examination method. (3, 5, 32, 48, 109, 128, 156, 169−171) *Nevertheless, liver biopsy was almost completely excluded from the world of clinical diagnosis.* (s. tab. 7.2)

| First performance of liver biopsy | | |
|---|---|---|

**Tab. 7.2:** Historical development of percutaneous liver biopsy (1 = Germany; 2 = Italy; 3 = USA; 4 = Denmark; 5 = Austria; 6 = China; 7 = France; 8 = Great Britain) (city names are given in the original language)

► In 1957 (not 1958 as is usually and wrongly quoted!) G. Menghini presented the first report on a new biopsy method: using thin-walled, small calibre needles with a sharply slanting bevel and without a trocar, it was pos-

sible to puncture the liver in a split second (so-called *"one-second needle biopsy"*). (104) This new concept brought acclaim and led finally to the application of liver biopsy worldwide. • **In this way, Menghini biopsy marked the birth of histological liver diagnostics.**

## 1.2 Indications

The *first* and most important *prerequisite* for avoiding complications is a precise indication. • This differs from case to case − and the relative importance of the indication (weighting) varies individually from "minimal" to "absolutely necessary".

▶ Percutaneous liver biopsy ranks highly as a diagnostic method. The experience gained over many years in all sorts of locations has culminated in an exact definition and confirmation of the specific indication. (12, 15, 19, 24, 44, 51, 63, 65, 66, 71, 72, 81, 84, 87, 90, 92, 97, 107, 110, 111, 120, 129, 134, 138, 139, 145, 149, 153, 158, 162, 166, 170, 175, 176) (s. tab. 7.3)

▶ The **indication** for carrying out a liver biopsy is in principle given if:
(*1.*) a definitive diagnosis cannot be drawn up based on anamnesis together with clinical, laboratory and sonographic findings or other imaging procedures (66, 111, 145, 149),
(*2.*) it is likely to provide significant information concerning the patient with regard to therapy or prognostics on the basis of morphological findings,
(*3.*) during the course of laparoscopy, further important findings are likely to be found from a biopsy,
(*4.*) laparoscopy is indeed indicated, but it poses a greater risk and therefore has to be converted into a non-contraindicated liver biopsy,
(*5.*) additional morphological clarification can be acquired without any difficulty during a cholecystectomy, particularly with suspected concomitant hepatobiliary disease (100, 126, 181),
(*6.*) it is necessary to identify and assess diseases in the transplanted liver, such as acute and chronic (so-called ductopenic) rejection reactions, inflammatory or vascular processes as well as recurrence of the basic disease,
(*7.*) there is fever of unknown aetiology with liver involvement, whereby diagnostic clarification may be attempted by means of bacterial cultures. (63, 97)

▶ Furthermore, histological immuno- or histochemical processing of the liver material procured by biopsy is of extremely high value for gaining new scientific insight.

▶ It must, however, be considered that a biopsy punch of 1.5−3.0 cm in length is proportionate to approx. 1/50000th of the normal liver volume (J. VOLMER et al., 1981). For histological assessment, the punch should be > 1.5 cm long and include at least 4 portal fields; the weight of such a bioptate generally amounts to 20−30 mg. The smaller the sample, the more difficult is the histological

1. Unclarified cholestasis
2. Unclarified non-obstructive jaundice
3. Unclarified laboratory results
4. Acute hepatitis
   - with anicteric course
   - with atypical course
   - with issues relating to differential diagnosis
   - to check course and therapy
   - to furnish proof of healing
   - to detect posthepatic sequelae
5. Chronic hepatitis (28, 120)
   - validation of diagnosis
   - to ascertain the degree of activity and severity
   - with issues relating to differential diagnosis
   - prior to interferon therapy
   - to check course and therapy
6. Toxic liver damage
   - validation of diagnosis
   - to ascertain the extent of liver damage
   - to control course and therapy
7. Fatty liver
8. Thesaurismosis and metabolic diseases
   e.g. haemochromatosis (91), porphyria (16)
   - for differential diagnosis
   - to ascertain the extent of liver damage
   - to check course and therapy
9. Suspected infectious liver damage
   - in viral, bacterial or parasitic liver damage
   - in AIDS (99, 132)
10. Suspected granulomatous liver diseases
11. Histological assessment
    - prior to commencement of potentially hepatotoxic medication
12. Condition after liver transplantation
    (23, 46, 139, 147, 160)

*Tab. 7.3:* Indications for liver biopsy − unless definitive validation is possible by other procedures. • *The diagnostic significance of an indication is different in each individual case and can be categorized in steps ranging from "of little significance" through to "very important" or "absolutely necessary"*

assessment; at a length of < 1.5 cm diagnostic reliability drops to < 60%, at a length of < 0.5 cm it is only 20−40%. • It must also be considered that a disease of the liver is not necessarily expressed evenly, so that the biopsy punch may indeed suffer from a certain degree of unreliability. Above all, this applies to chronic hepatopathy. The varying expressivity of chronic hepatitis was already detected in 1962 (!) by L. WANAGAT (s.p. 181). • It must furthermore be considered *that in the case of percutaneous biopsy, only a limited area in the right lobe of liver can be reached.* (s. fig. 7.8) Thus histological findings should actually be limited to this biopsy site alone. In every laparoscopy with non-distinct focal lesion or insufficiently diffuse expressivity, we have always taken one (or two) bioptates from the right as well as the left lobe of liver. *We have often discussed the variability in biopsy findings with a pathologist, and occasionally the*

*pathologist even had doubts as to whether the bioptates were indeed taken from the same patient!* The reduced reliability of a percutaneous biopsy sample has been repeatedly referred to in the literature (1, 6, 64, 96, 148, 171) − *but too little attention is paid to this fact!*

## 1.3 Contraindications

The *second* important *prerequisite* for avoiding complications is to exclude contraindications. (s. tab. 7.4)

1. *Clotting disorders*
2. *Cardiac insufficiency*
3. *Respiratory insufficiency*
4. *Cerebral insufficiency*

5. Thoracic empyema (right), subphrenic abscess (right), pleuropneumonia (right)
6. Purulent cholangitis
7. Obstructive jaundice and cholestasis with dilated bile ducts
8. Portal decompensated liver cirrhosis
9. Ascites
10. Peritonitis
11. Focal liver findings
    - Polycystic liver
    - Echinococcosis
12. Increased bleeding tendency
    - Leukaemic infiltrates of the liver
    - Osteomyelosclerosis
    - Amyloidosis of the liver
    - Haemangioma
    - Adenoma
    - Malignant foci
13. Anatomic features
    - Liver positioned on edge (transverse rotation of liver)
    - Diaphragmatic hernia (right)
    - Diaphragmatic paresis (right)
    - Diaphragmatic relaxation (right)
    - Severe pulmonary emphysema
    - Chilaiditi syndrome
    - Situs inversus
14. Lack of co-operation on the part of the patient

*Tab. 7.4:* Contraindications for percutaneous liver biopsy

Threshold values for **blood coagulation** may only be taken as guidelines. They have to be critically assessed in each individual case. Recommendations for percutaneous biopsy in hospitalized patients are: (*1.*) Quick's value > 60%, (*2.*) bleeding time < 3(−4) minutes, and (*3.*) thrombocytes > 100,000, although the function of the thrombocytes is more important than their mere number. • Even with reduced coagulation parameters, biopsy can still be carried out following the administration of vitamin K, fresh frozen plasma, etc.

We regard **stasis in dilated bile ducts** as a contraindication of biopsy, although there are controversial views in the literature concerning this point. (108, 151) The risk of biliary complications should not be underestimated, especially since new examination techniques have indeed

made such risky biopsies unnecessary. By contrast, even excessive jaundice (> 20mg/dl) is per se no contraindication. • We are also against percutaneous biopsy in **ascites.** Laparoscopic biopsy with visual monitoring involving almost complete removal of the ascites does not lead to any complications if haemostasis is guaranteed. • Moreover, with **focal liver findings**, we principally give preference to laparoscopy with targeted biopsy over percutaneous biopsy of the lesion. • This also applies in the event of suspected **amyloidosis**, as the amyloidotic tissue is brittle and can easily split under biopsy, causing considerable afterbleeding. Therefore laparoscopically directed biopsy is recommended in such cases. • With **dialysis** patients, liver biopsy should occur 1 day after dialysis; prior to biopsy, the administration of desmopressine is useful.

## 1.4 Technique of liver biopsy

The *third* important *prerequisite* for avoiding complications is the correct performance of the biopsy coupled with adequate experience of the investigating physician. (12, 24, 51, 86, 90, 92, 110, 135, 161)

**Instruments**
- Biopsy needle with a blunt pin within its shaft (also available as a disposable needle): diameter usually 1.40 mm or possibly 1.60 mm (when faced with a potentially greater puncturing risk, the diameter should be 1.20 mm)
- Syringe (10 ml), best fitted with a Luer-Lock and containing 2 to 3 ml isotonic (0.9%) NaCl solution; syringe (5 ml) with 3 to 6 ml local anaesthetic (e. g. 1% to 2% lidocaine)
- Incision lancet to perforate the skin
- Thin injection needle for skin anaesthesia, thicker and longer needle for bathyanaesthesia
- Glass dish with 2−3 ml 0.9% NaCl solution
- Sterile pads and first-aid dressing

Both classical and modified types of biopsy needles are available: *suction needles* (e. g. Menghini, Klatskin, and Jamshidi) and *cutting needles* (e. g. Vim-Silverman and Tru-cut) as well as *spring-loaded needles.* (12, 26, 86, 123, 129, 158, 162)

**Preparation of the patient**
(*1.*) *Correct briefing* of the patient including written consent to the biopsy;
(*2.*) *Examination of blood coagulation* (see above);
(*3.*) *Premedication:* atropine (1 ml/0.5 mg s. c.) about 15 minutes prior to the biopsy (paying due attention to atropine contraindications). (15)

Prior to percutaneous liver biopsy, it is not necessary to perform either a chest-X-ray or a cholecystography, or to determine the blood group. *These examinations are of no practical significance.*

**Preparation of the biopsy**
(*1.*) *Location of the biopsy:* Liver biopsy can be carried out in the patient's room, in the ward examination room or in the endoscopy department. The medicaments and appliances required for possible emergency treatment must be available.
(*2.*) *Positioning of the patient:* The patient (fasted condition) lies on his/her back, turned slightly to the left (established technique

in line with G. Menghini), the right arm stretched over the head (or right hand under the head). To stabilize the position, a pillow may be tucked underneath the right lumbar region. • During the biopsy, the patient stays in his/her own (normal) bed (= no postbioptic repositioning, which is psychologically advantageous!).

(*3.*) *Site of puncture:* Prior to carrying out a percutaneous liver biopsy, a *sonographic examination* of the liver (for focal processes) as well as of the adjacent organs (to rule out morphological anomalies) should be effected. This can be carried out directly prior to the biopsy or a few hours to one week preceding the biopsy. The suitable puncture site is established directly prior to the biopsy by ultrasound and subsequently marked (possibly by the print of a fingernail). The puncture site as determined by percussion clearly differs in 13% of cases to that determined by sonography. The puncture canal is transthoracic in 6th or 7th intercostal space. The abdominal (i.e. subcostal) method is only acceptable in a markedly enlarged liver. It is as a rule safe with sonographic monitoring even under outpatient conditions. (117, 130) This *ultrasound-guided biopsy* (54) does not call for sonography during the actual performance of the puncture. (117, 118, 178) • **Percussion-guided liver biopsy is considered obsolete today!**

(*4.*) *Disinfection of the skin.*

(*5.*) *Anaesthesia:* Skin wheal as large as a thumb nail; anaesthesia of the intercostal space through to the (painful) peritoneum: this is the site for the anaesthetic depot.

(*6.*) *Perforation of the skin* with a lancet.

(*7.*) *Attempted apnoea:* 4−6 sec after normal expiration. • *An experienced physician can carry out the biopsy in a split second at the end of an expiration phase, so that the patient need not be asked to hold his breath and is thus not subject to "expectation anxiety"!*

### Slow (extrahepatic) phase

(*1.*) Examination of the needle: its diameter, sharpness and in particular ultimate strength.

(*2.*) Insertion of the needle.

(*3.*) Injection of 0.5 to 1.0 ml 0.9% NaCl solution (to clear the needle) after penetration of the intercostal fascia.

(*4.*) Apnoea at the end of normal expiration.

(*5.*) Aspiration: retraction of injection plunger, whereby the direction of puncture is dorsocranial towards the xiphoid.

### Rapid (intrahepatic) phase

**Puncture** involving a swift, straight movement forwards and backwards without rotation and without sideways deviation (2 to 4 cm penetration depth depending on the body volume) immediate withdrawal of needle with syringe in aspiration position. • *This phase normally takes a maximum of 0.5 seconds.*

> The swiftness of the intrahepatic puncture phase reduces the danger of bleeding. For this reason, a **modified puncture technique** with the Menghini needle has become established practice: this involves a straight, forward movement, effected in a split second and performed *at the same time* as rapid aspiration suction followed by immediate withdrawal of the needle with continuing suction − *a customary method of biopsy, which we have also found to be most satisfactory.* With an experienced operator, the intrahepatic phase can be reduced to < 1/10 second and, at the same time, aspiration suction can be remarkably increased.

Intrahepatic biopsy is performed as swiftly as possible using standard instruments (available as a disposable set with a Menghini needle); this ensures the "shooting" of the biopsy needle into the liver after release of the spring tension (based on the principle of the spring-loaded needle). Today's high-speed biopsy sets are obtainable with needles of varying diameters; they allow comfortable one-hand operating techniques and enable penetration shots with adjustable depth (e.g. 15 or 20 mm).

### Handling the bioptic material

Placing a pin in the needle ensures that the **puncture cylinder** stays in the needle lumen, so that it is not aspirated into the syringe. It is thus guaranteed that the still intact specimen (2 to 3 cm long) can be ejected with the rest of the NaCl solution into the Petri dish with 0.9% NaCl solution. The biopsy material obtained usually amounts to 20−30 mg (up to 70 mg). • The frequency of "unsuccessful" biopsy is 0.4%−0.6%.

The biopsy material should be observed under **UV fluorescence** (366 nm; so-called Wood light) to rule out porphyria. (s. fig. 7.10) Only after UV-fluorescence assessment has been carried out can the biopsy material be fixed in the formalin solution. A short written description of the biopsy material should then be made. • Depending on the individual diagnostic issue in question, the material is prepared in compliance with **special regulations** (frozen section, electron microscopy, RNA detection, etc).

### Aftercare of the patient

**Positioning** of the patient on the right side with the elbow against the site of biopsy. This position should be maintained for about 2 hours.

**Bed rest** for 24 hours; as from the 8th hour, bed rest can be semistrict. This is, however, not generally called for in the literature. (105, 135)

**Control** of pulse rate and blood pressure every quarter of an hour for up to 2 hours; from then on, every half hour through to the 6th hour.

## 1.5 Postpuncture complaints

▶ Postpuncture complaints can be observed in 5−10% of patients. They are found more frequently in anxious patients and − it would appear − especially when no parasympathetic blocking agent in the form of atropine has been administered. All these ailments are unpleasant but harmless. Occasionally, symptomatic measures are required.

(*1.*) **Upper abdominal pain:** Traction at the falciform ligament due to the puncture as well as a subcapsular haematoma can lead to slight pain.

(*2.*) **Pain in the right shoulder** and possibly cervicalgia on the right side due to irritation of the phrenic nerve.

(*3.*) **Respiratory pain** as a result of a subcapsular haematoma.

(*4.*) **Vagus shock:** Irritation of the pleura or peritoneum due to stimulation of the vagus nerve can result in a vagal (or peritoneal) shock: bradycardia, a drop in blood pressure, practically instantaneous violent pain in the right upper abdomen, guarding of abdominal muscles, weak pulse − the patients are pale, they sweat and hardly dare to breathe. • Such a situation appears threatening for both the patients and their environment − however, during more than 30 years of experience, we have only observed one such "dangerous" event. We would rate this as being the positive outcome of *basic premedication with atropine.* Because of the rare contraindications of atropine premedication on the one hand and the very unpleasant

event of a vasovagal reaction on the other hand, we would always recommend such a procedure.

▶ Vagus shock might also be caused by **postbioptic biliary leakage** with acute irritation of the serosa. H. Thaler observed this event 19 times in 7,500 biopsies; we have witnessed it just once with 4,124 biopsied patients. This would suggest that bile-related acute irritation of the serosa is only in rare cases likely to be the cause of a peritoneal shock.

## 1.6 Complications

Each invasive examination procedure is limited by its own risks and complications. These depend on a variety of individual **influencing factors.** (s. tab. 7.5) In each individual case, the physician must always examine whether influencing factors are involved in a complication and if so, what they are, how they must be considered, and to what extent they can be avoided in future. • *There is no doubt that many of the complications cannot be attributed in any way to the method of liver biopsy itself! (This is also true of laparoscopy!)*

▶ *Disregard of contraindications*
▶ *Incorrect or uncritical evaluation of the indication*

1. **Influence exercised by the investigating physician**
   • perfection of method
   • continuous acquisition of experience
   • manual dexterity

2. **Influence exercised by the patient**
   • mental state
   • anatomical features

3. **Influence exercised by existing disease(s)**
   • underlying disease
   • secondary diseases

4. **Instrumentation and personnel**
   − optimal
   − limited
   − insufficient

*Tab. 7.5:* Factors that influence frequency and severity of complications in liver biopsy and laparoscopy

**Causes** of morbidity and mortality as a result of percutaneous liver biopsy have been assigned to a variety of circumstances. (15, 27, 44, 46, 59, 62, 70, 85, 87, 98, 119, 121, 156−158, 161, 179) (s. tabs. 7.5, 7.6)

**Puncture of the gall bladder** (with impending bile peritonitis) is practically always due to a faulty technique in performing the biopsy and is only rarely caused by an anomaly in the position of the gall bladder; such an anomaly is usually detected in prebioptic sonography. • **Puncture of the adjacent organs** (s. tab. 7.6) is usually harmless and only rarely leads to complications. • Sub-

sequent **bleeding** is mostly observed within the first 2 hours and only rarely during the following 6 hours. Depending on the localization and severity of the bleeding, this effect can develop "asymptomatically" through to "dramatically". More pronounced bleeding is to be expected in about 0.2% of patients. (17, 39, 60, 78, 95, 102, 103, 123, 127, 146) • Different investigators have witnessed **intrahepatic haematomas** in 1.1%, in 4%, in 7% and even in 23% of cases. Application of the Menghini needle yielded the best results. Such haematomas are usually not significant, since they are resorbed spontaneously. (52, 79, 105, 125, 142, 152, 154) • Likewise without clinical significance and generally unnoticed are **a.v. fistulas,** found in about 5% of cases. (68, 94, 113, 115, 124) Occasionally, **haemobilia** occurs as a result of an arterio-portal fistula (detectable today by means of MRCP), rendering embolization necessary in individual cases. This event was even observed up to 10 days after liver biopsy. (2, 42, 82, 83, 94, 115, 146) • A **pneumothorax** is a very rare occurrence (< 0.01%) and in itself harmless due to the rapid resorption of the gas used in laparoscopy. (116, 143) • A **haematothorax** has also been observed in rare cases. (121)

1. **Puncture of the gall bladder** (48)
2. **Puncture of adjacent organs**
   • frequent:  kidneys, colon, lung
   • less often: pancreas, small intestine, adrenal gland
3. **Haematoma**
   • intrahepatic
   • subcapsular
4. **Bleeding**
   • early bleeding
   • late bleeding (78, 127, 177)
5. **Arteriovenous fistula**
   • intrahepatic (possibly with haemobilia)
   • intrarenal (possibly with haematuria)
6. **Haemothorax** (121)
7. **Biliary leakage** (55, 121)
   • peritoneal shock
   • bile peritonitis (85, 131, 156)
   • biliary pleural effusion (122)
   • haemocholascos
   • bilhaemia (165)
   • bile embolism (29)
8. **Pneumothorax** (116, 143)
   • pleural effusion (121)
9. **Breakage of biopsy needle** (121)
10. **Infection**
    • sepsis (121)
    • liver abscess
    • subphrenic abscess (7)
11. **Anatomical variants**

*Tab. 7.6:* Causes of morbidity and lethality after percutaneous liver biopsy (with some additional references)

There are only isolated reports of **late bleeding** (4th to 13th day). (78, 127, 177) This may be attributed to late fibrinolysis of the thrombus in the area of the biopsy canal. These reports do not, however, exclude more obvious causes, e.g. abdominal press, traumatization, rupture of a subcapsular haematoma, influence on blood

coagulation. • Late bleeding occurred in some 61% of patients within the first 2 hours, in 21% during the following 8 hours (= 82%) and in 14% within the following 14 hours; i.e. 96% of the complications were noticed in the course of the first day. (121) The frequency of complications does not depend on the length of post-bioptic bed rest. (135)

In the case of suspected postbioptic bleeding or biliary leakage, **emergency laparoscopy** is indicated as the primary possibility after previous abdominal sonography and before exploratory laparotomy is deemed necessary. The diagnosis can generally be clarified by means of laparoscopy, and the bleeding or biliary leakage can be managed. (184, 267)

## 1.7 Frequency of complications

▶ The **literature** available to us does not provide adequate confirmation of the high lethality rate of 1% following "blind" liver biopsy in the pre-Menghini era as published by I. Snapper in 1951. In a summary covering 18,894 directed as well as non-directed liver biopsies (D. Gemsjäger, 1957), lethality was 0.17%. In other compiled statistics relating to 15,274 biopsies, lethality was put at 0.22%. (179) A. Terry observed a lethality rate of 0.07% and a morbidity rate of 0.32% in 7,532 biopsies. (156) In another study comprising 13,150 liver biopsies, the lethality rate was 0.21% (H. Lüdin, 1955). The calculations of L. Schiff (1951) register no fatal cases at all. (138) Other publications may be referred to in this respect. (62, 119, 161)

> Since the introduction of Menghini's technique in 1957 (104), the risk of complications has been reduced to one quarter and lethality to one tenth.

One of the first major compilations of statistics was produced by H. Thaler in 1964: in 23,382 biopsies, the lethality rate was 0.017% and the complication rate 0.10%. (158) In evaluating 79,381 liver biopsies, H. Lindner (1967) calculated a lethality rate of 0.015% and a morbidity rate of 0.34%. (85) In 19,563 liver biopsies, E. Wildhirt registered no fatal cases with a morbidity rate of 0.089%. (176) In a multicentre study carried out by F. Piccionino et al., 68,276 liver biopsies were recorded during the period 1973−1983 with a lethality rate of 0.009% and a morbidity rate of 0.21%. In this study, the Vim-Silverman and Tru-cut needle types proved to have the highest risk rate (0.31% to 0.34%). (121) Severe complications were found in 0.57% of cases by J.F. Cadranel et al. (15) Among *4,124 of our own biopsies* (Menghini needle), we registered no cases of death whatsoever from 1961 to 1987; the complication rate was 0.15% (s. tab. 7.7).

▶ In 1990 D.B. McGill et al. reported on the evaluation of 9,212 liver biopsies with an amazingly high complication rate (102): 10 cases of severe bleeding proved fatal (0.11%), whereas 22 cases (0.24%) could be managed. In malignant liver tumours, the frequency of bleeding with lethal outcome was 0.40% and the frequency of arrest of bleeding 0.57%. In patients without liver tumours, there was a lethal bleeding risk rate of 0.04% and non-lethal rate of 0.16%. Only the needle types Tru-cut, Vim-Silverman

| Morbidity | | | |
|---|---|---|---|
| Thaler, H.* | (1964) | 23,382 | 23 = 0.98% |
| Lindner, H.* | (1967) | 79,381 | 273 = 0.34% |
| Wildhirt, E. | (1981) | 19,563 | 16 = 0.082% |
| Piccionino, F.* | (1986) | 68,276 | 141 = 0.21% |
| Kuntz, E. | (1987) | 4,124 | 6 = 0.15% |
| Eisenburg, J. | (1988) | 35,000 | 6 = 0.017% |
| | | 229,726 | 465 = 0.20% |
| **Lethality** | | | |
| Thaler, H.* | (1964) | 23,382 | 4 = 0.017% |
| Lindner, H.* | (1967) | 79,381 | 12 = 0.015% |
| Wildhirt, E. | (1981) | 19,563 | – |
| Piccionino, F.* | (1986) | 68,276 | 6 = 0.009% |
| Kuntz, E. | (1987) | 4,124 | – |
| Eisenburg, J. | (1988) | 35,000 | – |
| | | 229,726 | 22 = 0.001% |

***Tab. 7.7:*** Frequency of liver biopsy complications broken down into morbidity and lethality (* = compiled statistics). • The results of E. Wildhirt and J. Eisenburg are particularly worth noting

and Jamshidi had, however, been used here. • The lethality rate of 0.10% found by G.H. Millward-Sadler et al. (1985) is also unusually high (7−10 times higher compared to other published data).

A closer look at the publications, however, often reveals that some *contraindications* and *problem situations* (e.g. ascites, amyloid degeneration, liver tumours, leukaemia, obstructive jaundice) were not heeded. Likewise, *inadequacies* in applying the various methods may be responsible for complications. Biopsy needles with a larger diameter of >1.6 mm (e.g. Vim-Silverman, Jamshidi) were also found to involve greater risks.

> Given the correct indication (s. tab. 7.3), due attention to possible contraindications (s. tab. 7.4) and continuous experience on the part of the investigating physician (s. tab. 7.5), an upper limit of about **0.30%** for **morbidity** and about **0.01%** for **lethality** should be set for ultrasound-guided liver biopsy. Any higher frequency of complications should not be accepted!

## 1.8 Liver biopsy in children

Indications and contraindications in children are the same as in adults. In general, the diameter of the needle should not exceed 1.2 mm. Premedication is advisable to ensure a smooth (and hence low-risk) biopsy. • D. Feist et al. (1972) reported on 385 biopsies with just one complication (no fatal cases) (40), and H. Thaler (1979) observed only 2 minor complications in 764 biopsies (159), while M.B. Cohen et al. (1992) reported a lethality rate of 0.60%, slight complications in 11.7% and serious events in 4.5% of cases. (25) A.O. Scheinmann et al. found complications in 6.83% of cases, of which 2.4% were severe; lethality was 0.4%. (137) Liver biopsies have also been successfully carried out in children under outpatient conditions. (53)

## 1.9 Outpatient liver biopsy

▶ Many investigators have reported in the **literature** on their wide experience concerning outpatient liver biopsy. (22, 35, 36, 43, 49, 70, 76, 88, 106, 167, 174) E. RICHTER et al. (1972), K. TEUBNER (1975) and H. THALER (>4,000 complication-free outpatient biopsies!) have also reported on this subject. Additional statements have been made by R. DECKING (1991) (30), the latter following recommendations issued by the "Patient Care Committee" (W.H. JACOBS et al., 1989). More recent results obtained by A. GIGER et al. (1993) (50) and S. VIVAS et al. (1998) further advocate this method. The Jamshidi needle also proved to be low in risk.

We have acquired *our own experience* with 318 outpatient biopsies, included in our total number of 4,124 biopsies − we observed no complications whatsoever in these 318 patients. (s. tab. 7.7) • Evaluation of the publications quoted and our own experience show that the **frequency of complications** tends to be even lower than in hospitalized patients. This is probably due to the fact that only very experienced physicians perform outpatient biopsies and that indications and contraindications are heeded with greater stringency.

Isolated instances of *objections* to outpatient biopsies are neither objectively nor legally justifiable, provided the necessary criteria are duly observed. Besides the paramount requirement concerning the qualification of the investigating physician, we have always been in favour of and have insisted on *"restricted indications with expanded contraindications"*. In contrast to percutaneous liver biopsy under hospital conditions, outpatient percutaneous biopsy calls for *normal blood coagulation parameters.* • We have extended the list of **contraindications** (s. tab. 7.4) to include some additional points. (s. tab. 7.8)

---

1. Previous intake of acetylsalicylic acid or other substances which affect blood coagulation
2. Unclear diagnostic conception
3. Inadequate prediagnostics
4. Biopsies at the request of a general practitioner
5. Diameter of needle in excess of 1.6 mm
6. Patient-related problems
   - long or complicated journey home
   - unsuitable means of transport
   - lack of telephone contact
   - lack of monitoring at home
   - unreliability on the part of the patient

---

***Tab. 7.8:*** Additional contraindications for outpatient liver biopsy (complementary to table 7.4)

There are differing recommendations concerning the direct **monitoring time** following a biopsy. Due to the fact that most complications occur within the first 3 hours, an initial monitoring period of *6 hours* may be considered adequate; contact observation of the patient is imperative, while the pulse rate and blood pressure are taken (and charted!) every 15 minutes during the first hour and subsequently every half hour. However, we have always adhered to a 6−8 hour monitoring period because of clinical factors. **Transport** of the patient to his home must always be "passive" (i. e. with family members or friends, possibly by taxi).

Both the patient and the accompanying person must be given a careful **briefing.** Upon the occurrence of symptoms, the hospital where the biopsy was performed is to be informed immediately by telephone (for this reason the patient always has to be given the telephone number and name of the emergency doctor in writing). In such a case, the local practitioner should not be consulted − so as to avoid any loss of time! The emergency physician at the hospital has to be informed of the name and residence of the biopsied patient, so that he is "prepared" for a telephone call at all times. • Should the biopsy have been carried out at a specialist surgery, it is advisable to inform an emergency physician at a nearby hospital of the name and residence of the patient − upon the occurrence of complications, the patient should be taken immediately to that hospital (and not to the local practitioner's surgery!).

## 1.10 Transjugular liver biopsy

Transjugular venous liver biopsy was first described by W. HANAFEE et al. in 1967. It has been successfully performed (monitoring by ECG!) with few complications in high-risk patients (e. g. ascites, bleeding tendency, severe adiposity, massive intra-abdominal adhesions), both adults and children. Furthermore, the biopsy material obtained by this method (albeit shorter than in percutaneous biopsy) has generally been rated as adequate for assessment. The modified 15 G or 16 G Ross needle, but also an 18 G automated core biopsy needle, are considered preferable over the Trucut needle. The technique is deemed to be safe and reliable, and the complication rate is acceptable. (s. tab. 7.9) (4, 13, 14, 21, 31, 33, 34, 45, 47, 58, 69, 74, 80, 101, 112, 133, 136, 168, 182)

---

1. Neck haematoma
2. Pneumothorax
3. Transient Horner syndrome
4. Transient trachyphonia
5. Passing abdominal pain
6. Passing fever
7. Cardiac arrythmias
8. Intrahepatic a.v. fistula
9. Perforation of the liver capsule
10. Cardiac arrest

---

***Tab. 7.9:*** Complications of transjugular liver biopsy in up to 20.2% of cases (mortality rate 0.1−0.5%)

## 1.11 Transfemoral liver biopsy

The technique of transfemoral liver biopsy using flexible forceps was described by M.W. MEWISSEN et al. in 1988. Some studies have shown this to be just as safe and efficient as the transjugular method. (74, 80, 89, 95, 155)

## 1.12 Ultrasound- or CT-guided biopsy

The first **ultrasound-guided liver biopsy** (using the A technique) was carried out by WANG HSIN-FANG et al. in 1964 to diagnose and treat liver abscesses. (s. tab. 7.2)

**Ultrasound-guided Menghini biopsy** was recommended in 1983 as an alternative to percussion-guided biopsy. (54) • *Today, it is deemed the method of choice.* (20, 26, 36, 56, 58, 72, 88, 118, 163, 175, 178, 180) (s. tab. 7.2)

**Ultrasound-guided fine-needle biopsy** was introduced by A. Lundquist in 1971. It is deemed to be a low-risk method for the sampling of cytological material and is almost indispensable for differential diagnosis between benign and malignant foci. (10, 11) Its sensitivity is $60-80\%$ and its specificity higher than 90%. This form of biopsy can also be used for the treatment of abscesses. (141) The use of cutting biopsy needles (involving greater risks) even makes it possible to sample liver tissue for histological assessment. There are many reports on the biopsy technique as well as on the results and complications involved. (9, 18, 29, 37, 38, 41, 61, 93, 150, 172, 270) Up to now, reports have been received on 10 fatal cases subsequent to fine-needle puncture of abdominal organs $-$ 6 of them as a result of liver biopsy. • Spreading of tumour cells via the bloodstream or lymphatic system can be more or less ignored. The genesis of vaccination metastases and spreading of tumour cells or infectious material into the biopsy canal is considered rare. • Even if the commonly used fine needle with a cutting surface of 22 G only has a diameter of 0.7 mm (cf. Menghini needle with 17 G and Jamshidi needle with 15 G), the possibility of afterbleeding, though rare, must still be considered. (60; quot. 172) • The evaluation of 11,700 abdominal fine-needle biopsies by T. Livraghi et al. (1983) yielded a complication rate of 0.55%; serious complications occurred in 0.05% of patients. The frequency of pronounced bleeding given by M. Gebel et al. (1986) was $1.5-2.5\%$, depending on the tumour type. (quot. in 172) (s. p. 136)

**CT-guided liver biopsy** was reported for the first time by J. R. Haaga et al. in 1976. Biopsy of *focal lesions of the liver* may also be carried out by CT guidance. (20, 57, 164, 173)

# 2 Laparoscopy

## 2.1 Historical development

▶ The first laparoscopy following a pneumoperitoneum was reported by the surgeon Georg Kelling from Dresden at a lecture given in Hamburg on 23.9.1901. He presented this method of examination, using the term **coelioscopy.** (quot. 246) In the same year (1901), Dimitri Edler von Ott also described this technique in St. Petersburg, calling it **ventroscopy.** (282) • The name **laparoscopy** originates from Hans Christian Jacobaeus, who in 1910 reported on the examination of the abdominal cavity using Nitze's cystoscope following pneumoperitoneum placement. (237) In the USA, this method was termed **organoscopy** (B. M. Bernheim, 1991) (189), **peritoneoscopy** (B. H. Orndoff, 1920) (281), and **abdominoscopy** (O. Steiner, 1924) (307). The first atlas of laparoscopy was published by R. Korbsch in 1927, based on his own experience since 1921. (248) Following these publications, laparoscopy was adopted in numerous countries as a new method of examination. (s. tab. 7.10)

▶ The so-called **3rd developmental stage** of laparoscopy is linked to the name of H. Kalk, who (commencing in 1923/1924) systemat-

ically revised the technique of laparoscopy in Frankfurt and brought out the first publication on the subject in 1929. (240) His experience has mainly been documented in papers dating back to the years 1935 (Indications and dangers) (241), 1942 (Introduction to photolaparoscopy), 1943 (Directed liver biopsy under laparoscopic vision) as well as 1948, 1953 and 1955. • The clinicians N. Henning (Leipzig), C. Fervers (Solingen) who became the first to carry out minor adhesiolysis (1933), J. C. Ruddock (Los Angeles) and E. B. Benedict (Boston) were also particularly involved in this development phase. (s. tab. 7.10)

It was only the consistent work of H. Kalk which gave laparoscopy its worldwide high status. (263) • Further perfecting of laparoscopy, attributable to K. Beck, W. Brühl, J. Eisenburg, H. Henning, H. Lent, H. Lindner, W. Siede, L. Wannagat and E. Wildhirt $-$ to name just a few of the German schools of thought $-$ resulted in laparoscopy becoming an integral part of clinical diagnostics. With continual further development of medical technology, important additional techniques have been rendered possible.

| **First performance of laparoscopy** | | |
|---|---|---|
| 1901 | G. Kelling *(coelioscopy)* | Dresden[1] |
| 1901 | D. Edler von Ott *(ventroscopy)* | St. Petersburg[2] |
| **New description of laparoscopy** | | |
| 1910 | H. Ch. Jacobaeus *(laparoscopy)* | Stockholm[3] |
| 1911 | B. M. Bernheim *(organoscopy)* | Baltimore[4] |
| 1920 | B. H. Orndoff *(peritoneoscopy)* | Chicago[4] |
| 1921 | R. Korbsch (1927: 1st atlas of laparoscopy) | Oberhausen[1] |
| 1924 | O. Steiner *(abdominoscopy)* | Atlanta[4] |
| **Third phase of "laparoscopic discovery"** | | |
| 1923/24 | H. Kalk | Frankfurt[1] |
| 1928 | N. Henning | Leipzig[1] |
| 1934 | J. C. Ruddock | Los Angeles[4] |
| 1939 | E. B. Benedict | Boston[4] |
| **Fourth laparoscopic development phase** | | |
| 1980 | K. Beck (Ed.): Coloured atlas of laparoscopy, 2nd edition with 1016 figures (1st edition 1968) | |
| since 1980 | *laparoscopic surgical procedures* | |
| since 1980 | *laparoscopic sonography* | |
| since 1995 | *exploratory mini-laparoscopy* | |

*Tab. 7.10:* Historical development of laparoscopy (a selection of important steps) (1 = Germany; 2 = Russia; 3 = Sweden; 4 = USA)

After 1950 there was an enormous worldwide increase in the number of laparoscopic examinations. Statistics from H. Lindner et al. (1976) reflect this with 141,981 laparoscopies in European countries. (259) The highest level of laparoscopic examinations (between 1970 and 1980) was estimated as being in excess of one million!

The introduction of new examination methods into hepatological diagnostics (virus serology, sonography, CT, ERC, to name just a few) has led to a considerable reduction in the frequency of laparoscopic examinations since 1975. Even in hospitals with very high laparoscopy figures, frequency has been reduced to about 10%. (230)

This *"laparoscopic slump"* is also obvious in our own statistics. (253)

## 2.2 Definition of laparoscopy

Laparoscopy is a low-risk instrumental examination technique for the abdominal cavity with a high degree of diagnostic relevance and low personnel input.

**Laparoscopy**, like the terms **coelioscopy, ventroscopy, organoscopy, peritoneoscopy** and **abdominoscopy** (s. tab. 7.10), actually means an *"endoscopy of the abdomen"* and not only of the *"liver"* − unfortunately, such a "hepatoscopy" was all too often performed on its own. *(see page 2 for further details on the term "hepatoscopy")*

## 2.3 Indications

Morphological findings are deemed to be an essential part of detailed diagnosis in liver diseases. Yet the results of percutaneous liver biopsy lead all too easily (e.g. with focal findings) and to a somewhat high percentage (e.g. with liver cirrhosis, chronic virus hepatitis C) to misinterpretations. *Non-directed liver biopsy does not always make it possible to detect changes which are representative of the entire liver.* Additionally, in 1−2% of cases, the material yield does not necessarily suffice for histological assessment. (64, 96, 148) (s. p. 160)

Assessment of the liver surface can often be the decisive starting point for diagnosis and histological interpretation. Furthermore, laparoscopy makes it possible to inspect the entire abdominal cavity. As a result, indications for exploratory laparoscopy are significantly extended. Yet modern imaging procedures can quite often produce false-negative results as well. In individual cases, laparoscopy (possibly with directed biopsy) can be taken as a method of reference. This is also true for other specific issues, such as congenital anomalies. (298)
• With the introduction of imaging procedures and their perfected methods, the indication list with regard to laparoscopy has changed. Based on the information found in the literature as well as on our own experience with 6,000 laparoscopies (1955−1987) (253), indications for exploratory laparoscopy are given for many hepatobiliary diseases. (192, 194, 196, 197, 200, 203, 205, 208, 213, 215, 227, 230, 245, 253−255, 257, 259, 260, 265, 268, 269, 276, 277, 285, 294, 304, 308, 314, 319, 327) (s. tab. 7.11)

## 2.4 Exploratory laparoscopy

The arguments put forward by G. KELLING (1923) apply just as much today as they did in the past − exploratory laparoscopy of the abdominal cavity is one of the most important aims of laparoscopy. (246) (s. tab. 7.12) • In working towards a diagnosis, it is a fundamental principle that exploratory laparoscopy should be given priority over exploratory laparotomy. (197, 205, 213, 215, 218, 227, 245, 253, 254, 277, 293, 294, 315)

1. Chronic hepatitis (238, 253, 286, 317)
   − for differential diagnosis
   − for morphological differentiation
2. Unclarified hepatomegaly and/or increasing liver consistency
3. Unclarified splenomegaly (253)
4. Unclarified rise in liver enzymes
5. Unclarified occupation of abdominal space
6. Unclarified gall bladder findings (247, 253)
7. Unclarified abdominal symptoms (250, 295)
   − adhesions (185, 234, 253)
   − suspected tuberculous peritonitis (191, 233)
   − suspected carcinomatous peritonitis (199, 253)
   − appendicitis (195, 312, 324)
8. Suspected liver cirrhosis (201, 231, 274, 279, 289)
   − differential diagnosis (222, 253)
   − assessment of further complications (243, 310)
   − demarcation of a scarred liver (253, 309, 310)
9. Suspected focal liver lesions (198, 253, 256)
   − adenoma, echinococcosis, haemangioma (253), focal nodular hyperplasia (204, 236, 253), tuberculosis (253), sarcoidosis (200, 253), Hodgkin's disease (253, 296, 330), liver abscess (232), *etc.*
10. Suspected malignant tumours
    − primary liver cell carcinoma (224, 242, 261, 332)
    − malignancy in haemochromatosis
    − gall-bladder carcinoma (209, 251)
    − liver metastases (193, 199, 332)
    − abdominal metastatic spread (253)
11. Suspected parasitic disease
12. Fever of unknown aetiology (229, 249, 304)
13. Ascites of unknown aetiology (207, 290)
14. Cholestasis of unknown aetiology (280, 299)
15. Clarification of systemic diseases
16. Tumour staging: "pre-look" prior to surgery, "second look" after carcinoma surgery
17. Assessment of indication for transplantation
18. Suspected lack of one liver lobe (253)
19. Emergency laparoscopy (184, 267)
    − in postbioptic bleeding
    − in postbioptic biliary leakage
    − following blunt abdominal trauma
20. Vascular processes
    − peliosis hepatis (236, 305)
    − Budd-Chiari syndrome (190)
    − Osler disease (306)

*Tab. 7.11:* Indications for (exploratory) laparoscopy − where no definitive diagnosis is guaranteed by other procedures. • *The diagnostic significance of an indication is individual and different in each case and can be categorized in steps ranging from "of little significance" through to "very important" or "absolutely necessary"*

In calling for **quality assurance** in diagnostics, it is not possible to do without the relevant accuracy and significance of laparoscopy. For this reason, the indications outlined have to be reviewed in each individual case. They can either be viewed more stringently or interpreted more widely; their diagnostic significance may be greater or less, depending on the respective case.

Laparoscopy is always indicated if an abdominal clinical picture has not been clarified or a hepatobiliary disease could not be defined by non-invasive or minimally invasive procedures (such as sonography, CT, ERC, scintigraphy, MRI). (s. tab. 7.12) (245, 253, 276, 294)

| **Main targets of laparoscopy** |
| --- |
| Assessment of: |
| 1. liver and gall bladder |
| 2. spleen |
| 3. peritoneum, omentum, ligaments, free diaphragmatic areas |
| **Secondary targets of laparoscopy** |
| Assessment of: |
| 1. free stomach wall areas, intestine, appendix |
| 2. female minor pelvis in a head-down position (uterus, ovaries, tubes) |
| 3. hernial orifices |
| **To a limited extent** — pancreas — kidneys |

**Tab. 7.12:** Organ-related examination targets (main and secondary) in exploratory laparoscopy

▶ With considerably less inconvenience to the patient, exploratory laparoscopy offers a better view of the minor pelvis through to the subphrenic space than can be provided by exploratory laparotomy with the limitations imposed by incision. Adhesions can also be viewed better with the help of laparoscopy as compared to laparotomy.

▶ Time and personnel involved as well as the costs of nursing are all far lower with exploratory laparoscopy than with laparotomy. In the vast majority of cases, exploratory laparoscopy renders exploratory laparotomy superfluous. Above all, this is true for the detection of nonoperable carcinomas.

▶ With women, every laparoscopy should include an inspection of the minor pelvis in the head-down position.

▶ Each abnormal or pathological finding is to be recorded by photographic documentation. A surgeon or gynaecologist should be consulted in assessing specific findings relating to his field.

▶ With selected patients, *outpatient laparoscopy* has proved to be a safe and cost-saving (approx. 30% less expensive) method with follow-up monitoring of 3−4 hours under hospital conditions. (313)

*Mortality risk* is given as being about 0.1% (−0.2%) for exploratory laparoscopy, whereas exploratory laparoscopy has a lethality rate of about 2.5% − i.e. about 20 times higher! In advanced carcinomas, the lethality rate is as high as 50% for exploratory laparotomy versus 7.4% for laparoscopy.

The strategy generally applied in a diagnostic clarification in the case of suspected **"liver tumour"** is outlined later in a **flow algorithm.** (s. p. 196) (s. fig. 9.4)

## 2.5 Contraindications

Attention must be paid to severe clotting disorders, cardiac and coronary insufficiency, severe cardiac arrhythmia, serious hypertension, respiratory insufficiency and purulent peritonitis as possible contraindications. The same is true of Bekhterev's disease and cerebral insufficiency (depending on the respective severity). Despite a wide range of indications, the list of contraindications (with the exception of hepatogenic clotting disorders) only covers severe extrahepatic diseases. In these cases, it is the treatment of the serious condition which is of paramount importance and not the diagnostic clarification of abdominal or hepatobiliary diseases. (228, 244, 254, 266, 275) (s. tab. 7.13)

**Relative contraindications:** Given the technical experience of the physician and the implementation of adjuvant measures, certain contraindications can be categorized as relative, and accordingly overcome; in such cases, however, a greater risk is to be expected. • *Pronounced adhesions, extreme adiposity and severe meteorism are reasons for greater restraint and due caution.* (s. tab. 7.13)

| **Absolute contraindications** |
| --- |
| 1. Clotting disorders |
| 2. Cardiac and coronary insufficiency, severe cardiac arrhythmia |
| 3. Severe hypertension |
| 4. Respiratory insufficiency |
| 5. Bacterial peritonitis |
| 6. Large hiatus hernia |
| **Relative contraindications** |
| 7. Bekhterev's disease |
| 8. Cerebral insufficiency |
| 9. Pronounced adiposity |
| 10. Severe meteorism |
| 11. Massive adhesions |

**Tab. 7.13:** Absolute and relative contraindications for laparoscopy

**Adhesions** are not deemed to be general contraindications, yet in some cases they do involve considerable technical difficulties and a higher risk of complications

− e. g. as a result of the perforation of adherent bowel loops or of the stomach. (185, 234, 287) This was also shown by three of our own cases with a bland course of disease. (253) Another factor to be feared is the puncturing of vessels in the area of the adhesions, particularly in the presence of portal hypertension with "spontaneous Talma" effect. (s. p. 155) (s. figs. 7.5; 14.11). We observed this event in 4 cases, all of which could be well managed. (253) *"Extensive adhesions will always be the worst enemy of laparoscopy"* (H. Kalk, 1929). (240) • With suspected postoperative adhesions, above all in the laparoscopic working area, we have occasionally carried out a lateral X-ray examination after placement of the pneumoperitoneum. The relevance of this examination should, however, not be overestimated. (s. fig. 7.1) This *"diagnostic method using X-ray with a gas-filled abdominal cavity"* was described for the first time by O. Goetze in 1918. • Nevertheless, it must be clearly emphasized that abdominal adhesions are also present in a considerable percentage of patients who have not undergone surgery in the abdominal cavity. These **spontaneous adhesions** can be found in all areas of the abdomen (14.6% of cases) and are due to trauma, intestinal inflammations, pancreatitis or cholecystitis. (322) • Photographic documentation is an absolute necessity in the case of adhesions! • Frequently, symptoms related to adhesions in themselves constitute an *indication for laparoscopy.* In the course of establishing a differential diagnosis for unclarified abdominal discomfort (nausea, vomiting, etc.), it may be necessary, after ruling out all other possibilities, to consider a painful adhesion-related **"serosa syndrome".** (253, 254) By means of an exploratory probe, the pain characteristics familiar to the patient can indeed often be triggered and then localized in the area where the adhesions exist. (s. figs. 7.2, 7.3) In the case of **adhesiolysis** (C. Fervers, 1933), free adhesive bridles can be severed by thermocautery, and occasionally relief from pain is achieved. • Sail-like adhesions can be carefully "fenestrated" by thermocautery in order to advance the laparoscope into areas which have hitherto been out of sight. In retrospective evaluation, we applied *thermocautery* in 120 cases (253): 87 times to fenestrate and improve visibility and 33 times as adhesiolysis for therapeutic reasons in cases of previously indeterminate abdominal pain. Almost all of these 33 patients had been through extensive diagnostic procedures, often over a number of years, with multiple courses of therapy. *One of these patients with pericholecystitic adhesions (an example of which is shown in figure 7.3) had been unsuccessfully treated for almost three years (even psychotherapeutically), but after adhesiolysis, she was ultimately freed from her discomfort.*

▶ In cases of unclarified abdominal pain − *after* all other diagnostic steps have failed − exploratory laparoscopy should constitute the next step *before* commencing psychotherapy!

**Fig. 7.1:** Pneumoperitoneum with pronounced cord-like or sail-like adhesions in the abdominal cavity (X-ray from the side)

**Fig. 7.2:** Extensive postoperative adhesions and bridles

**Fig. 7.3:** Pericholecystitic adhesions causing years of abdominal pain ("serosa syndrome") − *without* previous operative intervention in the abdominal cavity

**Adiposity** is undoubtedly a laparoscopic problem. The abdominal walls can be enormously rich in fat, and the fatty mass is often deposited in the abdominal omentum. Sometimes excessively long instruments are required (such as anaesthesia needles, Veres needle). In two of our own cases, we were only able to carry out the examination under tremendous difficulty because the trocar was too short. The highest reported weight of a patient undergoing laparoscopy is 160 kg. (228)

**Hernias** likewise do not constitute a general contraindication. (228) In numerous cases, we have observed no complications. (253) • Large hiatus hernias are, however, an accepted contraindication.

**Advanced age** is not in itself a contraindication. The patients were above 80 years in 0.3−0.7% of cases. In our group of patients (253), 11 men and 8 women (0.32%) were older than 80, of whom 5 (0.08%) were aged between 85 and 90 years. There were no complications. Nevertheless, in cases of advanced age, indications should be viewed critically.

**Children** can undergo laparoscopy without particular difficulty. (216, 268, 326) The youngest child was an infant aged 14 days (H. Selmair et al., 1973). We ourselves experienced no problems in examining 9 children aged between 5 and 14 years. (253) Laparoscopy is performed under general anaesthesia. With older children (as in our own cases), neuroleptic analgesia or an individual sedation is sufficient. Hepatosplenomegaly, jaundice, metabolic diseases, tumours, chronic hepatitis and portal hypertension are some of the indications.

## 2.6 Laparoscopic technique

Once the indications have been drawn up and critically considered, and possible contraindications weighed up, the *briefing of the patient* follows (on the day prior to laparoscopy) and the *patient's written consent* is obtained. All further measures are then taken. (s. tab. 7.14)

**Sterility** and **asepsis** are imperative for all instruments used and for the places where they are deposited (e. g. instrument trolley). We also recommend the use of sterile drapes as well as sterile surgical gowns (caps and masks are not required) after having disinfected the patient's abdomen. Once the photographic documentation has been completed (using reflex camera, Polaroid, video, etc.), gloves and drapes should be changed. Even though experience has shown the risk of infection to be extremely low for the patient, and although the sterility and asepsis aimed at are not guaranteed in certain working sequences, we still advocate, as a matter of principle, that *laparoscopy should be carried out under conditions that are largely sterile.*

### Premedication

It is advisable to prepare anxious patients with sedation (e. g. doxepin 10 mg) on the evening prior to laparoscopy. For premedication

---

1. *Sonography*
2. *Blood coagulation tests*
   − *Quick's value, thrombocyte count, bleeding time*
3. *Possibly ECG, pulmonary function*

4. **Preparation for laparoscopy**
   - patient under fasting conditions (ca. 12 hours, avoiding gas-forming vegetables)
   - voiding of the bladder
   - stabilizing and protecting a possible hernia with an external adhesive bandage
   - with men, shaving of the abdominal area
   - premedication
     − promethazine (50 mg) + pethidine (50 mg) i. m.
       *or:*
       promethazine (50 mg) + doxepin (25 mg)
       *or:*
       midazolam (0.05−0.1 mg/kg BW)
       (i. m., some 20−30 minutes prior to laparoscopy)
       *or:*
       midazolam (initially 1 mg−2.5 mg) slowly i. v., up to 5 mg total dose
     − atropine (0.5 mg) s. c. about 15 minutes earlier
       (After administration of triflupromazine, we occasionally observed extrapyramidal side-effects; for this reason we ceased using this substance.)
   - positioning of the patient: precisely, comfortably, with wrists and knees fixed loosely to an operating table which can be tilted on all sides
     − padded support of the ulnaris nerve
     − support of the greater trochanter from the side
   - positioning of neutral electrode for coagulation, generally on the right thigh
   - sterile draping of the patient
   - disinfecting the abdomen

*Tab. 7.14:* Preparation for laparoscopy

purposes, the following drugs have proved to be suitable (s. tab. 7.14): pethidine (50 mg) + atropine (0.5 mg), or hydromorphone (2 mg) + atropine (0.5 mg), or midazolam (individual dosage upwards of 1 mg) + atropine (0.5 mg). • *We would recommend the administration of atropine in principle and not only if vagovasal reactions occur.* (s. p. 145)

### Local anaesthesia

Local anaesthesia is effected as intracutaneous skin wheal using a thin needle, whereas for bathyanaesthesia a long injection needle is applied. Lidocaine is recommended as an anaesthetic (0.5% or 1.0%). With the continuous injection of anaesthetic, a sharp pain is reached in the peritoneum, where a preperitoneal depot is then placed.

### Veres cannula

▶ A description of the **Veres needle** was published by J. Veres in 1938. (316) *His name was, however, wrongly printed as Veress in this publication − the correct spelling of his name is "Veres" and the correct pronunciation is "veresch".* • After a stab incision with the tip of the scalpel (i. e. lancet), the needle is inserted against abdominal muscular pressure on the part of the patient. The resistance of both fascia and peritoneum can be felt clearly. A hollow internal cannula with a rounded end stays retracted within the Veres needle during penetration. As soon as the peritoneum has been penetrated, the blunt stylet springs out of the sharp cannula in the peritoneal cavity, and a double clicking sound of the Veres needle is audible. The free position of the needle is checked by the rapid injection of 10−20ml physiological NaCl solution. (s. fig. 7.18)

## Pneumoperitoneum

The point of placement used for the pneumoperitoneum is the so-called **Kalk's point** (this is the later site of insertion for the laparoscope) or the **Monro-Richter line** in the left lower abdominal region (this is the connecting line between the umbilicus and the left anterior superior iliac spine). In the third outer quarter of the line (or at the lateral tertiary point) is the "classical point" for abdominal puncture as well as for the pneumoperitoneum. • Even if a later, second anaesthesia is required for the laparoscope, we consider it useful to maintain the functional capacity of the Veres cannula throughout the whole procedure *as a possible insufflation channel that can be used if required − without discomfort to the patient*. • As a variation on the above-mentioned points of insertion, sites can also be selected below and to the left of the umbilicus. • In 1918 O. Goetze (Halle) introduced an **automatic needle** for producing the pneumoperitoneum. (s. p. 153) (s. fig. 7.1) (s. tab. 7.15)

## Insufflation

Insufflation with nitrous oxide ($N_2O$, i.e. laughing gas) is now carried out by an **automatic-charting $N_2O$ gas insufflator.** The free inflow of nitrous oxide is detectable by auscultation as an even, gentle noise above the Veres needle. After insufflation of the first 300 to 500 ml nitrous oxide, the liver dullness fades, and after a further 1 to 2 litres $N_2O$, a tympanitic percussion sound is generally ascertained. (262, 272, 301, 329) • From the beginning of the slow and evenly maintained process of insufflation, it is advisable to shake the vertically held Veres needle so as to remove any fragments of the omentum which may have been speared. At the same time, fragments which might be caught up between the needle and the stylet can be removed by retraction and forward thrusting of the blunt stylet. Under constant observation of the filling pressure (10 to 20 mm Hg), the required $N_2O$ amount is introduced (3 to 5 litres, in certain cases even more) and the insufflator then switched over to automatic refill. Intraperitoneal pressure is now about $10-12$ mm Hg. The abdominal walls should be evenly raised. • *$CO_2$ is unsuitable for exploratory laparoscopy!*

1. **Formation of emphysema**
   - skin emphysema
   - preperitoneal emphysema
   - omentum emphysema
   - mediastinal emphysema
   - scrotal emphysema
2. **Injuries from insertion**
   - laceration of intestine
   - laceration of blood vessels
   - laceration of an ovarian cyst
3. **Circulatory disorders**
   - collapse
   - arrhythmia
   - cardiac arrest

*Tab. 7.15:* Possible complications in producing the pneumoperitoneum or inserting a trocar

## Insertion of the trocar

The site of insertion for the trocar is **Kalk's point:** $2-3$ cm to the left of and above the umbilicus at the medial edge of the *rectus abdominis*. Further to the left, laterally, there is some danger due to the proximity of the superior epigastric artery, and further to the right, above the umbilicus, there is a certain risk of injuring the round ligament and the umbilical vein as well as the gall bladder. The right lower abdominal region in the area of *McBurney's point* is also to be avoided regarding the insertion of the trocar. • With ascites and adiposity, the navel moves caudad (with gynaeco-logical cystoma, craniad), which must be considered when selecting the point of insertion. In hepatomegaly, splenomegaly and tumours, or with operation scars, the normal site of insertion should be varied accordingly. (s. tab. 7.15)

**Local anaesthesia** is effected in the same way (see above). After some gas has penetrated the syringe sheath, either spontaneously or after slight suction, the depth of the gas-dome and the free lateral mobility is checked with the anaesthesia needle. The **incision** is horizontal, $1-1.5$ cm in length (subcutis and muscles must not be severed!). The **insertion of the trocar** (s. fig. 7.18) is carried out under abdominal muscular pressure on the part of the patient in the inspiration phase and by exerting considerable left-right rotating pressure. A finger of the guiding hand placed along the shaft of the trocar acts as an **"emergency brake"**. After perforation of the peritoneum by the trocar (perceived by the sudden feeling of penetration into a free space and an audible outflow of gas from the tap), the trocar tip is withdrawn and the tap closed. • We most definitely prefer a trocar with a conical, tapering tip (N. Henning, 1950) as opposed to the three-edged tip. (s. fig. 7.18) With the three-edge tipped trocar, we experienced pronounced venous bleeding of the abdominal wall, which, however, could be overcome conservatively.

The sterile **side-view laparoscope,** which has been slightly warmed, is then introduced under direct vision. (s. fig. 7.18) Subsequently, the insufflation tube is removed from the Veres cannula and fitted to the trocar. It has proved beneficial to leave the closed Veres needle (ready for use) in its position throughout the procedure of laparoscopy.

## Staff requirements

Apart from the endoscopist (with intensive-care experience), a further physician should attend the laparoscopy (if possible). Two nurses trained in intensive care are required to assist. This staff constellation has proved optimal. (253)

## Monitoring by apparatus

The patient is monitored by means of blood pressure measurement, ECG, and pulse oximeter. A trolley with emergency equipment must always be at hand in the endoscopy room. Further, the possibility of electrocoagulation should be given in case there is delayed bleeding. • Consideration must be given to a number of **dangers** which can be involved in producing the pneumoperitoneum or inserting a trocar. (183, 188, 206, 217, 220, 254, 262) (s. tab. 7.15)

## 2.7 Course of examination

Initial inspection focuses on the position of the Veres needle and, if necessary, the position is adjusted. • To ensure correct examination, an established **inspection schedule** has proved useful. When such a schedule is applied as a matter of routine, important findings or additional information will not be overlooked. • With *extreme changes in position*, vertigo, nausea, respiratory distress and a tendency to collapse may be witnessed, but these symptoms rapidly ease off once the body position has been normalized. • Altogether, the examination procedure entails 4 different positions. In this way, optimal results can be obtained.

| | |
|---|---|
| **Position 1** | All-round view of the entire abdominal cavity in a supine position (= peritoneum, omentum, bowel loops, adhesions). |
| **Position 2** | Inspection of the right upper abdomen with the upper body raised in left rotation (= right lobe of liver, gall bladder, round ligament, falciform ligament, duodenum). |
| **Position 3** | Inspection of the left upper abdominal region with the upper body raised in right rotation (= left lobe of liver, spleen, round ligament, falciform ligament, phrenicocolic ligament, stomach, diaphragm with oesophageal foramen, pancreas). |
| **Position 4** | Inspection of the minor pelvis in a head-down position and in right and left rotation (= coecum, appendix, uterus, Fallopian tubes, ovaries, hernial orifices). |

### 2.7.1 Assessment of the portal vessels

The development of *portal hypertension* is detectable at a very early stage by the dilatation of small venous vessels in the greater omentum, at the serosa of the stomach, at the parietal peritoneum, and in particular at the round ligament and falciform ligament. A further increase in portal hypertension produces tortuosity of the dilatated fine calibre veins. • *Collateral circulatory pathways* ultimately develop, mostly noticeable at the phrenicocolic ligament, round ligament and falciform ligament with a progredient recanalization of the umbilical vein (s. figs. 6.7; 14.12; 35.11) and paraumbilical veins (= *Cruveilhier-von Baumgarten syndrome*) (s. fig. 7.4) as well as in an area with adhesions ("spontaneous Talma" effect). (s. pp 152, 256) (s. figs. 7.5; 14.11)

### 2.7.2 Assessment of the spleen

Each laparoscopy should aim at a visual assessment of the spleen in terms of (*1.*) *size*, (*2.*) *colour*, (*3.*) *shape*, and (*4.*) identifiable *spleen diseases*. Special mention should be made of capsular fibrosis, hyalinosis ("sugar-coated spleen"), tumours (e. g. Hodgkin's disease, retothelial sarcoma), tuberculosis, splenic cysts, splenic infarction (s. fig. 35.10) and splenic haematoma. Given appropriate positioning, the spleen is visible in 80% of cases. In the case of myeloproliferative diseases, a biopsy of the spleen (e. g. by means of the Menghini technique) can provide a definitive diagnosis. (s. pp 135, 253) (s. figs. 11.1; 14.7) (*see chapter 11*)

**Fig. 7.4:** Cruveilhier-von Baumgarten syndrome in alcohol-induced cirrhosis

**Fig. 7.5:** Portal hypertension with pronounced collateral circulation in an area with adhesions ("spontaneous Talma" effect)

### 2.7.3 Tumour staging

In 1979 T. Hald et al. reported on the importance of laparoscopy in the staging of tumours of the efferent urinary tract. In 30−60% of cases, imaging procedures do not allow the inoperability of liver tumours to be recognized. Preoperative staging by means of laparoscopy showed a sensitivity of 78% and a specificity of 100%. Some 70% of the liver surface can be assessed (as can parts of the underside of the liver when the lobes are lifted). After the noninvasive staging procedure (= recording of TNM classification and other prognostic factors) has been performed, laparoscopy should be used to evaluate operability. (254) • It is also possible for metastases to develop in liver cirrhosis; this was confirmed in 11.4% of cases. (332) • Despite careful preliminary examinations, it was only laparoscopic staging which rendered the detection of peritoneal metastases

possible in 9.1% (211), 35% (321) and 40% (252) of cases, whereupon inoperability was established. • After surgery on ovarian cancer, peritoneal metastases can be expected frequently due to lymphogenic factors − in 22% of cases, this could only be detected by means of laparoscopy. (211) • In tumour staging after application of the available imaging methods in patients with oesophagus and/or gastric cardia cancer, metastases could actually be detected by means of laparoscopy in 24% (210) to 76% (323) of cases. (219, 252, 273, 278, 291) • In patients with pancreatic carcinoma, the laparoscopic detection rate for abdominal metastases varied from 24% to 42%. (186, 292, 320, 321) • In 23−38% of cases, an unnecessary laparotomy could be avoided. (186, 278, 291, 321) Laparoscopy is the best method for the detection of metastases of the omentum and/or peritoneum. (187, 199, 218, 223, 239, 253, 258, 302, 330) (s. figs. 7.6; 37.28, 37.29)

**Fig. 7.6:** Metastasis of a melanosarcoma in the area of the greater omentum (it is as a rule not detectable with US or CT)

### 2.7.4  Fever of unknown aetiology

It is not always possible to attribute the symptom of "fever" to a specific disease. In unexplained febrile states, laparoscopy provides valuable diagnostic aid in differentiating the respective changes of the liver in order to detect rare and otherwise unidentifiable diseases. (63, 97, 229, 249, 304) • This was impressively demonstrated by *one of our own cases of small nodular liver tuberculosis detected by laparoscopic (and histological) diagnostics, which had been preceded by sojourns at two hospitals and unsuccessful implementation of all diagnostic possibilities.* (254) (s. fig. 24.5) (s. also p. 737 and fig. 24.2) In view of the "uncertainty" inherent in unexplained febrile conditions with liver enzyme activity, we consider percutaneous liver biopsy to be too dangerous and too unreliable in its outcome. By means of laparoscopy, it was possible to explain the cause of fever (after ineffective application of every other examination method) in 37% (with the involvement of the abdominal organs in up to 94%) (229) and in 66% of cases. (304)

### 2.7.5  Assessment of the lymphatic vessels

The transparent-white lymphatic vessels, which normally are not (or hardly) identifiable, allow the lymph to flow to the falciform ligament in a deltoid manner. Visible lymphatic vessels are in general deemed to be congested and hence are indirectly suggestive of liver disease. Congested lymphatic vessels appear as blue-grey/silver-grey pathways, often displaying fine fibrotic introsusceptions. In cases of jaundice, the lymphatic vessels take on a distinct yellowish/brownish colour. With pronounced dilation, segmentation of the walls is evident. (s. figs. 7.7; 16.4)

**Fig. 7.7:** Congested lymphatic vessels in the area of the medial part of the right lobe of liver (insertion of the left falciform ligament can be clearly identified) with partial vessel wall segmentation. Here in chronic toxic hepatitis

### 2.7.6  Ascites of unknown aetiology

According to our knowledge, the explanation of the aetiology of ascites goes back to O. E. Nadeau et al. (1925) and S. M. Fierst et al. (1975). After the unsuccessful application of all diagnostic procedures available today, laparoscopy ascertained the cause of ascites in 86% of cases. (207, 290) (s. figs. 16.9; 37.22)

## 2.8  Photographic documentation

Each pathological or interesting finding should be documented by colour photography. Laparoscopy without photographic documentation would be rather like *an X-ray examination without the X-ray picture.* However precisely a particular finding might be described, it can never convince in the same manner as a coloured photo can. Written findings and colour photography must complement one another. (cf. physician's obligation to keep records!)

It would be of great benefit to the **pathologist** if a colour Polaroid shot was enclosed with each sample of laparoscopic material obtained by liver biopsy − in addition to laboratory values, diagnostic issue in question and description of the liver surface. In evaluating the liver biopsy, the pathologist should be aware of the traditional dual assessment of an organ: *macroscopy + histology.*

Documentation of findings is facilitated by **reflex camera** and **Polaroid camera** for coloured photos. Various zoom ranges are used with extracorporeal flash. The film material should be highly sensitive and fine-grained. The photos should be sharply focused close-ups of the main subject. The middle ray of light should be directed vertically, and not tangentially. For photolaparoscopy, the sterile drape of the patient is covered with an extra sterile slit drape, so that the nonsterile photographic techniques can be carried out on top of it. Once the photos have been taken, the slit drape is removed and new sterile gloves put on.

## 2.9 Directed biopsy

Providing there are no contraindications, each laparoscopy should incorporate a directed liver biopsy (H. KALK et al., 1943). This is mainly performed by making a *second incision* in the right upper abdominal region below the costal arch in the area of the right liver lobe, as a rule using a *Menghini needle.*

▶ In cases of **cirrhosis** and pronounced **fibrosis** or **scarred liver**, the danger of bleeding can be greater than the benefit of additional histological information. Moreover, use of the Menghini needle only produces crumbly liver fragments from the cirrhosis (rich in connective tissue), which are not reliable in their histological relevance (compare the fragments of fibrotic liver in chronic porphyria cutanea tarda as shown in figure 7.10!). Even without a biopsy of the cirrhosis, the requirement for objective documentation of all important findings is fully satisfied by coloured photographs. (s. figs. 7.15, 7.16)

▶ Unclear structures can be punctured with a fine needle initially as an exploratory procedure (consistency? cyst? blood vessel?) before the Menghini needle is used. Reports have been written, for example, on the laparoscopic diagnosis of Budd-Chiari syndrome (190), liver abscesses (232), peliosis hepatis (236, 305), FNH (204, 236), Osler's disease (306), and unclarified cholestasis. (280, 299)

▶ In all cases of doubt, or when findings of the right and left lobe of liver differ, both lobes should be biopsied (possibly at two different sites): the right lobe by using the customary second puncture, the left lobe by using a particularly long Menghini needle inserted through the operating laparoscope.

▶ It should be noted that findings in the area of the right lobe of liver can be checked later by percutaneous biopsy − whereas this is not possible in the case of the left lobe.

▶ With all difficult cases, there is a possibility of taking a second or third biopsy punch to produce a greater histological yield (e. g. in cases of granulomatous changes, haemochromatosis).

▶ The *site of puncture* must be easy to observe. The *direction of the puncture* should be as diagonal as possible to the liver surface, mainly in the lateral (or medial cranial) part of the right lobe of liver. (s. fig. 7.8) When puncturing the left lobe, thought must be given to its significantly smaller diameter (and the danger of "piercing through").

**Fig. 7.8:** Recommended, low-risk and contraindicated areas of puncture for liver biopsy

In cirrhosis and fibrosis, the biopsy needle used will either be the **Vim-Silverman** needle or the **Tru-Cut** needle. Adequate tissue can thereby be obtained for assessment. Because of the increased bleeding tendency connected with these needle types, the diameter should not exceed 1.6 mm (which is generally not required anyway). The liver is punctured tangentially, mainly in the lateral area of the right lobe. Subsequent to the puncture, the stylet is removed, the outer cannula advanced, the inner needle sheath pushed forwards in a rotating movement out of the outer cannula before both are finally withdrawn together.

With circumscribed liver findings, the liver biopsy can mostly be carried out using **Robbers' forceps** (H. ROBBERS et al., 1951) (= double-spoon forceps with both lancet jaws opening). By reason of the very shallow and diagonal setting of the biopsy, there is less danger of bleeding and biliary leakage. • Occasionally, certain findings call for **combined tissue biopsy** by means of needle biopsy and forceps biopsy of the liver and/or forceps biopsy in the area of the remaining abdominal cavity.

**Aftercare** for each point of puncture should be continued until the bleeding has definitively stopped and delayed biliary leakage can be ruled out. Upon termination of laparoscopy, the site of puncture and the abdominal cavity as well as the point of exit of the Veres cannula must be checked for signs of bleeding. The Veres cannula should be withdrawn under observation.

**Bleeding** after liver biopsy generally stops spontaneously and definitively. Compression of the low-angle puncture canal ($20-30°$) with a (bulbous) probe can help in this respect. Further methods of arresting the bleeding include local application of thrombin solution, electrocoagulation, Heather method, BICAP technique (s. p. 351), fibrin glue injection (311), positioning of a gelatine cylinder (221), argon-plasma coagulation, and arterial embolization. (83, 115)

Management of **biliary leakage** (s. fig. 7.9) can be attempted by using a dissecting sponge, compressing the puncture canal with a palpation probe or drawing off the bile by suction. Electrocoagulation is also deemed reliable, as is the introduction of a drain through an appropriately placed trocar. It was also our own experience (253) that operative intervention was not necessary. (121)

*Fig. 7.9:* Biliary leakage from biopsy canal after puncture

## 2.10 UV fluorescence

Porphyria cutanea tarda and chronic hepatic porphyria are characterized by porphyrin fluorescence in the liver cell. For every 1,000 biopsies, there are $3-5$ red fluorescent liver specimens. Unfortunately, such UV examinations of the biopsy material are not carried out regularly. In cases of indeterminate diagnosis, red fluorescence can confirm chronic hepatic porphyria that has hitherto remained unidentified. (s. fig. 7.10)

After being extracted, each **biopsy specimen** should be examined in a dish with physiological NaCl solution under **UV light (366 nm)** for a period of some 15 minutes, so as not to overlook the typical red fluorescence of **chronic hepatic porphyria:** *types A* and *B* only show isolated red fluorescent spots in the liver sample, *type C* (as a clinically latent form) already displays a net-like red fluorescence and *type D* (as a manifest form) a homogeneous distribution of red fluorescence. (s. fig. 7.10) • The pathologist will notice the uncharacteristic liver changes, but is not in a position to attribute their genesis to porphyria. (16) For this reason, chronic hepatitis or cirrhosis sometimes remain unexplained and hence "cryptogenic".

*Fig. 7.10:* Red fluorescent liver specimen in porphyria cutanea tarda (type D)

## 2.11 Extrahepatic findings

The diagnostic yield of unexpected, even surprising, extrahepatic findings is quite high at $5-10\%$. Among our 5,992 laparoscopies, we witnessed 452 such findings ($= 7.5\%$): e.g. adhesions (s. figs. 7.1−7.3), peritoneal tuberculosis (191, 233) (s. fig. 7.11), and carcinosis (199) (s. figs. 7.6; 37.28, 37.29), diverse malignomas (s. fig. 7.12), Fitz-Hugh-Curtis syndrome (s. fig. 24.2), endometriosis, myomas, ovarian cysts, Stein-Leventhal syndrome (s. fig. 7.13), Hodgkin's disease (s. fig. 38.8), chronic appendicitis, echinococcus, and so on. (253) • In cases of unexplained pain in the abdomen, laparoscopy is indicated as a last resort for clarification of the complaints. (254, 295) This is necessary above all in differential diagnosis between gynaecological disease and appendicitis. (195, 250, 324) In suspected appendicitis, appendectomy frequently proved to be the wrong decision: in 23% of cases involving young women, a gynaecological cause of complaint was found; however, in older patients (> 50 years), appendicitis was actually detected in $92-96\%$ of cases. (195) • The clinical picture of an acute abdomen could be clarified in > 85% of cases by means of exploratory laparoscopy. (184, 267, 295) • *The opportunity of clarifying unexplained symptoms by exploratory laparoscopy should be made use of whenever possible.* At this early point, it is of no importance whether the ultimate explanation or definition of
**Fig. 7.11:** Peritoneal tuberculosis: fever of unknown aetiology in a severe course of disease

**Fig. 7.12:** Gall-bladder carcinoma: clinical and radiological suspicion of "cholecystopathy"

findings proves to be clinically relevant in the individual case, or without significance. (200, 230, 251)

## 2.12 Complications

The type and frequency of complications involved in laparoscopy are determined by the same **influencing factors** as were outlined for the complication rate of percutaneous liver biopsy. (s. tab. 7.5) With each complication, these factors should be considered critically and without bias.

The most frequent complication by far is **bleeding.** If this cannot be stopped conservatively, it may require surgery − or it can even prove lethal. Injuries may occur during the insertion of the *Veres cannula* and the *trocar* when vessels and varices in the abdominal wall and omentum as well as abdominal vessels have been pierced. Isolated cases of bleeding have been reported after injury to the spleen − which is perhaps understandable in splenomegaly, but nevertheless avoidable. *Liver puncture* (as well as *forceps biopsy* in the case of pathological abdominal findings) can be a further cause of bleeding, above all in cirrhosis or liver tumours.

**Fig. 7.13:** Stein-Leventhal syndrome: white, thickened capsule of the right ovary. Clinical suspicion of pronounced liver damage due to hormone therapy

Other *severe complications* worth mentioning include: perforation of hollow organs (gall bladder, colon, stomach, small intestine, ovarian cysts), emphysema formation due to gas insufflation, circulatory and cardiac arrhythmia, respiratory arrest, rupture of the spleen (212) and injury to the spleen (264), as well as the complications occasionally occurring with liver biopsy (haemobilia (288), haematoma, a. v. fistula (297), biliary leakage, sepsis (214), etc.). (183, 192, 215, 220, 228, 244, 266, 275, 284, 303) The (disturbing) occurrence of bradycardia is not usually evident when atropine is administered as routine premedication. (s. pp 145, 153) • Among our own 5,992 laparoscopies, we recorded 58 complications (0.97%), yet no instance of death. In five cases of bleeding, operative treatment was required (0.08%). (253)

> During laparoscopy, we routinely maintain an intravenous *drip*. This has proved beneficial for additional sedation as well as in those cases where complications occur; it can therefore be recommended as a general principle.

## 2.13 Frequency of complications

Compiled statistics and publications involving a larger number of patients provide an overview of the frequency of complications and cases of death. (s. tab. 7.16) In 17 laparoscopy series covering 46,364 patients, a complication rate of 0.149% and a lethality of 0.054% were established. (275) • Occasionally, the complication rate was somewhat higher in centres with more frequent examinations: it is indeed possible that the greater the experience on the part of the physician, the more likely it is that risks are taken in evaluating contraindications. • *With a decrease in the number of laparoscopies performed, however, it must be expected that laparoscopic experience will also decline, so that the incidence of complications will (unfortunately) rise − a fact which might*

| Author | Total number | Complications | | Cases of death | |

***Tab. 7.16:*** Frequency of laparoscopic complications and cases of death (* = compiled statistics)

*be blamed all too easily on laparoscopy itself. Neither of these extreme situation-related developments can be accepted.* • Some of the complications observed in the past (202, 220, 241, 284, 308) should not really be expected today, given modern technical possibilities. Some statistics not only included severe complications, but also harmless ones, a fact which explains the differences in percentages. • The frequency of *more severe complications* is **0.15−0.80%,** the *total rate* of significant complications can be put at **<1.0%.** Based on compiled statistics, the lethality rate is up to **0.07%.** • Some **0.08−0.2%** of complications required *operative intervention.* • Registration of all complications (even slight or harmless events) resulted in a complication rate of 3.0% (266) and 4.87% (228). • In 6,000 laparoscopies of our own, the complication rate was 0.97%, with a mortality rate of 0%. (253) • Out of 20,000 laparoscopies, the largest number ever registered in one hospital, E. WILDHIRT reported just 2 cases of death (0.01%). (328) • The largest number of laparoscopies to be performed in a single hospital is believed to be over 50,000 (R. LLANIO et al., Habana/Cuba) *(personal communication).*

## 2.14 Diagnostic validity

The accuracy of histological diagnosis depends on (*1.*) the *biopsy specimen* being large enough (>1.5 cm, 5−10 portal fields) as well as being definitively assessable (1, 64, 96, 148, 171) and (*2.*) whether the specimen can be deemed to be *representative for the liver* − bearing in mind that the usual weight of a biopsy punch amounts to 20−30 mg (i.e. 1/75,000 to 1/50,000) of the total liver. • It depends equally on the *hepatological experience* of the investigating pathologist and on the findings available to him (possibly including a Polaroid photograph of the liver!). • It was shown in a study that when the histological result was double-checked by a pathologist with extensive experience in hepatology, there was complete agreement only in 34.4%, considerable discrepancy in 28% and slight discrepancy in 37.6% of cases. (6)

**Diffuse liver diseases:** Histological findings of the biopsy specimen are generally considered to be representative for the given liver disease. The accuracy of percutaneous bioptic diagnosis is 80% to 100%. • The colour of the biopsy specimen, which varies from pale yellow (fatty liver) to greenish-black (metastasis of melanoma), may give a hint of the respective underlying disease. (s. fig. 7.14) (28, 107, 109, 111, 134, 166, 222, 227, 238, 257, 286, 209, 317, 319, 328)

***Fig. 7.14:*** Liver biopsy specimens: I. in fatty liver (pale yellow), II. in a metastasis of a malignant melanoma (greenish-black)

**Focal liver diseases:** Biopsy material cannot be guaranteed as being representative. A higher degree of diagnostic accuracy can be achieved by a 2 to 3 fold liver biopsy in the course of a laparoscopic-bioptic examination of both lobes of liver. The same is true for peliosis hepatis (236, 305), granulomas and chronic hepatitis C, for example. (120)

▶ **Cirrhosis:** In cases of cirrhosis, consideration must be given to the fact that the condition relates to the entire liver − yet not necessarily to each lobular area. For this reason, micronodular cirrhosis is generally better targeted (95%) than macronodular cirrhosis (60%). (84) Under certain circumstances, the biopsy of a large regenerative node can lead to the (understandably) wrong diagnosis of a "practically normal liver parenchyma".

*Consequently, the false-negative rate with percutaneous biopsy of cirrhosis lies between 9.3% and 51%* (84, 201, 231, 238, 253, 274, 283, 289, 309, 317, 318, 331) and can even be as high as 80% if the yield is smaller than 5 mm. (64) This high error rate is caused by the Menghini needle slipping off the cirrhotic connective tissue and penetrating the neighbouring soft regenerations. The Menghini technique usually only produces *crumbly fragments* of a cirrhotic liver, since fibrous tissue septa remain in the liver, rather like the panicles of a stripped leaf. Such fragments generally suggest the presence of cirrhosis, even if the pathologist is unable to make a definitive diagnosis. (s. figs. 7.15, 7.16) • *A percutaneous bioptic diagnosis of cirrhosis is not acceptable because of the wide margin of error and the greater risks involved with the biopsy. Laparoscopy with its additional techniques − now deemed to be the gold standard − ought to be performed instead.* • The diagnosis of liver cirrhosis, and its differentiation from fibrosis and scarred liver, can as a rule be reliably established by looking closely at the surface of the liver ("glance diagnosis"). Findings should also be documented by colour photography. (s. figs. 14.3; 16.5; 28.7, 28.13; 31.24; 32.5; 33.4; 35.2, 35.3, 35.6, 35.8, 35.14!)

**Fig. 7.15:** Active, micronodular, in part moderately nodular (alcohol-related) cirrhosis with pronounced pathways of postnecrotic connective tissue

Due to their cutting action (which differs from the Menghini technique), **Vim-Silverman** and **Tru-cut needles** produce a sufficiently large and almost intact cirrhosis tissue sample. As a consequence, the false-positive results can be brought down to below 10%. Nevertheless, the risk of subsequent bleeding is clearly higher. For this reason, the diameter of the needle should not exceed 1.6 mm.

▶ The combined examination with **laparoscopy** and **directed biopsy** (thick- or fine-needle biopsy or use of Robbers' forceps) yields the greatest diagnostic accuracy at 97−100%. This has been impressively confirmed in *children* as well. • Foci not visible by laparoscopy can be

**Fig. 7.16:** Inactive, micronodular (drug-related) cirrhosis with fine pathways of connective tissue; clinically and histologically definable as "liver fibrosis" (sonographically no signs of portal hypertension)

detected by ultrasound- or CT-guided biopsy and fine-needle puncture. Occasionally, an existing liver disease cannot be differentiated morphologically, simply because biopsy is contraindicated.

▶ Laparoscopy is particularly significant in differentiating between **benign** or **malignant foci,** such as adenoma with malignant degeneration (s. fig. 29.14), haemangioma (s. figs. 36.6, 36.7), focal nodular hyperplasia (s. fig. 29.12), Hodgkin's disease (s. fig. 38.8), carcinoma in cirrhosis (243) (s. fig. 37.7), metastases in the area of the liver, ligaments or serosa (s. figs. 37.28, 37.29), etc. Exploratory laparotomy, which was used in the past, is now obsolete. • Usually, in such cases, there is often no need of "one-second needle biopsy" − just "one-second glance diagnosis" might well be fully sufficient for an exact assessment. *(see chapters 36 and 37)*

▶ The **cost factor** must likewise be considered; in Germany, for example, laparoscopy is very reasonable at about 75 US dollars as compared to scintigraphy (approx. 130 US dollars), CT (approx. 240 US dollars) and MRT (approx. 400 US dollars).

▶ From the point of view of hepatological **detailed diagnosis,** it is necessary to carry out liver biopsy, laparoscopy or fine-needle biopsy, depending on the diagnostic issue in question. They are part of the diagnostic routine of a clinical hepatologist. (24, 135) A high degree of experience resulting from the routine performance of laparoscopy also guarantees a maximum of diagnostic findings in combination with a minimum of complications. In this connection, a laparoscopic training programme has proved most useful. (285, 315) Such programmes might help in future to revive laparoscopy as a routine method of investigation − even under outpatient conditions.

# 3 New technical progress

► With the help of fibre optics it has been possible to develop much smaller instruments with a diameter of 2 mm (max. 2.75 mm) − so-called **mini-laparoscopy**. (s. fig. 7.18) Clinically speaking, this revolutionary technique has stood the test in an excellent manner. (235) This also applies to the field of hepatology, especially concerning high-risk patients. (225, 226, 271, 300) The lighting conditions are still not completely satisfactory and illumination is often insufficient. Up to now, only prograde optics have been available (cf. **conventional laparoscopy** with side-vision and angle optics). (s. fig. 7.17) Nevertheless, we now have a minimally invasive, elegant and safe technique for exploratory laparoscopy and targeted biopsy at our disposal. This new technique will signify the renaissance of laparoscopy, probably also under outpatient conditions.

► The introduction of **laparoscopic sonography** has opened up new diagnostic possibilities. (s. p. 138) (s. tab. 7.10) This applies above all to the detection of intrahepatic metastases, lymphnodular metastases and changes in the vascular system. In 46% of patients, new insight was gained, which led to a modification of therapy in 40% of cases. (219) In 10% of patients, intrahepatic metastases, some with a diameter of <1 cm, were discovered with the help of this technique, even in segments 3 and 4 (H. FOROUTANI et al., 2000).

► It is to be expected that by means of **light-induced fluorescence diagnostics**, further improvements in the differentiation of morphological findings can be achieved.

*Fig. 7.17: Conventional laparoscopy equipment:* (*1.*) laparoscope, ∅ 10 mm, distortion-free, angle of view 0°, working length 300 mm; (*2.*) laparoscope, ∅ 5.3 mm, distortion-free, angle of view 25°, working length 300 mm; (*3.*) laparoscope ∅ 3.5 mm, working length 180 mm; (*4.*) Veres cannula including Luer connector, working length 120 mm; (*5.*) operating laparoscope, ∅ 10 mm, distortion-free, with right-angled eyepiece, 5 mm working channel, with detachable automatic instrument valves, angle of view 0°, working length 265 mm; (*6.*) trocar sleeve, with insufflation tap and magnetic-ball valve, metal sleeve standard, straight distal tip, working length 100 mm; (*7.*) trocar, pyramidal tip. # Diagnostics in Liver Diseases

## 8  Radiological diagnostics

# 8 Radiological diagnostics

A definite diagnosis is often not obtained in liver disease despite the combined use of the **mainstays of diagnostics:** (*1.*) *clinical findings*, (*2.*) *laboratory examination data*, and (*3.*) *ultrasonography.* Possibly even (*4.*) *morphological analysis* has been unproductive or was not indicated at all. This raises the question of using special radiological and nuclear medical examination techniques. • Diagnostic problems may arise, especially with regard to the following **issues:**

- Identification of intrahepatic foci
- Clarification of the benignancy or malignancy of focal liver lesions
- Differentiation of vascular-related liver diseases
- Detection of alterations regarding the bile ducts
- Differential diagnosis of mechanical jaundice
- Assessment of portal hypertension
- Extent of collateral vessels
- Unclarified diffuse alterations of the liver parenchyma
- Control following liver trauma
- Staging of malignant tumours
- Checking indications for surgical intervention
- Examination before and follow-up after liver transplantation

Different **radiological procedures** are available for clarifying these diagnostic issues. (s. tab. 8.1)

1. Computer tomography (CT)
2. Magnetic resonance imaging (MRI)
3. Arteriography
4. Portography
5. Phlebography
6. Cholangiography

**Tab. 8.1:** Radiological procedures used in the diagnosis of hepatobiliary diseases

▶ These various imaging techniques (s. tab. 8.1) − as well as some nuclear medicine-based methods (*see chapter 9*) − enable key features of benign and malignant tumours to be recognized, including (*1.*) vascularity, (*2.*) internal structure, (*3.*) hepatocyte functions, (*4.*) biliary tract, (*5.*) bile secretion, (*6.*) calcification, and (*7.*) Kupffer cell activity.

# 1 Computer tomography

▶ Tomography was developed by A.E.M. Bocage and registered as a French patent in the same year. It was further developed in the form of transversal (and axial) tomography by H. Vieten (1936) and registered as a German patent. A research team headed by A. Gebauer presented a device for use in clinical practice in 1945. • The **introduction** of computer tomography (CT) into medicine by G.N. Hounsfield in 1971 (skull CT) and as computerized transverse axial scanning (tomography) in 1973 was a revolutionary event comparable with the discovery of X-rays by W.C. Röntgen in 1895. (15) • As early as 1975, the first normal CT scan of the upper abdomen was reported (R.J. Alfidi et al.) (1), and in the same year, the first pathological findings from abdominal diseases (relating to the liver) were also presented (D. Schellinger et al., 1975). (38)

## 1.1 Principle

In computer tomography, the attenuations of many finely focused X-rays are measured by detectors and converted to electrical signals. These values are transmitted to a computer. Subsequently, the absorption value of each image point is calculated and displayed in a complex digital image. The transmission of X-rays through the body occurs in the form of fan beams and is recorded by a rotating detector fan (3rd CT generation). The 4th CT generation is characterized by a static detector crown, spanning 360 degrees, around which the X-ray source continually rotates. (9) • More advanced spiral CT facilitates spiral scanning, permitting continuous imaging of the analyzed area while the patient holds his/her breath. This provides accurate anatomical data without respiratory artefacts and with optimum exploitation of the CM bolus. (3, 5, 6, 10, 12)

In contrast to ultrasonography, which is based on the recording and imaging of the reflection of sound waves between tissues with varying acoustic impedance, the radiological signal is produced by **differences in absorption.** • With the **radiation doses** used ($100-140$ kv), the absorbed dose of energy corresponds to 0.013 Gy (1.3 rad) per tomographical slice. By using many finely focused X-rays, the dose is largely restricted to the body layer to be imaged. Therefore, only a relatively low scatter of radiation has to be taken in consideration. The radiation exposure of a CT scan is comparable with that of a plain radiograph of the abdomen.

With consecutive tomograms, the thickness of each section of the body is 5-8-10 ($-12$) mm. In individual cases, additional thin-section tomograms of 1 mm can be obtained. Resolution is $1 \times 2$ mm in the hepatic area, with an accuracy in attenuation values of up to 0.5%. In this way, the values for a particular cross-section and their spatial distribution are visualized in a scan. This results in blur-free, anatomically precise imaging of a layer of the body in an axial plane. CT scans provide satisfactory information if an object diameter of 1.5 to 3 mm is resolved with a density gradient of 0.5% to the surrounding area at an integral dose of 10 mGy.

## 1.2 Hounsfield units

The attenuation values are given in Hounsfield units (HU), the density scale ranging from $-1,000$ (= air) through 0 (= water) to $+1,000$ (= bone). These 2,000 shades of brightness are recorded by the computer, but

are not perceived by the human eye. Due to the technical possibility of choosing only a small part of the Hounsfield scale and shifting it within an organ section, smaller differences in density can be more easily detected. Thus within certain limits, CT is indeed able to provide information about the kind of lesion involved. The special value of CT lies in the possibility of determining the density of various tissues, e.g. the structure of fatty tissue is identifiable. This option helps with the differential diagnosis of space-occupying processes (benign vs. malignant). There may be slight fluctuations in the normal Hounsfield units caused by *small vessels* included in the measuring volume. • The terms **hypodense, isodense** and **hyperdense** are used to describe pathological changes. (s. p. 126)

## 1.3 Contrast media

(*1.*) A major improvement in the diagnostic power from **native CT** is achieved by the use of contrast media (CM) (1−1.5 ml/kg BW; 1−5 ml/sec), transported via the kidney or in the bile. The CM is administered as i.v. infusion using programmable infusiomates or in the form of an i.v. or intra-arterial bolus. With the currently used conventional CT apparatus (which has a short scanning period of 0.7−5.0 seconds), i.v. administration of a CM bolus (if necessary, with additional i.v. infusion of CM) has proved most effective with regard to the subsequent rapid imaging (4−8 pictures during the first minute) of **dynamic-sequential CT.** This provides detailed assessment of CM dispersion in the intravascular and extravascular areas. (25) The differences in density between the various organs and between the normal liver parenchyma and pathological tissue structures are markedly accentuated. Furthermore, the arterial phase, enhancement of the parenchyma and the phase of venous drainage are recorded simultaneously. • The value of **cine CT** with extremely short scanning periods (7 pictures per second) has not yet been defined with respect to liver diagnostics.

(*2.*) Application of **CT arteriography** (CTA) through the hepatic artery or **CT arterioportography** (CTAP) corresponding to indirect splenoportography (i.e. via the superior mesenteric artery or splenic artery) is considered to be the most efficient procedure in the diagnosis of focal liver lesions. However, it has the disadvantage of being an invasive method. Exact indications (above all for preoperative use) have been defined. • *Modern* **spiral CT** *(SCTA or SCTAP) with i.v. (not intra-arterial!) injection of contrast medium facilitates excellent angiographic tissue reconstruction on an outpatient basis.* (6)

## 1.4 Normal liver

The normal liver is characterized by smooth contours and a homogeneous density of 1.068 ± 0.005 g/cm$^3$. The absorption values are 60 ± 6 HU (or 64 ± 5 HU). Major vessels are delineated as hypodense areas with values of 40−45 HU. The bile ducts near the hilus are occasionally recognized by their hypodensity (5−15 HU); imaging is improved by using a biliary contrast material. CT permits good visualization of the gall bladder. The density of a normal liver is either the same as or up to 8 HU higher than that of the spleen. In some cases, the segments can be delineated.

**Volumetry:** Using CT, it is possible to determine the size, shape and volume of the liver with considerable accuracy. Hepatic volumetry can be performed with high-level reliability (deviation ± 5−10%). (48)

**Falciform ligament:** Reduction in the density values in the area of the falciform ligament is explained in the literature by fat deposition. (s. fig. 8.1) • In more than 6,000 laparoscopies, I have never observed any fat deposition at the areas of attachment of the falciform ligament (neither in the liver nor at the abdominal wall) or on the transparent ligament itself. (s. fig. 16.4!) • I did, however, frequently find mesenteric fatty tissue along the *round ligament*. In addition, intrahepatic fat deposits under the falciform ligament are not known either to the anatomist or the pathologist. • This finding is probably the round ligament, which is occasionally rich in fat, or regional (pathological?) fatty degeneration, as shown in figures 8.3 and 8.4. (s. p. 127)

▶ *Up to now such (oval) fat deposition has been interpreted by the radiologist as being a falciform ligament (s. fig. 8.1) − this viewpoint must now be reconsidered. It should in any case be noted that the falciform ligament is totally devoid of fat!*

*Fig. 8.1:* Frequently recorded reduction in density in the area of the falciform ligament (here: 11.4 HU) resembling "fatty tissue" (possibly a round ligament?) (s. pp 127, 132)

## 1.5 Contraindications

Contraindications include (*1.*) pregnancy, especially in the early stages, (*2.*) known contrast-medium intolerance (restricted to native CT), and (*3.*) renal insufficiency (in which only native CT may be used). With creatinine levels of >1.5 mg/dl, the administration of contrast material is only advisable after consulting an experienced nephrologist. (*4.*) In existing hyperthyreosis

(latent or manifest), the thyroid gland must be blocked with sodium perchlorate and even treated with carbimazole if necessary − because of the application of a CM which contains iodine (ca. 300 mg/ml). • A *relative contraindication* applies to diabetics treated with the oral antidiabetic metformin hydrochloride, as this compound competes with the CM in the kidney for elimination. The drug should be discontinued 2 days prior to the administration of the contrast medium.

## 1.6 Indications

The indication for the use of CT is only given after a careful (and as far as possible repeated) ultrasonographic examination. Due to the considerable amount of technical equipment required and the high costs involved as well as the radiation exposure associated with this method, CT is not a routine examination procedure. Clinical indications should be assessed thoroughly and must in themselves be justified. (9) (s. tab. 8.2)

1. Primary liver tumours
   - Primary liver cell carcinoma (5, 11, 18, 23, 28, 30, 31)
   - Haemangiopericytoma, -endothelioma
   - Cholangiocarcinoma (55)
   - Cystadenocarcinoma (4)
2. Secondary liver tumours
   - Metastases (22, 39, 50, 53, 57)
3. Benign liver tumours
   - Cysts (51)
   - Abscesses
   - Adenoma, FNH (2, 23, 24, 26, 34, 37, 42, 52)
   - Haemangioma (17, 32, 35, 40, 54)
   - Echinococcus (8)
   - Tuberculosis (19, 21)
   - Lipoma
4. Parenchymal disorders (29)
   - Focal fatty infiltration (13, 36, 39, 45, 56)
   - Cirrhosis (49)
   - Haemochromatosis (20, 29)
   - Primary sclerosing cholangitis (7)
5. Mechanical jaundice (47)
6. Condition following liver trauma (33, 41)
   - Haematoma
   - Rupture
7. Caroli's syndrome (16, 44)
8. Prior to and after liver transplantation (43)
9. Fasciola hepatica (14)
10. Unknown ascites
11. Splenomegaly
12. Budd-Chiari syndrome (27)
13. Portal vein system (46)
14. Interventional measures
    - punctures, drainage tubes
    - chemoembolization

***Tab. 8.2:*** Indications for computer tomography in hepatobiliary diseases (with some references)

## 1.7 Diffuse liver diseases

### 1.7.1 Fatty liver

In correlation with fatty infiltration, the fatty liver shows a *diffuse reduction in density* with decreased Hounsfield units. The fatty liver appears much darker than the spleen (so-called grey liver). Hepatomegaly with smooth contours is visible. The parenchyma is isodense or hypodense compared with the vessels and bile ducts, which is why (depending on the degree of fatty infiltration) there is a reversal of density (so-called "negative scan"). A linear correlation exists between the extent of the fatty infiltration and the decrease in the density recorded. An increase in the relative fat content by 10% leads to a reduction in density of 17(−20) HU.

With fatty degeneration of about 80%, the density is decreased to approx. −50 HU. CT may be useful in controlling the course of a fatty liver, a scan through the middle of the liver being sufficient for this purpose.

***Fig. 8.2:*** Pronounced, toxic fatty liver following cytostatic chemotherapy with recorded values of between −9.9 and −1.1 HU. The liver is homogeneously dark (compared to the bright spleen). The vessels appear brighter (values of between +40 and +50 HU)

***Fig. 8.3:*** Pronounced focal (regional) fatty degeneration of the liver of varying intensity: both visual and confirmed by Hounsfield units (−14, −9, +4, +30). Native CT, normal value +65 HU

Stage differentiation between hepatocellular *fatty infiltration* and *fatty liver* is not feasible with CT. The success rate for diagnosing a fatty liver by means of CT is 85−95%. (s. fig. 8.2) • Besides being diffuse and homogeneous, the fatty liver may also exhibit regional (lobular or segmental) *focal fatty infiltration* of varying degrees. (s. figs. 8.3, 8.4) (cf. figs. 6.12, 6.13) Occasionally, focal infiltration is only barely, or not at all, distinguishable from a malignant tumour. Here MRI is an important additional procedure. (13, 36, 39, 45, 56) *(see chapter 31.3)*

**Fig. 8.4:** Segmental fatty degeneration of the liver (2 = 37.3 HU) following application of CM compared with liver parenchyma of normal density (1 = 68.5 HU), and the spleen (3)

### 1.7.2  Liver cirrhosis

As a rule, liver cirrhosis exhibits absorption values which are no different from those of a normal liver. Advanced stages show an enlargement of the caudate lobe and possibly also of the left lobe as well as alterations in form or shrinkage of the right lobe (or both lobes) with fine to coarse nodular irregularities on the surface. In some cases, an increase in density of up to 60−70 HU is verifiable. Usually, splenomegaly and further signs of portal hypertension are present. • Hypodense foci may indicate HCC and should be examined with the aid of contrast medium or MRI. (7, 29, 46, 49)

### 1.7.3  Haemochromatosis

Haemochromatosis leads to an increase in the density of the liver parenchyma, which correlates with the accumulation of iron. CT scans reveal a remarkably dense and bright liver parenchyma with density values of up to +140 HU (so-called white liver). The deposition of 1 g iron results in a rise in density of 1 HU. (20) CT densitometry clearly facilitates effective control of therapeutic success in this storage disease. It is not possible, however, to differentiate pronounced secondary haemosiderosis. • *Hyperdense values* are also found in longterm **gold therapy,** in **glycogen thesaurismosis** and **M. Wilson,** or in chronic **arsenic poisoning.**

## 1.8  Focal liver lesions

Even by means of computer tomography (like ultrasonography), a definitive distinction cannot be made between primary and secondary or benign and malignant liver tumours, except in the case of liver lipoma. However, differentiation is greatly improved by using contrast medium and CT angiography. Radiomorphological identification of focal lesions with a diameter of <0.3−0.8 cm is not (yet) possible, even with the aid of more sophisticated appliances: geometric resolution and density resolution have their limits. The density analysis of focal findings will thus only yield reliable information if the diameter of the focal lesion is within the range of the twofold thickness of the section plane used. Compared with liver parenchyma, most focal lesions are hypodense. *Hyperdense values* (see above) are encountered with calcifications and occasionally also with fresh bleeding and scar tissue. (2, 12, 18, 23)

The **sensitivity** of CT for the confirmation of focal lesions is 84−96%, with a **specificity** of 86−100%. Differentiation between intra- and extrahepatic obstruction was successful in 77−97% of cases; the location of the obstruction was clarified in 79−98%, and the aetiology of the obstruction was established in up to 76% of cases.

### 1.8.1  Benign liver tumours

1. **Adenoma** is not characterized by any specific features in CT. Density varies between hypodense and slightly hyperdense. The contours are smooth. Following the administration of CM, brief and homogeneous accumulation mostly occurs in the adenoma with the appearance of an initially hypodense margin, which is enhanced in the late phase as a hyperdense border. However, contrast medium which is transportable in the bile cannot enter the adenoma, because it does not contain any biliary structures. An adenoma is frequently distinguished from FNH by evidence of necrotizing areas or sites of fresh bleeding; the latter are recognizable as hyperdense areas. (24, 26, 52)

2. **Focal nodular hyperplasia (FNH)** is distinctly circumscribed, usually round or oval in shape and isodense to slightly hypodense. As a rule, a predominantly hyperdense, central scar zone with stellate septa consisting of connective tissue is visible. Following application of CM (by i.v. infusion), equal concentrations are seen in the liver parenchyma and hepatic tumour, so that the latter may easily pass undetected. In contrast, following i.v. bolus injection of CM, a short, marked and homogeneous enhancement occurs, except in the central cicatricial area. • By means of hepatobiliary sequential scintigraphy, the diagnosis of FNH can be confirmed, particularly with regard to its differentiation from adenoma. (26, 34, 37, 42, 52) (s. p. 194)

173

3. **Cavernous haemangioma** is hypodense; in some cases, small hyperdense calcified foci are seen within the generally thrombotic centre. The contours of the haemangioma are usually smooth. Density is 35−55 HU. *Bolus injection of CM* is an important diagnostic tool. In the early phase (10−30 seconds), increased, predominantly irregular or garland-form enhancement is observed in the periphery, followed within a few minutes by a slow centripetal increase in density up to isodense values (so-called *"iris-diaphragm phenomenon"*). In the late phase (>10−15 minutes), even hyperdense values may be recorded with a parallel decrease in the density of the surrounding liver parenchyma. (s. fig. 8.5) Haemangiomas with a diameter of >1.0 cm can usually be diagnosed. Thrombotic or fibrotic processes within the haemangioma make differential diagnosis more difficult. (17, 32, 35, 39, 54) • In our opinion, *percutaneous fine-needle biopsy is not advisable!*

*Fig. 8.5:* Haemangioma (see arrow). Dynamic CT (contrast-enhanced); portal venous phase (s. figs. 6.15; 8.9; 36.6, 36.7)

### 1.8.2 Vascular lesions

1. **Hepatic haematoma** mostly appears as a well-defined hypodense area; branching is seen in some cases. Intrahepatic haematomas are predominantly round-oval, whereas subcapsular haematomas are mainly crescent-shaped. Depending on their persistence, haematomas have different density values: initially, they are as a rule slightly hypodense (40−50 HU), but moderately hyperdense values can already be recorded after a few hours following the reabsorption of plasma. The values become more hypodense (10−20 HU) with increasing lysis and exceed 80 HU in the presence of calcification. Connective tissue structures generally show values ranging from 50 to 60 HU.

2. **Liver injury:** Fresh bleeding can be reliably differentiated from a long-standing haemorrhage by CT, which is of importance when surgical procedures are being considered. (33, 41)

3. **Hepatic infarct** generally leads to a sharply delineated, in most cases triangular, hypodense area, possibly extending up to the liver surface.

4. **Budd-Chiari syndrome** may be imaged in CT as hypodense zones; the findings are not, however, reliable. (27) A definitive diagnosis can be obtained by angiography or MRI.

### 1.8.3 Hepatic cysts

1. **Dysontogenetic cysts** are solitary or multiple. They are clearly distinguishable from their surroundings, have smooth walls and are readily recognizable by their hypodense (water-equivalent) density values (0−20 HU). In the case of bleeding into the cyst, higher density values are recorded. (This also applies to infections of the cyst fluid or the occurrence of mucous contents.) Following i.v. application of CM, the cyst exhibits no increase in density (in contrast to metastases). A cystic liver is usually associated with cystic kidneys or cystic pancreas. (51) (s. figs. 6.10; 8.6; 36.9)

*Fig. 8.6:* Pronounced dysontogenetic cystic liver and cystic kidney

2. **Echinococcus cysticus** is generally visualized as a multilocular septate cyst with embedded secondary cysts. Both primary and secondary cysts are surrounded by inflammatory granular tissue. During the subsequent course of the disease, calcium deposition is seen in the cystic wall. The application of CM results in mural enhancement. The resulting demarcation of the cysts within the liver is relatively sharp. (8) (s. p. 497)

3. **Echinococcus alveolaris** presents a totally different picture: during the exocystic development of secondary cysts, the parasite gives the impression of growing in an infiltrative, destructive manner. CT scans reveal vaguely outlined, hypodense lesions of a cyst-like nature with nodular calcification (in most cases). Following the application of CM, an inhomogeneous increase in density is observed within the perifocal inflammation. Echinococcus alveolaris is, therefore, easily confused with malignant tumours. (s. p. 500)

4. **Caroli's disease** presents with multiple tubular structures, which correspond to focal cystic dilations of large interlobular bile ducts. The reduced density values of

these ectatic structures in CT are bile-equivalent. Intravenous application of a biliary CM provides the definitive diagnosis. Both portal fibrosis and portal hypertension are present. (16, 44) (s. p. 662)

5. **Choledochal cysts** are congenital, segmental dilations of the larger intrahepatic bile ducts and/or the common bile duct. Diagnosis is obtained by i.v. administration of a biliary contrast medium. Choledochal cysts are frequently combined with tumours, so that additional corresponding signs of biliary obstruction may be verified by means of CT.

### 1.8.4 Inflammatory liver lesions

1. **Liver abscesses** are mostly (approx. 80%) localized in the right lobe of liver. A pyogenic abscess is visible as a hypodense lesion (0−30 HU) corresponding to the suppurative material with relatively sharp contours. It is surrounded by a hyperdense rim, caused by the well-vascularized granulation tissue. Should a perifocal oedema be present, it may produce an additional hypodense rim. Following the application of CM, an increase in the density of the hyperaemic and hyperdense abscess wall is observed, whereas the density of the abscess remains unchanged. Gas formations inside an abscess caused by anaerobes are easily recognizable on a CT scan. The success rate for detection is 95%. (s. figs. 6.11; 9.2; 25.1; 27.1) *(see chapter 27)*

2. **Macronodular tuberculosis** as screened by CT may be very problematic with respect to its differentiation from benign or even malignant liver tumours. (19, 21)

## 1.9 Malignant liver tumours

Most malignant liver tumours are hypodense; the difference in value to normal liver parenchyma is usually 15−25 HU. Evidence of hepatic malignancy is obtained by CT, especially by CTAP, in approx. 85% of cases with tumours of >0.5 to 1 cm in diameter. (50, 53)

1. **Hepatocellular carcinomas** are extremely variable on CT scans because of their different forms of growth. Morphologically, they appear as (*1.*) isolated masses, (*2.*) multinodular infiltration, or (*3.*) diffuse parenchymatous infiltration. In addition to the mainly hypodense areas, hyperdense regions are also distinctly visible. The often somewhat irregular and slightly blurred, but nevertheless clearly hypodense border shows marked enhancement following CM application. Space-occupying lesions, hitherto unrecognizable, may become discernible at this point. Evidence of hypodense areas in liver cirrhosis always strongly suggests primary liver carcinoma. Segmental or lobar decreases in density as a result of frequently occurring infiltrations of the portal vein indirectly suggest the presence of a tumour. Lymph node metastases can also be detected. It is much easier to recognize involvement of the vascular system with the help of CTAP or spiral CT. Depending on the size and location of the hepatocellular carcinoma, contour bulging is also observed. The sensitivity is approx. 75%. CT is an indispensable feature in planning surgery. (5, 28, 30, 31)

2. **Liver metastases** are frequently multiple. They vary in size and are usually hypodense. In contrast to liver parenchyma, they display relatively sharp contours, with a difference in density of at least 10−15 HU. In fatty liver, metastases may even appear hyperdense. Liver metastases are mainly supplied by arterial blood. Therefore i.v. (or even intra-arterial) bolus injection of CM produces the best diagnosis: the metastasis shows increased CM enrichment during the short hypervascular phase; additionally, a peripheral margin forms as a result of the increased concentration of CM. Metastases of 5−10 mm can be detected. Data in the literature confirm a *sensitivity* of 65−91% (in breast cancer up to 100%) and a *specificity* of 81−92% with a *success rate* of 80−85%. Proof of metastases clearly depends on the histology of the primary tumour; the best diagnostic results are obtained in breast and colon carcinomas. (22, 39, 50, 53, 57)

3. **Malignant lymphomas** may appear in the liver as focal, hypodense lesions. By contrast, diffuse impairment of the periportal region is only demonstrable with CT using special CM. Additionally, extrahepatic lymphomas can be detected at the same time.

## 1.10 Bile duct obstruction

Obstruction of a large bile duct leads to dilated intrahepatic bile ducts, which appear on CT scans as ramified linear or rounded structures with bile-equivalent density. Their luminal diameter increases progressively in the direction of the hilus. (47) Segmental dilation of the bile ducts may be indicative of a tumour. A dilation of the bile duct of >9 mm points to a peripheral obstruction, mostly near the papilla of Vater.

## 1.11 Surgical therapy

Pre- and post-therapy CT examinations must be carried out in resections and transplants as well as arterial ligatures, embolization therapy with or without chemotherapy, and also regional chemotherapy. Haematomas, seromas and abscesses can occur around the edge of the resection; compensatory hypertrophia from the residual parenchyma can be identified if no complications occur. After a transplant, hypodensities may point to complications (e. g. necrosis, infarcts, rejection foci). Portal veins enhanced by accompanying hypodense lines are a sign of rejection. Postoperative fluid in the abdomen can also be easily detected using ultrasound and computer tomography. Thromboses in the hepatic artery are discernible with the aid of dynamic CT.

The strategy generally applied in diagnostic clarification in a case of suspected **"liver tumour"** is shown later in a **flow diagram.** (s. p. 196) (s. fig. 9.4)

# 2 Magnetic resonance imaging

► Magnetic resonance imaging (MRI) − also known as magnetic resonance tomography (MRT) or nuclear magnetic resonance tomography (NMRT) − was introduced into medical diagnostics by P.C. LAUTERBUR in 1973.

## 2.1 Principle

The production of a strong magnetic field induces alignment of the protons along this magnetic field. This homogeneous alignment is perturbed by appropriate high-frequency signals. The protons are diverted and set in a spinning motion. As a result of their efforts to return to the original position, energy is released, which is registered as a signal, calculated by computer analysis and converted to images. The resulting MR signal is dependent on hydrogen nuclei in the object and on the tissue-based time constants $T_1$ and $T_2$, i.e. the signals can deviate from the norm (= **isointensive**) by being either **hypointensive** or **hyperintensive**. In this way, (*1.*) tissues with different proton density values can be distinguished, (*2.*) concentrations of body-own elements (C, F, N, P) can be determined, and (*3.*) chemical compositions of certain tissue areas are clarified by means of supraconductive apparatus with magnetic fields of $0.5 - 2.0$ tesla (T).

**Four parameters** are thus imaged in MRI by means of mathematical calculations: (*1.*) *proton density*, (*2.*) *relaxation time $T_1$* (= binding force between the nuclear spin grate and the surrounding molecular grate), (*3.*) *relaxation time $T_2$* (= binding effect between the various nuclear spins), and (*4.*) *flow velocity.*

**Two types of appliance** are used: (*1.*) resistance (or iron) magnets and (*2.*) supraconductive magnets.

**Paramagnetic substances** such as manganese or gadolinium compounds (Gd-DTPA, Gd-EOB-DTPA, Gd-BOPTA, Gd-DOTA of Mn-DPOP) are used as i.v. contrast media. They are absorbed by the hepatocytes, so that healthy liver tissue appears lighter on $T_1$ images ("whitener" effect). These substances are excreted via the biliary and renal system. • **Supermagnetic colloidal solution of iron oxides** (SPIO) is a new contrast medium for exact localization of focal liver lesions and for differentiation of normal and pathological regions. The $3-5$ nm iron oxide nuclei grow to a size of $45-60$ nm due to the polysaccharide sheath. They are principally absorbed by the RES (but also collect temporarily in the extravascular space). These iron oxide nuclei are broken down into lysosomes and taken into normal iron storage; the respective iron uptake corresponds to the average nutritional intake of $2-3$ days. Healthy liver tissue appears as dark areas in $T_2$ images ("darkener" effect). This shows that CM is also stored in the fatty liver and FNH. Foci of up to $2-3$ mm can be detected. Hepatic metastases appear extremely "light" compared to the "black" parenchyma. (62, 84, 89, 97, 103)

## 2.2 Advantages

These techniques can be used to achieve a very *sharp contrast between various tissues.* This permits better differentiation and characterization of normal or pathological tissues, compared with ultrasonography and CT.

• A great advantage of MRI is the possibility of imaging not only transverse *cross-sections* (as is the case with CT), but also *longitudinal sections* of various planes (e.g. sagittal and coronary) in the hepatic area − without changing the patient's position. Topographic analysis and the interpretation of findings are hence less complicated than with CT. The thickness of the section planes is usually 10 mm. • MRI is also capable of differentiating static from flowing conditions and calculating the *flow rate* in various vascular areas. • Furthermore, the concentration of certain *elements* and the *proton density* can be measured. MRI is thus a valuable diagnostic tool in certain situations, serving to supplement CT and at the same time replacing intra-arterial angiography or scintigraphy. • A further major advance is the development of **MR angiography** − which may well prove to be a (better) alternative to invasive catheter angiography. (99)

## 2.3 Disadvantages

The use of first-generation MRI was associated with certain problems, e.g. **artefactual images** caused by respiratory movement, cardiac action, vascular pulsation and intestinal peristalsis. The introduction of turbo-spin-echo-pulse sequences, however, led to a drastic shortening of recording periods, so that artefacts due to breathing and peristalsis are now rare. It is important that the patient breathes normally and is in a resting position. In addition to the reduction in recording periods with modern apparatus, the time needed for reconstruction has been shortened thanks to new computer imaging techniques (polytomography, 3D-layer batch). • Thought should be given in this respect to the **physical stress** experienced by the patient through a static magnetic field, temporally varying magnetic fields and high-frequency fields in the megahertz range. No clinically significant damage has been reported when complying with the contraindications. • In individual cases, the time spent in the magnetic tunnel may, however, cause **mental distress.** Sometimes this claustrophobia may require sedative premedication. In order to suppress **intestinal peristalsis,** administration of spasmolytics or glucagon (0.5 to 1.0 mg i.v.) is recommended. • The operators should be aware of potential **contrast-medium incidents.** In practice, however, such adverse reactions are rarely seen.

**Contraindications** are internal *ferromagnetic objects* in the body, e.g. implants, clips, splinters and especially cardiac pacemakers. Through their electromagnetic effects, they may cause biomolecular disturbances, and even cellular damage. Based on the current level of knowledge and the developmental stage of the technical equipment and contrast media, it is advisable that *pregnant women* and *nursing mothers* as well as *epilepsy patients* be generally excluded from MRI examinations (however, such contraindications become relative in the face of a strong indication).

## 2.4 Normal liver

On MRI scans, a normal liver shows a picture similar to that obtained by CT. The parenchyma appears as a homogeneous area with relatively high signal intensity ($T_1$). The portal and liver veins are easily differentiated as signal-free or low-signal structures. With prolonged echo-time, the signal intensity of the liver veins also increases. (s. fig. 8.7)

*Fig. 8.7:* Normal MRI: **a)** $T_1$-weighted scan; **b)** $T_2$-weighted scan. • Branches of the portal vein ($\rightarrow$), aorta (---▶), spleen (S), inferior vena cava ($\Rightarrow$) with stellate ramifications of the hepatic veins

## 2.5 Diffuse liver diseases

**Acute hepatitis:** In the early stages of the disease, the $T_2$-scan shows an increase in signal intensity, whereas a prolongation of $T_1$ tends to be observed before the occurrence of liver cell necrosis.

**Fatty liver:** Fatty infiltration into liver cells is not detected by MRI, even though fatty tissue shows high signal intensity on spin-echo imaging. The water associated with the (hyperdense) fatty liver may lead to a signal reduction during the $T_1$-time, whereby the plus and minus variations in signal intensity result in an indifference, which corresponds to normal liver tissue; $T_1$ and $T_2$ thus remain unchanged. Only markedly $T_1$-weighted scans exhibit increased signal intensity. MRI is an important method in searching for (hypodense) metastases in a (hyperdense) fatty liver. (39, 62, 89) (s. p. 129, 172)

**Cirrhosis:** Like CT, MRI also portrays cirrhosis-related changes in liver size and shape, irregular superficial contours, dilated portal vessels and collaterals (generally also reversal of portal flow) as well as splenomegaly. As a result of the enhanced blood engorgement, the spleen

*Fig. 8.8:* Haemochromatosis: characteristic signal elimination in the liver as a sequel of a disturbed magnetic field from the deposited iron (flash 2D sequence with $T_1$)

shows a clear increase in signal intensity. Regeneration nodes are distinguishable because the $T_1$ and $T_2$ signal is weaker here than in cirrhotic tissue. So-called siderotic nodes are found in 25% of cases ($T_2 \downarrow$). Malignant foci do not contain any iron. This results in "nodes within nodes", where malignant growth occurs in a regeneration node. (86, 92, 93, 96, 107)

**Haemochromatosis:** As a result of the accumulation of iron in the liver cells, the relaxation time $T_2$ is considerably shortened, with a corresponding decrease in signal intensity. This can also be determined quantitatively. Depending on the iron content, the liver appears dark grey to black. (s. fig. 8.8) The success rate is 100% at an iron concentration of 1 mg/g liver tissue. An iron-free node may suggest HCC. • *Haemosiderosis* with iron deposition in the RES is also characterized by similar, yet less marked findings. A fall in signal intensity is discernible when the iron content/g in the liver tissue has almost quadrupled. (58, 64, 78, 91, 94, 113)

**Primary biliary cirrhosis:** In correspondence with the extent of copper deposition in the liver, the relaxation times $T_1$ and $T_2$ are shortened, with a decrease in signal intensity. (121)

Further study results are available relating to amyloidosis (29, 111), primary sclerosing cholangitis (73), peliosis hepatis (105), Budd-Chiari syndrome (29, 60, 108), schistosomiasis (29, 79), biliary tract diseases (75, 82, 120), echinococcosis (69, 71), and adenoma. (67, 74)

## 2.6 Focal liver lesions

Focal liver lesions of >2 mm in diameter are detectable in MRI. In addition, the specificity of MRI is higher than can be achieved by means of CT examination. (2, 29, 61, 62, 89, 97, 106, 119)

**Cavernous haemangioma:** The visualized findings consist of a roundish, homogeneous high-signal ($T_2$-weighted "light bulb") area and a well defined hypointense to isointense ($T_1$-weighted) area. (s. fig. 8.9) Usually, no in-

ternal structures are visible. The imaging effect is best accomplished following i.v. administration of Gd-DTPA on the $T_1$-weighted scan with centripetal contrast-medium enhancement. Because of the paramagnetic component of methaemoglobin, the signal intensity may be more pronounced, although it is usually reduced in a $T_1$-weighted scan. (63, 76, 83, 87, 101, 110, 114, 116, 122)

*Fig. 8.9:* Cavernous haemangioma: a large (2.5 × 4.2 cm) hyperintense (white) lobular focus with an afferent vessel ($T_2$-weighted scan; transverse) (s. figs. 6.15; 8.5: 36.6)

**Focal nodular hyperplasia:** On MRI scans (as with CT), FNH shows the characteristic central venous star. Otherwise, the signal intensity of FNH is homogeneously isointense ($T_1$) or slightly hyperintense ($T_2$). Immediately following the i.v. administration of CM (Gd-DTPA), a distinct but rapidly fading enhancement is observed. (65, 95, 100, 102, 110, 118)

**Malignant tumours:** Due to their markedly prolonged relaxation times, malignant tumours are sharply demarcated from the liver parenchyma. On $T_1$-weighted scans they are low-signal, on $T_2$-weighted scans they are high-signal areas. Differentiation of tumour tissue from central necrosis is possible. Intrahepatic, tumour-induced vascular displacements as well as capsular structures and perifocal oedema may be demonstrated. This is characterized by an intact ring of enhancement on hepatic arterial dominant-phase images. There is sometimes a peripheral or heterogeneous washout of contrast agent in the hepatic venous phase or a washout leading to hypointensity even in hypervascular metastasis. It is not (yet) possible to define the type of tumour. Moreover, differentiating malignant tumours from adenomas (67, 74) and haemangiomas (76, 87, 101, 122) or from focal fatty infiltration (39) may be problematic. The success rate for differentiating patients devoid of liver tumours from those with metastatic liver is 87% (CT: 84%) with a specificity of 98% (CT: 91%). (70, 97) • Proof of metastases (23, 29, 39, 66, 70, 72, 76, 87, 101, 102, 117, 119, 122) (s. fig. 8.10) or hepatocellular carcinomas (29, 66, 68, 80, 81, 85, 90, 96, 98, 112) is obtained in 85−95% of cases. Study results in patients with cholangiocarcinoma

(77), mesenchymal tumours (104, 109) and plasmocytoma are also available. Small-nodular carcinosis in the omentum or peritoneum (without concommitant ascites) and subcapsular hepatic metastases (< 5 mm) remain undetected with sonography, CT or MRI−they can only be found by means of laparoscopy.

*Fig. 8.10:* Diffuse metastazation in pancreatic carcinoma ( ↑ ); numerous focus-like signs of aerobilia (⇑); thrombosis of the left portal vein (▲)

**Hepatic cysts:** Cysts are visualized on the $T_1$-weighted scan as low-signal (= black) and on the $T_2$-weighted scan as homogeneously high-signal (= bright), closely circumscribed, focal lesions. An increase in signal intensity on the $T_1$-weighted scan suggests bleeding into the cysts.

**Hepatic abscesses:** An abscess is displayed as low-signal in the $T_1$ image and signal-intensive in the $T_2$ image. The perifocal oedema cannot be separated from the lesion. Gadolinium CM can be used to visualize a thick abscess wall in the $T_1$ image. Gas appears hypodense and cannot be differentiated from prior bleeding. • Treatment of such abscesses is easily monitored.

**Portal veins:** There are reports on MRI visualization of large intrahepatic portovenous shunts (59), collaterals in the portal vein (92, 115) and VOD staging. (88)

# 3 Angiography

For clarifying vascular liver diseases and alterations of vessels associated with liver diseases (especially tumours), angiographic procedures are available, should CEDS, CT and MRI yield no definitive diagnosis. With the help of contrast media, they make possible the imaging of the afferent arterial or portal vessels and the efferent veins in the area of the liver. (s. tab. 8.3)

**Arteriography**
1. Coeliac artery (coeliac trunc HALLERI) (s. fig. 8.11)
2. Selective arteriography
   - common hepatic artery
   - superior mesenteric artery
   - splenic artery
   - right/left hepatic artery

**Portography**
1. Direct splenoportography
   − percutaneous (s. fig. 8.12)
   − laparoscopic
2. Indirect portography
   − splenoportography via the splenic artery
   − portography via the superior mesenteric artery (s. fig. 8.11)
3. Omphaloportography (s. fig. 8.13)
4. Transhepatic portography

**Phlebography**
1. Cavography
2. Phlebography of the hepatic veins
3. Transhepatic phlebography

***Tab. 8.3:*** Angiographic hepatic examination methods which are possible in principle, but which are now partially obsolete

## 3.1 Arteriography

▶ Selective arteriography uses a transfemoral catheter technique (S. I. SELDINGER, 1953; P. ÖDMAN, 1959). (s. fig. 8.11) • The catheter may also be introduced into the axillary artery. Super-selective CM visualization of hepatic arteries via the proper hepatic artery shows blood vessels down to the 6th division; the smallest depictable diameter is approx. 0.5 mm. Imaging of the arteries is effected by nonionic iodine-containing contrast medium at a reduced flow rate (20−30 ml, 6−8 ml per second). Using this infusion technique, 8 to 12 angiograms can be produced within a period of approx. 12 seconds. In this way, both the early arterial phase and the parenchymal phase as well as the venous phase can be recorded. Visualization of the CM-filled blood vessels is effected by (*1.*) *conventional film angiography* which has been replaced by digital subtraction angiography, (*2.*) *digital subtraction angiography* (DSA) using an image-intensifying TV link instead of the X-ray film, (*3.*) *CT arterioportography,* or (*4.*) *MRI angiography* and meanwhile *whole body MR arteriography* using gadolinium. (133)

### 3.1.1 Indications

Focal liver lesions of $>1−1.5$ cm in diameter are usually detectable. Even hypervascular foci with a diameter of $>0.5$ cm are visible when using the infusion technique. In about 75−90% of cases, a normal arterial blood supply to the liver is guaranteed via the proper hepatic artery. Alterations relating to the hepatic arteries can be angiographically confirmed in virtually 100% of cases. Vascular anomalies (10−20%) are usually of no clinical significance. Knowledge of their existence may, however, be important in hepatic surgical procedures. Variations in the location and shape of the liver and changes in the region of the caudate lobe and quadrate lobe are also recognizable. Despite the common initial use of non-invasive imaging methods, and possibly laparoscopy, hepatic arteriography is still indicated in some hepatological situations, especially for the purpose of *angio-*

***Fig. 8.11:*** Arterioportography: coeliacography with good visualization of the branches of the coeliac trunk including the fine ramifications. Small hypervascularized haemangioma ( ↑ ); S = spleen. (The pancreatic vessels are also visible.) • Normal depiction of the portal vessels in the venous phase

1. Vascular anomalies, stenoses or aneurysms
2. Preoperative study of vascular blood supply
3. Haemobilia
4. Arteriovenous fistula
5. Occlusive (including posttraumatic) embolization
6. Angiotherapy within the framework of a transjugular intrahepatic portosystemic stent shunt (TIPS)
7. Treatment of liver tumours
   − chemoinfusion, chemoperfusion, chemoembolization

***Tab. 8.4:*** Possible indications for hepatic arteriography if modern contrast-medium-based CEDS, CT and MRI fail to provide reliable information or if angiotherapy is indicated

*therapy.* (123, 124, 128, 135, 136, 141, 145, 147, 148, 151, 157) (s. tab. 8.4)

### 3.1.2 Contraindications

Hepatic arteriography is contraindicated in cases of severe *coagulation disorders*. Cut-off values are deemed to be: Quick's value of $>60\%$, thrombocytes of $>100,000$, and bleeding time of $<3$ minutes. These figures only serve as a guide; a more careful assessment must be made in each individual case. • In the presence of *renal failure*, the use of contrast media, and thus arteriography, is contraindicated.

### 3.1.3 Complications

With strict heparinization, the incidence of serious complications is below 1%. A lethality rate of 0.06% has been reported. Arterial

puncture is associated with certain risks relating to the introduction of a guide wire or catheter (thrombosis, formation of haematomas, arteriovenous fistula) and to the catheter itself (damage to the vascular wall, thrombosis, vascular perforation). Intolerance reactions to the contrast medium may also occur (in 3−5% of cases). With DSA, however, the complication rate decreases.

### 3.1.4 Focal lesions

In the diagnosis of focal liver lesions, angiography is fundamentally no longer of any practical value. The angiogram of focal liver lesions is usually nonspecific. • *With regard to its indications, hepatic arteriography has lost importance as a diagnostic tool, but has become more valuable as a therapeutic approach.* • Hypervascular foci and foci situated in the peripheral liver sections are identified more reliably than those in the central areas. The intermediary region between the right and left lobe of liver shows less vascularization; additional vascular supply variants are seen here more often. In the case of hypervascular tumours, the success rate for detection is >90%. This success rate is further improved by the use of angio-CT.

**Primary malignant liver tumours** with a predominantly hypervascular blood supply mainly comprise carcinomas and sarcomas. Depending on the vascularization of the tumour, the parenchymal phase shows areas that are lower in CM density and others with increased CM density ("pooling"). In areas with insufficient blood flow, this pooling often results in patchy images. The *criteria of malignancy* are neovascularization, irregular outline, "vascular break-offs", "blood lakes" as a result of dilated vessels, early discharge of contrast material via arteriovenous anastomoses in pathological veins, vascular occlusions, increase in the calibre of nutritive hepatic arteries, reduced intratumoural circulation, corkscrew-shaped arteries of different calibres, and vascular displacements (stretching, spreading or arciform displacement of arteries). Cholangiocellular carcinomas and the hepatocellular carcinomas related to liver cirrhosis are mainly hypovascular. For this reason, they are hardly recognizable. (130, 139, 144, 149−151)

**Secondary malignant liver tumours,** such as metastases of adenocarcinomas, are also hypovascular and therefore usually not identifiable by arteriography. In contrast, the metastases of malignant goitre, hypernephroid carcinoma, insulinoma and chorionepithelioma are hypervascular and therefore readily visible.

**Benign focal lesions** usually lead to a smoothly curved displacement of arteries (and veins). In the parenchymal phase, they show more or less sharply delineated filling defects. (132, 145, 156)

In 80−90% of cases, *focal nodular hyperplasia* shows a typical, radial (spoke-like) arrangement of coiled vessels in the area of the tumour, which originate from a circular artery. Occasionally, fine a.v. shunts are present. The smooth-edged lesion is hypervascular. The parenchymal phase, with its homogeneous concentration of contrast medium, allows the lesion to be clearly demarcated from healthy liver tissue. (156) • *Hepatic adenoma* is generally hypervascular. Displaced vessels are frequently visible.

A nutritive vessel extends into the tumour from the periphery. Neovascularization and irregularities of the vessels may be shown, which complicates differential diagnosis with regard to malignancy. In the parenchymatous phase, the tumour exhibits marked enhancement. (156) • The *cavernous haemangioma* shows late filling of the hollow spaces; the contrast medium initially accumulates in the form of lacunes at the margin of the tumour. Patchy, blurred outflows of contrast material subsequently appear in the whole tumour area. The contrast medium persists for an extremely long period of time into the parenchymatous phase. No arteriovenous fistulas are detected. (129) • Intrahepatic *haematomas* lead to separation of the major vessels with vascular break-offs and extravasations. Arteriovenous shunts may occur. There is no visualization of the parenchyma. • *Haemobilia* is characterized by an arteriobiliary flow of CM with imaging of the intra- and extrahepatic bile ducts. (142) • *Echinococcus alveolaris* with its invasive and multilocular growth produces an image similar to that seen in malignant liver tumours. At the periphery, irregular, often twisted and stenotic or occluded arteries and small CM extravasations are visible. In the parenchyma, contrast medium-free areas as well as occasional CM enhancement can be detected.

### 3.1.5 Diffuse liver diseases

Arteriography is not a suitable method for diagnosing **liver cirrhosis.** It may only be used in special situations (e. g. planned surgical procedures). In liver cirrhosis, the arteries appear dilated in some cases or take the form of narrow vessels; mostly, the arterial presentation is sparse. At the periphery, the arteries often follow a spiral course. The parenchymal phase exhibits an inhomogeneous, patchy image; regions with connective tissue appear hypovascular. Regeneration nodes can resemble benign liver tumours in arteriograms. In advanced stages of cirrhosis, the hepatic artery may dilate as a result of increased arterial flow, with a subsequent reversal of the flow in the gastroduodenal artery. The latter is therefore no longer visible in coeliacography. In patients with cirrhosis showing dilation of the hepatic artery and a reversed blood flow in the gastroduodenal artery, the blood circulation and functions of the liver are better than in patients without this "steal effect". *Such a finding may be an important criterion when considering a portacaval shunt operation.* (123, 127, 141, 143)

### 3.1.6 Therapeutic infusion

In traumatic bleeding in the area of the liver, haemostasis may be performed within the framework of diagnostic arteriography by means of embolization. Arterial access likewise facilitates embolization and cytostatic treatment of liver tumours (following angiographic insertion of the catheter). (s. tab. 8.4)

## 3.2 Portography

▶ In animal experiments, a contrast medium was first injected percutaneously into the spleen by S. ABEATICI et al. in 1951 in order to visualize the portal circulation by means of X-ray. This method was later introduced into clinical practice as direct splenoportography by J.L. LEGER (1951) and R. BOULVIN et al. (1951).

Portography is defined as the radiological visualization of the portal vein and its various afferent branches as well as their distribution in the liver. (s. tab. 8.3) It facilitates not only the direct measurement of portal pressure, but also the exact localization of portal flow obstruction and thus the differentiation between pre-, intra- or posthepatic block. The prehepatic block can be located at the edge of the splenic and/or portal vein. Blood flow is predominantly in a hepatopetal direction. Central blocks are frequently the result of an infection in the umbilical vein during early childhood. (s. p. 182) This usually leads to cavernous transformation of the veins in the hepatoduodenal ligament and the formation of periportal veins. An intrahepatic block results in hepatofugal blood flow. Portal high pressure can be recognized in the early stages by a widening of the left gastric vein (> 5−6 mm). For surgical planning in portal hypertension, knowledge of portal vascular morphology and haemodynamics is a major prerequisite. • Shunt function, blood flow to the liver and collateral circulation are accurately displayed with the aid of indirect mesenteric and splenic portography. In more difficult cases, the shunt can be monitored using a direct probe via the inferior vena cava. (128, 137)

Impressive images of portal arteries and hepatic veins can be produced by MR angiography. (131, 152) Nowadays, CM-supported MRA is the method of choice in monitoring the portal artery system (primarily before and after TIPS insertion). (152)

### 3.2.1 Indications

Ultrasound and, more particularly, colour-encoded Doppler sonography are the methods of choice for the diagnostic study of the portal venous system. • Equivocal findings are an indication for contrast-medium CT or MRI, both of which provide superior angiographic images following i.v. injection of an appropriate CM − this is equally possible on an outpatient basis. • Portographic examination techniques should only be used in special instances which are not sufficiently clarified by these imaging procedures. The various techniques may have different indications in individual cases. The appropriate method should be carefully selected, depending on individual considerations. (s. tabs. 8.3, 8.5)

| 1. Differentiation of various forms of portal hypertension, with measurement of blood pressure if necessary |
| 2. Checking on the possibility of anastomosis in portal vessels |
| 3. Detection of spontaneous splenorenal shunts |
| 4. Proof of collateral flow in bleeding oesophageal varices |
| 5. Follow-up after shunt operation |
| 6. Suspected Budd-Chiari syndrome |
| 7. Identification of the morphological course of hepatitis (with variations between the single segments) |

**Tab. 8.5:** Potential indications for portography if modern contrast-medium CEDS, CT and MRI fail to provide reliable findings

### 3.2.2 Direct splenoportography

1. **Laparoscopic splenoportography** has three important **advantages** over the percutaneous technique (153): (*1.*) splenic puncture is performed under visual control, (*2.*) the procedure can be repeated several times during the same examination if necessary, and (*3.*) complications are rare. • The **examination** itself is not subject to any pressure of time, thus permitting measurement of the "standing" blood column with imaging for up to 10 minutes and longer following the injection of contrast medium. The needle is inserted from the medial splenic margin 4−5 cm deep into the caudal or medial segment, axially and in the segmental central line. The correct positioning of the needle in the spleen can be checked, using the **decholine test,** which also provides information on the portal circulation. With open arterial crus and simultaneously closed venous crus or with both vascular crura open (filling and flow phases), pseudoarterial afterbleeding lasting for 10 minutes or longer may occur, which spontaneously ceases when there is a change in phase from filling to emptying. Coagulation measures are only advisable in cases of prolonged secondary haemorrhage.

2. **Laparoscopic transhepatic retrograde splenoportography** allows early diagnosis of portal hypertension by segmental portography of the liver. The puncture cannula is correctly positioned in a portal vessel when the injected contrast medium is distributed like the crown of a tree and the measured portal pressure (normal 8−15 mmHg) exceeds the pressure of the hepatic vein (normal: 4−8 mmHg). • Direct splenography using laparoscopy also allows identification of different morphological alterations in various segments. (153, 154) *Particular consideration must be given to this factor when assessing a liver biopsy specimen.* With laparoscopic angiography, both *segmental portography* and *segmental arteriography* have proved effective. (155)

3. **Percutaneous splenoportography** has lost its importance. Should a direct procedure be indicated, laparoscopic splenoportography is a possible alternative. Recently, a **new technique** has been described. (134) • The percutaneous splenic puncture is performed using a thin needle under screen control, with the needle directed at the splenic hilus. The pressure of the splenic pulp can be measured directly in order to estimate the portal vein pressure. Contrast medium is injected manually or by a special device. From this depot in the red pulp, the splenic vein, the portal vein and the intrahepatic branches of the portal vein are contrasted within a few seconds. (s. fig. 8.12) • Complications resulting from percutaneous splenoportography include afterbleeding from the spleen, bilateral rupture of the spleen, arterial aneurysms and a.v. shunts − these complications are serious in nature, but rare. • *Contraindications* for the procedure should be carefully observed. (s. tab. 8.6)

| 1. Clotting disorders |
| 2. Ascites |
| 3. Adhesions, especially perisplenic adhesions |
| 4. Inoperability with respect to a shunt procedure |
| 5. Splenic diseases (cysts, tumours, leukaemia, *etc.*) |

**Tab. 8.6:** Contraindications for direct (particularly percutaneous) splenoportography

*Fig. 8.12:* Use of direct percutaneous splenoportography in portal hypertension

### 3.2.3 Indirect splenoportography

Except where there are individual unresolved diagnostic issues, direct portography has been replaced by arteriography. Using selective arteriography, the same examination yields (in $80-90\%$ of cases) an indirect splenoportogram through the splenic artery and an indirect portogram via the superior mesenteric artery. In addition, the hepatofugal collaterals are shown, so that it is possible to assess the hepatic block and the direction of the blood flow. Portal pressure cannot be measured by means of this technique. • Following injection of a contrast medium into the coeliac trunk, the CM flows through the splenic artery into the spleen and returns through the splenic vein. Thus, in addition to the arterial system, the portal vein with its extra- and intrahepatic branches is also visible. (126) (s. fig. 8.11) • The *contraindications* and *complications* valid for any transfemoral catheterizations apply equally to indirect splenoportography. The low frequency of complications together with a good diagnostic yield make indirect splenoportography useful in clarifying specific issues. • In the case of severe **splenomegaly,** the attempt to visualize the splenic vein via the splenic artery usually fails, even with high doses of contrast medium of $60-80$ ml — the CM simply "sinks into" the large spleen. In these cases, direct splenoportography is the method of choice.

### 3.2.4 Omphaloportography

Umbilical portography was first described by D. G. DUVINER in 1954 and introduced into clinical use by O. GONZALES GARBALHAES in 1959. The umbilical vein consists of a right branch (which is totally obliterated postpartum) and a left branch (the cranial portion of which is closed, whereas the section in the vicinity of the liver is only sealed by endothelium); the latter is frequently preserved as a residual channel. The omphaloportographic **technique** is based on the surgical opening (at a point $5-7$ cm above the umbilicus) and bouginage of the umbilical vein, with the subsequent insertion of a catheter. The probe is successful in $90\%$ of cases. The (specially shaped) catheter can be inserted as far as the splenic or mesenteric vein. By injecting a contrast medium, the portal venous system is successfully imaged. (s. fig. 8.13) Visualization of single portal branches may be attempted using special catheters. Portal vein pressure can be measured directly. **Indications** are rare. It is, however, possible to determine the pressure in the portal vein directly (e. g. prior to shunt operations). (138) In the case of suspected apudomas, blood samples can be taken from the splenic vein for hormone analysis. It is also possible to use high-dosage chemotherapy (e. g. in colorectal liver metastases). In a laparotomy, omphaloportography may be useful for clarifying certain issues in isolated cases. (s. tab. 8.7) • Potential **complications** include perforation, thrombosis and infection. The complication rate is $10-15\%$. (138, 146)

| |
|---|
| 1. Preoperative diagnosis prior to hepatic resection or shunt operation |
| 2. Status after thrombosis of the splenic vein or after splenectomy |
| 3. Suspected "pseudo-obstruction" of the portal vein |
| 4. Use as an extracorporeal makeshift vessel |
| 5. Diagnosis directly from portal blood (e.g. measurement of portal pressure, apudoma) |
| 6. Therapeutic instillation into portal blood (e.g. targeted high-dose chemotherapy in colorectal liver metastases) |

*Tab. 8.7:* Indications for omphaloportography which are possible in principle, but now largely obsolete

*Fig. 8.13:* Use of omphaloportography in portal hypertension

### 3.2.5 Percutaneous transhepatic portography

This method was developed as an alternative to laparoscopic transhepatic portography. 40 ml of CM are usually injected at a rate of 10 ml/sec. It is a difficult technique, takes more time and involves greater risks. This method allows the portal pressure to be measured. After positioning the catheter with the aid of a guide wire, any branch of the portal vein can be visualized in a superselective manner following application of CM. This method can also be used to take blood samples from various veins for the purpose of hormone analysis. If oesophageal variceal bleeding occurs, targeted obliteration of the coronary vein is possible. Existing collaterals, including splenorenal connections, can be visualized. The frequency of severe complications (e. g. bile peritonitis, bleeding) is $2-3\%$.

### 3.3 Phlebography

The venous system of the liver can also be shown by X-ray. (s. tab. 8.3) Such radiological methods have their specific diagnostic yields and thus their own indications. (125, 131, 140)

1. **Cavography** may be useful in patients with suspected Budd-Chiari syndrome or anomalies of the hepatic veins as well as prior to liver transplantation and in clarifying the aetiology of a posthepatic block. Cavography can be performed both through the femoral vein and inferior vena cava and through the arm or jugular vein via the right atrium and superior vena cava.

2. **Transvenous hepatophlebography** is based on experimental studies in dogs and on initial clinical experience (A. M. Rappaport, 1951). This radiological method for imaging the hepatic veins was introduced into clinical practice by G. Tori in 1953. Selective hepatography introduces a catheter through the femoral vein (also via the median cubital vein or jugular vein) into a hepatic vein.

3. **Percutaneous transhepatic hepatophlebography** involves a typical puncture of the liver with a needle from the right midaxillary line to enter a hepatic vein. Pressure measurement and CM injection ensure that the position of the needle or the catheter is correct. Thrombosis of the portal vein is an absolute contraindication, which is why indirect splenoportography must be carried out prior to percutaneous hepatophlebography. Serious complications occur in 1.5−4.0% of cases.

# 4  Cholangiography

Visualization of the bile ducts can be accomplished indirectly or by means of various direct methods. (s. tab. 8.8)

**Indirect cholangiography**
1. Intravenous injection
2. Intravenous infusion
3. Spiral CT
4. MRI cholangiography

**Direct cholangiography**
1. Endoscopic retrograde
2. Percutaneous transhepatic
3. Transvenous
4. Intraoperative
5. Postoperative via drain

*Tab. 8.8:* Indirect and direct methods of cholangiography

## 4.1  Indirect cholangiography

In terms of the success rate, conventional X-ray diagnosis of the efferent bile ducts cannot be entirely replaced by (stress-free, easy-to-repeat, technically uncomplicated and less costly) ultrasonography. For example, for diagnosing **choledocholithiasis**, *i.v. cholangiography* and *tomography* are much more efficient (90−92%) than sonography (67%). The use of (invasive) ERC, however, provides 3−4 times more reliable diagnostic information than does i.v. cholangiography (V. Myllylä et al., 1984). Furthermore, ultrasonography or i.v. cholangiography (as a rule in conjunction with tomography or MRCP)

produces a noninvasive, but inadequate assessment of the **intrahepatic bile ducts.** In this respect, the methods of direct cholangiography are infinitely superior. • The use of i.v. cholangiography is restricted due to severe damage to the liver cells (transaminases 100−150 U/l), increased serum bilirubin (>3−4 mg/dl) or cholestasis (AP >300−350 U/l). It is further limited by the high technical requirements in individual cases (tomography, infusion cholangiography). • In the case of significant sonographic findings in the area of the bifurcation of the cystic duct and common bile duct (e. g. suspected *Mirizzi syndrome*), consideration should first be given to i.v. cholangiography (with tomography) and then to ERC. Intravenous cholangiography is also indicated for noncongested bile ducts and in cases where ERC has proved unsuccessful. (163, 176)

### 4.1.2  Spiral CT and MRCP

Biliary secretion of CM under **spiral CT** is used to produce 3D models of the biliary tract, enabling 70−75% of intraductal concrements to be detected. Malignant and benign processes were diagnosed in 75% and 93% of cases. (180) In cholestasis, the biliary tract could also be visualized without the use of CM. (187)

The introduction of **MR cholangiography** by B.K. Wallner et al. (1991) represents a significant development in this field. (185) If CM is not used, the biliary passages in the biliary tract are visualized by distinct $T_2$-weighted sequences in a coronary display. More rapid gradient systems have further improved display quality (160, 178); here it was possible to achieve comparable results to those obtained in MRC and ERC procedures. (158, 167, 179, 184)

## 4.2  Direct cholangiography

The use of direct cholangiography is indicated (*1.*) if alterations in the area of the efferent bile ducts could not be clarified by ultrasound and i.v. cholangiography or (*2.*) if the use of i.v. cholangiography is contraindicated, not indicated or likely to be inadequate. Various direct cholangiographic methods are available depending on individual pathological situations and diagnostic issues. (s. tab. 8.8)

### 4.2.1  ERC

First described by W. S. McCune et al. (1968) and I. Oi et al. (1969), endoscopic retrograde cholangiography (ERC) is now a valuable and standardized examination method.

**Indications:** Due to the continuous improvement of ERC (better diagnostic value and reduced complication rate), a number of indications have now been established. (s. tab. 8.9)

1. Suspected mechanical obstruction
   - choledocholithiasis
   - bile-duct tumour
   - bile-duct stricture
   - compression of a bile duct, *etc.*
2. Unresolved hepatobiliary diseases
   - primary sclerosing cholangitis
   - chronic (possibly recurrent) cholangitis
   - intrahepatic gallstones
   - parasitic diseases, *etc.*
3. Prior to surgical procedures on bile ducts
4. Postoperative epigastric symptom complex
5. Negative or unresolved cholangiography
6. Suspected bile-duct anomalies, papillomatosis
7. Suspected congenital intrahepatic bile-duct cysts (Caroli's disease)
8. Follow-up biliodigestive anastomosis
9. Suspected acute biliary pancreatitis
10. Contrast-medium intolerance

**Tab. 8.9:** Indications for endoscopic retrograde cholangiography

1. Endoscopy of the bile duct allows parasitological (e. g. proof of larvae or eggs), bacteriological or cytological *analysis of the bile* in hepatobiliary issues.

2. A number of other new *therapeutic procedures* have developed against the background of ERC, including the transpapillary insertion of stents for palliative bridging of ductal stenosis.

3. In cases of *mechanical jaundice,* not only the location of the obstruction in the biliary tract is determinable, but usually the type and extent of the (partial or complete) obstruction as well. (s. fig. 8.14) As a result, a decision can often be taken during the same examination concerning causal or palliative treatment. The coagulation parameters should be within a range which renders papillotomy, stone extraction or tissue biopsy possible without danger to the patient.

4. The clarification of *hepatobiliary diseases* is an important indication for ERC. (s. tab. 8.9) • Suppurative cholangitis related to mechanical flow obstruction in a bile duct is a clear indication for ERC, whereby appropriate therapeutic measures (e. g. papillotomy, stone extraction, insertion of tubes or stents) should be carried out at the same time. Septic cholangitis is considered to be an emergency indication. • For diagnosing primary sclerosing cholangitis, ERC is the method of choice. Complete visualization of the intrahepatic biliary system ought to be possible with this method.

**Success rate:** The success rate for visualizing the biliary tract is 95%, whereas in patients with gastric resection (Billroth II) and Braun's anastomosis, the success rate is only 30−40%. Ultrasonography permits the differentiation between intra- and extrahepatic cholestasis in 75−80% of patients, whereas with ERC the rate is 90−95%. For identifying the type of obstruction, ERC shows even better success rates (89% vs. 58%). On the whole, this method provides a definitive diagnosis in biliary tract disorders in 78−93% of cases. (159, 161, 165, 167, 169, 170, 172, 175, 179, 182, 183)

**Fig. 8.14:** Use of ERC in obstructive jaundice induced by a large biliary concrement, with congested extra- and intrahepatic bile ducts. Secondary findings: shrunken gall bladder with a cholecystocholic fistula

**Contraindications:** Fundamentally, there are no absolute contraindications to ERC when performed by an experienced endoscopist, except in the case of uncooperative patients. • Clotting disorders, however, call for special caution when applying this method in view of its invasive nature. With organ decompensation, especially cardiac or respiratory insufficiency, or severe arrhythmia, ERC is generally not the primary method for hepatobiliary diagnosis. In cases of oesophageal varices, an intra-abdominal increase in pressure due to retching during the examination may promote or cause variceal bleeding. With high-risk patients, antibiotics should be given as a prophylaxis. The patients must be informed of the increased risk associated with the examination.

**Complications:** Complications include pancreatitis (0.8−1%), cholangitis and sepsis (0.6−0.8%), adverse reactions to premedication and contrast media (0.4−0.6%), and instrument-induced injuries (0.2%). The frequency of bacteriaemia is 15%. An increase in pancreatic enzymes is observed in 15−20% of patients, whereas a rise

in transaminases, γ-GT and AP only occurs in isolated cases. These increases in enzymes are mainly found with injections involving high-viscosity CM, larger doses or excessive pressure. • *Sepsis* can develop after injection of CM into a congested biliary tract. Therefore, in this situation, parallel papillotomy and decompression drainage are required together with peri-interventional prophylactic antibiotics. The complication rate is 1.0−2.3%. Lethality is 0.1%.

## 4.2.2 PTC

▶ The method of percutaneous transhepatic cholangiography (PTC) was first described by H. Burckhardt et al. in 1921 and by P. Huard et al. in 1937, and revived by R. F. Carter et al. in 1952. Routine use was recommended by F. Glenn et al. in 1962. After the development of a thin and flexible puncture needle (Y. Tsuchiya, 1969) and the Okuda technique using a Chiba needle (K. Okuda et al., 1974), PTC became a widely used clinical method. (174)

**Indications:** The indications for PTC have become increasingly limited in favour of ERC, since preference is given to the visualization of the biliary tract through the major duodenal papilla (= physiological access) over invasive and non-physiological transhepatic access. Moreover, the rate of complications regarding PTC is clearly higher than with ERC. • *Obstructive jaundice* not clarified by ERC is an indication for diagnostic PTC. However, the higher success rate of approx. 90% for ERC in clarifying obstructive jaundice, compared with approx. 70% for PTC, makes ERC the method of choice. PTC is also indicated if drainage of congested bile is necessary. Furthermore, it is recommended for preoperative diagnosis and drainage before operations on bile ducts, above all in the area of the hepatic hilus. PTC may also be necessary in cases involving nondilated bile ducts where suspected biliary obstruction could not be clarified by i.v. cholangiography and ERC. (s. fig. 8.15) The use of PTC as an operation channel for therapeutic measures in the biliary system is of great importance in a wide range of diseases, e. g. stone extraction, bile-duct dilation, antibiotic rinsing in suppurative cholangitis, electroresection and intraluminal radiation. • With dilated bile ducts, the puncture is successful in >95% and with nondilated bile ducts in 50(−70)% of cases. No more than 5 attempts at puncture should be made. With a correctly positioned needle in a bile duct, the CM only flows slowly and in a mediocaudal direction, remaining in the vessel once the injection has been stopped. (166, 172, 181, 186)

**Technique:** PTC is relatively easy to carry out and requires minimal technology. It is performed under sonographic or X-ray control. The target is the liver hilus where it joins with larger bile ducts at the level of the 12th intercostal space, 3 "finger breadths" from the right margin of the 12th thoracic vertebra. The *target technique of Okuda* has proved most useful for determining the correct position and direction of the puncture. (174) • Rapid flow of the contrast medium with a tree-like ramification shows that the needle is located in a branch of the portal vein; some blood also escapes from the cannula. Should the CM flow rapidly in the direction of the

inferior vena cava, then the needle is positioned in a branch of the hepatic vein. Fine and irregular vessels depicted with a slowing down of the mediocaudal flow of the CM suggest the filling of the lymphatic vessels. After administration of the contrast medium and removal of the needle, it is possible, by altering the patient's position, to ensure adequate filling of the intrahepatic bile ducts and gall bladder; when the upper part of the body is raised, the bile duct (= d. choledochus) is also well visualized. One drawback is the general inability to assess the biliary situation distal to the occlusion (comparable with ERC cranial to the occlusion) if this point cannot be visualized due to the fact that the CM was not able to pass the obstruction.

*Fig. 8.15:* Use of percutaneous transhepatic cholangiography in benign papillary stenosis. Hard fibrotic tissue after repeated passing of gallstones associated with colics over a period of three years. Treatment: papillotomy

**Contraindications:** Contraindications include clotting disorders, echinococcus cyst, marked ascites, liver abscess, liver metastases and cirrhosis.

**Complications:** In 3−6% of cases, complications occur; compiled statistics showed a frequency of up to 10.2% and 13.2%. In 3.4% of cases, a surgical procedure was required. The main complications are bilious peritonitis, haemorrhage, haemobilia, cholangitis and sepsis. Lethality was 0.06−0.08% − even 0.9%. There is a risk of piercing unidentified abscesses, tumours and metastases along the transhepatic route. The gall bladder must also be circumvented. A long intrahepatic course of the puncture channel is designed to ensure greater safety with regard to biliary leakage. Even in cases of incomplete obstruction, biliary decompression (which can be achieved for example by aspirating bile prior to injecting the CM or by rinsing) is advisable in order to avert

dangerous increases in pressure in the bile ducts. As far as possible, the amount of CM should not exceed 20−40 ml. Prophylactic antibiotics are recommended.

**Laparoscopic transhepatic cholangiography (LTC)**
This technique, as described by M. ROYER in 1952, is a PTC variant. Although it entails fewer complications, the success rate is also reduced, since the length of the intrahepatic puncture channel is only 3 cm. The puncture is performed at a point approx. 3 cm away from the falciform ligament and 5 cm cranial to the edge of the liver, with a puncture angle of 45°.

### 4.2.3 TVC

**Transvenous cholangiography (TVC)** was described by W. HANAFEE et al. in 1967 as a transjugular form of direct cholangiography. In this procedure, a catheter is introduced through the right jugular vein into a hepatic vein; by transhepatic advancing of the catheter, a bile duct is punctured with an improved Ross needle. This method was modified by R. GÜNTHER (1975), who used the right subclavian vein as the site of access. (166) Catheterization through a basilic or cubital vein (I. F. HAWKINS jr. et al., 1976) is not considered to be of advantage for this method. TVC is more complicated than PTC in terms of time and instruments. The success rate for congested bile ducts is 65−93%, for cases of non-congestion 10−69%. Generally, there is no need to prepare for surgery. TVC is only indicated in exceptional cases. • The *complication rate* is 8.9% (mild complications 5.5%, serious incidents 3.4%), with a lethality of 0.4%. The main complications are intraperitoneal bleeding, subcapsular liver haematoma, haemobilia, bilihaemia and sepsis. No bile peritonitis has been reported so far. • *Contraindications* are deemed to be acute cholangitis, hepatic echinococcus and liver abscess.

### 4.2.4 PTCS

**Percutaneous transhepatic cholangioscopy** (PTCS) is indicated (*1.*) to clarify the benignancy or malignancy of bile-duct stenoses, (*2.*) to visualize the biliary tract by X-ray using a guide wire and a catheter positioned by the endoscopist's naked eye, and (*3.*) to perform lithiotripsy of bile duct stones and also remove any local obstruction of bile flow. The examination is carried out with a percutaneously placed biliocutaneous fistula, which is stable enough after 8 to 10 days to permit insertion of a cholangioscope. Endoscopic evaluation is carried out under continuous rinsing with a physiological NaCl solution. (171)

### 4.2.5 Intraoperative cholangiography

**Intraoperative cholangiography** was introduced into biliary diagnosis by P. L. MIRIZZI in 1932. Since then, this technique has been under development and it is (still) used as an indispensable, additional intraoperative diagnostic tool in borderline cases. Interventions in the area of the gall bladder or bile ducts are generally unacceptable without the possibility of a cholangiographic ex-

amination of the biliary tract. (162, 164, 168, 173, 177) • Intraoperative cholangiography should be reserved for resolving special **issues**. (s. tab. 8.10)

| |
|---|
| 1. Length and width of the common bile duct |
| 2. Choledocholithiasis |
| 3. Hepaticolithiasis |
| 4. Examining the biliary tract for |
|    − anomalies       − ligatures |
|    − breaks          − contour irregularities |
|    − fistulas         − intraoperative injuries |
|    − stenoses |
| 5. Examining the major duodenal papilla |
| 6. Examining the pancreatic duct, if necessary |

*Tab. 8.10:* Indications for intraoperative cholangiography

Several **methods** are available for intraoperative cholangiography. These are used prior to or after opening the common bile duct: (*1.*) direct cholangiography consisting of puncture of the bile duct by a sharp cannula, (*2.*) cholangiography through the cystic duct, whereby a blunt and curved button cannula or a Nélaton's catheter is inserted by stab incision through the cystic duct (which is situated under the ligatures) into the bile duct, (*3.*) transvesical cholangiography, including the introduction of a special trocar cannula into the fundus of the gall bladder, and (*4.*) cholangiography after choledochotomy by means of a blocker catheter or a double-balloon T-catheter. • Using these methods, the bile ducts can be shown by X-ray in both the direction of the liver and the duodenum. (188)

### 4.2.6 Postoperative cholangiography

**Postoperative cholangiography** is an indispensable follow-up prior to removing the drain. This method is aimed at confirming surgical success and obtaining proof of an undisturbed bile flow into the duodenum. The examination, performed with the patient in a head-down position, also enables visualization of the intrahepatic bile ducts, so as to exclude the presence of small residual concrements. The injection of contrast medium can be combined with the simultaneous measuring of pressure. Imaging is performed during consecutive stages of biliary filling.

**Synopsis**

| |
|---|
| Since the discovery of X-ray by W. C. RÖNTGEN (1895), several radiological examination methods have been developed. They have also been used in the field of hepatology with great instrumental subtlety and manual skill. These methods have proved irreplaceable in the imaging of vessels and bile ducts. • The development of CT and MRI − in particular helical CT and MRI cholangiography − constitutes a breakthrough in radiology once held to be inconceivable. |

The introduction of various contrast-medium techniques not only in sonography (CEDS) but also in CT and MRI has led to rapid changes in the field of radiological diagnosis in hepatology. • *Particularly in the visualization of portal, venous and arterial vessels, fascinating angiographic tissue reconstruction has become possible, even on an outpatient basis.* • Similarly, with respect to the differentiation of tissue structures, more detailed information, which was long deemed beyond reach, can now be obtained. It can be expected that even cellular metabolic processes will be shown by imaging techniques in the future — an absolutely fascinating idea!

It was therefore seen as a matter of great importance in this chapter to follow the path of radiological diagnosis in hepatology, tracing the course of the examination methods hitherto applied (and now deemed in part to be out of date and obsolete) through to those techniques still undergoing development.

# Diagnostics in Liver Diseases

## 9  Scintigraphic diagnostics

# 9 Scintigraphic diagnostics

**Indications** for scintigraphic methods may be given in specific situations: (*1.*) to evaluate certain partial liver functions, (*2.*) to clarify special issues when other imaging techniques (including laparoscopy) are not feasible, and (*3.*) to differentiate benign and malignant tissue. The most commonly used short-lived radionuclide [99m]technetium (with a physical half-life of 6 hours) is associated with a strongly limited and justifiable radiation dose (total body $<1$ mGy $= 0.1$ rad; screened organ $10-20$ mGy $= 1-2$ rad). [99m]Tc may be marked both with colloids (proof of storage by Kupffer cells) and with erythrocytes (proof of perfusion and venous pooling); HIDA derivatives are tracers that can be excreted by hepatocytes and canaliculi. (s. tab. 9.1)

| Colloids | storage capacity of Kupffer cells and of the RES (e.g. [99m]Tc sulphur or albumin colloids) |
|---|---|
| **Iminodiacetate derivatives** | uptake, transformation and excretion by the hepatocytes (e.g. IDA, HIDA, DISIDA) |
| **Galactosyl neoglycoalbumin** | hepatocyte-specific ligand |
| **Erythrocytes** | pooling and perfusion (e.g. [99m]TcO$_4$) |
| **Homotaurocholic acid** | bile flow (e.g. [75]Se HCA) |
| **Carcinoma antibodies** | immunoscintigraphy in colorectal liver metastases (e.g. [99m]Tc AB CEA) |

*Tab. 9.1:* Various radionuclides with their main characteristics and functions

**Contraindications** are pregnancy and lactation as well as intolerance to mucinous antibodies.

▶ The great value of nuclear medical examinations lies in the fact that the test results (including those produced by static scans) reflect biological functions. Furthermore, such methods can help to define the benignancy/malignancy and structural origin of the respective focal lesion.

## 1 Principle

The term scintigraphy, or scanning, describes the production of a planar, two-dimensional image showing the distribution of radioactivity in an organ in which a radioactive substance has been stored. Depending on the radionuclide used, **information** regarding the hepatic area is obtained on (*1.*) functional capacity of the RES, (*2.*) hepatocellular function, (*3.*) biliary excretion kinetics, and (*4.*) hepatic blood flow. (4, 8, 11, 12, 19, 21, 27, 36, 37)

The **images** taken by means of high-resolution large-area gamma-cameras are (*1.*) (static) liver scans or (*2.*) (dynamic) sequential scans. • Further technical and diagnostic improvements comprise: *positron emission tomography* **(PET)** and *single photon emission computer tomography* **(SPECT)**.

## 2 RES scintigraphy

In the RES of the liver (as well as of the spleen and bone marrow), $80-90\%$ of the radio-labelled colloids (e. g. ^{99m}Tc-S colloid) are usually taken up. This procedure is therefore also termed **static colloid scintigraphy**. Colloid particles of $200-1000$ nm are usually taken up in the liver RES. The size and shape of the organ can be determined. Areas of the RES with reduced or no uptake of radioactivity appear as defective, i.e. silent or cold, zones ("negative scan"). • The **extent of uptake** of the radiocolloids is reflected by different *shades of colour*, ranging from dark red ("hot") through yellow, light green, dark green, blue-green and blue to blue-black ("cold"). Multiple accumulations are a rare occurrence. These storage defects do not have any specific significance. • *Further evidence of centrally located defects is obtained by carrying out additional SPECT scintigraphy. (34)*

### 2.1 Liver cirrhosis

Following the administration of $100-200$ MBq ^{99m}Tc-sulphur colloid intravenously, liver cirrhosis is characterized by a reduction in the uptake of radioactivity in the liver and an increased uptake by the spleen and bone marrow. Colloidal uptake in the liver is thus a valuable parameter for assessing any functional loss of the hepatic RES and for evaluating the residual parenchyma which is still functioning. It should be noted that the phagocytic capacity of the hepatic RES is closely related to the sinusoidal blood flow, the reduction of which is a result of the development of collaterals in the area of the hepatic

sinusoids − this is an early sign of portal hypertension. (s. fig. 9.1) *(see chapter 35)*

*Scintigraphic proof* of cirrhosis is based on (*1.*) enlarged rectangular liver, (*2.*) reduced and patchy uptake of radioactivity by the hepatic RES ("mottled liver"), (*3.*) shift in the maximum activity from the right to the left lobe of liver, and (*4.*) increased uptake by the spleen and bone RES. • The recorded scintigraphic findings permit *assessment of the course* of liver cirrhosis and provide information on focal complications such as (*1.*) occlusion of the branches of the portal vein with locally impaired perfusion and (*2.*) development of hepatocellular carcinoma.

*Fig. 9.1:* Liver cirrhosis: diffuse decrease in the uptake of radioactivity by the liver with a markedly increased uptake by the clearly enlarged spleen (= colloid shift)

Thus the liver and the spleen form an anatomical and functional unit by being interlinked not only through the lienoportal vascular system, but also through the reticuloendothelial system.

## 2.2 Budd-Chiari syndrome

In the Budd-Chiari syndrome, the central area of the liver shows a normal or even increased concentration of radioactivity, whereas the peripheral regions of both lobes of liver exhibit reduced or even no uptake ("hot spots" and multiple focal storage defects). Only the caudate lobe shows increased activity; due to its separate venous flow, it is not functionally affected by hepatic vein thrombosis. (26)

## 2.3 Focal liver lesions

*Focal lesions* with a diameter of > 1.5 cm can be detected with a sensitivity of > 80% and are visible as circumscribed storage defects, e. g. in the case of amoebic ab-

scesses. (s. figs. 9.2; 6.11; 25.1) FNH is a liver tumour with maintained or even increased phagocytosis activity. • The nuclear medical diagnosis of *metastases* is now obsolete, having been replaced by more efficient imaging techniques. (s. fig. 9.3) (5, 9, 11, 22, 27, 29, 39) • If necessary, immune scintigraphy using antibodies (e. g. $^{99m}$Tc-AB-CEA) may be applied in colorectal liver metastases. In HCC diagnosis, use of $^{99}$Tc-anti-alpha fetoprotein produces a sensitivity of 90−95% in SPECT.

*Fig. 9.2:* Amoebic abscesses: storage defects and indistinct liver contours with hepatomegaly (s. fig. 25.1)

*Fig. 9.3:* Liver metastases: Anterior view during scintigraphy using Tc$^{99m}$-S-colloid (100 MBq): three foci in the right lobe of liver in colon carcinoma

## 3 Hepatobiliary sequential scintigraphy

$^{99m}$Tc-iminodiacetic acid derivatives (IDA, HIDA, DISIDA, BIDA) usually reach their maximum concentration in the hepatocytes 2−5 minutes after i.v. injec-

tion and are then excreted into the bile ducts. After 30−45 minutes, the radioactive substance has largely been cleared from the liver. (4, 14, 25) • $^{99m}$Tc-mebrofenin correlates well with the ICG clearance test. It provides information of segmental functional liver tissue, which is of additional use when planning liver resection. (8) (s. tab. 9.2)

| |
|---|
| 1. Examination of the hepatic perfusion of focal lesions |
| 2. Evaluation of radionuclide uptake by hepatocytes (parenchymal phase): assessment of liver function |
| 3. Detection of biliary obstruction, such as in cholestatic syndrome with and without jaundice <br> − search for (posttraumatic or postoperative) biliary leakage (e. g. following liver transplantation) |
| 4. Examination of bilio-digestive anastomosis |
| 5. Monitoring runoff after papillotomy |
| 6. Follow-up after liver transplantation |
| 7. Differential diagnosis of neonatal jaundice (below 10−12 mg/dl) vs. neonatal biliary atresia |
| 8. Contrast-medium intolerance |
| 9. Acute cholecystitis (exact visualization of the gall bladder excludes acute cholecystitis) |
| 10. Focal nodular hyperplasia |

**Tab. 9.2:** Indications for hepatobiliary sequential scintigraphy

## 3.1 Cholestasis

Differentiation between obstructive and parenchymatous cholestasis is possible in >90% of cases. A serum bilirubin level of up to 30 mg/dl is not seen as a methodological impediment to sequential scintigraphy. In incomplete obstruction with nondilated bile ducts, this technique provides more information than can be obtained using ultrasound. (17, 18)

The **homotaurocholic acid test** (SeHCAT) using $^{75}$Se to evaluate the hepatobiliary function (e. g. in the bile-acids losing syndrome) is also worth mentioning here. (40)

Scintigraphic assessment of **liver transplants** is helpful (e.g. perfusion, rejection, bile-duct obstruction or bile leakage). (28)

## 3.2 Focal nodular hyperplasia

FNH is the second most frequent benign hepatic tumour. It is a pseudotumorous regenerative node, most frequently occurring in women. Four-phase cholescintigraphy using $^{99m}$Tc-IDA is currently the best method of detection. In 80−90% of cases, perfusion is good with hypervascular tumours of >2−3 cm in diameter. This results in initial enhancement of the FNH. However, the

tracer cannot be discharged into the bile ducts quickly enough, because in FNH they only consist of irregular proliferations. This results in tracer retention in the excretion phase (so-called "trapping") in FNH, whereas the surrounding liver parenchyma is already tracer-free. Preserved colloid uptake by the RES is typical, whereas occasional uptake is deemed pathognomonic. • In 10−20% of cases, no intact RES is available in FNH. Thus the latter is scintigraphically "cold". (14, 38)

## 3.3 Hepatic adenoma

Hepatic adenoma consists of atypical, strand-like hepatocytes. It is characterized by normal perfusion and an extensive absence of Kupffer cells as well as irregularity of the bile ducts. Scintigraphically, it is possible to demonstrate that there is no elimination of iminodiacetates from the adenoma and that uptake of the radioactive tracer is prolonged compared with the normal liver parenchyma ("trapping" on IDA scans). (38) No colloidal albumin or $^{99m}$Tc-colloid is taken up − this allows differentiation of an adenoma from focal nodular hyperplasia. The use of the SPECT technique increases sensitivity.

## 3.4 Biliary leakage

Hepatobiliary sequential scintigraphy has proved useful in tracing biliary leakage, especially when it is posttraumatic or postoperative. With the help of this method, it is possible to demonstrate pathognomonic extrahepatic nuclide accumulation in the traumatized areas. A biliary leakage of 0.5 ml/min can be easily detected. Sensitivity and specificity are as high as 100%. This procedure is used as an initial screening modality in suspected biliary leakage. (31, 40)

## 3.5 Liver blood flow

$^{99m}$Tc-DTPA: Arterial perfusion accounts for 20%−40% of the circulation; in portal hypertension, cirrhosis causes arterial perfusion to increase to over 60%. In portal vein thrombosis, only an arterial curve is visible. Liver metastasis usually displays relatively high arterial perfusion. In (rare) occlusions of the hepatic artery, only a portal venous curve is visible. When a bolus injection of 400 MBq $^{99m}$Tc-diethylenetriamine pentaacetic acid (DTPA) is applied, scintigraphy is able to reveal a biphasic time-activity curve. The initial increase of activity is produced by the arterial influence and the second peak by the portal venous inflow. Both curves can be evaluated quantitatively. (36) • Perfusion scintigraphy may be useful in the case of liver trauma, TIPS, hypervascularized hepatic tumours and partial liver resection as well as after liver transplantation.

## 3.6 Diffuse liver disease

**99mTc-NGA:** Hepatic binding protein (HBP) found on the hepatocyte surface can bind desialylated glycoproteins with terminal galactose residues. There is a close correlation between a change in HBP activity due to liver trauma and an increase in bonding inhibitors in plasma. • Galactosyl-neoglycoalbumin (NGA) belongs to a group of hepatocyte-specific tracers, whose accumulation is dependent upon HBP bonding; this can be measured scintigraphically using 99mTc-NGA (D.R. VERA et al., 1984). The lysosomes mark the end of the tracer take-up in the hepatocytes (> 90 %). • The first clinical findings in cases of liver trauma were reported on by the same group (R.C. STADALNIK et al., 1980). Results of the investigation into liver cirrhosis and HCC were presented later. It has not yet been possible to obtain any substantial findings in diffuse liver damage using conventional tracer methods. However, use of the hepatocyte-specific tracer 99mTc-NGA can be helpful in assessing liver injury and recovery. (16, 35)

## 3.7 Hepatocellular carcinoma

**67Gallium:** The uptake of 67gallium by HCC is greater than in normal liver tissue. It is possible to differentiate foci in cirrhosis with the help of this radionuclide. In the case of a focus measuring more than 2 cm, the specificity is 91% and the sensitivity 96%. This method should also be used for detecting early recurrent HCC. The tracer 67gallium is, however, non-specific, since it is also taken up by non-hepatocyte-derived tumours and inflammatory lesions. (32) • Colloid scintigraphy and IDA derivates are not significant in HCC diagnosis.

## 4 Erythrocyte scintigraphy

Blood pool scintigraphy using bolus injection of 750 MBq 99mTc-labelled erythrocytes may lead to a diagnosis of intrahepatic space-occupying processes which cannot be differentiated by ultrasonography or CT. This applies especially to haematomas, haemangiomas and haemangiosarcomas. The SPECT technique helps to increase sensitivity. With regard to angiographic imaging reconstruction, however, the modern contrast medium-based imaging techniques which are available today produce by far the best results.

## 4.1 Haemangioma

Cavernous haemangiomas are the most common form of benign liver tumours. They occur in the form of a single lesion in approx. 90% of cases. When using 99mTc-pertechnetate labelling, haemangiomas exhibit a reduced uptake of radioactivity in the early perfusion phase compared with adjacent liver tissue; in the late phase, however, an increased uptake is detectable. This "fill in" occurs faster in small haemangiomas than in larger ones due to the lower stasis. In the latter case, scanning should be carried out at a later phase. At 1.5 cm, a specificity and sensitivity of up to 100% is obtainable using a high-resolution three-headed system. (41) With haemangiomas exceeding 3 cm in diameter, a specificity and sensitivity of up to 100% is obtainable. Smaller haemangiomas (< 2 cm) can be identified by interference-free SPECT in up to 90% of cases. (15, 34) The RES, hepatocytes and bile ducts show no scintigraphic reaction. (1−3, 15, 20, 24, 41)

## 5 Positron emission tomography

Positron emission tomography (PET) has two significant advantages compared to single-photon emission computer tomography (SPECT): (*1*.) improved spatial resolution, and (*2*.) absolute quantification of tracer take-up.

Positron emission tomography with 18F-DG visualizes partial physiological and biochemical functions and thus also pathophysiological and pathobiochemical aspects at the molecular level in a nuclear medical procedure. PET may be a useful method for the differential diagnosis of hepatic foci (malignant/benign). Liver metastases of gastrointestinal tumours can be detected with significantly greater sensitivity using 18F-FDG-PET. In relapse diagnosis of colorectal carcinoma, sensitivity is 93−100% and specificity 95−98%. (5, 33) Malignant melanoma takes up the most 18F-FDG, enabling foci as small as 1.5 mm (as well as affected lymph nodes) to be identified with a high degree of accuracy. Hodgkin's lymphoma, which accounts for approx. 1% of all carcinomas, is a rare entity. In stages I and II, the 10-year survival rate is around 80%. PET has proved to be a useful tool in staging and monitoring. (6) • In the field of (still experimental) hepatology, a wide range of **scientific issues** may be amenable to PET. (s. tab. 9.3).

Tumour cells frequently display increased glycolysis. A radioactive-marked glucose derivative can therefore be taken up in the tumour cells and demonstrated by means of a PET scan after 40−45 minutes. The glucose cellular metabolism can be measured after i.v. injection of **18F-fluoro-2-deoxy-D-glucose** (18F-FDG). This tracer is easily absorbed by the cells before being converted by hexokinase in to 18F-FDG-6-phosphate which, after phosphorylation, is subsequently trapped inside the cells for a prolonged period ("metabolic trapping"). Its half-life is 110 minutes. In the field of hepatology, 18F-FDG-PET has also become clinically significant in staging, therapy follow-up and relapse diagnosis of liver tumours. (5, 7, 10, 13, 23, 30, 33)

1. lentodegenerative alterations in Wilson's disease
2. biochemical changes related to hepatic encephalopathy
   − measurement of the blood-brain barrier by ⁶⁸Ga-DTPA

# 6 Flow diagram in suspected "liver tumour"

Various tumourous and pseudotumourous foci may form in the area of the liver and the hepatobiliary system. Differential diagnosis may therefore become challenging. A definitive diagnosis is, however, necessary to be able to initiate therapeutic measures and to establish a prognosis.

After carrying out the imaging techniques (if necessary with contrast media) *(see chapters 6, 8, 9)* and laparoscopy/biopsy *(see chapter 7)*, the strategy of establishing a diagnosis by **flow diagram** may be recommended in suspected **"liver tumour".** (s. fig. 9.4)

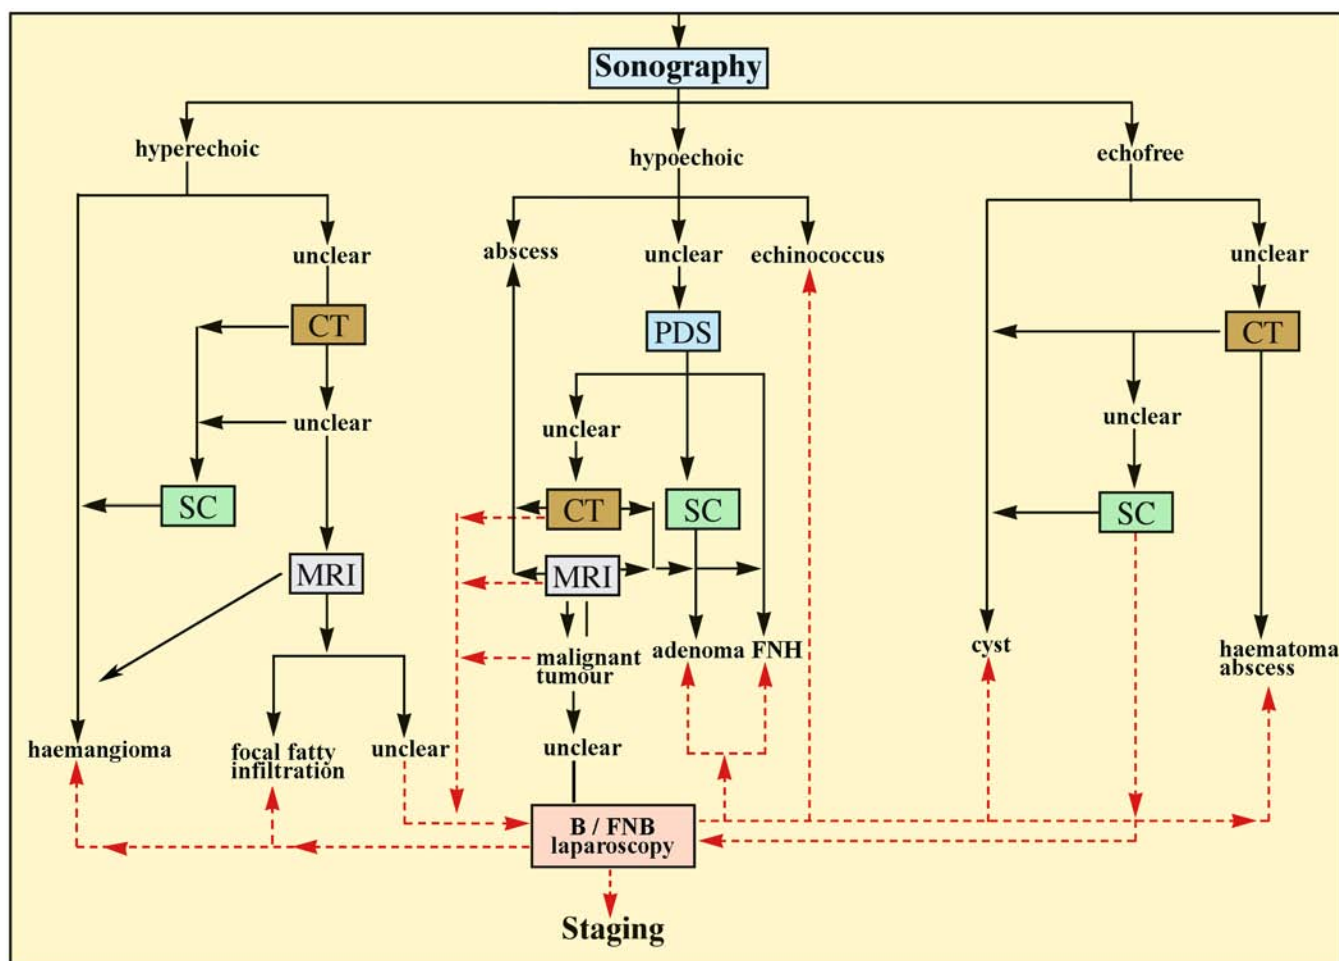

***Fig. 9.4:*** *Flow chart for use in clinically suspected "liver tumour" with positive sonographic findings.* • Imaging procedures (─▶) which may be indicated include power-Doppler sonography (PDS), computer tomography (CT), magnetic resonance imaging (MRI) and scintigraphy (SC). • Histological diagnosis is indicated in some cases in order to confirm or exclude imaging diagnosis. (---▶)

A flow chart should include echocomplex focuses and a distinction between single and multiple focuses. Haematoma and (especially) abscesses, are not always echofree; they may also be hypoechoic or reveal varied echoes. This must be taken into account in the diagnosis of these two conditions. Scintigraphy is becoming less significant, whereas MRI is considerably more important today. However, scintigraphy may be indicated when carrying out a differential diagnosis for adenoma and FNH. Economic constraints may make it necessary to omit some diagnostic steps regarding imaging procedures in order to produce a faster and more cost-effective diagnosis. As an alternative, targeted FNB, biopsies or laparoscopy are recommended. It may even be desirable in individual cases to obtain an earlier histological diagnosis and, if necessary, follow the flow chart in the opposite direction. • *All in all, an extremely careful and critical assessment is required, taking into account the risks, costs and benefits involved.* (s. fig. 13.2)

► In cases of suspected *"liver tumour"*, **ultrasonography** is the method of choice. If the type of focal process cannot be adequately identified even by very experienced investigators, a sonographic monitoring should be performed within a short period of time. Even in cases where the differential diagnostic approach fails, pathological or potentially positive findings can still be obtained with a certain degree of reliability. If an exact diagnosis cannot be achieved, however, imaging techniques are then as a rule indicated. (s. fig. 9.4)

► In order to clarify pathological results or potentially positive findings, **computer tomography** is indicated. The use of CT may also be advisable even with negative sonographic findings if the clinical and laboratory parameters point to a focal process in the area of the liver or the biliary tract. (s. fig. 9.4)

► In the case of differential diagnosis of adenoma versus focal nodular hyperplasia, **scintigraphy** is indicated, whereas in the case of metastases, more reliable imaging techniques are preferred. (s. fig. 9.4)

► In suspected haemangioma, sonography, scintigraphy and MRI are the most efficient procedures. • In individual cases, these three imaging techniques might be interrelated with respect to diagnosis/indication. (s. fig. 9.4)

► Should the differential diagnosis of focal liver findings remain unresolved despite the use of imaging techniques, **laparoscopy** is indicated (possibly with targeted forceps biopsy or liver biopsy). Depending on the findings, *explorative laparoscopy* is also undertaken for the purpose of tumour staging. • Medical assessment of the clinical and sonographic findings may, in some cases, suggest laparoscopy with targeted tissue biopsy − even without previous CT − when an accurate diagnosis is required. (s. p. 150) (s. fig. 9.4)

► The indications for sonography- or CT-guided **fine-needle biopsy** (FNB) are (*1.*) contraindications to the use of laparoscopy (s. p. 149) or (*2.*) if it seems unlikely that previously unresolved findings will be clarified by laparoscopy. • In consideration of all relevant findings from sonography or CT as well as the patient's condition, it may be necessary in individual cases to resort to FNB as the primary approach instead of biopsy or laparoscopy. (s. fig. 9.4) • The non-availability of laparoscopy or insufficient experience with this technique are in themselves not an "indication" for percutaneous fine-needle biopsy. (s. fig. 9.4)

Basically, the **prioritization of methods** within a diagnostic flow diagram should be determined by the question of whether (*1.*) use of an examination technique is indicated, (*2.*) indication applies at the given moment, and (*3.*) definitive diagnosis is likely to be obtained. • *Usually, only a definitive diagnosis allows statements to be made on therapy and prognosis!*

In view of growing financial constraints in many countries regarding the health service, the question of the cost/benefit ratio should also be taken into consideration. In the current situation, the **total costs** incurred for the respective examination methods can be substantial.

# Diagnostics in Liver Diseases

## 10 Neurological and psychological diagnostics

# 10 Neurological and psychological diagnostics

There are **two basic dimensions** in the way the human brain copes with everyday routine; these are known as crystalline and fluid intelligence (R. B. CATELL, 1963).

1. **Crystalline intelligence** is acquired by education and experience; it proves susceptible to disturbance at a relatively late stage in life and to a relatively small extent. • Crystalline (cognitive and verbal) intelligence implements the contents of what has been learned or acquired at an earlier stage to perform tasks or to solve problems. This verbal ("cognitive") intelligence is retained for a long time, so that any impairment of cerebral function is noticed at a relatively late stage in people who pursue mental occupations.

2. **Fluid intelligence** depends largely on the speed at which information is processed; it becomes impaired relatively early and to a greater extent. • Fluid (practical and nonverbal) intelligence is characterized by the capability for solving new problems without reference to experience or education in the course of processing information. This form of intelligence deteriorates at an early stage with any impairment of cerebral function, which is why the intelligence involved in performing practical tasks, so-called handling intelligence, is most susceptible to disturbance − it is for this reason that manual activities are primarily impaired.

Many different **brain functions** are available to enable routine everyday tasks to be mastered correctly. (s. tab. 10.1)

1. Attentiveness
2. Intellectual capacity
3. Logical thinking
4. Memory for design
5. Perceptive faculty
6. Power of concentration
7. Psychomotoricity
8. Reactive capacity
9. Short-term memory
10. Spatial perception and mental comprehension of numbers or letters, *etc.*

*Tab. 10.1:* Brain functions important for mastering routine everyday tasks

## 1 Brain disorders in liver diseases

In the case of cerebral dysfunction, it is possible for these disorders to be reflected individually in differing states of intensity and in a variety of combinations. This results in a very varied pathophysiological and clinical picture of **encephalopathy**. Such a collective term for restrictions in the function of the brain does not, however, yield any statement as to their origins or pathogenesis. Encephalopathy can be triggered by some 50−60 disorders and aetiological factors − including liver diseases. *(see chapter 15)*

**Hepatic encephalopathy (HE)** is defined as a functional, potentially reversible disorder of the brain in the wake of severe (either acute or chronic) liver disease. The term comprises all neurological and mental symptoms.

▶ Diagnosis of the 4 clinical stages of **manifest HE** (stages I−IV) is simple and reliable. However, it is important first of all to recognize **latent HE** (stages 0, 0−I), which is also called *subclinical hepatic encephalopathy (SHE)* or *minimal HE*. • At this stage, no clinically identifiable mental or neurological defects can be detected, nor do the laboratory parameters provide any particular clues. Yet, there are (still reversible) neurophysiological and neuropsychological deviations from the norm which can be quantified.

**Early diagnosis of HE** at the **latency stage** is of great significance in social terms, for industrial medicine and for prognostics; therefore it is of enormous economic importance as well. The development of latent (minimal and subclinical) or subsequent manifest HE (stages I−IV) depends on various factors. • *Latent HE is considered to be the "most frequent complication" in hepatology.*

## 2 Diagnosis of disorders in cerebral performance

It should be noted that the diagnosis of latent HE (stages 0, 0−I) can cause great **difficulties.**

▶ Despite the considerable medical and social implications of SHE, which in objective terms are undeniable, the patient subjectively feels unchanged and free from symptoms. There are no ailments or malaise felt by the patient which point to the development of SHE, and neither the conversation with the physician nor the anamnesis are suggestive of this condition. *Verbal intelligence is not affected!*

▶ Neither clinical findings nor laboratory parameters (including intensive and scientific tests) correlate with the stage of SHE. There are no neurological abnormalities (no hyperreflexia, tremor or asterixis, etc.). • *For the diagnosis of subclinical hepatic encephalopathy, only electroencephalographic and neuropsychological (psychometric) test procedures are available so far.*

### 2.1 EEG

**Spontaneous EEG** can occasionally show a minimal increase in slow waves and a deceleration of the basic activity below the normal

alpha wave range (8−12 Hz), yet there is no correlation with the occurrence of SHE. Only with knowledge of the individual's normal state and with the help of the regular spontaneous EEG as follow-up procedure for cirrhosis can SHE be recognized in 30−50% of cases. However, this is not feasible on a regular basis. With the manifestation of HE (stages I, II), the spontaneous EEG slows down to the theta and delta wave ranges (4−7.5 and 1−3 Hz), which are deemed to be pathological in a waking state. Groups of relatively even waves at a rate of 2 or 3 times per second, and above all frontotemporal delta Faren rhythms, are considered to be hints of a more severe HE. (7, 18, 20, 29, 43, 44, 47) (s. p. 275)

**Visually evoked potentials:** In the diagnosis of SHE, neither the use of visually evoked potentials (VEP) nor acoustically or somatically evoked potentials yielded better results than the spontaneous EEG. Using these exogenously evoked potentials, functional disorders of sensory pathways are identified by assessing the P-100 wave. (2, 10, 12, 21, 26−28, 36, 43, 47, 49−51)

▶ **P-300 wave:** The technique of *endogenously evoked potentials (EEP)* can be applied for the registration of stimulus assessment processes and "attention processes". The *P-300 wave* is deemed to be the electrophysiological correlate of stimulus assessment processes (E. Donchin, 1979). P-300 latency indicates the time required for assessment and categorization of a stimulus. About 30% (45) to 71% (16) of patients with SHE and some 70% (45) to >85% (16) of cases with stage I HE show a lengthening in the latency of the P-300 wave. The sensitivity of this test procedure for the diagnosis of SHE is therefore good. The specificity is minimal because of the widely differing origins of HE. • Determination of the P-300 wave is, however, both time-consuming and expensive, calling for specialized knowledge and experience. For this reason, this diagnostic process is not suitable as a routine test. • *Neverless, in diagnosing SHE, assessment of the P-300 wave in an endogenously evoked EEG is deemed to be the most valuable neurophysiological method of examination.* (5, 11, 26, 37, 42, 48)

▶ The use of **proton MR spectroscopy,** with glutamine as a marker, has opened up new diagnostic horizons. (35) (s. p. 195)

## 2.2 Neuropsychological test procedures

In order to objectify disruptions in brain performance, numerous test procedures have been established in clinical psychology. With the help of these procedures, various cerebral functions can be tested. (s. tab. 10.1)

The term **psychometrics** signifies the most objective recording possible concerning mental functions and personality features with the aid of a variety of test procedures.

**Quality criteria and secondary criteria:** Test procedures applied in clinical psychology should fulfil the requisite **quality criteria** including (*1.*) objectivity, (*2.*) reliability, and (*3.*) validity. • Alongside these main criteria, neuropsychological test procedures should also incorporate other **secondary criteria**, such as (*1.*) standardizability, (*2.*) comparability, (*3.*) cost factor, (*4.*) usefulness, and (*5.*) sensitivity. • *Obviously, it will not always be possible to meet all of these criteria in full in every case.*

*No single test is absolutely reliable or even accurate.* The results of neuropsychological tests are subject to various **influences** and thus confounded by a number of factors occurring individually to differing degrees of intensity and in a variety of combinations. (s. tab. 10.2) • This no doubt explains the widely differing assessments of the frequency of SHE which are reported in the literature. An examination of several of the multiple brain functions (s. tab. 10.1) requires the skilful selection of test procedures with their respective targets.

1. **Influential factor "test procedure"**
   - desired test targets
   - suitable test combination
   - professional implementation of the test
2. **Influential factor "liver disease"**
   - severity
   - aetiology and pathogenesis
   - acute or chronic state
   - portosystemic collaterals
3. **Coexistent factors**
   - consumption of alcohol
   - cerebral noxae
   - cerebral or cerebrovascular damage
4. **Individual factors**
   - age
   - intelligence
   - social status
   - fluctuation in the course of SHE

**Tab. 10.2:** Factors influencing the reliability of test results and the detection of SHE frequency

Quite clearly, it is not a single test, but rather a combination of tests, focusing on as many different brain functions as possible, which guarantees an overall result that is meaningful.

**Neuropsychological tests:** Among the large number of neuropsychological tests available, several procedures are considered apt for the detection of subclinical brain disturbances. Some involve complex methods and also call for specialized knowledge. Nevertheless, a few of them can be regarded as the *"gold standard"* for clinical issues involved in the diagnosis of SHE. (1, 6, 15, 17, 43) (s. tab. 10.3)

**Test combinations:** For clinical purposes, suitable test combinations can be set up on the basis of the overview given (s. tab. 10.3) and in accordance with the respective issues. Due to their feasibility and reliability, the following tests are particularly useful: (*1.*) basic intelligence test, (*2.*) multiple-choice vocabulary intelligence test, (*3.*) short test for general intelligence, (*4.*) short test for cerebral intelligence, (*5.*) attentiveness-concentration test, (*6.*) Benton test, (*7.*) syndrome short test, and (*8.*) trail-making test. • In scientific clinical studies, the Wechsler adult intelligence scale (WAIS) is often used. (14, 38, 40, 41) In these studies, the WAIS verbal IQ is seen to be largely undisturbed, whereas there are clear deficits in that *part of the WAIS which relates to performing practical tasks* (handling IQ), particularly in the number-symbol test and in the mosaic test. At the same time, other psychological test procedures are applied, mainly the trail-making test as well as EEG (VEP, P-300 wave).

# 3 Basic psychometric programme

▶ The principle of both early diagnosis and early treatment of a disease together with the prevention of a progressive or complicated course are seen as fundamental targets in everyday medical routine. *This applies especially to latent hepatic encephalopathy, which can be found in a high percentage of patients suffering from liver disease.*

**Intellectual capacity**
1. Hamburg-Wechsler adult intelligence test
   (D. Wechsler, 1964); 60−90 minutes
2. Basic intelligence test
   (R. B. Cattell et al., R. H. Weiss, 1972)
3. Multiple-choice vocabulary intelligence test
   (S. Lehrl, 1977); 5−8 minutes
4. Short test for general intelligence
   (S. Lehrl et al.); 8−10 minutes
5. Short test for cerebral intelligence
   (S. Lehrl et al.)

**Powers of attention and concentration**
6. Attentiveness and concentration test
   (R. Brickenkamp, 1968); 5 minutes
7. Revision test
   (G. Marschner, 1972); 8 minutes

**Memory**
8. Benton test
   (A. L. Benton, 1953)
9. Syndrome short test
   (H. Eerzigkeit); 15 minutes
10. Mini-mental-status test
    (M. L. Folstein et al., 1975); 10 minutes
11. Wechsler memory test
    (D. Wechsler); 45−60 minutes

**Recognition of shapes**
12. Visual-design-potential test
    (L. Bender, 1946); 20 minutes

**Speed of cognitive performance**
13. Trail-making test (parts A and B)
    (R. M. Reitan, 1955)
14. Number-connection test (part A of trail-making test, fourfold variations)
    (H. O. Conn, 1977)

**Reactive capacity**
15. Measurement by technical appliances
    − speed of response
    − accuracy of response

*Tab. 10.3:* Neuropsychological test procedures with respective test target priorities (and average duration of test)

## 3.1 Psychometric test procedures

Obviously, the EEG examinations and psychological tests outlined above are not suitable for use at the doctor's surgery or in clinical routine as a screening programme for the presence of SHE. Although they meet the required quality criteria, they are time-consuming and cost-intensive, and thus unacceptable. • In the course of the past thirty years, some 50 simple *psychometric screening tests* have been developed and reports

made on their application (in a variety of combinations). (4, 6, 8−10, 14, 15, 19, 22, 23, 25, 30, 31, 34, 38, 39, 41, 43, 45) (s. tab. 10.4) • The *multiple-choice determination device* is another example of a test which has proved its worth.

1. Alphabetic deletion test
2. Archimedes spiral test
3. Block design test
4. Circle-dotting test
5. Colour word test
6. Digit-span test
7. Dot test
8. Handwriting-specimen test
9. Line-labyrinth test
10. Line-tracing test
11. Logical inductive test
12. Memory for design test
13. Number and symbol test
14. Perceptual maze test
15. Raven's matrices test
16. Serial-subtraction test
17. Star-construction test
18. Story-retelling test
19. Tracing of geometric figures
20. Visual motor design test
21. Visual retention test
22. Word-pair retention test     *etc.*

*Tab. 10.4:* Selection of psychometric screening tests (in alphabetical order)

### 3.1.1 SIP

Use of a questionnaire comprising 136 questions relating to the "sickness impact profile" (SIP) indicated a marked decrease in patients' capacity to perform routine daily activities and a diminished quality of life in 27% of cases of latent HE. (9)

### 3.1.2 Mechanical testing procedures

With the help of appliance-based tests, it is mainly possible to measure both reaction time and accuracy of response.

*Multiple choice determination device:* Five electronically controlled coloured light pulses (yellow, red, green, blue, white) are activated in alternating sequences. Pressing a button with the same colour indicates that the test person has recognized and registered the colour both instantly and correctly. This device has proved to be a useful instrument in clinical testing environments. (14)

*Posner test:* This mechanical testing procedure is designed for measuring spatial-visual attention and orientation (M.I. Posner et al., 1988). The test persons are required to sit in front of a computer monitor using a cross in the middle of the screen as a fixation point. A square is visible on either side of the cross. In the neutral position, a question mark is displayed as a cue 200 milliseconds before the stimulus (= asterisk) appears in one of the squares. In the valid position, the cue is an arrow

directed towards the square where the stimulus will appear. In the invalid position, it is directed towards the opposite square. When the stimulus appears, the test person pushes a button as quickly as possible. The Posner test reveals the varying delay in reaction time in patients with cirrhosis; it does not appear to have a higher sensitivity than the number-connection test. (1)

*Critical flicker frequency:* The principle of flicker-fusion frequency analysis was first introduced by E. SCHAFHÄUTL in 1855 and later developed for clinical use by L. GOLD-BERG in 1943. This method has since been widely used in differential diagnosis of organic brain syndromes. • It was first established in patients with latent HE in 2002. (13) The patient observes what appears to be a constant red light shining on the screen, but which is in fact flickering at a high frequency. This flickering is normally detected by the test persons above 42 light pulses/sec. with individual variations. However, in patients with latent HE, this occurred below 39 pulses/sec. (cutoff value), in HE stage I below 36 pulses/sec., and in stage II below 32 pulses/sec. The results are independent of the patient's education level; there is no learning effect when the test is repeated.

These simple psychometric screening tests do, however, have certain **disadvantages,** which have to be considered when results are being assessed. (s. tab. 10.5)

1. Several complementary screening tests are required for the identification of SHE
2. It has not been adequately defined which functional brain areas are covered by the tests
3. Standardized test evaluation is often not possible
4. There is still no adequate basis for comparison with scientifically established test procedures in neuropsychology

*Tab. 10.5:* Disadvantages of psychometric testing

## 3.2 Psychometric test programmes

Based on the results in the literature (which also correspond to our own experience), psychometric test programmes have been developed for use in the hospital and the doctor's surgery.

1. Simple to carry out
2. Easy to assess
3. Low time factor
4. Minimal costs
5. Reproducibility
6. Semiquantitative evaluability
7. Allows examination of various functional areas or performance capacity of the brain (even if not specifically defined or differentiated)

*Tab. 10.6:* Requirements for psychometric test procedures relevant for application in the doctor's surgery

Such test programmes make it possible to objectify neuropsychic disturbances and hence yield semiquantitative identification of the subclinical (latent) stage (0, 0−I) as well as manifestation stage I (or I−II) of HE. These programmes can be considered relatively reliable owing to the standardized instructions for their implementation and adequate objectivity in the evaluation process. A psychometric test programme suitable for use in the doctor's surgery and at the hospital should meet the **requirements** given above. (s. tab. 10.6)

1. **PSE syndrome test** (W. HAMSTER, M. KLUCK, H. SCHOME-RUS): The **short form of the test** is comprised of (*1.*) number-connection test (part A) and (*2.*) line-tracing test. The test results are converted into standard values according to age. • The **long form of the test** is made up of (*1.*) number-symbol test, (*2.*) number-connection test (part A), (*3.*) circle-dotting test, (*4.*) target-fixing test, and (*5.*) line-tracing test.

2. **Psychometric test set** (E. KUNTZ, H.-D. KUNTZ): This test set facilitates psychodiagnostic monitoring of potential liver-diseased patients, identification of SHE and control of therapeutic measures. In some cases, the very simple *four basic tests* can be evaluated in their overall assessment with even greater reliability by means of *supplementary tests*, which are likewise easy to implement. (19) (s. tab. 10.7)

**Basic tests**
1. Handwriting-specimen test
2. Number-connection test (part A)
3. Line-tracing test
4. Star-construction test

**Supplementary tests**
1. Serial-subtraction test
2. Story-retelling test
3. Mechanical testing procedures

*Tab. 10.7:* Psychometric test programme for identification and monitoring of SHE (E. KUNTZ, H.-D. KUNTZ, 1991) (19)

### 3.2.1 Handwriting-specimen test

The handwriting-specimen test (I. SZAM, 1977) is a simple procedure which provides an insight into fine motor control. Subtle changes in the handwriting are thought to be a sign of constructive apraxia, i. e. there are disturbances in carrying out learned expedient movements, although the powers of perception and mobility are still intact. The possibilities of applying *medical graphology* in hepatology have been presented in detail in the literature. (24) • **Regular handwriting tests are quite correctly known as the "poor man's EEG".**

▶ In line with neurophysiological findings, the patient should write his first and last name and *not* texts, place-names or dates! *The signature constitutes a swift, habitual sequence; as a reflex action which does not involve the application of willpower; it is considered to be a person's* **graphological identity**. In the early stages of HE, fine, swift and controlled movements of the hand are im-

paired. The handwriting-specimen test correlates well with the number-connection test and the subtraction test. • *Impaired handwriting* is reflected in small jagged peaks, hooks, interruptions in the flow, subtle irregularities, fluctuations in pen pressure, size of the lettering, etc. The assessment is based on the subjective criteria of the physician, which is, however, perfectly adequate for hospital or surgery purposes. (s. figs. 10.1; 15.3) • In addition, the results can be graded according to the physician's personal scoring system. (s. tab. 10.8)

**Fig. 10.1:** Specimens of a patient's handwriting (first name and surname) in stage II (17 Oct.), in the SHE stage (29 Oct.) and in a normal state (5 Dec.) (s. fig. 15.2)

| Changes | Score (points) | Stage of HE |
|---|---|---|
| not detectable | 0 | no HE stage 0 |
| very minimal or minimal | 1 | SHE, 0 − I |
| moderate | 2 | I, I − II |
| clearly evident | 3 | II |
| pronounced | 4 | II − III |

**Tab. 10.8:** Assessment criteria for the handwriting-specimen test

### 3.2.2 Number-connection test

▶ The **trail-making test** (R. M. REITAN, 1955) originated from the "army individual test" (1945) and the test results of S. G. ARMITAG (1946). It comprises two parts: the *number-connection test* **(NCT)** with numbers from 1−25 (part A) and the *number and letter combination test* **(NLCT)** with numbers from 1−13 and the letters A−L (part B). (32, 33) (s. fig. 10.2)

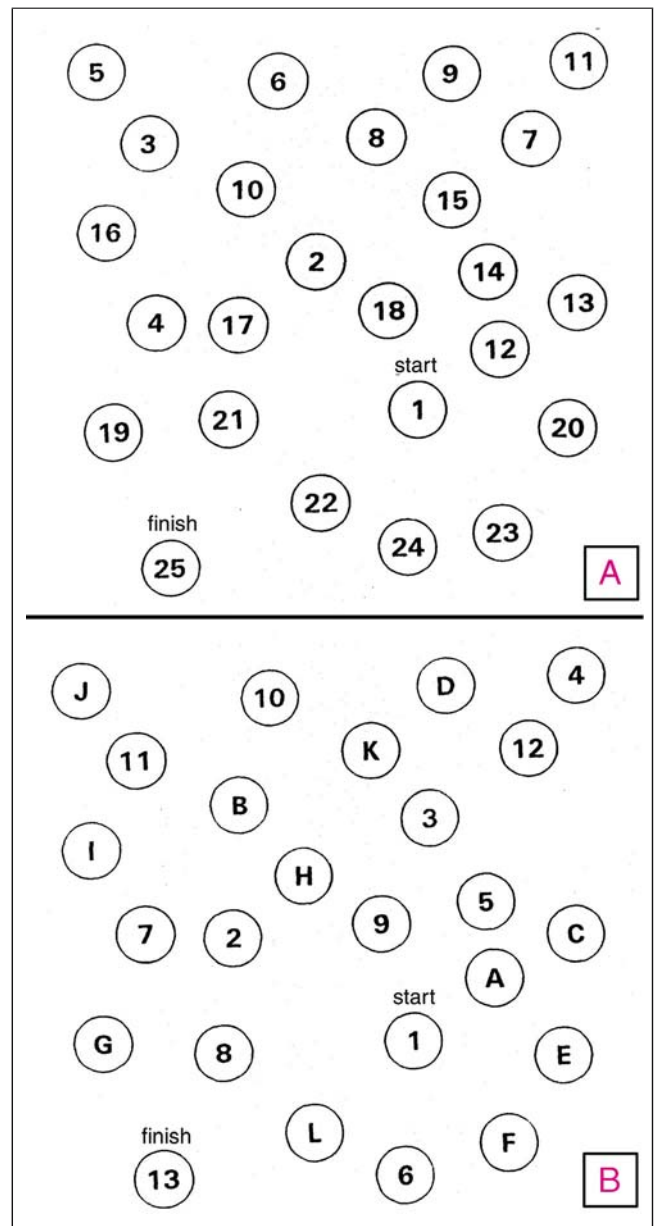
The *number-connection test* presented by H. O. CONN in 1977 (3) corresponds to part A of the *number-connection test* as described above; however, 4 different test sheets are used, each with a different arrangement of figures. In this way, a possible learning effect from sheet to sheet is ruled out. The 4 different test sheets are of equal difficulty and generally require the same period of time to complete. • With the number-connection test (parts A and B), logical thinking, powers of concentration and perception, together with the capacity to handle three-dimensional numbers and letters are assessed. Swift cognitive speed in thought processing is called for as well as the capacity to adapt. (19, 38, 46, 49)


**Fig. 10.2:** Number-connection test (NCT; part A) and number-letter-connection test (NLCT; part B) (R. M. REITAN, 1955; H. O. CONN, 1977)

| Time in seconds | Score (points) | Stage of HE |
|---|---|---|
| < 40 | 0 | no HE, stage 0 |
| 41−60 | 1 | SHE, 0 − I |
| 61−90 | 2 | I, I − II |
| 91−120 | 3 | II |
| > 121 | 4 | II − III |

**Tab. 10.9:** Assessment criteria for the number-connection test (NCT; part A)

In order to complete the test, either the 25 figures in part A or the numbers 1−13 in consecutive alternation with the letters A−L in part B have to be correctly linked up by lines as quickly as possible, whereby any corrections are included in the time allotted. If the

patient is unable to complete the test within 150 seconds, it is broken off. The last correctly linked number and the respective time are noted (e.g. 17/150). The time required by the patients for part A of the number-connection test, as used by us in the psychometric examination set, allows a relatively reliable clinical interpretation to be made. In the number-connection test (part A), the **normal value** should be set at no more than 40 seconds. • The relevant score can be noted as an assessment criterion. (s. tab. 10.9)

### 3.2.3 Line-tracing test

The line-tracing test (LTT) is used to determine the accuracy of a person's fine motor control. A test sheet (s. fig. 10.3) shows a relatively complex "road map", 5 mm in width (corresponding to a 2.5 m wide lane). The patient is asked to trace this not-so-easy path with a pencil from start to finish, as quickly as possible, without going over the edges. The number of errors provides a semiquantitative assessment. • In addition, the respective number of points can be recorded in the score sheet. (s. tab. 10.10)

**Fig. 10.3:** Line-tracing test (LTT) using a difficult path, 5 mm in width

### 3.2.4 Star-construction test

The star-construction test examines the patient's psychomotor function, recognition of shapes, and short-term memory. A test sheet (s. fig. 10.4) is presented to the patient, who is requested to look at the five-pointed star drawn on it for about 10 seconds (E. A. DAVIDSON et al., 1956). (4) The test sheet is then covered or turned over. The patient is now asked to copy the star using 10 matchsticks, whereby the tips of the matches should form the pointed tips of the star. A lack of precision or errors in arranging the matchsticks and/or any confusion which arises during the test are rated as mistakes. • In addition, the respective number of points can be recorded in the score sheet. (s. tab 10.10)

**Fig. 10.4:** Star-construction test (E. A. DAVIDSON et al., 1956) (4)

| Number of errors | Score (points) | Stage of HE |
|---|---|---|
| no error | 0 | no HE, stage 0 |
| 0−2 | 1 | SHE, 0 − I |
| 3−5 | 2 | I, I − II |
| 6−9 | 3 | II |
| > 9 | 4 | II − III |

**Tab. 10.10:** Assessment criteria for the line-tracing test and star-construction test

The results of these 4 tests can be summarized by means of their score to give a **total number of points**, thereby simplifying the clinical interpretation in the individual case. (19)

The **time needed** for each test procedure (explanation, implementation and evaluation) is about 3−4 minutes, provided the necessary test materials are already at hand (test sheets, stop-watch, pencil, matchsticks, etc.). • It is possible to have the tests carried out by trained personnel.

These simple test procedures can be executed in any surgery, if the indication is given. A code number could be assigned as the *cost-calculation item* for health-insurance purposes. • It is neither organizationally possible, nor medically justifiable, let alone financially viable to make the implementation and assessment of these tests dependent on a specific professional qualification, such as is acquired in further education programmes. • *Every doctor is capable of carrying them out!*

Should it be impossible to assess the presence of SHE by means of these tests, some additional, basic **supplementary tests** can be applied at the surgery. They require no test materials. The time needed for each test is roughly 3 or 4 minutes.

### 3.2.5 Serial-subtraction test

With the help of the serial-subtraction test, patients' powers of attention and concentration can be tested as

well as their short-term memory and mental arithmetic capabilities.

From a specific initial figure selected at random (such as 100 or 110 or 130), the patient is asked to deduct another number, likewise selected at random (= subtrahend), continuing the subtraction procedure through a number of steps by "mental arithmetic" (e. g. $100 - 7 = ?$, $- 7 = ?$, $- 7 = ?$). After the 3rd or 4th arithmetical step, a patient with SHE and a disturbed short-term memory usually no longer knows which number he/she has to deduct from which previous result. This simple test can likewise be adequately quantified for practical purposes. • *If the test is repeated, the same numbers can be taken for the same patient and the results compared. There is virtually no learning effect involved.*

### 3.2.6 Story-retelling test

Another psychometric supplementary test that can be used is the retelling of a story. Here the patient's short-term memory, perceptive faculties and logical thinking are tested.

The physician tells the patient the following story (lasting about one minute), which then has to be retold by the patient (also in about one minute): *"A bee flies to the brook to take a bath and falls into the water. A dove sees the bee and saves it from drowning. The dove lays the bee on a leaf to dry off. The next day, a hunter comes into the wood and takes aim to shoot at the dove. The bee flies at him and stings the hunter's hand so that his shot misfires."* It is important to note any **incorrect renderings of the plot** which are typical of SHE — e. g. the hunter or the dove drown, the dove stings the bee, the hunter shoots the bee, the dove stings the hunter, etc.

▶ Such a test programme makes screening for SHE very simple; it is reliable for both surgery and hospital purposes. The test sheets and test results should be documented and filed for an appropriate period of time. • Patients who display cerebral dysfunction during these simple tests generally show more pronounced impairment of cerebral functions when complex and specific test procedures are applied. • *Psychometric tests are highly sensitive as regards disturbances in cerebral performance, yet they have no specificity regarding underlying causes or the disease itself — for this reason they are not "specific to the liver" either.*

In suspected subclinical hepatic encephalopathy, psychometric tests are extremely important for the diagnosis and cannot be substituted by other examination procedures (e.g. anamnesis, inspection, laboratory analysis, imaging).

▶ The transition from the latent stage (SHE) to stage I of clinically manifest HE can be gradual, as demonstrated by the results of the psychometric tests. In this *transitional zone (SHE I)*, there may occasionally be minor neurological findings, such as hyperreflexia, fine tremor or asterixis. (s. p. 272) (s. tab. 15.5)

# Symptoms and Syndromes

## 11  Hepatomegaly and splenomegaly

# 11 Hepatomegaly and splenomegaly

## 1 Hepatomegaly

### 1.1 Definition

Hepatomegaly is present if (*1.*) *palpation* locates the lower border of the right lobe of liver to be more than 2 cm (1−2 finger breadths) below the left costal arch (MCL lateral to rectus abdominis) (caution: phrenoptosis), (*2.*) the absolute liver dullness on *percussion* is more than 14 cm, or (*3.*) the longitudinal diameter of the liver in the MCL is greater than approximately 15 cm in the *sonogram*.

Hepatomegaly is a cardinal symptom in a number of liver diseases or a concomitant reaction of the liver in various extrahepatic or systemic diseases. When detected, differential diagnostic clarification is always necessary.

Hepatomegaly can affect the entire liver as a *diffuse* enlargement or only a certain region of the liver as a *circumscribed* increase in volume. • Under clinical conditions, the **liver size** is ascertained by the combined application of *palpation* (to determine the inferior border of the liver) and *percussion* (to determine the border between the liver and lungs). (s. pp 77, 79) Determination of the liver size by *sonography* is considerably more precise. • It is also necessary to assess the **liver consistency** (soft, elastic, firm, compact, hard), the **liver surface** (smooth, protuberant), the **tenderness on pressure**, and the sonographically detectable **internal structure** (homogeneous, inhomogeneous, formation of foci, enlarged bile ducts or vessels). The **density** of the normal liver in the CT is $60 \pm 6$ HU. (s. p. 171)

### 1.2 Pathogenesis

#### 1.2.1 Replication of cells

A diffuse enlargement of the liver can be caused by cell replication.

(*1.*) Replication of *hepatocytes* in the form of excessive hyperplasia can occur occasionally after extensive parenchymal necrosis or partial liver resection. However, this does not generally cause a clinical discernible form of hepatomegaly.

(*2.*) In systemic haematological diseases, the liver is usually involved in *extramedullary haematopoiesis*. This can result in hepatomegaly.

(*3.*) Diffuse enlargement of the liver can also be brought about by *lymphohistiocytic cell infiltrations*. This generally involves inflammatory reactions to viral or bacterial diseases.

(*4.*) Diffuse hepatomegaly is also expected to occur as a result of *malignant cell growth*.

#### 1.2.2 Enlargement of cellular structures

An increase in the volume of sinusoidal cells and hepatocytes due to an enlargement of their cellular structures can be caused *actively* by proliferation or *passively* by storage processes.

(*1.*) *Endothelia* and *Kupffer cells* can be stimulated to considerable proliferation, so that in clinical terms hepatomegaly occasionally results.

(*2.*) Proliferation of the *smooth endoplasmic reticulum* due to the prolonged induction of the biotransformatory system localized at this site as a result of toxins, noxae or chemicals can bring about clinically and sonographically detectable hepatomegaly.

(*3.*) Hepatocellular *storage* of abnormal quantities of cholesterol, fat, glycogen, proteins, mucopolysaccharides, copper, iron, etc. occasionally leads to pronounced hepatomegaly. Hydropic swelling of the hepatocytes is also included in this category.

#### 1.2.3 Augmentation of the extracellular space

Diffuse enlargement of the liver can also arise from augmentation of the extracellular space.

(*1.*) An increase in *blood* both in the sinusoids and in Disse's spaces culminates in hepatomegaly. This can be witnessed particularly in cases of right heart failure, constrictive pericarditis, veno-occlusive disease and the Budd-Chiari syndrome. Inflammation-related hyperaemia also occurs in acute viral hepatitis.

(*2.*) An enhanced formation of *lymph* or reduced lymph drainage can cause enlargement of the liver. Here fluid-filled *cysts* can also be regarded as a cause of hepatomegaly.

(*3.*) A disorder of the *bile flow*, particularly in infants, leads to extensive hepatomegaly.

(*4.*) An increase in the extracellular *matrix* due to collagens, elastin, proteoglycans, glycoproteins, etc. also produces various degrees of hepatomegaly.

### 1.2.4 Local processes

*Circumscribed enlargement* of the liver is precipitated by local lesions such as cysts, abscesses, parasites (e. g. echinococcus) and benign or malignant tumours; this also results in *diffuse enlargement* of the liver in some cases.

## 1.3 Causes

A number of liver diseases are accompanied by an enlargement of the liver. The liver can also be involved in extrahepatic or systemic pathological diseases, possibly with the simultaneous development of hepatomegaly. Differential diagnosis is extremely varied, necessitating a broad spectrum of investigations in individual cases. (1−3, 6−8, 10, 11) (s. tab. 11.1)

## 1.4 Diagnosis

### 1.4.1 Subjective symptoms

Hepatomegaly is occasionally accompanied by a feeling of pressure or even *tenderness* in the right epigastrium. (5) This tension pain of Glisson's capsule mainly occurs with a rapid increase in the liver volume (acute viral hepatitis, acute congestive liver, etc.), whereas gradually developing hepatomegaly may be without pain. • The liver parenchyma itself is insensitive to pain. (s. pp 22, 78) Not to be associated with this is pain arising from a specific underlying disease in the liver region, which generally has no direct effect on liver enlargement, e. g. malignant tumours, cholangitis, perihepatitis.

### 1.4.2 Clinical findings

Hepatomegaly can easily be ascertained by *palpation* and *percussion*; its size can also be well assessed. Asthenic patients may display simulated liver enlargement. (s. pp 77, 78) • In addition to the typical dextral *elevation of the diaphragm* in hepatomegaly, there is often a downward *displacement of intestinal loops* as well.

▶ *Sonography* is an indispensable investigative method for clarifying the following issues: (*1*.) differentiation between diffuse and circumscribed hepatomegaly, (*2*.) assessment of the internal structure (homogeneous or inhomogeneous), (*3*.) determination of foci, cysts, nodes, etc., and (*4*.) confirmation of hepatomegaly or detection of a simulated enlargement of the liver due to extrahepatic pathological diseases. (4, 9)

### 1.4.3 Methods of examination

In the majority of cases, the causality can be established on the basis of the hepatological findings or the prevailing disease. Often, however, definite clarification can only be achieved by additional investigative methods. • The indication for *computer tomography* (9), and per-

**1. Inflammatory liver diseases**
  − acute viral hepatitis
  − acute autoimmune hepatitis
  − alcoholic hepatitis
  − concomitant hepatitis with infections
  − bacterial sepsis
  − miliary tuberculosis
  − parasitoses (e. g. echinococcus, toxocariasis, capillaria hepatica, schistosomiasis)
  − HIV infection
  − liver abscess
  − bacterial cholangitis, *etc.*

**2. Chronic liver diseases**
  − chronic hepatitis
  − liver cirrhosis
  − hepatic granulomatosis, *etc.*

**3. Metabolic / toxic diseases**
  − fatty liver
  − hepatic porphyrias
  − amyloidosis of the liver, *etc.*

**4. Biliary diseases**
  − biliary obstruction
  − primary biliary cholangitis
  − cholestasis
  − Byler's syndrome, *etc.*

**5. Vascular liver diseases**
  − congestive liver,
  − peliosis hepatis
  − constrictive pericarditis
  − Budd-Chiari syndrome
  − veno-occlusive disease
  − arterial diseases, *etc.*

**6. Tumours**
  − benign liver tumours
  − malignant liver tumours
  − metastatic liver

**7. Cystic liver**

**8. Congenital diseases**
  − hereditary liver storage diseases (haemochromatosis, Wilson's disease, amyloidosis, glycogenoses, lipopathies, tyrosinaemia, Zellweger's cerebrohepatorenal syndrome, fructose intolerance, $\alpha_1$-antitrypsin deficiency, Burka's syndrome, galactosaemia, Mauriac syndrome, *etc.*)
  − malformations of the liver or the bile ducts

**9. Systemic haematological diseases**

**10. Systemic immunological diseases**

*Tab. 11.1:* Causes of hepatomegaly

haps also *angio-CT*, should be checked first. As non-invasive procedures, these should be given priority over bioptic methods. (s. tab. 8.2) • *Angiography* may be indicated in cases where enhanced vascularity is suspected. (s. tab. 8.3)

If *biopsy* proves necessary, thought must be given to whether a fine-needle biopsy or a liver biopsy is appropriate. (s. tab. 7.3)

It should not be overlooked, however, that some indistinct liver findings can be diagnosed reliably and at little risk by *laparoscopy*, with or without biopsy. (s. tab. 7.11)

# 2 Splenomegaly

## 2.1 Normal values of the spleen

A *normal spleen* is 11 (10−14) cm in length, 7 (6−8) cm in width and 4 (3−4) cm in depth. The weight of the spleen varies considerably (<100 g to >250 g); a mean value of 150−170 (−180) g can be accepted. • The normal diameter of the *splenic artery* is 4−5 mm, while that of the *splenic vein* is 8−14 mm with a normal mean value of about 10 mm. With a *flow rate* of 500−700 ml per minute, the blood flow through the spleen exceeds the arterial blood supply of the liver by a factor of almost 3. • The *longitudinal axis* of the spleen runs parallel to ribs 9−11 from the upper dorsal to the lower ventral.

The size and volume of the spleen can be determined quite reliably by present-day methods of investigation, so that even slight increases in the size of the organ can be detected. However, in view of the wide spectrum of variation in the size of the "normal" spleen, thought must be given to the following questions: (*1.*) at what point should "splenomegaly" be diagnosed, and (*2.*) once a spleen has been classed as enlarged, should it be regarded as pathological.

**Determination of the size** of the spleen by *palpation* and *percussion* is most unreliable. (19) (s. p. 79) • *X-ray examination* only permits determination of the longitudinal axis in 50−90% of cases, whereas measurement of the thickness is totally inadequate, and measurement of the width is not even possible.

▶ The values of a normal or enlarged spleen can be recorded quite reliably in a *sonogram*. (16, 18, 23, 26) Assessment is sometimes made more difficult by overlying ribs or as a result of air in the stomach or intestines. Due to the uncertain sonographic identification of the upper pole of the spleen, it seems adequate to determine the maximum width and thickness in the transverse section. *Normal values* are 4 × 7 × 11 cm (whereby the transverse diameter is 4−5 cm and the longitudinal diameter is <11 cm). (s. p. 135)

▶ The size of the spleen can be determined with an accuracy of ± 5% by *computer tomography*. The maximum width and thickness can be measured directly from the transverse section. The length is calculated from the difference between the upper and lower splenic poles.

*Normal values* are as follows: longitudinal extension 11−15 cm, longitudinal axis of the ellipsoid cross-section 7−10 cm, transverse axis 4−5 cm. The product of the normal mean values gives the *CT spleen index*, which correlates quite well with anatomical reality: 11 × 7 × 4 cm = 308 (160−440). In computer tomography, the normal density of the spleen is 46 ± 12 HU or 50 ± 8 HU.

▶ Selective *spleen scintigraphy* by chemically or heat-denatured erythrocytes and [197]Hg-BMHP-, [51]Cr- or ^{99m}Tc-labelling provides very reliable measurements.

## 2.2 Definition

The symptom of **splenomegaly** is defined as an enlargement of the spleen in which the normal values (4 × 7 × 11 cm) are clearly exceeded by >2−3 cm in at least two dimensions − with a corresponding rise in the normal CT index (160−440). Sonographic reliability depends largely on spleen thickness: >5 cm = 67%, >6 cm = 85%, and >7 cm = 100%. The thickness of the spleen is therefore regarded as the parameter which correlates best with clinical findings. An increase in the longitudinal diameter to well over 11 cm is also considered to be "splenomegaly". • A diameter of the splenic vein of >10 mm is deemed pathological.

***Fig. 11.1:*** CT (native) showing splenomegaly in non-Hodgkin lymphoma (L = liver, S = spleen, arrow = calcified aorta)

The large individual variations in the "normal" values as well as the differing results yielded by various methods of examination (palpation, sonography, CT and scintigraphy) call for greater precision in definition. Whenever the diagnosis "splenomegaly" is established, the method by which the diagnosis was obtained should be given. (s. fig. 11.1)
***Fig. 11.2:*** Laparoscopy showing splenomegaly in portal hypertension due to liver cirrhosis

## 2.3 Pathogenesis and causes

Enlargement of the spleen can have numerous causes. It is important to rule out any possibility that the method of investigation itself could lead to splenomegaly being simulated, such as "upside-down" spleen, accessory spleen(s) or wandering spleen. The involvement of the spleen in disorders of the lymphatic and reticuloendothelial system as well as of the portal and systemic circulation explains why splenomegaly is frequently found in connection with widely differing diseases. (18, 20, 23, 34−38) (s. tab. 11.2)

Splenomegaly is very closely related to a number of liver diseases and, in particular, to the clinically recognizable involvement of the liver in a variety of pathological processes. Inclusion of the differential diagnosis of splenomegaly can, therefore, provide valuable information for the clarification of hepatological findings. (s. figs. 11.1; 11.2; 14.7; 35.10)

## 2.4 Functional sequelae

As a *mechanical component*, splenomegaly exerts pressure on neighbouring organs. • In addition, splenomegaly has mechanical and functional *sequelae* on the lienoportal vascular system. There is also a close relationship between splenomegaly and the quantitative or qualitative composition of the blood, which can ultimately develop into a splenogenic marrow maturation arrest. Consequently, a number of findings in liver diseases can be associated with splenomegaly or hypersplenism.

## 2.5 Therapy

Once the cause has been diagnosed differentially with great thoroughness, splenomegaly therapy is directed solely at the underlying disease − on the assumption that symptomatic and curative therapy options are available. (21)

**Drainage disorders in the portal and systemic circulation**
- Liver cirrhosis (37), liver tumours, liver echinococcosis, portal vein thrombosis, thrombosis of the splenic vein, right heart failure, Budd-Chiari syndrome, peliosis hepatis (39), *etc.*

**Hepatolienal storage diseases**
- Amyloidosis, fatty liver, glycogenoses, Wolman's syndrome, hyperchylomicronaemia, Wilson's disease, Zellweger's cerebrohepatorenal syndrome, Niemann-Pick disease, mucopolysaccharidoses, *etc.*

**Infectious diseases**
- Acute viral hepatitis, acute salmonellosis, measles, bacterial sepsis, histoplasmosis, leptospirosis, malaria, mononucleosis, Bang's disease, visceral leishmaniasis (22), rickettsioses, toxoplasmosis, tularaemia, schistosomiasis, *etc.*

**Chronic infections**
- Cholangitis, endocarditis lenta, malaria, eosinophilic granuloma, tuberculosis, chronic hepatitis (27), *etc.*

**Collagenoses and rheumatic diseases**
- Felty's syndrome, lupus erythematosus, Reiter's disease, Still's disease, Wegener's disease, histiocytosis, *etc.*

**Diseases of the haematopoietic system**
- Acute leucosis, chronic lymphadenosis, chronic myelosis, erythroblastosis, haemolytic anaemias, Werlhof's disease, osteomyelosclerosis, polycythaemia vera, thalassaemia, shunt hyperbilirubinaemia, *etc.*

**Diseases of the lymphoreticulohistiocytic system**
- Lipogranulomatosis, lymphosarcoma, Hodgkin's disease (36), Brill-Symmers disease, Waldenström's disease, *etc.*

**Chronic exposure to arsenic** (29, 31)

**Isolated (primary) splenomegaly**
- Echinococcus (13), splenic abscess (12), splenic tumours (30), splenic cysts (14, 15, 17, 24−26, 32, 33, 40), *etc.*

**Non-tropical idiopathic splenomegaly**
- Dacie's syndrome (J. DACIE, 1969) (28)

**Tropical idiopathic splenomegaly syndrome**

***Tab. 11.2:*** Causes of splenomegaly (with some references)

# Symptoms and Syndromes

## 12 Jaundice

# 12 Jaundice

> For doctor and patient alike, the phenomenon of **jaundice** evokes the idea of a disease of the liver or of the bile ducts. Indeed, awareness of the condition of jaundice is undoubtedly as old as medical science itself. (s. pp 6, 7)

## 1 Definition

The term **jaundice** or **icterus** is used to depict the yellowish discolouring of the skin, mucous membranes and body fluids witnessed as a result of hyperbilirubinaemia in excess of 2.5 mg/dl, with subsequent deposition of bile pigments in tissue which is rich in elastin. In cases of severely impaired liver function or renal insufficiency, bilirubin values can rise dramatically. • The term **subicterus** is used to describe a low-grade icteric condition occurring in the region of the white sclera with a serum bilirubin value of >1.8 mg/dl; for this reason, it is also known as *scleral icterus.* (s. pp 80, 99)

> Jaundice is a **disorder in the metabolism of bilirubin** (s. p. 33); it is thus neither directly related to the bile acid metabolism (s. p. 35) nor to *cholestasis. (see chapter 13)*

> *Jaundice is a symptom and not a disease. • It can occur with and without cholestasis.*

## 2 Localization of bilirubin

Bilirubin is a hydrophobic organic anion. It shows a varied affinity to the individual tissues, so that differentiation can be made between bilirubinophilic and bilirubinophobic tissues (F. ROSENTHAL, 1930). Above all, tissue which is rich in elastin (skin, sclera, intima of the vessel wall, ligaments) absorbs bilirubin rapidly and intensively. Jaundice is thus first manifested at the sclera, where it remains detectable longest. Subsequently, the face, chest and abdomen as well as inner organs (such as the liver) and, to a lesser degree, the extremities are the most affected areas. Cartilage and nerve tissue are rarely yellow-coloured as a result of the icteric condition, and if so, only to a minor degree. The soles of the feet and palms of the hands only show slight icteric staining, if at all. • Saliva, lacrimal fluid and gastric juice are not stained icteric-yellow. Cerebrospinal fluid occasionally contains bilirubin and takes on a yellow hue, such as in hepatic coma (D. S. AMATUZIO et al., 1953) or Weil's disease (W. H. CARGILL Jr. et al., 1947).

In cases of obstructive jaundice, bilirubin enters the lymphatic vessels, so that the lymphatic fluid is already icteric when it enters the thoracic duct. Exudates and transudates are always yellow-coloured in a certain correlation to the serum bilirubin values, although they contain less bilirubin (in accordance with their lower protein content) than the serum itself. Due to their larger protein content, exudates are more icteric in colour than transudates. • Icteric colouring is hardly or not at all evident on paralyzed parts of the body. It would appear that bilirubin concentration also depends on normal nerve function. As a rule, jaundice is not detected in the region of an oedema (J. MEAKINS, 1927; J. H. PAGE, 1929).

## 3 Different shades of jaundice

The respective colouring of jaundice depends on a number of different factors. The reddish shade in hepatitis patients used to be defined as **rubin jaundice;** the lemon yellow with a reddish hue observed in haemolysis was known as **flavin jaundice** (*flavus* = Latin for *yellow*) and the greenish shade observed in long-term cases of obstructive jaundice was called **verdin** or **green jaundice.** In obstructions lasting for several months, greyish-green to greenish-black tints were observed with jaundice, resulting in the term **melas jaundice** (from the Greek word *melas*, meaning *black*). (s. p. 80) • These colour differences, as interesting as they might be in the individual case, are of little help in differentiating between the various types of jaundice − *nearly every shade is possible in every single jaundice patient!*

**Differential diagnosis:** Jaundice has to be clearly delimited from **carotene jaundice** or **xanthodermia**, which may appear after an abundant ingestion of carrots, blood oranges and mangoes or the use of medication and cosmetic agents containing carotene. • **Lycopenaemia** can occur after an excessive ingestion of tomatoes. • A yellowing of the skin similar to that seen with increased serum bilirubin levels can also occur after an intake of quinacrin or busulfan.

## 4 Clinical classification of jaundice

> ▶ The **classification of jaundice** introduced by J. W. MCNEE (1923) still holds true today. It distinguishes between (*1.*) haemolytic, (*2.*) parenchymal, and (*3.*) obstructive. (s. p. 6) • Equally important is the classification of jaundice put forward by H. DUCCI (1947), which comprises various forms (*1.*) prehepatic, (*2.*) intrahepatic, and (*3.*) posthepatic.

Three types of bilirubin are found in the serum: unconjugated (indirect), conjugated (direct), and covalent albumin-bound bilirubin. *(see chapter 3.3)*

(*1.*) **Unconjugated** bilirubin IXα is almost insoluble in water and therefore reversibly bound to albumin in the

blood (< 1% free bilirubin remaining). Bilirubin enters the hepatocytes with the aid of transporters (= bili-translocases); during this process, it is dissociated from albumin. Transport inside the hepatocytes is facilitated by the two carrier proteins, Y (= ligandin) and Z (= transport reserve).

(*2.*) **Conjugated bilirubin** is now formed in both rough and smooth ER, where it is conjugated with glucuronic acid. The result is a water-soluble bilirubin monoglucuronide and subsequently the respective diglucuronide. This glucuronidation process is catalyzed by uridine diphosphate-glucuronosyltransferase (UDPGT), which occurs in the form of two isoenzymes. Excretion of bilirubin into the bile (20−40% as monoglucuronide, 60−80% as diglucuronide, 0.5−2.0% as unconjugated bilirubin) is actively carried out by ATP-dependent transporters (cMRP2, cMOAT). Bilirubin is transported into the bowels in mixed cells (together with bile acids, cholesterol and phospholipids). Bacterial glucuronidases then produce apolar, water-insoluble, unconjugated bilirubin, which is converted to urobilinogen by bacterial reductases.

(*3.*) **Delta bilirubin** describes a small amount of conjugated bilirubin in the serum, which is irreversibly bound to albumin by covalent bonding. In laboratory tests for bilirubin levels, delta bilirubin is determined together with conjugated (direct) bilirubin. • In pronounced and prolonged jaundice, the delta bilirubin level increases proportionally. The half-life of conjugated (direct) albumin-bound bilirubin is approx. 17 days, which is the same as that of albumin. This accounts for the relatively slow regression of jaundice.

---

**1. Prehepatic jaundice**
    = overproduction jaundice
    = repression jaundice

**2. Intrahepatic jaundice**
  *a. Dysfunction of bilirubin transport*
  • diminished bilirubin uptake in the liver cell
    = absorption jaundice
  • dysfunction of intracellular bilirubin transport (i.e. premicrosomal)
  *b. Dysfunction of bilirubin conjugation*
    = conjugation jaundice (i.e. microsomal)
  • congenital
  • postpartal
  • acquired
  *c. Dysfunction of bilirubin excretion*
    = excretion jaundice (i.e. postmicrosomal)

**3. Posthepatic jaundice**
    = obstruction or regurgitation jaundice
  *a. Extrahepatic jaundice*
  *b. Intrahepatic jaundice*

**Tab. 12.1:** Localization and developmental mechanisms of the various types of jaundice

---

In line with their *mechanisms of development* and *localization*, the various forms of jaundice can be subdivided into a well-established classification scheme. (s. tab. 12.1).

---

**Unconjugated (= indirect) hyperbilirubinaemias**

**1. Bilirubin overproduction**
  • Haemolysis
  • Dyserythropoiesis
  • Jaundice from pulmonary infarction, from large haematoma, from repeated blood transfusions, occasionally in postoperative icterus
  • Repression of bilirubin from its albumin binding by endogenous or exogenous substances

**2. Diminished bilirubin uptake**
  • Long periods of fasting
  • Flavaspidic acid, rifampicin, *etc.*
  • Sepsis
  • Right heart failure
  • Portacaval shunt
  • Gilbert-Meulengracht syndrome (on occasions)

**3. Diminished bilirubin storage**

**4. Dysfunction of bilirubin conjugation**
  • Congenital disorders
    − Crigler-Najjar syndrome
    − Gilbert-Meulengracht syndrome
  • Severe neonatal icterus
  • Acquired disorders
    − medication-induced toxicity (e.g. ethinyloestradiol, gentamycin)
    − hyperthyroidism
    − hepatocellular diseases

**Mainly conjugated (= direct), on occasions also combined, hyperbilirubinaemias**

**1. Diminished bilirubin excretion**
  • Congenital dysfunctions
    − Dubin-Johnson syndrome
    − Rotor syndrome

**2. Dysfunctions of the hepatocytes**
  • Acquired dysfunctions
    − acute viral hepatitis
    − acute liver failure
    − liver cell necrosis in severe shock
    − chronic aggressive hepatitis
    − liver damage due to alcohol toxicity
    − pronounced storage diseases
    − severe fatty liver
    − liver cirrhosis
    − congestive liver
    − toxic liver damage

**3. Biliary obstruction**
  • Extrahepatic obstruction
  • Intrahepatic obstruction
    − mechanical
    − toxic

**4. Special forms**
  • Recurrent intrahepatic cholestasis
  • Recurrent cholestasis in pregnancy
  • Postoperative jaundice (on occasions)

**Tab. 12.2:** Different forms of jaundice classified in relation to the metabolic disorder of bilirubin and glucuronidation of bilirubin

Another way to subdivide the different forms of jaundice is based on *bilirubin conjugation*, which enables all forms of jaundice to be classified into **two systems:** unconjugated and conjugated forms of hyperbilirubinaemia. This particular systematization can result in overlapping terminology or produce pathogenetic combinations. (s. tab. 12.2)

## 4.1 Prehepatic jaundice

Prehepatic jaundice is usually generated by **haemolysis.** Overproduction of bilirubin results in unconjugated hyperbilirubinaemia, whereby the serum bilirubin level is rarely in excess of 5 mg/dl. *Unconjugated bilirubin* cannot pass through the kidney, so that no traces of bilirubin are detectable in the urine despite the icteric state. • The bile is pleiochromatic and lithogenic. Chronic prehepatic jaundice can give rise to cholelithiasis due to the formation of pure pigment gallstones. In severe cases of haemolysis, the *conjugated bilirubin* in the serum may also increase, so that bilirubin is now detectable in the urine. As a result of haemolysis-related hyperbilirubinaemia, increased formation and renal excretion of *urobilinogen* occur. (s. tabs. 5.8; 12.1) (s. pp 33, 99) (s. fig. 5.3)

Apart from the multicausal facets involved in the haemolytic syndrome or the disorders leading to haemolysis (e. g. erythrocyte defects, toxins, noxae, antibody-mediated or mechanical factors), other **causes** of prehepatic jaundice are worthy of mention:

(*1.*) **Dyserythropoiesis** refers to an increasing presence of abnormal erythrocyte precursors in the bone marrow and spleen (with splenomegaly, but no hepatomegaly) due to ineffective erythropoiesis and early labelled bilirubin production *(primary shunt hyperbilirubinaemia)*. Jaundice is indicated by serum bilirubin levels of 1.5 − 8 mg/dl between the ages of 20 and 30. Levels of urobilinogen in the urine are elevated and normoplastic erythroid hyperplasia occurs in the bone marrow. Prognosis is, however, good. (3, 10)

(*2.*) **Pulmonary infarction jaundice** following extensive haemorrhagic pulmonary infarction with haemolysis of the erythrocytes which have passed into the alveoli.

(*3.*) **Haematoma jaundice** with retrogression of large haematomas due to the fact that 1 litre of blood produces about 5 g bilirubin, which is 20 times the normal daily bilirubin production.

(*4.*) **Postoperative jaundice:** In some cases, postoperative hyperbilirubinaemias may also be caused by haemolysis, in particular when unconjugated bilirubin is detectable. (2, 7, 15)

(*5.*) **Blood transfusions:** Haemolysis is due to the shortened lifespan of transfused erythrocytes.

(*6.*) **Displacement of bilirubin** from its albumin bond. Various endogenous substances (e. g. long-chain fatty acids and bile acids) or exogenous compounds (e. g. medication, such as ampicillin, ajmaline, quinidine, furosemide, indomethacin, probenecid, rifampicin, sulphonamide etc., and X-ray contrast media) can compete with bilirubin, not only with respect to its specific binding site, but also for its carrier protein.

Irrespective of the aetiology and pathogenesis of **haemolysis,** certain **symptoms** are generally witnessed. (s. tab. 12.3)

1. Serum bilirubin ↑
   − mainly indirect bilirubin, seldom > 5 mg/dl
2. Urobilinogenuria +, bilirubinuria +
   − only in severe haemolysis
3. $LDH_{1,2}$ ↑
4. Haptoglobin ↓
5. LDH/GOT quotient > 12
6. Reticulocytes > 20‰
7. Splenomegaly: frequent
8. Liver biopsy: normal
   − possible detection of haemosiderin
9. Erythropoiesis in the bone marrow ↑

**Tab. 12.3:** General signs of haemolysis

## 4.2 Intrahepatic jaundice

Multiple influences may cause a **disorder in the metabolism of bilirubin** inside the hepatocyte. This dysfunction may be localized in the *premicrosomal, microsomal* or *postmicrosomal* region of the liver cell. (s. tab. 12.2)

(*1.*) Jaundice may result from a **diminished bilirubin uptake** in the liver cell. This is possibly caused by bile acids, medication or chemicals (e. g. vermicides such as flavaspidic acid). Extensive periods of fasting (N.A. GILBERT et al., 1907; E. MEYER et al., 1922) (< 300 calories/day, > 48 hours) and toxaemia with sepsis (14, 18, 23) can also give rise to unconjugated hyperbilirubinaemia.

(*2.*) **Reduced storage of bilirubin** can be caused by the bilirubin competing with exogenous substances for binding to the Y protein or with long-chain fatty acids for binding to the Z protein. Thus bilirubin may diffuse back from the liver cell into the blood.

(*3.*) **Dysfunction of the glucuronosyltransferase activity** is mainly attributed to congenital defects, resulting in functional, unconjugated hyperbilirubinaemias. In contrast, acquired impairment of glucuronidation as a result of medicaments (chloramphenicol, pregnanediol, testosterone, etc.) or due to hypothyroidism is deemed to be rare. This particular form of jaundice shows an increase in indirect bilirubin without occurrence of bilirubinuria. Medication-induced jaundice is rarely due to an inhibition of glucuronosyltransferase activity, because other enzyme systems in the biotransformation process (phase 2) show overlapping effects.

(*4.*) Jaundice is also caused by **dysfunction in the secretion of bilirubin.** The mechanisms involved in the excretion of bilirubin into the biliary capillaries are, however, still largely unresolved, which is why the starting points of the disruptive factors are still unknown. This dysfunction is a postmicrosomal regurgitation jaundice with increased levels of both unconjugated and conjugated bilirubin.

▶ *Congenital defects* include the Dubin-Johnson syndrome and Rotor syndrome. (s. tab. 12.4) Both of these diseases present a genetically determined disorder in the secretion of bilirubin.

▶ *Acquired liver diseases* (e. g. cirrhosis, liver cell necrosis in severe shock (11), pronounced toxic liver damage, cardiac congestion (11, 17), alcohol-related and medication-induced diseases of the liver) very frequently

cause jaundice as a result of disorders in the secretion of bilirubin. The uptake, storage and conjugation of bilirubin are usually not impaired. A number of medicaments merely produce elevated bilirubin levels (so-called *jaundice type*). • Intrahepatic jaundice − with and without cholestasis − is most frequently attributed to acquired defects of the respective functions of the liver cell as a result of pronounced liver damage. Conjugated (sometimes even unconjugated) hyperbilirubinaemia is evident in connection with bilirubinuria and urobilinogenuria. The greater the liver damage, the higher are the frequency and degree of severity of jaundice (possibly even with additional cholestasis).

▶ *Additional cholestasis:* Isolated defects in the transport mechanisms of bilirubin not only display jaundice, but also an impairment in the secretion of bile. The outcome is additional intrahepatic, nonobstructive cholestasis.

## 4.3 Posthepatic jaundice

This form of jaundice is initiated by a *mechanical obstruction* in the region of the extrahepatic or intrahepatic bile ducts, which is why the terms "mechanical jaundice" or "obstructive jaundice" are also common. The congestion of the bile flow is either *incomplete* or *complete*. Bile stasis results in dilation of the extrahepatic and intrahepatic bile ducts, allowing *hepatomegaly* to develop. (8, 9, 16, 19) (s. tab. 12.1)

**Histologically,** obstructive jaundice is characterized by biliary thrombi in the canaliculi as well as the storage of bile pigments in hepatocytes and Kupffer cells. These changes are most pronounced at the centres of the lobules, since there is less chance of outflow here than in the lobular periphery.

**Biochemically,** a change in structure relating to the mucopolysaccharides (neuraminic acid?) and monohydroxy bile acids probably accounts for the formation of biliary thrombi. Some of the "underhydroxylated" bile salts appear in crystalline form; the bile becomes increasingly viscous and its flow is impeded. This defect in the excretion of bile salts culminates in dysfunctions in the secretion of bilirubin, which is why bilirubin is regurgitated into the blood. The bile which accumulates in the bile ducts ultimately becomes mucous and white because of the reabsorption of bile pigments by the epithelia of the small bile ducts.

▶ **Extrahepatic obstructive jaundice** is caused by stenosing processes. The region of Vater's papilla is particularly affected, for example by inflammations, stones, duodenal diverticula, carcinoma, parasites, cicatricial stenosis or adenomatosis. In this respect, special mention should also be made of carcinoma, cicatricial strictures and gallstones (s. figs. 8.14, 8.15; 32.1, 32.15), compression of the common bile duct due to a cystic duct stone (= *Mirizzi syndrome*), haemobilia, and various parasites − such as Ascaris lumbricoides (s. fig. 25.8!). All of these disorders can be found in the area of the extrahepatic bile ducts. (9, 19)

▶ **Intrahepatic obstructive jaundice** relates to the intrahepatic bile ducts, which can be blocked, above all *mech-*

*anically*, by inflammatory processes (cholangitis, primary biliary or primary sclerosing cholangitis), intrahepatic stones, granulomas, tumours, cysts, amyloid degeneration, eosinophilic gastroenteritis, and cystic fibrosis of the pancreas − to name but a few examples. • In addition, biliary obstructive jaundice can also be caused by *drug-induced toxicity*, e.g. with $C_{17}$-substituted steroids, erythromycin estolate, chlorpromazine, chlorpropamide, ajmaline, halothane, methylthiouracil. • Further intrahepatic forms of obstruction include recurrent intrahepatic cholestasis and recurrent cholestasis in pregnancy. (s. tab. 12.4)

▶ **Special forms:** There are a multitude of factors involved in the pathogenesis of intrahepatic *benign postoperative jaundice;* hypoxia, hypotension, haemolysis, toxins, sepsis and medicaments are just a few of them. (5, 6, 14, 18, 23) • Likewise, jaundice in *intensive-care patients* (2, 7, 15) as well as after long-term *total parenteral nutrition* belong to this category. (1, 4)

# 5 Functional hyperbilirubinaemias

Hyperbilirubinaemia relates to functional disorders in the hepatocellular metabolism of bilirubin − with and without cholestasis (W. SIEDE, 1957). This means either dysfunctions regarding bilirubin conjugation (= *conjugation jaundice*) or bilirubin excretion (= *excretion jaundice*).

**Unconjugated hyperbilirubinaemias**

As a result of impaired bilirubin conjugation, unconjugated lipophilic bilirubin IXα increases (80−85% of the total bilirubin gives rise to an *indirect diazo reaction*). This free bilirubin can pass unhindered through biological membranes and hence have a toxic impact on cells. Many factors may affect the various stages of the metabolic process, which is still incomplete up to this point. Cholestasis is absent in these diseases. (59) (s. tab. 12.4)

## 5.1 Neonatal and infant jaundice

### 5.1.1 Physiological neonatal jaundice

In about 90% of all neonates, jaundice occurs after the first 2−5 days of life and rarely exceeds 6 mg/dl serum bilirubin. In premature infants, bilirubin levels can rise to 10−12 mg/dl. • The **cause** is related to a number of factors: (*1.*) reinforced degradation of haemoglobin as a result of the short erythrocyte survival span of 70−90 days (120 days in adults), (*2.*) reduction in cellular transport proteins, above all ligandin, (*3.*) deficiency of uridyltransferase and glucuronosyltransferase, and (*4.*) increasing intestinal absorption of meconium bilirubin.

| **3. Idiopathic connatal or neonatal hepatitis** |

**Tab. 12.4:** Functional, partly neonatal, partly connatal-hereditary hyperbilirubinaemias

After approx. 10 days, newborn jaundice subsides without any further consequences. Bilirubin also acts as an antioxidant and can thus provide protection from oxygen radicals, if necessary. • Peripartal complications can, however, reinforce or prolong this state. This may occur in infantile hypothyroidism or when medication is administered directly to the infant as well as via breast milk (particularly when bilirubin is displaced from its albumin binding by drugs). In more pronounced jaundice, phototherapy and an increase in the oral intake of fluids may be advisable. (44, 45, 48, 53, 58, 64)

### 5.1.2 Kernicterus

Kernicterus may occur as the result of immaturity of the blood-brain barrier in *severe neonatal icterus* and can occasionally be found in *premature infants* as well, with bilirubin levels usually higher than 20 mg/dl. Unconjugated bilirubin is deposited in the basal ganglia of the hippocampus and the hypothalamus nuclei as bilirubin-phosphatidylcholine precipitate, where it gives rise

to neuronal necroses. *Risk factors* (e.g. asphyxia, acidosis, hypothermia, hypoglycaemia, sepsis with lower UPT activity, and medication) promote the occurrence of the dreaded kernicterus. • In clinical terms, sucking weakness, vomiting, attacks of fever, convulsions, reflex anomalies, shrill shrieking, apathy and muscular hypotension can be observed, with subsequent muscular hypertonicity, cramps, opisthotonus, strabismus, nystagmus and apnoea. The lethality rate is about 75%. Survival is accompanied by cerebral paresis, deafness and retardation. • *Therapy* focuses on exchange blood transfusions, plasmapheresis and phototherapy (430−470 nm; 8−12 hours daily). (13, 25, 28, 64, 69).

### 5.1.3 Lucey-Driscoll syndrome

This is a familial form of neonatal hyperbilirubinaemia (J. F. Lucey et al., 1960) (52) and can probably be attributed to the inhibitive effect of a progestagen steroid in the maternal blood serum, which impedes bilirubin conjugation. Babies show sucking weakness. Bilirubin values can be in excess of 6 mg/dl. This disorder, which occurs from approximately the 2nd day of life onwards, regresses after 2−3 weeks. There is no hepatomegaly or splenomegaly; bilirubin and urobilinogen cannot be detected in the urine. The prognosis is good. In severe (extremely rare) cases, exchange blood transfusions may be indicated.

### 5.1.4 Breast-milk jaundice

Prolonged neonatal breast-milk jaundice is found in 0.5−1% of all breast-fed infants as from the 4th day and within the first 2 weeks of life. Bilirubin levels are drastically elevated (15−25 mg/dl). Nevertheless, this clinical picture does not generally give rise to kernicterus. Even if breast-feeding is discontinued immediately, the condition can take up to 10 weeks to regress. Possible causes are long-chain fatty acids or a pregnane derivative (pregnane-3-α-20β-diol) in the breast milk; this steroid inhibits glucuronosyltransferase activity. Apart from that, intestinal bilirubin uptake is elevated. (24, 40, 71)

### 5.1.5 Blood group incompatibility

Rh-erythroblastosis occurs in 0.2‰ and ABO erythroblastosis in 0.6% of all pregnancies. In clinical terms, the course of the latter disease is usually more moderate. Due to severe haemolysis, unconjugated bilirubin levels rise rapidly, often reaching relatively high values. • *Therapy* includes phototherapy, exchange blood transfusions and administration of immunoglobulin (500 mg/kg BW).

### 5.1.6 Hereditary haemolytic anaemia

Thalassaemia, spherocytosis, sickle-cell anaemia and glucose-6-phosphate dehydrogenase deficiency are rare causes.

### 5.1.7 Crigler-Najjar syndrome

▶ In 1952 the clinical picture of this congenital, familial, non-haemolytic type of jaundice was described by the American paediatricians J. F. CRIGLER and V.A. NAJJAR (31). • Differentiation is made between the *homozygous type I* (progressive with lethal outcome) and the *heterozygous type II* (more moderate and favourable in its course). • The **cause** is a hereditary recessive (or dominant in type II) autosomal deficiency in UDP-glucuronosyltransferase. Consanguinity is common within the families affected. The gene is located on chromosome 2.

The (rare) Crigler-Najjar syndrome **type I** can be attributed to the *almost total lack* of the 2 isoenzymes in bilirubin UDP-glucuronosyltransferase activity (as a result of mutations in UGT-1A1 locus). Consequently, hepatic bilirubin clearance is reduced to $1-2\%$ of the standard rate. Bilirubin is excreted as unconjugated bilirubin $IX\alpha$ or in the form of polar diazo-negative metabolites. Because of the absence of conjugation, severe unconjugated hyperbilirubinaemia with bilirubin values of $18-50$ mg/dl occurs during the first days of life. Within a few days, kernicterus develops with pronounced neurological disorders. (50) Stools and urine are of normal colour, the bile is colourless. The liver and spleen are not enlarged. All hepatic laboratory parameters are normal. Except for the presence of biliary thrombi, the histology of the liver is quite regular. As a result of the biliary thrombi in the dental canaliculi, the teeth can take on a yellow colouring, and enamel hypoplasia appears. • The *course of disease* is progressive and generally lethal. The mean life expectancy ranges between 6 and 18 months. Only a few of the $150-200$ patients whose case histories have so far been published reached puberty. • *Therapy* consists of exchange blood transfusions and plasma separations as well as intensive phototherapy ($8-12$ hours daily), possibly in combination with cholestyramine, agar, zinc and calcium carbonate or calcium phosphate. Indol-3-carbinol is also recommended as an inductor of CYP 450-1A1/-1A2. Liver transplantation may be indicated. (68)

In Crigler-Najjar syndrome **type II** (I. M. ARIAS, 1962) *(Arias syndrome)* (26), glucuronosyltransferase activity is *merely reduced*, since only one isoenzyme is defective. For this reason, bilirubin conjugation is only minimally restricted. Bilirubin is largely excreted as monoglucuronide. The uptake of bilirubin into the liver cell might also be impaired. Jaundice generally occurs within the first year of life, but occasionally during the following $20-30$ years. (28) Bilirubin values fluctuate between 6 and 20 mg/dl. A more pronounced rise in bilirubin levels can be caused by various stress factors (e. g. fasting, infections, acidosis, metabolic dysfunctions). In such cases, kernicterus can occasionally occur. Like type I, type II does not display any particular stigmata: the colour of the stools and urine, the size of the liver and spleen as well as the laboratory parameters are normal. Now and again, histology displays biliary thrombi while, as with type I, hypertrophy of the smooth endoplasmic reticulum and of the Golgi apparatus is also in evidence. • The *course of disease* is more moderate, so

that prognosis is usually good. Nevertheless, repeated attacks of kernicterus can culminate in permanent neurological damage (intention tremor, changes in the EEG, impaired intelligence). • As *therapy*, phenobarbital ($3 \times 60$ mg) in combination with calcium phosphate has proved useful. Phototherapy is likewise indicated. (13, 28) Alternatively, phenytoin or phenazone can also be applied. The effect is derived from the induction of the glucuronidation enzyme and the enhancement of the synthesis of the Y protein. Careful guidance of the patient is important, particularly in order to avert attacks of kernicterus. (38, 39, 43, 45, 50, 61, 67, 73)

## 5.2 Jaundice in adults

### 5.2.1 Gilbert-Meulengracht syndrome

▶ In 1901 A. GILBERT and P. LEREBOULLET described a clinical picture using the term *cholémie simple familiale*. (36, 37) The *icterus intermittens juvenilis* (56) described by E. MEULENGRACHT in 1939 (subsequently termed familial, nonhaemolytic jaundice or constitutional hyperbilirubinaemia) proved to be identical.

The **frequency** of this harmless disorder in the metabolism of bilirubin is quite high: it affects $5-12\%$ of the population. The syndrome is 4 times more common in men than in women. Frequency in the affected families lies between 5% and 55%. • *Genetic transmission* occurs in a dominant autosomal way with differing degrees of penetrance, which accounts for the heterogeneous clinical picture. Sporadic occurrences of this syndrome have also been observed. The gene is located on chromosome 2.

The **pathogenesis** is characterized by several mechanisms: (*1.*) elevated production of hepatic haem bilirubin; (*2.*) in some 60% of the patients, minor haemolysis is evident due to a lower survival span of erythrocytes; (*3.*) the activity of the glucuronosyltransferase is diminished (by about one third of the norm) due to mutations in UGT-1A1 locus, and there is above all a deficiency in monoglucuronosyltransferase activity, because bilirubin monoglucuronide excretion in the bile is considerably higher than is the case in healthy persons; (*4.*) disorders in membrane fluidity are responsible for reduced bilirubin uptake in the hepatocytes. Ligandin and Z protein levels in the hepatocytes are reduced. • However, none of these mechanisms in itself provides an explanation for the symptoms of the Gilbert-Meulengracht syndrome.

The **subjective complaints** of the patients are reflected in irritability, moodiness, fatigue, vegetative dysfunctions, epigastric discomfort and abdominal bloating. Such complaints, however, show no correlation with the intensity of hyperbilirubinaemia. It is still not clear whether these ailments can be regarded as concomitant symptoms (= epiphenomena) or as a sequela (= hypochondriac reaction) of jaundice.

The **clinical picture** is characterized by intermittent jaundice with bilirubin levels of 1.5 to 2.5 mg/dl; there are also phases in which normal values are registered. Increased bilirubin values are not only discernible after fasting and physical exercise, but also as a result of infections, alcohol

consumption, menstruation, medication and severe stress. Bilirubin levels fluctuate considerably, even during the course of several days. This syndrome usually becomes manifest between the ages of 15 and 30. It is rarely found in neonates or infants. There are no further findings: liver and spleen are normal in size; urine and stools show no noticeable changes in colour; transaminases are regular, and cholestasis is not detectable. Generally, there are no signs of haemolysis, except to a slight extent in patients with higher bilirubin values. Only in 20−40% of cases is it possible to find a defect in the uptake of organic anions (e. g. indocyanine green). (54) However, reduced glucuronidation of certain medicaments was observed (e. g. acetaminophin, clofibrate, rifampicin, tolbutamide). (32) Gilbert's syndrome is classed as a clinically significant complication only when it occurs together with thalassaemia or simultaneous ingestion of ifinotecan.

**Diagnosis** is founded on: (*1.*) normal transaminase values, (*2.*) regular ultrasound findings, and (*3.*) an elevated level of unconjugated serum bilirubin. • The diagnosis can be confirmed by various laboratory parameters, findings or tests:

(*1.*) Serum values of bile acids, haptoglobin and reticulocytes are normal.

(*2.*) The monoglucuronide/diglucuronide quotient is elevated.

(*3.*) Fasting (< 400 calories per day for 2 days) raises bilirubin levels to 2 (−3) times the initial value.

(*4.*) Maintaining a diet normal in calories yet strictly lipid-free for 2 or 3 days can cause bilirubin levels more or less to double.

(*5.*) Rigorous physical exercise (sports) for 1 or 2 days results in noticeably increased bilirubin values.

(*6.*) The nicotine acid test (50 mg nicotine acid i.v.) produces a rise in bilirubin of more than 0.9 mg/dl in excess of the initial value, measured at 4 hours after the injection. The specificity and sensitivity of this test are almost 100%. (35, 42, 62)

(*7.*) Administration of phenobarbital (3 × 60 mg/day) leads to a decrease (possibly normalization) in bilirubin values.

**Histology** of the liver is normal. An accumulation of intralobular bile ducts (H. THALER, 1982) is noticeable. There may be centroacinar deposits of higher amounts of lipofuscin. Ultrastructurally, an increase of 5 to 10 times the norm is observed in the rough endoplasmic reticulum.

**Therapy** of this "cosmetic defect" is not necessary. In severe cases of jaundice, short-term administration of phenobarbital (60−180 mg/day) may be considered. • The *harmless nature* of this congenital, purely cosmetic ailment must be pointed out to the patient. Diets or even medication are quite out of place, as are "alternative" courses of treatment. • In isolated cases, a biopsy of the liver may be required (although this is in itself not indicated) in order to provide evidence of the harmless nature of this syndrome to the patients, who are by this time often neurotic and utterly convinced that their condition is chronic and can no longer be treated. (27, 32, 45, 46, 49, 51, 52, 54, 55, 57)

**Conjugated (partly combined) hyperbilirubinaemias**

Conjugated hyperbilirubinaemia derives from a congenital disorder which causes decreased bilirubin excretion in the canaliculi. This is why serum bilirubin, which reacts directly, is drastically elevated during an icteric episode. More than 40% (−85%) of the total bilirubin in the serum produces a *direct diazo reaction*. Unconjugated bilirubin is also found in the blood. Bilirubin is covalently bound to albumin. Bilirubinuria and urobilinogenuria are in evidence. (59) (s. tab. 12.4)

### 5.2.2 Dubin-Johnson syndrome

▶ The clinical picture first described by I. N. DUBIN and F. B. JOHNSON (1954) (33) was observed at the same time by H. SPRINZ and R. S. NELSON (1954). (70)

The **frequency** of this syndrome, which shows a recessive autosomal inheritance pattern, is clearly characterized by ethnic differences. Up to now, over 200 confirmed reports have been published. The real number is considerably higher, since not all cases are actually diagnosed or communicated. The mutations are located on chromosome 10q 23−24. Genetic evidence of this syndrome can also be obtained from skin biopsies (= detection of MRP2 in fibroblasts).

▶ *We observed two patients who were suffering from a Dubin-Johnson syndrome, one of them in connection with acute viral hepatitis A. (s. figs. 12.1, 12.2)*

*Manifestation* can occur at any age, although it is generally diagnosed between the ages of 10 and 30. The disease can develop both gradually and acutely, often triggered by infections, acute viral hepatitis, alcohol, excessive physical or mental strain, contraceptives, pregnancy, etc. • The *cause* is considered to be a dysfunction of the bilirubin transport system in the canalicular membrane of the hepatocytes. The result is a dysfunction of (conjugated) bilirubin excretion into the bile. A deficiency of MRP 2 (MOAT) is deemed to be a causative factor.

The **subjective ailments** of patients, especially in the case of icteric episodes, include fatigue, languor, inappetence, nausea, and pain on pressure in the right epigastrium − sometimes even of a colic-like nature.

The **clinical picture** is characterized by chronic or intermittent jaundice with values between 2 and 6 mg/dl, and in rare cases between 6 and 12 mg/dl. With acute icteric episodes, values can be in excess of 20 mg/dl. The proportion of conjugated bilirubin in the serum is about 60%, almost exclusively in the form of diglucuronidated bilirubin. The liver or spleen are only occasionally enlarged (50−60% or 10−15% of cases, respectively). Both the laboratory values and the bile acids in the serum are normal; cholestasis is absent. Coagulation factor VII is frequently reduced (approx. 60% of cases). In more pronounced jaundice, bilirubinuria and urobilinogenuria are in evidence. Excretion of coproporphyrin I in the

urine is elevated, but that of coproporphyrin III is reduced. (34) • The oral cholecystogram is "negative", whereas the gall bladder appears normal after i.v. administration of contrast medium.

***Fig. 12.1:*** Dubin-Johnson syndrome. (Clinically: persistent jaundice following acute viral hepatitis A.) Massive intracellular storage of lysosomal brownish pigment (Berlin blue)

**Histologically,** the clinical picture is characterized by the deposition of brown, coarsely grained, iron-free, melanin-like *pigments* (= *black liver jaundice*). (s. fig. 12.2) The lipomelanin (?) is stored in the lysosomes between the cell nucleus and canaliculus, so that *pericanalicular pigment pathways* are formed. The pigment is possibly a polymerization product of catecholamines. It is detected in differing degrees of intensity and seems to fluctuate during the course of disease as well as upon regeneration of the liver cell, e.g. following acute viral hepatitis. (s. fig. 12.1) (s. p. 421)

**Laparoscopically,** the liver is bluish-green to bluish-black in colour (= *black liver*). The surface is smooth and shiny, with intricate vascular multiplication; the lymphatic vessels of the capsule of the liver can appear more pronounced. (s. fig. 12.2)

***Fig. 12.2:*** Dubin-Johnson syndrome (so-called black liver)

*Therapy* is not required for this benign disease, nor is it effective. During icteric episodes, it is advisable to administer phenobarbital. The *harmless nature* of the syndrome must be explicitly pointed out to the patient, even in the case of "chronic jaundice". Stress factors, such as contraceptives, may trigger an icteric episode and should be avoided. However, there are no medical objections to pregnancy, where increased bilirubin values are often encountered. (30, 34, 41, 45, 47, 60, 65, 72, 73, 76)

### 5.2.3 Rotor syndrome

▶ The Rotor syndrome was first described by A.B. ROTOR et al. in 1948 (63), after G. CANALI had already reported on this form of jaundice (albeit not histologically investigated) in 1945.

This clinical picture shows a recessive autosomal inheritance pattern. In approx. 40 cases published to date, there are no obvious signs of a gender-related preference. Conjugated hyperbilirubinaemia of this syndrome derives from a disorder of the uptake, intracellular bonding (storage) and excretion of bilirubin. Other organic anions (bromosulphophthalein, indocyanine green) are also subject to delayed excretion.

This form of jaundice is found in childhood and adolescence as conjugated hyperbilirubinaemia. Bilirubin values range between 2 and 5 mg/dl with intercurrent icteric episodes, which (as in the Dubin-Johnson syndrome) are mostly triggered by various stress factors. Bilirubinuria and urobilinogenuria may likewise appear, depending on the bilirubin values. All hepatic laboratory parameters are normal. Excretion of total coproporphyrins in the urine is elevated. Oral administration of a contrast medium allows the gall bladder to be visualized. Histology of the liver shows no pathological findings; in particular, there is no pigment deposition. • *Therapeutic measures* are not necessary, and in fact none are known. Prognosis is good. Any factors that might set off an icteric episode should be avoided. (29, 45, 75, 76)

### 5.2.4 Hepatic storage disease

Hepatic storage disease (J. GOLAN et al., 1985) is deemed to be a **variant of Rotor syndrome**. This dysfunction is witnessed during the first years of life. Bilirubin values are only moderately elevated (2−4 mg/dl). About half of the bilirubin is conjugated. The pathogenetic mechanisms are presumably the same as in Rotor syndrome. • *Treatment* is likewise not required for this benign disorder.

**Conjugated (partly combined) hyperbilirubinaemias with impaired drainage of bile acids**

The principal symptoms of this form of disease are (*1.*) largely conjugated (partly combined) hyperbilirubinaemia with **jaundice** and (*2.*) **cholestasis** with pruritus and scratch marks. • This group includes (*1.*) recurrent intrahepatic cholestasis in pregnancy, (*2.*) benign recurrent intrahepatic cholestasis (BRIC) as well as the Aagenaes form, and (*3.*) progressive familial cholestasis (PFIC) and the Byler form. *(see chapter 13)*

# 6 Differential diagnosis of jaundice

▶ Each case of jaundice calls for differential diagnostic clarification. The clinical spectrum ranges from the so-called cosmetic, perfectly harmless defect through to malignant obstructions. (2, 5, 8, 9, 12, 16, 20−22, 59) • *It is of the utmost importance to differentiate between nonobstructive and obstructive jaundice.*

Based on a targeted and exact *anamnesis*, subjective *complaints* by the patient and careful **physical examination** (s. tab. 12.5), it is possible in most cases to make a clear distinction between four different categories of jaundice: (*1.*) haematological, (*2.*) hepatocellular, (*3.*) biliary obstructive, and (*4.*) hereditary. (s. tabs. 12.1, 12.2, 12.4)

| **1. Precise anamnesis** |
| --- |
| − Start of jaundice?<br>− Fluctuations in intensity?<br>− Relapses?<br>− Correlation with surgery, infusions, injections?<br>− Correlation with pregnancy?<br>− Journeys abroad?<br>− Occurrence of jaundice within the family?<br>− Alcohol abuse?<br>− Medication?<br>− Contact with chemicals?<br>− Pre- or coexistent hepatobiliary diseases? |
| **2. Subjective complaints** |
| − Pain in the right epigastrium?<br>− Colic?<br>− Lack of appetite? Loss of weight?<br>− Nausea?<br>− Itching?<br>− Arthralgia?<br>− Colour changes in stools or urine?<br>− Fatigue?<br>− Decrease in vitality? |

| − Hepatomegaly?<br>− Tenderness on pressure?<br>− Splenomegaly?<br>− Scratch marks?<br>− Type and intensity of jaundice?<br>− Skin stigmata of liver diseases?<br>− Hyaline cast in urine sediment?<br>− Stool and urine examination results? |

*Tab. 12.5:* Important anamnestic and clinical findings for setting up a differential diagnosis of jaundice

If there is no interference in terms of **colour reactions in the urine** due to pronounced yellowing, a preliminary categorization of the jaundice form is possible. A persistently negative urobilinogen sample, concurrent with evidence of bilirubinuria, points to a complete obstruction or serious restriction of hepatic function. A persistently positive urobilinogen reaction in the absence of bilirubinuria suggests prehepatic (haemolytic) jaundice. (s. tab. 12.6)

At the outset of clinical investigations, priority is given to determining the direct and indirect *bilirubin* reaction in the serum with the help of the diazo reaction. Other **laboratory parameters** as well as the enzyme quotients (s. tabs. 5.6, 5.7) often allow the differential diagnosis of jaundice to be made at this stage. (s. tab. 12.7)

- Determination of total bilirubin with differentiation between direct (conjugated) and indirect (unconjugated) bilirubin
- Determination of cholestasis-indicating enzymes (AP, LAP, γ-GT); bile acids and bile pigments in the urine (s. tab. 12.6)
- Test for signs of haemolysis (s. tab. 12.3)
- Determination of transaminases and (possibly) enzyme quotients (s. tabs. 5.6, 5.7)
- Antimitochondrial antibodies (s. tabs. 5.20, 5.21)
- Hepatitis serology (s. tab. 5.17)
- Determination of total coproporphyrin and coproporphyrin I and III in the urine

*Tab. 12.7:* Important laboratory parameters for the differential diagnosis of jaundice

▶ **Noninvasive** procedures used consecutively are ultrasound and, if necessary, computer tomography. For the diagnosis of extrahepatic jaundice, both test procedures have about the same sensitivity and specificity, yet their degree of accuracy is no greater than that obtained through clinical and laboratory examinations. Laboratory diagnosis facilitates a precise differentiation between the types of hyperbilirubinaemia and their possible combination with cholestasis.

1. *Ultrasound examination* is always indicated for the clarification of jaundice. The results determine the subsequent diagnostic steps. It is important to clarify whether the bile ducts are dilated, which is a hint for obstructive jaundice. (s. tabs. 6.8, 6.9) (s. p. 131)

2. *Computer tomography* can be indicated in isolated cases, particularly in order to establish the cause of obstruction or when focal lesions are present.

The diagnostic strategy for clarification of **cholestasis** and **jaundice** is outlined later in a **flow diagram.** (s. fig. 13.7) (s. p. 239)

| Type of jaundice | Bile | Colour of stool | Colour of urine | Urobili-nogen | Bilirubin |
| --- | --- | --- | --- | --- | --- |
| Prehepatic jaundice | dark | dark | normal | + | ∅ |
| Intrahepatic jaundice | light | light | dark | + | + |
| Posthepatic jaundice | light or ∅ | acholic | dark | (+) or ∅ | + |

*Tab. 12.6:* Main colouration of duodenal bile, stools and urine as well as the results of bile pigment tests in the urine of jaundice patients (∅ = negative)

▶ If a particular jaundice cannot be categorized, **invasive methods** are indicated:

1. *Liver biopsy* has often proved indispensable for the differentiation and validation of unresolved prehepatic or intrahepatic jaundice. (s. p. 143)

2. *Laparoscopy* should always be considered if the previously applied procedures have not provided any differential diagnosis. (s. p. 150)

3. *ERC* facilitates precise visualization of the bile ducts — this is also possible by means of *PTC* in cases of sonographically determined dilation of the bile ducts with suspected biliary obstruction. PTC is likewise indicated if ultrasound examination fails to produce evidence of enlarged bile ducts and/or ERC has proved inconclusive even though clinical and laboratory examinations suggest biliary obstruction. (s. pp 183, 184)

# 7 Therapy

*Jaundice is a symptom. For this reason, there can be no standardized therapeutic concept for its treatment. Therapy is solely directed at the underlying primary cause, provided that symptom-related and curative therapeutic options are at hand.*

**Causal therapy:** Only those forms of *obstructive jaundice* related to benign causes are open to causal treatment in the form of endoscopy (e. g. sphincterotomy) or surgery. *Operative procedures* and *interventional endoscopy* have significantly broadened the scope of therapy for mechanical jaundice, such as (*1*.) application of a stent, (*2*.) transhepatic biliary drainage, (*3*.) recanalization of strictures or stenoses, (*4*.) extraction of concrement left behind intraoperatively, and (*5*.) radiotherapy of tumour obstruction. (9, 19) • Jaundice resulting from *bacterial infection* of the bile ducts calls for the systemic and/or topical application of suitable *antibiotics*. (14, 18) • **Cholagogue agents**, which are plant extracts, have become popular as supplementary therapy for stimulating bile flow, even in long-term treatment. *(see chapter 32)*

**Functional hyperbilirubinaemias:** These forms of jaundice do not require therapy. It is of primary importance to provide the patient with detailed and convincing information regarding the harmless nature of these forms of jaundice. • Should short-term therapy be indicated in specific cases, this can be successfully effected with phenobarbital (60−180 mg/day). Long-term administration is not advisable. Both cholestyramine and cholestipol or naltrexone can be used in the treatment of pruritus. (s. page 241!) • In Crigler-Najjar type II, it may prove effective to administer phenobarbital (60−180 mg/day in 3 or 4 single doses together with calcium phosphate), phenazone or phenytoin. With the cholestatic forms, ursodeoxycholic acid and S-adenosyl-L-methionine can be applied. • No therapeutic method is as yet available for the treatment of Crigler-Najjar type I. Phenobarbital is ineffective in this respect. In severe cases, exchange blood transfusions or plasmapheresis as well as phototherapy (13) and possibly even liver transplantation are indicated.

# Symptoms and Syndromes

## 13  Cholestasis

# 13 Cholestasis

## 1 Definition

> **Cholestasis** is defined as a disorder of cholepoiesis and bile secretion as well as a mechanical or functional stoppage of the bile flow in intrahepatic or extrahepatic bile ducts − with bile components passing into the blood. • *Cholestasis can occur both with and without jaundice.*

**Morphology:** The morphologist uses the term cholestasis to describe the presence of bile in the hepatocytes as well as in hypertrophic Kupffer cells (= *cellular bilirubinostasis*), particularly in the form of inspissated bile droplets and copper within the more or less dilated canaliculi (= *canalicular bilirubinostasis*). • In extrahepatic cholestasis, bile is additionally found within the likewise mostly dilated interlobular bile ducts (= *ductular bilirubinostasis*) as well as in the parenchyma in the form of *"bile infarcts"* or *"bile lakes"*.

**Pathophysiology:** The biochemist defines cholestasis as a decrease in the secretion of bile as well as a reduction in the proportion of water, together with a respective effect on the substances dissolved in it.

**Clinical aspects:** The clinician diagnoses cholestasis by the increase in bile acids, special enzymatic markers and cholesterol in the serum.

▶ The *principal biochemical symptom of cholestasis* is the rise in bile acids in serum (as well as changes in its spectrum) in combination with an increase in enzymatic markers of cholestasis (AP, LAP, γ-GT, 5′-nucleotidase). Cholestasis is directly related to the metabolism of bile acids. • In clinical terms, the subsequent rise in activity of enzymatic markers of cholestasis may be attributed to cholestasis, yet these enzymes are not necessarily specific to this condition. (s. p. 89)

▶ Dysfunction in the metabolism of bile acids (= *cholestasis*) is often combined with an additional dysfunction in bilirubin metabolism (= *jaundice*). The rise in bilirubin is the main biochemical and clinical symptom of jaundice; it is based on a disorder of bilirubin metabolism. Thus cholestasis is related not directly but indirectly to jaundice. • Depending on the constellation of the biochemical and clinical findings, the term *"jaundice with cholestasis"* or *"cholestasis with jaundice"* can be applied. (s. tabs. 12.1, 12.2, 12.4; 13.1) • *The main clinical sign of advanced cholestasis is pruritus.*

> Various hepatobiliary diseases remain unchanged as either **cholestasis** or **jaundice.** • Often, however, a *combination of both disorders* is present from the very beginning or appears during the course of disease.

## 2 Pathogenesis

*The liver cell is a polar unit.* • The resorptive processes take place at the sinusoidal and lateral membrane, the secretory processes on the surface of the canaliculi. The cytoskeleton (microfilaments, microtubules, intracellular membranes) maintains the polar orientation of the hepatocyte. (24, 33, 42, 44, 71, 80) (s. fig. 13.1)

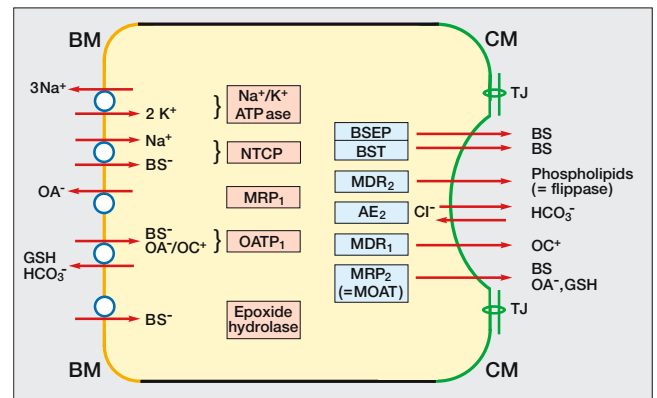

**Fig. 13.1:** The hepatocyte as a polar unit. • *Major hepatocellular transport systems:* CM = canalicular membrane, BM = basolateral membrane, TJ = tight junctions, $BS^-$ = bile salts, $OA^-$ = organic anions, $OC^+$ = organic cations, GSH = reduced glutathione, $AE_2$ = ATP-dependent anion exchange ($Cl/HCO_3^-$; GSH), BST = ATP-dependent bile acid transporter, NTCP = sinusoidal $Na^+$-dependent taurocholate cotransporting protein, $OATP_1$ = sinusoidal $Na^+$-independent organic anion (and cation) transporter protein, BSEP = bile salt export pump for monovalent bile salts, $MRP_2$ = canalicular multispecific organic anion transporter (= MOAT), $MDR_1$ = ATP-dependent organic cation transporter, $MDR_2$ = ATP-dependent phospholipid transporter (= flippase), $MRP_1$ = sinusoidal multidrug resistance-associated protein

### 2.1 Obstructive cholestasis

Obstructive cholestasis − initially often without jaundice, thereafter generally with jaundice − is caused by a mechanical impediment of the bile flow. Because of this, the bile flow is reduced and biliary stasis is generated, which, depending on the localization of the impediment, subsequently affects the bile ducts of (*1.*) the entire liver or (*2.*) only certain subzones of the liver.

Even in cases of a total obstruction with jaundice, there is no total stoppage of bile secretion due to the residual function of the hepatocytes. What happens, in fact, is that a certain form of **circulation of intrahepatic bile acids** is maintained by way of resorption processes taking place in the bile capillaries and mechanisms of regurgitation occurring at the tight junctions. This circulation of bile acids mainly runs via the periportal sections of the hepatic lobules, so that biliary thrombi are only rarely detectable here − even in cases of prolonged cholestasis. • In obstructive cholestasis, with its secondary repercussions on bile capillaries and hepatic cells, including *morphological changes,* it is probable that *functional disorders* in the polarity of the hepatocytes will ultimately appear.

## 2.2 Non-obstructive cholestasis

*Pathogenetically, non-obstructive cholestasis is a multifactorial process.* • The factors that cause intrahepatic cholestasis lead to biochemical dysfunctions and/or damage to subcellular structures, with changes in the metabolism of bile acids.

(*1.*) Various substances (taurolithocholate, ethinyl oestradiol, drugs, toxins) cause increased retention of cholesterol in cellular membranes. As a result, the permeability of hepatocellular membranes, including the tight junctions, is decreased. Hypothermia and hypoxia also disturb membrane fluidity. The osmotic pressure gradient, necessary for biliary secretion, is no longer maintained because of decreased membrane permeability.

(*2.*) Considerable dysfunction of membrane lipids is caused by a change in the double-bonding of their unsaturated fatty acids due to lipid peroxidation. More pronounced lipid peroxidations are found particularly in alcohol-induced liver damage − often accompanied by cholestasis.

(*3.*) $Na^+/K^+$-ATPase localized in the sinusoidal and lateral hepatocyte membrane is inhibited by cholestasis factors (chlorpromazine, oestrogens, atypical bile acids, protoporphyrin, etc.) as well as by a change in the viscosity and fluidity of the membrane. $Na^+/K^+$-ATPase activity works like a metabolic pump and supplies the energy needed for the cellular uptake of bile acids (along with bicarbonate and chloride).

(*4.*) $Mg^{2+}$-ATPase activity can likewise be inhibited in the canalicular side of the membrane by cholestatic factors (in particular bile acids). This metabolic pump transports bicarbonate and chloride into the canaliculi and is probably closely associated with the function of the microfilaments.

(*5.*) Transmembranous transport of biliary acids requires the functional competence of the carrier proteins in the sinusoidal and canalicular membrane. Cholestatic factors may also appear. Furthermore, it is possible for various substances, above all medicaments, to effect competitive inhibition of the carrier proteins in the sinusoidal wall as a result of the low substrate specificity of these proteins.

(*6.*) Intracellular transport of bile acids mainly takes place through the cytoskeleton and intracellular structures (Golgi apparatus, endoplasmic reticulum). Here, too, cholestatic factors can prove to be damaging. Microfilaments are contractile elements: not only is the intracellular transport of the bile acids disturbed, but the peristaltic activity of the canaliculi (so-called **paralytic cholestasis** within the lobules) is also reduced if the functional capacity of those microfilaments becomes diminished.

(*7.*) Shifting of the calcium gradient between the intracellular and extracellular space (normally 1 : 10,000) results in significant metabolic dysfunctions as well as cholestasis, especially in alcohol-induced liver damage.

(*8.*) Inhibition of the neosynthesis of bile acids from cholesterol leads to a decrease in the bile acid pool.

(*9.*) Monohydroxy bile acids (such as lithocholic acid produced in the intestine) are deemed to be cholestatic factors. They can, however, also be generated in the liver as a result of damage to the smooth endoplasmic reticulum, with a decrease in activity of cytochrome P 450-dependent 7α-hydroxylase: in cases of cholestasis, 3β-hydroxy-5δ-cholic acid is formed from cholesterol and converted into lithocholic acid and allo-lithocholic acid (so-called **foetal metabolic pathway of bile acids**). (10)

(*10.*) Intracellular accumulation of bile acids continues to maintain the state of cholestasis. Bile acids are detergents that cause damage to biomembranes.

**Endotoxins** generated in the body are broken down in the RES. Given inadequate clearance (e. g. in cholestasis) or when they are formed to excess, the state of cholestasis is reinforced. Endotoxins also lead to inflammatory reactions in the liver and are possibly the cause of complications in cases of prolonged cholestasis. (51)

The mechanisms of disorder leading to cholestasis are based on many different aetiopathological factors. One single cause of cholestasis generally disturbs several subprocesses in the metabolism of bile acids, which in turn may trigger additional cholestatic mechanisms. Such disorders result in damage to cellular and biliary structures, leading to further dysfunctions and reinforcing cholestasis. Thus pathogenic mechanisms, acting in a synergy of addition or potentiation, set up a vicious circle culminating in a cholestatic condition. (15, 18, 22, 33, 44, 71, 80)

# 3 Morphological changes

In the development of morphological damage to hepatocytes and bile capillaries, *lipid peroxidations* as well as the formation of *leukotrienes* (C4, D4, E4) play a key role, with *prostaglandin $E_2$* having a reinforcing effect.

▶ After only a few days, cholestasis causes potentially reversible **ultrastructural changes:**
− hydropic swelling of periportal hepatocytes,
− reinforced granulation of the cytoplasm,
− formation of Mallory's bodies,
− change in the mitochondria, formation of giant mitochondria,
− hypertrophy and subsequent reduction as well as loss of the Golgi apparatus at the canalicular pole,
− hypertrophy of the pericanalicular filaments,
− hypertrophy of the SER and RER with subsequent reduction,
− apoptosis due to bile acids.

▶ As the disease advances, **histological changes** in cholestasis can be detected by light microscopy:
− dilation of the bile capillaries due to stasis, or loss of tone in the pericanalicular microfilaments,
− flattening and ultimate loss of the microvilli at the canalicular membrane,
− formation of bile thrombi in the bile capillaries (= *cholate stasis*),
− damage to cell membranes leading to greater permeability,
− leakage at the tight junctions with subsequent paracellular regurgitation of bile into the blood,
− centroacinar, perivenular cholestasis with traces of bilirubin, and often copper, in hepatocytes and dilated canaliculi (= *bilirubinostasis*),
− formation of secondary bile capillaries, which are surrounded by more than three hepatocytes (= *liver cell rosette*) (48) − this represents reversion to previous phylogenetic stages,

- uptake of biliary precipitates and components into the ductular epithelia,
- proliferation of the ductules in the portal tracts; periductal oedema,
- periportal and mesenchymal inflammatory reactions,
- widening of the portal tracts due to an increase in collagenous connective tissue; periductular sclerosis,
- hepatocytes with foamy pale cytoplasm (= *feathery degeneration*), (s. p. 238) (s. fig. 13.4)
- isolated necroses of hepatocytes (= *network necrosis*),
- extensive focal necroses of hepatocytes with the central part of each displaying a marked accumulation of bilirubin due to the fact that bilirubin has a stronger affinity for necrotic tissue (= *bile infarcts*),
- formation of bile extravasates in the parenchyma (= *bile lakes*),
- development of microabscesses,
- cell death with cellular condensation and cell shrinkage (= *apoptosis*), (18)
- development of lipid-laden macrophages (= *xanthoma cells*). (s. fig. 13.2)

***Fig. 13.2:*** Chronic cholestasis with granuloma-like accumulation of lipid-laden macrophages (xanthoma cells) (HE)

Persistent cholestasis with concomitant inflammatory and connective tissue reactions leads to irreversible cholestasis and, after months/years, to **biliary fibrosis** with preserved liver structure or to (primary or secondary) **biliary cirrhosis**. (15, 18, 23, 55, 64, 70)

# 4 Forms of cholestasis

In classifying cholestasis, the *cause, localization* and *duration* of the disease as well as the involvement of *bilirubin metabolism* must be considered. Laboratory parameters of *liver cell damage* (increased activity of GPT, GOT and GDH) may be attributed to the underlying liver disease, but can also appear subsequently during the course of cholestasis-related hepatocellular damage. (s. tab. 13.1)

Concurrent **jaundice** is either due to an additional disorder of bilirubin metabolism or to mechanical biliary stasis (= if more than two-thirds of the efferent bile ducts are obstructed). During the course of its development, cholestasis may also lead to dysfunction and/or morphological damage, with subsequent jaundice.

***Tab. 13.1:*** Forms of cholestasis

# 5 Causes of cholestasis

There are many causes of cholestasis − *with or without jaundice* − which is why this condition proves to be an ambiguous symptom in terms of differential diagnosis.

## 5.1 Extrahepatic obstructive cholestasis

The bile flow is interrupted in its passage from the porta hepatis to the duodenum as a result of (*1.*) intraluminal obstruction, (*2.*) obliterating disease of the biliary duct walls, or (*3.*) compression of the extrahepatic efferent bile ducts. This form of cholestasis can be sudden in onset or progress slowly, may be transient or persistent, and occurs either as incomplete or complete obstruction with jaundice. (s. tab. 13.2) (s. figs. 8.12, 8.13; 25.8)

## 5.2 Intrahepatic obstructive cholestasis

This form of cholestasis is derived from a temporary or permanent obstruction of the intrahepatic bile ducts. Diffuse processes of disease can act as mechanical obstacles in the hepatic parenchyma, or major bile ducts may be subject to regional obstruction. (s. tab. 13.3)

## 5.3 Intrahepatic cholestasis

Non-obstructive, function-related intrahepatic cholestasis has numerous causes, primarily disturbing the metabolism of bile acids at various sites of action. (s. tab. 13.4)

| Obstruction in the area of the papilla of Vater | |
|---|---|
| − inflammation | − adenomatosis |
| − choledocholithiasis | − choledochal cyst |
| − neoplasia | − parasites |
| − scars | − heterotopic gastric mucosa |
| − duodenal diverticulum | *etc.* |

| Obstruction in the area of the bile ducts | |
|---|---|
| − choledocholithiasis | − duodenal diverticulum |
| − neoplasia | − papillomatosis |
| − postoperative strictures | − haemobilia |
| − cicatricial distortions | − actinomycosis |
| − pancreatic cyst, pancreatitis | − parasites |
| − pancreatic carcinoma | − bile-duct atresia |
| − gall-bladder carcinoma | − Mirizzi syndrome |
| − choledochal cyst | *etc.* |

**Tab. 13.2:** Causes of extrahepatic obstructive cholestasis (with or without initial jaundice; however, consecutive jaundice may develop later)

| Focal changes of the liver | |
|---|---|
| − adenomas | − Hodgkin's disease (31) |
| − haemangiomas | − parasites |
| − cysts | − hepatolithiasis |
| − tumours | − Caroli's syndrome |
| − abscesses | − congenital liver fibrosis |

**Disseminated changes of the liver**
- sarcoidosis (62)
- tuberculosis
- other types of granulomatosis
- mucoviscidosis

**Infiltrative changes of the liver**
- leukaemia
- amyloidosis (4, 59, 61, 79)
- primary storage diseases
- fatty liver

**Inflammatory proliferation of bile ducts**
- primary biliary cholangitis
- primary sclerosing cholangitis
- bacterial cholangitis
- autoimmune cholangitis
- cholangiofibromatosis (35)

**Other partially unclarified causes**
- haemobilia
- graft-versus-host disease
  (following bone-marrow transplantation)
- chronic rejection reaction
  (following liver transplantation)
- syndromatic bile-duct hypoplasia
  (Alagille's syndrome) (see also tab. 13.4)
- non-syndromatic bile-duct hypoplasia
  (Zellweger's syndrome) (see also tab. 13.4)

**Tab. 13.3:** Causes of intrahepatic obstructive cholestasis (with some references)

However, it is not always clear with regard to the respective cause how the pathogenic mechanism triggers cholestasis. It cannot be adequately explained why one particular cause acts as a cholestatic factor in the individual case or why the same factor possibly has no effect at all. It would appear that genetic disposition is of decisive importance. Influences of everyday life (xenobiotics, drugs, alcohol, etc.), differing performances of biotransforma-

    = defect of 3-oxo-δ4-steroid-5β-reductase

**Tab. 13.4:** Causes of non-obstructive intrahepatic cholestasis (with or without concurrent jaundice)

tion or coexistent diseases possibly all play their part in whether an individual cause has a cholestatic effect or not. The *primary form* of intrahepatic cholestasis occurs without any prior disease of the liver, whereas with the *secondary form*, there is evidence of a previous or coexistent liver condition. (19, 45−47, 51, 70, 71)

**Alcohol-induced cholestasis:** Alcohol is the most frequent cause of cholestasis. Concomitant jaundice is found in relatively few cases and is generally a sign of a severe course of disease. (52) (s. figs. 28.15, 28.16)

**Drug-induced cholestasis:** Many drugs can cause cholestasis (so-called *cholestasis type*). (s. tab. 13.5) It can be extremely difficult to pinpoint which drug has led to the condition. Interestingly, some homeopathic remedies, such as Chelidonium majus, may also cause cholestasis. Simultaneous uptake of other hepatocellular irritants can trigger or produce cholestasis. Concomitant jaundice is not usually present at first, but may develop at a later stage of disease. Many drugs cause *cholestatic hepatitis* per se or in conjunction with others. (s. tab. 29.6) As a rule, cholestasis regresses gradually after discontinuation of the drug or elimination of further irri-

tants. It should, however, be noted that cholestasis is sometimes only diagnosed when a drug has been discontinued; with some other drugs (e.g. amoxicillin-clavulanic acid, ticlopidine), the condition may even progress until the bile ducts have completely disappeared (= *vanishing bile-duct syndrome*). (12) (s. pp 662, 665)

**Tab. 13.5:** Drugs known to cause cholestasis/cholestatic hepatitis (s. figs. 29.3, 29.4) (s. tab. 29.10)

**Virus infections:** *Acute viral hepatitis* (HAV, HEV, HCV) is accompanied by cholestasis in 5−20% of cases. (63) The frequency differs from country to country. It is most prevalent in those with a severe form of the disease, elderly people and women. • Cholestasis is also common in *viral infections with concomitant hepatitis*, especially due to CMV, Coxsackie virus, rubella virus, HSV (types I, II, IV), HIV, REO virus (type III), parvovirus (type B 19), and ECHO virus (types 9, 11, 14, 19).

**Perinatal asphyxia:** In 8−10% of asphyxiated newborns, transient cholestasis was found. The actual condition was related to the severity of neonatal stress. (23)

There are many *other causes* of intrahepatic cholestasis that make differential diagnosis considerably more complex. (s. tab. 13.4)

## 5.4 Genetically determined cholestasis

In various forms of genetically determined cholestasis, jaundice can be the most obvious primary clinical symptom leading to the clinical classification of functional hyperbilirubinaemia. • However, in most cases, pronounced cholestasis is the principal feature of the clinical picture in the diseases explained below. Many primary storage diseases, especially childhood cholestasis, can only be identified through careful differential diagnosis. Genetically determined intrahepatic cholestasis

can be divided into three categories: (*1.*) bile duct defects (syndromatic or non-syndromatic), (*2.*) primary storage diseases, and (*3.*) familial intrahepatic cholestasis.

### 5.4.1 Primary storage diseases

When cholestasis is observed in children or young adults, a differential diagnosis is necessary to detect the possible presence of a primary storage disease. (s. tab. 13.4) Such diseases include α$_1$-antitrypsin deficiency, fructose intolerance, galactosaemia, Gaucher's disease, type IV glycogenosis, haemochromatosis, urea cycle deficiencies, Niemann-Pick disease, thyrosinaemia, and Wilson's disease. In genetically determined cholestasis, laboratory evidence of cholestasis is ultimately a secondary symptom, since primary storage diseases usually have their own specific phenotypical markers, which makes differential diagnosis easier. • *Evidence of cholestasis, with or without increased transaminases, should always be taken as a hint of a primary storage disease.*

### 5.4.2 Recurrent intrahepatic cholestasis in pregnancy

Since the first description of this condition was given by A. SVANBORG (1954), observations regarding both non-recurrent forms (W. C. NIXON et al., 1947) and recurrent forms (G. LUNDGREN, 1956) have been summarized under this collective term. • *Nevertheless, jaundice does not necessarily develop as a symptom, which is why anicteric courses of the disease can also be assigned to the "cholestasis" group.*

The disease is subject to **recessive autosomal transmission.** Given a genetic disposition (a defect in phosphatidylcholine transport (?) located on chromosome 7 q 21), a concurrent sensitivity to oestrogen, or inhibition of bile acid transport due to an increase in oestrogen/progesterone metabolites, the frequency is 1:2,000 bis 8,000. There is no preference for any particular age group. The frequency is influenced by geographic, ethnic and seasonal factors. The relapse quota is 40−60%.

As a **clinical symptom,** severe *itching* (initially on the palms and soles of the feet and then all over the body), which can be intolerable at night, occurs during the 2$^{nd}$ or 3$^{rd}$ trimester. This results in pronounced sanguineous *scratch marks* (s. p. 235) • About 2 weeks after the onset of pruritus, *jaundice* (2−6 mg/dl) is evident in 50−70% of patients. There is conjugated hyperbilirubinaemia with bilirubinuria and urobilinogenuria in 60−80% of cases. *Laboratory biochemistry* reveals an elevation of bile acids in the serum which is 10 to 30(−100) times the standard level. Primary bile acids are usually displaced in favour of secondary forms and trihydroxylated bile acids in favour of dihydroxylated forms. AP (including placental AP) increases 6 to 10 times, and LAP is likewise drastically elevated. Surprisingly, γ-GT is normal to subnormal, which can probably be attributed to the impact of oestrogen, especially in those pregnant women who are sensitive to this hormone. (s. p. 98) The transaminases are only moderately increased, GDH is almost always normal. There is a

marked rise in cholesterol and neutral fats. Quick's value is diminished owing to disorders in the absorption of vitamin K. HLA A1 and B8 as well as BW 16 are frequently detected. Steatorrhoea is often seen. Cholelithiasis is common in these women. • Occurrence of this syndrome is indicative of a *high-risk pregnancy*. In about 20% of cases, delivery is premature and/or the newborn is small for date; in 5−10% of cases, perinatal mortality can be expected. Fetal malformations are not to be feared. There is no danger to the mother, which is why there are no grounds for a termination of the pregnancy from this point of view. Induction of labour should, however, be considered from the 37th week onwards. (14, 43, 54, 58, 71)

**Histologically,** cholestasis is moderate, focal and irregular, and the biliary capillaries are dilated, displaying biliary thrombi. Bile pigments may be detectable in the liver cells. Cell necroses and signs of inflammation are absent.

**Therapy** involves the use of *cholestyramine* (3 x 4 g/day) or *cholestipol* (3 x 5 g/day) to alleviate and eliminate the intense itching, which is generally intolerable. *Epomediol* has also proved effective. Good results can be achieved with *ursodeoxycholic acid* (10−15 mg/kg BW/day); it was reported that high doses of UDCA (1.5−2.0 g/day) were most efficacious. There have been no reports of negative effects after application in human beings. Treatment with *S-adenosyl-L-methionine* is also worth considering. Administration of *medium-chain fatty acids* and fat-soluble vitamins, in particular vitamin K, is also recommended. The prognosis is good. After delivery, the clinical picture recedes without additional consequences. Relapses can be expected in further pregnancies and after administration of oestrogen. (54)

### 5.4.3 Benign recurrent intrahepatic cholestasis

▶ This benign course of disease was described by W. H. J. SUMMERSKILL et al. (1959) (67) and N. TYGSTRUP (1960). (72) Since then, this form has been known as the *Summerskill-Tygstrup type*.

Benign recurrent intrahepatic cholestasis (BRIC) is subject to recessive autosomal transmission. The genetic defect is located on chromosome 18q21 − q22, as in Byler's disease (PFIC 1). Up to now, publications have focused on about 100 cases. It manifests at any age, but not before the 6th−9th month of life. Even after many years without symptoms, it may be triggered by infections, toxins, allergens or other chemical substances. It begins usually with nausea, loss of appetite, abdominal pains and pruritus, followed about 1 or 2 weeks later by jaundice with intermittent bilirubin values of 5−50 mg/dl. Mainly conjugated bilirubin is detectable (60−80%), covalently bound to albumin. The jaundice lasts for about 2 or 3 months. On occasions, (inexplicable) coughing was observed as well as gingivitis following bilirubin decrease. Extreme tiredness is usually experienced. (34) During the icteric phase, the urine shows increased concentrations of bilirubin and urobilinogen as well as porphyrinuria, whereas stools are (largely) acholic and as such decolourized. In most cases, steatorrhoea is in evidence. Laboratory values reveal an elevation of bile acids (particularly the hepatoprotective cholic acid), AP and LAP. The transaminases are normal or moderately elevated; γ-GT shows more or less regular levels (oestrogen effect?). Quick's value can be lower as a result of steatorrhoea. Hepatomegaly is frequently detectable; splenomegaly is only rarely observed. Laboratory parameters may periodically improve or even normalize. The prognosis is good. Cholelithiasis is, however, frequently present. • *Histologically*, intracanalicular biliary thrombi (which are capable of regression) as well as periportal round-cell infiltrations are evident.

Bile pigment can be detected in the hepatocytes and Kupffer cells. Focal necroses are rare. Histology is normal during the disease-free period. A fine fibrosis may develop in cases of prolonged illness. (8, 11, 26, 28, 39, 49, 55, 56, 66−68, 72, 73, 75)

**Treatment** of icteric episodes with *phenobarbital* (3 x 20−60 mg/day) together with *phototherapy* (430−470 nm, 8−12 hr/day) and/or *plasmapheresis* is indicated. • *Cholestyramine* (3 x 4 g/day) or *cholestipol* (3 x 5 g/day) may be used to treat pruritus. Other recommended effective antipruritics are *naloxone* (2−3 x 0.4 mg/day, i.v.) or *naltrexone* (2−4 x 25−50 mg/day), which act as opioidergic neurotransmitters. (69) It is also possible to use the 5-HT3 antagonist *ondansetron* (3 x 4.8 mg/day, i.v. or orally). (64) Refractory cholestasis pruritus has recently been treated successfully with *dronabinol* (50) and also with *sertraline*. • Administration of ursodeoxycholic acid (22, 53), medium-chain fatty acids, PUFA (65) and fat-soluble vitamins (especially vitamin K) is recommended. (s. pp 6, 47) (s. tab. 13.11)

### Aagenaes type

This rare form, which is inherited via a recessive autosomal route, was described in 1968 as a variant of BRIC. (1, 2) The genetic defect is located on chromosome 15 q. A specific feature of this disease in neonates is giant-cell hepatitis with cholestasis. (s. p. 417) From about the 6th year of life until puberty, pathogenetic hypoplasia or ectasia of the lymphatic vessels with oedema are found in the lower extremities. It is not clear whether (suspected) congenital hyperplasia of lymphatic vessels in the liver is the prime cause of cholestasis. Pronounced fibrosis is often in evidence, whereas cirrhosis only occurs rarely.

### 5.4.4 Progressive familial intrahepatic cholestasis

Progressive familial intrahepatic cholestasis (PFIC) was described by R.C. JUBERG et al. (1966) (30) and R.J. CLAYTON et al. (1969) (9). This rare clinical picture was previously known as *Byler's disease* or *Juberg-Clayton type*. It com-

prises a heterogeneous group of patients with chronic non-recurrent cholestasis and is inherited via an autosomal recessive route. The disease was originally named after Jacob and Nancy Byler because it was first found in members of this Amish family.

The pathogenesis arises from deficiency of one or more genes that encode essential proteins required for bile secretion. This results in a bile secretion disorder and impaired bile flow. The key transport proteins have since been discovered, so that it is now possible to differentiate between *four PFIC syndromes*. (3, 11, 13, 27, 71, 74, 76)

**Byler's disease:** In this disorder, which is also known as *PFIC 1*, the genetic mutations are positioned on chromosome $18q21-22$. The PFIC 1 defect can be found on the canalicular membrane of the hepatocytes and apical membrane of cholangiocytes. (17) As a result, aminophospholipid transport is impaired. This gene mutation also occurs in other epithelial body tissue, which explains the multisystem manifestation of this disorder. • The disease usually has its onset around the end of the first year of life and is characterized by pruritus and hepatomegaly as well as elevated bile acids in the serum. Gamma GT values are normal or reduced. Jaundice episodes of varying intensity together with cholestasis lead to severe malabsorption and developmental disorders. Chronic bronchitis is common in childhood. Byler's disease is generally fatal after 3-20 years. Liver cirrhosis with consequential hepatocellular carcinoma frequently develops in these patients. (9, 16, 17, 37)

**Byler's syndrome:** Mutations of genes *PFIC 2−4* are associated with this syndrome and inherited via an autosomal recessive route. All these forms are characterized by non-recurrent cholestasis.

*PFIC 2:* This gene mutation, which is located on chromosome 2q24, impairs the canalicular bile salt export pump (BSEP), resulting in the accumulation of bile acids in hepatocytes. Laboratory tests show an increase in bile acid, AP and LAP levels with lowered gamma GT and cholesterol levels. Pruritus is common. There is histological evidence of neonatal giant cell hepatitis. Prognosis is poor.

*PFIC 3:* The gene mutation is located on chromosome 7q21. This produces an MDR-3 protein deficiency, resulting in anomalous secretion of phospholipids, which leaves the bile ducts unprotected against bile acids. AP, LAP and gamma GT levels are elevated and bile acid and cholesterol concentrations increase; LP-X can be detected. Pruritus and hepatomegaly also occur. Clinical symptoms appear later in life than is the case with forms 1 and 2. Histology reveals ductal proliferation with inflamed portal and periportal infiltrates, resembling primary sclerosing cholangitis.

*PFIC 4:* This syndrome is caused by a genetically determined 3β-hydroxy-$C_{27}$-steroid dehydrogenase deficiency, resulting in disturbed bile acid metabolism. There is no pruritus; bile acids and gamma GT levels are reduced, and the concentration of conjugated bilirubin increases. • In the PFIC 4 syndrome, the combined application of cholic, chenodeoxycholic and ursodeoxycholic acid leads to good results. (77)

The **treatment** for these disorders is limited. Antipruritic agents and UDCA are indicated for itching. Good dietary management lowers the risk of malnutrition. Biphosphonates and calcium can have a positive effect on bone density. As yet, there is no medical treatment available for the often annoying chronic fatigue syndrome. • Liver transplantation may ultimately be indicated.

### 5.4.5 Zellweger's syndrome

This syndrome was first described as **cerebrohepatorenal syndrome** by P. Bowen et al. in 1964. It was named after H. Zellweger, a coauthor of the publication, who had observed two infants with such complex malformations. (6) The syndrome is an autosomal recessive genetic absence of peroxisomes in the liver and kidneys caused by mRNA mutation of peroxisome assembly factor 1. This impairs bile acid synthesis in the side chain and compromises β-oxidation of long-chain fatty acids. The peroxisome enzymes are not fully synthesized on free polysomes and thus unable to enter the peroxisomes. The absence of peroxisomes and the enzyme deficiency usually result in congenital abnormalities. • Biochemical examination reveals an accumulation of long-chain fatty acids in plasma, brain and fibroblasts, a reduction in tissue plasmalogens, hyperpipecolic acidosis, and dicarboxylic aciduria. Bile acid synthesis remains at the $C_{27}$-bile acid stage. This is usually followed by damage to the mitochondria, which appear strikingly small and dense. • Clinical examination shows multiple abnormalities of the skull, face, brain and nervous system with areflexia and hypotonia; polycystic kidneys with renal insufficiency and hepatomegaly are also found. Laboratory findings include hypothrombinaemia, cholestasis, jaundice and hypersiderinaemia (with iron deposits in liver, brain and kidneys). Liver fibrosis or cirrhosis and enlarged bile ducts develop rapidly. • Although *treatment* using clofibrate has not been effective, improvements were observed after administration of cholic acid and chenodeoxycholic acid. However, prognosis is still poor and infants generally die after a few months. (36, 41) (s. tab. 13.4)

### 5.4.6 Infantile Refsum's syndrome

This rare condition was first discovered in 1937, but not reported until 1945 by S. Refsum, who termed it *heredoataxia hemeralopia polyneuritiformis*. (57) Refsum's syndrome is caused by an autosomal recessive genetic defect in several peroxismal enzymes. It is primarily due to a phytanic acid-α-hydroxilase deficiency. This causes an increase in phytanic acid levels in the serum, with subsequent deposition of the substance in liver, brain, kidney and skin tissues. • Clinical examination reveals

neonatal cholestasis with jaundice and hepatomegaly. Pigmentary retinopathy, peripheral polyneuritis and ataxia also occur (21). (s. tab. 13.4)

# 6 Diagnosis

## 6.1 Anamnesis

Careful anamnesis (with meticulous precision and detailed detective work) allows important information to be gathered for the distinction between intrahepatic and extrahepatic cholestasis. Questions about medication and hormone intake, chemicals (occupation, hobbies, house and garden), alcohol, teas (containing alkaloids), cosmetics, etc. as well as about fever, arthralgia, pruritus and discolouration of the stools or urine are mandatory in this context. (s. tab. 12.5) (s. p. 76)

## 6.2 Clinical findings

### 6.2.1 Fatigue

In chronic cholestasis, pronounced fatigue occurs in 65−68% of patients with PBC, which is the same frequency as in PSC and drug-induced cholestasis. In approximately half of these patients, fatigue is regarded as the most unpleasant symptom. However, fatigue has no correlation with the degree of cholestasis, liver histology or age. (71) Four possibilities are discussed with respect to pathogenesis: (*1.*) alteration of the hypothalamus-pituitary-adrenal axes, (*2.*) altered serotoninergic neuro-transmission, (*3.*) an increase in interleukin 1 (IL 1), and (*4.*) decreased hypothalamic nitric oxide formation. Fatigue is a frequent symptom in chronic hepatitis C, especially in women, in whom a surprising correlation with increased plasma leptin levels was found (T. PICHE et al., 2002). Treatment with UDCA has proved unsuccessful and the use of serotonin antagonists (5HT$_1$A), IL-1 receptor antagonists (IL-1ra) and antioxidants (34) is still at an experimental stage.

### 6.2.2 Pruritus and scratch marks

**Pruritus** can occur at a very early stage − perhaps as a first sign of a cholestasis that has hitherto gone unnoticed. It is more pronounced at night and in wintertime. With a chronic course of disease, this can become excruciatingly painful and may occasionally culminate in a suicidal tendency on the part of the patient.

It is justified to assume that cholestatis-related pruritus is caused by substances that are normally excreted in the bile. Nevertheless, it has not been possible to detect a specific **causative substance** up to now. Under experimental and clinical conditions, raised *bile acid levels* in the serum or in the skin are found both with and without pruritus − but no adequate correlation could be established. Recent findings point to an increased *tonus of the opioid system* in the CNS (endorphins) as being of prime importance in the pathogenesis of cholestasis-related pruritus. Endogenous lipophilic bile acids possibly effect the release of hitherto unknown prurito-

genic substances, which stimulate opioid receptors in the CNS. It has thus been possible to eliminate pruritus straightaway and for a considerable period of time using opioid antagonists (e. g. naloxone, nalmefene). (38, 63, 64, 71) (s. p. 85)

Pruritus is accompanied by **scratch marks** (s. pp 85, 232), which the tormented patient inflicts, often with great intensity, on all accessible parts of the body (*"as long as it bleeds, it doesn't itch any more"*). Fresh scratch marks on the skin alternating with older, blood-encrusted sites are characteristic of the body surface of a patient suffering from chronic cholestasis, such as primary biliary cholangitis. (s. fig. 13.3)

***Fig. 13.3:*** Scratch marks resulting from pruritus in recurrent intrahepatic cholestasis

### 6.2.3 Xanthelasmas and xanthomas

In chronic cholestasis, xanthelasmas and xanthomas occur as a result of impaired catabolism and reduced excretion of cholesterol. Only when cholesterol levels of >400 mg/dl persist over a period of more than 3 months do these deposits form in the skin. Occasionally, peripheral *xanthomatous neuropathy* is witnessed.

**Xanthelasmas** are depositions, reddish-brown to yellow in colour, sharply defined, striated, up to the size of a fingernail, slightly raised (*xanthelasma planum*) or slightly humpy (*xanthelasma tuberosum*). They are most frequently found on the eyelids (*xanthelasma palpebrarum*), particularly at the inner angle of the eye.

**Xanthomas** are found in the form of small nodular foci or as nodulations, mainly symmetrical, on the buttocks, elbows, knees, fingers, feet and toes, neck, tendons, and below the breast. They are reddish-brown to yellow in colour. These depositions of cholesterol are reversible − particularly with a marked reduction in the cholesterol level due to liver cirrhosis. Following transplantation of the liver, they generally disappear after one or two years. (s. p. 85) (s. figs. 4.14−4.16)

### 6.2.4 Changes in biotransformation

In the course of cholestasis, lower concentrations of cytochrome P 450 are found together with increased activities of some microsomal oxidases. For this reason, the biotransformation of xenobiotics can be unpredictably and permanently altered. This is largely connected with the cholestasis-associated shift in bile acids from the periportal to the intermediary and perivenous zones.

## 6.3 Laboratory diagnostics

Diagnosis of cholestasis is easy and accurate with the help of laboratory methods. (s. tab. 13.6) The retention of substances essential to the bile triggers biochemical changes which may also be of diagnostic significance. The visual diagnosis of subicteric conditions or jaundice can be related to hyperbilirubinaemia as well as to cholestasis with jaundice; this differentiation is possible using just a few laboratory parameters. The diagnostic methods applied must always aim to yield sufficiently reliable information on the aetiology, severity and sequelae of cholestasis.

*Differentiation between obstructive ("surgical") and non-obstructive ("conservative") cholestasis is the most important diagnostic task, because this can have consequences which are of decisive importance in terms of therapy and prognosis.* (25, 32)

1. *A rise in* **bile acids** *is the main biochemical sign of cholestasis.* For this reason, the bile acid values are well-suited for early diagnostic purposes as well as for follow-up and prognosis. The serum level can be in excess of 300 µmol/l (normal 1.0−6.0 µmol/l). (s. pp 35, 101)

In each form of cholestasis, **atypical bile acids,** such as monohydroxy bile acids, allo-bile acids, 1- or 6-hydroxylated bile acids and their sulphated or glucuronidated derivatives, are found in the serum and/or urine. In cholestasis, the increase in the neosynthesis of atypical bile acids that pass into the kidney can be seen as a compensatory mechanism which eliminates *potentially hepatotoxic bile acids* by renal clearance. The highest renal excretion quota is demonstrated by tetrahydroxy bile acids.

2. An increase in **enzymatic markers of cholestasis** is a laboratory sign of cholestasis, with *alkaline phosphatase* being of paramount importance. Normal AP activity does not necessarily exclude cholestasis! It is a ubiquitous enzyme and therefore not specific to cholestasis, which is why LAP (as well as γ-GT) ought to be determined additionally in order to confirm AP if the existence of cholestasis is uncertain. In cholestasis, γ-GT is about 9 times more sensitive than LAP and about 6 times more sensitive than AP. The sluggish reactions of LAP are, however, far more cholestasis-specific than those of AP and γ-GT. Some forms of cholestasis demonstrate elevated AP and LAP values, yet normal γ-GT values. (s. p. 101) (s. tabs. 5.9; 13.6)

▶ These enzymes (AP, LAP, γ-GT, 5′NU) as well as $Mg^{++}$-*ATPase* are localized on the *canalicular side of the hepatocyte* (AP and $Mg^{++}$-ATPase are also detectable on the luminal surface of the ductular epithelia cells). Even under normal conditions, yet more so in cholestasis, the enzymes are released through the detergent effect of bile acids (in quantitative dependence on their concentration) and can thereby pass into the bile and blood.

3. **Serum lipids** reflect a complex picture of changes, depending on the duration and severity of the disease. A pronounced increase in *cholesterol* is witnessed, with a disproportionate rise in free cholesterol. The *phospholipids* are also clearly increased. Neutral fats are just slightly elevated as a rule. Detection of *lipoprotein X* is deemed to be a useful cholestasis parameter. The serum is not turbid. (s. pp 103, 106) (s. tab. 13.6)

**Lipoproteins** are increased and show great changes: (*1.*) clearly elevated LDH contain lipoprotein X (LP-X), (*2.*) VLDL have fewer apolipoproteins E and C, (*3.*) HDL are decreased and contain less apolipoprotein A1, yet more E, and (*4.*) LCAT activity is reduced.
• **Lipoprotein X** is a lipoprotein rich in phospholipids (ca. 60%) and cholesterol (ca. 25%), with a protein content of about 6%. It has a bilamellar discoidal structure, a diameter of 40−60 nm and a thickness of 10 nm. It is formed by the interaction of bile with blood components. LP-X inhibits the uptake of chylomicron remnants in the liver cells and supports the synthesis of cholesterol by triggering HMG-CoA reductase activity. Degradation of LP-X is effected in the RES. Despite the alleged differentiation into largely increased LP-X$_1$ in intrahepatic cholestasis and LP-X$_2$ in extrahepatic cholestasis, it is not possible to distinguish between the two forms of cholestasis in the chemical laboratory.

4. **Jaundice** does not necessarily accompany cholestasis. In severe and prolonged cholestasis, particularly if obstructive, jaundice is generally always in evidence. In cholestasis, the third fraction, known as *delta bilirubin*, can largely be detected by means of the diazo method. This fraction is firmly bound to albumin and can therefore only be dissociated and excreted slowly. For this reason, jaundice occurring together with cholestasis tends to subside at a significantly slower rate than the increased bile acid level in the serum. • In this case, jaundice is due to a reflux of bilirubin from the canaliculus into the blood or a bidirectional transport of bilirubin via the sinusoidal membrane. Sometimes jaundice is caused by metabolic dysfunction of the liver cells. • Bilirubin also acts as an antioxidant.

5. An increase in **GDH** often proves to be a sensitive parameter for bile stasis. In acute obstruction of the biliary tract, the GDH level rises at an early stage (*according to our own observations, up to 112 U/l on discharge of a gallstone*). • With right-side colic, a swift and pronounced increase in GDH can point to a choledochal concrement, whereas colic caused by a renal calculus has no effect on the GDH level. • A malignant obstruction shows constantly high or still increasing values, whereas GDH activity tends to decrease in benign cholestasis. (s. tab. 13.6)

6. **Quick's value** can be reduced in long-term cholestasis by vitamin K deficiency (owing to a disorder in the synthesis of clotting factors dependent on vitamin K). In this respect, the intravenous *Koller test* can facilitate the differential diagnosis between dysfunction of synthesis

in the liver cell or vitamin K deficiency due to impaired absorption. (s. p. 105) (s. tab. 13.6)

7. **Cholinesterase** activity continuously declines in prolonged cholestasis − pointing to an impaired synthesis capacity of the liver cells. (s. p. 103) (s. tab. 13.6)

| | |
|---|---|
| 1. Serum bile acids | ↑ |
| 2. Alkaline phosphatase (AP)<br>Leucine aminopeptidase (LAP)<br>γ-GT<br>5′nucleotidase | ↑ |
| 3. Cholesterol<br>Phospholipids<br>Lipoprotein X | ↑ |
| 4. Bilirubin | N−↑ |
| 5. GDH | N−↑ |
| 6. Quick's value, cholinesterase | ↓ |
| 7. Copper, ceruloplasmin | ↑ |
| 8. IgA, IgM | ↑ |
| 9. Antithrombin III, haptoglobin | ↑ |
| 10. Various antibodies (s. tab. 13.7) | ↑ |

**Tab. 13.6:** Possible laboratory results in cholestasis (N = normal)

8. The serum value for **copper** is increased. Some 80% of the absorbed copper is normally excreted via the bile in the stool. In prolonged cases of cholestasis, copper is deposited in other organs − even forming a faint Kayser-Fleischer ring on the cornea (as observed in Wilson's disease). The retained copper is not toxic. (s. p. 102)

9. In the case of non-dilated bile ducts, further **specific laboratory parameters** may be necessary for differential diagnosis, such as electrophoresis, immunoglobulins, hepatitis serology (s. p. 116) and $\alpha_1$-foetoprotein (s. p. 106). Determination of the AMA should always be considered. (s. p. 120) (s. tabs. 5.19−5.21; 13.7)

In cholestasis, various *antibodies* (e. g. CEA 19) may be falsely evidenced as being increased in the serum. This is because antibodies can no longer be excreted via the bile, as they usually are.

> It is not possible to differentiate between intrahepatic and extrahepatic cholestasis by means of laboratory parameters.

## 6.4 Imaging procedures

### 6.4.1 Sonography

At this stage of the examination, sonography is now required to diagnose obstructive cholestasis and posthepatic jaundice and to localize the cause. In 90−95% of cases, this can be done successfully; the cause can be clarified in 71−88% of cases. Ultrasound examination methods are deemed to be routine, and when aiming at the clarification of jaundice and/or cholestasis, they have a high degree of reliability. Dilated bile ducts (generally presented as a double-barrelled phenomenon) with a diameter exceeding 7−8 mm and an enlarged lumen through to the porta hepatis or papilla of Vater (extrahepatic obstruction) are clearly visible. It is usually possible to differentiate between an obstruction which is located high up in the bile duct and one which is located distally. (s. tabs. 6.4; 13.8)

| Localization | Dilation | | |
|---|---|---|---|
| | Gall bladder | Choledochal duct | Intrahepatic bile ducts |
| Extrahepatic cholestasis<br>− proximal<br>− distal | ∅<br>+ | ∅<br>+ | +<br>+ |
| Intrahepatic cholestasis | ∅ | ∅ | ∅ |

**Tab. 13.8:** Ultrasound criteria for the differentiation of cholestasis (or jaundice)

| Disease | AMA M₆ | AMA M₂ | AMA M₄ | AMA M₈ | AMA M₉ | ANA | LMA | SMA | ANCA | AHA |
|---|---|---|---|---|---|---|---|---|---|---|
| Primary biliary cholangitis | ∅ | +++ | + | + | + | (+) | ∅ | ∅ | ∅ | ∅ |

**Tab. 13.7:** Possible antibody constellations in chronic cholestatic liver diseases

| Criterion | Clinical and laboratory findings | Sonography | CT | MRC / ERCP, PTC |
|-----------|----------------------------------|------------|-----|-----------------|
| Sensitivity | 95−100% | 55−95% | 74−76% | 40−100% |
| Specificity | 30−40% | 71−96% | 90−94% | 90−100% |

*Tab. 13.9:* Efficiency of diagnostic procedures in cholestasis: determination of cholestasis (= sensitivity), differentiation between intrahepatic and extrahepatic cholestasis (= specificity)

### 6.4.2 CT, MRI and MRC

The degree of accuracy for CT in cholestasis is 74−96% sensitivity and 90−94% specificity, which practically corresponds to that of sonography and MRI. When cholestasis is still unresolved, MRC (B.K. WALLNER et al., 1991) should be used as well. (s. tab. 13.9)

### 6.4.3 ERC, PTC and EUS

If definitive clarification of cholestasis has still not been reached (even with MRC imaging), dilated bile ducts indicate an ERC or, if this is technically impossible, a PTC. The diagnostic sensitivity is 60−70%, the specificity 90−95 (−100)%. The ERC should also be used to visualize non-dilated bile ducts by means of direct presentation − e.g. in cases with suspicion of destructive primary biliary or sclerosing cholangitis as well as regionally restricted intrahepatic obstruction. (s. figs. 8.12, 8.13) (s. tab. 13.9)

## 6.5 Liver biopsy and laparoscopy

**Liver biopsy:** In the case of a hitherto non-clarified differential diagnosis of cholestasis, thought should be given to percutaneous liver biopsy or laparoscopy. Although this is only indicated in isolated cases, it does promise to be successful. (s. tabs. 7.3, 7.10) (s. fig. 13.5) • *Explorative laparotomy should not be performed!*

Even by means of **histology**, however, it is not possible to differentiate reliably between intrahepatic and extrahepatic cholestasis.

*Feathery degeneration* is the term used to describe the delicate honeycomb-like, brownish streaky change of liver cells, which is due to bilirubin impregnation of the visible cytoplasmic structures. It can occur following long-term cholestasis. Cellular hydrops is evident with dilation of the endoplasmic cisternas, caused by the toxic impact of biliary acids. (s. fig. 13.4)

*Eosinophilic infiltrations* in the portal fields generally point to intrahepatic cholestasis. • By contrast, *ductular changes* with bile cylinders, ballooning, acidophilia of the liver cells at the lobular centres, bile infarcts, increase in the copper content, etc. are usually signs of extrahepatic cholestasis. (s. fig. 13.5) (s. tab. 13.10)

| Finding | Intrahepatic cholestasis | Extrahepatic cholestasis |
|---------|--------------------------|--------------------------|
| 1. Periportal field | | |
| − leucocytes | (+) | +/++ |
| − eosinophilia | +++ | (+) |
| − foam cells | (+) | +/++ |
| − fibrosis | ∅ | +/++ |
| − ductular changes | (+) | +/++ |
| 2. Bile ducts | | |
| − dilation | (+) | +/++ |
| − bile cast | + | +/++ |
| 3. Liver cells | | |
| − bile pigment | +/++ | +/++ |
| − necroses | + | +/++ |
| − fatty infiltration | (+) | +/++ |

*Tab. 13.10:* Histological findings as criteria for intrahepatic or extrahepatic cholestasis

*Fig. 13.4:* Obstructive jaundice with feathery degeneration of hepatocytes (→)

*Fig. 13.5:* Bilirubinostasis with bile droplets (→) in the hepatocytes and canaliculi. Clinical diagnosis: extrahepatic obstructive jaundice

**Laparoscopy:** In laparoscopy, cholestasis is usually presented as greenish to brownish green "spotting" or as diffuse greyish green colouration of the liver surface.

***Fig. 13.6:*** Smooth, brownish-green sprinkled liver surface (due to azathioprine)

This greyish green colour does not always correlate with the bilirubin value (in pronounced icteric virus hepatitis, for example, the surface of the liver shows no cholestatic change). In intrahepatic obstructive cholestasis, the surface of the liver can indeed show a cholestatic discolouration, although only in the affected area. • In long-term cholestasis, however, obstructive and non-obstructive courses of the disease display clear differences: in the obstructive form, fine uneven sites increasingly appear on the liver surface, ultimately leading to granulation as well as to perivascular proliferation of connective tissue and capsular fibrosis. By contrast, in non-obstructive forms, the liver surface remains unchanged, i.e. smooth and shiny, even after weeks of cholestasis. (s. figs. 13.6; 28.15, 28.16)

The strategy of diagnosing **cholestasis** or **jaundice** is outlined in a **flow diagram**. (s. fig. 13.7)

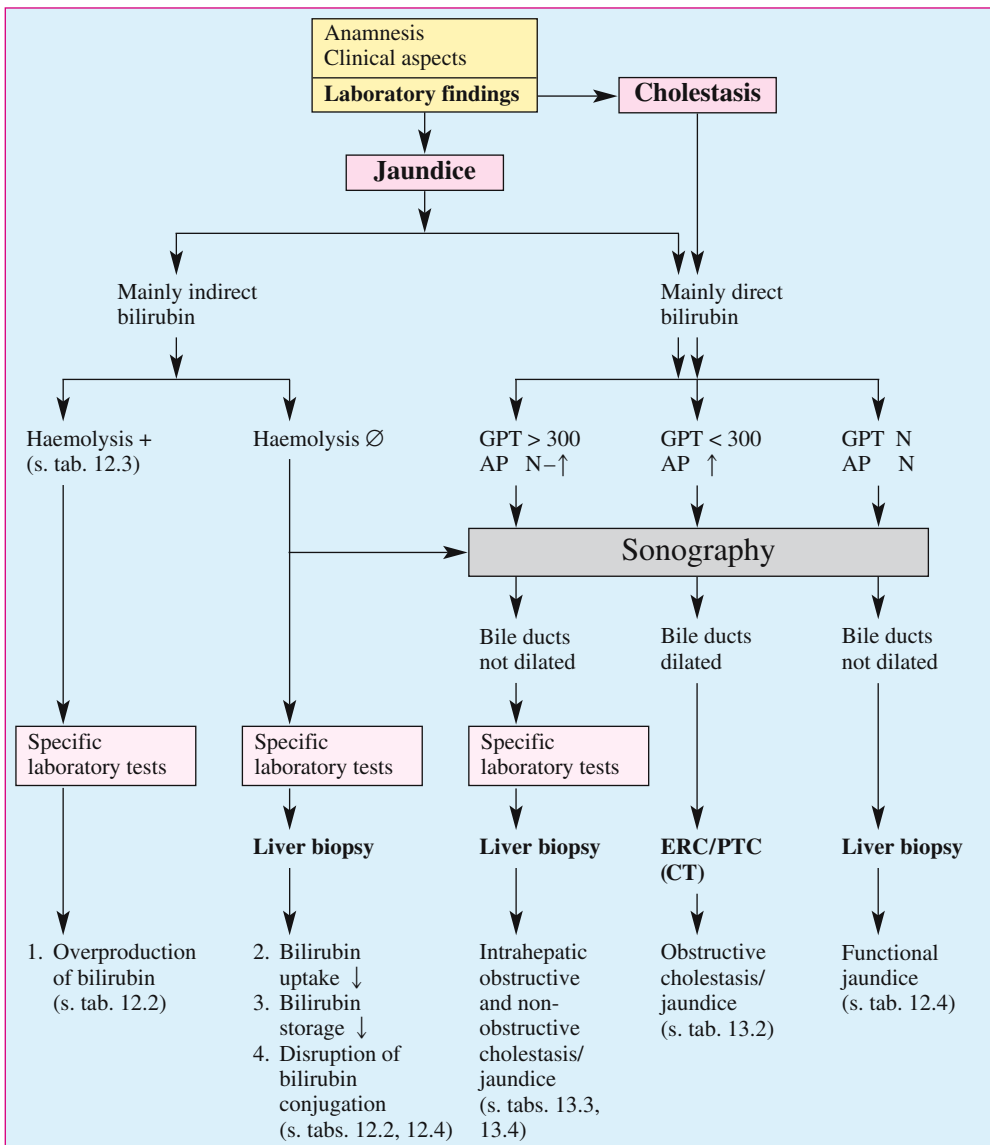

***Fig. 13.7:*** Flow diagram of cholestasis and jaundice (N = normal, ∅ = not present) (s. fig. 9.3)

# 7 Clinical sequelae

In prolonged cholestasis and/or biliary deficiency in the intestine, a number of unpleasant and grave symptoms are likely to occur.

## 7.1 Abdominal complaints

Bile deficiency in the stools causes disturbed bacterial flora as well as insufficient digestion and absorption of nutritional fats. This leads to intestinal complaints, such as meteorism, bloating, lack of appetite, intolerance of fatty foods through to nausea and vomitus.

## 7.2 Steatorrhoea and diarrhoea

*Biliary steatorrhoea* is characterized by higher stool weight (> 200 g) and increased excretion of fat (> 7 g/day). This condition correlates with the degree of severity of cholestasis. Stools are soft and smell unpleasant. • Steatorrhoea is accompanied by additional *diarrhoea*. All these changes in the stools lead to a loss of liquid, electrolytes, fat-soluble vitamins and important trace elements. • Intestinal bile deficiency causes the characteristic *acholic stools*. (s. tab. 12.6) (s. fig. 13.8)

**Fig. 13.8:** Acholic fatty stool in recurrent intrahepatic cholestasis

## 7.3 Malabsorption

Steatorrhoea and diarrhoea cause malabsorption and subsequent weight loss. In prolonged cholestasis, deficiency symptoms may result from the loss of vitamins A, D, E and K. • *Vitamin A deficiency* leads to dry and atrophic skin, xerophthalmia and impaired scotopia with night blindness as well as damaged hearing. *Vitamin E deficiency* may result in cerebral ataxia, retinal degeneration, neuropathy and myopathy (especially in children) as well as prolonged cholestasis. Vitamins A and E are also important radical scavengers, which explains why deficiency of these vitamins results in lipid peroxidation. *Vitamin K deficiency* causes coagulative disorders with haemorrhagic diathesis. *Vitamin D deficiency* leads to increased intestinal loss and reduced absorption of calcium.

## 7.4 Osteopathy

Cholestasis-linked osteopathy (M. LOEPER et al., 1939), which occurs much more frequently in the form of osteoporosis than osteomalacia, can be expected in up to 50% of cases. The pathogenesis is complex. Vitamin D status can be examined by determining 25-OH-cholecalciferol in the serum. Intestinal calcium loss and reduced calcium absorption due to vitamin D deficiency are key pathogenetic factors. It is still a matter of debate whether vitamin K deficiency (which can lead to reduced osteocalcin synthesis) and deficiencies in IGF I and II (which can cause dysfunction of the osteoblasts) are possible causes of this condition. Muscle and bone pain are frequent clinical symptoms, occurring mainly in the wrists and ankles.

## 7.5 Renal dysfunction

Elimination of *endotoxins* is reduced owing to the restricted filtering function of the RES in cholestasis. (s. p. 65) Renal dysfunction may occur as a result of endotoxins or deposits of *IgA immunocomplexes* in the glomerula. The kidneys are occasionally swollen and contain bilirubin deposits. (s. p. 327)

# 8 Therapy

## 8.1 Mechanical cholestasis

Mechanically induced cholestasis is usually accompanied by *obstructive jaundice*. In both conditions, the primary aim is to eliminate the mechanical obstruction. This can be achieved surgically or endoscopically. In malignant obstructions, palliative measures, such as endoscopic retrograde or percutaneous transhepatic stenting, should be considered, depending on localization and various clinical aspects; if necessary, a surgical bypass may be performed to eliminate the cholestasis. • Careful preparation of each individual patient must include the following measures: normalization of blood coagulation and the electrolyte, water and acid-base balance, stabilization of blood circulation using suitable infusions, mannitol infusion (only if fluid balance is given), administration of lactulose for intestinal detoxification (in particular for endotoxinaemia), broad spectrum antibiotics and possibly zinc. • Once the obstruction of biliary flow has been removed, administration of *ursodeoxycholic acid* (10−15 mg/kg BW/day, up to 1,800 mg/day) is recommended. • There has been growing interest in the use of *cholagogue agents* as adjuvant therapy, particularly in prolonged treatment.

## 8.2 Functional cholestasis

Function-related cholestasis calls for identification and elimination of the causes. Because this is fundamental for the outcome, it must be carried out effectively.

| General measures |
|---|
| • Reduced intake of neutral fats (< 40 g/day) with supplementary administration of medium-chain triglycerides (> 40 g/day) |
| • Substitution with vitamins A, D., E., K (i.m.) |
| • Substitution with calcium (1 g/day) |
| • Substitution with other electrolytes and zinc |
| • Short fingernails |
| • Increase in physical activity |

| Drug therapy |
|---|
| • Ursodeoxycholic acid (22, 53) |
| • S-adenosyl-L-methionine (20) |
| • Cholestyramine, cholestipol |
| • Opiate antagonists (29, 38, 63) |
|   – naxolone |
|   – naltrexone (69) |
|   – nalmefene (5) |
| • 5HT3 antagonist |
|   – ondansetron (64) |
| • Dronabinol (50) |
| • Serotonin reuptake inhibitor |
|   – sertraline (50−100 mg/day) |
| • Enzyme inducers |
|   – Rifampicin (78) |
|   – phenobarbital (100 mg in the evening) |
|   – promethazine (25−150 mg in the evening) |
| • Antacids |
|   – aluminium hydroxide |
|   – $H_2$-receptor blockers |

| Non-pharmaceutical therapies |
|---|
| • UV light (65) |
| • Dialysis, exchange transfusion (7) |
| • MARS (26, 40, 66) |

**Tab. 13.11:** Treatment of functional cholestasis and pruritus

*General measures* should include: (*1*.) reduction in the intake of neutral fats in the food (< 40 g/day) with supplementary administration of medium-chain triglycerides (> 40 g/day), (*2*.) substitution of fat-soluble vitamins A, D, E and K, (*3*.) substitution of calcium (1 g/day) as well as other electrolytes and zinc, (*4*.) reduction of scratching by constantly checking for short fingernails, and (*5*.) regular muscular activity. • Many studies using *drug therapy* have shown the effectiveness of ursodeoxycholic acid (10−15 mg/kg BW/day, up to 1,800 mg/day) (22, 53), S-adenosyl-L-methionine (1,600 mg/day) (20), cholestyramine (starting at 1 x 4 g/day and increasing to 3 x 4 and 4 x 4 g/day) and cholestipol (3 x 5 g/day) as well as rifampicin (2 x 150 mg/day, up to 2 x 300 mg/day in exceptional cases). (78) Opiate antagonists have also proved successful: naxolone (2−3 x 0.4 mg/day i.m.) or naltrexone (2−4 x 25−50 mg/day) (69) as well as the 5-HT3 antagonist ondansetron (3 x 4−8 mg/day, i.v. or orally). (64) Dronabinol has also been successfully used to treat intractable pruritus. (50) Sertraline as a selective serotonin (neuronal) reuptake inhibitor can reduce pruritus due to cholestasis with long-term efficacy. Phenobarbital (3 x 5 mg/kg BW/day and/or 100 mg in the evening) is thought to be effective through enzyme induction or direct impact on the peripheral or central nervous system. Promethazine (25−150 mg in the evening) should also be mentioned here. In some cases (especially in pregnancy chole-

stasis), prednisolone may be administered in the morning, gradually decreasing the dosage over a limited period. Tauroursodeoxycholic acid appears ineffective in preventing or treating total parenteral nutrition-associated cholestasis in neonates. *Non-pharmaceutical alternatives* in the treatment of severe intractable pruritus include UV phototherapy (8−12 hours/day), dialysis or plasmaphoresis. The molecular adsorbents recirculating system (MARS) was developed by J. STANGE et al. in 1993 as supplementary treatment in acute liver failure. This procedure has been commercially available since 1999. It is based on the removal of water-soluble and protein-bound toxins that accumulate as a result of liver failure. Since 2000, many patients have undergone successful treatment and this method is now being used with BRIC to produce excellent results. (26, 40, 66) (s. tab. 13.11)

# Symptoms and Syndromes

## 14 Portal hypertension

# 14 Portal hypertension

## 1 Definition

A persistent pressure elevation of >12 mmHg in the portal vein circulation, dilation of the portal vein to >13 mm or an increase in the portal pressure gradient of >7 mmHg (difference between the pressure of the portal vein and that of the inferior vena cava) is termed portal hypertension. At pressure values of more than 20 mmHg, collaterals generally develop. • *Portal hypertension is regarded as a systemic disease which affects a number of organ systems.*

## 2 Pathogenesis

The portal vein is 5−8 cm long with a diameter of 1.2 ± 0.2 (or 0.97) cm. The portal venous pressure is 3−7 (−12) mmHg. It is dependent on several *criteria*: posture, intra-abdominal pressure (e. g. coughing, compression), respiratory phase, Valsalva's manoeuvre and a number of biochemical mediators. (20)

**Hepatic circulation:** About 70−75% of the hepatic circulation (1,500 ± 300 ml/min, or 1.4−1.5 ml/min/1.73 $m^2$ body surface) pass through the portal vein (25−30% via the hepatic artery). Hepatic circulation increases after the ingestion of food, but decreases by about 30% after physical exertion as a result of sympatheticotonia. The oxygen content of portal venous blood is lower than that of arterial blood, but is significantly higher than in the rest of the venous system. The portal vein supplies about 10−12 ml $O_2$/min × 100 g, i.e. 50−60% of the liver's oxygen requirement. The liver is very adaptable in this respect and balances an increased or decreased oxygen supply by decreasing or increasing oxygen extraction (by almost 100%) from the portal and arterial blood. (4, 10, 17, 87, 99) (s. pp 826, 833, 836)

**Hepatic blood flow:** In addition to the autoregulation of the arterial hepatic system, the hepatic blood flow is mainly regulated via neural (sympathetic) stimulation and the effects of hormones, mediators or pharmaceuticals. • Agents such as α-agonists, histamine, serotonin, noradrenaline, endothelin and angiotensin have a constrictive effect on the portal venous system. A vasodilatory effect on the arterial system is brought about by β-agonists, nitric oxide (NO) (51, 118), glucagon, prostaglandins, pentagastrin, etc. • Under pathological conditions (e. g. lowered response to vasoconstrictors), individual factors of these biochemical regulation systems may be present to a greater or lesser extent and thereby lead to pathophysiological mechanisms. This also applies to the action of endotoxins with regard to an elevation of the portal pressure. • **Ito cells** are key targets for vasodilators: they regulate the hepatic microcirculation. (118)

**Hepatic resistance:** Various areas of resistance can regulate the circulation of blood in the liver: (*1.*) arterioles of the hepatic artery, (*2.*) arterioles in the region of the splanchnic vessels, (*3.*) presinusoidal portal venules, (*4.*) sinusoids and postsinusoidal sections of vessels, and (*5.*) portosystemic collaterals.

**Forward-flow hypothesis:** When hepatic resistance is constant, increased blood supply causes an elevation of the portal pressure. • **Backward-flow hypothesis:** This primarily requires an increase in hepatic vascular resistance. The subsequently reduced circulation of blood in the liver is compensated by increased circulation in the splanchnic vessels.

The portal hypertensive syndrome is caused by (*1.*) increased resistance in the portohepatic circulation and (*2.*) an increase in the splanchnic vein blood supply.

▶ The *increase in vascular resistance* is the decisive factor and, in the majority of cases, is even the sole cause. It can be *functional and reversible* as well as *structural and irreversible*. Blood flow correlates directly with vessel diameter to the 4th power, i.e. small radial changes cause large changes to vessel resistance. An increase in the blood supply may favour the occurrence of portal hypertension or enhance its clinical development. The persistent interference with biochemical mechanisms which regulate the blood circulation in the liver and the impact of pathological substances may have further pathogenic effects. (23, 62, 72, 81, 118, 128) (s. fig. 14.1)

Despite the development of *portosystemic collaterals*, which ought to lead to a fall in portal hypertension, the *hyperdynamic circulation* accompanied by splanchnic vasodilation (= increased cardiac output, decreased systemic vascular resistance, hypervolaemia, systemic arteriolar vasodilation) maintains portal hypertension in both the splanchnic and systemic vascular systems. (10, 47, 87) The hyperdynamic circulation is either the cause

or the result of portal hypertension − or both. The arterial blood pressure is normal or slightly decreased.

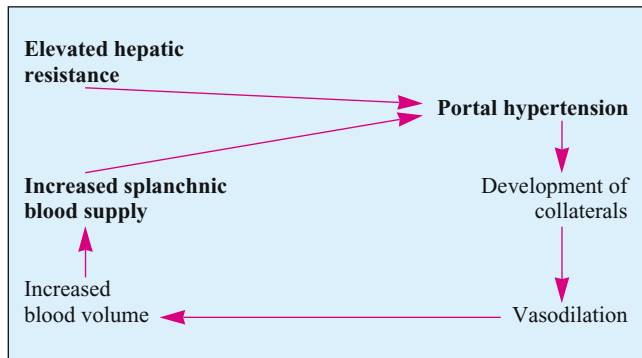

**Fig. 14.1:** Pathogenesis of portal hypertension

# 3 Forms and aetiology

Portal hypertension is classified according to the *localization* of the flow resistance. Increases in pressure in the portal vascular system are rapidly transferred to the preceding vascular sections, since the portal vein does not possess any venous valves. Depending on whether the localization lies before, within or beyond the liver, the portal hypertension is broken down into *prehepatic, intrahepatic* and *posthepatic blocks*. The intrahepatic form is further subdivided into a presinusoidal, sinusoidal and postsinusoidal rise in resistance. Underlying *morphology* allows distinction between cirrhotic and non-cirrhotic portal hypertension. • Sometimes the aetiology is unknown (= *idiopathic, non-cirrhotic portal hypertension*). (22, 23, 37, 38, 54, 65, 69, 71, 102, 115, 140, 142, 154, 158) (s. tab. 14.1)

**Tab. 14.1:** Forms and localization of portal hypertension

## 3.1 Prehepatic portal hypertension

Prehepatic (non-parenchymatous) portal hypertension develops (*1.*) as a result of an increase in the portal blood supply in the form of hyperkinetic hypertension or (*2.*) due to occlusion of the portal vein or its trunks. The frequency is 10−20%. The liver is morphologically normal, but is diminished in size. Its function is not impaired. The reduced afferent portovenous flow is compensated by arterial perfusion of the liver. Ascites occurs only rarely.

There are a variety of known causes for this portal block form. (s. tab. 14.2) (s. figs. 14.4, 14.5)

**Tab. 14.2:** Forms and causes of prehepatic portal hypertension

Phylogenetically, the portal vein is derived from sections of several fused embryonic vessel components. Malformation can lead to *atresia* or *hypoplasia* of the portal vein and cause portal hypertension in newborns. (100, 159)

### 3.1.1 Cavernous transformation

The most common cause of prehepatic portal hypertension in early childhood is cavernous transformation, a primary angiomatous malformation of the portal vein (H. Breining et al., 1968; C. Marks, 1973). • In adults, septic diseases (appendicitis, pancreatitis, cholecystitis, etc.) and traumas are held to be responsible, since they trigger a slow occlusion of the portal vein (H. W. Clatsworthy, 1974). Myeloproliferative syndromes, hepatic tumours and cirrhosis are also possible causative factors. • This transformation consists of a spongy convolute of paraportal, tendril-like interlaced vascular structures in place of a single portal vein, mainly in the area of the hepatoduodenal ligament. Symptoms are abdominal pain, haematemesis, splenomegaly and oesophageal varices. The diagnosis can be made using sonography and CT. A cavernous transformation of the portal vein usually appears sonographically as a string of bead-like varicose collaterals in the hepatoduodenal ligament. (8, 9, 131) (s. p. 834!)

### 3.1.2 Cruveilhier-von Baumgarten disease

The **Cruveilhier-von Baumgarten disease** develops when postnatal occlusion of the umbilical vein is absent (P. von Baumgarten, 1907). An open, dilated umbilical vein connects the left portal vein with the systemic venous circulation in the navel area. This collateral vein has a diameter of > 3 mm and a hepatofugal flow of > 5 cm/

245

sec. Sonography shows an echofree tubular structure. In addition to the persistence (and, in most cases, malformation) of the umbilical vein, a hypoplastic portal vein system is found. (12) The resulting hypoplasia of the liver and its vessels culminates in portal hypertension. Typical of this condition are the massive varicose collaterals between the portal vein and the abdominal wall veins in the form of a Medusa's head (s. p. 87), a continual venous hum below the xiphoid ("bruit de diable" or "humming-top murmur") (s. p. 87), and splenomegaly. (s. p. 212) • In the **Cruveilhier-von Baumgarten syndrome,** the postnatally closed umbilical vein in the region of the round ligament is recanalized due to portal hypertension; thus the blood from the left portal branch is drained caudally. As a consequence of haemodynamically effective "shunting", flow values of >10 cm/sec can be measured.

### 3.1.3 Arterioportal fistulas

Hyperkinetic hypertension in the prehepatic portal vein system is caused by arterioportal fistulae with resulting increased blood flow. About 150 cases of such aneurysmal anomalies are known from the literature. (2) They occur more frequently, however, after abdominal traumas or iatrogenic interventions (e. g. liver biopsy, cholangiography, arteriography) and in the presence of malignant liver tumours. They are found mainly in the proximity of the splenic artery or mesenteric vessels. Arterial flow into the low-pressure portal region is unaffected. Oesophageal varices, splenomegaly and, in some cases, ascites develop very rapidly despite a "healthy liver" (no abnormal clinical or laboratory findings). This is followed by the subsequent development of secondary thrombosis of the portal vein as a result of fibromuscular hyperplasia of the intima and fibrosis in the portal area (= *hepatoportal sclerosis*). Clinically, a "machinery murmur" in the abdomen can be ascertained on auscultation. Diagnosis can be made with the aid of duplex sonography or radiological procedures.

### 3.1.4 Portal vein thrombosis

The most frequent cause of prehepatic portal hypertension in adults is portal vein thrombosis. Sonography displays the fresh thrombus as a hypoechoic structure in the initially dilated portal vein. (89, 103, 144) The blood flow (during the reversal phase from a hepatopetal to a hepatofugal flow) slows down as a result of liver cirrhosis, and this is deemed to be the causative factor in over 30% of all cases of portal vein thrombosis. The liver function is considerably restricted. Ascites is frequently witnessed and proves difficult to treat. The presence of thrombophilia is considered to be a predisposing factor. • Other causes are: thromboembolism (95), abdominal operations, traumas (68), pregnancy, collagenoses, portography, polycythaemia vera, osteomyelosclerosis, Budd-Chiari syndrome, primary hepatocellular carcinoma, hepatic echinococcus cysts (107). Septic processes (e. g. umbilical vein

infection in newborns, appendicitis, diverticulitis, pancreatitis, colitis) play a major role. Tuberculosis is a rare cause. (120) (s. tab. 39.4) The severity of the clinical picture of portal vein thrombosis depends on how quickly and extensively the obstruction develops. Rapid occlusion, due to the haemorrhagic infarction of the intestine, leads to extreme abdominal pain, haematemesis, melaena, haemorrhagic shock, and ultimately death. When the obstruction is more gradual, splenomegaly develops rapidly together with paraportal collateral vessels which function as intrahepatic portal branches (= cavernous transformation), thus permitting partial compensation. With normal WHVP (= wedged hepatic vein pressure), there is a rise in intrasplenic pressure. (s. tab. 14.9) Diagnosis is possible with the aid of duplex sonography, splenoportography or modern radiological methods. Disorders of liver function are only apparent at a later stage. *Hepatoportal sclerosis* may develop. (121) (s. p. 835!)

### 3.1.5 Segmental portal hypertension

An increase in peripheral resistance following *thrombosis of the splenic vein* is termed segmental portal hypertension. Bleeding from gastric fundus varices is frequently found. Due to the intact liver function, bleeding from the upper gastrointestinal tract is better tolerated. Parasplenic variceal convolutes can be visualized by means of colour-encoded duplex sonography. As a rule, ascites does not occur. Pressure in the enlarged spleen is greatly elevated. The WHVP remains unchanged even with normal portal pressure. For this reason, a shunt operation is contraindicated in cases of bleeding from oesophageal or gastric fundus varices owing to segmental portal hypertension. (44, 76, 82)

## 3.2 Intrahepatic portal hypertension

Intrahepatic portal hypertension is caused by lesions which are easy to distinguish morphologically as well as pathogenetically and which occur in the following regions: (*1.*) presinusoidal veins of the intrahepatic periportal triangles, (*2.*) liver sinusoids, and (*3.*) draining postsinusoidal veins. Pathogenic overlapping is possible, since some lesions affect both the presinusoidal and sinusoidal vascular sections simultaneously. Frequency is estimated at 70−80%. (s. figs. 14.4, 14.5)

### 3.2.1 Presinusoidal block

► The presinusoidal block can be classified under nonparenchymatous portal hypertension. The WHVP is normal. There is no impairment of liver function until a later stage of the underlying disease has been reached. This type of block is caused by a congenital or acquired constriction of the lumen or by a reduction in portal venous branches within the periportal triangles. (s. tab. 14.3)

Fibrocystic liver diseases, which show an autosomal-recessive inheritance pattern, may hence cause a presinus-

oidal block within the clinical picture of *cholangiodysplasia*. Histological differentiation between cirrhosis and cholangiodysplastic pseudocirrhosis is very difficult. • *Congenital liver fibrosis* (D.N.S. KERR et al., 1962), an autosomal recessive disease involving the kidneys, causes an increase in presinusoidal pressure due to increased vascular resistance. *Rendu-Osler-Weber disease* and *Gaucher's disease* should also be mentioned as forms of a congenital presinusoidal block, the portal hypertension here possibly also being of sinusoidal origin. (s. tab. 14.3)

| Presinusoidal block |
|---|
| **Congenital** |
| 1. Rendu-Osler-Weber disease |
| 2. Gaucher's disease |
| 3. Cholangiodysplasia or congenital liver fibrosis (microcystic liver), congenital polycystic disease |
| **Acquired** |
| 1. Thrombosis of the portal venous branches (89, 103)<br>  − severe bacterial cholangitis<br>  − malignant diseases |
| 2. Primary biliary cholangitis (78),<br>  primary sclerosing cholangitis |
| 3. Sclerosing granulomas<br>  − schistosomiasis (30, 116)<br>  − sarcoidosis (75, 138, 143)<br>  − tuberculosis (120) |
| 4. Toxically induced hepatoportal sclerosis/periportal fibrosis<br>  − arsenic (88, 97, 110, 113)<br>  − vinyl chloride monomers (13)<br>  − insecticides (particularly with copper sulphate) (113)<br>  − cytostatics (methotrexate, 6-mercaptopurine) (125)<br>  − immunostatic agents (azathioprine) (79)<br>  − cyanamide |
| 5. Myeloproliferative syndromes (28, 80) |
| 6. Collagenoses (26, 27, 58) |
| 7. Haemoblastoses (e.g. mastocytosis) |
| 8. Lymphoblastoses |
| 9. Wilson's disease |
| 10. Haemochromatosis |
| 11. Malignant diseases |
| 12. Liver adenoma |
| 13. Nodular regenerative hyperplasia (93, 112, 133, 153) |
| 14. Partial nodular transformation (126, 152) |
| 15. Idiopathic (non-cirrhotic) presinusoidal block (54, 154) |

**Tab. 14.3:** Causes of elevated presinusoidal resistance in intrahepatic portal hypertension (with some references)

Various infectious, toxic or immunological lesions lead to a presinusoidal block in adults. From a primary endothelial lesion, endophlebitis ensues. Rich in fibres and deficient in cells, it is ultimately responsible for the obliteration and even disappearance of the portal branches. • *Obliterative portal venopathy* (N.C. NAYAK et al., 1969) with portal and periportal fibrosis and subsequent perisinusoidal sclerosis is referred to as *hepatoportal sclerosis* (W. P. MIKKELSEN et al., 1965). This is a complex disorder involving splenomegaly, hypersplenism and portal hypertension, which has also been described as non-cirrhotic portal fibrosis (J.L. BOYER et al., 1967) or idiopathic portal hypertension (K. OKUDA et al., 1982). (121, 127) *Banti's syndrome* (7) probably fell into this group;

this is, however, now an obsolete term. The WHVP and flow rates are normal and liver function is not affected. Cirrhosis may develop in cases of prolonged illness.

*Thrombosis of small portal veins* due to bacterial cholangitis with pericholangitis or to malignant and subsequently thrombotic processes can cause an increase in presinusoidal resistance.

Even in the early stage of *primary biliary cholangitis,* immunological or scar-related atrophy of the small portal veins is evident. (78) • In *primary sclerosing cholangitis*, these changes are only manifested once cirrhotic transformation has set in. (s. tab. 14.3)

The most common cause of presinusoidal hypertension throughout the world is *schistosomiasis*. The eggs of the parasite are washed "embolically" into the portal veins. Thus portal hypertension is induced, whereby the increase in pressure correlates with the quantity of obstructing eggs. The WHVP is normal. In addition, a granulomatous foreign-body reaction takes place with immunologically induced eosinophilic infiltrations. This leads to pronounced portal-periportal fibrosis, in which the periportal triangles are distended with nodules and scars and incorporate the axis of the Rappaport acini (so-called "pipe-stem fibrosis"). (30, 116) (s. p. 497) (s. fig. 25.13)

Both *liver adenomas* and *nodular regenerative hyperplasia* can cause a presinusoidal block due to distortion of the portal veins. • *Wilson's disease* leads to an overlapping of presinusoidal and sinusoidal portal hypertension. • In *alcoholic cirrhosis*, there is an overlap of the sinusoidal and postsinusoidal forms.

### 3.2.2 Sinusoidal block

▶ The sinusoidal block can be attributed to a number of *pathogenic mechanisms*: (*1.*) compression of the sinusoids via hepatocellular storage of substances (e.g. steatosis), (*2.*) prolonged action of hepatotoxins with increasing collagen formation and fibrosis, (*3.*) disturbed passage in Disse's space (e.g. as a result of oedema), (*4.*) storage processes in the sinusoidal cells, (*5.*) influence of vaso-active substances on the sinusoids, and (*6.*) compression of the sinusoids by the formation of nodules. The increase in resistance is thus always due to a constriction or reduction of the sinusoidal vessels. The sinusoidal block is the most common cause of portal hypertension. It is ascribed to intrahepatic parenchymal hypertension of the portal vein. Hepatomegaly can be demonstrated in nearly every case. (s. tabs. 14.1, 14.4, 14.9) (s. figs. 14.4, 14.5)

**Alcohol:** With regard to hepatotoxins, by far the greatest importance must be attributed to alcohol. The development of alcohol-mediated portal hypertension is complex. The increasing accumulation of fat in the hepatic cells interferes with the microcirculation, since the sinusoids become both longer and narrower as a result of fatty degeneration of the hepatocytes. In cases of fatty liver, a greater microcirculation is observed in the arterioles at the same time. Stimulation of the Ito cells is an important pathogenic

factor; it induces collagenization of the perisinusoidal reticular fibres. Scar areas develop around the central veins, with perivenous sclerosis and ultimately even further obliteration of these vessels.

| Sinusoidal block |
| --- |

Storage of substances<br>  – fatty liver<br>  – acute fatty liver in pregnancy<br>  – amyloidosis (161)<br>  – glycogenosis type III (85)<br>  – Gaucher's disease<br>  – Niemann-Pick disease (136)<br>  – $\alpha_1$-antitrypsin deficiency<br>2. Hepatotoxins<br>  – alcoholic hepatitis<br>  – vitamin A (119)<br>  – vinyl chloride, methotrexate<br>3. Severe parenchymal loss<br>  – acute viral hepatitis (145)<br>  – acute liver failure (96)<br>  – malaria<br>4. Peliosis hepatitis<br>5. Chronic hepatitis (74)<br>6. Regenerative nodes in cirrhosis<br>7. Formation of nodes<br>8. Cirrhosis |

*Tab. 14.4:* Causes of a sinusoidal block in intrahepatic portal hypertension (with some references)

**Vitamin A intoxication:** Prolonged and marked vitamin A intoxication leads to a substantial increase in individual Ito cells. This in turn causes constriction of the sinusoids; the accompanying fatty degeneration of the hepatic cells supports this obstructive effect. The Ito cells are responsible for perisinusoidal fibrosis. The liver surface is strikingly smooth despite marked portal hypertension (often with considerable oesophageal varices). (119) (s. figs. 14.2, 14.3)

*Fig. 14.2:* Slight lobular inflammation. Periportal/perisinusoidal delicate fibrosis as a result of chronic vitamin A intoxication (same patient as in fig. 14.3) (Ladewig)

**Cirrhosis:** Irrespective of its aetiopathogenesis, cirrhosis always leads to portal hypertension. In addition to the principal sinusoidal factors, it is also affected by presinusoidal mechanisms. In some cases, it is not always possible to assess the pathogenic significance of individual factors. The real cause of portal hypertension lies within the sinusoids. Because of the cirrhotic conversion of the liver and the regeneration of nodes, the portal veins are nearly always compressed, allowing hypertension to build up due to the vascular resistance. The sinusoids, thereby stiffened, trigger phlebectasia in their immediate vicinity, and a compensatory increased

afferent arterial flow is produced. This can be detected due to muscular hyperplasia of the small arteries and the occurrence of shunts between the small arteries and portal veins.

*Fig. 14.3:* "Smooth" cirrhosis with smooth surface and portal hypertension resulting from chronic vitamin A intoxication (same patient as in fig. 14.2)

### 3.2.3 Postsinusoidal block

▶ The postsinusoidal block is due to increased resistance in the hepatic veins and venules beyond the sinusoids. This block form is attributed to parenchymatous portal hypertension. (s. tabs. 14.1, 14.5, 14.9) (s. figs. 14.4, 14.5)

| Postsinusoidal block |

Alcoholic hepatitis<br>  Alcoholic central hyaline sclerosis<br>4. Partial nodular transformation of the liver (126, 152) |

*Tab. 14.5:* Causes of a postsinusoidal block in intrahepatic portal hypertension (with some references)

**Liver cirrhosis** is the most common cause of postsinusoidal portal hypertension. The greater resistance in this vascular zone is predominantly due to the expansive pressure caused by regenerative nodes on the small vein branches. An additional pathogenic factor is the elevated arterial blood flow to the liver. There is increasing evidence of arterioportal anastomoses. The arterial component of blood flowing to the liver can be raised by up to 80%. The blood flow from the splanchnic area is also higher. The internal pressure in the spleen and the WHVP rises in accordance with the respective stage of cirrhosis. Infiltration of portal fields, portal/periportal fibrosis and fibrous septa in cirrhosis leads to constriction and rarefaction of

the portal venules and thus culminates in a presinusoidal block. For this reason, after the positioning of a portacaval shunt, the WHVP is hardly (if at all) reduced. It is possible to ascertain the respective extent of a presinusoidal block by way of the splenosinusoidal pressure gradient.

**Budd-Chiari syndrome** is the term used for the clinical picture resulting from the occlusion of the hepatic veins. This occlusion may be acute or chronic, total or partial. Thrombosis of hepatic veins was first described in 1845 by G. Budd. In 1899 H. Chiari compiled all previously recorded observations and categorized them as an independent pathological entity. There are numerous causes: congenital anomalies of the hepatic veins, inflammatory diseases of the hepatic veins, localized or diffuse liver diseases, extrahepatic pathological processes, traumas, haematological or malignant diseases, pregnancy, myeloproliferative processes, etc. (s. p. 830)

**Veno-occlusive disease** (VOD) describes the occlusion of small hepatic veins and is defined as a *radicular form* of the Budd-Chiari syndrome. A variety of endotheliotoxic noxae, particularly phytotoxins, are responsible for this clinical picture. In 1951 reports were simultaneously published for the first time both in South Africa (G. Selzer et al.) and Jamaica (K. R. Hill) dealing with this disease of the small venous branches, which results from chronic intoxication with pyrrolizidine alkaloids. (s. pp 548, 571) Similar morphological and clinical effects can also be caused by cytostatic agents (6-mercaptopurine, dacarbazine, thioguanine), azathioprine, contraceptives and exposure to X-rays. Since 1957, the term *Stuart-Bras syndrome* has also been used to describe the occlusion of the small hepatic veins. (s. p. 832)

**Obliterative hepatic endophlebitis** is also referred to as *Chiari's disease* and can be distinguished from the Budd-Chiari syndrome as its *truncal form*. It presents as primary, independent phlebitis of the large hepatic veins with secondary thrombosis. (s. tab. 14.5) In Chiari's disease, the hepatic veins are affected to differing degrees and at differing stages; this characterizes the clinical picture. Possible causes are rheumatic or paraneoplastic diseases and disorders of the immune system. Total occlusion of the hepatic veins has a dismal prognosis. Partial occlusion results in portal hypertension with hepatosplenomegaly, ascites and oesophageal varices.

**Alcoholic hepatitis** also leads to a postsinusoidal block following the deposition of alcoholic hyaline in the centrilobular zone, with perivenous fibrosis and subsequent occlusion of the small veins.

### 3.3 Posthepatic portal hypertension

In posthepatic portal hypertension (prevalence about 5%), the flow hindrance is in the region of the inferior vena cava or the right heart. Extrahepatic processes impede the efferent flow of venous blood from the hepatic veins. Parenchymatous portal venous hypertension develops with a simultaneous elevation of pressure in the femoral vein. Liver findings correspond to the truncal form of the Budd-Chiari syndrome. (s. tabs. 14.6, 14.9) (s. figs. 14.4, 14.5)

| **Heart** |
|---|
| 1. Right heart insufficiency |
| 2. Constrictive pericarditis |
| 3. Tricuspid valve incompetence |
| 4. Idiopathic dilative cardiomyopathy |

| 3. Thrombosis |
| 4. Tumours |
| 5. Nephrotic syndrome |
| 6. Polycythaemia vera |

| **Hepatic veins** | |
|---|---|
| 1. Anomaly | 3. Tumours |
| 2. Chiari's disease | 4. Amoebic abscess |

***Tab. 14.6:*** Causes of posthepatic portal hypertension

The most frequent **cause** of posthepatic portal hypertension is *right ventricular insufficiency*. The central venous pressure is transferred to the hepatic veins and the sinusoids. • *Constrictive pericarditis* leads to a state of pronounced posthepatic portal hypertension with the early development of ascites. • Severe *tricuspid valve incompetence* also culminates in this condition. • A *membranous obstruction* of the inferior vena cava was likewise described in 1968 as a genetically determined cause of posthepatic portal hypertension (S. Yamamoto et al.). Three variants can be distinguished by angiography, depending on the different ways in which the hepatic veins are involved or whether they are affected at all. • *Thrombosis* of the inferior vena cava can develop either from thrombosis of the pelvic veins or independently in the presence of predisposing factors.

## 4 Diagnosis

Hypertension of the portal vein, with its numerous intrinsic or acquired causes, may not display any symptoms for several years. Portal hypertension itself is very often a concomitant symptom in a number of liver diseases. (65) It can lead to severe or even fatal complications. For this reason, hepatological investigation frequently needs to explore (*1.*) the presence of portal hypertension, (*2.*) its aetiology, (*3.*) its severity, and (*4.*) potentially successful treatment of the underlying causes − in order to produce a favourable effect on portal hypertension. (22, 23, 33, 37, 38, 69, 158)

### 4.1 Anamnesis

Specific investigation of the patient's medical history can provide evidence of existing portal hypertension.

The main *anamnestic details* given by the patient are related to various targeted questions:

| Anamnestic details |
| --- |
| − existence of a liver disease<br>− existence of extrahepatic diseases<br>− alcohol abuse, medication<br>− consumption of tea containing alkaloids<br>− tarry stools, haematemesis, bleeding tendency<br>− thrombophilia<br>− visits to tropical regions (e. g. malaria)<br>− oedema, abdominal pain |

## 4.2 Clinical findings

In the physical examination, particular attention should be paid to a number of *clinical findings*:

| Clinical findings |
| --- |
| Hepatomegaly or atrophic liver cirrhosis, splenomegaly, skin stigmata of liver diseases, anorectal varices, oedema or ascites, epigastric pulsation, congested neck veins, venous patterns on the surface of the abdomen, and vessel sounds (e. g. venous hum, "machinery" murmur). |

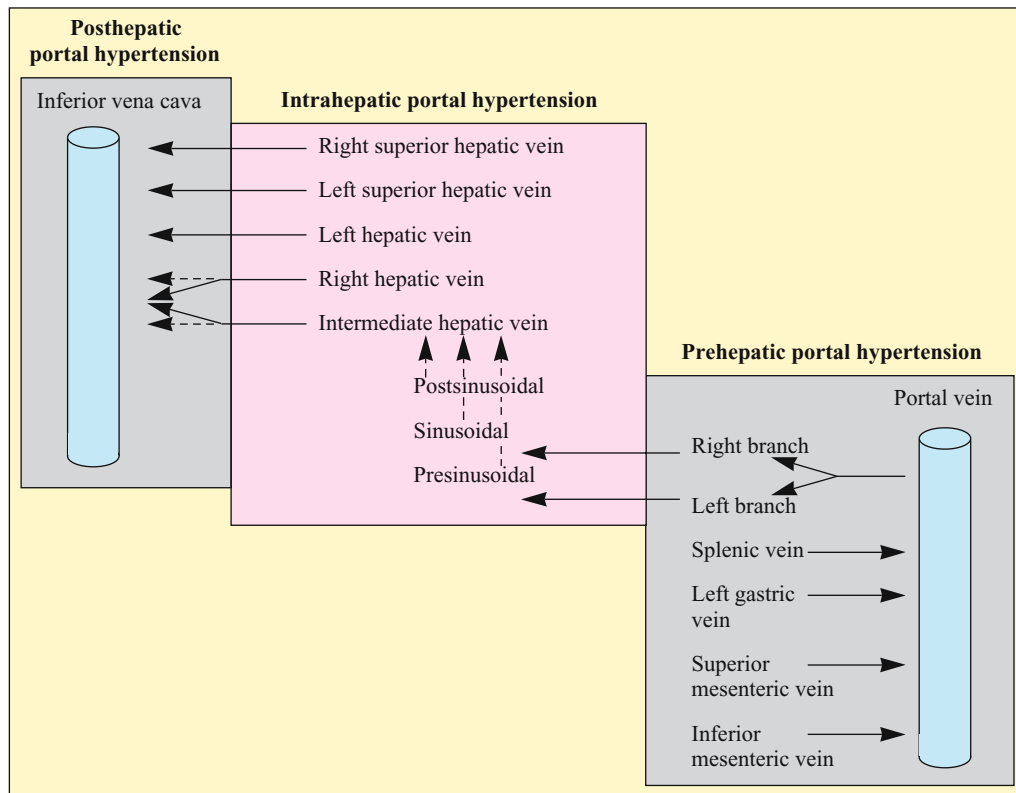

*Fig. 14.4:* Anatomical systematics of portal hypertension

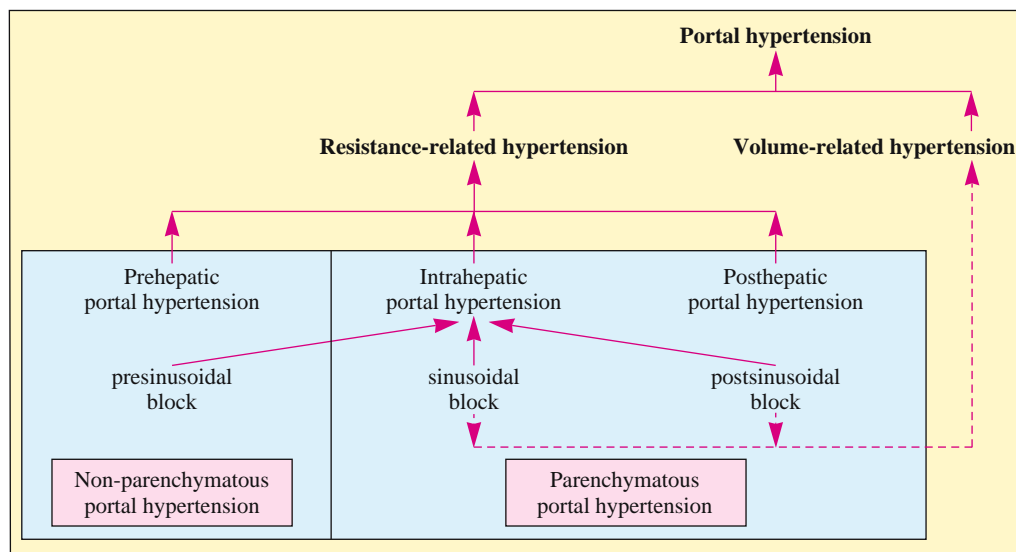

*Fig. 14.5:* Forms, localization and systematics of portal hypertension (resistance-related and volume-related hypertension can occur either as primary or secondary forms)

## 4.3 Laboratory findings

Laboratory parameters are not suitable for detecting portal hypertension. Only *thrombopenia* ($<100,000/$mm$^3$) can be taken as evidence of a splenomegaly due to portal hypertension; decreased *haemoglobin values* can be seen as a sign of a continuous loss of blood. Testing for *occult blood* in faeces is obligatory when portal hypertension is suspected. Elevated *ammonia values* hint at an existing shunt circulation. *Cholinesterase* provides more information on the functioning of the liver, hence facilitating a prognosis.

## 4.4 Sonography

Sonography provides a reliable means of detecting splenomegaly, which is often, but not always present with portal hypertension. Normal spleen findings generally rule out this condition. The sonographically based suspicion of a particular liver disease should at the same time draw attention to the possible existence of portal hypertension. Nevertheless, diagnosis should not simply be founded on the diameter of the portal vein, since the values obtained from healthy subjects and from patients with portal hypertension overlap. Studies showed that the blood flow sometimes slows down even when the portal vein is normal. Furthermore, the diameter of the portal vein (and also of the splenic vein) depends on the capacity of existing collaterals. (46, 61, 84, 94, 124, 150, 158) (s. tab. 14.7)

- Splenomegaly ($>4 \times 7 \times 11$ cm) (s. p. 135)
- Dilation of the portal vein ($>13$ mm)
- Dilation of the splenic vein ($>10$ mm)
- Dilation of the ventricular coronary vein ($>6$ mm)
- Restricted respiratory modulation of the vascular width of up to 3 mm (increase on inspiration and decrease on exspiration) regarding the portal vein and more particularly the splenic vein and the superior mesenteric vein. • Decrease in width of the lumen by more than 50% on exhalation = absence of portal hypertension
- Jump in calibre of the portal vein
- Reversal of flow in portal vessels
- Stasis of the gall bladder and gastric walls
- Visible evidence of collaterals
- Recanalization of the umbilical vein (s. fig. 6.7)
- Cavernous transformation of the portal vein

*Tab. 14.7:* Sonographic criteria in portal hypertension

**Vaginal sonography** revealed rectal varices in about 50% of cases and pararectal varices in about 80%. The varices had a diameter of $2.1-5.5$ mm. (83)

**Endoscopic sonography** is ideally suited for displaying intramural and perimural oesophageal varices. (134) (s. fig. 19.6) Endoscopic colour Doppler sonography is

another promising procedure, particularly for demonstrating a (still) evident variceal perfusion.

## 4.5 Doppler sonography

Valuable information on the haemodynamics in the portal vein system can be obtained with the aid of pulsed or colour-encoded Doppler sonography − predominantly by using a transducer with 3.5 MHz. • With this method, all forms of portal hypertension can also be classified and quantified in terms of severity. • A marked deceleration of the portal flow ($<10$ cm/sec) together with evidence of portosystemic collateral vessels as well as a reversal of the portal blood flow (= hepatopetal to hepatofugal), which may also occur in the splenic vein, demonstrate a severe impediment in flow capacity. In the case of portal hypertension, a hepatofugal portal flow can be witnessed in $6-10\%$ of patients. A dilation of the left gastric vein of $>6$ mm points to the presence of oesophageal varices, since this vein is the main collateral vessel in such cases; evidence of high hepatofugal flow (more than 15 cm/sec) represents a distinct risk of variceal bleeding. (s. p. 137)

The **Doppler effect** is produced by changes in wavelength due to the reflection of sound on moving particles (e. g. erythrocytes). Consequently, the *direction of flow* (away from or towards the sound source) as well as the *flow rate* in arterial and venous vessels can be determined. The *flow volume* is then calculated by additional sonographic measurement of the vessel diameter. It has been shown that the rate of flow is clearly dependent upon the respiratory activity, so that an increase in blood flow velocity can be determined with maximum exspiration as well as postprandially (normal value: $18-30$ cm/sec). (14, 19, 32, 34, 42, 77, 91, 162)

Fibrous transformation in the structure of the liver leads to a **change in hepatic haemodynamics.** Stenosis in the region of the hepatic veins can be recognized by an increased flow rate. Yet, even in cases of marked liver fibrosis or cirrhosis, the *hepatopetal flow in the portal vein* may only be slightly lowered or even normal owing to the dilation of the portal vessels and the formation of collaterals. In cirrhosis, the arterial flow is greater than the portal flow, the rate of which is about 30% lower than in healthy persons. The relative *change (in %)* following stimulation by a ***standard test meal*** provides a more exact diagnosis of portal hypertension. Postprandial flow, due to digestive hyperaemia, may reach 40 cm/sec. (73, 77) In the case of a distinct reduction in the flow rate, the flow direction may be reversed (= *hepatopetal to hepatofugal*). Blood flow in the portal venous system is normally hepatopetal as opposed to pulsatile (or only slightly pulsatile) and follows an increased exspiration flow rate. • Undulating blood flow when inhaling (= hepatopetal) and exhaling (= hepatofugal) is evidence of portal hypertension. (10, 87, 99)

**Congestion index (CI):** This parameter is the most reliable indicator of portal hypertension. It relates the portal cross-sectional area to the portal blood flow rate. The CI ranks higher than the direct pressure level in the diagnostics of the portal system and the HVPG. These three techniques (in this order) are considered to be the *gold standard* in early diagnosis of portal hypertension. CI levels of $>0.1$ are associated with excessive portal pressure with $>95\%$ sensitivity and specificity. (92) Sonographic imaging of *cavernous transformation* in the portal vein usually shows beaded varicose collaterals in the hepatoduodenal ligament.

## 4.6 Endoscopy

▶ **Oesophagogastroscopy** is considered to be the diagnostic procedure of choice for the detection of oesophageal or gastric varices. This examination should always be extended to the antrum and the duodenum, since varices can also occur there. Endoscopy allows the detection of oesophageal varicosis at an early stage of development. It also enables an assessment to be made of the size and preferred localization of the varices as well as imaging the surface of these veins, where red spots or stripes can often be found. Blackish-brown spots are due to intramucosal haemorrhage. (s. p. 255) With the aid of gastroscopy, it is also possible to identify *erosive gastropathy* caused by portal hypertension. (s. p. 257) In combination with **coloscopy,** examination initially focuses on the presence of anorectal varices. Endoscopy of the colon frequently reveals the presence of erosive colopathy with mucosal findings similar to those in the stomach. In rare cases, colonic varices are also found. (s. p. 256)

**Laparoscopy** permits the very early detection of portal hypertension due to the dilation and meandering of the fine peritoneal, intestinal or gastric vessels. (101) (s. p. 155) (s. figs. 7.5; 14.6, 14.11, 14.12; 16.9)

*Fig. 14.6:* Dilation and meandering of the fine peritoneal vessels at the initial stage of portal hypertension

## 4.7 Angiography

**Splenoportographic procedures** allow an accurate depiction of the portal vein and its afferent flow areas. Despite the development of new techniques, these methods are of importance in clarifying the cause of portal hypertension, and they are (still) deemed to be a prerequisite for operations aimed at reducing the pressure and volume in the portal venous circulation. Vessels with a diameter of <1 cm are unsuitable for long-term patency of a shunt. Direct and indirect procedures are available. (16, 35)

In the light of a possible shunt operation, it has become more important to obtain additional information on the arterial blood supply to the liver. As regards cirrhosis with portal hypertension, **arteriographic investigations** have shown that the more the blood flow through the liver increases, the more the portal blood flow is reduced. Thus the blood flow relationship through the liver can become almost completely reversed: as little as 20% via the portal vein and as much as 80% via the hepatic arteries. Evidence of haemodynamically active stenosis in the arteries supplying the liver therefore constitutes a contraindication for shunt operations.

**Direct splenoportography** is the most informative procedure for visualizing the portal vein system and its collaterals. (s. p. 181) Yet this technique is costly, time-consuming and high-risk. The injection of contrast medium into the spleen is carried out either percutaneously (sonography-guided) or, preferably, by laparoscopy. It is also possible to *measure the pressure* in the portal vein system. In addition, this method ensures access to the collaterals if *radiological obliteration* is planned. (s. p. 181)

**Indirect splenoportography** via the femoral artery is not only very important, but also low-risk. (s. p. 182) Using radiography, the arterial branches of the abdominal aorta initially become visible, followed by the spleen, the splenic vein and the portal vein together with its afferent veins and collaterals. This procedure provides **information** on: (*1.*) localization of vascular resistance-related hypertension, (*2.*) cause of portal hypertension (in individual cases), (*3.*) patency and diameter of the respective vessel, (*4.*) extent of collateral circulation, (*5.*) hepatopetal or hepatofugal direction of flow in the portal vein, and (*6.*) shunt capacity of the splenic vein or superior mesenteric vein. (s. p. 182)

**Hepatic vein phlebography** via the femoral vein and the inferior vena cava facilitates visualization of the hepatic veins; it is technically simple, practically risk-free and puts little strain on the patient.

**Other procedures** that can be applied are indirect mesentericoportography, transjugular or transhepatic splenoportography, umbilical portography (s. p. 182) and scintigraphic splenoportography.

## 4.8 CT and MRI

Additional examination with CT or spiral CT may be necessary with respect to certain diagnostic questions (e. g. retroperitoneal space, CT portography). This also applies to MRI (e. g. in pronounced obesity or meteorism). Thus MRI angiography is a valuable additional diagnostic procedure. (63, 86, 137, 151)

## 4.9 Carbon dioxide wedged venography

Injection of carbon dioxide into a catheter in the wedged hepatic venous position facilitates excellent venography of the hepatic venous and portal venous tree. (25)

## 4.10 Portal pressure measurement

**Vein-occlusion pressure:** It is possible to measure the vein-occlusion pressure by inserting a measuring catheter through the cubital or jugular vein into a hepatic vein. Measurement can be made as free hepatic venous pressure (FHVP), whereby hepatic venous blood flows around the measuring catheter, or as wedged hepatic venous pressure (WHVP), whereby occlusion of the hepatic vein is achieved by inserting the measuring catheter into a branch of the hepatic vein or by inflating the measuring catheter balloon. The WHVP correlates closely with the portal vein pressure. Its normal value is 7−12 mm Hg. • The FHVP corresponds to the intra-abdominal pressure, which is normally 3−11 mm Hg.

**Hepatovenous pressure gradient:** The difference between WHVP and FHVP is used to calculate the hepatovenous pressure gradient (HVPG). This is equivalent to the portal (= sinusoidal) venous pressure. The pressure difference between the portal vein and the inferior vena cava is 1−4 mm Hg. Pressure levels of ≥8 mm Hg result in the formation of collateral vessels or ascites. At 12 mm Hg and higher, bleeding of the oesophageal varices occurs. The HVPG can be an important prognostic factor in terms of survival in patients with bleeding oesophageal varices. (108, 157, 158) The examination can be carried out on an outpatient basis; this takes about 15 minutes, whereby the length of exposure to radiation is <2 minutes. Accordingly, it is possible to carry out follow-ups over a number of years. Normal WHVP values are 4−8 mm Hg. In cases of intrahepatic portal hypertension, particularly with liver cirrhosis, the WHVP corresponds to the directly measured portal venous pressure. In the case of a prehepatic and presinusoidal block, the WHVP is normal. Posthepatic portal hypertension displays increased hepatic venous pressure. (90, 108, 157, 158) (s. tab. 14.9)

# 5  Sequelae of portal hypertension

The **clinical picture** of portal hypertension can vary greatly, since it is either characterized by the respective underlying disease or the symptomatology of the latter is still prevalent. • Irrespective of their aetiology and pathogenesis, all forms of long-standing portal hypertension generally lead to the same **sequelae,** albeit of differing intensity. (s. tab. 14.8)

| **Morphological sequelae** |
| :-- |
| 1. Splenomegaly |
| 2. Portacaval collateral circulation |
| 3. Formation of hepatic lymphocysts |
| 4. Portal hypertensive intestinal vasculopathy |
| − portal hypertensive gastropathy |
| − portal hypertensive colonopathy |
| **Haemodynamic sequelae** |
| 1. Elevated cardiac output |
| 2. Lowered peripheral resistance |
| 3. Elevated heart rate |
| 4. Lowered arterial blood pressure |
| **Pathophysiological sequelae** |
| 1. Reduced detoxification of noxae |
| 2. Impaired biotransformation |
| 3. Coagulation disorders |
| 4. Hepatopulmonary syndrome |
| 5. Endocrine and metabolic disorders |
| 6. Disposition to bacterial infections |
| 7. Insufficiency of lymph drainage |
| 8. Ascites |

*Tab. 14.8:* Characteristic morphological, haemodynamic and pathophysiological sequelae of portal hypertension

Depending on the localization of the portal resistance, differing portal and hepatic **pressure values** and clinical findings are obtained for the five forms of portal hypertension. In this way, it is possible to gain more information for differential diagnosis. (s. tab. 14.9)

## 5.1  Splenomegaly

Splenomegaly following portal haemostasis (s. fig. 14.7) leads to increased haemolysis as well as leukopenia and thrombopenia. The last two conditions can also result from the sequestration of blood in the enlarged spleen or from an inhibited function of the bone marrow. Generally, these haematological findings only normalize in about 25% of cases following splenectomy or a shunt operation. It should be noted that a normal-sized spleen does not exclude portal hypertension. (41) There is no close correlation between the severity of portal hypertension and the size of the spleen. Morphological analysis reveals a thickened capsule with a firm consistency and dark blood oozing from the surface. An increase in fibres mainly affecting the sinus walls is the principal morphological manifestation. Sinusoids are dilated and lined with thickened epithelium. In addition to this fibroadenia, hyperplasia of the RES ensues. Haemorrhages often develop adjacent to arterioles of a Malpighian corpuscle. Splenic infarction occurs frequently. (s. fig. 35.10) Prolonged portal hypertension sometimes leads to the formation of **Gamna-Gandy nodules.** These are brown-yellow, siderin-laden fibrous nodules within the sinus, apparently caused by microhaemorrhaging. *(see chapter 11)*

*Fig. 14.7:* Splenic tumour in portal hypertension following posthepatitic liver cirrhosis

## 5.2  Portacaval collateral circulation

Portacaval collaterals represent the final stage of pressure-induced changes to the portal vessels. Initial *dilation* of the small portal vein branches is followed by the development of *meandering vessels*. This produces a compensating gain in vascular volume. In the long term, however, the thin-walled portal vessels are unable to withstand the elevated portal venous pressure. As a result, portacaval anastomoses form, which ultimately culminate in *varices* and frequently also in extensive *collateral circulation*. In addition to this, the portal vein itself occasionally develops different degrees of ectasia.

| Forms | Portal pressure | WHVP | Spleno-megaly | Oesophageal varices | Ascites |
|---|---|---|---|---|---|
| 1. **Prehepatic portal hypertension** | ↑ | N | + + | + + | ∅, (+) |
| 2. **Intrahepatic portal hypertension** • presinusoidal • sinusoidal • postsinusoidal | ↑ ↑ ↑↑ | N ↑ ↑↑ | + + + + + | + + + + + + + + | (+) + + + + + + |
| 3. **Posthepatic portal hypertension** | ↑ | ↑ | + | + + | + + |

**Tab. 14.9:** Haemodynamic and clinical findings in the 5 localized forms of portal hypertension (elevated hepatovenous pressure gradient = >9 mm Hg; increased risk of oesophageal varix bleeding = >12 mm Hg) (N = normal; ∅ = not present)

However, this reaction is generally accompanied by fibrosis and increased elasticity of the vessel wall. Portal hypertension leads to the dilation and reopening of veins which connect the portal vein system to the superior or inferior vena cava. Hence collateral circulation develops in the region of the oesophagus and gastric fundus as well as in the intestinal tract, retroperitoneum, lungs, spleen and kidneys, and at the anterior abdominal wall. (s. p. 253) (s. tab. 14.10) (s. figs. 7.5; 14.11, 14.12; 16.9)

---

**Cranially draining collaterals**
1. coronary gastric vein → azygous vein → short gastric veins → azygous vein
2. paraumbilical
3. portocoronary
4. portorenal
5. veins of Glisson's capsule, splenic capsule and diaphragm

**Caudally draining collaterals**
1. paraumbilical
2. gastrolienal
3. splenorenal
4. superior and inferior mesenteric veins → Retzius veins → ovarian/spermatic vein → haemorrhoidal venous plexus

---

**Tab. 14.10:** Possible formation of portacaval collaterals

### 5.2.1 Oesophageal and gastric varices

The collateral circulation described by H. EPPINGER (1937) leading to the formation of oesophageal and fundic varices is still valid. (s. fig. 14.8) The hepatofugal blood flow of the portal vein passes through the coronary gastric vein to the perioesophageal venous plexus, which can form varices of the fornix or fundus. The blood is transported to the submucosal venous complex in the lower oesophagus. There are collaterals to the spleen via the short gastric veins. Anastomoses lead from the lower third of the oesophagus to the azygous and hemiazygous vein. In the central third of the oesophagus, a varicose venous plexus is formed due to stasis of the hepatopetal blood flow. From here, anastomoses run to the pericardial and intercostal veins as well as to the superior mediastinal and the diaphragmatic veins. These vessels conduct the blood to the azygous and hemiazygous veins, draining the entire blood flow into the superior vena cava.

At the junction between the central and upper third of the oesophagus, the oesophageal varices disappear. This is a result of the balance of pressure with the right atrium created by the azygous vein. In line with the caudocranial blood flow, these oesophageal varices are also referred to as **"uphill" varices** (V. BUCHTALA, 1950) or as *type I varices*. The *pressure in the oesophageal varices* is temporarily raised by the ingestion of food and by an intra-abdominal increase in pressure (e.g. coughing, straining, lifting heavy loads). However, the pressure in the oesophageal varices is not raised in the head-down position. (40, 117, 123, 132)

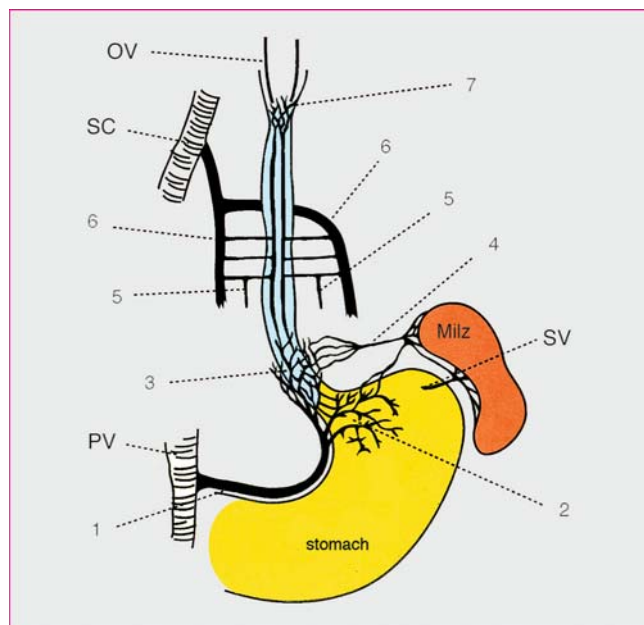

**Fig. 14.8:** Diagram showing the formation of oesophageal varices in portal hypertension (modified from H. EPPINGER, 1937) • OV = oesophageal veins; SC = superior vena cava; SV = splenic vein; PV = portal vein; 1 = coronary gastric vein; 2 = perioesophageal venous plexus; 3 = submucous venous complex in the lower oesophagus; 4 = short gastric veins; 5 = hemiazygous vein; 6 = azygous vein; 7 = venous plexus of the central oesophagus

**Oesophageal variceal pressure:** The size of the oesophageal varices does not correlate with the magnitude of the portal venous pressure, but it does correlate with the oesophageal variceal pressure. This measurement is defined as the difference in pressure between the oesophageal lumen and the varix lumen. Measuring is done by fine-needle aspiration of a varix and the use of an extracorporeal pressure recorder. The procedure is technically simple and reliable;

it does not precipitate bleeding. Intravariceal pressure levels are a key factor in predicting variceal bleeding. (98) Measuring by way of a pressure sensor applied directly only yields valid results with large varices.

The **frequency,** localization and severity of oesophageal varices determine the life span of patients with portal hypertension. Oesophageal varices can be detected in about 80% of patients (i.e. some 20% of patients surprisingly do not present varices). In 90−95% of cases, the varices are located in the lower and central thirds of the oesophagus. The simultaneous occurrence of gastric fundic varices is only observed in 5−10% of patients. *Regression* of oesophageal varices (e.g. after alcohol abstinence) may occur.

The **radiographic detection** or **monitoring** of oesophageal varices using contrast medium is only carried out in rare cases (after immobilizing the oesophagus by medication). When this procedure is applied, the areas of the cardiac and fornix fundus should be carefully examined. (s. fig. 14.9)

The best method of detection is **oesophagogastroscopy.** (s. fig. 14.10) Localization, extent and severity of varices can be reliably determined with this method. (42, 130) The literature features a number of **staging schemes,** most of which have been developed empirically. (quot. 130) The main assessment *criteria* (with differing degrees of emphasis) are: length extension, vessel diameter, variations in diameter, number and colour of varices, mucosal changes (red spots, folding). Three-dimensional venous imaging (luminal prominence, length extension, diameter) can also be carried out. According to a well-accepted classification (1988), the criterion for stage I is defined as the possibility of depressing and squeezing out the varices, while stage II is characterized by the absence of this possibility. The circular enlargement of varices is defined as stage III. (s. tab. 19.6)

▶ **Downhill varices:** The so-called downhill varices (B. Felson et al., 1964), which only occur in the proximal third of the oesophagus, are of both diagnostic and clinical significance. They were first described by M. Israelsky and H. Simchowitz in 1932. These varices do not result from portal hypertension, but are due to an elevation of pressure in the superior vena cava. This leads to a craniocaudal "downhill" blood flow. If there is an obstruction of the superior vena cava and/or the azygous vein, the blood flows from the head, neck and mediastinal region via the inferior thyroid vein and the mediastinal collateral veins into the oesophageal veins and then via the coronary gastric veins (hepatopetally) into the portal vein (= *type II*). Causal factors are goitre or recurrent goitre (45−60%), mediastinal fibrosis and malignant tumours with mediastinal lymph nodes (25−35%).

*Type IIa* is characterized by the patency of the azygous vein. Varices are only found in the upper third of the oesophagus. Retrosternal goitre has proved to be the

*Fig. 14.9:* Moderately dilated oesophagus with irregular surface. Numerous, differently sized filling defects as a result of varices

*Fig. 14.10:* Oesophagogastroscopy: pronounced varicosis (degree of severity III) in the lower third of the oesophagus

most frequent cause. A superior vena cava syndrome is generally not detectable. • *Type IIb* is produced by the additional occlusion of the azygous vein. The entire blood volume must now be redirected to the inferior vena cava. • Although downhill oesophageal varices mainly occur in the upper third section, they often spread over the entire oesophagus in relation to the severity of the neck vein distension and the duration of the pathological condition. They are generally very pronounced and hence represent a genuine differential diagnosis of oesophageal varices in portal hypertension. The vertebral venous plexus and the thoracic veins are also used for drainage of

the blood. • Bleeding from downhill oesophageal varices is rare, since (*1.*) there is a smaller blood volume with a lower pressure in the region of the superior vena cava, (*2.*) there is generally no coagulation disorder, and (*3.*) the mechanical burden in the upper oesophageal third is considerably lower. Bleeding is, however, quite possible in type IIb. • For this reason, *clarification of oesophageal varices* should always take into account the clinical picture of downhill oesophageal varices from the pathogenic and prognostic viewpoints. (29, 31)

### 5.2.2 Anorectal varices

Blood from the haemorrhoidal venous plexus passes via the azygous superior rectal vein into the inferior mesenteric vein and thereafter into the portal vein. By contrast, the paired middle rectal vein and inferior rectal vein discharge their blood via the iliac vein into the inferior vena cava. In portal hypertension, anorectal varices are found in the region of the rectum, the anal canal and the external anal region. • **Haemorrhoids** are distended and dislocated cavernous bodies in the rectum, which have no connection to the portal venous system. • Although haemorrhoids and anorectal varices are two different clinical pictures, it is quite possible for them to occur simultaneously. The frequency of anorectal varices (40−80%) is dependent upon the extent and duration of portal hypertension. The bleeding tendency is low (7−14%). However, there have also been reports of massive haemorrhages. (21, 45, 55, 66, 83, 105, 156) (s. tab. 14.10)

### 5.2.3 Intestinal varices

Varices occasionally occur in the stomach (122), duodenum (59, 148), small intestine, gall bladder (84) and colon (18, 45, 48, 63, 146) − excluding the transverse colon − as well as in the proximity of operative anastomoses or stomata. This generally involves collaterals between the branches of the inferior or superior mesenteric vein and small veins leading to the inferior vena cava. Colonic varices, which have not been detected endoscopically can be demonstrated by visceral angiography with a sensitivity of about 95%.

### 5.2.4 Abdominal wall varices

Pronounced anastomoses can develop between the mesenteric veins and the anterior abdominal wall. This is largely a result of spontaneous or postoperative adhesions (so-called *spontaneous Talma effect*). (s. figs. 7.4; 14.11) Reopening of the umbilical vein in the round ligament (s. fig. 14.12) causes anastomoses to form with the epigastric veins in the anterior abdominal wall. (101) This can occasionally result in **caput Medusae:** radial, bluish, tortuous vessels, which are sometimes slightly raised and sometimes nodally varicose, leading from the navel to the abdominal wall. Generally, however, only a few larger collateral vessels are detectable as opposed to a complete caput Medusae. (s. p. 87) (s. fig. 14.13)

**Fig. 14.11:** Postoperative adhesions in the region of the abdominal wall with "spontaneous Talma effect" resulting from portal hypertension

**Fig. 14.12:** Dilation and convolution of the small veins in the region of the round ligament (= teres) with recanalization of the umbilical vein resulting from portal hypertension (s. fig. 6.7)

**Fig. 14.13:** External caput Medusae in liver cirrhosis. • The thick paraumbilical vein (diameter 2 cm) is shown subcutaneously at the exit of the vessel from Glisson's capsule. The colour-encoded vessel with a varicose enlargement at the exit point of the paraumbilical vein from Glisson's capsule is visible immediately below the ventral layers of the abdominal wall

### 5.2.5 Retroperitoneal varices

There is a direct blood flow from the veins of the colon into the inferior vena cava via anastomoses with retroperitoneal veins.

### 5.2.6 Splenorenal varices

In about 5% of cases, blood passes through the short gastric veins to the splenic vein and then through other collateral veins to the left renal vein (= spontaneous splenorenal shunt).

### 5.2.7 Retzius' veins

Distally, the suprarenal veins and Retzius' veins provide a pathway into the inferior vena cava via the renal vein. The Retzius' veins act as anastomoses between the portal vein branches in the intestinal and mesenteric regions and the branches of the inferior vena cava. (57)

### 5.2.8 Sappey's veins

These veins are located between the surface of the liver or spleen and the diaphragm. They are used for collateral circulation. Drainage takes place into the inferior vena cava.

### 5.2.9 Bronchial varices

Tracheobronchial varices with haemoptysis in alcoholic cirrhosis with portal hypertension were reported for the first time in 1994. (160)

### 5.2.10 Biliary varices

Biliary varices are defined by means of endosonography as serpiginous, anechoic vascular channels in and/or surrounding the extrahepatic biliary ducts as well as the gall bladder. (36, 63, 106, 157) (s. p. 258)

### 5.2.11 Sublingual varices

Sublingual varices may be a rare source of expectorated blood in portal hypertension. (60)

## 5.3 Formation of hepatic lymphcysts

Particularly in intrahepatic portal hypertension, the portal vein system is relieved by an increase in hepatic lymph formation. The hepatic lymph flow is raised up to 7 ml/min (about 8 times the normal level), and the lymphatic pressure rises to 18 cm $H_2O$ (normal value 11.6 cm $H_2O$). The increase in lymphatic pressure leads to the formation of lymphcysts on the surface of the liver. Lymph, which is rich in albumin, is then able to drip from these lymphcysts into the abdominal cavity. (s. p. 291) (s. fig. 16.5)

## 5.4 Portal hypertensive vasculopathy

Endoscopic examination of the gastrointestinal tract often reveals erosion in the form of *portal hypertensive*

*intestinal vasculopathy.* (52, 147) These findings correlate with the degree of severity of portal hypertension. Intestinal erosion is generally the cause of a positive blood test in the faeces of patients with cirrhosis (= occult bleeding). In *portal hypertensive gastropathy* (frequency 20−30%), hyperaemic mucosa is in evidence due to dilation of the vessels and submucosal arteriovenous shunt formations. There is a mosaic-like pattern with small polygonal areas, surrounded by a whitish-yellow depressed border. Red marks (= lesions) signify a high risk of bleeding. These changes can usually be detected in the fundus, but may extend throughout the stomach. Hypoxaemia of the mucosa increases its susceptibility to aggressive elements. Numerous petechial lesions with punctiform deposits of haematinized blood are observed on the otherwise apparently intact gastric mucosa. (39, 114, 139) Levels of prostaglandin $E_2$ in the mucosa are reduced. (155) (s. fig. 14.14)

About 10% of patients with cirrhosis have ulcers that bleed, whereas in 20−25% of cases, bleeding is caused by portal hypertensive gastropathy. (3, 5, 24, 38, 49, 53, 109, 129, 141, 149) • Erosive vasculopathy can also be detected endoscopically in the region of the colon as *portal hypertensive colonopathy.* (11, 45, 67, 111, 135) Bleeding following vasculopathy of this kind requires local measures (e. g. laser), medication or shunting.

## 5.5 Pathophysiological sequelae

▶ Portosystemic collaterals can divert up to 80% of the portal vein blood away from the liver. This initially results in haemodynamic disorders with subsequent (multifactorial) *hyperdynamic splanchnic circulation.* More and more varices develop around the bypasses in various venous areas, primarily in the form of oesophageal varices. Damage to the mucous membrane in the stomach and in the colon takes the form of hypertensive

*Fig. 14.14:* Portal hypertensive gastropathy with linear and patch-shaped erosions

gastropathy/colopathy. Rechannelling of the umbilical vein leads to the Cruveilhier-von Baumgarten syndrome. (47) (s. tab. 14.8)

▶ A grave consequence of collateral circulation is the reduced detoxification of exogenously administered noxae or endogenously produced toxins. This can lead to the development of latent, or eventually manifest, *hepatic encephalopathy* or neuropathy as well as to additional toxically mediated liver damage, or even liver insufficiency. • *Impairment of biotransformation* may cause unpredictable changes in the pharmacokinetics of medicaments or indeed trigger adverse drug reactions and interactions. (s. p. 52)

▶ In addition to this, the occurrence of collateral circulation induces a protracted derangement of the numerous *RES functions*. (s. p. 65) As a result, the clearance capacities of activated coagulation products and inhibitors of the coagulation and fibrinolysis systems are reduced. Besides this, changes in the intrahepatic vascular architecture lead to a disorder of the portal microcirculation and trigger intravascular coagulation. (70) (s. p. 344) The increased RES activity results in hypergammaglobulinaemia and the subsequent inhibition of albumin synthesis. Inadequate elimination of endotoxins leads to endotoxinaemia with damage to the biological membranes, interference in hepatocellular metabolic processes, development of vasoactive substances, haemolysis, coagulopathy, etc.

▶ Portosystemic collaterals also divert *hormones* past their target organ, the liver, with the result that they do not fully develop their activity (e. g. insulin and glucagon) or are not broken down and eliminated (e. g. aldosterone and steroids).

▶ *Portopulmonary hypertension* (PPH) is defined as a secondary form of pulmonary hypertension in patients with portal hypertension. It is characterized by increased pulmonary vascular resistance in normal pulmonary capillary wedge pressure. Pulmonary hypertension typically features an anatomically fixed pulmonary vasoconstriction. The vascular changes depend on (*1.*) vasoconstriction, (*2.*) structural remodelling of the pulmonary arteries (fibroelastosis of the intima, hyperplasia of the media), and (*3.*) formation of microthrombi. Thus the histological changes are similar to those found in primary pulmonary hypertension. • Frequency of PPH in cirrhosis is $2-5\%$. Diagnosis is established using Doppler echocardiography and right heart catheterization. Prognosis is poor. In some patients, it was possible to improve the pulmonary blood flow by means of i.v. prostacyclin. (50, 112) *(see chapter 18)*

## 5.6 Portal biliopathy

Portal biliopathy as an entity was first described by S.K. SARIN et al. in 1992. This condition may be observed in portal hypertension, particularly in patients with extrahepatic portal vein obstruction. Such changes have also been reported, however, in a milder form in non-cirrhotic fibrosis, congenital hepatic fibrosis and cirrhosis.

The venous drainage of the common bile duct is guaranteed both by an paracholedochal Petren's venous plexus (T. PETREN, 1932; quot. 21) and a pericholedochal Saint's venous plexus (J.A. SAINT, 1961; quot. 21). The veins of these plexuses vary in size, but their diameter is usually no larger than 1 mm. • The development of portal hypertension leads to the opening of numerous collaterals. (s. pp 253−256) Likewise, the formation of varices in these plexuses may be observed. The first description of choledochal varices with subsequent compression of the common bile duct was given by A.H. HUNT in 1965. The same process causes collaterals around the gall bladder and the bile ducts.

The bile duct wall is thin and pliable, thus allowing protrusion of the varices into the lumen (a picture resembling oesophageal varices). This results in partial (and occasionally complete) bile duct obstruction, a condition which explains the usual clinical features: abdominal pain, recurrent fever, jaundice, increase of γGT and AP. It should be noted, however, that most patients are asymptomatic at onset and indeed for a long period after that. Development of choledocholithiasis is a frequent sequela. It is the cause of recurrent cholangitis and subsequently of secondary biliary cirrhosis. Therefore, in patients with portal hypertension who show signs of biliary obstruction (clinical, biochemical, sonographical, cholangiographical), portal biliopathy may well be suspected. Sonography and MR-cholangiography, if necessary ERC, are essential for establishing the diagnosis.

*Therapy*: Asymptomatic patients do not need any treatment. With symptomatic patients, it is important to use therapeutic strategies which are directed towards the predominant symptoms. These include removal of gallstones by means of sphincterotomy (beware of varices!), antibiotics, placement of a stent, cholagogue agents, TIPS and surgical techniques. (21, 36, 63, 106, 157)

# 6 Therapy

*The underlying cause of portal hypertension must first be found. Elimination of this cause (if possible) is even more important than treating the portal hypertension itself.*

## 6.1 Conservative therapy

In cases of acute thrombosis, *fibrinolytic therapy* may occasionally be necessary.

Both vasodilators and vasoconstrictors can be used in the medicinal therapy of portal hypertension. However,

the extensive literature available is limited almost exclusively to their use in treating oesophageal varix bleeding; less attention is paid to long-term therapy with the objective of lowering portal hypertension. The combination of β-blockers with, for example, nitrovasodilators, α-adrenergic antagonists or spironolactone leads to an additional decrease in the portal venous pressure. (6, 15, 22, 38, 69, 128, 163) (s. tab. 14.11)

| | |
|---|---|
| Clonidine | = α$_2$-adrenergic agonist |
| Isosorbide dinitrate | = nitrovasodilator |
| Isosorbide-5-mononitrate | = nitrovasodilator |
| Molsidomine | = nitrovasodilator |
| Nadolol | = β-blocker (nonselective) |
| Prazosin | = α$_1$-adrenergic antagonist |
| Propranolol | = β-blocker (nonselective) |
| Spironolactone | = aldosterone antagonist |
| Terlipressin | = vasopressin derivative |

*Tab. 14.11:* Substances for lowering portal hypertension

*Propranolol*, which was used for the first time by D. Lebrec et al. in 1980, brings about an approx. 50% reduction in portal venous pressure in some two thirds of patients. Dosage is established in line with the slowing-down of the heart rate (to about 25% less than that of the initial value, but not below 55/min). Propranolol also appears suitable for preventing erosive gastropathy. (6) In cases of bleeding, intravenous administration of terlipressin should be considered. (s. pp 360, 361)

*Nadolol* has also been shown to reduce portal venous pressure. Gradually increasing the dosage to 2 x 1 mg/day is usually sufficient. (1)

*Clonidine* is an α$_2$-adrenergic agonist and can therefore be used effectively in portal hypertension at an average dosage of 0.075−0.3 mg/day.

*Prazosin* belongs to the α$_1$-adrenergic antagonist group and can also be administered in portal hypertension at an average dosage of 2−4 mg/day.

*Molsidomine* is a prodrug. This substance is especially effective due to the fact that no tolerance develops. It leads to a fall in portal pressure of up to 40%, even after long-term use. Administration of this substance (e. g. 2 x 8 mg/day) is therefore recommended. (56) (s. p. 361)

*Spironolactone* is used as the basic medication in liver cirrhosis. By means of this therapy (upwards of 50 mg/day), it is possible to achieve a reduction in pressure in the portal system of about the same magnitude as with propranolol. (1, 64) (s. p. 306)

Total *abstinence from alcohol* (an absolute "must") can have a long-lasting beneficial effect in lowering elevated portal pressure values.

▶ These recommendations regarding medication are limited by the respective pharmacological properties, interactions and unwanted side effects. Such factors must always be taken into account. Therapeutic expectations with regard to adequate and constant reduction in portal pressure should not be set too high. Nevertheless, every possibility to reduce elevated portal venous pressure should be exploited.

## 6.2 Invasive therapy

In systemic diseases, *splenectomy* has to be considered. A *shunt operation* may be indicated in haemorrhage-free intervals. A proven alternative to the operative shunt is the transjugular intrahepatic portosystemic stent shunt.

**Transjugular intrahepatic portosystemic stent shunt** (TIPS) is available as an invasive therapy for portal hypertension. This concept has now been methodologically standardized. The success rate is extremely high. By means of balloon-expanded stents, portal decompression can be adapted to the respective situation in every single patient. The Palmaz stent can be placed with an accuracy of one millimetre; its diameter can also be adjusted in millimetre increments. The Wall stent can be used as an alternative in individual cases. **Indications** for this therapy in portal hypertension, where there is a persisting danger of variceal bleeding, are: (*1.*) lack of success with all medication therapy, including repeated sclerotherapy, (*2.*) inoperability in terms of a shunt operation, (*3.*) when a liver transplantation is not feasible, and (*4.*) bridging the time gap before an indicated liver transplantation. However, in up to 50% of patients, the period from stenosis to stenting ranges from 6 to 24 months; the stent must therefore be monitored constantly. (141) (s. pp 314, 362)

**Shunt operations:** Surgical shunts are only to be considered in cases where iatrogenic refractory bleeding occurs after all forms of conservative therapy have failed. A therapeutic shunt is only justified in the form of a (delayed) emergency shunt following massive haemorrhage or as an elective shunt following bleeding. Portosystemic anastomoses are carried out in the form of a complete shunt (i. e. without maintaining residual portal perfusion) or as an incomplete shunt (i. e. maintaining residual portal perfusion with only a slight fall in the portal pressure). Portacaval end-to-side anastomosis as a complete shunt is technically the most simple and also the safest form, with the lowest risk; the thrombosis rate is less than 2%. (s. p. 363) A central total shunt is more successful in variceal bleeding or ascites (but there is a greater tendency for postoperative HE). A peripheral shunt reduces the tendency to bleed, but may cause deterioration of status in patients with ascites (however, HE is less frequent). A central shunt should not be carried out on patients who are scheduled to have a liver transplantation. There is no indication for prophylactic shunting or sclerosing of oesophageal varices before bleeding. (104) (s. p. 870)

**Liver transplantation** not only removes the continued risk of variceal bleeding, but also eliminates the underlying liver disease causing portal hypertension. However, due to the scarcity of liver donors, limited financial resources and the life-long immunosuppression required, this major surgical intervention can only rarely be considered − perhaps in cases where a previous shunt operation or the creation of a TIPS was not possible. The survival rate for transplantation is higher than when recurrent bleeding is treated by repeated sclerotherapy (73% versus 17% after 4 years). The indication for transplantation (e. g. cirrhosis Child B or C) should be set as early as possible. (s. p. 872)

# Symptoms and Syndromes

## 15  Hepatic encephalopathy

# 15  Hepatic encephalopathy

It seems that even HIPPOCRATES may have recognized a relationship between liver disease and brain disorder when he noted: *"depravedness of the brain arises from phlegm and bile".* • One can also quote SHAKESPEARE, who wrote in Twelfth Night (1605): *"I am a great eater of beaf but I believe that does some harm to my wit."* • Such a form of **"meat intoxication"** was first described by N.V. ECK (1877) as being the cause of a subsequent neurologic syndrome in dogs with a portacaval shunt, which had been fed on a diet of meat.

▶ **Cerebral symptoms in the wake of liver diseases** were already described by F.TH. FRERICHS (1861) and H.I. QUINCKE (1899) as well as over the following decades by E. POLLAK (1927), H.-J. SCHERER (1933), G. ZILLIG (1947), V. GAUSTAD (1949), R.D. ADAMS et al. (1949), J.M. WALSHE (1951), S. SHERLOCK et al. (1954), E.A. DAVIDSON et al. (1956) (23), F. ERBSLOEH (1958, 1974), G.A. MARTINI (1975) (63), and others.

Such **terms** as "hepatargy", "leucoencephalopathy", "shunt encephalomyelopathy" and "encephalomyelopathy" were put forward to classify these central nervous disorders. • The term **portosystemic encephalopathy** was introduced by S. SHERLOCK (1954). Changes in the central nervous system which occur after a long course of disease were also termed "chronic hepatoportal encephalopathy". In line with neuropsychiatric definitions, preference is given to the term "hepatic (portosystemic) encephalopathy".

## 1  Definition

Encephalopathy is defined as a pathological non-inflammatory brain disease resulting from heterogeneous pathological effects, which involve various neurological and/or psychic symptoms. In itself, this term says nothing about the aetiopathogenesis, nor about the respective regions of the brain affected.

Hepatic encephalopathy (HE) is defined as the totality of all cerebral dysfunctions which can occur during the course of serious − acute or chronic − liver disease. The neurological and mental symptoms, which as a rule are potentially reversible, can be witnessed to varying degrees of intensity and in different combinations, so that it is possible to subdivide hepatic encephalopathy into several well-defined grades of severity or distinct stages. Clinical symptomatology ranges from moderate neuropsychiatric disorders through to coma.

## 1.1  Causes of encephalopathy

Encephalopathy can be triggered by **(1.) degenerative causes** (cerebral sclerosis, arterial hypertension, diabetes, etc.), **(2.) hypoxaemia** (chronic cardiac insufficiency, constrictive pericarditis (2), respiratory insufficiency, chronic anaemia, etc.), **(3.) metabolic causes** (enzymopathies, endocrine disorders, hypokalaemia, hyponatraemia, acidosis, alkalosis, exsiccosis, hypercapnia, paraproteinosis, etc.), **(4.) traumatization** (Friedmann's vasomotor syndrome, boxer's encephalopathy, etc.), **(5.) toxic causes** (alcohol, lead, organic solvents, bismuth, mussels contaminated with domoic acid, burn-related toxins, bilirubin [= kernicterus], vidarabine, uraemia, infectious diseases, liver insufficiency, etc.), and **(6.) cerebral causes** (intracranial space-occupying lesions, alcohol withdrawal syndrome, manic depression, schizophrenia, etc.).

All in all, more than 50 possible kinds of damage are known to cause encephalopathy. This large number of aetiological possibilities has to be considered when setting up the differential diagnosis, especially since symptomatology, therapy and prognosis are always determined by the respective underlying cause.

## 1.2  Impaired consciousness

**Consciousness** is defined as the totality of mental and emotional processes perceived as current events in combination with an awareness of the subjectivity of experience. • **Quantitatively impaired consciousness** is the collective term for disturbances in awareness (= restricted vigilance). This condition is characterized by a limited readiness to show interest and concern, restricted attentiveness and impaired elements of consciousness. The activity of the ascending reticular system of the reticular formation is compromised, a condition which is generally accompanied by changes in the electroencephalogram (EEG). Moreover, disorders or loss of function are displayed in the area of the cerebral hemispheres and/or their afferent pathways, which are responsible for the subjective sensation of consciousness. • Differentiation is made between **four types** of clouded consciousness (W. HACKE, 1986):

**1. Disorientation:** A slight degree of impaired of consciousness without clouding, yet with impediment to and deceleration of mental capacity and memory, compromised perception and reactivity (transitional psychosis).

**2. Somnolence:** Disorientation with additional, abnormal sleepiness, though arousal is still possible, and there can be memory gaps. • **Lethargy** is deemed to be the tendency to sleep without interruption, with greatly reduced mental/emotional responsiveness and absence of arousal reaction to normal stimuli.

**3. Sopor:** A condition resembling deep sleep with short-term attempts at orientation when being addressed, orderly movements of defence in reaction to pain − yet with no capability to react spontaneously.

**4. Coma:** Impaired consciousness of the most serious nature with long periods of profound unconsciousness and unresponsiveness to any form of address through to the absence of pain reaction and reflexes. • The term **stupor** is used to denote a disease with total absence of physical and/or mental activity due to loss of drive, yet with full consciousness. Amimia, lack of spontaneity, unresponsiveness to external stimuli or attempts at establishing contact, and mutism are witnessed. • Stupor is also deemed to be unconsciousness of cerebro-organic origin, as for example in a serious transitional syndrome; it may be regarded as a physically substantiated, non-specific psychosis.

# 2 Pathogenesis

▶ As early as 1904, C. Neuberg and P.F. Richter reported on an increase in amino acids in the blood in cases of hepatic coma. These results were subsequently confirmed, arousing biochemical interest in this clinical picture (J. Feigl et al., 1917; F. Umber, 1922; K. Hoesch, 1931). A rise in xanthoprotein (K. Hoesch, 1931) and ammonia (E. Kirk, 1936; E.J. Conway et al., 1939) was also observed. Application of ammonia salts resulted in a temporary restriction of in consciousness in a cirrhotic patient (C. Van Caulaert et al., 1932). From the wealth of results published, mention should be made of the detection of hypokalaemia and hypomagnesaemia, increases in pyruvic acid, cystine, methionine and glutamine, disruptions of the acid-base balance, and the higher levels of free amino acids in the serum. It was previously assumed that toxins absorbed by the intestine were inadequately detoxified in the diseased liver and, as such, reached the brain through the blood circulation, where they ultimately had a toxic effect (T.L. Murphy et al., 1948; D.J. Farquhar et al., 1950).

**Preconditions**

1. **Severe (acute or chronic) liver disease**
   and/or:
2. **Portosystemic collateral circulation**

**Pathogenic factors**

1. **Endogenous neurotoxins** ↑
   - ammonia
   - mercaptans, methionine derivatives
   - short- or medium-chain fatty acids
   - phenols, phenol derivatives
2. **Amino acid imbalance**
   - aromatic amino acids ↑
     − phenylalanine, tyrosine, methionine, tryptophan
   - branched-chain amino acids ↓
     − leucine, isoleucine, valine
3. **Disturbances of neurotransmitters**
   - false neurotransmitters ↑
     − octopamine, phenylethanolamine, etc.
   - excitatory neurotransmitters ↓
     − dopamine, noradrenaline
   - inhibitory neurotransmitters ↑
     − serotonin, GABA
4. **Change in postsynaptic receptors**
   - benzodiazepine receptor activity ↑
   - picrotoxin
5. **Alteration in the blood-brain barrier**
   - change in permeability
   - compromised substrate transport

*Tab. 15.1:* Preconditions for hepatic encephalopathy and its development as a synergy of multiple pathogenic factors

## 2.1 Preconditions

▶ The occurrence of hepatic encephalopathy (HE) is only possible under the following conditions: (*1.*) a serious (acute or chronic) **liver disease,** in which the detoxification function is significantly restricted, has to be present, and/or (*2.*) a functional or anatomic portosystemic **collateral circulation** must exist − this can be placed surgically or in the form of a TIPS (72, 90) − through which the nondetoxified portal blood bypasses the liver, so that toxic substances can reach the brain.

In the presence of just one of these two conditions, the occurrence of HE can be anticipated, depending on the underlying disease. (s. tab. 15.1)

While hepatic encephalopathy is nearly always found in acute liver failure, it can only be expected in some 25−40% of patients with a portosystemic shunt. When these two preconditions coincide, as in the case of liver cirrhosis, manifest hepatic encephalopathy is witnessed in 30−50% of patients and a subclinical course of disease in 50−70%. In other words, the frequency, the degree of severity and the course taken by HE depend on the underlying conditions.

## 2.2 Hypotheses

With respect to the correlation between liver disorders and the functions of the brain, discussion currently focuses on **five hypotheses** concerning the development of hepatic encephalopathy: (*1.*) intoxication hypothesis, (*2.*) neurotransmitter hypothesis, (*3.*) deficiency hypothesis, (*4.*) synergistic neurotoxicity, and (*5.*) hypothesis of primary gliopathy.

1. **Intoxication hypothesis:** Substances which impair or damage the functioning of the central nervous system are inadequately detoxified by the diseased liver and/or pass the liver unaltered by way of existing collateral circulatory pathways. Differentiation should be made here between (*1.*) ammonia-induced neurotoxicity and (*2.*) synergistic neurotoxic interaction between ammonia, mercaptans, short-chain fatty acids and phenols.

*The so-called* **ammonia hypothesis** *was set up as early as 1952* (G.B. Phillips et al.). (76) (see above: C. Van Caulaert et al., 1932)

2. **Neurotransmitter hypothesis:** Apart from a disorder of the postsynaptic receptors, discussion centres on (*1.*) formation of false neurotransmitters such as octopamine and phenylethanolamine due to the accumulation of phenylalanine and tyrosine, (*2.*) decrease in excitatory neurotransmitters such as dopamine and noradrenaline, and (*3.*) increase in inhibitory neurotransmitters, such as GABA and serotonin.

3. **Deficiency hypothesis:** Substances which are essential to the smooth functioning of the central nervous system are not provided, or are only inadequately provided, by a seriously damaged liver. This hypothesis relates to the branched-chain amino acids as well as cellular deficits of zinc, potassium, magnesium and unsaturated fatty acids.

4. **Synergistic neurotoxicity** (L. Zieve, 1981): *None of these substances or mechanisms is "comagenic" in itself.* Nevertheless, if present at the same time − even in low quantities(!) − they can cause the development of hepatic encephalopathy. The neurotoxicity of ammonia can be enhanced by these substances. (115)

5. **Primary gliopathy:** This hypothesis (M.D. Norenberg, 1979, 1987, 1992) (73) has been backed up by recent examinations carried out by proton MRI spectroscopy. (11, 28, 38, 55, 58, 88, 96) The cerebral detoxification of ammonia by means of glutamine formation takes place in the astrocytes. The ammonia binds with α-ketoglutarate to form glutamate or is converted enzymatically via glutamine synthetase to form glutamine. *Astrocytes are the sole cellular elements of the brain which possess glutamine synthetase for ammonia detoxification.* The markedly increased accumulation of glutamine in the glia cells is normally lowered by amino acid ex-

change and then equalized by the compensatory output of inositol, thus maintaining the osmotic balance. A constant surplus of ammonia (with its osmotic potency) and hence also of glutamine (with higher glutamine discharge from the CNS) will cause the glia cells to swell due to increased water intake. The elevated glutamine levels in the astrocytes cause glutamine to enter the liquor, where it can be detected in high concentrations in patients with HE. At the same time, there is a deficiency of glutamate at the synapse with defective glutamatergic neurotransmission. This produces an imbalance between excitatory and inhibitory activity, whereby the latter (i.e. damping effect) is predominant. *The reduction in intracerebral inositol, which functions as an osmolyte in the brain, is deemed to be the earliest sign of HE.* Swelling of the glia cells alters the cytoskeleton and compromises metabolic functions, transport properties and gene expression. • Furthermore, hypoxia, hypercapnia, benzodiazepines, electrolyte disorders, inflammatory mediators and manganese (56, 87, 100) can also cause a *swelling of the glia, so that a multifactorial pathogenesis is indeed given.* (s. p. 269)

## 2.3 Endogenous neurotoxins

The decreased hepatic metabolism of endogenous, nitrogenous neurotoxins together with their simultaneously increased formation in the intestine are generally considered to be responsible for the development of HE. Such neurotoxins include ammonia, mercaptans, short-chain or medium-chain fatty acids, phenols, etc. (s. tab. 15.1)

### 2.3.1 Ammonia

Ammonia is present either in its gaseous form (= $NH_3$) or in its ionized form (= $NH_4$) (i.e. dissolved in water). Ammonia is produced in the **small intestine** as a catabolite of glutamine, whereas in the **large intestine,** it is formed during the microbial breakdown of proteins, amino acids and urea. It is primarily Escherichia coli and Proteus mirabilis (as urease producers) which lead to the formation of ammonia. Helicobacteria in the stomach and duodenum are also urease producers, but the small amount of ammonia which they generate cannot be detected in the plasma. Particularly during physical exercise, considerable quantities of ammonia can be discharged from the **musculature.** The forming of ammonia in the **kidney,** minimal in itself, can, however, be considerably increased by hypokalaemia and alkalosis. In the **liver,** ammonia is produced through the breakdown of proteins and by the deamination of amino acids − and is in turn immediately detoxified. As much as 99% of the $NH_3$ is found in the form of $NH_4^+$ ions. Levels of >100 µmol/l in arterial blood are regarded as pathological. (s. pp 56, 107, 862) (s. figs. 3.13, 3.14)

The **detoxification** of ammonia is largely effected by the synthesis of urea and glutamine in the liver. These two metabolic pathways are positioned heterogeneously in the liver acinus, i.e. they are metabolically zoned. Periportal hepatocytes detoxify ammonia with high capacity but low affinity. In contrast, central perivenous hepatocytes (so-called scavenger cells) are free from urea cycle enzymes and mostly specialized in the synthesis of glutamine. *However, this hepatic detoxification process (urea and glutamine synthesis) is reduced by about 50% in cases of marked fatty liver and by about 80% in cases of cirrhosis* − with a simultaneous increase in hepatic glutamine synthetase activity to more than 2−3 times the norm. This is where the tendency towards metabolic alkalosis arises. Some 20% of the urea present is hydrolyzed by the bacterial flora of the colon, and the ammonia thus formed is once again transported to the liver for detoxification. Part of the ammonia is eliminated by uptake in the muscles. Some 70−90% of the

ammonia is detoxified in the urea cycle. The remainder is transformed into glutamine through glutamine synthetase and excreted in the kidney or converted back by glutaminase into glutamine, which is then available for glutamine synthesis again. (s. p. 58) (s. figs. 3.12−3.15)

The extent of **hyperammonaemia** ($NH_3 \uparrow$), and possibly that of HE, hence depends on a number of factors:

1. nitrogenous intestinal content
2. change in the intestinal flora, with a greater population of colibacillus and coliform gram-negative bacilli in the colon (102) as well as helicobacter (18, 43, 65, 171), which can even ascend into the small intestine (there is no relationship between Helicobacter pylori infection, ammonia formation and HE) (s. pp 56, 62)
3. degree of disruption of liver function, as a result of which adequate elimination of ammonia by the urea cycle and glutamine synthesis can no longer be guaranteed
4. compromised urea synthesis due to congenital or acquired enzyme defects
5. extent of portacaval collaterals, through which portal blood, rich in ammonia, enters the circulation and hence the brain after bypassing the liver
6. shift in the dissociation equilibrium (pK = 8.9) as a result of metabolic alkalosis with hypokalaemia: $NH_4^+ \rightleftharpoons pH \rightleftharpoons NH_3 + H^+$
7. presence of hyperglucagonaemia

▶ The **neurotoxic effects of ammonia** are attributed to the direct influence of inhibitory and exhibitory neurotransmission and the indirect influence of accumulated neurotoxic metabolites of tryptophan in the brain. Thus there is a certain correlation between hyperammonaemia and HE. However, this general correlation is not present in specific cases or in certain phases of HE. *Ammonia can pass the blood-brain barrier easily.* Some 11% of the ammonia in the arterial blood is metabolized in the brain (*1.*) by binding to α-ketoglutaric acid during the formation of glutaminic acid and (*2.*) by ATP-dependent amidating of glutamate during the formation of glutamine. • Of all biochemical parameters, the **glutamine level** in the cerebrospinal fluid correlates best with the degree of severity of HE. The neurotoxic effects of ammonia might thus be attributed to the increased formation of glutamine: (*1.*) uptake of glutamine (as inactive, false neurotransmitter) into the peripheral nerve endings in place of excitatory glutamate, (*2.*) inhibition of cerebral energy metabolism, possibly in the form of an energy deficit due to compromised transport of reducing equivalents in the mitochondria or reduction in the NADH/NAD quotients in the mitochondria of the astrocytes due to ammonia (B. Hindfelt et al., 1977), (*3.*) changes in the blood-brain barrier with increased permeability for amino acids, above all tryptophan, and (*4.*) direct effects on the neuronal membranes, possibly with a change in neurotransmitter receptors. *These effects may largely be explained by the hypothesis of primary gliopathy.* • Ammonia also intervenes in the metabolism of amino acids through **glucagon** and **insulin.** Hyperammonaemia leads to increased glucagon secretion with a subsequent rise in gluconeogenesis and the resulting consumption of gluconeoplastic amino acids as well as enhanced protein catabolism. The increase in gluconeogenesis itself effects a boost to the secretion of insulin and this in turn generates an additional uptake of **branched-chain amino acids** into the muscles, with a reduction in these amino acids in the plasma. (11, 19, 27, 31, 33, 45−47, 62, 68, 110)

► Recently, however, a correlation has been found between the pH-dependent (gaseous) partial pressure of the arterial $NH_3$ and the clinical degree of HE. (54) A recent study showed that ammonia levels (arterial and venous) as well as arterial and venous partial pressure of ammonia correlate with the severity of HE. It was hereby demonstrated that venous sampling is adequate for ammonia measurement. (75) Another study suggests there is no significant difference between arterial and venous ammonia levels or partial pressure of ammonia; no correlation of these three ammonia values with HE was found. (71)

The actual extent of the increase and the toxicity of non-ionized ammonia ($NH_3$) are influenced by **additional factors:**

1. **Alkalosis:** Alkalosis shifts the equilibrium between $NH_4^+$ and $NH_3$ to the *non-ionized, toxic $NH_3$*. Only this form is able to pass the blood-brain barrier and the membrane of the cerebral cells. (37) (s. fig. 15.2)
2. **Hypokalaemia:** Hypokalaemia increases the activity of renal glutaminase, so that more ammonia is formed and transported back via the blood of the renal vein. A lack of potassium in the brain cells is in itself a further cause of serious cerebral dysfunction. (s. fig. 15.2)
3. **Aldosterone:** Hyperammonaemia acts as an additional stimulus in aldosterone formation, so that a vicious circle is created comprising hyperammonaemia → secondary aldosteronism → hypokalaemia → hyperammonaemia.
4. **Catabolism:** Increased catabolism of body protein leads to the additional formation of ammonia.
5. **Synergy:** Endogenous neurotoxins display a synergistic effect, i.e. the neurotoxic concentration of ammonia always depends on the concentration of the other endogenous neurotoxins.

► *Taking into account these additional factors, the mechanisms described above may explain why as yet a correlation between ammonia levels and the degree of HE has only seldom been detected.*

### 2.3.2 Mercaptans and methionine derivatives

Patients with HE often show an excessive (up to 30-fold) increase in methionine in the serum, CSF and brain. The administration of methionine in patients with cirrhosis may induce or aggravate HE. Methionine sulphoxim, for example, is an inhibitor of glutamine synthetase in the astrocytes. At the same time, cerebrotoxic oxidation products are found, such as methionine sulphoxide and methionine sulphoxim. Neurotoxic mercaptans (e.g. methanethiol, ethylmercaptan, dimethyldisulphide) are formed from methionine in the liver as well as by microbial action in the colon. It would appear that hydrogen sulphide ($H_2S$), and not methanethiol, is a determinant mediator. These substances are greatly increased in the serum, CSF, brain and urine. (10) • *Dimethylsulphide* or *trimethylamine* are mainly considered to be responsible for the typical sweet odour of the **hepatic foetor** in the exspiratory air. (s. pp 87, 379)

### 2.3.3 Short-chain fatty acids

With hepatic encephalopathy, there is often an increase in short-chain fatty acids such as propionate, butyrate, valerate and octanoate in the serum and CSF. They are formed as a result of incomplete β-oxidation of long-chain fatty acids in the intestine. They are not − or only inadequately − metabolized in the damaged liver. The neurotoxic effect is based upon inhibition of various enzymes (including enzymes of the urea cycle) and competitive

inhibition in the binding of other toxins with albumin − and on the displacement of tryptophan from its binding to albumin, with a corresponding increase in free tryptophan in the serum and brain.

### 2.3.4 Phenols and phenol derivatives

Phenols are largely formed in the intestine from the aromatic amino acids tyrosine and phenylalanine. These amino acids are generally elevated in the early stages of HE. Phenols are detoxified in the liver by esterification with glucuronic acid and sulphuric acid. In severe cases of HE, free phenols and phenol derivatives are elevated in the serum and urine.

## 2.4 Amino acid imbalance

The liver plays an essential part in the metabolism of amino acids. (s. p. 38) (s. tab. 3.6) For this reason, a shift of the amino acid profile in the plasma has to be reckoned with in severe liver diseases. There is clear evidence of an *increase in aromatic amino acids* as well as a *reduction in branched-chain amino acids*. (s. tab. 15.1) Extrahepatic mechanisms (glucagon, insulin, lactate acidosis, etc.) can also effect significant changes to the amino acid spectrum. Multiple biochemical repercussions may result from this, affecting the development of HE. (8, 13, 45, 48, 53, 61, 68, 71)

**Fig. 15.1:** Branched-chain amino acid cycle and glutamate cycle in the brain (A = astrozyte, N = neuron, BBB = blood-brain barrier, GNT = glutamate neurotransmitter, BCAA = branched-chain amino acids, BCKA = branched-chain keto acids) (150)

An **increase in the aromatic amino acids** *phenylalanine* and *tyrosine* occurs due to the lowered hepatic uptake of enterally released amino acids and their restricted catabolism in the liver. They are also released to a greater extent from the muscles in cases of cirrhosis with catabolism. Furthermore, phenylalanine hydroxylase

activity is reduced in the cirrhotic liver. Free aromatic *tryptophan* is clearly elevated as a result of hypalbuminaemia, while the protein-bound tryptophan is simultaneously suppressed by the elevated concentration of short-chain fatty acids. Elevated cerebral tryptophan levels enhance the synthesis of serotonin. This substance, which acts as a depressant agent, causes fatigue and somnolence. Increased AAS in the brain inhibits tyrosine-3-monooxygenase and induces the formation of false neurotransmitters (e. g. octapamine, phenylethanolamine). (31, 75) • Because of bacterial putrefaction in the intestine, the volatile catabolites **indole** and **skatole** are produced from tryptophan, often giving the stools of the cirrhotic patient an intense smell.

The **reduction in the branched-chain amino acids** *leucine, isoleucine* and *valine* is caused by the higher clearance rate in HE, probably as a result of a hyperammonaemia-related increase in the secretion of insulin. These amino acids compete with the aromatic amino acids for a common carrier system through the blood-brain barrier. Because of the decrease in branched-chain amino acids, more aromatic amino acids reach the brain. This process is stimulated by ammonia. (s. fig. 15.1) (s. tab. 15.1) However, such an abnormal amino acid ratio can also be found in patients without HE.

## 2.5 Disturbances of neurotransmitters

Biochemical processes at the intersections (= synapses) between nerve cells as well as between nerve cells and the plasmalemma of other cells trigger the conduction of action potentials. The **synapse** comprises a pre- and postsynaptic part, separated by the synaptic gap. The neurotransmitters (noradrenaline, dopamine, serotonin, γ-amino butyric acid, etc.) are released from the presynaptic area into the synaptic gap and effect a change in permeability for ions (inflow/outflow) at the postsynaptic membrane, with changes in the bioelectrical membrane polarization. The transmitter effect is enzymatically stopped, with subsequent repolarization of the membrane. Up to now, about 80 neurotransmitter systems have been detected in the brain. The most important forms of neurotransmission are: (*1.*) GABAergic, (*2.*) glutamatergic, (*3.*) dopaminergic, and (*4.*) serotoninergic. Excitatory and inhibitory neurotransmitters are found together with their corresponding **receptors.** In cases of HE, the balance between the two systems possibly shifts in favour of the inhibitory transmitters.

### 2.5.1 False neurotransmitters

The **hypothesis of false neurotransmitters** (J. E. FISCHER et al., 1971) (26) is founded on the complex shifting of the profile of the amino acids in the serum. The elevated concentration of *phenylalanine* in the brain leads to a boost in the formation of the false neurotransmitters phenylethylamine and **β-phenylethanolamine.** Furthermore, the intracerebral increase in phenylalanine leads to competitive inhibition of tyrosine-3-monooxygenase, which generally guarantees the enzymatic synthesis of the normal neurotransmitters dopamine and noradrenaline. A higher concentration of tryptophan also reduces the synthesis of these normal neurotransmitters while at the same time impeding the catabolism of tyrosine and stimulating the additional formation of tyrosine from phenylalanine. This high surplus of *tyrosine* is decarboxylated to tyramine and converted into the inactive and hence false neurotransmitter **octopamine** by β-hydroxylase activity. In HE, an increased concentration of tyramine may be detectable in the serum. This finding is also considered to be of significance regarding the occurrence of HE. Tyr-

amine is formed from tyrosine by microbial action in the intestine and catabolized in the liver. Higher tyramine levels lead to increased formation of the false, inhibitory neurotransmitter octopamine. This accumulates in the synapses and severely impairs the synaptic transfer of impulses due to its very low excitatory activity. (114)

### 2.5.2 Reduction in neurotransmitters

The reduction of the normal neurotransmitters **dopamine** and **noradrenaline,** which trigger an excitatory effect at the synapses, is caused, among other things, by competitive inhibition of tyrosine-3-monooxygenase as a result of the higher concentration of phenylalanine. Furthermore, the increase in tryptophan leads to a reduction of these two physiological neurotransmitters, noradrenaline also being produced from dopamine by copper-containing dopamine hydroxylase. Dopamine receptors are found on neurons, which are mainly located in the substantia nigra, the reticular formation, the tegmentum of the mesolimbic system and the infundibular nerve of the hypothalamus. The reduced concentration of noradrenaline may also be responsible for peripheral vasodilation with hyperdynamic regulation of the circulation in portal hypertension. (s. p. 244) Moreover, *glutamate, aspartate* and *glycine* are also important excitatory neurotransmitters, the reduction of which (furthered by hyperammonaemia) intensifies neurodepression in cases of HE.

### 2.5.3 Increase in neurotransmitters

An increase in the neurotransmitters **serotonin** and **γ-amino butyric acid** (GABA) has an inhibitory effect on the neurons. Enhanced concentration of tryptophan boosts the synthesis of the physiological transmitter serotonin (5-hydroxy-tryptamine). Hence a higher concentration of serotonin in the CSF and of its metabolite 5-hydroxyindolacetate activates the serotonergic neurons. Animal experiments with serotonin antagonists brought about an improvement in HE. The increase in the postsynaptic inhibitory transmitter *γ-amino-butyric acid* observed in HE is a fundamental principle of the **GABA hypothesis** (D. F. SCHAFER et al., 1982). (93) GABA can be formed from glutamic acid in the presynaptic neurons and initially stored there. In reaction to specific impulses, GABA binds to postsynaptic receptors and, as a result, permeability of the membrane to chloride ions is increased with subsequent hyperpolarization of the postsynaptic membrane. GABA is either removed from the synaptic gap and broken down by enzyme action or returned to the presynaptic vesicles. GABA is also synthesized in the intestine by bacterial action. The portal vein can display a higher concentration of GABA, which is, however, clearly decreased in line with a reduction in intestinal bacteria. GABA is broken down in the liver with the help of GABA transaminase. Patients with cirrhosis and with gastrointestinal bleeding showed increased GABA levels in the blood. The augmented GABAergic tonus can also be explained by "endogenous" benzodiazepines. The GABA levels of plasma and CSF do not correlate with HE. (6, 19, 59, 60, 64, 68, 84, 106) (s. tab. 15.1)

Apart from GABA, the GABA receptor also binds benzodiazepines, barbiturates, picrotoxin, etc. As regards the pathogenesis of HE, changes in the affinity and density of postsynaptic receptors play an important role for GABA as well as for other neurotransmitters. The binding of benzodiazepine to GABA receptors intensifies the effects of GABA. Consequently, there is an increase in GABA receptors − just as in zinc deficiency − together with a decrease in receptors for the excitatory neurotransmitters glutamic acid and aspartic acid, shifting the balance, once again, in favour of the inhibitory neurotransmitters. **Benzodiazepine antagonists** (e. g. flumazenil, bicuculline) have a favourable effect upon the development of HE.

## 2.6 Deficiency of essential substances

The energy metabolism of the brain is carried out solely by **glucose.** During this process, 5−10% of the glucose supplied is metabolized to lactate, 25−30% is directly decarboxylated by oxydative action in the tricarboxylic acid cycle for energy procurement, and 60% is converted into amino acids, mainly glutamine and glutamic acid, via α-ketoglutaric acid. (s. p. 39) In cases of cirrhosis with HE, these mechanisms of glucose metabolism are disrupted in the individual in a variety of ways. (47, 53) A pronounced **deficiency of zinc** is generally observed in cirrhosis and in alcoholic liver disease. This trace element is, however, of paramount importance to the activation of many enzyme systems, especially those of the urea cycle. Thought should thus be given to the substitution of zinc as a prophylactic measure against the development of HE. (34, 81, 153, 169) (s. p. 50) It is advisable to ensure that the serum values of **potassium** and **magnesium** are balanced. **Unsaturated fatty acids** are also likely to be significant for the pathogenesis of HE, since they are of vital importance for the normal morphology and functioning of all biological membranes. (16)

The **outcome** of the enormous efforts made in experimental and clinical research into the pathogenesis of HE can be defined as follows: *There is a metabolic imbalance between excitatory and inhibitory neuronal activity.* (15, 20, 25, 30, 44, 45, 49, 68, 74)

1. Up to now, no one substance can be shown to precipitate hepatic encephalopathy or coma under clinical conditions, and no single hypothesis can explain it.
2. The substances and mechanisms outlined above all have their own part to play in the development of HE. However, one of the two precursory conditions (serious liver disease and/or portosystemic collateral circulation) has to be fulfilled.
3. HE is not a metabolically homogeneous entity, but is deemed to be a multifactorial occurrence which is characterized differently in each case.
4. The multiple pathogenic possibilities interact synergistically. For this reason, successful prevention or treatment of HE is only possible if consideration is given to its multifactorial pathogenesis.

▶ *Neurotoxic ammonia indeed plays an essential but not exclusive role in the development of HE.*

## 3 Morphological damage to the CNS

As early as 1927, E. Pollak observed a "glia reaction" in Wilson's disease and other liver diseases in the form of enlarged glia elements, which he described as being poor in chromatin and with naked nuclei. These findings were confirmed by H.-J. Scherer in 1933.

▶ In HE due to acute liver failure, marked *brain oedema* is predominantly evident with a spongy loosening of the tissue, capillary proliferation and a hypoxia-related loss of function of the ganglion cells (F. Erbsloeh, 1958). In 1953, R. D. Adams et al. detected diffuse hyperplasia of the astrocytes in chronic HE, with enlarged cell nuclei, yet practically without cytoplasm. Chromatine is often driven to the edge of the nucleus and vacuolated in the process. Protein concentration in the cytoskeleton is reduced. Glycogen (PAS-positive) is often deposited in the enlarged lobular, loosened nuclei of the naked astrocytes. The storage of glycogen points to considerable disruption of the cerebral metabolism, since normally no glycogen is deposited in brain cells. This form of macroglial reaction is known as *liver glia* or *Alzheimer glia type II*. Such astrocytosis is largely or even solely caused by ammonia. Furthermore, there are *changes in the ganglion cells* with the loss of Nissl's substance, distension of the cytoplasm due to the deposit of lipoproteins, and karyopyknosis. Localized failure of the ganglion cells, vascular proliferation and marrow oedema are the outcome. There is evidence of vessel-dependent blanching and softening as well as a *status spongiosus* which is largely independent of the vessels.

The morphological damage to the CNS in acute liver failure differs from that observed in chronic HE. Furthermore, the nature and localization of the damage also depend on the duration of HE as well as on its degree of severity. In chronic HE due to cirrhosis, reduction in cerebral blood flow and diminished uptake of oxygen and glucose certainly play a major role. This may well be of importance for the close correlation that exists between the astroglia − which is part of the blood-brain barrier − and the neuronal metabolism. (s. p. 265) These changes are found in the cerebral cortex and the brain stem as well as in the thalamus, putamen, pallidum and red nucleus. In the subsequent course of the disease, the spinal cord is affected in the form of damage to the axis cylinder and demyelination. Peripheral neuropathies and retrobulbar neuritis have also been witnessed. (11, 13, 21, 30, 96, 109, 111) • With $T_1$-weighted MRI, a symmetrical hypertense globus pallidus can be demonstrated in about 70% of cirrhotic patients − even in cases without simultaneous HE. (28, 67) This finding may be explained by the accumulation of (neurotoxic) manganese − although the reason for this manganese deposition is unclear. (s. p. 265)

## 4 Causative and trigger factors

In the course of serious **liver disease** (acute or chronic), the occurrence of HE must always be reckoned with. Various pathogenic factors or mechanisms can interact from case to case in a variety of ways and may spontaneously trigger this occurrence synergistically. For the most part, the pathogenetic and pathophysiological reactions are set in motion or reinforced by **trigger factors.** It is therefore clinically important to recognize and avoid them as far as possible. (s. tab. 15.2)

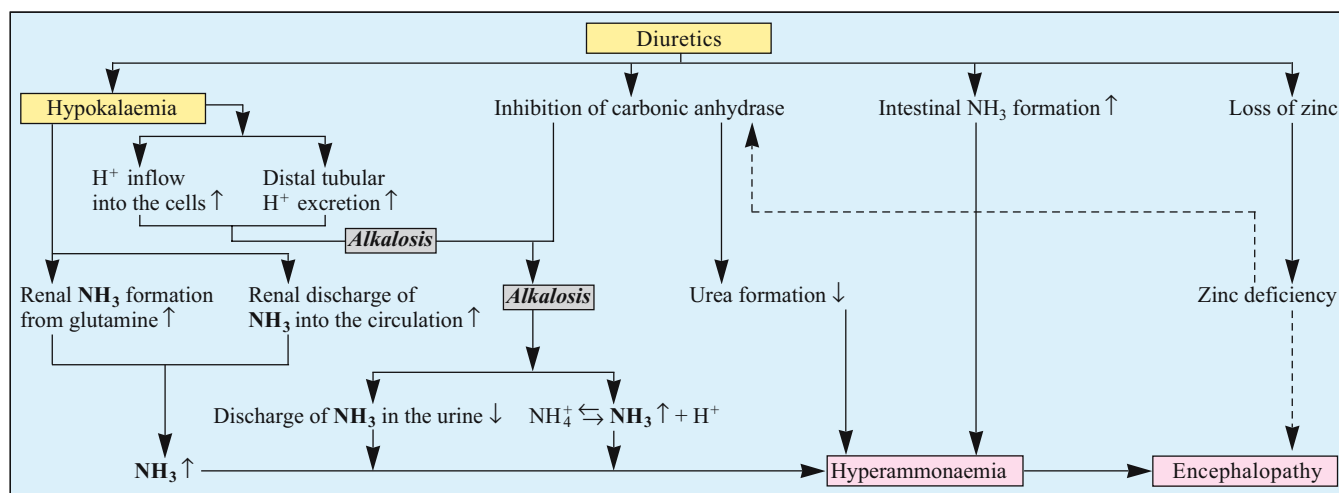
The forming of microbial $NH_4^+$ in the intestinal tract is increased if the dietary **protein intake** is too high. (9, 24, 70, 89, 97, 101, 102,


**Fig. 15.2:** Diagram illustrating the development of hepatic encephalopathy due to diuretics and/or hypokalaemia

1. **Intestinal protein supply** ↑
   − protein-rich diet (7−10%)
   − gastrointestinal bleeding (25−30%)

2. **Protein catabolism** ↑
   − albumin deficiency, bleeding of soft tissue, fever, surgery, infection, hyperglucagonaemia

3. **Overtaxed detoxifying mechanisms**
   − alcohol, medicaments, chemicals, toxins, endotoxins, infections (10−18%)
   − obstipation

4. **Tumour necrosis factor** ↑

5. **Binding to GABA receptors** ↑
   − benzodiazepines, barbiturate, phenothiazine, sedatives/tranquillizers (10−15%)

6. **Metabolic imbalance**
   − acidosis, lactate acidosis, azotaemia (25−30%)
   − hypoglycaemia

7. **Electrolyte disorders**
   − potassium ↓, sodium ↓, magnesium ↓

8. **Circulatory disorders**
   − hypovolaemia, hypoxia

9. **Inhibition of urea synthesis**
   − diuretics (25−35%), zinc ↓, acidosis

10. **Manganese** ↑

**Tab. 15.2:** Causes of hepatic encephalopathy and hyperammonaemia (frequency in %) (s. fig. 15.2)

122) *Gastrointestinal bleeding* involving large quantities of plasma and erythrocyte protein is also deemed to constitute protein intake. It should be noted that 100 ml blood contain 15−20 g protein, from which large quantities of pathogenetically unfavourable aromatic amino acids and biogenic amines are formed by microbial action. The concentrations of ammonium stored in the erythrocytes are released during erythrocyte breakdown in the intestine. Occult bleeding, which is detected in the stools by chemical testing, may also cause HE. Enhanced *protein catabolism* leads to an increase in the release of aromatic amino acids, which intervene in various pathogenic mechanisms.

> **In the same way as diabetics have their own specific glucose tolerance threshold, all cirrhotic patients likewise have their own protein tolerance threshold.**

The **detoxifying hepatic mechanisms,** restricted in the case of severe liver disease, are overtaxed and become insufficient due to the additional *noxae*. With the presence of *obstipation*, the absorption of intestinal toxins and their transport via the portal vein are intensified, so that the diseased liver becomes subjected to an additional burden. • The administration of sedatives or analgesics leads to **neurodepression** with additional binding to (and blocking of) GABA receptors. For this reason, these medicaments can have an unexpectedly strong impact, even in low doses and with a once-only application!

► **Hyperammonaemia** as well as **hypovolaemia** and **hypokalaemia** (especially when caused by diuretics) give rise to **secondary aldosteronism,** which in turn reinforces hypokalaemia, hypomagnesaemia and zinc deficiency. (s. fig. 15.2) • It is clear that additive factors also act as triggers of HE, setting in motion a vicious circle, so that a multiple and **complex process** results. • This may well explain the variety of biochemical, neuropsychiatric and clinical findings in HE. (15, 25, 44, 68) (s. tabs. 15.3, 15.5)

# 5 Clinical forms

The expression hepatic encephalopathy (HE) is a collective term covering **five clinical forms of disease** (H. O. CONN, 1989): (*1.*) Reye's syndrome, (*2.*) enzyme deficiency of the urea cycle, (*3.*) pseudoportosystemic encephalopathy, (*4.*) fulminant liver failure, and (*5.*) portosystemic encephalopathy. • It is not known whether the pathogenic mechanisms of these various clinical forms are identical. (s. tab. 15.3)

An additional **three forms** should also be mentioned: (*1.*) deficiency of acyl-CoA dehydrogenase, (*2.*) encephalopathy in Wilson's disease, and (*3.*) encephalopathy in hepatic porphyria.

A **new nomenclature** of HE existing since 2002 distinguishes three forms: (*1.*) type A (= HE associated with acute liver failure), (*2.*) type B (= HE associated with portosystemic bypass without liver disease), and (*3.*) type C (= HE associated with liver cirrhosis).

1. Reye's syndrome
2. Enzyme deficiency of the urea cycle
   − hyperammonaemia type I
   − hyperammonaemia type II
3. Pseudoportosystemic encephalopathy (pseudo-PSE)
4. Fulminant liver failure
5. Portosystemic encephalopathy
   − subclinical (latent, minimal) form
   − acute form
   − acute recurrent form
   − chronic persistent form
   − chronic recurrent form

**Tab. 15.3:** Clinical forms of hepatic encephalopathy (HE)

## 5.1 Reye's syndrome

The term Reye's syndrome (R. D. K. REYE et al., 1963; G. M. JOHNSON et al., 1963) (s. p. 589) denotes an acute, non-inflammatory syndrome with acute liver failure and encephalopathy. (7) Such a "hepatocerebral syndrome" is fatal in 30−60% of cases. It is observed in infants and children (mainly between the ages of 6 and 14 years) after feverish infection − particularly of the respiratory organs. This disease is seldom observed in adults. • The *cause* is still not completely clear, even though a virus infection (influenza A or B, Coxsackie B2, varicella), the intake of acetylsalicylic acid and mycetism are all considered to be responsible. The toxic substances, similar to those found in HE, lead to *neuronal damage* including the inhibition of neurotransmitters, brain oedema with hypoxic damage, vascular changes and demyelination. • In the region of the *liver*, severe periportal fatty degeneration is observed with cell necrosis. Examination with the electron microscope reveals marked damage to the mitochondria. (12) As a consequence, mitochondrial carbamoylphosphate synthetase is impaired, preventing ammonia from being channelled into the urea cycle. The oxidative breakdown of fatty acids in the mitochondria is also impaired. Large quantities of fat are deposited in the *visceral organs*. • The *clinical picture* commences with vomiting and fever. Stupor and tonic-clonic seizures follow, progressing into coma. Laboratory investigations show acidosis, hyperammonaemia, impaired synthesis of VLDL, hypoglycaemia, electrolyte imbalance, increased activity of transaminases and creatine phosphokinase as well as a drop in the Quick's value.

A clinical picture similar to that of Reye's syndrome can be witnessed in children with a deficiency of **acyl-CoA dehydrogenase.** This enzyme complex is responsible for the β-oxidation of medium-chain and long-chain fatty acids in the mitochondria without, however, causing any pathological changes.

## 5.2 Enzyme deficiency in the urea cycle

As a *congenital disorder*, an enzyme deficiency in the urea cycle relates to carbamoylphosphate synthetase or N-acetyl-glutamate synthetase (= hyperammonaemia type I) and ornithine carbamoyltransferase (= hyperammonaemia type II) (D. B. FLANNERY et al., 1982). (27) (s. p. 594) This condition mainly affects the channelling of ammonium into the mitochondria and the conversion of ornithine into citrulline. (s. fig. 3.12) • Similar *acquired enzymopathies* can be expected in Reye's syndrome and in cases of zinc deficiency. Such a hyperammonaemia syndrome can also produce the clinical picture of HE.

## 5.3 Pseudoportosystemic encephalopathy

Pseudoportosystemic encephalopathy (pseudo-PSE) has been termed "non-ammonia-induced HE", "false liver coma" (H. KALK, 1958) or "electrolyte coma". It is mainly attributed to severe **electrolyte derangement** in the form of hypokalaemia and/or hyponatraemia (107) with a cerebro-intracellular increase in volume due to hypotonic dehydration. Hypomagnesaemia may also be present, which can likewise cause neuropsychiatric symptoms, since magnesium deficiency compromises all biochemical reactions in which ATP is involved.

Even without a simultaneous increase in nitrogenous substances, **metabolic disorders** (e. g. hypoxia, hypercapnia, hypoglycaemia) can give rise to neuropsychiatric symptoms. The primary pathogenic point of action is likely to be the damaging of the blood-brain barrier, also called the boundary structure of the glia. Here, the astrocytes and their projections encircle the blood capillaries and regulate the normal transport of substances between the blood stream and nerve cells. It is more than likely that multiple metabolic disorders or **endocrinopathies,** depending on their degree of severity or joint effect, will cause lasting damage in the area of the blood-brain barrier. (35) Neuropsychiatric symptoms with pseudo-PSE are not only to be expected in cirrhosis (as yet without any increase in nitrogenous substances), but also in other liver diseases; such symptoms likewise appear with metabolic or endocrinological disturbances. (91, 103, 166) In this case, the clinical and laboratory findings largely reflect the underlying origins of the disease. Pseudo-PSE is thus of particular significance in the differential diagnosis of hepatic encephalopathy.

## 5.4 Fulminant liver failure

Fulminant liver failure (FLF) is caused by an extensive lost of the liver parenchyma, which results in a severe deterioration of liver function. This clinical picture, which in most cases ends fatally, is also known as *"liver cell degeneration coma"*, *"endogenous liver coma"*, *"acute liver insufficiency"* or *"acute liver failure"*. Its causes are multiple and its pathogenesis is complex. (*see chapter 20*)

The onset is generally abrupt, sometimes even unexpected and without any hint of a previous or coexistent liver disease. A marked hepatic foetor is present at an early stage. The neuropsychiatric symptoms of FLF are largely similar to those of PSE due to chronic liver disease, especially since their pathogenesis is virtually the same or even identical. Yet, the neuropsychiatric picture is much more progressive and generally characterized by aggressive or agitated modes of behaviour as well as screaming fits and delirious phases. The subsequent course of the disease comprises rigor, spasticity and seizures, passing into somnolence and coma. If the pupils do not react to light, this is deemed to be indicative of therapy-resistant cerebral pressure due to brain oedema. (13, 21, 111)

## 5.5 Portosystemic encephalopathy

Portosystemic encephalopathy (PSE) develops in chronic liver diseases and/or in the wake of portosystemic circulation. Liver cirrhosis with its hepatofugal collateral circulatory pathway is thus the focus of interest in this clinical form of disease. The term PSE is identical to *"exogenous liver coma"* or *"liver cell failure coma"*. PSE can be further subdivided according to its symptomatology and depending on its form and degree of severity. There are three forms of portosystemic encephalopathy: (*1.*) subclinical (or latent) PSE, (*2.*) acute or acute recurrent (episodic) PSE, and (*3.*) chronic recurrent or chronic persistent PSE.

### 5.5.1 Subclinical (latent) form

Subclinical (latent) PSE is founded on observations made by H. PENIN (1967), who noticed that patients with liver cirrhosis may display personality changes despite normal EEG findings. • In 1970 R. ZEEGEN observed minor cerebral dysfunction in 40% of his cirrhotic patients. (s. p. 200) • Changes in the form of a psychosyndrome with neurasthenic features were summarized by F. ERBSLOEH et al. in 1974 as *"chronic subclinical cirrhosis-related encephalopathy"*.

With regard to an altered state of consciousness, *the subclinical form of PSE ranges between stages 0 (= normal) and I (= manifestation)*. (s. pp 270, 276) It is to be expected, as is the case with the majority of diseases, that the manifestation of hepatic encephalopathy will be preceded by a stage of latency.

▶ The **diagnosis** of latency is extremely difficult because the patients show no clinical abnormalities and retain their verbal intelligence for a long period of time. By contrast, the *practical (fluid) intelligence* is disturbed at an early stage. No clinical findings are detectable which point to the existence of the latent (or subclinical) stage. (s. tab. 15.4)

1. No subjective complaints
2. No clinical findings
3. No laboratory parameters
4. No neurological abnormalities
5. No spontaneous changes in the EEG

*Tab. 15.4:* Normal examination results in the latent (subclinical) stage of HE

Despite the considerable objective clinical importance of latent HE, the patient subjectively feels unchanged and free from symptoms. There are no complaints or malaise pointing to the stage of latency, nor does the patient's conversation with the physician or the anamnesis (= *verbal,* i.e. *crystalline, intelligence*) yield any relevant clues. There are no neurological findings (hyperreflexia, asterixis, tremor, etc.), nor do examinations of the blood or CSF yield any results correlating with the stage of latency.

For this reason, diagnostic efforts focus on the **electroencephalogram.** In the *spontaneous EEG*, individual cases can display a minor increase in slow waves or a slowing down of base activity below the normal alpha range (8−12 Hz). Only by knowing the individual normal status and by regularly reviewing the spontaneous EEG as a cirrhosis follow-up is it possible in 30−50% of cases to recognize features which could be interpreted as latent HE. However, this is not practicable. • The application of exogenous *visually evoked potentials* (VEP) likewise yielded no reliable correlation. • The determination of the **P-300 wave** as an electrophysiological correlate of endogenously stimulated potentials showed a lengthening of latency in some 30−70% of cases of subclinical HE. Although its sensitivity is high, this method is not appropriate for the initial diagnosis; for the follow-up, however, it is quite reliable. The procedure itself is very time-consuming and calls for specialized experience, which is why it is generally not suitable for routine diagnostics. (2, 72, 92, 98) (s. pp 200, 201 with more references)

In 1952 G. J. GABUZDA et al. proposed the following **triad** for identifying HE: (*1.*) mental disturbances, (*2.*) tremor, and (*3.*) EEG changes. • In this context, it seemed logical to include **neuropsychological test procedures** that had proved reliable in clinical psychology. (s. p. 201) (s. tab. 10.3) However, these test procedures, which can prove difficult to perform, are time-consuming and call for special training. Regarding scientific studies, neuropsychological tests are considered to be the *gold standard*. Combined use of several tests (s. tab. 10.3) produces the most reliable diagnosis of latent HE − *even though no test is absolutely conclusive or entirely valid.* Of course, these tests provide no information on the underlying cause of encephalopathy and are consequently not "specific" to HE. The reliability of the test results depends on a number of *influential factors*, which always have to be taken into account. (s. tab. 10.2) • The fading of the myoinositol signal viewed in **proton MR spectroscopy** has proved to be a more sensitive method for the detection of latent HE. (11, 28, 38, 55, 58, 88, 96)

The **frequency** of subclinical HE is given as 40−70% in cirrhotic patients, the different frequency rates being attributed to the way in which the individual influences the test procedures and to the respective underlying cause of cirrhosis. It appears that subclinical HE is most frequently found in alcoholic cirrhosis. A conservative estimate of the situation in Germany puts the number of cirrhotic patients at >700,000. The frequency of subclinical HE is therefore >400,000. *Hence subclinical HE is by far the most frequent complication associated with liver disease.* It can be assumed that patients suffering, for example, from severe fatty liver, particularly as a result of alcohol abuse, show a similarly high percentage of subclinical HE. In patients suffering from serious liver disease, cerebral dysfunction can be detected in >80% of cases. In view of the multiple causes and

factors influencing the development of HE (s. tab. 15.2) and due to its own considerable frequency, the stage of latency is of major clinical significance. (22, 29, 32, 42, 61, 78, 79, 82, 85, 91, 92, 95, 104)

▶ The **objective disease status** (in contrast to the subjective feeling of illness!) was first demonstrated by H. SCHOMERUS et al. (1981). (94) More than 50% of clinically normal cirrhotic patients with latent HE were **unfit to drive.** In other words, they wrongly assessed traffic situations, braked too late, drove through red traffic lights, underestimated bends and speed, etc. Another 25% were categorized as being only *partially fit to drive*. • Note that during a so-called *blackout* (equals a loss of consciousness of just one second), a distance of 14 metres is covered by the car without any control (!) at a speed of 50 kph (= 30 mph).

A number of impairments, often quite severe in nature, affect the patient's **working life:** lack of concentration when operating machinery, disturbances in fine motor function during manual tasks, improper handling of equipment, uncertainties with production sequences, etc. As a result, the number of occupational accidents rises; in addition, there is greater damage to equipment or machinery and generally more production wastage.

▶ **Early diagnosis** of HE in the stage of clinical latency is of tremendous importance in daily life and at work, including fitness to drive (112); thus the repercussions are of an economic, prognostic and prophylactic nature. In practical terms, it allows a therapy to be carried out which is successful, efficient and economical as well as low-risk. (61) If treatment is started in time, progression to severe stages of manifest HE, with the subsequent complex and cost-intensive period of hospitalization, can be prevented. Moreover, it is imperative to avert irreversible damage to the brain cells, which may result from the chronic impact of neurotoxins. (49, 83)

For this reason, simple **psychometric test procedures** have been developed to identify latent HE. (s. p. 202) (s. tab. 10.6) They do, however, have certain **disadvantages** which must be taken into account:

(*1*.) The cerebral functions and areas of function covered by the respective tests (s. tabs. 10.1, 10.3) are not sufficiently known or defined.

(*2*.) Given the varied functional disturbances in the brain (s. tabs. 10.1, 10.3), psychometrics should not rely on "one" test only.

(*3*.) The possibility of quantitatively reliable test evaluation is often lacking.

(*4*.) Various factors (s. tab. 10.2) can influence the reliability of test results.

(*5*.) As yet, there are neither enough comparative values available relating to normal behaviour nor sufficient results from scientifically established tests.

▶ From the publications available, we selected clinically applicable tests (s. tab. 10.4) and compiled a **psychometric test programme** (s. tab. 10.6) which largely complies with the general criteria for psychometric testing (s. tab. 10.5); many years of experience have shown this programme to be appropriate. (57) A subsequent development was a *psychometric examination set*, available for use in both the practitioner's surgery and the hospital as well as in occupational and road-traffic medicine; the programme is simple, cheap and reliable. (1, 72, 92) (s. p. 203) (s. tab. 10.6)

### 5.5.2 Acute recurrent form

The acute or acute recurrent form can be equated with the manifestation of portosystemic encephalopathy in chronic liver disease. It is also known as "acute episodic form". Discrete psychometric disorders usually precede the manifest picture as a *latent stage*. Manifestation includes *stages I−IV* and hence covers a wide spectrum of clinical, neurological and psychopathological symptoms. Once the liver function is stabilized and the trigger factors are eliminated, all the symptoms of this form are as a rule reversible.

### 5.5.3 Chronic persistent form

In 1965 M. VICTOR et al. termed this form the "non-Wilsonian type" of chronic hepatocerebral degeneration. (109) This chronic form of hepatic encephalopathy is rare. It is mainly found in patients with extended collateral circulatory pathways, in particular after surgically created portosystemic anastomoses. At the outset, the clinical picture is similar to that of the acute recurrent form. There is evidence of irritability as well as moody or childish behaviour, indifference or depressiveness; occasionally, euphoria and talkativeness are experienced together with phases of confusion. Gradually, ataxia, choreo-athetosis, paraplegia and lancinating pains set in − similar to those of *portacaval myelopathy*. Such functional disorders are usually irreversible. The clinical picture ends in cerebral atrophy and dementia.

# 6 Clinical stages

In line with R. D. ADAMS et al. (1953), the following years witnessed the differentiation of HE into a number of stages, of which at least 3, generally 4 or even 5 were defined (F. H. NETTER et al., 1957; C. TREY et al., 1970; B. RUEFF et al., 1973; S. SHERLOCK, 1975, and others). • For practical reasons, it is recommendable, and indeed clinically possible, to use just one (uniform and/or standardized) diagnostic system to categorize the stages for describing the severity of HE. The application of 4 stages does adequate justice to the multiplicity of the symptoms and findings and allows a patient to be assigned precisely to a standardized stage. These stages can, however, over-

lap, with each one being reversible. A manifest stage of HE is one of the five criteria in the Child-Pugh classification and can therefore be seen as a prognostic criterion. (s. tab. 15.5)

### Coma assessment

► One tried and tested semiquantitative method for coma assessment is the **Glasgow scale** (G. M. TEASDALE et al., 1974) with a score of 3 to 15. It has a high consistency level, irrespective of the investigator ("interrogator stability"). As the severity of coma increases, the total score drops from 15 down to 3:

| Criteria | Points |
|---|---|
| **1. Opening of the eyes** | |
| – spontaneously | 4 |
| – upon command | 3 |
| – upon pain stimulus | 2 |
| – no response | 1 |
| **2. Verbal reactions** | |
| – oriented and conversant | 5 |
| – confused responses | 4 |
| – inadequate responses | 3 |
| – incomprehensible sounds | 2 |
| – no response | 1 |
| **3. Motor reactions** | |
| – normal | 6 |
| – localized/hemilateral | 5 |
| – drawing away | 4 |
| – abnormal flexion response | 3 |
| – extensor reaction/stretching | 2 |
| – no reaction | 1 |
| Total | |

This Glasgow coma scale with its score points can be expediently combined with an additional *clinical coma profile*. The final result is a clinical **coma check-list,** which provides a basis for informative and reliable monitoring in the intensive care unit:

1. **Pupillary reaction**
   – normal ☐
   – weakened ☐
   – no reaction ☐

2. **Corneal reflex**
   – normal ☐
   – no reaction ☐

3. **Tendon reflexes**
   – normal ☐
   – hyperreflexia ☐
   – hyporeflexia ☐
   – areflexia ☐

4. **Muscle tone**
   – normal ☐
   – increased ☐
   – diminished ☐
   – slackened ☐

5. **Respiration**
   – normal ☐
   – hyperpnoea ☐
   – hypopnoea ☐
   – apnoea ☐

► The so-called **Innsbruck coma scale** (F. GERSTENBRAND et al., 1984) can be used as a check-list at the bedside. The results are noted, giving the date and time of day. The highest number of points for grading a coma patient is 19. (The number of points 20−23 can be used for the waking-up period.) A sum total below 6 at the beginning of the coma and an average score below 11 during the subsequent phase point to a poor prognosis:

| Name of patient | | Date, time of day |
|---|---|---|
| Reaction to acoustic stimuli: | attention paid | 3 .......... |
| | better than extensor reflex | 2 .......... |
| | extensor reflex | 1 .......... |
| | no reaction | 0 .......... |
| Reaction to pain (pinching; edge of the trapezius muscle): | directed defence reaction | 3 .......... |
| | better than extensor reflex | 2 .......... |
| | extensor reflex | 1 .......... |
| | no reaction | 0 .......... |
| Physical posture and movement: | normal | 3 .......... |
| | better than stretching position | 2 .......... |
| | stretching position | 1 .......... |
| | slumped | 0 .......... |
| Opening of eyes: | spontaneous | 3 .......... |
| | upon acoustic stimuli | 2 .......... |
| | upon pain | 1 .......... |
| | no opening of eyes | 0 .......... |
| Pupillary width: | normal | 3 .......... |
| | narrowed | 2 .......... |
| | expanded | 1 .......... |
| | wide | 0 .......... |
| Pupillary reaction: | extensive | 3 .......... |
| | minimal | 2 .......... |
| | hardly perceptible | 1 .......... |
| | no reaction | 0 .......... |
| Ocular bulb status and movement: | eyes follow an object | 3 .......... |
| | pendular bulb | 2 .......... |
| | divergent, changing position | 1 .......... |
| | divergent, fixed position | 0 .......... |
| Oral automatisms: | spontaneous | 2 .......... |
| | upon external stimuli | 1 .......... |
| | none | 0 .......... |

A categorization of the clinical picture of HE is not "liver-specific", but encompasses "encephalopathy" and its multiple aetiological aspects. Similarly, the phenomena of the individual stages do not allow conclusions to be drawn as to the type of liver coma (liver cell necrosis or functional liver cell failure). However, the course of HE with acute liver cell necrosis is more progressive and more severe.

**Neurological findings:** During the early stage, there is evidence of hyperreflexia, muscular hypertonicity, distortions in handwriting and speech as well as delicate flapping tremors. • A gross "flapping tremor", initially described as "wing beating" by F. TH. FRERICHS (1858) and as "asterixis" by R. D. ADAMS et al. (1949), is deemed typical of liver insufficiency. It is witnessed in stages II and

III and comprises swift bending and stretching movements of the metacarpal joints with the hands laid out flat and the wrists dorsiflexed or with outstretched dorsiflexed hands and fingers. The swift flapping movements, occurring at irregular intervals, are often accompanied by lateral spreading movements. Usually, the "flap" is bilateral; it is not synchronously bilateral, however, and mostly affects one side more than the other. (s. tab. 15.5)

**EEG changes:** EEG changes (e.g. decrease in frequency of the basic rhythm, pseudoparoxysmal activities) may be expected at all stages of manifest HE. (s. p. 200) A grading system for EEG changes was developed by B.G. PARSONS-SMITH et al. in 1957. EEG evaluation has been considerably improved by computer analysis. (s. tab. 15.5)

As from **stage I**, the base activity (normal alpha-range 8−12 Hz) slows down, there is a greater diffusion of interim waves and a symmetrical pattern of theta waves (5−8/sec). These changes generally begin at the frontotemporal region and progress posteriorly. The slowing down of the base activity can be detected in the subclinical stage of HE in 15−20% of patients. Application of exogenous visually evoked potentials (VEP) or endogenous stimuli together with evaluation of the P-300 wave made it possible for a considerably higher percentage (30−40% and 50−75%) of pathological EEG changes to be detected. • In **stage II**, the alpha rhythm is even more retarded (5−7/sec), the curves become flatter, and the intermittent theta waves increase. In some cases, bi- and triphasic potentials are witnessed. • In **stage III**, the theta and theta-delta activity is accentuated and the base frequency continues to slow down (3−5/sec). Monophasic to quadriphasic complexes are observed episodically (R.G. BICKFORD et al., 1955). The individually different polymorphic waves with a high amplitude of the theta or delta type (3−5/sec and 1.5−3/sec, respectively) were termed "pseudoparoxysmal activities" (D. SILVERMAN, 1962). • At the beginning of **stage IV**, pseudoparoxysms were detectable as frontal or generalized occurrences, with the continued slowing down of the base frequency and prevailing delta rhythm (2−3/sec). During the further course of disease, the triphasic complexes and the pseudoparoxysms disappear. Delta and subdelta waves continue to level out, and isoelectric stretches become evident. (s. tab. 15.5)

By means of psychometric tests, neurological/psychiatric findings and possibly also EEG changes, an accurate assessment can be made regarding the degree of severity of HE − this guarantees a reliable follow-up, in which the efficiency of the therapy can be reviewed.

▶ Defects in the cerebral functions and disturbances in the water and electrolyte balance are considered to be the earliest and most reliable signs of **commencing decompensation** in a severe liver disease, particularly cirrhosis.

▶ Clinically, the commencing decompensation can be easily diagnosed as latent hepatic encephalopathy (by means of psychometric testing) and as latent oedema (by keeping note of the increase in body weight). *These findings, recorded on a **documentation sheet**, are also of considerable importance for monitoring chronic liver patients.* (s. figs. 10.1; 15.3) (s. pp 305, 744)

# 7 Diagnosis

Encephalopathy can occur in a number of **extrahepatic diseases**, such as toxic, metabolic or circulatory disorders, intracranial space-occupying lesions, hypothyroidism (35) and neurological/psychiatric diseases. (s. tab. 15.2) Identification of neuropsychiatric symptoms always calls for careful differential diagnosis.

Similarly, in various **liver diseases,** thought should be given to the presence of HE if neuropsychiatric disturbances occur. This is true for acute liver diseases (severe acute viral hepatitis, acute liver failure) and for severe (particularly alcohol-related) fatty liver, Wilson's disease, severe chronic hepatitis, severe infectious or parasitic liver diseases such as schistosomiasis, metastatic liver, nodular regenerative hyperplasia, and liver cirrhosis. (1, 16, 17, 22, 24, 28, 29, 67, 76, 78, 95, 104) The diagnosis of HE can prove difficult if the liver disease is (still) unknown.

A **portosystemic anastomosis** is most frequently associated with HE of differing degrees of severity. • The presence of a *surgically laid shunt* is naturally revealed during anamnesis and therefore does not constitute a diagnostic problem. (36, 40, 46, 48, 50, 60, 66, 77, 87, 91, 98)

In contrast, encephalopathic symptoms deriving from *congenital anastomoses* can render it difficult to make a differential diagnosis. (51, 80)

1. Besides direct questioning of the patient, valuable information may be obtained by asking the spouse or closest relatives about possible neuropsychiatric symptoms displayed by the patient. Specific questions should be asked regarding changes in personality, working capacity, sleep behaviour, powers of concentration, capacity to register and mental reactivity. (49, 83)

2. In all cases of suspected HE, **psychometric tests** (e.g. handwriting specimen, number-connection test B, line-tracing test, star-forming test) are a top priority. (1, 42, 57, 72, 92) (s. p. 203) (s. tab. 10.7) (s. fig. 15.3)

| Date | Handwriting specimen | Body weight | Stool frequency |
|------|----------------------|-------------|-----------------|
| 1.7. | *Albert Hofmann* | 71.5 | 2 × |
| 2.7. | *Albert Hofmann* | 71.4 | 2 × |
| 3.7. | *Albert Hofmann* | 71.7 | 2 × |
| 4.7. | *Albert Hofmann* | 71.9 | 1 × |
| 5.7. | *Albert Hofmann* | 71.9 | 1 × |
| 6.7. | *Albert Hofmann* | 72.3 | 1 × |

= onset of oedema

***Tab. 15.5:*** Diagram of the stages of hepatic encephalopathy (subclinical and latent forms and manifestation I−IV) as well as their respect-ive symptomatology

The pathological outcome of these tests does not only call for further neuropsychiatric and psychological examinations, but it also means that the patient (and if the patient agrees, also the spouse or closest family members) must be fully informed about the situation. Due account must be taken of road safety and/or safety at the workplace in the interest of both the patient and the immediate environment. Extensive **psychological test procedures** should always be considered if generally important or even bureaucratic and legal decisions have to be taken concerning the patient.

▶ All test results and the contents of the patient briefing as well as the patient's consent or refusal must be documented by the physician and confirmed in writing by the patient or by witnesses.

3. In certain cases, the **neurological status** will be ex-panded on by the neurologist. In this respect, the EEG or even the initiation of visually evoked (VEP), acoustically evoked (AEP) and somatosensorily evoked (SEP) poten-tials may be indicated. There is often a correlation be-tween autonomic neuropathy and the prolongation of the corrected QT interval (F. SZALAY et al., 1998). • Determi-nation of the **critical flicker frequency** makes possible the best assessment of a HE 0, 0-I. (52) (s. p. 203)

4. **Laboratory examinations** are of no relevance concerning diag-nostic procedures focusing on HE, as interesting as it might be to determine octopamine, β-phenylethanolamine, methandiol, free phenols and tyramine in the blood and urine as well as ethandiol, dimethylsulphide, thyroid hormones and prolactin in the serum. This is also true for the detection of greater concentrations of glut-amine in the CSF, which are believed to indicate the degree of severity of HE. • **Determination of ammonia** (4, 54) (s. p. 107!) in the arterial and, with less reliability, in the venous blood has *no correlation whatsoever with the degree of severity of HE*, especially since, even in a severe coma (stage IV), no hyperammonaemia is detectable in 10−15% of cases. Values of >100 μmol/l are definitely considered to be pathological. • **Breath ammonia** (measured using electrodes in collected expired air) correlates positively with **blood ammonia** levels. This method may be useful for diagnosis and fol-low-up in HE. (97)

5. For the differential diagnosis of HE, **computer tomography** can be important in tracing morphological changes in the brain. Even in HE, signs of atrophy were detectable in up to 50% of cases. CT, **magnetic resonance imaging** (28, 67) and **magnetic resonance spectroscopy** are not yet regarded as clinically significant in the diagnosis of HE.

# 8 Prognosis

The prognosis of HE with **acute liver failure** is generally very bad. Lethality is 80−85%; this can diminish or increase, depending on the acuteness and severity of liver cell disintegration. (1, 2, 14, 20, 39, 113)

In **endogenous hepatic coma** (= due to loss of liver parenchyma), which in most cases develops from an existing chronic liver disease ("acute on chronic"), the prognosis is better than for acute liver failure, but nevertheless remains extremely poor. According to the information available in the relevant literature, 10−20% of patients die in stage I and 40−50% in stage II; in stages III and IV, lethality is 80−90%, the same rate as in acute liver failure. *(see chapter 20)*

In **exogenous hepatic coma** (= due to loss of liver cell function), the prognosis seems to be somewhat better than in endogenous hepatic coma − although it is still poor: nearly all patients have a chance of survival in stage I, 60−75% in stage II, and some 30% in stages III and IV. About 30% survive 2−5 coma phases; 10−20% of the patients have a five-year survival time following the first coma. • These figures can only be taken as a guideline, since the prognosis depends on various **influential factors**:

1. Exogenous hepatic coma has a better prognosis than endogenous hepatic coma.
2. The size of the residual parenchyma and hence the remaining liver function is of decisive importance.
3. The aetiology of the underlying liver disease and the extent of the collateral circulatory pathways influence the prognosis in a variety of ways.
4. Advanced age and concomitant diseases render the prognosis less favourable.
5. The prognosis also depends on the trigger factors of HE being eliminated as rapidly and as completely as possible. This is particularly true of the swiftest possible elimination of blood from the intestinal tract.
6. Complications regarding cirrhosis, such as ascites, albumin deficiency, blood-clotting disorders, increasing jaundice and gastrointestinal bleeding (including occult blood), make for a considerably worse prognosis.
7. Of decisive importance is the stage at which proper treatment is initiated, so that progression can be hindered.

The best therapy results are obtained in the subclinical stage (0, 0−I) and the stage of disorientation (I). Nearly all of these patients can be successfully treated and brought back to the encephalopathy-free phase. • *Early diagnosis is of paramount importance for the prognosis.*

# 9 Therapy

Even in antiquity, it was assumed that there was a correlation between the liver and brain functions. *Normal functioning of the liver, in particular adequate detoxification, is a prerequisite for a smooth course of multiple cerebral reactions.* By contrast, decreased liver function leads to increasing impairment of the functioning of the brain.

## 9.1 Fundamental prerequisites

▶ The treatment of subclinical hepatic encephalopathy as well as of stages I−IV explicitly calls for the *elimination of trigger factors* and other possible causes together with the avoidance of additional noxae. (s. tab. 15.2) Often these measures suffice to prevent the manifestation or progression of HE. An inadequate response to the initiated treatment should be reason enough to carry out a more thorough investigation into other possible causative factors.

▶ **Normalization of liver function** is the main aim in the treatment of hepatic encephalopathy. Basically, this can only be accomplished by overcoming the acute liver failure through intensive care procedures with subsequent restitution or by means of liver transplantation. In patients with chronic liver disease, there are in principle two long-term **treatment goals:** (*1.*) averting or eliminating factors which lead to dysfunction and/or morphological damage to the residual liver parenchyma and (*2.*) use of all possibilities in order to promote the functioning of the liver and its ultimate morphological regeneration.

▶ **Normalization of laboratory parameters** must be guaranteed: (*1.*) regulation of serum electrolytes, acid-base equilibrium and blood sugar values, (*2.*) substitution of zinc, and (*3.*) compensation of hypovolaemia. • Metabolic alkalosis should not be balanced, since it is important for the urea cycle.

These measures apply equally to all forms of hepatic encephalopathy and to all degrees of severity − and they are part of the imperative *prophylaxis* of hepatic encephalopathy.

## 9.2 Basic therapy

### 9.2.1 Intestinal cleansing

Intestinal cleansing effects the removal of nitrogenous substances and toxins from the intestine, particularly in cases of gastrointestinal haemorrhaging, increased intake of animal protein and obstipation. In HE, intestinal cleansing is always indicated, modified according to the respective degree of severity. (s. tab. 15.6).

**Enemas** may be necessary in acute and severe coma episodes, with highly constipated patients or in cases of massive gastrointestinal bleeding. Occasionally, a rectal

enema can provide adequate purgation of the rectal ampulla and the lower sections of the colon. A *high enema* should reach the entire colon up to the caecum. This can be accomplished by initially effecting insertion with the patient in a left-side position, subsequently in a supine position combined with the simultaneous lifting of the lower abdomen and finally in a right-side position. The volume used should be at least 1,000 ml. Both *sodium acetate buffers* (pH 4.5) and *lactulose* (300 ml lactulose with 700 ml water, twice a day) have proved efficacious. (161)

**Oral purgatives,** more reliable when applied by drip infusion via the nose and stomach, are mostly quite adequate. They have a swift and reliable effect. For example, 1,000 ml of a *10% mannite solution* with an infusion time of 60−90 minutes achieve virtually complete purgation of the intestinal tract over the following 3 or 4 hours by way of osmotic diarrhoea. In cases of gastrointestinal bleeding, the mannite solution should be supplied to the stomach via a tube until the rectal run-off liquid is clear. The isotonic *Golytely solution* (sodium hydrogen carbonate, KCl, NaCl, $NaSO_4$, polyethylene glycol) has proved most successful. Likewise, 50−100 ml of a 20 or 30% $MgSO_4$ *solution* or 2,000 ml of a 10% mannitol solution can be administered per day through a nasogastral tube. This intensive intestinal cleansing is continued by treatment with lactulose. As a rule, in subclinical HE and in stage I, oral administration of lactulose is sufficient. • *Activated charcoal* may be added (orally or rectally) to bind aromatic substances.

### 9.2.2 Dietary measures

The **dietary treatment** of patients with chronic liver disease is *ranked highly as a therapeutic measure.* Thought must be given to the fact that the energy metabolism and the nutritive status of cirrhotic patients are at the level of long-standing inanition. • This was confirmed by the fact that a quantitatively and qualitatively adequate diet for dogs with **Eck's fistula** (= portacaval shunt) prevented the development of muscular atrophy and encephalopathy. (s. p. 264) • In patients with alcohol-related, stable liver cirrhosis, hyperalimentation improved the synthesis of proteins without the patient being exposed to the danger of HE.

The protein balance is normally in a steady state with a protein intake of some 1.5 g/kg BW/day. In HE, however, it is imperative to **restrict the protein intake.** In subclinical HE, the protein quantity should be reduced to about 40g/day (ca. 0.6 g/kg BW), in stages I and II to approx. 30 g/day (ca. 0.4 g/kg BW), and in individual cases even to protein deficiency for a period of 1 to 3 days − which is not difficult to carry out. In stages III and IV, an optimal diet can only be provided by a gastric feeding tube and i.v. solutions. (134) The oral protein intake should comprise vegetable protein and lactalbumin, since these are best tolerated by patients exposed to the danger of HE. Vegetable proteins contain less methionine and aromatic amino acids, yet more ornithine and arginine. • Cheeses containing ammonia

should be avoided, as should fish, eggs and meat; blood is least tolerated. (As long ago as 1893, M. HAHN triggered "meat intoxication" with ataxia, convulsions, stupor and coma after feeding meat to *dogs with Eck's fistula*.) An individually adjusted balance between lactalbumin products and vegetable proteins is necessary with a view to better tolerability and acceptance. (9, 69, 89, 117, 120, 125, 128, 133, 135, 162)

At intervals of 3 to 5 days, the lactovegetable protein intake is steadily increased by about 10 g, until a daily intake of 1−1.5 g/kg BW (in the long term up to a total of 80−100 g/day) is attained, provided this is tolerated. The **protein tolerance threshold** for lactovegetable protein and for the integration volume of animal protein can be determined with sufficient reliability by *psychometric tests.* (s. p. 203) (s. tabs. 10.6−10.9) • *All cirrhosis patients (or chronic liver patients) have their own protein tolerance threshold.* • Subsequent monitoring under outpatient conditions is carried out by the patients themselves in the form of self-checking, using a **documentation sheet.** (s. fig. 15.3) The use of the blood ammonia level for follow-up monitoring is unsuitable because of the sensitive pre-analysis and the low degree of reliability. • With a permanent albeit necessary restriction of protein intake to <60 g/day, the protein balance can be improved by the administration of **protein compounds** (enriched with vitamins and trace elements) or **branched-chain amino acids.** *Catabolism has to be avoided at all costs!*

A **calorie intake** of 1,800−2,500 kcal/day (ca. 30 kcal/kg BW/day) is guaranteed by the adequate administration of fats (70−140 g) and carbohydrates (280−325 g). Consideration should be given to the fact that cirrhotic patients show a resistance to insulin and a glucose intolerance, with a tendency to develop a diabetic metabolic condition. For this reason, it might well be necessary to administer insulin. Carbohydrates reduce the plasma levels of ammonia and free tryptophan.

▶ **Fructose, xylitol** and **sorbitol** should not be used in view of the danger of lactate acidosis. • Restraint is likewise called for with the application of **medium-chain triglycerides,** since substances such as octanoate are only metabolized slowly and also deemed to be potentially neurotoxic.

**Vitamins:** In particular, water-soluble vitamins have to be provided in adequate quantities. With a carbohydrate diet and alcoholic liver disease, the daily requirement is higher. A daily intake of multivitamins, best combined with *trace elements* and *minerals*, is recommended. As a rule, liposoluble vitamins are best administered by parenteral route due to inadequate absorption. • The therapeutic significance of **zinc** (s. pp 50, 99) should always be borne in mind. (34, 153, 155, 169)

## 9.3 Standard therapy

If possible, standard therapy should have an impact on both the intestine and the liver. The intestinal tract is

| | Latent HE | Manifest HE | | Chronic persistent HE |
|---|---|---|---|---|
| | | I−II | III−IV | |
| **Elimination of causative and trigger factors** | ++ | ++ | ++ | ++ |
| **Intestinal cleansing** | + | ++ | ++ | + |
| **Restriction or adjustment of protein intake** | + | ++ | ++ | + |
| **Lactulose** | ++ | ++ | ++ | ++ |

| **Zinc** | + | ++ | ++ | + |
| **Antibiotics** | ∅ | ++ | ++ | ∅ |
| **Flumazenil** | ∅ | + | ++ | + |

*Tab. 15.6:* Recommendations for therapy in various forms and stages of HE (∅ = not recommended, + = recommended or important in individual cases, ++ = important)

an important source of potentially toxic protein catabolites and endotoxins. (s. tab. 15.1) The liver must be able to cope at all times with the requisite detoxification and the respective cellular metabolic reactions. (44, 49, 83, 143, 156)

### 9.3.1 Lactulose

Since 1966, **lactulose** has been considered the therapy of choice in the treatment (and prophylaxis) of HE. (s. p. 858)

Its undisputed **efficacy** can be explained by the interaction between several pharmacological mechanisms (e.g. prevention of the absorption of ammonia or catabolic suppression of the protein metabolism of the intestinal bacteria due to a surplus of carbohydrates). As a result, ammonia and GABA (and apparently octopamine) are generated to a lesser extent in the intestine. Lactulose also has an anti-endotoxin impact and inhibits the splitting of glutamine in the mucosa of the small intestine. This inhibitory effect is also brought about by lactulose if the intestinal flora has been largely suppressed by antibiotics. (s. p. 280) Likewise detectable is an increased excretion of nitrogen in the stools. (s. tab. 15.6)

The **dosage** depends on the individual reaction and must be selected in such a way that two or three stools are purged off each day (*"never less than 2, never more than 3"*). With this dosage, the colon pH value lies in the required range below 6.0. Lactulose is administered in two or three single doses, each dose being adjusted in order to attain the required number of *stools*. Lactulose is deemed to be a long-term therapeutic measure, since it can (and should) be used for an unrestricted length of time, above all in patients at risk of encephalopathy. (121, 132, 139, 142, 154, 164, 165, 167)

*Adverse effects* are nausea, vomiting and lack of appetite (usually because of the sweet taste) as well as flatulence, meteorism and tenesmus (owing to the formation of gas in the intestine). Dehydration and electrolyte imbalance should not arise if two or three stools a day are maintained. *Compliance* on the part of the patient is considerably restricted due to the very sweet taste of lactulose. • *Pleasant in taste*, in contrast, are (*1.*) crystalline lactulose in the form of granulate, (*2.*) lactulose bound with lemon oil, and (*3.*) lactitol.

**Lactitol** has the same pharmacological effects, application guidelines and clinical results as lactulose, but with a better degree of acceptance in terms of taste and more rapid results. It is administered as a powder, mixed into drinks or food. The daily dosage (0.5−0.7 g/kg BW) is adjusted to the required 2 or 3 stools/day. (141, 154)

**Nicotine hydroxamic acid** is a urease inhibitor which reduces ammonia formation in the intestine. This substance has no systemic side effects. In a controlled double-blind study, it proved to be superior to treatment with neomycin (C. Hirayama et al., 1982).

**Probiotics** are defined as microbial preparations of living microorganisms having a "positive" effect on the intestinal flora after oral administration (R. Fuller, 1989). Bacterial cultures such as those derived from Lactobacillus acidophilus, Lactococcus lactis, Enterococcus faecium (see below), Bifidobacterium bifidum (see below), Lactobacillus casei and Lactobacillus thermophilicum have proved reliable.

**Enterococcus faecium** has proved to be equivalent to treatment with lactulose in patients suffering from cirrhosis and HE stages I and II. There has been no evidence of side effects. (139)

**Lactose** has a laxative effect when there is lactose intolerance in the intestinal mucosa (congenital or acquired). It is still not clear whether lactose and lactulose affect the intestinal flora and its metabolism. (Certain quantities of lactose are usually contained as an additive in lactulose syrup!) (164)

**Bifidum milk** is a compound of bifidobacteria, lactose, lactulose, galactose and protein. The dosage is 3 × 12 to 3 × 48 g/day, always postprandial. Even with long-term treatment, there are no side effects that are worth mentioning. (139)

### 9.3.2 Intermediates of the urea cycle

▶ As early as 1932, H. A. Krebs and K. Henseleit established that of the investigated amino acids, only ornithine was able to effect a real increase in the synthesis of urea from ammonia (although arginine also displayed low efficacy). (quot. 57) • Thus it seemed possible to raise the turnover of ammonia in the metabolism process by using intermediates of the urea cycle. (127) (s. tab. 15.6) (s. fig. 3.10) To this end, **ornithine aspartate** (oral and parenteral route), **arginine malic**

**acid** (oral route only), **ornithine α-ketoglutarate** (only available as i.v. infusion) and **sodium benzoate** (122, 159) were used.

*Urea synthesis* takes place mainly in the periportal hepatocytes. **Ornithine** has a threefold effect on urea synthesis in the detoxification of ammonia: (*1.*) as a substrate of urea synthesis, (*2.*) as an activator of carbamoylphosphate synthetase, and (*3.*) as an activator of ornithine carbamoyltransferase. Together with aspartate, ornithine also reinforces *glutamine synthesis*, which serves to detoxify ammonia temporarily. Glutamine synthesis (addition of ammonia to glutamate) takes place in the perivenous hepatocytes. The influence of **aspartate** is twofold: (*1.*) as a substrate in the formation of glutamine and (*2.*) as an activator of glutamine synthesis. Glutamate, ornithine and other dicarboxylates are taken up and serve as initial substances for the synthesis of glutamine in perivenous scavenger cells. Recent experimental and clinical results confirm the justification as well as the success of these substances as components of the therapy plan for HE. In therapeutical terms, **ornithine aspartate** is available as an intermediate of the urea and citric acid cycles. Depending on the severity of HE, this substance is used in granulate form or as a chewing tablet ($3 \times 3$ to $3 \times 6$ g/day) or administered as a concentrated i.v. solution with $2-4$ ($-8$) $\times$ 5 g/day. (136, 157, 158) (s. p. 862)

**Sodium benzoate:** Sodium benzoate has already been successfully used to treat congenital enzymatic defects of the urea synthesis (M. L. BATSHAW et al., 1981). In HE, the administration of sodium benzoate or sodium phenylacetate (each 10 g/day) achieved clinical success equivalent to lactulose therapy in ca. 80% of cases. (122, 144, 159) These substances (which are cheap and practically free of side effects) lead to an increased excretion of nitrogen through the conjugation of glycine and glutamine, whereby ammonium is bound as hippuric acid and excreted renally (bypassing the urea cycle).

## 9.4 Branched-chain amino acids

The application of branched-chain amino acids (BCAA) was based on the **therapeutic target** of compensating for the surplus of aromatic amino acids in order to suppress the synthesis of false neurotransmitters. Nevertheless, up to now, (*1.*) no correlation has been found between the amino acid imbalance in the plasma and the degree of severity of HE, (*2.*) no temporal correlation has been established between the normalization of the amino acid imbalance and the improvement of HE, and (*3.*) no influence has been detected on normal neurotransmitters in the CSF. These three counterarguments are, however, the subject of controversy and critical discussion.

The undoubtedly genuine **efficacy** of branched-chain amino acids cannot be explained merely by the improved metabolism of ammonia, but also by their complex influences on the metabolism of the muscles, liver and brain. The wide range of results may be the outcome of applying various test parameters as well as using different, possibly even unfavourable additives (xylitol, sorbitol, fructose, fats, etc.) Some 18 studies have been evaluated, but an ultimate assessment of the efficacy of BCAA on HE has not yet been achieved. (124)

In biochemical terms, the following **effects** on HE can be expected from branched-chain amino acids: (*1.*) decrease in protein catabolism of the musculature and liver, (*2.*) improvement of protein synthesis in the musculature (particularly induced by leucine), (*3.*)

improved urea synthesis in the liver (with higher concentrations of ornithine and N-acetylglutamate in the mitochondria), (*4.*) improvement of the nitrogen balance, (*5.*) reduction in the release of aromatic amino acids from the muscles, (*6.*) rise in glutamate and glutamine in the brain, and (*7.*) increase in oxydative phosphorylation in the brain in the form of an enhanced aspartate-malate shuttle.

> Hence branched-chain amino acids are *important energy carriers*, providing a *suitable protein input* for patients insufficiently supplied with or intolerant to proteins as well as for cases of increased catabolism in latent or manifest HE.

A daily **dosage** of 0.3 g/kg BW is recommended (approx. $3 \times 10$ g). The use of BCAA has become established for latent and manifest HE. It has even been possible to render patients fit to drive again. No side effects are known. The efficacy of branched-chain amino acids as parenteral *i.v. therapy* is well validated for the severe stages II−IV of HE. The concomitant intake of arginine and ornithine aspartate has proved to be particularly effective. (127) Fatty emulsions are to be avoided since they release tryptophan from the albumin binding and inhibit the utilization of branched-chain amino acids in the musculature. (123, 126, 129, 131, 133, 138, 140, 145, 148−151, 170) (s. p. 860)

## 9.5 Antibiotics

**Neomycin:** Since 1957, neomycin, which can only be minimally absorbed in the intestine, has been successfully used in the treatment of HE (A. M. DAWSON et al.). A *dosage* of $6-8$ g/day (oral or via stomach tube) is recommended initially, with a subsequent reduction to $2-4$ g/day, in 3 or 4 individual doses. A daily frequency of 2 or 3 stools should be achieved. Despite the minimal, individually variable absorption quantity ($1-3\%$ of the administered dose), ototoxicity and/or nephrotoxicity can occur as *side effects*. Moreover, when applied for longer periods or in higher doses, there is a risk of a malabsorption syndrome or intestinal bacterial superinfection as well as mycotic colonization of the intestinal tract. Neomycin should therefore only be used as a *short-term therapy* in stages II−IV of HE. A period of treatment lasting more than one week calls for a strong indication and careful patient monitoring. Following initial treatment with neomycin, a one-day overlap with subsequent long-term lactulose treatment has proved successful. The *combined application* of neomycin and lactulose may prove more effective for therapy-resistant patients because of its impact on various intestinal bacterial populations (F. R. COCKERILL et al., 1992). The principles of dosage and monitoring must be carefully observed. The *mode of action* of neomycin is complex: production of ammonia, alanine and glutaminic acid is reduced in the intestine, absorption of ammonia is impaired, and uptake of glutamine by the mucosa cells is inhibited. (121)

**Paromomycin:** In place of neomycin, paromomycin can be administered in an initial dose of $3-4$ g/day, with

subsequent reduction to $1-2$ g/day, in three or four individual doses. With regard to side effects, there seem to be certain *advantages* compared to neomycin: serum values are lower and of shorter duration, the serum plateau level area is about 2.5 times smaller, and it has a lower affinity to tissue.

**Metronidazole:** Up to 99% of the intestinal anaerobes that are largely responsible for the bacterial formation of ammonia are affected by metronizadole. Its efficacy corresponds to that of neomycin and paromomycin. The mode of action is still unresolved. The *dosage* is $3(-4) \times 0.4$ g/day with subsequent reduction to $2 \times 0.4$ g/day provided two or three stools can be produced each day. When used for longer periods, peripheral neuropathies can occur. For this reason, initial treatment with metronidazole should be replaced as soon as possible by long-term lactulose therapy. (147)

**Vancomycin** is known as a reserve antibiotic. It has been successfully used in patients with lactulose therapy failure. (160) Above all, vancomycin reduces the bacteroides population. The recommended *dosage* is $4 \times 0.5$ g/day.

When applied over a longer period of time and/or in higher doses, all of these antibiotics give rise to considerable **side effects.** Furthermore, the daily **requirement of tablets** is large, e. g. with neomycin (à 500 mg) or with paromomycin (à 250 mg), it amounts to $12-16$ tablets per day. This often presents certain difficulties. The **costs** are considerable. In contrast, **lactulose** costs merely $1-2$ $(-3)$ US dollars/day, has no or only minimal and harmless side-effects and is acceptable in usage − therefore it is the drug of choice, also in terms of expense.

## 9.6 Specific or adjuvant therapy

▶ The multifactorial aetiology and complexity of the pathogenesis together with the increasingly poor prognosis in terms of irreversible brain damage or lethality substantiate the use of "obvious" **polypragmasy.** This approach is also rendered plausible because specific pathogenic factors call for appropriate polypragmatic measures. From this point of view, "liver insufficiency" requires a therapy spectrum comparable to that used for "cardiac insufficiency" or "renal insufficiency", with equally specialized or adjuvant/supportive measures.

**Neuropharmaceuticals:** Given the neuropsychiatric symptoms of HE and considering the disorders of the neurotransmitter system, certain neuropharmaceuticals have started to attract attention. These are nootropic substances and benzodiazepine antagonists. They can be applied in patients resistant to other therapies.

**Flumazenil:** In 1985 the assumption that GABAergic neuroinhibition is increased in HE led to the therapeutic use of the benzodiazepine antagonist flumazenil (G. Bansky et al.). (116) An improvement in the neuropsychiatric symptoms of HE was achieved in 66% of patients. The recommended dosage is $0.2-0.3$ mg i.v. bolus, followed by 5 mg/

hour as i.v. infusion. Remarkable arousal effects and unexpected long-term success (50 mg/day orally) were described even in hepatic coma. In severity stage III of HE improvement occurred in 93% of cases, and in stage IV the rate was 48%. (5, 118, 119, 130, 137, 152) Recently, a meta-analysis showed that flumazenil improves clinical and electroencephalographic findings regarding HE in cirrhotic patients. (127)

**L-dopa,** a precursor of the neurotransmitters norepinephrine and dopamine, was introduced into HE therapy by J.D. Parkes et al. in 1970. The results were good. As yet, there is still no accepted opinion on the use of this substance. • **Piracetam,** as a nootropic substance, led to a clear improvement in typical electrical brain activities in animals displaying hepatic damage and symptoms of encephalopathy. • Similarly, a double-blind randomized cross-over study with the nootropic agent **centrophenoxine** partly showed positive effects in psychometric testing. • **Bromocriptine,** an agonist of the dopamine receptor, was also used in 1980 for chronic hepatic encephalopathy. (146, 163) • Application of **L-carnitine** (6 g/day orally, divided into two doses, for 4 weeks) leads to a marked reduction of hyperammonaemia and a clear improvement in clinical symptoms of HE in cirrhotic patients. (119) (s. p. 49)

## 9.7 Early detection and therapeutic success

The **early detection** of HE, if possible at the stage of latency or no later than in stage I, guarantees the best therapeutic results under outpatient conditions and thus avoids considerable cost-intensive hospital treatment.

**Elimination of the causative factors** of HE, insofar as this is possible at all, is the prerequisite for successful therapy. It is necessary because HE is seen as a potentially reversible impairment of brain functions, particularly in the "precoma" stages.

The various channels of pathogenetically and/or experimentally substantiated and clinically tested types of therapy applied as a **graduated therapy concept** are justified in HE − even though as a rule polypragmasy is to be viewed with some scepticism. Medication is based on the particular degree of severity of HE, the individual reaction of the patient and possible adverse effects.

# Symptoms and Syndromes

## 16  Oedema and ascites

# 16 Oedema and ascites

## 1 Water and electrolyte balance

**Water** is the most indispensable factor of life. By means of carefully coordinated regulatory mechanisms, the *water equilibrium* and hence the reservoir of body water is held constant. It is important to keep water intake and output in balance to maintain *isovolaemia*. (s. fig. 16.1)

**Water** is present in a free (non-osmotically bound) state and as a chemically bound hydrate solid structure. • The **clearance** of free water is controlled by vasopressin; it is calculated from the volume of urine/minute minus the osmolal clearance. A normal daily fluid intake of 1,700−2,200 ml (25−30 ml/kg BW) in addition to some 300 ml oxidation water is balanced by a fluid discharge of approximately 1,500 ml as urine, about 100 ml in stools, roughly 600 ml as perspiration and some 400 ml as expired air. (s. fig. 16.1)

About 60% of the body's weight (ca. 55% in women) consists of water. The reservoir of body water is distributed between the **intracellular space** (ca. 40% of BW) and the **extracellular space** (ca. 20% of BW). The extracellular compartment consists of plasma fluids (ca. 4% of BW) and interstitial water (ca. 16% of BW), the latter also containing transcellular water (ca. 2.5% of BW). Because of its high degree of permeability, the body water is evenly shared between the intracellular and extracellular compartments. The water distribution between plasma and interstitium, regulated by **Starling's forces,** depends on the hydrostatic and colloidosmotic pressure gradients along the capillary walls. • **Disturbances in the excretion of water** are derived from (*1.*) an increase in ADH activity, (*2.*) a reduction in distal filtrates available in the nephron, and (*3.*) greater absorption of water in the distal nephron, independent of ADH. Disruptions in the body water pool cause changes in serum sodium or serum osmolality.

**Electrolytes** are subject to dissociation into negatively charged anions and positive cations. The vital *electrolyte balance* guarantees the respective uptake and discharge and ensures the correct presence and distribution. This regulatory process is closely linked to the water equilibrium. The intracellular and extracellular spaces differ in their electrolyte content. (s. tab. 16.1)

|  | Plasma | Interstitial space (mval/l) | Intracellular space (mval/l) |
|---|---|---|---|
| **Cations** |  |  |  |
| Sodium | 142 | 145 | 10 |
| Potassium | 4 | 4 | 160 |
| Calcium | 5 | 5 | 2 |
| Magnesium | 2 | 2 | 26 |
|  | 153 | 156 | 198 |
| **Anions** |  |  |  |
| Chloride | 101 | 114 | 3 |
| Bicarbonate | 27 | 31 | 10 |
| Phosphate | 2 | 2 | 100 |

***Tab. 16.1:*** Constituents of the most important electrolytes (in mval/l) in extracellular and intracellular fluid

▶ An **ionogram** of the fluid spaces compares the cation and anion content in milliequivalents, since it is not the weight, but the chem-

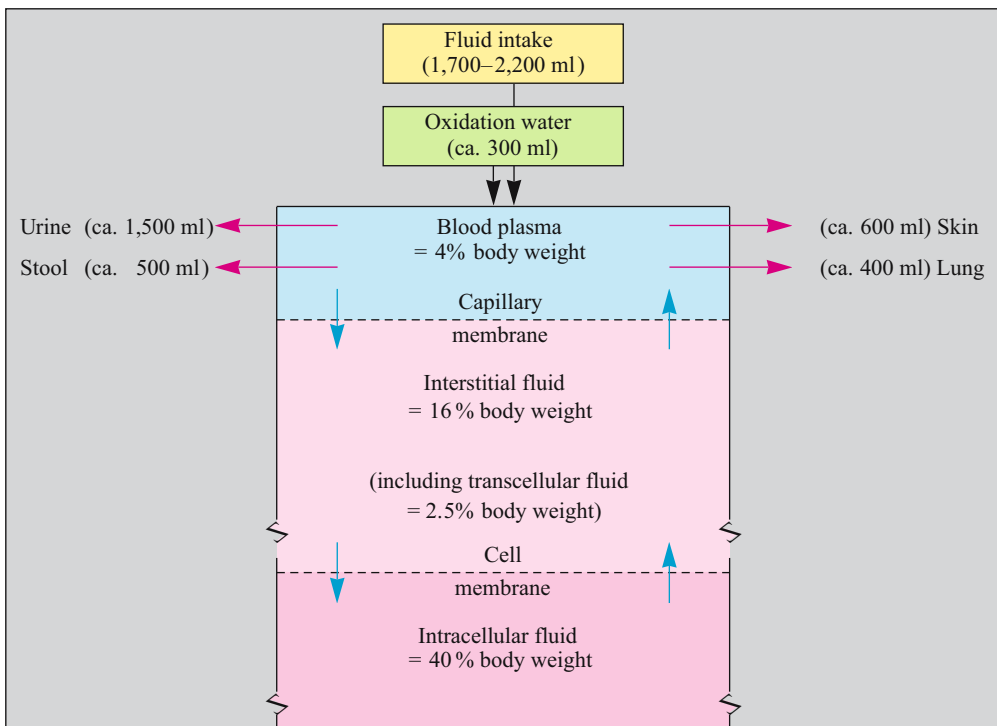

***Fig. 16.1:*** Fluid spaces and exchange of water (blood plasma + interstitial fluid = extracellular space, intracellular fluid = intracellular space)

ical-binding potential (mval) of the ions that determines the electrochemical reactions between them. The electrolytes, which are partially integrated into the structures of the cells, do not develop any osmotic activity. For this reason, there is no osmotic gradient between the intracellular and extracellular space despite the difference in the distribution of ions (153 and 156/198 mval). • Apart from this, the ionogram also provides information on the osmotic pressure (mosmol) of the respective fluid. This value does not depend on valence, but on the number of particles dissolved in each litre of solution (= **osmolarity**; mmol/l) or per 1 kg water (= **osmolality**; mosmol/kg). All fluids with an osmolality of $285-295$ mosmol/kg are isotonic with respect to plasma. (With 1-valent ions, mval, mmol and mosmol are identical; with 2-valent ions, 2 mval correspond to 1 mmol or 1 mosmol). The osmolality of urine is twofold to threefold the osmolality of serum (up to ca. 1,300 mosmol). • The normal **pH value** ranges between 7.35 and 7.45 in the extracellular fluid (blood plasma and interstitium) and between 6.8 and 7.0 in the intracellular fluid.

A number of transport systems guarantee the differing compositions of intracellular and extracellular fluid. Ion displacement gives rise to the development of concentration gradients between these two compartments. Water flows passively through the cell membranes in the direction of the hyperosmolar space. The regulatory mechanism of the so-called **Donnan equilibrium** takes effect (and generates a relative condition of ion equilibrium). To a certain extent, the compensation of osmolarity between the intracellular and extracellular spaces by way of fluid displacement in line with the **Darrow-Yanett principle** supports the homoeostasis process with the aim of maintaining iso-osmosis.

**Isotonicity** of the extracellular space is regulated by (*1.*) thirst mechanism, (*2.*) ADH, and (*3.*) dilution and concentration potential of the kidneys. • Maintenance of extracellular **isovolaemia** is effected by a change in renal sodium excretion. For this reason, disturbances in the sodium supply primarily result in changes in the extracellular fluid volume. • **Isohydria** is also continually regulated within the normal range.

▶ When fever occurs, the organism loses about *500 ml fluid* and some *25 mmol salts* per day for each one-degree rise in body temperature.

# 2  Definition

Depending on the extent of the extracellular volume, disorders of water and sodium balance are categorized as **dehydration** (= hypovolaemia) and **hyperhydration** (= hypervolaemia). In accordance with the behaviour of serum osmolality and serum sodium, these conditions of hydration are subdivided into isotonic, hypotonic and hypertonic forms. Should it no longer be possible to achieve iso-osmosis owing to sustained or permanent disruptive mechanisms, the physiological regulatory processes gain ever-increasing pathophysiological significance − creating a vicious circle.

## 2.1  States of hydration

In the field of hepatology, three varying states of hydration are important:

(*1.*) **Isotonic dehydration** due to isotonic loss of fluid on account of diuretic therapy, diarrhoea, ascites taps or loss of blood (= extracellular space decreased, overall sodium status depressed, serum osmolality and serum sodium normal).

(*2.*) **Hypotonic dehydration** as a result of the loss of sodium from long-term diuretic therapy and from diarrhoea as well as due to inadequate sodium intake (= extracellular space decreased, intracellular space increased, overall sodium status depressed, surplus of free water, hypo-osmolality and hyponatraemia).

(*3.*) **Isotonic hyperhydration** due to hypernatraemia with generalized oedema in decompensated liver cirrhosis (= extracellular space enlarged, overall sodium status elevated, serum osmolality and serum sodium normal).

## 2.2  Oedema and anasarca

The term **oedema** (το οιδημα = the swelling) describes an increase in the extracellular fluid volume as a result of isotonic hyperhydration. Oedema is a *symptom* with multiple causes, yet not an illness. • The term **anasarca** refers to a massive, generalized soaking of the subcutaneous tissue ("tissue dropsy"). (s. fig. 16.2)

*Fig. 16.2:* Pronounced anasarca in portal ascites as a result of alcoholic cirrhosis

Anasarca is a circumscribed or diffuse, practically painless accumulation of serous liquid (generally poor in protein at first, but in most cases) more rich in protein later on in the skin, mucosa, parenchymal organs and nerve tissue. • The *clinical manifestation* of oedema can only be discerned during a physical examination if the enlargement of the extracellular space amounts to at

least 3−5 litres. *Latent oedema* ("pre-oedema") can be identified by an increase in body weight of >1 kg within 4−5 days. (s. fig. 15.2)

**Oedema disease:** It has not yet been clarified to what extent the so-called oedema disease, a chronic generalized condition of hydration of the interstitial tissue, may be regarded as a disease in its own right.

## 2.3 Ascites

▶ Erasistratos (ca. 300−250 BC) already recognized the connection between ascites and hepatic disease; he objected to the puncturing of ascites as being a non-causal and unnecessary measure. A. C. Celsus (30 BC−50 AD) postulated the link between ascites and renal disease or a poor general condition (carcinoma?); he coined the term "ascites". (s. pp 6, 7) • In animal experiments, it was possible to induce ascites by means of ligature of the inferior vena cava below the diaphragm (R. Lower, 1671). F. Th. Frerichs (1858) frequently observed oliguria and renal dysfunction in cirrhosis patients. In 1863 A. Flint was able to demonstrate that in cirrhotic patients with ascites, the morphology of the kidneys was normal − thus there must be a functional disorder in the renal area. With portal hypertension, E. H. Starling (1884) and R. Heidenheim (1891) found an increase in the lymphatic flow in the thoracic duct. • In 1943 D. Adlersberg et al. detected a reduced excretion of free water in cirrhosis patients with ascites. Proof of increased sodium retention was obtained by E. B. Farnsworth et al. in 1945. With these observations, made some 60 years ago, two essential pathophysiological findings were identified in cirrhosis-induced ascites.

The term **ascites** (= hydraskos or abdominal dropsy) is defined as an accumulation of fluid in the abdominal cavity during the course of various diseases. Commensurate with the respective underlying disease, there is no homogeneity in the aetiology and pathogenesis of ascites. Hence ascites is not a disease as such, but rather a *symptom* of the advanced or severe course of an underlying disease. Generally, its prognosis is poor. The two-year rate of survival is about 50%. In liver disease or liver cirrhosis, the occurrence of ascites can give a clue to decompensation. • *Usually, ascites occurs in liver disease prior to the development of oedema.*

# 3 Pathogenesis

## 3.1 Oedematization

The **filtration pressure** (= difference between hydrostatic capillary pressure and tissue pressure) furthers the discharge of plasma fluid from the arterioles; as a result of the higher protein content of the plasma, the **colloidosmotic pressure** promotes the backflow of interstitial fluid into the venules. In the arteriole, the hydrostatic pressure is 40−45 mm Hg; it drops down to 10−15 mm Hg in the direction of the venous capillary loop. Both the colloidosmotic pressure and the tissue pressure remain unchanged at −25 to −30 mm Hg or −2 to −5 mm Hg along the arterial and venous parts of the capillaries. Consequently, an effective filtration pressure of 10−15 mm Hg is generated in the arterial capillary loop and of −10 to −15 mm Hg in the venous loop. (s. fig. 16.3)

The **pathogenesis** of oedema is derived from a change in these physical forces. The net flow from one compartment to the other is altered accordingly, as is the volume of the respective fluid space. (s. fig. 16.1) A disrupted distribution of the fluid can also be caused by damage to the capillary endothelium as a result of chemical, thermal, mechanical, toxic or immunological influences. This gives rise to a greater degree of permeability with increased protein transfer into the interstitium. • A reduction in the colloidosmotic pressure along the passage of the capillary results in less interstitial fluid being transported into the vascular lumen. (s. tab. 16.2)

1.  **Deposition of interstitial liquid is augmented**
    - with increased hydrostatic capillary pressure
    - with increased permeability of the capillary endothelium
2.  **Removal of interstitial fluid is restricted**
    - with depressed colloidosmotic pressure in the vascular lumen (e. g. hypalbuminaemia)
    - with augmented protein transfer into the interstitium
    - with decreased lymphatic drainage

**Tab. 16.2:** Causative factors of oedematization

**Fig. 16.3:** Fluid exchange between plasma and interstitial tissue (mm Hg)

The *primary event* in oedematization is the renal retention of sodium, which provokes a greater feeling of thirst with an increase in ADH secretion. The result is renal water retention. • *A total of about 1 litre of water is retained per 140 mmol (ca. 3.3 g) sodium.*

In liver diseases involving elevated hydrostatic pressure (e.g. as a result of portal hypertension), the inflow of fluid into the interstitium is increased, whereas the return of fluid into the vascular bed is decreased due to the depressed colloidosmotic pressure (e.g. as a result of hypalbuminaemia). Likewise, a boost in capillary permeability leads to an outflow of fluid into the interstitial tissue. (2, 5, 8, 12)

## 3.2 Formation of ascites

### 3.2.1 Mechanical factors

The complex pathogenesis of ascites calls for focus on four mechanical factors. (s. tab. 16.3) The pathogenic significance of the respective factors can differ considerably in relation to the underlying diseases and at the same time vary greatly from individual to individual.

| |
|---|
| 1. **Increase in hydrostatic pressure** <br> – portal hypertension <br> – narrowing of the inferior vena cava at the level of the diaphragm <br> – disruption of anatomic blocking mechanisms in the hepatic veins <br> 2. **Reduction in colloidosmotic pressure** <br> 3. **Disturbance of capillary permeability** <br> 4. **Insufficiency of lymphatic drainage** |

*Tab. 16.3:* Mechanical factors in the formation of ascites

1. **Increase in hydrostatic pressure:** Portal hypertension as a result of structural changes in the liver or its vessels, with peripheral and sinusoidal impediment to the outflow of blood, leads to blood stasis in the vessels, which are dilated by pressure. This inevitably generates an increase in hydrostatic pressure. The sinusoidal increase in pressure signals a greater retention of sodium in the kidneys. Another possible cause of ascites is constriction of the inferior vena cava at the level of the diaphragm resulting from regeneration nodes found in cirrhosis, especially since the inflow of blood into the liver is clearly increased at the same time. Disruptions of the anatomic blocking mechanisms in the hepatic veins may constitute further mechanical causes of elevated hydrostatic pressure.

2. **Reduction in colloidosmotic pressure:** The colloidosmotic pressure in the plasma is lower in liver cirrhosis patients. This results from (*1.*) restriction in the synthesis of albumin (which is, however, only clinically manifest after 3 or 4 weeks due to the half-life of plasma albumin), (*2.*) greater loss of protein-rich fluid in the abdominal cavity, and (*3.*) dilution of the vascular volume. A critical concentration of albumin in the plasma is deemed to be about 3 g/100 ml (ca. 435 μmol/l). Below this albumin value, there is a clear correlation between portal hypertension and the formation of ascites. • *The coexistence of portal hypertension and hypalbuminaemia (critical concentration 2.5−3.0 g/dl) is an important prerequisite for the formation of ascites.*

However, the significance of the decreased colloidosmotic (oncotic) pressure is not as great as has been hitherto assumed. Nevertheless, when the hydrostatic pressure is raised at the same time, **incongruity between these two Starling forces** is created, and fluid escapes into the abdominal cavity. This process is greatly furthered by the disparity between lymph production and lymph transport. These mechanical factors (s. tab. 16.3) may effect the formation of ascites, yet they cannot produce large quantities of ascitic fluid. Such a development, however, can be expected if the capillary permeability is additionally heightened due to toxic or inflammatory causes.

3. **Disturbance of capillary permeability:** Capillary permeability is increased by endotoxins, inflammations or immunological processes. As a result, the degree of permeability for protein-rich fluid is greater. For this reason, it is no longer possible to maintain a colloidosmotic pressure gradient, which is why the hydrostatic pressure (in the absence of any counteraction from the colloidosmotic pressure) triggers an outflow of fluid into the abdominal cavity. In contrast to the sinusoids with their high potential permeability for protein-rich fluid, intestinal capillaries are only minimally pervious to protein, so that only low-protein fluid can pass into the abdominal cavity. Because of structural changes in the sinusoids, however, their degree of permeability to protein diminishes as the cirrhotic disease progresses.

4. **Insufficiency of lymphatic drainage:** Insufficiency of lymphatic drainage is of paramount pathogenic importance, which is why the theory of lymph imbalance became a subject of discussion regarding the formation of ascites. (s. p. 294) Initially, it is possible to compensate the increase in transsinusoidal lymph filtration by greater drainage via dilated lymph vessels. (s. figs. 7.7; 16.4) The normal capacity of the thoracic duct of 0.8−1.5 litres/day can thereby be raised between 5 to 10 times the standard amount and, with ascites, even to over 20 litres/day. In cases where the lymph quantity is greater than the amount which can be removed, the lymph passes from the liver surface into the abdominal cavity (= *mechanical or mural lymph vessel insufficiency*). (s. tab. 16.4)

| |
|---|
| 1. **Dynamic lymph vessel insufficiency** <br> Lymph volume ↑ <br> Lymphatic drainage ↗ <br> 2. **Mechanical lymph vessel insufficiency** <br> Lymph volume ↑ <br> Lymphatic drainage ↘ <br> 3. **Mural lymph vessel insufficiency** <br> Lymph volume ↑ <br> Lymphatic drainage ↓ |

*Tab. 16.4:* Stages of lymph vessel insufficiency with cirrhosis (s. fig. 16.4)

▶ This development may progress through to the formation of numerous **lymphcysts** in the area of the vascularized liver capsule and to the extravasation of protein-rich lymph, above all via ruptured lymphcysts. • *Such a finding has often been observed during laparoscopy as so-called "liver weeping".* (s. fig. 16.5)

None of these mechanical factors can be considered "ascitogenic" in their own right. Nevertheless, they may be responsible for triggering a vicious circle in the formation of ascites due to the full impact of the mechanisms involved in elevated renal sodium and water retention.
***Fig. 16.4:*** Lymphostasis in the region of the liver capsule of the left liver lobe (lower part) and the falciform ligament

***Fig. 16.5:*** Numerous, partially ruptured lymphcysts (light red, dot-like ruptured openings) on the liver surface with extravasation of protein-rich lymph (so-called *"liver weeping"*) in alcoholic cirrhosis

### 3.2.2 Biochemical factors

A great number of humoral or hormonal substances are involved in the formation of ascites, which is itself triggered by mechanical or physical factors. (s. tab. 16.5) Although the respective effects are largely known, their pathogenic significance in the formation of ascites must be rated differently in each individual case.

The **difficulty in assessment** is based on a number of *plausible reasons*, which can also explain the differing, often even controversial, examination results and the interpretations derived from them:

(*1.*) The formation of an active substance as well as its inactivation or breakdown depend on the individual functional capacity of the liver.

(*2.*) The signals necessary to activate or increase the formation of a substance or a regulatory system depend on the point in time and intensity of a specific pathophysiological situation as well as on the respective liver disease and the developmental phase of the ascites.

(*3.*) The various active substances as well as the sympathetic nervous system display a multitude of interactions, so that it is probably not so much the measuring of the individual factors that allows assessment of the respective pathophysiological situation, but rather their collective interpretation.

(*4.*) A number of individual feedback effects of the biochemical and nervous regulatory systems intervene in the various pathogenic phases, as outlined in the different ascites theories. (s. p. 294)

***Tab. 16.5:*** Predominant changes in the concentration of biochemical factors in the blood and urine in portal ascites (N = normal)

1. **Renin-angiotensin-aldosterone system (RAAS):** The first description of aldosterone (S. A. SIMPSON et al., 1953) reflected awareness of its sustained effects on the electrolyte balance, which is why this hormone secreted by the adrenal cortex was originally given the name *electrocortin*. Aldosterone differs from the other adrenal cortex hormones by one "aldehyde oxygen", from which the name **ald-o-sterone** was derived.

Normally, the activity of the renin-angiotensin-aldosterone system is kept in balance by its own feedback mechanisms. Liver diseases have a lasting impact on this regulatory system by changing the formation and breakdown of the substances involved. • The **main stimuli** of the RAAS are hypovolaemia, hypotension, hypoxia,

hyponatraemia, hyperkalaemia and an inadequate renal circulation, as well as upright posture or physical strain; the **ancillary stimuli** include adrenocorticotropin (ACTH), thyroxine, oestrogen, ammonia and serotonin, to name but a few. Yet the extent to which these factors play either a primary or a secondary role in the individual instance of ascites formation is still not clear. • Given a half-life of aldosterone of $30-35$ minutes in the circulating blood, the effect sets in within $45-60$ minutes mainly at the distal tubular nephron as a sensitive regulator of sodium transport by stimulating the sodium-potassium ATPase at the interstitial cell membrane. • A **rise in aldosterone** leads to hypernatraemia (with retention of water), loss of potassium (with a hypokalaemia syndrome), loss of H-ions (with a tendency towards metabolic alkalosis) and loss of magnesium and chloride. • Angiotensin II effects a contraction of the vasa efferentia and reinforces the absorption of sodium at the proximal tubular nephron with subsequent retention of water. The serum levels of renin and aldosterone are closely correlated. The increased renin values do not depend on the degree of severity of ascites. Even with a redistribution of the intrarenal blood flow from the cortex, which is normally especially well-supplied with $80-90\%$ to the renal medulla (= *shift development*), a greater release of renin results with higher aldosterone values. • Nevertheless, augmented serum values of aldosterone are only detectable in some of the patients with severe liver disease. This finding together with the wide fluctuation range of renin and aldosterone values as well as an absence of the circadian rhythm of the RAAS show that highly diverging values can be found with the different phases of activity of the RAAS in the pathophysiological stages of ascites.

▶ In cases of severe liver disease or advanced cirrhosis, the occurrence of **secondary aldosteronism** must always be anticipated and initially rated as an *epiphenomenon*. Nevertheless, at a certain point, the activated RAAS can act as a signal for a boost to the renal retention of sodium and may intervene in the pathogenesis of ascites. The aldosterone value and the renal excretion of sodium are closely and inversely correlated. Yet a higher aldosterone value is not always accompanied by a reinforced retention of sodium. This is particularly the case if the feedback by means of sodium is ineffective (= *escape phenomenon*). The refilling of the plasma volume may well lead to normalization of the renin and aldosterone values, yet not to normalization of the sodium excretion. The reduction in increased aldosterone values is usually accompanied by reinforced natriuresis and diuresis — as has been observed after bilateral adrenalectomy. (s. p. 315) Cirrhosis patients with ascites thus usually show a reduced life expectancy if the renin-plasma value is increased, whereas the prognosis is clearly better if the renin value is normal. (for further reference, see 2, 4−6)

> The findings and observations described in the literature as well as the convincing efficacy of the aldosterone antagonist *spironolactone* confirm the importance of the RAAS in the genesis of renal sodium retention and hence also in the formation of ascites.

2. **Antidiuretic hormone (ADH):** In cirrhotic and ascitic patients, the ADH level is usually elevated. (s. tab. 16.5) With a reduced effective plasma volume, ADH is released by non-osmotic stimulation in the neurohypophysis and possibly broken down in the liver at a reduced rate as well. The plasma activity of ADH largely correlates with that of the RAAS and the sympathetic nervous system. ADH for its part stimulates the nervous synthesis of prostaglandins. It would appear that cirrhotic patients can be divided into excretors and non-excretors as regards the suppression of ADH secretion.

3. **Prostaglandins:** As vasodilators of the renal medullary vessels, prostaglandins influence the blood volume of the kidneys as well as glomerular filtration. They counteract vasoconstriction and thus help to maintain the glomerular filtration rate (GFR), even in cases of hypotension or hypovolaemia. Prostaglandins are natriuretic and diuretic in their action. They interact with the RAAS, the ADH and the kinins as well as with the sympathoadrenal system. Prostaglandins are formed from arachidonic acid, which may, however, be reduced in cirrhotic patients. • From the clinical point of view, it is important that acetylsalicylic acid or indometacin, for example, inhibit the synthesis of prostaglandins and hence bring about a reduction in sodium excretion, urine volume and diuretic efficacy. (s. tab. 16.5)

$PGE_2$ promotes the renal circulation and the excretion of sodium, while $PGF_{2\alpha}$ has an inhibitive effect in this respect. (No validated information on $PGD_2$ is available.) Prostacyclin increases the renal circulation, whereas thromboxane gives rise to renal vasoconstriction and reduced excretion of sodium and water. The vasodilatory prostaglandins are stimulated by noradrenaline and angiotensin II in correlation with the degree of hypovolaemia and sodium retention. An important pathogenic role may well be played not only by a reduction in prostaglandin $PGE_2$ and an increase in thromboxane, but also by an imbalance between the individual prostaglandin fractions.

4. **Natriuretic factors:** Animal experiments and clinical investigations point to the existence of these biochemical factors. After acute volume loading in healthy volunteers, it was possible to detect substances with a natriuretic effect in the blood and urine − *yet this was not the case in cirrhotic and ascitic patients.*

▶ In 1981 the natriuretic effect of an atrial myocardial extract was described for the first time (A. J. DEBOLD et al.). Confirmation of this **atrial natriuretic factor (ANF)** as a peptide hormone was presented in 1983 (T. G. FLINN et al.). The half-life of this factor, also known by the name of *cardiodilatin*, is about 3 minutes. Receptors for ANF are found in the liver and the kidneys. The ANF leads to a rise in the glomerular filtration rate and in the excretion of sodium. The diuretic, natriuretic and vasodilatory effect is restricted by hypovolaemia and hypotension. The RAAS is inhibited by an i. v. injection of ANF. An increase in atrial pressure is considered to be the main stimulus for the release of ANF, whereas physical exercise, thyroxin, ADH and adrenaline prove less stimulating. In cirrhotic and ascitic patients, normal as well as significantly elevated ANF concentrations are found. This large divergence in values most probably depends on the current volume status (reduced or increased plasma volume) of the respective ascites phase. (1, 13, 210) (s. tab. 16.5)

▶ In 1989 a **renal natriuretic factor (RNF)** was detected for the first time and termed *urodilatin* (P. SCHULZ-KNAPPE et al.). As examinations have hitherto shown, urodilatin is formed in the medial nephron of the kidney and causes a distad inhibition in the absorption of water and sodium. Its half-life is likewise about 3 minutes. Although ANF is most probably of limited significance for the excretion of sodium and its influence on sodium homoeostasis in cases of liver cirrhosis (with or without ascites) has still not been fully clarified, *urodilatin is deemed to be important for the regulation of the water and electrolyte balance.* (3) (s. tab. 16.5)

5. **Kallikrein-kinin system:** This system acts in a vasodilatory, diuretic and natriuretic manner. In cirrhotic and ascitic patients, there are lower prekallikrein and bradykinin levels as well as less renal kallikrein activity. The reduction in kallikrein excretion in the urine correlates with (*1.*) depressed glomerular filtration rate,

(*2*.) elevation of aldosterone values, and (*3*.) change in the synthesis of prostaglandin. Nevertheless, as with ANF and RNF, there is still much to be resolved as regards the pathophysiology of cirrhotic patients with concomitant ascites. (s. tab. 16.5)

6. **Endotoxinaemia:** Different degrees of endotoxinaemia are often detectable in patients suffering from severe liver disease as a result of restricted hepatic endotoxin clearance. There is a correlation between endotoxinaemia and renal dysfunction, and renal blood flow is reduced. Nitrogen monoxide is also released. By reducing endotoxinaemia (after treatment with polymyxin B, for example), the diminished functional activity of the kidney improves and diuresis as well as natriuresis increase. (s. tab. 16.5)

7. **Endothelin:** Endothelin-1 is a polypeptide with a vasoconstrictive effect. It is generally elevated in portal ascites. The rise in endothelin correlates significantly with augmented ADH, ANF and endotoxins. It would seem to have an additional impact on the development of disrupted renal function. (20, 67) (s. tab. 16.5)

8. **Sympathoadrenergic factors:** Even at an early stage, the activity of the sympathoadrenal system is enhanced in cirrhotic patients due to a rise in sinusoidal pressure (probably via a glutamine-mediated *hepatorenal reflex arc*). As a result, the levels of **noradrenaline** and **adrenaline** rise and continue to do so as the decompensation progresses. These substances have a vasoconstrictive effect in the region of the efferent vessels and hence stimulate the retention of water and sodium. Noradrenaline values and natriuresis are closely and inversely correlated, not only because of the altered renal haemodynamics, but also through the alpha receptors situated at the proximal tubulus. Moreover, the increased activity of the sympathetic system stimulates the secretion of renin with subsequent activation of the RAAS. Due to the continuing decompensation, the greatly elevated catecholamine values might also be partly attributable to inadequate inactivation in the liver (and kidneys). (12) (s. tab. 16.5)

### 3.2.3 Increase in renal sodium retention

An increase in the retention of sodium occurs in the early stages of severe liver disease, particularly in liver cirrhosis, without any disruption of the water balance. This early tendency towards sodium retention can be detected using the *NaCl-tolerance test*. The retention of sodium reduces the sodium excretion rate in the urine to <10 mval/day (normal rate: 120 to 220 mval/day). Diuresis is not primarily restricted; patients with ascites and oedema react to an excessive intake of water with an adequate excretion of diluted urine, albeit in the virtual absence of sodium excretion. The limited sodium excretion derives from increased, mainly proximal tubular reabsorption of sodium and not from diminished glomerular filtration. Overall maintenance of the liver architecture is usually accompanied by undisturbed sodium excretion, despite existing portal hypertension (such as in primary biliary cirrhosis). Marked sodium retention is, however, usually found in alcoholic-toxic cirrhosis. For this reason, such patients are not only the ones most frequently affected by ascites and oedema, but as a rule they display the most serious forms. This is probably also due to additional biochemical and hormonal factors which are present to a greater degree in patients with alcohol-related liver disease.

### 3.2.4 Theories of ascites formation

To explain the complex mechanisms of ascites formation, **four hypotheses** have been developed in the light of experimental and clinical findings: (*1*.) underfill theory, (*2*.) overflow theory, (*3*.) lymph imbalance theory, and (*4*.) vasodilation theory. (s. fig. 16.6)

1. **Underfill theory:** According to the underfill theory (S. SHERLOCK et al., 1963), the development of ascites is set off by mechanical factors and physical mechanisms ("imbalance of the Starling forces"). As a result, the effective plasma volume is reduced (so-called volume deficiency concept).

The **reduced intravasal volume** leads to a stimulation of volume receptors. In addition, the renin-angiotensin-aldosterone system as well as the sympathoadrenergic system are activated; the ADH level rises. This leads to a reduction in the glomerular filtration rate (GFR). The result is increased tubular sodium reabsorption, i.e. retention of sodium. Yet a reduced glomerular filtration rate is not a prerequisite for the retention of sodium, since this can occur even with a normal GFR. • This mechanism of ascites formation through the primary reduction in the effective plasma volume is reinforced by (*1*.) growing insufficiency of the lymph vessels as a result of portal hypertension, (*2*.) decrease in peripheral resistance due to the opening of intrahepatic and systemic arteriovenous anastomoses, and (*3*.) enhanced formation or diminished breakdown of substances with a vasodilatory effect. (s. fig. 16.6)

2. **Overflow theory:** The overflow theory (F. L. LIEBERMANN et al., 1970) (7) is based on the principle that retention of sodium already exists as a primary event and hence causes an expansion in volume.

Continuous damage to the liver architecture or a boost to the portal pressure are accompanied by a **salt-retaining signal** (with an antinatriuretic impact) being sent to the renal tubuli. Ascites formation, already triggered by the mechanical or physical factors described, is now significantly reinforced by the sodium-retaining effect with an "overflow" from the intravasal volume. The result is a further reduction in the effective plasma volume, which increasingly stimulates the volume receptors and activates the biochemical, hormonal and neural systems. (s. fig. 16.6)

▶ These two hypotheses, the *"underfill theory"* and the *"overflow theory"*, do not explain the development of ascites in each individual case. Neither do the two concepts exclude one another. They would appear to describe the respective disrupting mechanisms of the water and salt balance as being dependent on the degree of severity of the existing liver disease. • Discussion centres on the early stage of ascites formation being influenced by the overflow hypothesis, which would also explain the better efficacy of diuretics in this phase. • By contrast, the late stages of portal ascites are thought to be characterized by the theory of volume deficiency, which implies that greater therapeutic success would only be achieved by refilling the intravasal volume (once diuretic therapy has failed). (8, 10, 11)

3. **Lymph imbalance theory:** The lymph imbalance theory (C. L. WITTE et al., 1980) (16) contradicts the "classical" concepts of underfill and overflow. This theory is based

on the idea that the disruption of the equilibrium between the extravasation of fluid from the intravasal space and its reflux into the vascular system initiates the formation of ascites; in other words, the lymph production or the actual lymph quantity can no longer be drained via the lymph vessels. (s. tab. 16.4) (s. figs. 7.6; 16.4−16.6)

The **disrupted drainage of the lymph** is attributed to (*1*.) obliterated diaphragmatic lymph vessels, (*2*.) dilated visceral lymph vessels with subsequent clearly decelerated flow velocity, and (*3*.) limited lymph kinetics at the transition between the lymphatic system and the venous system. More and more disturbances in the fluid balance between plasma and interstitium increasingly activate the adrenal hormonal systems with elevated retention of sodium and water; the lymph imbalance continues to grow.

**4. Vasodilation theory:** The vasodilation theory (R.W. SCHRIER et al., 1988) (14) is a variant of the underfill concept. The initial pathophysiological change in cirrhotic patients is deemed to be peripheral arterial vasodilation, in particular in the splanchnic area, with a lower degree of vascular resistance. This leads to hyperdynamic circulation with an augmented cardiac output. The opening of arteriovenous anastomoses continues to reduce the degree of peripheral vascular resistance. The subsequent

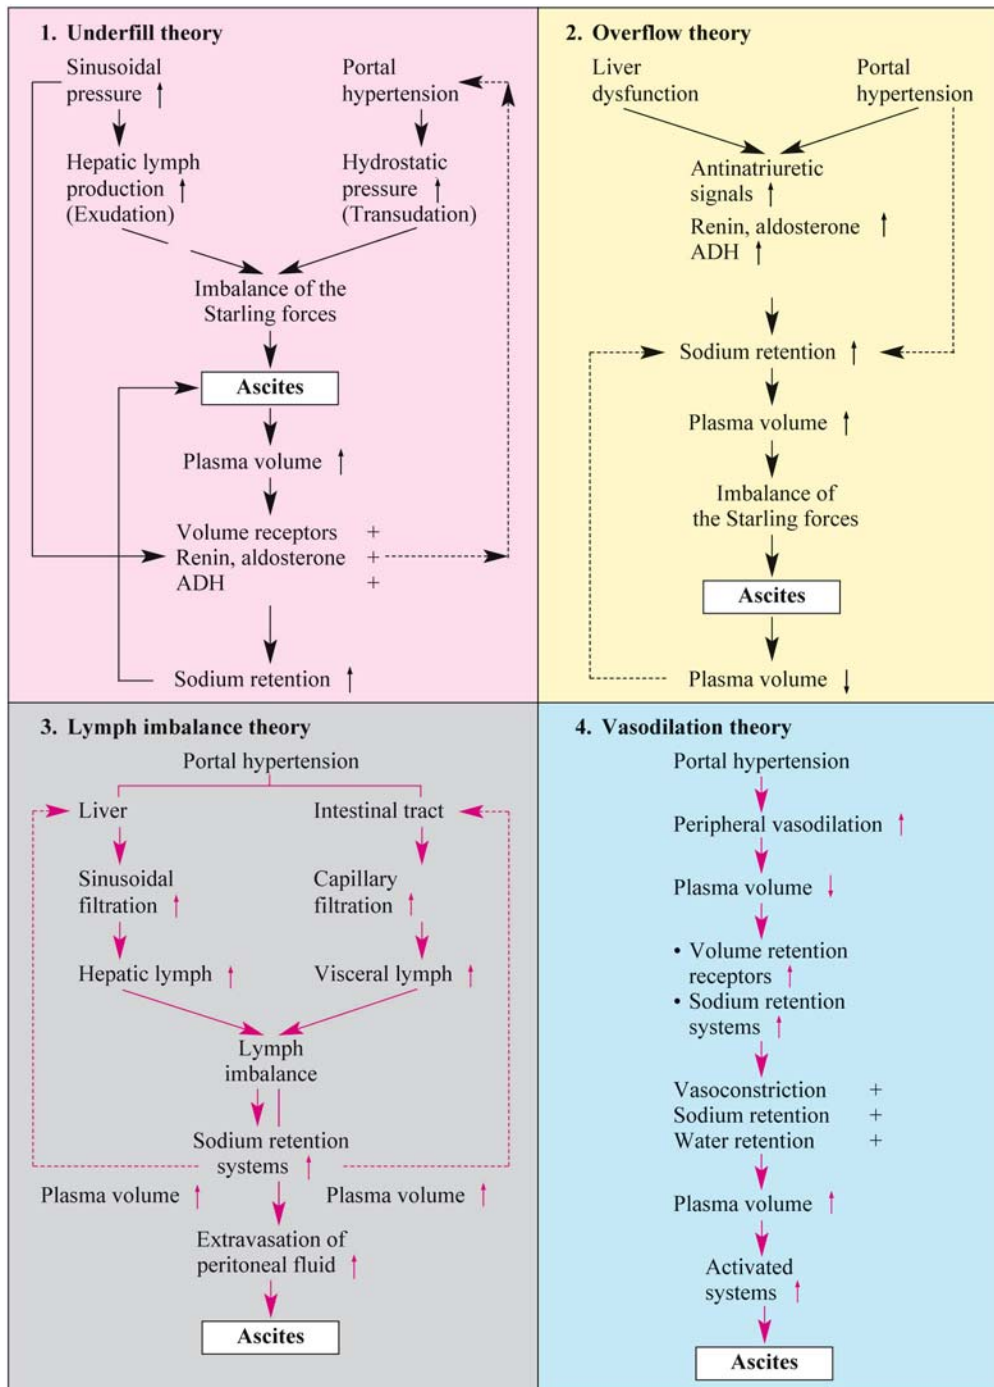

*Fig. 16.6:* Diagram of the main pathogenic mechanisms in the formation of ascites according to the four different theories

decrease in the effective plasma volume effects a rise in the levels of endothelin, renin, aldosterone, noradrenaline and vasopressin with subsequent renal vasoconstriction as well as the retention of sodium and water. The outcome is either a further increase or a normalization of the plasma volume. • This can be the reason why, in certain stages of ascites, the serum and urine values of these biochemical factors are (surprisingly) found to be within the normal range. (s. fig. 16.6)

Continuing deterioration of the liver disease results in renewed increase in peripheral vasodilation with a further drop in plasma volume. Under the influence of endotoxins and cytokines (tumour necrosis factor, interleukins, etc.), nitric oxide synthases are expressed in the liver, blood vessels and other organs, forming large quantities of **nitrogen monoxide** (NO). As highly potent vasodilators, nitric oxides effect a dilatation of the vessels with a reduction in the peripheral resistance. • Other **mediators of vasodilation** are prostaglandins, bradykinin, glucagon, false neurotransmitters, PAF, ANF, etc. Despite maximum activation of the sodium and water retaining systems, vasodilation and volume deficiency can ultimately no longer be offset; ascites begins to develop. (8, 9, 15)

### Synopsis

*Ascites formation is a complex, pathophysiological process with a multifactorial pathogenesis.* Severe (acute or chronic) liver diseases, mainly cirrhosis, have their own principal pathogenetic factors which give the respective starting signals at the appropriate time. • In the individual case, one of the four ascites theories hitherto discussed can explain ascites formation, whereas in other cases, the pathogenic sequences of two or three concepts are mixed, each with its own particular intensity and specific timing. • There are some hints that the early phase of ascites is predominantly accompanied by "overfilling" as a result of growing sodium retention (with simultaneous imbalance in the pressure of the vascular system and the lymphatics), while the late phase is chiefly evoked through "underfilling" (due to NO activation with simultaneous vasodilation). Some of these biochemical and sympathoadrenergic mechanisms act as mutual stimulators, inhibitors or additive factors and can even have a potentiation effect, depending on their momentary effectiveness. The importance of the respective mechanisms cannot be estimated in the individual case. (s. fig. 16.6) (s. tabs. 16.3, 16.5)

▶ *Sinusoidal portal hypertension* with increased hydrostatic pressure and decreased colloidosmotic pressure are of considerable, probably paramount importance for the onset of ascites formation. Further influencing factors could be the growing imbalance between the augmented lymph production and drainage as well as the higher degree of capillary permeability.

At the same time, the elevated sinusoidal pressure values transmit biochemical signals for a compensatory retention of sodium in the renal tubules. Likewise, "functional hyperaldosteronism" occurs at an early stage and the sympathoadrenergic system is activated with its impact on the splanchnic and renal haemodynamics; both events serve to counter volume deficiency and hypotension. The physiological effects of the various biochemical factors may vary under pathological conditions, depending on the respective ascitic phase; for this reason, they can be difficult to assess. Reciprocal interactions also render it more difficult to evaluate the individual factors.

▶ *Ultimately, decompensation of the water and electrolyte balance is the result of* (1.) splanchnic and peripheral arterial vasodilation, (2.) subsequent marked reduction in the effective arterial blood volume, (3.) increase in renin, aldosterone, vasopressin and noradrenaline, (4.) renal vasoconstriction with retention of sodium and water, and (5.) inadequate compensation of the plasma volume as a result of progressive hypalbuminaemia.

## 4 Aetiology of ascites

### 4.1 Differential diagnosis

Numerous diseases can cause ascites. In terms of *aetiology*, liver diseases, malignant processes and chronic cardiac diseases rank right at the top. Yet inflammatory, renal, metabolic, vascular and endocrinological causes also have to be borne in mind when drawing up a differential diagnosis. The mechanisms at work in the formation of ascites are often still unresolved, as is the case, for example, in hypothyroidism, diseases of the ovaries or the POEMS syndrome (P. A. Bardwick et al., 1980). (100, 168) (s. tab. 16.6)

### 4.2 Hepatogenic ascites

It is not clearly understood why in some cases oedema without ascites and in other cases ascites without oedema as well as ascites together with oedema or even pleural effusion without ascites occur. Ascites develops most frequently during the course of liver disease (= *hepatogenic ascites*), in particular in chronic liver diseases with portal hypertension (= *portal ascites*). (s. tab. 16.7) • Various mechanical, biochemical and neural disorders overlap in their effects and pathways, depending on the underlying liver disease. Only rarely is ascites found in diseases with presinusoidal localization of portal hypertension (such as portal vein thrombosis) or with minor restrictions in the synthesis of albumin (as in biliary cirrhosis). • Formation of ascites occurs in about 50% of all cirrhotic patients within 10 years of

***Tab. 16.7:*** Causes of hepatogenic or portal ascites

*We were able to observe pronounced oedema, anasarca and massive ascites with concomitant signs of hepatic encephalopathy in a case of so-called* **hepatitis oedematosa** (E. Gautier et al., 1952). *The patient was successfully treated by means of aldosterone antagonists.* (45)

# 5 Diagnosis of ascites

## 5.1 Clinical findings

Ascites may onset suddenly or slowly and unnoticed over the course of several weeks. There is a diminished tendency to sweat and the patient's skin often appears sallow and dehydrated. • With regard to the quantity of the fluid, ascites may be classified into *mild*, *moderate* or *tense.*

**Physical methods:** A *latent oedema* can be recognized by the deposition of fluid in the tissue (increase in body weight of > 1.0 kg in 4−5 days). (s. fig. 15.3) It is neither visible nor palpable. A *manifest oedema* typically shows dimpling upon digital compression. • *Ascites* without concomitant deposition of tissue fluid is generally diagnosed by a distinct increase in body weight. Detection of ascites by means of physical examination is only possible when an amount of fluid in excess of 1.5−2 litres is present. (30) This is best achieved when *dullness* is ascertained by percussion of the abdomen with the patient in the knee-elbow position. Larger amounts of ascitic fluid produce a typical *change in percussion sound* when the body position is altered; there is also *dullness in the flanks* and ultimately a noticeable *fluctuation wave* (i.e. ascites thrill due to excessive free fluid under tension). Reduced *movability* and/or corresponding *ele-*

the diagnosis being established. About half of these patients die within 2 years of the initial occurrence of ascites. Oedema and/or ascites develop during the course of the disease in about two-thirds of all cirrhotic patients. Statistically, alcoholic cirrhosis ranks highest on the frequency scale.

Surprisingly, alcoholic fatty infiltration of the liver and alcoholic hepatitis often display ascites as well, mostly only discernible when applying ultrasonic methods of examination. This might suggest that certain pathogenic mechanisms in the formation of ascites (such as increase in portal pressure, structural sinus changes, and stimulation of biochemical or sympathoadrenergic factors) are favoured or become more intense as a result of alcohol (and possibly also its chemical additives). • Ascites can also occur in severe acute viral hepatitis, in which case the course of disease deteriorates considerably. (28, 46, 64)

*vation of the diaphragm* can also be detected by percussion. (s. p. 79) • *Meteorism* is deemed to be a precursory state of ascites *("first the wind and then the rain")*.

▶ In 1959 a very reliable physical sign was described which is present consistently with as little as 120 ml of peritoneal fluid (**"puddle sign"**). This phenomenon also makes it possible to differentiate shifting dullness due to fluid-filled loops of bowel from that due to collections of free intra-abdominal fluid. The puddle sign is generally not influenced by obesity. (46)

**Inspection:** Upon inspection, pronounced cases of ascites are characterized by marked *protrusion* of the abdomen. The *umbilicus* becomes everted or bulging. The distance between the navel and the symphysis appears diminished as a result of caudal displacement of the former. With large quantities of ascitic fluid, the *abdominal skin* is taut and shiny. In long-standing cases of ascites, striae distensae, together with expanded collateral veins radiating from the navel, may be visible. Increased ascitic pressure sometimes causes the occurrence of a *hernia* (inguinal, femoral, umbilical or cicatricial). (s. fig. 16.7) (41, 48, 57)

***Fig. 16.7:*** Massive refractory ascites with large umbilical hernia. Muscular atrophy and loss of subcutaneous fatty tissue

Occasionally, *scrotal oedema* and *anasarca* are detectable. Ascites does not correlate with the incidence and extent of peripheral oedema. (s. figs. 16.2, 16.13)

## 5.2 Imaging procedures

**Sonography:** Sonography facilitates the diagnosis of ascites in its early stages (< 200 ml). If the fluid accumu-

lates at certain preferred sites, it is even possible to demonstrate amounts of < 50 ml. In cases of minimal and localized accumulation of fluid, sonographically guided tapping and collection of ascitic fluid as well as special examinations provide a swift and confirmed diagnosis. With massive ascites, floating intestinal loops are occasionally witnessed, forming the so-called *sea anemone phenomenon*. (25, 35) (s. p. 131)

**Radiology:** Ascites has a diffuse appearance similar to ground glass. In the individual case, various ascites-related clinical findings are observed (elevation of the diaphragm, plate-like atelectasis, cardiac rotation, hiatus hernia, distended intestinal loops, etc.). Extensive ascites may cause organ displacement (e. g. dislocation of the stomach or kidneys) or vascular compression (e. g. functional blocking of the inferior vena cava). (23, 27) The quantity of fluid can be 30 litres or more (as much as 70 litres has been recorded!). (s. figs. 16.7, 16.13)

**Hepatic hydrothorax** (C.S. Morrow et al., 1958) is evident during the course of liver cirrhosis with ascites in 0.4−12% of cases. The mean frequency is about 6%, although in two-thirds of the cases, a right-sided effusion (with the author's own patients a bilateral effusion) was ascertained. (66) (s. fig. 16.8) • Hepatic hydrothorax is a transudate: cell count <1,000/mm³, protein concentration <2.5 g/dl, total protein effusion to serum ratio <0.5, LDH effusion to serum ratio <2.3, serum to pleural fluid albumin gradient >1.1 g/dl. (s. also fig. 16.9) (17, 37, 47, 52−54, 66)

▶ Over a period of 10 years (1952−1963), I examined inpatient records at the University Medical Hospital in Giessen retrospectively. On evaluation of **25,682 documented cases,** 2,534 patients were found with pleural effusion (= 9.8%) validated by radiology or autopsy. • The **frequency** of hepatogenic pleural effusion was 110 cases (= 4.3%). I found 4 cases of a right-sided hydrothorax and 2 cases of bilateral hydrothorax in 6 patients with severe *viral hepatitis*. Hydrothorax was identified in 104 patients with *cirrhosis*. • The **localization** was, however, bilateral in 69%, left-sided in 18.7% and right-sided in 12.3%. • This **controversial finding,** which contrasts with the literature, is explained by the fact that an X-ray of the thorax was taken in each case of cirrhosis and that angle effusions or minimal infrapulmonal effusions were detected by autopsy in deceased patients. *(see footnote \*)*

*Causes* of hepatic hydrothorax, which can occasionally appear sanguinolently as a result of the cirrhosis-related bleeding tendency, are (*1.*) congenital or acquired defects of the diaphragm (70), (*2.*) diaphragmatic lymph paths, and (*3.*) increased pressure in the azygous vein/hemiazygous vein system. With rising intra-abdominal pressure (caused by large-volume ascites, coughing, pressing, etc.), congenital or acquired gaps may form between the muscle fibres of the diaphragm. These small

---

*Fig. 16.8:* Right-sided hepatic hydrothorax in liver cirrhosis

herniations (so-called pleuroperitoneal blebs) may rupture and allow fluid to move from the abdominal cavity into the pleural space. Occasionally, such diaphragmatic defects can be demonstrated by magnetic resonance imaging (70) or thoracoscopy. • It is clinically significant that considerable pleural effusion can even be present in liver cirrhosis *without concomitant ascites*. In cases of pulmonary complaints (e. g. dyspnoea), this possibility should be considered and investigated. (44, 56) • *Therapy* corresponds to that of ascites (s. pp 304, 306) and involves the administration of albumin. (s. p. 308) Thoracocentesis, if necessary repeated, in addition to i.v. infusion of octreotide and paracentesis (s. p. 309) is recommended. In the case of treatment failure, TIPS and eventually liver transplantation may be indicated.

**Spontaneous bacterial empyema** is found in 1−2% of patients with cirrhosis and ascites. The diagnosis is based on a positive bacterial test in the pleural fluid and a WBC count in excess of 250/mm³ (or a negative bacterial culture with a cell count exceeding 500/mm³) − which is analogous to spontaneous bacterial peritonitis. (105) (s. p. 302)

**Computer tomography:** A CT scan is only indicated in individual cases where there are problems with the differential diagnosis (e. g. in acute pancreatitis or suspected tumours). The sensitivity of fluid detection is, however, extremely high, since it is possible to demonstrate as little as 25 ml. (23, 42)

In patients with cirrhosis, CT sometimes demonstrates a mesenteric oedema (*"misty mesentery"*). (51) Such a mesenteric, omental and/or retroperitoneal oedema can vary from a moderate infiltrative type to a pronounced oedema compressing the mesenteric vessels. (32)

**Laparoscopy:** Laparoscopy should be carried out in all cases which could not be clarified or precisely defined

by means of clinical and biochemical laboratory examinations of the blood and ascitic fluid or using imaging procedures. (68) If a large amount of ascitic fluid is removed by laparoscopic paracentesis, it is essential to substitute volume and protein. (s. p. 309)

**Oesophagogastroscopy:** An ascites-related gastro-oesophageal reflux can result in reflux oesophagitis. However, this does not provoke the onset of bleeding from oesophageal varices.

Disorders of *cerebral functions* on the one hand and of the *water and electrolyte balance* on the other hand are the earliest and most reliable hints of the onset of decompensation in severe liver disease, especially cirrhosis. • In clinical terms, they can be easily diagnosed as latent hepatic encephalopathy (by carrying out psychometric tests) and/or latent oedema (by recording the increase in body weight). • For this reason, these examination methods are also of fundamental importance in the follow-up of chronic liver disease. (s. fig. 15.3)

## 5.3 Laboratory diagnosis

A **diagnostic puncture** is required to withdraw ascitic fluid. In extensive ascites, this can be performed without ultrasound guidance, whereas with smaller and localized accumulations of fluid, it is always necessary to carry out ultrasound-guided puncture. The ideal entry site is deemed to be the left lower abdominal quadrant (exactly opposite McBurney's point). Prior to puncturing, the skin should be shifted tangentially over the puncture mark, leaving a Z-shaped puncture channel on removal of the needle. This guarantees more reliable protection against any postpuncture leakage of ascitic fluid. Complications are very rare. (157) The tapping of ascitic fluid is considered a safe procedure. Using a thin needle (0.4 mm in diameter) or a special puncture needle, some 50 ml fluid are withdrawn, which suffices for a wide range of laboratory investigations. However, for bacteriological or cytological examinations (possibly following centrifugation), 200−250 ml are required. Biochemical parameters are always of great importance. (24, 26, 40, 63, 71, 79) (s. fig. 16.10)

**1. Colour:** The impressive range of colours found in individual cases is indeed interesting, yet of no great help in the differential diagnosis. A rough definition of the various forms can be given as follows, analogous to pleural effusion *(see footnote p. 298)*:

• *serous ascites* (e. g. hepatogenic, pancreatogenic, malignant or inflammatory) can be clear or turbid, green, straw-coloured or bile-stained; (s. fig. 37.22)

• *haemorrhagic ascites* (e. g. in malignant disease; in liver cirrhosis only rarely blood-tinged);

- *turbid ascites* (e. g. bacterially or parasitically infected, malignant or pancreatogenic, in the Budd-Chiari syndrome);

- *chylous ascites* (e. g. in liver cirrhosis due to impaired lymphatic drainage). Possible causes include: malignant disease, tuberculosis, intestinal lymphangiectasia, whipple disease. Lymphostasis can be assumed to exist if the total lipids of the ascitic fluid are twice as high as the plasma value, and/or the triglyceride concentration is greater than 400 mg/dl. (29, 31) (s. fig. 16.9)
*Fig. 16.9:* Chylous ascites with pronounced portal hypertension as a result of posthepatitic (HBV) coarse nodular cirrhosis

**2. Protein content:** Depending on the protein content of the ascitic fluid or its specific gravity, differentiation is made between a transudate and an exudate. A **transudate** is deemed to be a serous, fibrinogen-free fluid, low in cells and protein, of non-inflammatory genesis. The protein content is below 2.5 g/dl (specific gravity < 1,015). An **exudate,** generally inflammatory or malignant, is rich in cells; the protein value exceeds 3.0 g/dl (specific gravity > 1,016), and the bilirubin quotient (ascites : serum) amounts to more than 0.6. (36) • The **albumin gradient** (albumin value in the serum minus albumin value in ascites) is usually > 1.1 in portal hypertension and < 1.1 in malignant or inflammatory ascites, with a sensitivity of about 80%. (59) This gradient correlates well with the portal vein pressure. The reliability of differentiation seemed to improve with a discrimination limit of 1.5. (63) (s. fig. 16.10)

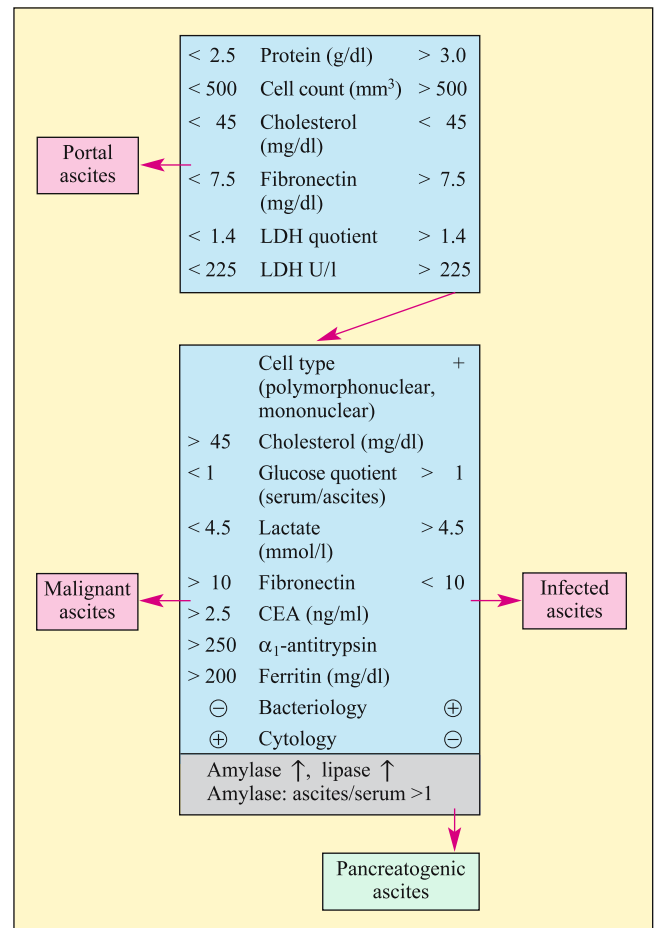
In cases of long-standing ascites, the **protein content** can drop due to reduced permeability of the sinusoids to protein or as a result of presinusoidal obstruction. However, because of its aetiology or as a result of diuretic therapy, the protein content may also increase. In 15−20% of cirrhotic patients with ascites, protein values of up to 4.3 g/dl are found. • *Even with a threshold ranging between 2.5 and 3.0 gldl, the transudatelexudate concept does not work as well with ascites as it does with pleural effusion!* The inconclusive information obtained from the ascites protein value in individual cases becomes more reliable if the cell count is determined at the same time. (39, 55, 63, 79)


*Fig. 16.10:* Diagnostic steps used to differentiate between portal, infected, malignant and pancreatogenic ascites (modified from J. SCHÖLMERICH, 1990)

**3. Cell count:** To determine the cell count and cell type, it is advisable to use an EDTA tube (monovette) for the ascitic fluid. The cell count for a transudate is generally below 250/mm$^3$ and for an exudate above 1,000/mm$^3$. Specificity is ca. 90%, and sensitivity is ca. 60%. The absolute count is more reliable in connection with a normal or raised protein value (transudate or exudate). However, in up to 30% of cases, there were cell counts in portal ascites of > 500 and in 5−20% of cases even > 1,000 leukocytes/mm$^3$. In patients with malignant ascites, the cell count was in excess of 1,000/mm$^3$ in more than 50% of cases. In individual instances of hepatogenic or malignant ascites, a higher number of polymorphonuclear cells were also detected. These results make identification of spontaneous bacterial peritonitis very difficult. Evidence of **polymorphonuclear neutrophils** (> 250/mm$^3$) suggests the presence of infected ascites. More than 80% of patients with spontaneous bacterial peritonitis show a higher value. The predominance of **lymphocytic cells** in ascites (> 20% of the total leukocyte count) − with an additional ascites-blood-glucose quotient of < 0.7 − suggests tuberculous peritonitis. (24, 63) In suspected tuberculosis, the Ziehl-Neelsen staining method and possibly also PCR is necessary.

**4. Bacteriology:** Ascites should be checked for aerobes and anaerobes by using haemoculture bottles. With infected ascitic fluid, the bacteriological examination yields a specificity of 100%, but a much lower sensitivity. It is possible to detect gram-negative bacteria in about 70% of cases, gram-positive microorganisms in some 25% of cases and anaerobes in about 5% of cases. In total, a bacterial infection of the ascitic fluid is present in 8−10% of cirrhotic patients. It is often hardly possible to distinguish between spontaneous and secondary bacterial peritonitis. (63, 71)

**5. Cytology:** Cytology has a specificity of 97−100% for the detection of malignant ascites. By contrast, the sensitivity is far lower, especially since the endothelial cells of the peritoneum are very similar cytologically to the malignant cells.

**6. Cholesterol:** In malignant ascites, the cholesterol level is clearly raised (R. A. Rovelstad et al., 1958). In differentiating the condition from portal ascites, the sensitivity is 90%, and the specificity is 95%. A threshold range of 45−48 mg/dl is deemed appropriate. Cholesterol determination is thus a valuable parameter for ascites. (39, 43, 61) (s. fig. 16.10)

**7. Fibronectin:** The values of fibronectin in malignant ascites are significantly higher than in cases of portal ascites. Given a threshold value of 7.5 mg/dl, it is possible to differentiate between the two forms of ascites with a sensitivity of 100% and a specificity of more than 95%. The combined determination of cholesterol and fibronectin allows malignant ascites to be identified reliably. (33, 39)

**8. pH levels:** The pH value in infected ascitic fluid is usually reduced to < 7.31 by acid residues (such as lactate, oxalate, succinate and fumarate), which occur mainly in anaerobic glycolysis. With hepatogenic transudate ascites, pH levels are higher than 7.45 and the pH gradient (serum value minus ascites value) amounts to < 0.10. In malignant ascites, the values are hardly any different. In isolation, the pH value and pH gradient have little meaning, whereas in connection with the protein value or cell count and cell type, they can be seen as helpful supplementary findings.

**9. Lactate:** The same assessment is true for the determination of lactate in ascitic fluid. The increase in this acid residue in infected ascitic fluid (> 4.5 mmol/l) is proportional to the decrease in the pH value. Malignant ascites generally yields values of < 4.5 mmol/l. (21, 58, 63, 79) (s. fig. 16.10)

**10. LDH quotient:** The LDH quotient (ascites value : serum value) is usually < 1.4 in portal ascites, whereas in infected or malignant ascites, values of > 1.4 are usual. The absolute discrimination value is given as being higher than 400 U/l.

**11. Ferritin:** The values in malignant and inflammatory ascites were regularly higher than those found in portal ascites. (63)

**12. $\alpha_1$-antitrypsin:** The identification of $\alpha_1$-antitrypsin yielded a respective specificity and sensitivity of > 95% in distinguishing between portal and malignant ascites. In cases with a malignant genesis, the values were nearly always elevated to > 120 mg/dl. (69)

**13.** Other examinations focused on the biochemical differentiation of ascites, such as determining **cholinesterase** (62) and **interleukin-6** (18) as sensitive parameters for bacterial infection as well as evaluating the **receptors** (p55 and p75) for the tumour necrosis factor. (19) An ascites/serum quotient for **$\alpha_1$-foetoprotein** of > 1 suggests hepatocellular carcinoma; an amylase quotient of > 1 is found in pancreatitis.

▶ As early as 1964 and in later publications, it was possible to demonstrate the significance of **glycoproteins** (hexosamine, fucose, sialic acid [34], etc.) and *cholinesterase* for the detection of non-inflammatory, inflammatory or malignant disease and their follow-up as well as for the distinction between transudate and exudate in a so-called **phlogogram** (E. Kuntz, 1964). *(see footnote p. 298)* Because of the significance and pathophysiological features of the mucopolysaccharides, appropriate biochemical parameters are likely to be of further interest. • In addition, elevated values of **hyaluronic acid** have been found in the ascitic fluid of cirrhotic patients.

Due to clinical, laboratory and therapeutic differences, it is possible to distinguish between simple and problematic ascites. The latter includes: (*1.*) recurrent ascites, (*2.*) refractory ascites, (*3.*) diuretic resistant ascites, and (*4.*) diuretic intractable ascites. (s. tab. 16.8)

|  | **Simple ascites** | **Problematic ascites** |
|---|---|---|
| **Quantity** | mild, moderate | tense |
| **Manifest HE** | ∅ | + |
| **Natriuresis**<br>**Sodium in serum**<br>**Albumin**<br>**Creatinine**<br>**Potassium in serum** | > 20 mmol/day<br>> 130 mmol/l<br>> 3.5 g/dl<br>< 1.5 mg/dl<br>3.6−4.9 mmol/l | < 10 mmol/day<br>< 130 mmol/l<br>< 3.5 g/dl<br>> 1.5 mg/dl<br>< 3.5 mmol/l<br>> 5.0 mmol/l |
| **Diuretic therapy** | mostly sufficient | insufficient |

*Tab. 16.8:* Differentiation of ascites according to its severity

The combination of several biochemical parameters in a diagnostic **stepwise approach** generally facilitates an adequately reliable differentiation between portal, infected, malignant and pancreatogenic forms of ascites. (s. fig. 16.10)

# 6 Complications of ascites

Ascites formation is generally accompanied by multiple complications. These mean considerable distress for the patient and constitute a genuine threat to life. Complications call for extra therapeutic measures, which are often quite complex. For this reason, emphasis should always be placed on any dangerous developments. As a rule, these are mechanical, bacterial, or metabolic in nature. (s. tab. 16.9)

| Mechanical complications |
| --- |
| 1. Increased physical immobility |
| 2. Respiratory impairment (= dyspnoea as a result of restrictive ventilation) − due to hepatic hydrothorax − due to an elevated diaphragm or plate-like atelectases |
| 3. Elevated portal venous pressure |
| 4. Compression of vessels − inferior vena cava syndrome − renal vein |
| 5. Formation of hernias |
| 6. Ruptured umbilical hernia |
| 7. Dislocation of organs − intra-abdominal − cardiac rotation, diminished cardiac function |
| 8. Promotion of a gastro-oesophageal reflux |
| **Bacterial complications** |
| 1. Spontaneous bacterial peritonitis |
| **Metabolic complications** |
| 1. Disturbances of electrolyte metabolism |
| 2. Disturbances of protein metabolism, catabolism |
| 3. Changes in pharmacokinetics |
| 4. Hepatic encephalopathy |
| 5. Hepatorenal syndrome |

***Tab. 16.9:*** Complications arising from ascites

Even though the mortality rate of spontaneous bacterial peritonitis can clearly be reduced by antibiotics, it still remains a very real danger for the patient. The hepatorenal syndrome has a very poor prognosis with a mortality rate of about 95%. *(see chapter 17)*

# 7 Spontaneous bacterial peritonitis

In severe liver diseases, particularly in cirrhosis, but also in acute viral hepatitis, bacterial infections are frequent. (75) In approx. 25% of cases, these infections are the cause of death. If there are additional complications (e.g. gastrointestinal bleeding, protein deficiency, inva-sive interventions, endotoxinaemia, liver metastases, continuous abuse of alcohol) which culminate in a fur-ther weakening of the body's defences, the cause of death can be attributed to bacterial infection in >50% of cases.

## 7.1 Definition

Spontaneous bacterial peritonitis (SBP) (H.O. CONN, 1964, 1971) is the term used to describe bacterially infected ascitic fluid in liver cirrhosis where the exact source of infection or path of infection is not known. It displays a high number of polymorphonuclear neutrophils ($>250/mm^3$), a protein content which is usually $<1.0$ g/dl and a positive bacterial culture ($>90\%$).

## 7.2 Forms and frequency

In terms of the number of neutrophils and the microorganisms identified, SBP can occur in ascites in **three forms** (76, 88, 89, 92, 94):

1. **Classical (complete) SBP:** $>250/mm^3$ polymorpho-nuclear neutrophils together with positive ascites culture; this constellation is the most frequent form.

2. **Culture-negative neutrocytic ascites:** $>250/mm^3$ neutrophils together with negative ascites culture; it appears in $4-5\%$ of patients suffering from cirrhosis with ascites and in up to 35% of cases with suspected SBP. This form does not differ from classical SBP as regards symptomatology, clinical and laboratory findings or efficacy of the antibiotic therapy required.

3. **Culture-positive neutrophil-low ascites:** $<250/mm^3$ neutrophils and mostly monoculture-positive ascites; gram-positive infectious agents predominate. As a rule, this form shows an asymptomatic course and a more favourable prognosis. It is interpreted as a bland bacterial infection with good defence potential (i.e. transi-ent colonization). Antibiotic therapy is not required, but ascites follow-up examinations are indispensable in order to initiate any necessary antibiotic treatment in good time.

Each of these 3 forms of SBP has to be delimited from **secondary bacterial peritonitis.** In bacterial ascites, several types of microorganisms, including fungi, can usually be identified after subculturing. As a rule, the cell count exceeds $10,000/mm^3$, the LDH value is elevated ($>225$ U/l), and the glucose concentration is $<50$ mg/dl.

The **frequency** of SBP is $10-25\%$. (74−76, 88, 106) With coexistent HE, it was found to be 36%, whereas in the absence of HE, SBP was detectable in only 10% of cases. Culture-negative ascitic fluid can be identified with SBP in up to 50% of cases and bacterascites in up to 30% of cases. (75, 95) **Relapses** occur at a rate of $43-69\%$ per

year. An ascitic protein concentration of < 0.75 g/dl is considered a significant predictive factor for a relapse.

## 7.3 Pathogenesis and predisposing factors

Even if pathogenesis has still not been fully resolved, it is generally attributed to various **regulatory defects in the immune system** (so-called *acquired immune defect syndrome in cirrhosis*): (*1.*) reduction in the opsonic and bactericidal activity of the ascitic fluid, (*2.*) impaired function of the RES phagocytosis system, and (*3.*) leukocytic functional deficiency. A decrease in $C_3$ concentration in the ascitic fluid (< 20 mg/dl) reduced the bacterial content and, according to the literature, led to the occurrence of SBP in 47% of cases within a short space of time.

This multifactorial weakness in defence allows **bacterial penetration** of the ascitic fluid to be effected by (*1.*) transmural migration in portal hypertension with greater permeability of the intestinal wall, (*2.*) systemic bacteraemia in terms of haematogenous dispersion (particularly in urinary tract and bronchopulmonary infections), above all in the presence of intrahepatic and extrahepatic shunts (so-called portal vein bacteraemia), (*3.*) invasion of bacteria via the Fallopian tubes, and (*4.*) lymphatic flow into the ascitic fluid (e. g. via leaks in the lymph vessels or lymph nodes).

**Predisposing factors** often interact to produce a considerably greater effect in the individual case (73, 75, 87, 88, 96):

(*1.*) **reduction** in the bactericidal and **opsonic activity** (C3 < 20 mg/dl) and in the **ascitic protein value (<1.0 g/dl)** as well as a dysfunction of the polymorphonuclear neutrophils;

(*2.*) dysfunction of the liver (e.g. bilirubin > 3.5 mg/dl, thrombocytes < 98,000/mm³) as a result of an accompanying decrease in antibodies or RES functions;

(*3.*) poor nutritional status;

(*4.*) upper gastrointestinal bleeding and application of balloon tamponade or varicosclerosation;

(*5.*) invasive measures such as endoscopic or angiographic techniques or peritoneovenous shunting (some 20% of cases) with a mortality rate of about 25%;

(*6.*) infusion of vasopressin, which leads to a deterioration in the circulation of the intestinal mucosa and hence to easier penetration by microorganisms;

(*7.*) bacterial foci with systemic bacteraemia through arteriovenous anastomoses.

## 7.4 Clinical aspects

**1. Pathogen detection:** The first decisive diagnostic criterion of SBP is the detection of the pathogen. However, this cannot be adequately achieved using conventional techniques. **Bedside inoculation** of 10 ml ascitic fluid per haemoculture bottle is recommended with a cultivation period of 5 to 7 days at 37°C, with subcultivation on days 1, 2 and 7. The yield of positive cultures is thus doubled. Demonstration of *one* type of pathogen is considered typical for SBP (> 90%), whereas determination of *several* types of pathogens or anaerobes generally suggests secondary peritonitis. In 60−80% of cases, gram-negative aerobes are found, half of which (40−50%) are E. coli. A small fraction is comprised of

Klebsiella, Citrobacter, Proteus and Enterobacter. Gram-positive microorganisms were detected in 25−30% and anaerobes in 4−6% of cases. Isolated reports have been published on the identification of Clostridia (77), Salmonella (80), Chlamydia trachomatis (83, 97) and Listeria monocytogenes (86, 91).

**2. Cell count:** The second important criterion of SBP is deemed to be a higher cell count (> 250 polymorphonuclear neutrophils/mm³). As a result, early diagnosis is possible with a sensitivity of 92% and a specificity of 95%. A higher leukocyte count in ascitic fluid does not correlate with peripheral leukocytosis (or vice versa). Mechanical assessment of the cell count, however, also identifies lymphocytes, serosal surface cells and peritoneal macrophages. For this reason, it is imperative to distinguish the polymorphonuclear neutrophils (and possibly the number of mononuclear forms) in the ascitic fluid smear. (71, 75, 79, 102, 106)

**3. Chemical parameters:** The additional determination of chemical parameters (*decreased:* fibronectin, pH value, glucose, cholinesterase, etc.; *increased:* lactate, LDH, etc.) can improve the certainty of the SBP diagnosis in individual cases and also provide a clearer picture of its severity. (79, 81, 90, 101, 106)

**4. Clinical findings:** In 10−50% of cases, SBP follows an *asymptomatic* course. Each sudden or inexplicable deterioration in the course of disease, manifestation or aggravation of encephalopathy, non-response to appropriate diuretic therapy, continued increase in ascites or signs of the onset of renal insufficiency all point clearly to SBP. However, *clinical symptomatology* can also develop slowly in cases of long-standing ascites. By contrast, SBP may pursue a more rapid course, with pronounced findings in the presence of existing as well as simultaneously developing ascites. (74, 75, 79, 83, 85, 87, 93, 94, 106) (s. tab. 16.10)

| | |
|---|---|
| Fever | Decreased bowel sounds |
| Abdominal pain | Nausea |
| Abdominal guarding | Tendency to diarrhoea |
| Onset of HE | Reduced diuresis |
| Meteorism | Arterial hypotension |

*Tab. 16.10:* Symptoms of spontaneous bacterial peritonitis

## 7.5 Prophylaxis and therapy

In decompensated liver cirrhosis or gastrointestinal bleeding, the use of antibiotics is recommended for the primary prevention of SBP as well as to avert a relapse. This is especially true if predisposing factors for SBP are present. In cirrhosis with ascites, for example, SBP occurs in about 80% of hospitalized patients within the first week. For this reason, SBP is deemed to be a *nosocomial infection* (H.O. CONN, 1987) although other investigators regard the domestic surroundings as the most

common site of infection. Such complications of ascites, which still have a poor prognosis despite cost-intensive therapy, should be prevented by suitable prophylactic measures.

► **Prevention** is achieved through simply reducing the *ascitic volume* by means of efficient diuretic therapy, so that the total protein and complement factors in ascites rise significantly. Paracentesis can also be helpful if the protein deficiency is compensated at the same time.

Long-term application of *lactulose*, possibly in short-term combination with neomycin or paromomycin, is recommended. This is especially true when there are signs of an onset of hepatic encephalopathy.

Recommended antibiotic prophylactic measures include *neomycin* (1 g), *colistin* (1.5 million units) or *nystatin* (1 million units) four times a day. Antibiotics which have been tried and tested are *norfloxacin* (400 mg/day), *cefotaxime* and *ceftriaxone*. They result in selective intestinal decontamination as well as bactericidal action in the serum, ascitic fluid and urine. Because of the possible impact of norfloxacin on the central nervous system, special caution should be exercised during the initial stages of HE. Primary prevention with norfloxacin in high-risk patients yielded a reduction in SBP frequency from 17% to 2% and from 32% to 0%. (72, 82, 87, 89, 94, 98)

► Where $>250/mm^3$ polymorphonuclear neutrophils are detected, immediate **antibiotic treatment** is called for using (*1.*) amoxicillin-clavulanic acid, (*2.*) cefotaxime (and other 3rd generation cephalosporins), (*3.*) gyrase inhibitors such as norfloxacin, and (*4.*) aztreonam. The latter, however, does not act against gram-positive microorganisms, so that there is a danger of gram-positive proliferation. *Therapy* lasting 4−5 days (longer application is of no further advantage) with cefotaxime (perhaps combined with metronidazole in the possible presence of anaerobes) or amoxicillin-clavulanic acid can provide a success rate of $>80\%$. Consequently, an *exploratory puncture* and follow-up examination of the ascitic fluid after a 48-hour antibiotic therapy is imperative. • In accordance with the **antibiogram,** it may prove necessary to change the initial antibiotics. Success is, however, usually achieved within a few days, using the substances of first choice (cefotaxime, amoxicillin-clavulanic acid). Therapy results can be markedly improved through simultaneous administration of albumin (1.5 g/ kg BW). (99) In order to avert a relapse, norfloxacin is recommended; this reduces the relapse rate from 68% to 20%. (76) The previously high mortality rate (some 90%) could be lowered to 40−78%, and in a recent study even to 37%. • With the additional administration of **selenite** (e. g. 500 µg as short-term infusion), it is apparently possible to improve the survival rate even further. (72, 74, 78, 84, 94, 96, 103, 106)

# 8 Conservative therapy of ascites

*"When the liver is full of water that flows off into the abdomen and the body is distended, then death is near."* (HIPPOCRATES)

Oedema and ascites call for extensive therapeutic measures. The daily life of the liver patient is additionally impaired by this condition, which may even be life-threatening. Awareness of the pathogenic factors makes it possible to apply prophylactic measures to prevent a disruption of water-electrolyte homoeostasis and to ensure appropriate therapy.

► In pathophysiological and prognostic terms, even ascites that can "only" be identified by ultrasonic methods is a **sign of decompensation** − either decompensation which is still latent, yet unstable, or decompensation which is slowly increasing by itself! • This latter condition ultimately calls for much more severe measures (also involving more side effects) than merely moderate and cautious efforts to restore the patient to a stable state of recompensation, which should then be as lasting as possible.

## 8.1 Prophylaxis

The principal prophylactic measures for ascites consist of a detailed consultation with the physician (preferably in the presence of a family member) and strict *guidance* of the patient with efficient *follow-up* checks in the practitioner's surgery. (s. fig. 15.2) An important prerequisite for successful prophylactic measures is an appropriate *lifestyle* on the part of the patient with regard to the disease.

► As far as the **costs** are concerned, a one-year course of prophylactic treatment including the necessary follow-up checks and possible *early treatment of commencing water retention* is less expensive than 3 or 4 days' hospitalization. • This solely economic viewpoint is likewise true for *prophylactic measures used in hepatic encephalopathy* as well as for its early diagnosis and successful therapy at the practitioner's surgery.

The **restriction of sodium** to 7−8 g daily (or even less) is an important step. Each excessive gram of sodium which is taken up and cannot be excreted leads to a water retention of 200−300 ml. (s. tab. 16.11)

All routine activities which can be carried out in a **supine position** should indeed be performed in this way (see below). As a result, renal perfusion is improved, the sympathicotonus lessened and the tubular absorption of sodium decreased. The breakdown of aldosterone is increased by $>30\%$, and its half-life returns more or less to normal. The central blood volume is enhanced. Removal of ascitic fluid via the subdiaphragmatic and mediastinal lymph vessels is facilitated.

**Intestinal detoxification** by means of lactulose, which, among other things, delays the production and/or portal uptake of endotoxins, is another important therapy step.

Should these measures prove inadequate, either because of insufficient compliance on the part of the patient or because of the advanced stage of the disease, **spironolactone** (50 mg every second day) is recommended. This dose is considered effective and sufficient (due to its longer half-life). As a rule, there are no side effects.

▶ The patient is instructed to record his morning *body weight* (always under the same conditions) every day on a **documentation sheet** (E. KUNTZ, 1989) as well as the *frequency of stools* (e.g. under lactulose therapy) and to enter a *handwriting specimen* (usual way of writing the first and last name) every one or two days. (s. fig. 15.3) • This documentation sheet is deemed to be a useful and efficient instrument (which can be kept as a medical record) in the control and follow-up of a chronic course of disease. An ancillary benefit is that the extent to which the patient is cooperating can also be deduced from the accuracy of the entries made. (s. p. 275)

Patients should immediately consult the doctor if their body weight rises steadily by >1 kg over a period of 3 or 4 days. This is *suggestive of a clinically not yet identifiable accumulation of water in the tissue* (= **latent oedema**). • Patients should also consult the doctor in the case of minor irregularities in their handwriting. Psychometric tests can be used to confirm or discount suspected cases of **latent HE**. (s. pp 203, 272) (s. fig. 15.3)

> ▶ **Self-monitoring** on the part of the patient makes it possible to identify the beginning of water accumulation in the organism (>1 litre), a reduced lactulose effect (which is inadequate for intestinal detoxication) and/or a latent phase of hepatic encephalopathy. • In such cases, immediate **outpatient treatment** is generally reliable and swift in its therapeutic success.

> *Diuretics are not indicated as a prophylactic measure!* (because of the possible activation of RAAS)

## 8.2 Basic therapy (stage I)

▶ The development of **latent oedema** can be recognized by means of daily weight checks when an increase in weight of >1 kg occurs within 4 days.

▶ **Latent ascites** (<250 ml) can be determined by sonography. Detection of fluid in the abdominal cavity signals decompensation of cirrhosis and the corresponding inefficacy of prophylactic measures. Medication is recommended as part of a stepwise therapy. To start with, the prophylactic measures for ascites should be applied more intensively and consistently. Both ascites itself and its treatment harbour risks for the patient.

The earlier ascites is identified, the more successful the therapy will be because less "aggressive" methods with minimal or no risks can be used; and, of course, the costs will also be lower. (s. tab. 16.11)

Absolute **supineness** (probably even with the head and upper body slightly lowered) promotes the excretion of water and sodium. This physical treatment significantly improves both the natriuretic and diuretic effect of a loop diuretic agent. (109, 123, 137) (s. tab. 16.11)

The aim should be to break through the positive sodium balance by **restricting sodium** to ≤ 5 g/day (= 88 mmol). Natriuresis should amount to >80 mmol/day. Given an extrarenal loss of sodium of approx. 10 mmol/day, determination of the sodium content in 24-hour urine provides a clue to the degree of compliance with the intended sodium restriction level of ≤ 5 g/day − i.e. with an excretion of >78 mmol/day, the desired negative sodium and fluid balance is achieved. The efficacy of a low-sodium diet in the treatment of ascites is evident. *Dietary sodium restriction* can be maintained by applying the following *rules:* (*1.*) preparation of food without salt, (*2.*) no extra salt to be added at the table, (*3.*) no use of baking powder, tinned food, highly salted food, mineral water or chocolate, (*4.*) no more than 0.25 l milk/day, and (*5.*) no use of medication or i. v. solutions containing sodium. *Liquorice is prohibited!* • Certain herbal mixtures can help patients to accept sodium restriction in the diet. Even food that does not taste salty may still contain significant amounts of sodium (e. g. sodium nitrate, sodium phosphate). A marked restriction of sodium is mostly accompanied by a parallel reduction in the general protein consumption; this must be averted by an adequate intake of lactovegetable proteins. Patients should always be given **dietary advice!** (s. tab. 16.11)

| Basic therapy (stage I) | |
|---|---|
| 1. Sodium restriction (intake < 5 g/day) | |
| 2. Water restriction (intake < 1,500 ml/day) | |
| 3. Supine position | |
| 4. Intestinal detoxification (with lactulose) | |
| 5. Spironolactone (50−100 mg/day) | |
| 6. Balancing of electrolytes | |
| 7. Substitution in zinc deficiency | |
| 8. Balancing of proteins | |
| **Success rate** | **20−30%** |

*Tab. 16.11:* Basic therapy of ascites (stage I)

Normally, the daily **fluid intake** is 1,700−2,200 ml; this includes water in a bound form (e. g. in fruit, yoghurt, tomatoes). If this amount is clearly reduced or exceeded, the cirrhotic patient may suffer considerable pathophysiological disturbances. From the clinical point of view, however, it is recommended to limit the fluid intake to 1,400−1,600 ml/day during this phase of therapy (in cases of hyponatraemia even to 800 ml). An increase in

the dosage of **spironolactone** to 50−100 mg/day has proved effective. With this measure, a loss in weight of >1.2 kg in four days can be achieved in 15−20% of cases (= excretion of retained fluid). (s. tab. 16.11)

**Follow-up checks** regarding sodium, potassium, magnesium, the acid-base equilibrium and possibly zinc are required; if necessary, the status has to be duly balanced. • **Hyponatraemia** must not be "treated" by the intake of sodium, but by a further *restriction of fluid* (while monitoring sodium levels). (s. p. 308)

## 8.3 Diuretic therapy (stage II)

Ascites is a defined compartment of the extracellular fluid volume, which is difficult to mobilize. If the reduction in weight is inadequate after appropriate basic therapy (<1.2 kg after 4 days), stage II should be initiated with the cautious administration of diuretics. The steps already detailed for stage I are to be continued, whereby the intake of dietary sodium is restricted even further (≤ 3 g/day). (s. tab. 16.12)

The peritoneum has a surface area of about 2 m². It has the effect of a semipermeable membrane and can transport a total of 720−840 ml/day between the plasma and the peritoneal cavity. Spontaneous diuresis allows *300 ml/day* to be excreted, whereas with the use of diuretics some *500 ml/day* are possible. The presence of peripheral oedema, however, permits a loss of fluid of about *900 ml/day* (L. SHEAR et al., 1970).

The **therapeutic target** is a weight reduction of about 1.5 kg in 3 days (maximum 500 ml/day) without oedema and of 3.0 kg in 3 days (maximum 0.7−1.0 l/ day) with concomitant peripheral oedema. (130)

▶ If diuretic therapy is to be low in complications, the following **prerequisites** are important: (*1.*) no electrolyte imbalance, (*2.*) no abnormality of the acid-base equilibrium, (*3.*) normal renal function, and (*4.*) no simultaneous application of non-steroidal antiphlogistics (since these inhibit the synthesis of prostaglandin and hence may cause renal dysfunction). • In line with the half-life of the diuretics, a *twice-daily administration* (morning, early evening) is more successful. As a rule, the early evening diuretic dose is lower (e. g. xipamide 20 mg and *10 mg*). This serves to prevent renewed retention of fluid during the night which occurs as a result of the continuously decreasing diuretic effect of just one morning dose. It may also be necessary to administer a third low diuretic dose at midday (e. g. xipamide or torasemide 20/ *10/10 mg*). (s. tab. 16.12)

### 8.3.1 Pharmacology of diuretics

Of the many diuretic agents with their differing points of impact on the nephron and their respective action profiles, some preparations, even in combined appli-

cation, have proved extremely successful in the treatment of portal ascites. It must be borne in mind here that liver diseases can change the pharmacokinetics of diuretics. (112, 113, 116, 125)

*Never provoke abrupt diuresis. • Never stop the use of diuretics suddenly!*

| **Diuretic therapy (stage II)** | |
|---|---|
| 1. **Aldosterone antagonist** | |
| • potassium canrenoate | (100−800 mg i.v./day) |
| • spironolactone | (50−400 mg/day) |
| 2. **Saluretics** | |
| • etacrynic acid | (50−400 mg/day) |
| • etozolin | (200−800 mg/day) |
| • furosemide | (20−500 mg/day) |
| • torasemide | (10−40 mg/day) |
| • xipamide | (10−40 mg/day) |
| 3. **Sequential nephron blockade** | |
| torasemide or xipamide combined with | (20−40 mg/day) |
| • butizide, *or* | (5 mg/day) |
| • hydrochlorothiazide, *or* | (25 mg/day) |
| • metolazone | (2.5−5 mg/day) |
| **Success rate** | **ca. 80%** |

*Tab. 16.12:* Diuretic therapy of ascites (stage II)

**1. Spironolactone** (J. A. CELLA et al., 1957) is deemed to be the preparation of first choice. Its clinical efficacy has been substantiated in numerous studies. • The onset of effect is after 8 to 24 hours. The natriuretic/diuretic action is maintained for 1 or 2 days. A faster onset of effect is given by *potassium canrenoate*, available as an i.v. application, particularly when absorption is assumed to be impaired or if oral administration is not possible. • *Spironolactone is not primarily considered to be a diuretic agent, but more a substance with neurohumoral action.* (107, 111, 114, 115, 117, 118, 129, 133, 135, 138; quot. 15)

As a specific **aldosterone antagonist,** spironolactone acts at the basolateral side of the upper-distal tubule as well as in the collecting tubule and prevents aldosterone from contacting its receptor. As a result, aldosterone-related stimulation of the sodium-potassium ATPase is inhibited at the cell membrane. For this reason, aldosterone is unable to reach the cell nucleus with its receptor complex. Synthesis of the aldosterone-induced protein, which opens the sodium canals, is prevented. The absorption of sodium is decreased and natriuresis reinforced, whereas the excretion of potassium remains normal or is diminished. In the presence of hyperaldosteronism, spironolactone is likely to be fully effective. Although aldosterone only controls some 2 (−4)% of the glomerular filtrated sodium at the tubule, a natriuretic/diuretic effect is gradually and continuously achieved. The positive effect of spironolactone on portal ascitic fluid can be attributed to an inhibition of the aldosterone-mediated absorption of sodium in the intestine, a reduction in the portal vein pressure and an increase in the synthesis of prostacyclin in the kidney. Spironolactone has no glucocorticoid impact and no influence on the metabolism of carbohydrates. *Due to an escape effect, it does not usually cause hyperuricaemia, hyponatraemia or hyperkalaemia.* Protein binding is 98% with a bioavailability of 60−90% and a half-life of 20 hours. In cases of cirrhosis, the pharmacokinetics of spironolactone remains unchanged. • The transtubular potassium gradient may be a suitable guide for the diuretic management of patients with cirrhosis and ascites. (49)

| Action profile of spironolactone | |
|---|---|
| **Natriuria** ↑ | **Zincuria** ↓ |
| **Kaliuresis** none-(↓) | **Hydrogen ions (in urine)** ↓ |
| **Magnesiuresis** none-(↓) | **Chloride (in urine)** ↑ |
| **Ammonia** ↓ | **Bicarbonate (in urine)** ↑ |
| | **pH value (in urine)** ↑ |

▶ As a result of a tubular hypersensitivity to aldosterone, cirrhotic patients usually display *functional aldosteronism* in the early stages of increased sodium retention. This would explain the diuretic and natriuretic efficacy of spironolactone even in cirrhotic patients with normal aldosterone levels.

*In no way do normal potassium values rule out hyperaldosteronism!*

The *dosage* of spironolactone is 100 to 400 mg/day in 2−3 single doses. That of potassium canrenoate amounts 100 to 800 mg/day. When therapy commences with potassium canrenoate, spironolactone should be administered orally 1−2 days prior to the intended termination of the i.v. application to ensure a smooth transition, since the onset of its effect is delayed. In 25−30% of male patients, long-term application leads to (generally reversible) potency disorders and gynaecomastia.

**2. Xipamide** is classed as a low-ceiling diuretic with its effective dynamics and intensity ranking between furosemide and the thiazides. For this reason, there are no extreme peaks of diuresis during prolonged therapy. Calciuria is typical for loop diuretics. With portal ascites, xipamide has proved to be almost diuretically equivalent to spironolactone.

The **efficacy** of xipamide is reflected at various sites of the tubule and Henle's loop. It reaches its point of impact at the early-distal tubule − from the peritubular side. With a threshold dose of 5 mg, a dose dependency ranging between 14 and 60 mg is thus produced for the excretion of water and urine; when in excess of 80 mg, there are no further effects. The bioavailability is 73% and protein binding 98%.

A *dosage* of 20 to 40 mg xipamide per day is recommended in 1−2 (−3) single doses. For long-term therapy, it is advisable to prescribe 10 mg. Diuresis sets in after about 1 hour with a peak after 2 to 8 hours. There is no rebound effect. The excretion of sodium and chloride is increased to an almost identical degree; calciuria, magnesiuresis and kaliuresis occur. For this reason, xipamide should be combined with spironolactone. Biotransformation of xipamide is clearly limited in cirrhotic patients, the half-life (7 hours) is not influenced. Xipamide passes into the ascitic fluid and reaches concentrations of 10−20% of the respective plasma level. It can even be used with restricted renal function, since it has no influence on renal haemodynamics.

**3. Torasemide** has proved successful in the treatment of portal ascites. The onset of effect takes between 15 and 30 minutes, and it reaches its peak after 6 to 9 hours. Torasemide has a high natriuretic and diuretic effective-ness, even with restricted renal function. Up to now, a *dosage* of 20 mg per day has been used (possibly in two single doses of 10 mg). A combination with spironolactone is very efficient. Torasemide is also available as an intravenous application. (108, 110, 120, 124)

In terms of **efficacy**, torasemide is a high-ceiling, long-acting diuretic, which shows a linear and rapid rise in the dose-effect curve in a higher dose range. Bioavailability is 80−90%, with a protein binding of 98%. The half-life is 3−4 hours. The site of action is deemed to be the ascending branch of the loop of Henle. There are marked increases in the amounts of potassium, magnesium and sodium in the urine, but excretion of bicarbonate and phosphate remains constant. In cirrhosis, the half-life is lengthened to 4−5 hours and biotransformation is impaired. (110) Torasemide has a favourable sodium-potassium excretion quotient. It does not accumulate in renal or liver insufficiency.

**4. Etacrynic acid,** especially in *combination* with spironolactone and xipamide, markedly enhances natriuresis and diuresis. The *dosage* is increased as required (e. g. 1 × 25 mg or 50 mg to 2 × 50 mg per day). With a low-dose application in the form of a combined diuretic therapy, there is usually no risk of hepatic encephalopathy developing. The effect of etacrynic acid sets in at the ascending branch of the loop of Henle (active chloride transport). Renovascular resistance is lowered due to enzymatic activity, presumably as a result of a rise in the release of prostaglandin.

**5. Furosemide** is considered to be a high-ceiling diuretic. The onset of effect is rapid with a strong (unwanted) rebound. With a half-life of 1.5 hours, the length of impact is short (3−6 hours). The bioavailability is 65%, protein binding 70−80%. In cases of cirrhosis, the half-life is lengthened and natriuresis is diminished. Reinforcement of potassium in the urine, alkalosis and hepatic encephalopathy are witnessed. Furosemide can promote enhanced formation of thromboxane in the kidneys with subsequent renal vasoconstriction. This could be the cause of renal failure in cirrhotic patients following high doses of furosemide. It only acts with intact $PGE_2$ synthesis, which is, however, often impaired in cirrhosis. (110, 112, 117, 129, 135, 138)

**Follow-up checks:** It is important to be aware of the pharmacological characteristics of diuretics and to carry out check-ups during diuretic therapy at short intervals, so that countermeasures can be initiated early enough in the event of therapeutic derailment. Intervals between check-ups as well as the diuretic dosage depend on the success of the treatment and the course of disease:

- Body weight and specimen of handwriting (daily) (s. pp 203, 305, 313) (s. figs. 10.1; 15.3)
- Urine volume (at the outset: each day)
- Electrolytes (at the outset: possibly each day)
- Serum creatinine (at the outset: possibly every 2−3 days)
- Acid-base status (at the outset: possibly every 3−4 days)

**Success rate:** With correctly applied diuretic therapy, the rate of success is about 80% (even in prolonged or recurring ascites).

**Failure rate:** If the diuretic therapy proves unsuccessful, investigation must initially focus on whether the therapeutic steps taken have been correctly implemented or whether exsiccosis with a contraction of the plasma volume has occurred as a result of excessively forced diuresis. Hypovolaemia leads to stimulation of the biochemical and sympathoadrenal regulatory systems with an occasionally deleterious effect on the course of disease.

### 8.3.2 Side effects

Diuretic treatment of ascites can, however, involve considerable hazards for the patient. Generally, one has to reckon with the following side effects: **encephalopathy** in 22−26% (as a result of 5−10% inhibition of carbonic anhydrase in the mitochondria of the liver cells), **hyponatraemia** in 40−50%, **azotaemia** in 20−40%, and **hypokalaemia** in up to 85% of cases. A rare event are diuretic-associated oedemas. (127)

> *Therefore, dose diuretics "as softly as possible"!*

These complications occur singly or in a combined form in 30−50% of all diuretically treated patients. The more aggressive the diuretic treatment is, the more frequently these types of complications can be expected. • *Hypokalaemia*, which does not respond to potassium substitution, is possibly accompanied by (unidentified, diuretically induced) *hypomagnesaemia*, particularly in elderly patients. (134) For this reason, it may be necessary to substitute magnesium. Thought should be given to the possibility of a *pseudo-Bartter syndrome* as a result of diuretic abuse and especially of excessive liquorice intake. (136) The very first signs of diuresis-related hazards call for immediate countermeasures − or even discontinuation of the diuretic therapy. *Nonsteroidal antiphlogistics* are contraindicated for cirrhotic patients with ascites.

### 8.3.3 Hyponatraemia

Elimination of hyponatraemia (< 125 mmol/l) is extremely difficult. In this case, the overall status of body sodium is increased, and hence the body fluid as well, whereas the sodium level in the serum is lowered (= *dilutional hyponatraemia*). Treatment is effected by strictly limiting the intake of fluid (< 700−900 ml/day) and rigidly restricting salt. • Should these measures fail to raise sodium levels in the serum and increase diuresis, intravenous administration of a hypertonic sodium chloride solution (3%) can be attempted (increasing serum sodium by no more than 1−1.5 mmol/l per hour and, if possible, never in excess of 130 mmol/l). This, however, automatically harbours the danger of tense ascites. For this reason, an i.v. application of furosemide should be given at the same time to promote the clearance of free

water. The sodium lost in the urine (measurable in six hourly intervals after administration of a saluretic) is replaced quantitatively by the supply of NaCl. This trick produces pronounced diuresis without a "genuine" input of sodium (R.W. SCHRIER et al., 1973). • With intact renal function, an attempt can be made at treatment with a 5% sorbitol solution or a 10% mannitol solution. (128) Haemofiltration or i.v. application of sodium-free albumin (122) is likewise recommended. (126) • The augmented release of ADH is depressed by vasopressin-2-receptor antagonist. (139)

### 8.3.4 Resistance to diuretics

Resistance to diuretics occurs if the reduction in body weight ceases despite confirmed diuretic intake or if a rise in creatinine and urea restricts further diuretic application. The phenomenon of *haemodynamic resistance to diuretics* may prove extremely problematic, i.e. the actual volume of circulating blood is reduced. (131) There is a **triad** status: (*1.*) rise in retention values, (*2.*) lower urine volume, and (*3.*) low excretion of sodium in the urine. At the same time, arterial hypotension as a result of pronounced peripheral vasodilation is present together with the opening of arteriovenous anastomoses. Palmar erythema or spider naevi can often be seen to "blossom". (s. p. 80) The greater the peripheral vasodilation, the more pronounced is the renal vasoconstriction. As a result, it is hardly (if at all) possible for the diuretics to reach their site of action in the nephron. • Another cause of diuretic resistance can be attributed to the fact that the substrate concentration required for the loop diuretics to have an effect is absent in the ascending part of Henle's loop because of the increased proximal tubular absorption of sodium − the diuretic is therefore ineffective. This renal deficiency of diuretics is wrongly equated with "resistance". The *therapy* recommended is a **sequential nephron blockade**, which is achieved by combining a loop diuretic with a thiazide, e.g. torasemide (20−40 mg) (124) with butizide (5 mg), hydrochlorothiazide or metolazone as well as low-dosed ACE inhibitors. (s. tab. 16.12)

An **ornipressin infusion** and **adrenaline infusion** plus **water immersion** (up to the neck, for a period of 5 hours) act on the lowered peripheral vascular resistance. (65) (s. p. 329) • Low-dosage dopamine and prostaglandin or ANF infusions may have an effect on the increased renovascular resistance. (132) A selective vasopressing-2-receptor antagonist induced a dose-related aquaretic response. (121)

## 8.4 Osmotic diuresis (stage III)

In cases of inadequate response to diuretic therapy (stage II), osmotic diuresis (stage III) may be advisable in order to improve *hypoalbuminaemia* and *hypovolaemia*. (s. fig. 16.16)

**Human albumin:** By means of the i.v. application of human albumin or fresh plasma, it is possible to bring

about a temporary rise in the osmotic pressure and improve the glomerular plasma flow. (99, 119) • Enlarging the plasma volume causes an increase in renal perfusion and urine excretion. • *The passage of infused human albumin into the ascitic fluid is prevented or reduced by means of prior administration of a plasma expander (100–200 ml) to ensure a preliminary boost to the oncotic pressure.*

**Mannitol:** Stimulation of osmotic diuresis is possible using mannitol (10–20% solution). (128) Mannitol is neither metabolized in the body nor reabsorbed by the tubules and is excreted almost totally through the kidney. Renal circulation and renal filtration are raised, and by reducing tubular absorption (= osmotic diuresis), water excretion is increased ("diuresis starter"). The saluretic effect is, however, relatively small. In the case of restricted renal function, application of mannitol is contraindicated. If necessary, the **mannitol test** (i.v. injection of 75 ml of a 20% solution) can be carried out beforehand. With enhanced diuresis of > 40 ml/hr, the kidneys still function adequately, so that it is possible to stimulate osmotic diuresis by means of a mannitol infusion.

In the individual case, these short-term measures (possibly also reinfusion of ascitic fluid) lead to a temporary improvement of hypoalbuminaemia and hypovolaemia, so that a diuretic therapy, which has been hitherto insufficient, can nevertheless be continued and successfully completed. • If stages I–III fail to be efficacious in eliminating ascites, paracentesis is indicated.

## 8.5 Paracentesis (stage IV)

Even in the days of antiquity, attempts were made to remove ascitic fluid by means of abdominocentesis (ERASISTRATOS 300–250 BC, CELSUS 30 BC–50 AD). PAULUS OF AEGINA (625–690 AD) gave a remarkably exact description of ascitic fluid being tapped. • In the 16th century, PARÉ removed ascitic fluid by means of an inserted seton (i.e. rope made of hair) after cauterizing the abdominal wall. In the 17th century, SANTORINI used a special instrument inserted through the navel to tap the abdominal cavity. • Figure 16.11 illustrates how the **tapping of ascitic fluid** was performed at that time **(1672).**

*Fig. 16.11:* Tapping ascitic fluid (1672) (German National Museum, Nürnberg)

Before resorting to invasive or even surgical procedures to eliminate ascites, paracentesis (stage IV) is indicated. Repeated (if necessary daily) paracentesis can remove 1,000–4,000 ml ascitic fluid in 1–2 hours. The loss of complement factors possibly heightens the threat of spontaneous bacterial peritonitis – yet in view of the reduced protein content in the ascitic fluid, this danger is more likely to be diminished. Relief is provided to the portal and renal vessels. When correctly performed, complications are rare. (164) It is possible to repeat paracentesis without incurring any actual risks and to remove substantial quantities of ascitic fluid (4–6 [–23] litres) by means of a pump (145, 148, 150, 151, 153, 154, 164) or even to evacuate a large amount of ascitic fluid almost totally. (140, 144, 147, 155, 159, 163) Therapy is successful in about 95% of cases. Paracentesis of 6 l of ascitic fluid removes 6 × 130 mmol/l sodium. Occasional circulatory dysfunction (as demonstrated by excessive activation of the RAAS) following paracentesis only rarely – or never – occurs when spironolactone and albumin substitution are applied.

The following criteria are important **indications** for performing paracentesis (114, 140, 146, 155, 160, 162):

1. Lack of success or inadequate feasibility of step-wise therapy (stages I–III)
2. Extensive ascites, possibly with complications
3. Sodium excretion < 10 mmol/day
4. Fractional excretion of sodium ($FE_{Na}$) $\leq$ 0.2%
5. Serum-ascites albumin gradient < 1.1 g/dl (= serum albumin concentration minus ascites albumin concentration)

With regard to paracentesis, the following **measures** are to be considered (140, 144, 146, 147, 149, 155, 159, 161):

1. Discontinuation of diuretic therapy some 3–5 days prior to paracentesis, maintenance of spironolactone (e. g. 2 to 3 × 50 mg/day).
2. Balancing of electrolytes, acid-base equilibrium and, if necessary, zinc substitution.
3. Replacement of sodium-free albumin (40 g or 6–8 g/litre ascitic fluid), half the amount prior to starting paracentesis; *or*: administration of 100–150 ml of a sodium-free plasma expander prior to paracentesis and prior to the replacement of albumin.
   ▶ *Prior administration of a plasma expander* raises the lowered oncotic pressure. As a result, the subsequent albumin intake is retained better in the blood stream (otherwise there is a possible danger of albumin loss from the "off-flow" into the ascitic fluid).
   ▶ Synthetic sodium-free plasma expanders are considerably (about 20 times) cheaper than albumin and equally efficient.

**Results:** The results of paracentesis have generally been good up to now: the number of successfully treated patients was higher, inpatient hospitalization was shorter, and complications were less frequent or less severe. The response to diuretic therapy improved considerably; discontinued diuretic therapy could be successfully taken up again. (158, 159) Plasma values of renin, aldosterone and norepinephrine dropped. There was an improvement in lung volume (141, 143) as well as in cardiac function values. (152, 153, 156) The pressure in the oesophageal varices fell. (150) • Paracentesis of 6 litres of ascitic fluid removes 6 × 130 mmol sodium.

**Dangers:** Thought must be given to averting the following dangers deriving from repeated and/or large-scale paracentesis: (*1.*) protein loss, (*2.*) loss of electrolytes, (*3.*) hypovolaemia, (*4.*) occurrence of ascitic leakage, (*5.*) occurrence of (secondary) bacterial peritonitis, (*6.*) restricted renal function, and (*7.*) acute haemoperitoneum. (142)

▶ An ascites fistula following paracentesis can be widely avoided by displacing the skin tangentially to the site of puncture, so that a Z-shaped puncture channel is created once the needle has been removed.

**Danger points** 1, 2 and 3 (see above) can be related to a quotation from Paulus of Aegina (625−690 AD): *"At all events, avoid any rapid evacuation of the fluid, since there are some ignorant operators who have removed the life and soul of the patient with the fluid, thereby bringing the life of the patient to an end."*

# 9 Refractory ascites

Before denoting ascites as refractory to conservative therapy in cases of liver cirrhosis, it is essential to rule out *what would appear to be pathogenetically or causally derived resistance to therapy.* The multiple causes of resistance to therapy must be considered in each individual case and excluded as far as possible. This can often be extremely difficult and is sometimes even impossible. (s. tab. 16.13) • Assessment of the renal cortical blood flow is facilitated by colour-encoded Doppler sonography: successful diuretic therapy of ascites requires good circulation in the renal cortex. A continuous decrease in the cortical blood flow correlates with growing therapy resistance of the ascites.

With reliable cooperation on the part of the patient, precise adherence to stepwise therapy (possibly including repeated paracentesis) and almost total exclusion of the causes of therapy resistance, it becomes clear that true **refractory ascites** or "sequestered ascites" is present in merely 5−15% of patients with portal ascites.

The prognosis of "true" refractory ascites is infaust − unless invasive measures can be applied. These would include reinfusion of ascitic fluid, peritoneovenous shunting or TIPS, and occasionally operative procedures. (38, 60, 132, 165−171, 184)

1. Unresolved cause of ascites
2. Excessive sodium levels in the body
   - inadequate sodium restriction
   - extremely high proximal reabsorption of sodium
3. Hypovolaemia
4. Absence of peripheral oedema
5. Excessive volume of ascitic fluid in the abdomen
   - disturbed cardiac function
   - compression of portal or renal vessels
6. Deterioration of renal function
7. Unfavourable diuretic effects
   - inadequate diuretic absorption
   - unsuitable diuretic agent
   - incorrect dosage
   - medication-related interactions
     (e. g. nonsteroidal antiphlogistics, aminoglycosides)
8. Spontaneous bacterial peritonitis
9. Deterioration of liver function
   - toxic or infection-related disorders
   - gastrointestinal bleeding
10. Haemodynamic resistance to diuretics
    - peripheral vasodilation
    - opening of arteriovenous anastomoses
    - relative hypotension
    - reactive renal vasoconstriction
11. Portal vein thrombosis
12. POEMS syndrome

*Tab. 16.13:* Pathogenetic or causal factors which may explain apparent resistance to ascites therapy

# 10 Invasive therapeutic procedures

## 10.1 Ascites reinfusion

In 1911 intravenous ascitic reinfusion was described as an invasive procedure to treat refractory ascites (J. Galud). This procedure was taken up again by M. Girard et al. in 1949 and by R. Emmrich et al. in 1951. In 1958 E. Adlercreutz filtered the ascitic fluid prior to intraperitoneal reinfusion and thus increased its protein concentration. (172)

During the following years, various **methods** were developed, all of which proved their worth and led to clinical success. The central venous pressure and the sodium-potassium quotient in the urine were swiftly normalized, and diuresis increased. Pathological sodium and potassium values in the serum were normalized. Natriuresis and the concentration of ADH were not influenced. There were no electrolyte disturbances. (145, 151, 174, 175−181, 184)

1. **Unmodified ascites:** Careful examination of the unmodified ascitic fluid prior to direct retransfusion is imperative. (s. fig. 16.10) It is likewise essential to determine the plasminogen level in the ascitic fluid.

By means of an automatic infusor or a roll pump, 300−400 ml/ hour are reinfused through a filter system with a pore diameter of 22 μm via a central vein catheter. Reinfusion time should be

limited to 8−12 hours/day, so that a daily reinfusion quantity of 3−4 (−5) litres is achieved. Reinfusion on every second day has also proved successful. This procedure can be carried out prior to the implantation of a peritoneovenous shunt. The transport volume is varied in such a way that a good response is not accompanied by cardiopulmonary complications due to hypervolaemia. Intensive monitoring of the patient is required.

2. **Modified ascites:** Reinfusion of modified ascitic fluid calls for prior "desalination" or "concentration" with the subsequent aim of "reproteinization". (173) The concentration of the reinfused protein was 4 to 6 times higher than the protein content of the ascitic fluid. Combined with a diuretic therapy, up to 13 litres of ascitic fluid were removed in 24 hours. A comparative study showed no difference in efficacy or complications between the reinfusion of unmodified and ultrafiltered ascitic fluid.

▶ Since 1960 discussion has focused on procedures for **extracorporeal dialysis** and since 1981 these have been used successfully (J. FELDMAN et al.). The **ultrafiltration** of ascitic fluid by means of haemodialysis and its subsequent reinfusion was described by E. R. HWANG et al. in 1982. Additional administration of foreign protein is not necessary. (145, 151, 177) A further development of ultrafiltration could be seen in the so-called *cascade filtration* or **double ultrafiltration.** (182) This procedure is described as safe, reliable and low in complications.

**Indications:** Indications and contraindications largely correspond to those of peritoneovenous shunts. For the short-term or repeated application of ascitic fluid reinfusion, the following indications can arise:

1. Refractory ascites
2. Inoperability of the patient
3. Pronounced hypovolaemia, hypotension and/or hypoalbuminaemia
4. Dilutional hyponatraemia
5. Preoperative elimination of ascites
6. Emergency situation
7. Bridging renal insufficiency that is in principle reversible

**Success rate:** Short-term success can be achieved in about 80% of cases, many of which also have the chance of long-term therapy success. Stage II treatment is continued parallel to the reinfusion of ascitic fluid.

**Complications:** Complications include clotting disorders (22, 183, 185) and the bacterial infection of ascites.

## 10.2 Peritoneovenous shunt

The short-term but nevertheless relatively good clinical results achieved with the reinfusion of unmodified ascitic fluid encouraged the development of another therapeutic procedure based on a similar principle, yet with long-term efficacy.

▶ Initial attempts were based on a peritoneovenous fistula with the great saphenous vein (M. RUOTTE, 1907). Later, it was the flow-controlled Spitz-Holter technique based on the principle of discharging CSF fluid from the hydrocephalus via a Holter valve (introduced by A. N. SMITH in 1962), which yielded convincing success. Consequently, a variety of pressure gradient-guided **shunt valves** were described over the following years: (*1.*) pump system of G. L. HYDE et al. (1966), (*2.*) Denver valve developed from the treatment of the hydrocephalus (W. R. WADDELL, 1971), (*3.*) LeVeen shunt (H. H. LEVEEN et al., 1974), (*4.*) Agishi valve (T. AGISHI, 1977), and (*5.*) Hakim-Cordis system (J. F. PATINO et al., 1979), based on the neurosurgical method developed by S. HAKIM et al. (1957). (186, 213)

**Method:** A silicone tube with roentgenopaque thread is positioned in the abdominal cavity with the intraperitoneal crus acting as an ascitic fluid collector. By means of a pressure-controlled valve, it is connected with the subcutaneously implanted section, the tip of which is introduced via the jugular vein or the subclavian vein into the superior vena cava. The ascitic fluid is forced through the valve as a result of the difference between the intraperitoneal and intrathoracic/central venous pressure. The valve only opens once this pressure gradient rises above ca. 3 cm $H_2O$. • Further development led to the production of pressure valves which could be operated manually by the patients themselves due to skilful surgical positioning. Each time the valve is pressed open, 4−6 ml ascitic fluid are transported. As a rule, the patient should use the pump 5 times per hour. In order to assess the effectiveness of a pump valve, certain **functional parameters** are applied: (*1.*) operative placement, (*2.*) opening pressure, (*3.*) pumping performance, and (*4.*) flow rate. In the light of these parameters, the Denver shunt (opening pressure 1−3 cm $H_2O$) is recommended as being most suitable despite its high flow rate (30−40 ml/min) because of its minimal obstruction rate and the possibility of non-operative recanalization. The decision as to which valve system is to be used must be taken in accordance with the four functional parameters described above and is ultimately made by the surgeon based on previous experience. (192, 199, 204, 212, 221) (s. fig. 16.12)

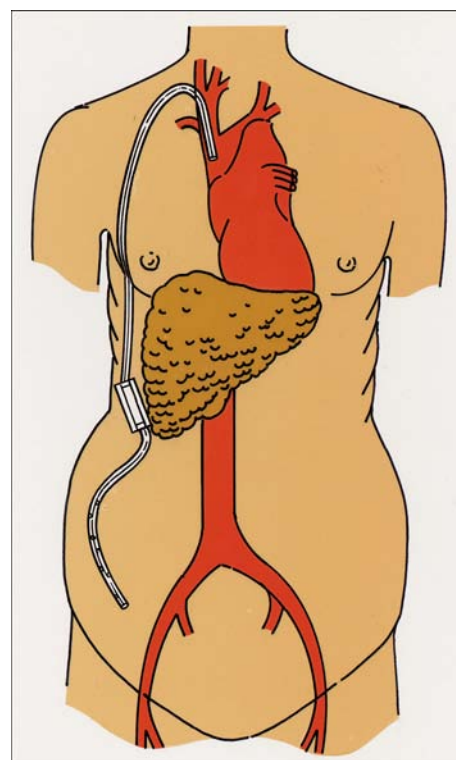

***Fig. 16.12:*** Diagram of the positioning of a peritoneovenous shunt (with Denver valve)

**Indications:** The indication for a peritoneovenous shunt (PVS) must be viewed critically. (s. tab. 16.14) Before any decision is taken on the shunt implantation, the indication for TIPS or a possible *liver transplantation* must be considered and discussed with the patient. Liver transplantation provides a real opportunity to eliminate ascites permanently − generally also with a longer survival time. (197, 202, 206, 208, 222, 223)

| 1. **Ascites in liver cirrhosis** |
|---|
| • refractory progression |
| • conservatively treatable albeit recurrent condition |
| • recurrent pleural effusions with ascites |
| • hernia with ascites and respective complications |
| • hepatorenal syndrome |
| 2. **Budd-Chiari syndrome** |
| 3. **Chylous ascites** |
| 4. **Pancreatogenic ascites** |
| 5. **Refractory malignant ascites** |
| • with considerable strain on the patient |

*Tab. 16.14:* Indications for a peritoneovenous shunt

**Contraindications:** Experience since 1974 with over 12,000 implanted peritoneovenous shunts has established a wide-scale consensus with respect to contraindications. Such contraindications, which are categorized as relative, have to be considered in each individual case. Successful treatment can, however, change contraindications into a correct indication, i.e. implantable condition. (s. tab. 16.15)

| **Absolute contraindications** |
|---|
| 1. Bacterially infected ascites, peritonitis |
| 2. Severe general bacterial infection |
| 3. Liver insufficiency |
| • clotting disorders |
| • hepatic encephalopathy (stages II−IV) |
| • bilirubin > 10 mg/dl |
| 4. Cardiac insufficiency |
| 5. Respiratory insufficiency |
| 6. Blood-tinged, highly viscous ascites |
| **Relative contraindications** |
| 1. Increased fibrinolytic activity of the ascites |
| 2. Previous bleeding of oesophageal varices |
| 3. Oliguric renal insufficiency |
| 4. Malignant ascites |

*Tab. 16.15:* Absolute and relative contraindications for peritoneovenous shunt implantation

**Complications:** The frequency of postoperative complications is extremely high at 43−83% (mean complication rate 65−70%). In connection with the high postoperative mortality rate (20−22%), the question is raised as to why such simple surgery involves such a wealth of complications. The **cause** can largely be sought in the generally very poor initial condition of the patient, whose prognosis is deemed infaust anyway. Nevertheless, the opinion is also held that a considerable percentage of complications can be attributed to *avoidable mistakes.* • Differentiation is made between **early complications** (intra- and postoperative) and (as from the first or second week) **late complications,** although no exact time spans are given. Some complications can develop at an early stage as well as at a later point in time. (188, 193, 196, 198, 203, 205, 206, 211, 217, 221) (s. tab. 16.16)

| **Early complications** |
|---|
| 1. Methodological/surgical errors (10−20%) (217, 221, 226) |
| • misplacement of venous crus |
| • top of venous crus set at too great an angle to the vascular wall |
| • flexion of the venous crus |
| • venous crus too long/too short |
| • ligature too narrow |
| • lack of compressibility in the chamber |
| • nuchal haematoma |
| • injury to the recurrent nerve |
| • pneumothorax |
| • perforation of the coronary sinus |
| • cardiac tamponade (due to perforation of the ventricle) |
| 2. Fever (20−30%) |
| 3. Clotting disorders (15−30%) (22, 200, 214, 219) |
| • hyperfibrinolysis |
| • disseminated intravascular coagulation |
| 4. Bleeding as a result of a clotting disorder |
| 5. Fluid overload of the organism |
| • lung oedema (194) |
| • cardiac insufficiency |
| • acute respiratory distress syndrome |
| 6. Tachycardia due to misplacement of the venous crus in the right ventricle |
| 7. Cholesterol/fat embolism in the lung |
| 8. Bleeding of oesophageal varices (216) |
| 9. Bacterial infection (217, 218) |
| • wound infection |
| • bacterial peritonitis (229) |
| • sepsis |
| • infection of the shunt valve |
| • endocarditis |
| 10. Leakage |
| **Late complications** |
| 1. Shunt obstruction (10−20%) |
| • fibrin-related obstruction |
| • chyle-related obstruction (228) |
| • thrombosis of the superior vena cava (189, 195) |
| • thrombosis of the jugular vein/subclavian vein (201) |
| • ascitic pseudocyst of the superior vena cava (225) |
| • superior vena cava syndrome (227) |
| 2. Intestinal occlusion |
| 3. Air embolism with intestinal perforation (207, 209) |
| 4. Phlegmonous gastroenterocolitis (190) |
| 5. Abdominal abscess |
| 6. Renal failure |
| 7. Liver insufficiency |
| 8. Shunt wandering (193) |

*Tab. 16.16:* Early and late complications following peritoneovenous shunt implantation (with some references)

**Mortality:** Since the surgical technique is well standardized and relatively simple, there is practically no *operative mortality* (0%−1.0%). In contrast, *postopera-*

*tive mortality* is put at 10−52% (mean mortality rate 20−22%), depending on the initial condition of the patient. The causes of death are: (*1.*) infections (27%), (*2.*) liver insufficiency (16%), (*3.*) cardiac and/or respiratory insufficiency (14%), (*4.*) consumptive coagulopathy/hyperfibrinolysis (15%), (*5.*) gastrointestinal bleeding (13%), (*6.*) renal failure (5%), and others (10%). (220, 221)

**Risk reduction:** The high frequency of mortality and complications can, however, be reduced markedly. It is possible to limit risks in the positioning of a PVS and in postoperative care by ensuring adherence to fundamental principles. Numerous examinations are called for prior to positioning a PVS as well as for the reinfusion of ascitic fluid. (s. tab. 16.17)

---

1. **Differential diagnosis of ascites** (s. fig. 16.10)
2. **Correct indication** (s. tab. 16.14)
3. **Consideration of contraindications** (s. tab. 16.15)

4. **Detailed preliminary examinations**
   − chemical laboratory values, blood coagulation values
   − plasminogen (and $\alpha_2$-antiplasmin) in ascitic fluid
   − daily urine flow
   − daily body check
   − psychometric tests (s. p. 203)
   − Doppler ultrasonography of the jugular vein
   − central venous pressure
5. **Appropriate pre- and postoperative treatment**
   − basic and diuretic therapy (stages I and II)
   − optimal balancing of electrolytes
   − prophylactic use of antibiotics (s. pp 280, 304)
   − intestinal detoxification (s. p. 277)
   − intraperitoneal injection of dexamethasone on suspicion of increased fibrinolytic activity
   − ornithine aspartate (s. p. 279)
6. **Good cooperation on the part of the patient** (s. tab. 16.18)

*Tab. 16.17:* Risk reduction criteria for PVS

---

The determination of **plasminogen** in the ascitic fluid (with a normal value of >0.7 CTA U/ml), possibly also of $\alpha_2$-*antiplasmin* (with a normal value of >0.1 IU/ml), is a priority. These values can help to estimate the risk of hyperfibrinolysis after the placing of a shunt. With a reduction in plasminogen (E. KÖTTGEN et al., 1982) to <0.7 CTA U/ml (or of $\alpha_2$-*antiplasmin* to <0.1 IU/ml), there is frequently a higher fibrinolytic activity of ascites (in some 40% of patients). Plasminogen activators are formed by peritoneal macrophages, the synthesis and release of which are stimulated by intestinal endotoxins. In some 50% of patients, endotoxins can be detected in ascites, yet not necessarily at the same time in the serum as well. In these cases of greater fibrinolytic activity, the injection of **dexamethasone** (16 mg) into the ascitic fluid is indicated. As a result, the synthesis of plasminogen activators in the macrophages is inhibited. Generally, the values of plasminogen and $\alpha_2$-antiplasmin rise to within the normal range after 24 hours, so that the dangers are considerably diminished following the placement of a PVS and the subsequent infusion of ascitic fluid into the blood stream (J. SCHÖLMERICH, 1987). With inadequate response of plasminogen (>0.7 U/ml) or of $\alpha_2$-antiplasmin (>0.1 IU/ml), the intraperitoneal administration of dexamethasone (16 mg) should be repeated. Once values have normalized, the shunt can be placed. A repetition of the intraperitoneal administration of dexamethasone may also prove necessary during the postoperative

period. • **Intestinal detoxification,** which is principally desired and which can be achieved by means of *neomycin* and/or *lactulose*, serves to diminish the complication of hyperfibrinolysis by reducing the endotoxins. Where the fibrinolytic activity of ascites is increased and the efficacy of (repeatedly administered) dexamethasone proves inadequate, it is advisable to remove the ascitic fluid intraoperatively to carry out an **abdominal lavage** with a physiological NaCl solution and to instil a saline-albumin solution prior to the operative closure of the wound. • Should **clotting disorders,** in particular hyperfibrinolysis, still occur, treatment with *protease inhibitors* (e. g. aprotinin 500,000 units as bolus, then 100,000 U/hour by perfusion over 3−4 days) is required.

**Antibiotics:** Administration of antibiotics (e. g. cefotaxime) is advisable, starting 2 days prior to and continuing for about 3 days after shunt placement.

**Compliance:** Cooperation on the part of the patient is imperative for the long-term success of a peritoneovenous shunt. Some of the complications are possibly due to negligence or inadequate adherence to the principal measures required. (s. tab. 16.18)

**Success of PVS:** In general, a two-year survival time in ca. 50% of cirrhotic patients with ascites is considered to be a clinical success. The mortality rate for refractory ascites is almost 100% after a short period of time. • The **efficacy parameters** of PVS can be described as (*1.*) reduction in abdominal girth and body weight with improved respiratory function, physical mobility and subjective feeling of well-being, (*2.*) greater diuresis and natriuresis, (*3.*) enlargement of the intravasal fluid volume, (*4.*) increase in the renal plasma flow and glomerular filtration rate with improved creatinine clearance (187, 204), (*5.*) reduction in ADH, NAF and renin-aldosterone values (187, 191, 210, 224), and (*6.*) diminished pressure in the portal vein system.

---

1. Respiratory training exercises
2. Wearing of an abdominal binder
3. If a manual pump system is placed, it should be used 5−6 times per hour
4. Appropriate life-style

5. Daily weight check and handwriting test (s. pp 203, 305) (s. fig. 15.3)
6. Correct treatment in line with stages I and II
7. Polypragmatic, albeit mosaic-like, concomitant therapy for underlying ascitic disease
8. Laboratory check-ups at acceptable intervals (e. g. potassium, sodium, creatinine, haematocrit, thrombocytes, Quick's value, haemoglobin, AT III, cholinesterase, electrophoresis)
9. Physical check-ups
10. Ultrasonographic check-ups

*Tab. 16.18:* Necessary measures for the patient and medical check-ups after placement of PVS

---

**Our own experience** (since 1982 at Wetzlar Hospital for Internal Medicine, including the monitoring of outpatients) is founded on the use of the LeVeen shunt (8 cases) and Denver shunt (6 cases). The patients (all suffering from alcoholic cirrhosis) were selected in line with the above criteria, examined and treated (with determination of plasminogen and application of dexamethasone, if required). The survival rate in these 14 cases amounted to 10 patients after 2 years (ca. 72%), 8 patients after 3 years (ca. 57%) and 4 patients after 4 years (ca. 29%). (s. figs. 16.13, 16.14)

**Fig. 16.13:** Enormous refractory ascites in alcoholic cirrhosis. Bilateral inguinal hernia with scrotal oedema. Muscular atrophy. Hepatic encephalopathy (II−III) (same patient as in fig. 16.14)

**Fig. 16.14:** Retrogression of ascites and oedema, increasing stabilization of biochemical and physical findings 16 weeks after placement of a LeVeen shunt (→) (survival time 45 months with two shunt recanalizations). (same patient as in fig. 16.13)

After the positioning of a PVS, there was a **survival rate** of 40−67% after 1 year and 20−43% after 2 years, with a considerably improved quality of life. It is realistic to expect that a three-year survival rate can be achieved in 30−40% of these patients nowadays. Yet this calls for close adherence to and fulfilment of the criteria on risk reduction. (s. tab. 16.17) All instructions given to the patient must be duly observed (s. tab. 16.18, points 1−5), and the medical measures taken must be appropriate to the respective situation. (s. tab. 16.18, points 6−10) • *For patients with refractory ascites, the peritoneovenous shunt or TIPS can provide real help in a situation that is otherwise hopeless!*

## 10.3 TIPS

On the basis of animal experiments carried out by J. Rösch et al. (1969, 1971), a transjugular intrahepatic portosystemic stent shunt (TIPS) was positioned for the first time in human surgery by R. F. Colapinto et al. in 1983. The relatively minor invasive intervention achieves a clear drop in pressure in the portal circulation with haemodynamic effects similar to side-to-side anastomosis. This technique, originally introduced for the treatment of oesophageal varicose bleeding, has since been used with success for refractory ascites. The success rate (i. e. complete remission of ascites) is 70−75%. The TIPS leads to a reduction in plasma renin, aldosterone and the serum-ascites albumin gradient as well as an up to fourfold increase in natriuresis (such as can be observed with PVS). With both PVS and TIPS, subsequent liver transplantation is not compromised, so that these procedures can be used both for recompensation and for bridging the time prior to a transplantation. (s. pp 259, 337, 362) (s. fig. 16.15)

**Fig. 16.15:** Placement of a TIPS (according to M. Rössle et al., 1989)

**Method:** The internal jugular vein is punctured. A catheter is introduced into the right hepatic vein. A 55 cm-long needle is pushed through the catheter. With sonographic and radiological guidance, an intrahepatic branch of the portal vein is punctured (a). The portal vein system is then viewed radiologically. The tissue tract is dilated using a balloon catheter (b), and the dilated tissue tract is laid in a metal stent splint. (s. fig. 16.15)

▶ The **underlying disease of liver cirrhosis** does not remain stable "in itself". Furthermore, it causes a multitude of dysfunctions as well as disease-related conditions of deficiency and malnutrition, which impair the entire organism biochemically in a variety of ways. These conditions, however, can often be permanently influenced by supporting the patient with various **therapeutic measures.** The survival time is restricted by the underlying disease. • For this reason, decision focuses on the alternatives of "optimal" conservative treatment or liver transplantation. On reviewing all clinical reports from over 100 publications available to us, it can be concluded that it is most definitely possible to improve the mortality rate and reduce the complications as well as to achieve a genuinely better quality of life while slowing down the course of disease and thus lengthening survival time. (166, 167, 230−236)

# 11 Surgical treatment

Formerly, the possibilities of treatment were limited. At one time, 80 (−90)% of all ascites cases were considered to be refractory to therapy. Death could be expected within a short space of time. This explains the development of a multiplicity of surgical techniques − which seemed justifiable in spite of the high mortality rate (30−60%) − in order to achieve a longer survival time with a better quality of life for the individual. Despite sophisticated ideas, which indeed appeared to be logical at the time, these techniques generally proved inadequate and unfeasible in the long run. (s. tab. 16.19)

Probably the first surgical step was **hepatopexy,** which was performed by Ch. Th. Billroth in 1894. After the first **omentopexy** (or epiplopexy) was carried out by D. Drummond et al. in 1896 (243) and by S. Talma in 1898 (259), attention continued to focus on surgical ways to treat ascites. With regard to the pathophysiological aspects, the techniques described can be categorized into six groups:

1. Interventions in the portal vein system
2. Interventions in the abdominal arterial system
3. Interventions in the endocrinium
4. Coating of the liver
5. Drainage operations
6. Liver transplantation

• By means of **visceropexy** (e. g. hepatopexy, omentopexy, splenopexy, rectus wick operation), an attempt was made to relieve the portal vein circulation by the gradual spontaneous development of venous collaterals and also to improve the collateral circulation. (238, 243, 246, 249, 259)

• Following the first **portacaval anastomosis** on a human being carried out by E. Vidal in 1910 (this operation had already been successfully performed on an animal by N. V. Eck in 1877), this technique was then used to treat ascites. Here, side-to-side anasto-

**I.  Interventions in the portal vein system**
   1. Hepatopexy (Ch. Th. Billroth, 1884)
   2. Omentopexy
      (D. Drummond et al., 1896; S. Talma, 1898)
   3. Splenectomy (I. N. Rafferty, 1900)
   4. Splenopexy (Bunge, 1902)
   5. Rectus wick operation
   6. Anastomosis operation:
      − portacaval (E. Vidal, 1910);
      − mesocaval; splenorenal
   7. TIPS (R. F. Colapinto et al., 1983)

**II.  Interventions in the arterial system**
   1. Ligature of the hepatic artery (A. Narath, 1909)
   2. Ligature of the splenic artery
      (R. M. Moore et al., 1950)
   3. Ligature of the left splenic-hepatic-gastric artery (J. K. Berman et al., 1952)
   4. Ligature of the splenic-hepatic artery
      (J. L. Madden et al., 1953)
   5. Ligature of the coeliac artery (R. Wanke, 1956)

**III. Interventions in the endocrinium**
   1. Total adrenalectomy (F. G. W. Marson, 1954)
   2. Thyroidectomy (J. W. Canter et al., 1959)

**IV. Coating of the liver**
   1. Hepatodematosis (G. Oselladore et al., 1963)

**V.  Drainage operations**
   1. Sapheno-peritoneostomy (M. Ruotte, 1907)
   2. Tissue, skin (P. Patterson, 1910)
   3. Retroperitoneum
   4. Ureter, renal pelvis (C. Ferguson, 1943)
   5. Urinary bladder (D. Mulvany, 1955)
   6. Ileoentectropy (C. G. Neumann et al., 1956)
   7. Pleuroperitoneostomy (I. El-Toreai, 1961)
   8. Peritoneovenous shunt (H. N. Smith, 1962)
   9. Thoracic duct − azygous vein
      (A. E. Dumont et al., 1963)
   10. Hepatophrenopexy (A. L. Meier, 1970)
   11. Hepatospleno-pneumopexy
      (H. Akita et al., 1980)
   12. Thoracic duct − subclavian vein
      (E. L. Coodley et al., 1980)

**VI. Liver transplantation**

***Tab. 16.19:*** Surgical attempts to eliminate refractory ascites (s. also tab. 19.7!)

mosis proved superior to end-to-side anastomosis. With the help of portacaval as well as mesocaval or splenorenal anastomosis, it was possible to achieve a sustained reduction in the portal blood flow to the liver, yet success was poor in terms of eliminating the ascites. (239)

• Likewise, an attempt was made to eliminate ascites surgically by reducing the portal and arterial blood flow to the liver. This was achieved by **arterial ligation** in the root zone of the portal vein as well as by ligation of the hepatic artery. The results were disappointing.

• In 1953 animal experiments demonstrated that bilateral **adrenalectomy** culminated in clear natriuresis, causing the ascites to disappear (J. O. Davis et al., 1953). This observation was confirmed in 1954 in a patient with portal ascites and bilateral adrenalectomy.

An explanation for this success was found in the normalization of increased aldosterone values witnessed in ascitic dogs after adrenalectomy was performed. (237, 248, 252) • **Thyroidectomy** (J. W. Canter et al., 1959) proved similarly favourable in terms of its effect on ascites. (237, 240)

• Both in animal experiments and in human beings, it was demonstrated that **hepatodematosis** can prevent the development of ascites. This coating of the liver was effected using a plastic adhesive or polyvinyl sponge. Yet, this procedure had no clinical significance.

• There were many variations in the attempts to **drain the ascitic fluid.** Repeated paracentesis was carried out, in which knobs or tubes with closing caps were inserted into the abdominal walls. It was recommended to channel the ascitic fluid into the skin, tissue or retroperitoneal spaces. Drainage was laid to allow the ascitic fluid to run off into the renal pelvis, ureter or urinary bladder, a procedure which was rather complicated, dangerous and at the same time useless. Lymphovenous anastomoses between the thoracic duct and the azygous vein or subclavian vein likewise yielded no satisfactory results. Other surgical techniques, such as pleuroperitoneostomy, ileoentectropy, hepatospleno-pneumopexy, hepatophrenopexy, etc., were interesting as regards their methodology, yet proved to be of no clinical benefit. (241, 242, 244, 245, 250−252, 253−260)

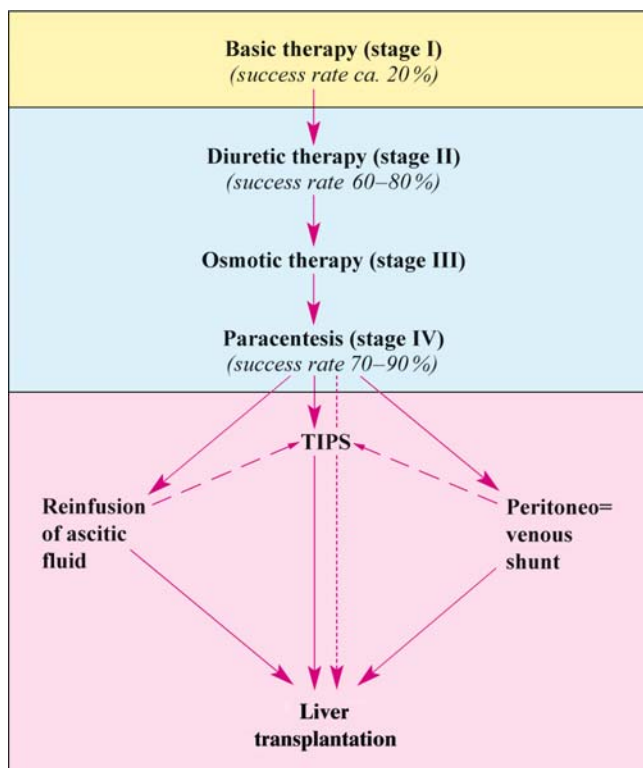

**Fig. 16.16:** Steps in conservative and invasive or surgical treatment for hepatogenic ascites

# 12  Liver transplantation

Transplantation of the liver essentially gives patients with refractory portal ascites a chance to start a new life. However, in the presence of large-scale ascites, the surgeon is faced with a number of specific *problems* such as overdilated and thin abdominal walls, existing hernia, spontaneous bacterial peritonitis, significant volume displace-

ment and hypotension as a result of the complete removal of ascites, large protein losses, restricted renal function or a greater consumption of erythrocyte concentrates due to more pronounced collateralization. Nevertheless, the *survival rate* of patients with refractory ascites was 91.7% after one year and 84.3% after three years, which was, in fact, practically identical to the survival rates of patients without detectable ascites or with intraoperatively minimally detectable ascites. These very good results in the treatment of refractory ascites are achievable after orthotopic as well as heterotopic auxiliary liver transplantation. (s. fig. 16.16) • Nevertheless, mention must be made of the fact that ascites can even occur for the first time after liver transplantation. (254) Causes of **postoperative ascites** include (*1.*) intraoperative disruption of the perihepatic lymph discharge, (*2.*) stenosis of existing caval anastomoses, (*3.*) hypalbuminaemia, (*4.*) relapse of the underlying disease, and (*5.*) chronic rejection of the transplant. *(see chapter 40.7)*

**Synopsis**

This resumé of the possibilities open for the treatment of hepatogenic ascites presents a successful **step-by-step therapy programme.** (s. fig. 16.16)

In all patients, **conservative therapy** is initially founded on basic and diuretic therapy, which is successful in 60−80% of cases. In individual instances, the therapeutic measures of stage III are recommended. Apparent refractory forms of ascites call for paracentesis (stage IV), unless there are reasons against this. Some 80−90% of all patients with portal ascites can be successfully treated conservatively. Given the appropriate indication, reinfusion of ascitic fluid is also feasible.

If the results of conservative therapy (stages I−IV) are unsatisfactory, **invasive treatment** should be considered. The decision in favour of a particular procedure in each individual case is initially determined by hepatological factors such as (*1.*) general condition and age of the patient, (*2.*) underlying disease of the ascites, (*3.*) severity of the liver disease, (*4.*) complications of the ascites, and (*5.*) secondary findings as well as additional diseases. These factors yield clear hints as to the indication or contraindication for a specific invasive procedure. Following this preliminary decision, an indication is evaluated together with the surgeon or radiologist. In the light of the probable three-year survival time − a period which cannot be achieved by any other surgical technique − the indication for *liver transplantation* should be a primary consideration. The problem, however, is that, given the inadequate number of donor livers available, a suitable liver cannot always be obtained, and usually not in the time required. This is why a liver transplantation should always be planned in advance, if possible.

It may indeed be necessary to postpone the transplantation or to bridge the period prior to the transplantation owing to ascites factors or other particular difficulties, including the absence of a suitable liver transplant. To this end, the *peritoneovenous shunt* and *TIPS* are suitable temporary operative steps. Indeed, it is these techniques which actually make subsequent liver transplantation possible. • *Thus PVS and TIPS are principally indicated if it is not (or not yet) possible to carry out a liver transplantation.*

# Symptoms and Syndromes

## 17  Hepatorenal syndrome

# 17 Hepatorenal syndrome

▶ *The coexistence of a liver and kidney disease is a frequent clinical event.* • In fact, reports in the literature date back more than 100 years (F. Th. Frerichs, 1861; K. W. H. Nothnagel, 1874; P. J. Moebius, 1877; A. Weil, 1886). As early as 1863, A. Flint observed the coexistence of cirrhosis with ascites and oliguria, although autopsy revealed the kidneys to be normal. In animal experiments, M. Pawlow (1893) was able to show the occurrence of albuminuria after the placement of a portacaval anastomosis. Jaundice mainly developed parallel to renal damage. Richardière (1890) coined the term "hépatonéphrite" to describe this clinical picture. (49) In 1911 both P. Clairmont et al. and F. Steinthal reported for the first time on renal failure with fatal outcome following surgery on the bile ducts for obstructive jaundice. This renal failure in biliary obstruction was described by F. C. Helwig et al. in 1932 as *"liver-kidney syndrome"*. (27)

The term **"hepatorenal syndrome"** was introduced by P. Merklen in 1916 and taken up by W. Nonnenbruch in 1939. The following description is still largely accepted today: *"A combination of anatomically defined liver disease with a sometimes severe restriction in the function of the kidneys, which display few, if any, morphological changes. Liver disease can be the outcome of hepatocellular damage of any type, i. e. it can be toxic or infectious and originate from cirrhosis or cancer."* (44)

## 1 Definition

The hepatorenal syndrome (HRS) is a functional, oliguric, progressive, in principle reversible, circulation-related kidney failure occurring in severe liver disease and portal hypertension and increasing liver insufficiency − assuming there are indeed no other causes of the renal insufficiency.

▶ This syndrome is, in fact, prerenal kidney failure − yet *without response to an adjustment of the effective plasma volume,* i. e. expansion of the intravasal volume does not influence the renal function. This functional renal failure is due to extreme intrarenal vasoconstriction and reduced perfusion in the area of the renal cortex, whereby the blood supply to the medullary parts of the kidney is largely normal. The extrarenal circulation is undisturbed (arterial vascular resistance and vascular filling as well as cardiac output are normal). In cases of cirrhosis, systemic vasodilation becomes increasingly prevalent, together with hyperdynamic circulatory disturbance. In clinical terms, the ultimate outcome is pronounced sodium and water retention with oliguria and excretion of practically sodium-free urine − without or with only slight (< 500 mg/dl) proteinuria.

## 2 Pathogenesis

The frequent **coexistence** of the *hepatorenal syndrome, ascites* and/or *hepatic encephalopathy* suggests that similar pathogenetic mechanisms are responsible for these three intricate developments.

## 2.1 Biochemical factors

The numerous biochemical substances that may be considered with regard to hepatic encephalopathy or ascites have been outlined in detail. (s. tabs. 15.2; 16.5) • Similarly, an extensive synopsis of pathogenetically effective biochemical factors can be drawn up for HRS as well. All of them ultimately interfere − directly or indirectly − with the renal retention or excretion of sodium and/or the balance between vasodilation and vasoconstriction. RAAS is markedly activated. (5, 28, 33, 41, 62, 64, 65) (s. tab. 17.1) • Vasodilative factors under discussion include bilirubin, bile acids, nitrogen monoxide (NO), false neurotransmitters, calcitonin peptide (25) as well as platelet-activating factor (PAF). In more recent studies, considerably higher plasma values of the vasoconstrictor leukotrienes (C4 and D4) (41) and endothelin 1 and 3 (42) were detected.

| | Liver | Plasma | Kidneys/Urine |
|---|---|---|---|
| Angiotensinogen synthesis | ↓ | | |
| Kininogen synthesis | ↓ | | |
| Renin breakdown | ↓ | | |
| Angiotensin II breakdown | ↓ | | |
| Aldosterone breakdown | ↓ | | |
| Endotoxin breakdown | ↓ | | |
| Vasopressin breakdown | ↓ | | |
| Renin (62) | | ↑ | |
| Angiotensin II | | ↑ | |
| Aldosterone | | ↑ | |
| Endotoxin | | ↑ | |
| Noradrenaline | | ↑ | |
| Vasopressin | | ↑ | |
| Endothelin 2 and 3 (42) | | ↑ | |
| Leukotriene $C_4$ and $D_4$ (41) | | ↑ | |
| Calcitonin peptide (25) | | ↑ | |
| Antidiuretic hormone (ADH) | | ↑ | |
| Kallikrein | | ↓ | |
| Bradykinin (62) | | ↓ | |
| Atrial natriuretic factor (ANF) | | ↓ | |
| Renin | | | ↑ |
| Angiotensin II | | | ↑ |
| Aldosterone | | | ↑ |
| Endothelin | | | ↑ |

| Prostacyclin | | | ↑ |
| Bradykinin | | | ↑ |

***Tab. 17.1:*** Synopsis of the activity of biochemical factors in the liver, plasma and kidneys or urine relating to the hepatorenal syndrome (with some references)

## 2.2 Haemodynamic factors

Hepatorenal syndrome is characterized by pronounced vasoconstriction of the renal cortex with tortuosity and narrowing of the interlobular and arcuate arteries. The blood supply to the renal cortex may be almost totally interrupted and, at the same time, the blood flow is diverted into areas containing cortical vessels

near the medulla. The renal medulla is, however, supplied with blood in a regular way, thus allowing the nephrons to function normally. The insufficient blood supply to the renal cortex is aggravated by intrarenal arteriovenous shunts, leading to rapid changes in haemodynamics. This instability in renal perfusion is possibly due to reduced synthesis of angiotensinogen in the liver. Disturbances in the renal blood supply can proceed continuously through the non-azotaemic and azotaemic stages to the ultimate oliguric final phase. • The **functional nature** of renal vasoconstriction was also demonstrated by the fact that the ischaemia of the renal cortex, which had been ascertained by selective angiography in vivo, was not evident in the postmortem evaluation of the kidney. Indeed, the cortical vascular network had completely regained its normal structure. • Increased levels of *neuropeptide Y* could be found in HRS. This is related to circulatory dysfunction as well as to stimulation of the sympathetic nervous system and may thus contribute to renal vasoconstriction. (5, 28, 33, 52−54)

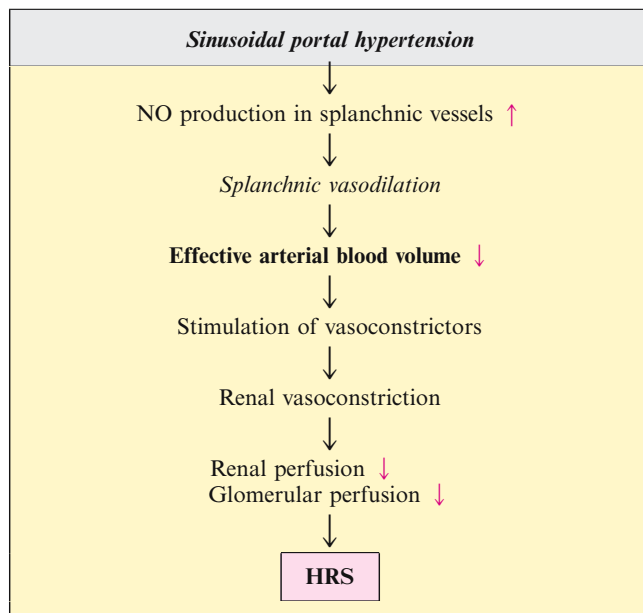

**Fig. 17.1:** Hypothetic pathogenesis of the hepatorenal syndrome in cirrhosis

# 3 Clinical aspects

In liver cirrhosis, hepatorenal syndrome is nearly always (> 80%) accompanied by ascites. HRS is most common in alcoholic cirrhosis. In some 75% of cases, hepatic encephalopathy is witnessed at the same time, and jaundice is evident in about 40% of cases. HRS occurred in 18% of all cirrhotic patients with ascites within one year and in 32% within 5 years. (21)

**Histological findings** are minimal in HRS. No constant or specific changes are known. In most cases, histology is either completely normal, or only minor degenerative changes of the tubuli and glomeruli are present. • Nevertheless, with a severe and protracted course of disease, the occurrence of acute tubular necroses can become more pronounced, resulting in end-stage renal failure.

## 3.1 Risks and predictive factors

Numerous risk situations are able to trigger HRS and various predictive factors make it possible to ascertain the development of HRS in non-azotaemic patients with cirrhosis and ascites. Often the actual cause is not directly recognizable (e.g. undisclosed alcohol abuse, environmental noxae). Typical liver function parameters do not help to anticipate the development of HRS. (11, 19, 21, 53, 60) (s. tab. 17.2)

| **Risk factors** |
|---|
| Alcohol abuse |
| Bleeding oesophageal varices |
| Cholestasis |
| Electrolyte imbalance |
| Excessive diuresis |
| Increased intra-abdominal pressure (tense ascites!) |
| Inexpert paracentesis |
| Infections |
| Nephrotoxic drugs |
| Poor nutritional status |
| Previous episodes of ascites |
| Spontaneous bacterial peritonitis |
| **Predictive factors** |
| Creatinine ↗ |
| Glomerular filtration ↘ |
| Natriuresis ↘ |
| Plasma osmolality ↘ |
| Potassium ↘, (↗) |
| Urea ↗ |
| Urine osmolality ↗ |

**Tab. 17.2:** Risk and predictive factors in patients with cirrhosis and ascites regarding the development of HRS

## 3.2 Courses of disease

There are **three ways** in which the hepatorenal syndrome can become manifest:

1. **acute HRS (type I):** rapid elevation of creatinine (> 2.5 mg/dl), reduction of 24-hour creatinine clearance (< 20 ml/min), oliguria (< 500 ml/day) and natriuria (< 10 mmol/l) as well as jaundice, hypoprothrombinaemia, hypalbuminaemia and encephalopathy − but no proteinuria. • All courses of disease which do not correspond to type I are assigned to one of the other two types;

2. **chronic HRS (type II):** slow course of this complicated condition, renal function is more stable, reduction of 24-hour creatinine clearance (< 40 ml/min). This (most frequent) form is often long-standing, although only slightly increased creatinine values in the serum (> 1.5 mg/dl) and natriuria (< 20 mmol/l) are clinically detectable. Type II is frequently accompanied by a diuretic-resistant ascites;

3. **acutely exacerbated chronic HRS.**

## 3.3 Complaints

Subjective factors suggestive of HRS are unknown or uncharacteristic. The clinical picture is influenced by the underlying liver disease. (s. tab. 17.3)

1. Liver cirrhosis, especially in
   - alcoholic cirrhosis
   - ascites and diuretic therapy
   - hepatic encephalopathy
   - oesophagogastrointestinal bleeding
2. Acute liver failure
3. Acute viral hepatitis (34, 45)
4. Primary liver cell carcinoma (39)
5. Liver metastases (51)
6. Hemihepatectomy
7. Acute fatty liver of pregnancy

**Tab. 17.3:** Severe liver diseases with the occurrence of a hepatorenal syndrome (with some references)

## 3.4 Diagnosis

The diagnosis is initially based on the principal symptom of **oliguria** (urine volume < 500 ml/day). When setting up a differential diagnosis, the classification of oliguria is facilitated by a *probationary volume replenishment* (1500 ml of 0.9% NaCl solution or 5% human albumin). A clear improvement in or normalization of urine excretion achieved in this way is evidence *against* hepatorenal syndrome and *in favour of* prerenal kidney failure. (s. tab. 17.4)

**Azotaemia** develops progressively with an increase in creatinine and urea. These findings point to a drop in the glomerular filtration rate (GFR) and renal blood flow. The quotient of creatinine in the urine and plasma is high (>40). Likewise, the quotient of urea-N in the urine and plasma is elevated (>8). There is a reduction in creatinine clearance within 24 hours to <40 ml/min. The serum value of urea displays a disproportionate increase compared to creatinine (urea-N/creatinine ratio >20), since the tubular reabsorptive capacity with respect to urea depends on diuresis (maximum 2 ml/min). In hepatorenal syndrome, the minimal urinary flow gives rise to a longer tubular period of contact with greater tubular reabsorption of urea.

In general, the *sediment* in the **urine** is normal. Proteinuria or erythrocyturia are not characteristic of hepatorenal syndrome. • The *excretion of sodium* in the urine is lower than 10 mmol/day, with a fractional excretion of sodium of <1%. For this reason, there is likewise increased renal retention of water. • The *urine osmolality* is greater than the plasma osmolality, which results in a quotient of >1.3. With increasing severity of hepatorenal syndrome and transition of the penultimate phase, the urine becomes iso-osmotic with an osmolality quotient of 1 or <1. (19, 43, 52, 53, 60) (s. tab. 17.4)

| Criteria | Hepato-renal syndrome | Acute kidney failure | Prerenal kidney insufficiency |
|---|---|---|---|
| Specific weight | >1,030 | 1,020 | >1,030 |
| Oliguria (<500 ml/day) | + | + | + |
| Azotaemia | + | + | + |
| $Urine_{osm}$ (mosm/kg) | > 500 | < 350 | > 500 |
| $Urine_{Na}$ (mmol/l) | < 10 | > 30 | < 20 |
| $Urine_{osm}/P_{osm}$ | > 1.3 | < 1.1 | > 1.3 |
| $Urine_{urea}/P_{urea}$ | > 8 | < 3 | > 8 |
| $Urine_{creat.}/P_{creat.}$ | > 30 | < 20 | < 30 |
| $Fe_{Na}$ (%) | < 1 | > 1.5 | < 1 |

**Tab. 17.4:** Urine findings for the differential diagnostic definition of hepatorenal syndrome − provided that there has been no previous diuretic therapy. • Generally, however, this has proved necessary, which could be a reason for the considerable differences in the factors and figures reported in the literature

*Reduced free water clearance* is characteristic. It is the cause of **hyponatraemia** (serum sodium < 130 mmol/l), which is often evidenced − this can be precipitated by an increased intake of free water (elevated sodium level in the presence of excessive water). This dilutional hyponatraemia is a sign of a reduced serum osmolality (< 280 mosm/l). (4, 14)

In cirrhotic patients, elevated **gastrin values** in the serum, which are due to restricted excretion of gastrin in the urine and/or reduced gastrin inactivation in the liver, are suggestive of hepatorenal syndrome.

A rise in the **resistance index** of the kidneys and a reduction in renal perfusion as shown by *Doppler duplex sonography* make possible an early diagnosis before renal dysfunction is clinically evident. (47) • *Coloured sonography* has proved of great value in determining renal haemodynamics (which is in posture position deteriorates).

## 3.5 Prognosis

The prognosis of HRS, especially type 1, is poor with a **lethality rate** of 87−98%. The survival time amounts to 1.7−2.6 weeks. (20) Death results from acute renal failure or complications of cirrhosis, such as gastrointestinal bleeding or hepatic coma. Patients with HRS type II have a better prognosis (6−12 months). Spontaneous **reversibility** of hepatorenal syndrome has been demonstrated following a decisive improvement in liver function − yet it can only be rarely expected (in 3−5% or 2−13% of cases). With the spontaneous regression of portal ascites, the impaired renal function is generally improved. Liver transplantation likewise led to a normalization of renal function (13, 30, 50) − just as the kidneys of a patient with hepatorenal syndrome functioned normally again following transplantation into a patient with a healthy liver. (5, 6, 11, 19, 20, 43, 60)

# 4 Differential diagnosis

The diagnosis of hepatorenal syndrome calls for the exclusion of prerenal, renal or postrenal kidney insufficiency. (s. tabs. 17.4, 17.6) • The presence of disease in both the liver and kidney in the sense of a pseudohepatorenal syndrome must also be ruled out. (s. tab. 17.5)

---

1. **Circulatory disorders**
   - Cardiac insufficiency
   - Shock
2. **Congenital malformations**
   - Congenital liver fibrosis
   - Cystic liver and cystic kidney
3. **Experimental**
   - Choline deficiency
     *etc.*
4. **Infections**
   - Legionnaire's disease
   - Leptospirosis
   - Malaria
   - Sepsis
   - Viral hepatitis
   - Yellow fever
5. **Intoxications**
   - Burns
   - Chemicals
     - carbon tetrachloride
     - chrome, lead, arsenic, mercury
     - copper sulphate
     - trichloroethylene, methanol
   - Endotoxins
   - Hyperthermia
   - Mycotoxins
   - Snake venoms
   - Waterhouse-Friderichsen syndrome
6. **Medicaments**
   - Halothane
   - Iproniazid
   - Methoxyflurane
   - Paracetamol
   - Sulphonamide
   - Tetracycline
7. **Metabolic diseases**
   - Acute intermittent porphyria
   - Amyloidosis
   - Diabetes mellitus
   - Eclampsia
   - Glycogenosis I
   - Haemochromatosis
   - Reye's syndrome
   - Sickle-cell anaemia
   - Tyrosinaemia, oxalosis
   - Wilson's disease
8. **Systemic diseases**
   - Lupus erythematosus
   - Periarteritis nodosa
   - Rheumatoid arthritis
   - Sarcoidosis
9. **Tumours**
   - Hypernephroma
   - Metastases

*Tab. 17.5:* Coexistent disease of the liver and kidneys (comorbidity), so-called pseudohepatorenal syndrome (H. O. CONN, 1973)

## 4.1 Pseudohepatorenal syndrome

Numerous diseases can impair both liver and kidneys at the same time. Each individual case reflects different levels of damage and severity, the liver and kidneys being affected to varying degrees. The prognosis is determined by this wide scope of variability. Simultaneously occurring diseases of the liver and kidneys are subsumed under the term **pseudohepatorenal syndrome** (H. O. CONN, 1973). (s. tab. 17.5)

## 4.2 Prerenal kidney insufficiency

Dehydration with diminished volume (bleeding, large water losses, diuretic therapy, paracentesis, intravasal volume shifting) can lead to prerenal azotaemia. Typically, renal function normalizes again when fluid intake is increased, *i. e. in contrast to the hepatorenal syndrome, the intravasal volume can be influenced by therapy.*

## 4.3 Primary kidney diseases

Initially, it is important to rule out primary kidney diseases, including all glomerular, interstitial and vascular forms, as well as acute tubular necrosis resulting, for example, from nephrotoxins, sepsis, hypoxia or shock. In severe or protracted kidney disease, various chemical findings can point to liver involvement (as suggested by a rise in GPT, GOT, GDH and AP or by impaired liver function). These pathological laboratory parameters are also reflected in cellular or canalicular forms of impairment. The treatment of primary kidney diseases (e. g. with immunosuppressives, cyclosporin) may give rise to liver damage, which can be ascertained morphologically and in laboratory investigations.

## 4.4 Secondary kidney diseases

In various diseases of the liver and biliary ducts, with or without jaundice, a wide range of secondary kidney diseases can occur. They differ greatly in their degree of severity and their prognosis and can cause considerable **difficulties** in the drawing up of a **differential diagnosis.** (53, 54) (s. tab. 17.6)

---

**Glomerular kidney diseases**

1. Impaired renal function with acute viral hepatitis
2. Immune complex nephritis with chronic HBV and HCV infection
3. Glomerulosclerosis with cirrhosis
   - mesangial form
   - IgA nephropathy
   - membranous proliferative form

**Tubular kidney diseases**

1. Renal tubular acidosis
   - distal form (type I)
   - distal and proximal form (type II)
2. Acute tubular necrosis (acute kidney failure)
3. Biliary nephrosis

*Tab. 17.6:* Forms of secondary kidney damage in the course of hepatobiliary diseases

**Mild renal dysfunction** in the form of clinically non-significant proteinuria and erythrocyturia in acute viral hepatitis subsides once the acute viral hepatitis has been cured. Occasionally, serum creatinine levels may be slightly raised. Histologically, small deposits of immune complexes can be found in the glomeruli.

**Immune complex nephritis** is generally caused by the deposition of circulating immune complexes in the glomeruli, mostly in chronic

viral hepatitis B and C (men are affected four times as often as women). Proteinuria and haematuria are in evidence, together with the retention of substances usually eliminated in the urine. A nephrotic syndrome possibly leading to renal insufficiency with hypertension may develop. Treatment of this perimembranous glomerulonephritis with interferon alpha has proved beneficial.

Some 50−95% of patients with liver cirrhosis show histological evidence of **glomerulosclerosis.** This course of glomerulonephritis may take *three different forms:* (*1.*) mesangial form with thickening of the mesangial matrix and basal membrane of the capillaries, (*2.*) glomerulosclerosis with glomerular deposition mainly of IgA (= IgA nephropathy), and (*3.*) membranous proliferous form with obvious cellular proliferation and additional glomerular deposition of IgA. As a rule, proteinuria and erythrocyturia are only minimal. Up to now, treatment has not been possible − and is usually not required. (s. tab. 17.6)

**Renal tubular acidosis** in liver cirrhosis is due to an inadequate concentration of sodium ions on the distal tubuli (type I). As a result, the secretion of hydrogen ions is reduced. This is attributed to cellular immune processes as well as to toxic effects such as copper or bile acids. (s. tab. 17.6)

**Acute tubular necrosis** can occur in the course of a hepatobiliary disease. In an aetiopathogenetical context, hypoxia, hypotension, nephrotoxins and so far undefined biochemical substances are deemed responsible. The outcome is a disruption in the reabsorption of sodium and water; the urine is less concentrated (isosthenuria). There is a greater excretion of sodium (> 30 mEq/l) and of beta-2 microglobulin in the urine. Acute, yet in principle reversible renal failure can develop. Therapy thus consists of bridging the phase of insufficiency temporarily by dialysis.

In cases of acute **biliary nephrosis,** histological investigation reveals swellings of the tubular cells and bilirubin renal casts. This is due to elevated concentrations of bilirubin and bile acids in the serum. The kidneys show a marked sensitivity to oxygen deficiency, with the danger of acute kidney failure. This explains the relatively frequent occurrence of renal insufficiency in diseases of the extrahepatic bile ducts, in obstructive jaundice or following bile duct surgery. (s. tab. 17.6)

After exclusion of these differential diagnostic possibilities in liver diseases with renal symptoms, the likely diagnosis is **hepatorenal syndrome.** In the case of a severe and protracted course, this functional impairment of the kidneys can progress to true, acute renal failure, even with tubular necrosis.

# 5  Prophylaxis and therapy

**Prophylactic measures** with regard to the hepatorenal syndrome are of decisive and vital importance. It must be borne in mind that the *water balance is extremely sensitive in cirrhotic patients*. The cause can almost always be found in an enormous iatrogenic intervention in the volumetric balance (aggressive diuresis, imbalance in the tapping of ascitic fluid, excessive restriction of fluid). For this reason, it is important to avoid all substances which could worsen renal function (e.g. nonsteroidal antirheumatics, aminoglycoside antibiotics) and all measures which could lead to a reduction in the effective plasma volume. Furthermore, care should be taken to apply the principles of prophylaxis and therapy

for hepatic encephalopathy (s. p. 277) and ascites (s. p. 304). Spontaneous bacterial peritonitis should be treated at an early stage. (s. p. 303) • The most significant therapy target is to decrease the tonus in the efferent vessel of the glomerule.

## 5.1  Maintaining homoeostasis

The *electrolytes* and *acid-base balance* should be restored in careful coordination with the renal function. • In **hyponatraemia,** either the fluid intake should be reduced to 700−1,000 ml/day, or a combination of a hypertonic salt solution (3%) and a loop diuretic should be administered intravenously. (s. p. 308) Likewise, an attempt can be made using a combination of diuretics and urea diuresis. Generally, sodium and water intake should be restricted. It is imperative to achieve an even volumetric balance, possibly supported by the cautious intake of fluid.

## 5.2  Improvement of liver function

To date, there is no effective therapy for the hepatorenal syndrome. Therapeutic possibilities are very limited due to the loss of function of two vital organs, liver and kidneys. The ideal goal would be to improve liver function, since clear improvement in the condition of the diseased liver has always preceded the reversibility of the hepatorenal syndrome. • Even if there is only a slight chance of improving liver function, certain biochemically justifiable and pharmacologically plausible procedures can indeed be implemented in serious cases of disease: (*1.*) *optimal nutrition*, (*2.*) *substitution measures* (e.g. multivitamins, trace elements, branched-chain amino acids, essential phospholipids), and (*3.*) *supportive therapy programme* (reducing endotoxinaemia by means of lactulose, influencing the synthesis of urea by means of ornithine aspartate, etc.). (5, 7, 9, 52, 58, 63)

## 5.3  Conservative treatment

► The overriding aim of therapy is to increase renal blood flow. This can be achieved either indirectly through splanchnic vasoconstriction or directly by encouraging renal vasodilation. Hereby, certain problems arise concerning substances which spill over into the splanchnic circulation causing splanchnic vasoconstriction and at the same time exacerbating the renal vasoconstriction already present. (5−7, 10, 12, 19, 33, 43, 58, 60, 63)

Many investigations have focused on the efficacy of conservative treatment for improving both systemic and renal haemodynamics or for suppressing the activated hormone systems. • The complexity of the pathogenesis of hepatorenal syndrome, which varies in each individual case, explains the differences in impact of the substances used. For this reason, there are pathogenetic

grounds for the simultaneous application of the pharmacological possibilities mentioned. (12)

Optimal **fluid management** is necessary. Fluid overload must be avoided. Measurement of the central venous pressure is important.

Attempts at treatment through **"head-out" water immersion** (M. EPSTEIN et al., 1976) can be deemed relatively effective and, above all, low in risk, provided this is feasible with a seriously ill patient. This simple method increases the central blood volume (= redirecting extracellular fluid to the vascular system). There is a significant rise in the volume of the urine and in natriuresis − although one must also reckon with a number of non-responders when applying this method.

A **lumbar blockade** of the sympathetic nervous system is a methodologically simple procedure, practically free from complications, which has proved to be effective in individual cases. (58)

Intravenous application of sodium-free **albumin** and/or 10% **mannitol** can be successful, possibly with the additional administration of low-dose *diuretics* (such as xipamide, torasemide), whereby due attention should be paid to renal function. Diuretics or aldosterone antagonists may only be used if the indication is precise and all risks have been considered.

Thought can be given to i.v. application of low-dosed **dopamine** (100 mg/12 hr or < 5 µg/kg BW/hr). This vasodilator was able to improve the angiographic appearance of the renal cortical vasculature and the cortical blood flow. No change was seen in GFR or urine output. Dopamine alone cannot be recommended. (quot. 6, 12, 43)

**Ornipressin** is a vasopressin analogue that primarily leads to vasoconstriction of the splanchnic vasculature. The first report outlining its use was compiled in 1985 by K. LENZ et al. (36) Dosage was 25 IU/12 hr or 6 IU/4 hr. The outcome was a fall in renal vascular resistance and an improvement in the glomerular filtration rate. (23; quot. 6, 10, 12, 43) • The combined administration of *ornipressin* (2−6 IU/hr) and *albumin* (20−60 g/day) for a period of 2 weeks (with intensive care monitoring!) has led to remarkable therapeutic success. (24)

**Terlipressin** (2 mg/day, multiple doses) was likewise successfully administered over a temporary period. No side effects were reported. Terlipressin produced an improvement of renal function in 70−75% of cases and an increased survival in patients with type 1 HRS. (2, 11, 26, 43, 57) • *Terlipressin* (0.5−2.0 mg/4 hr, i.v.) plus *albumin* (20−40 g/day) (19, 59) or plus *hydroxyethyl starch* (500 ml/day) appears to be an effective treatment for HRS.

The combined application of **midodrine** and **octreotide** (i. e. an α-adrenergic agonist as a vasoconstrictor plus a substance inhibiting the release of endogenous vasodilators such as glucagon) led to an improvement in both GFR and natriuresis. (3)

Therapeutic attempts using **angiotensin II / noradrenalin** (first described by R. AMES et al. in 1965) or ACE inhibitors, sympathicomimetic agents and α- as well as β-receptor blockers yielded no (or only brief) success. • The combined i.v. application of noradrenalin (0.5−3.0 mg/day) plus albumin and furosemide shows a remarkable improvement in type 1 HRS. (15)

A therapeutic effect has been achieved by administering **N-acetylcysteine** (150 mg/kg BW for 2 hours and subsequently 100 mg/kg BW for 5 days). (29)

Likewise, reports have been published on the positive effect of **misoprostol,** a synthetic prostaglandin$_{E1}$, after oral administration (4 × 0.4 mg/day) (17, 21) or with intra-arterial application.

A few isolated reports are available on the elimination of renal vasoconstriction, particularly using **ANP** (atrial natriuretic peptide) with its pronounced diuretic and natriuretic effects.

Treatment with **branched-chain amino acids** led to a reduction in azotaemia and creatinine as well as an increase in natriuresis. (9)

## 5.4 Invasive therapy

The infaust prognosis of hepatorenal syndrome and the short space of time preceding its fatal outcome not only call for the swift and concurrent use of multiple conservative measures, but also make invasive therapy worth considering. Here, too, any decision with regard to therapy must initially focus on the clinical difficulties relating to the respective underlying disease.

**Haemodialysis** may be indicated after the condition has passed from functional renal failure to true renal insufficiency. Discussion should also centre on dialysis as a possible way to bridge the phase of renal insufficiency or to gain time for the liver function to improve and allow the hepatorenal syndrome to become reversible. (31) • **Peritoneal dialysis** achieved temporary success in treating azotaemia and hyponatraemia, but the lethality rate could not be reduced. Nevertheless, some cases of successful treatment were observed. (48)

**PVS:** There are many reports on experience made with peritoneovenous shunts (s. p. 311), the positive tenor of which justifies its incorporation when planning therapy for hepatorenal syndrome with marked ascites. (16, 18, 31, 32, 37, 38, 46, 61, 64)

**TIPS:** In its function as a portacaval side-to-side shunt (s. pp 259, 314, 362), TIPS has also proved to be successful in the treatment of HRS. The survival rate after 18 months was 35%, whereas only 10% of non-shunted patients survived 3 months. (8) However, patients with type I HRS and those with bilirubin levels of 15 mg/dl or higher as well as patients with a Child-Turcotte-Pugh

score greater than 12 have a low response rate to TIPS and a high mortality rate.

**MARS:** A new therapeutic option that could improve renal function and prolong survival, especially in risk patients to TIPS, can be found in the molecular adsorbent recirculating system (MARS). It represents a cell-free liver dialysis technique and enables the selective removal of albumin-bound substances using an albumin-enriched dialysate fluid. Significant improvements for different biochemical and clinical parameters as well as a 30-day prolongation of survival were reported. (40) (s. p. 385)

**Portacaval shunt:** In some cases, the placement of a portacaval shunt (side-to-side) resulted in the restoration of normal renal function. (55, 56)

**Liver transplantation:** Where the hepatorenal syndrome occurs, consideration should understandably be given to liver transplantation in view of the increasing liver insufficiency. (s. p. 387) With suitable cases, this intervention proved to be efficacious. (12, 13, 22, 30, 35, 50) In severe forms of HRS and with inadequate response to conservative therapy, the indication for liver transplantation should be reviewed without further delay. The feasibility of surgical intervention will largely depend on whether the phase of hepatic and renal insufficiency can be bridged − with as favourable clinical findings as possible and perhaps supported by suitable invasive measures − until transplantation can be carried out. The three-year and four-year survival rates were both given as 65.7%. (22)

**Support systems:** Artificial renal and liver support systems may also be considered in order to bridge the period of time until liver transplantation is performed. (1)

# Symptoms and Syndromes

## 18 Hepatopulmonary syndrome

# 18 Hepatopulmonary syndrome

▶ Recognition of a hepatopulmonary syndrome goes back over one hundred years (1884) to the detection of the **triad:** *cyanosis, clubbed fingers* and *liver cirrhosis.* (18). The same constellation of findings was described by A. GILBERT et al. in 1895 in juvenile patients suffering from hypertrophic biliary cirrhosis. • Reports on **hypertrophic osteoarthropathy** were published by A.A. HIJMANS VAN DEN BERGH in 1901. • A.M. SNELL detected **hypoxaemia** in chronic liver patients for the first time in 1935. (49) A right shift of the dissociation curve of oxyhaemoglobin was ascertained by A. KEYS et al. in 1938. In the course of acute progressive liver failure, R. RYDELL et al. (1956) also observed hypoxaemia; at autopsy, this patient showed intrapulmonary **arteriovenous shunts.** (43) Since then, there have been many reports on the detection of arteriovenous anastomoses in the lungs (further details in references 6, 7, 25). These arteriovenous shunts had already been attributed to vasoactive substances. The development of clubbed fingers was deemed to be the result of arteriovenous anastomoses in the tips of the fingers and the impact of reduced ferritin. (35, 50) • The term **hepatopulmonary syndrome** was used by T.C. KENNEDY et al. (1977) and likewise by L.S. ERIKSON et al. (1989) to describe the correlation between hypoxaemia and liver cirrhosis.

## 1 Definition

The hepatopulmonary syndrome (HPS) is defined as a disorder in pulmonary gas exchange (= mismatch of ventilation and perfusion) due to intrapulmonary vasodilations (= reduction of pulmonary vascular resistance) in cases of chronic liver disease or acute liver failure. • Other criteria must also be met: (*1.*) ruling out of underlying pulmonary or cardiac disease, (*2.*) increase in the alveolar-capillary oxygen gradient (> 20 mm Hg) without or with hypoxaemia (< 70 mm Hg partial oxygen tension), with a clear drop of the $O_2$ value when changing from the supine to the upright body position, and (*3.*) detection of intrapulmonary vasodilations and/or a.-v. shunts.

## 2 Epidemiology

Hypoxaemia ($p_aO_2$ < 70 mm Hg) is observed in 45−69% of patients suffering from cirrhosis or liver insufficiency. Only rarely has severe hypoxaemia been demonstrated ($p_aO_2$ < 50 mm Hg). (6, 32, 51, 52, 56) • Intrapulmonary vasodilations could be ascertained in 13−47% of liver transplant candidates. (27) In about 50% of all cirrhotic patients, a decline in the diffusion capacity for carbon monoxide was detected. (24) About 30% of cirrhotic patients showed no (physiological) reduction in pulmonary vasoconstriction under conditions of hypoxia. The prevalence of HPS in cirrhotic patients varies between 4% and 19%. It occurs more

frequently in patients with cirrhosis than with extrahepatic portal venous obstruction. (21, 45)

## 3 Causes and pathogenesis

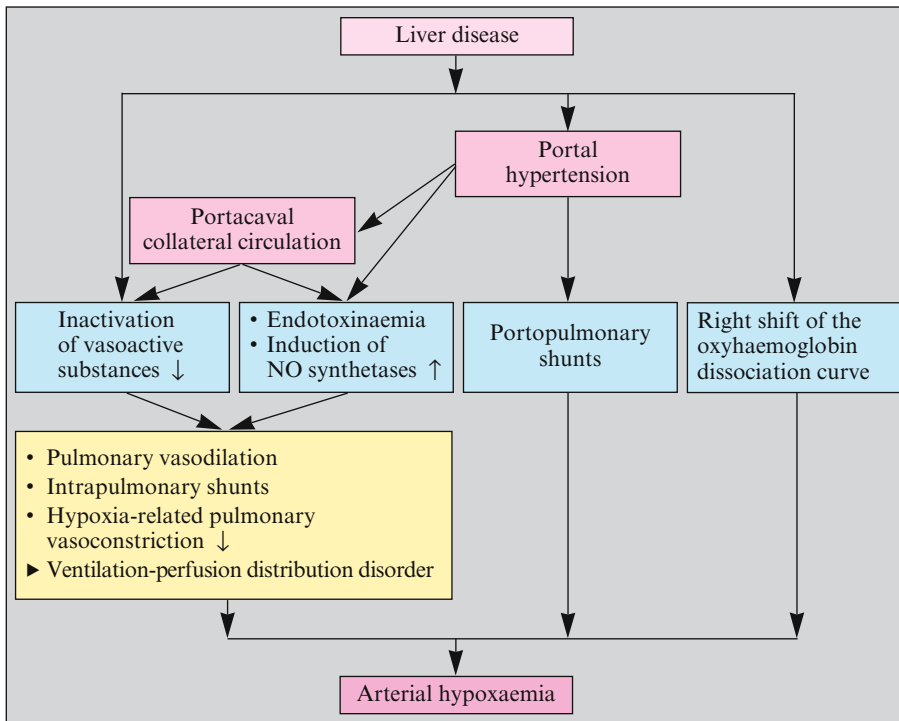
In theory, there are **three causes** for the occurrence of HPS (since hypoventilation is not deemed a possible cause): (*1.*) arteriovenous shunts, (*2.*) disturbed alveolocapillary oxygen diffusion in terms of impaired diffusion-perfusion, and (*3.*) mismatches between ventilation and perfusion. Consequently, there are numerous liver diseases which are associated with HPS. Transient HPS in acute viral hepatitis A and B has recently been reported. (17, 38) (s. tab. 18.1)

| | |
|---|---|
| $\alpha_1$-antitrypsin deficiency | Liver cirrhosis |
| Biliary atresia | Nodular regenerative |
| Budd-Chiari syndrome (13) | hyperplasia (9) |
| Chronic active hepatitis | Peliosis hepatis (8) |
| Chronic hepatic allograft | Postsurgical shunt (22) |
| rejection | Primary biliary cirrhosis |
| Congenital cystic fibrosis (20) | Schistosomiasis |
| Fulminant liver failure (55) | Tyrosinaemia |
| Inf. vena cava obstruction (12) | Wilson's disease |

**Tab. 18.1:** Liver diseases associated with hepatopulmonary syndrome. • Portal hypertension is considered to be an essential factor in the pathogenesis of HPS (with some references)

The existence of *portal hypertension* is probably the decisive factor in the development of HPS. The pathophysiological principles of HPS and the change in haemodynamics in cirrhotic patients have been presented as a review. (6) A marked *pulmonary vasodilation* due to vasodilative substances is deemed to be the essential causative factor of HPS (K.R. REISMANN, 1956).

### 3.1 Vasodilation

Endotoxin is capable of inducing nitric oxide synthetases in the vascular endothelia of the liver and lung. *Nitric oxide* (NO) is a powerful **vasodilator** (through activation of guanylate cyclase) and is identical to the endothelium-derived relaxing factor (EDRF). An increase in NO in the vascular endothelia of cirrhotic patients is deemed to be one of the causative factors in the development of a hyperdynamic circulatory condition (= lower peripheral resistance), yet also of hepatopulmonary syndrome (= lower pulmonary vascular resistance). NO concentration is increased in the expired air of patients with HPS. (11, 53) Animal experiments likewise suggested endothelial nitric oxide synthetase as being another causative factor. (16) In the same way, elevated values of glucagon, histamine, VIP, prostacyclin,


calcitonin, substance P, atrial natriuretic factor and platelet-activating factor are considered to be vasodilators in the pulmonary vascular system. • Animal models of HPS showed that an increase of ET-1 production in the liver correlates with both pulmonary nitric oxide synthase levels and pulmonary dysfunction. (33, 57) In patients with liver cirrhosis, a markedly increased serum value of the vasoconstrictor ET-1 was demonstrated. Therefore it may be assumed that pronounced endothelinaemia leads to a modulation of NO production, which results in extensive intrapulmonary vasodilation. • *In cirrhotic patients, a decrease in the pulmonary vascular resistance with formation of intrapulmonary shunts occurs more frequently than pulmonary hypertension; the reason for these very different modes of reaction is unknown.*

### 3.2 Shunt formations

The assumption that **a.-v. shunts** play a causative role in HPS is founded on (*1.*) the presence of very small intrapulmonary a.-v. shunts in the lung parenchyma and on the pleura (= *pleural spider naevi*) at autopsy (7), (*2.*) dilation of the capillary and precapillary intrapulmonary vessels, particularly in the basal lung region, and (as a very rare finding) (*3.*) isolated links detected between the branches of the portal vein and the pulmonary vessels. • These a.-v. anastomoses are mainly **functional shunts.** They are found in about 50% of cirrhotic patients. Given a normal width of the lung capillaries (8−15 μm), precapillary vascular dilations can attain a diameter of 15−150 (−500) μm. This is reversible. HPS (probably only type 1) can therefore completely recede

after liver transplantation − analogous to the hepatorenal syndrome. It remains uncertain, however, whether the vascular changes imply dilated capillaries or opened a.-v. anastomoses. • **Anatomic shunts,** which may be intrapulmonary and portopulmonary as well as pleural, are rare. In terms of haemodynamics, they have no noteworthy effect. (9, 25, 26, 32, 42, 54, 55) (s. fig. 18.1)

### 3.3 Impairment in diffusion and perfusion

The pathogenesis of HPS has not yet been fully clarified. Presumably, however, substances with vasodilator activity can bypass the liver through collateral vessels, thus effecting vasodilation of the pulmonary vessels. There is oxygen desaturation of the erythrocytes flowing centrally through the dilated vessels (= increased distance from vessel wall to vessel centre). Moreover, insufficient oxygen saturation of the erythrocytes is induced by a hyperdynamic circulatory state (= reduced blood-oxygen contact time) − giving rise to a **diffusion-perfusion defect.** As a result, inadequately oxygenated or non-arterialized blood reaches the pulmonary veins, leading to hypoxaemia. (4, 24, 52, 56) (s. fig. 18.1)

### 3.4 Ventilation-perfusion distribution disorder

In poorly ventilated lung areas, perfusion is diminished (= *von Euler-Liljestrand reflex*). This reflex is impaired in liver cirrhosis. The decrease in or loss of hypoxia-induced pulmonary vasoconstriction leads to the greater perfusion of poorly ventilated lung areas; this results in an increase in the intrapulmonary shunt volume and

thus in a ventilation-perfusion distribution disorder with hypoxaemia. (4, 15, 24, 32, 52, 54, 56) (s. fig. 18.1)

A particular pathophysiological finding with HPS is a **right shift of the oxyhaemoglobin dissociation curve.** The cause of this diminished affinity of haemoglobin for oxygen is assumed to be the greater concentration of 2,3-diphosphoglycerate found in erythrocytes. This results in arterial hypoxaemia.

## 4 Clinical aspects

In most HPS patients, pulmonary discomfort or findings generally remain absent for a long period of time; the $p_aO_2$ is still within the normal range ($> 80$ mm Hg). Some patients, however, display *dyspnoea* at an early stage.

HPS becomes manifest $3-7$ years after the development of portacaval and/or splenorenal collateral vessels. In an advanced, more or less rapidly progressing course of disease, *cyanosis* (19) develops with even more pronounced *hypoxaemia* ($p_aO_2 < 70$ mm Hg). Both hypoxaemia and dyspnoea generally worsen in an upright position (see below) due to increased cardiac output with shortened pulmonary transit time. Patients with distinct *spider naevi* show noticeably more severe pulmonary disorders than those where this skin stigma of liver disease is absent or only developed to a minor degree. Frequently, signs of respiratory *alkalosis* due to hyperventilation can be found. There is a decreased diffusing capacity for $CO_2$. • Some $85-90\%$ of HPS patients show *platypnoea* (= clear improvement of dyspnoea when the body position is changed from the vertical to the horizontal) and/or *orthodeoxia* (= decrease in $p_aO_2$ of $> 3$ mm Hg upon assuming an upright body position); it is usually accompanied by aggravated dyspnoea. (40) Orthodeoxia can be diagnosed by blood gas analysis or pulse oximetry in the recumbent and standing position. The cause of platypnoea and orthodeoxia is the reinforced perfusion of the dilated pulmonary vessels in the poorly ventilated basal lung areas in an upright body position. This leads to an increased shunt volume and hence to a deterioration of the ventilation-perfusion disorder. *Hour-glass nails* and *drumstick fingers* are frequently observed. (s. fig. 4.18) • There might even be a connection with the formation of *oesophageal varices.* (10) • Patients with functional shunts and impaired diffusion and perfusion present significantly better values regarding the arterial $O_2$ partial pressure upon *inspiration of 100% $O_2$*; patients with anatomic shunts show no improvement. • Tachycardia, higher cardiac output and lower values of mean arterial pressure and peripheral vascular resistance point to a *hyperdynamic circulatory condition*. There is always a risk of *bacterial infection* with a corresponding deterioration in prognosis. (4, 6, 9, 21, 28, 45)

The *chest radiograph* usually shows reinforced basal, interstitial vascular markings (bilateral, basilar, nodular or reticulonodular opacities). (36) • *Spirography* yields normal volumes and expiratory resistance. The detection of intrapulmonary shunts (23, 26, 54) is effected by *scintigraphy* ($^{99m}$Tc-labelled macro-aggregated albumin); tracer particles with a diameter of $20-60$ μm are not retained in the lung capillaries, but are directly passed on through shunts and pulmonary vasodilations to the brain, liver, kidney and other organs. (2, 27) By means of contrast-medium *echocardiography* (generally using oxypolygelatine solution), it is also possible to identify intrapulmonary shunts. This procedure is deemed to be the screening method for the diagnosis of HPS, prior to the occurrence of alterations in blood gas. (3, 4, 27) *Angiography* produces normal or reduced pressure values in the pulmonary artery, diminished pulmonary vascular resistance and increased cardiac output; a net-like dilated vascular system is visible. • The ventilation-perfusion status in the lung can be defined exactly by means of the *multiple inert gas elimination technique* (MIGET). At the same time, it is possible to differentiate between intrapulmonary shunts and vasodilations.

One can differentiate between **two distinct patterns** of HPS, whereby type 2 is only very rarely detectable:

**Type 1:** By means of angiography, minor to pronounced vasodilations of speckled or sponge-like appearance may be demonstrated. Additionally, spider-like vascular ramifications are identifiable. Depending on the extent of the vasodilations, marked or only slight improvement in hypoxaemia may be observed in patients following administration of 100% oxygen. Liver transplantation is the most successful therapeutic approach in the treatment of type 1. With a good response to the administration of 100% oxygen, regression of HPS is to be expected after OLT.

**Type 2:** As a rule, only slight vascular changes resembling a.-v. shunts or vascular malformations are identified by means of angiography. No hypervascularization is found. There is no significant improvement in hypoxaemia following administration of 100% oxygen. Liver transplantation generally turns out to be unsuccessful regarding HPS. • In the individual case, embolization may be indicated.

## 5 Hypertrophic osteoarthropathy

Hypertrophic osteoarthropathy (hour-glass nails, clubbed fingers) (s. fig. 4.18), which has been known since 1884, is not caused by hypoxia, as has been assumed up to now. (18) The cause is to be found in the intrapulmonary arteriovenous shunts: from the venous limb of the pulmonary vessels, megakaryocytes and thrombocyte aggregates pass directly through the shunts into the arterial limb and hence (unfiltered, uncatabolized or not

inactivated) into the circulation. These (and possibly also other) substances are deposited in the acra; they effect the release of the platelet-derived growth factor. The PDGF induces nail bed oedema (= *hour-glass nails*) and an increase in collagen synthesis by activating the fibroblasts (= *drumstick fingers*). (14, 19, 50)

# 6 Therapy

Up to now, there is no satisfactory drug therapy for HPS available. Spontaneous improvement of HPS after recovery from an underlying liver disease has been reported. Often HPS has deteriorated despite stable liver function. Improvements in HPS with the help of various substances, for which a certain therapeutic effect was considered plausible, were only achieved in individual cases and for just a limited time. (4, 28, 45)

▶ By administering *100% oxygen* (as long-term oxygen therapy), a higher and nearly normal partial oxygen pressure can be achieved in the dilated pulmonary vessels (albeit only in some of the patients and just temporarily). • Intravenous application of *prostaglandin $F_{2a}$* has produced some improvement in hypoxaemia. (48) With the help of *antibiotic therapy*, which led to a reduction in bacterial endotoxins in the intestines, it was possible to improve the arterial hypoxaemia considerably. (5) *Indomethacin* has likewise been effective. (48) By administering *allium sativum* (garlic) for a period of several months, a significant improvement in arterial $O_2$ saturation could be achieved. (1) Only isolated cases involving treatment with *methylene blue* (= inhibitor of NO-related guanylate cyclase) have been reported. (41, 44) In HPS due to multifocular nodular hyperplasia, *glucocorticoids* and *cyclophosphamides* have been successful. (9) *Somatostatin antagonist*, *NO antagonist* and *almitrine bimesylate* have proved ineffective.

▶ *Implantation of a TIPS* has brought about a clear improvement in cases of hypoxaemia, probably due to a decrease in endotoxinaemia and the resulting reduction in the formation of nitric oxide. There was a rise in pulmonary perfusion together with a marked decrease in pulmonary vascular resistance. Consequently, placement of a TIPS would serve to bridge the period of time until a liver transplantation can be carried out. (4, 31, 39, 47)

▶ **Liver transplantation:** Like hepatorenal syndrome (s. p. 330), HPS (probably only type 1) is, in principle, reversible after transplantation of the liver. The postoperative prognosis depends on the severity of hypoxaemia prior to transplantation (postoperative lethality is <5% if preoperative hypoxaemia is >50 mm Hg). An increase in arterial $pO_2$ when the patient is inhaling 100% $O_2$ in a horizontal position is a good prognostic sign for transplantation. It was possible to demonstrate improvement and normalization regarding arterial blood gas values and intrapulmonary shunt volumes as well as restoration of the responsive capacity of the von Euler-Liljestrand reflex. HPS may prove reversible within a few days of liver transplantation. However, other studies have shown that the process of recovery can last much longer (2−18 months). (15, 29−31, 34, 46)
• *Embolization* may be indicated in the individual case of a.v. fistulas. (28, 37)

# 7 Portopulmonary hypertension

This clinical picture was described for the first time in 1951 by F. MANTZ et al. (65) and confirmed in 1983 by P.J. McDONNELL et al. • Portopulmonary hypertension (PPH) is defined as a secondary form of pulmonary hypertension with portal hypertension. Frequency in patients with cirrhosis is given as 2−4%, in patients in an advanced stage of cirrhosis (e.g. presenting for liver transplantation) as 5−10% of cases. (s. pp 258, 735)

## 7.1 Definition, morphology and diagnosis

**Definition:** Characteristic criteria of PPH include (*1.*) elevated pulmonary artery pressure (>25 mm Hg), (*2.*) increased pulmonary vascular resistance (>120 dyne/sec/cm$^{-5}$), and (*3.*) normal pulmonary capillary wedge pressure (<15 mm Hg). An elevated transpulmonary gradient (mean pulmonary artery pressure/pulmonary capillary wedge pressure = >10 mm Hg) is likewise used as a diagnostic criterion. (62, 70) • *The presence of portal hypertension is considered as a prerequisite for the development of PPH.*

▶ The main difference between PPH and HPS is to be seen in the fact that the latter reveals an impaired gas exchange with hypoxaemia and a reduction in pulmonary vascular resistance due to vasodilation. The coexistence of these two pathological conditions (*vasodilation* on the one hand and *vasoconstriction* on the other hand) has recently become documented more often. Any illnesses which lead to pulmonary hypertension must be ruled out as part of the differential diagnosis.

**Morphology:** PPH is characterized by anatomically fixed pulmonary vasoconstriction. Vascular changes are brought about by (*1.*) vasoconstriction, (*2.*) structural remodelling of the pulmonary arteries (intimal fibroelastosis, hyperplasia of the media), and (*3.*) formation of microthrombi. In the further course, there is a proliferation of capillaries, followed by angioma-like changes with fibrinoid necroses of the arterial wall (= *plexogenic arteriopathy*). These findings are disseminated unevenly throughout the lungs. Thus the histological changes of PPH are similar to those of primary pulmonary hypertension. (68) • Remarkably, the combined occurrence of the primary antiphospholipid syndrome and PPH with the presence of anticardiolipin antibodies and microthrombi was observed. (58)

**Diagnosis:** Clinical symptoms of PPH can appear approximately 5 years after the diagnosis of portal hypertension. At the beginning, patients have no complaints regarding PPH. In the further course, however, effort dyspnoea, syncope and chest pains may occur. Occasionally, haemoptysis is observed. Additional findings include a loud $P_2$ heart sound, prominent central pulmonary arteries on the chest roentgenogram and changes on ECG (right ventricular hypertrophy, right axis deviation, right bundle branch block). • An initial diagnosis can be made using Doppler echocardiography. This proved to be an excellent screening test for identifying all patients with PPH before they presented for liver transplantation. (59) Respiratory alkalosis on room air arterial blood gas can be used as an adjunctive screening test, whereby exaggerated values are indicative of PPH. (63) Diagnosis is established using right heart catheterization, which is considered as the "gold standard". (s. fig. 35.15)

## 7.2 Endothelin and ET-receptor antagonist

**Endothelin-1** was first isolated in 1988 by M. YANAGISAWA et al. from endothelial cells as a peptide comprising 21 amino acids linked through two sulphide bridges. In 1989 the same team discovered two further isoforms, endothelin-2 and endothelin-3, also in endothelial cells and smooth muscle cells. These endothelins closely resemble the cardiotoxic poison, sarafotoxin, a potent vasoconstrictor toxin found in the Israeli mole viper. Endothelin-1 (ET) is the most important isoform in humans. The two ET receptors, ETA and ETB, can be detected on smooth muscle cells, in especially high densities in the pulmonary and coronary vessels, and produce intense vasoconstriction (T. SAKURAI et al., 1992). ETB receptors can likewise be found in large numbers on endothelial cells. Activated under normal physiological conditions, they stimulate the release of vasodilatory substances (e. g. NO, prostacycline). Vasoconstriction is predominant under pathological conditions. Some results have shown that ETB receptors are upregulated in certain diseases, such as liver cirrhosis. (71). ET has a low plasma concentration and a short half-life of $4-7$ minutes. It therefore acts as a local hormone rather than a circulating endocrine hormone. Apart from immediately producing vasoconstriction (ET is one of the strongest and slowest-acting endogenous vasoconstrictors), it stimulates numerous medium and long-term pathophysiological effects. (66) (s. tab. 18.2)

**Bosentan** was first described as an ETA/ETB receptor antagonist by S.M. GARDINER et al. in 1994. These two receptors are features of the intense vasoconstrictory as well as the proliferative and profibrotic effects of ET. Pharmacological characterization was carried out in 1994 by M. CLOZEL et al. and in 1999 by S. ROUX et al.

The effects of bosentan have since been confirmed in numerous studies, and this substance was approved for use in the treatment of pulmonary arterial hypertension (WHO classes III and IV) in 2001. (67) • This dual ET receptor antagonist shows a number of important properties. (s. tab. 18.3)

*Tab. 18.3:* Main properties of bosentan

## 7.3 Prognosis and therapy

**Prognosis:** Prognosis is poor. The patients die of liver insufficiency or right heart failure as well as from various infectious diseases. The mean survival period after diagnosis was 15 months, with a 6-month mortality of 50%.

**Therapy:** Up to now, no effective therapy is known. • *Inhaled nitric oxide* as a specific pulmonary vasodilator may be useful perioperatively with regard to liver transplantation. In several studies, the use of nitric oxide as well as *calcium channel blockers* only proved successful in single cases and then just for a short time. • *Epoprostenol* is a potent vasodilator with a short half-life ($3-5$ min), so that a permanent supply is required; this is made possible with the help of an indwelling i.v. catheter attached to a continuous pump. (61) A significant reduction in pulmonary hypertension could be achieved following a 5-month period of application (8 ng/kg BW/min). (60) Further studies have also shown an improvement in haemodynamics and exercise tolerance as well as prolonged survival in patients with PPH. (62, 63) It was also shown that long-term administration of epoprostenol led to a remodelling of the right ventricle. • The newly developed endothelin-receptor antagonist *bosentan* has proved successful in the treatment of arterial pulmonary hypertension. (67) As a last resort, a combination of bosentan and epoprostenol (or other prostanoids) can also be recommended. As yet, there have

only been isolated cases involving the use of bosentan in PPH. • In the meantime, PPH is no longer considered to be an absolute contraindication for *liver transplantation*. The indication is given in cases involving a mild or moderate course of the disease. (64, 69) A well-functioning right ventricle is a prerequisite for liver transplantation.

# Symptoms and Syndromes

## 19  Coagulopathy and haemorrhage

# 19 Coagulopathy and haemorrhage

The leakage of blood from the blood vessels is referred to as **haemorrhage**. Its causes include: (*1.*) increased permeability of the vascular walls, (*2.*) pathological blood vessel condition, and (*3.*) injury to a blood vessel. • Generally, a haemorrhage may become considerably more severe in the presence of **coagulopathy**, i. e. clotting disorder. It is also quite possible for a coagulation defect to arise as a separate disorder even without existing tissue damage.

## 1 Coagulopathy

### 1.1 Forms of haemostasis

By means of the complex process of **haemostasis**, the organism seeks to protect itself spontaneously against bleeding and the corresponding loss of blood. • **Three components** are available to this end: (*1.*) blood vessels themselves (= vascular haemostasis), (*2.*) platelets and endothelial cells (= cellular haemostasis), and (*3.*) blood-clotting factors (= plasmic blood coagulation).

1. **Vascular haemostasis** comprises reflex contractions of the arteries, reinforced by the release of vasoconstrictor substances from the vessel walls (e. g. catecholamines, serotonin, thromboxane $A_2$).

2. The **cellular phase** of the arrest of bleeding commences as so-called **primary haemostasis,** during the course of which thrombocytes, with the aid of von Willebrand's factor, adhere to collagen fragments released from the injured vascular endothelium. The discharge of various factors from the thrombocytes then ensues. The prostaglandin-thromboxane system is directly involved in the subsequent aggregation of thrombocytes.

3. **Plasmic coagulation** is effected by a system of 15 coagulation factors. (s. p. 104) (s. tab. 5.12) So-called **secondary haemostasis** begins with the progressive activation of the plasmic coagulation system. All the coagulation factors involved are proteins and for the most part enzymatic. They are normally present in the plasma in their inactive form, and with the initiation of plasmic coagulation, they become successively activated. The clotting process (= **coagulation**) has the function of converting soluble fibrinogen into stable, insoluble fibrin. *Procoagulation and anticoagulation factors* regulate the process of coagulation.

**Exogenous activation** is initiated by tissue thromboplastin (= tissue factor) and the activated form of factor XII in the plasma. This complex is enlarged by ionic calcium and platelet factor 3. As a result, the activation of factors IX to IXa and X to Xa is triggered, thus forming a cross-connection between the endogenous and the exogenous system. (s. fig. 19.1)

**Endogenous coagulation** commences with the activation of factor XII. Factor XIIa then catalyzes the conversion of prokallikrein to kallikrein, plasminogen to plasmin and factor XI to XIa. The presence of factor XV is necessary for the activation of IX to IXa. This creates a complex comprising IXa, VIIIa, calcium and phospholipids, which then activates factor X to Xa. (s. fig. 19.1)

Depending on the causative mechanism, either the exogenous or the endogenous coagulation system is activated. These progress differently until the activation of factor X, which then allows both pathways to merge into a common final phase of coagulation. • At this point, the activation of **prothrombin II** to thrombin by the Xa/Va/calcium/phospholipid complex represents the final step of both coagulation cascades. The prothrombin complex (factors II, VII, IX and X) does not exist as such − it refers to various proteins, the synthesis of which depends on vitamin K. Soluble **fibrinogen** (I) is converted with the aid of thrombin into insoluble *fibrin*, which infiltrates and thereby solidifies the thrombocytic embolus. Thrombin simultaneously activates factor XIII to XIIIa and protein C to protein $C_a$. The fibrin network is further strengthened by factor XIIIa. The most effective **inhibitors** of coagulation are antithrombin III, $\alpha_2$-macroglobulin, $C_1$-inactivator and protein $C_a$ as well as fibrinogen-fibrin degradation products.

### 1.2 Fibrinolysis

The minor coagulation processes constantly taking place in the vascular system (whereby fibrin is deposited) are counteracted by simultaneous fibrinolysis. *Coagulation and fibrinolysis are thus in continuous dynamic balance.* Plasminogen is converted to plasmin by activators such as urokinase PA (isolated from urine) and tissue PA (isolated from tissue). The effect of tissue PA is strongly enhanced by the presence of fibrin. Fibrinolysis is stimulated by protein C, while plasmin activity is maintained in balance by inhibitors (e. g. $\alpha_2$-antiplasmin, $\alpha_2$-macroglobulin). (s. fig. 19.1)

### 1.3 Vasopathies

Vasopathies may arise from direct injuries to the vessel wall, but also from pathological changes in the vessel wall or in the endothelium. It can be expected that vasopathies will occur or become more severe during the course of various liver diseases or with concomitant coagulopathy.

The most common congenital vasopathy is the **Osler-Rendu-Weber disease** (*haemorrhagic telangiectasia*). It is an autosomally inherited structural defect of the blood vessels with accompanying decrease in muscular and elastic fibres in the capillaries and venules. Multiple telangiectases are most frequently found in the upper body and in the mucous membranes. Severe bleeding may occur from the nasal and pharyngeal passages as well as from the gastrointestinal tract.

The most important acquired vasopathy is the **Schoenlein-Henoch disease** (*anaphylactoid purpura*) due to toxic or allergic inflammatory blood-vessel damage accompanied by immunological reactions. Bleeding may be present in the skin, in the form of petechiae or ecchymoses, or in the gastrointestinal mucosa.

### 1.4 Thrombocytopathies

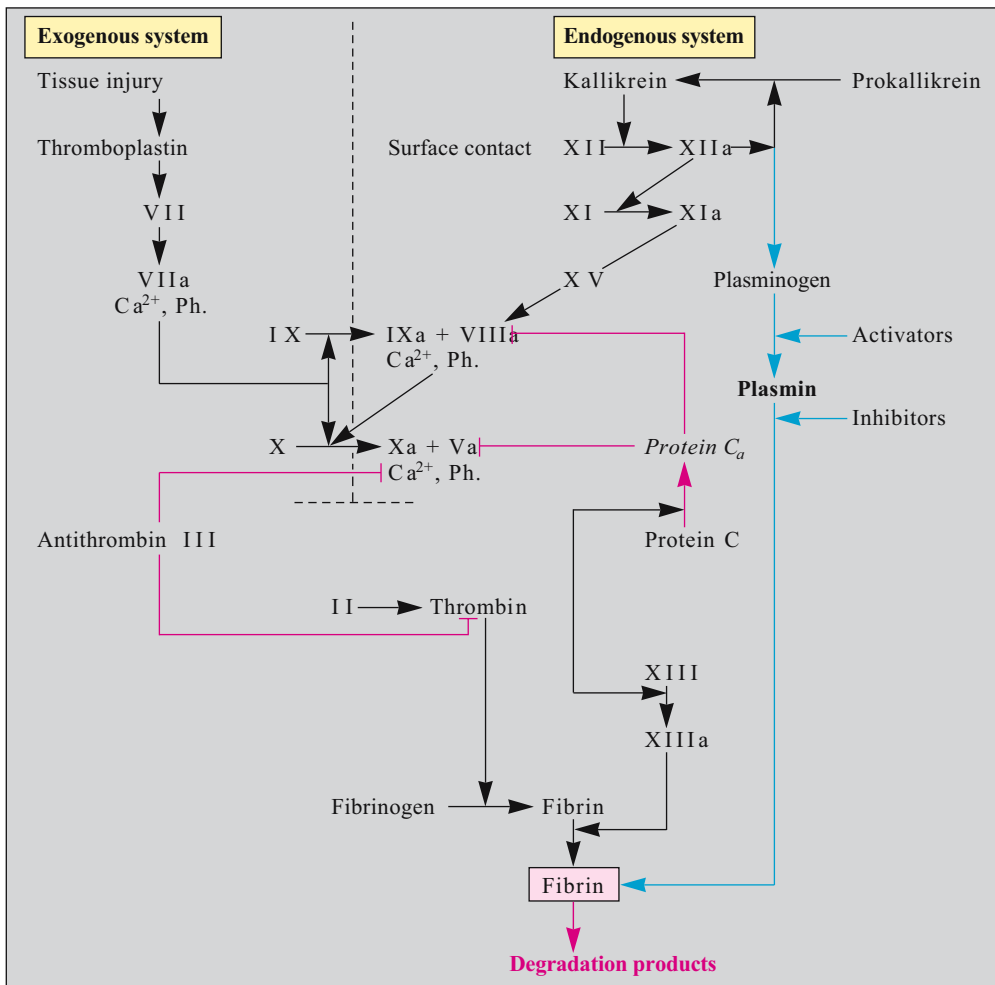
Thrombocytopathies may arise in the course of a liver disease and during the measures taken to treat it as well


*Fig. 19.1:* Exogenous and endogenous plasmic coagulation cascade (with inhibition by antithrombin III and protein C$_a$) and the fibrinolysis pathway through plasminogen-plasmin. Proteolytic plasmin principally hydrolyzes the cross-linked fibrin clot into high molecular weight fragments and D fragment dimers (s. tab. 5.12)

as from complications. This can lead to serious disturbances in haemostasis. Thrombocytic bleeding is typically observed as punctate or petechial haemorrhaging in mechanically stressed skin areas as well as in mucous membranes. Ecchymosis is found less frequently. • A *leftward shift* in the differential blood count may indicate thrombocytopathy.

1. **Thrombocytopenia** may be caused by various metabolic disturbances: (*1.*) synthesis disorders (e. g. medicaments, alcohol, folic acid deficiency), (*2.*) replacement disorders (e. g. immunologically derived degradation, consumption coagulopathy, loss of blood), and (*3.*) distribution disorders (e. g. increased sequestration in the enlarged spleen, involving up to 90% of the thrombocytes).

2. **Thrombocytosis** is a (generally temporary) rise in the thrombocyte count. Thromboembolic complications may arise. This disorder occurs in hepatocellular carcinoma, for example, following splenectomy or portosystemic anastomosis as well as after haemorrhage or cortisone therapy.

3. **Thrombocyte dysfunction** frequently emerges in the course of liver diseases and their complications, especially in the case of coagulation disorders and elevated fibrinolysis. Thus a decrease in both thrombocyte aggregation and the release of platelet factor 3 may occasionally be witnessed in cirrhosis. In most cases, this is caused by medication (acetylsalicylic acid, non-steroidal antirheumatic agents, dextran, antibiotics, etc.).

## 1.5 Plasmic coagulation disorders

Defects in liver function are of fundamental significance to the haemostatic system: (*1.*) almost all coagulation and fibrinolytic factors are synthesized in the liver; (*2.*) numerous pro- and anticoagulation factors must be metabolically converted into their functionally active forms in the liver, and (*3.*) various plasmic coagulation and fibrinolytic factors are removed from the bloodstream by clearance mechanisms in the liver. Consequently, liver diseases can disrupt the haemostatic system at various stages of coagulation or fibrinolysis and with varying degrees of intensity. In this situation, it is the severity of the liver disease which is of decisive importance rather than its acute or chronic character or its aetiology (with the possible exception of liver carcinoma). Appropriate *diagnostic tests* are: thrombocyte count, Quick's value and AT III. Plasmic coagulation defects in liver disease are derived from acquired disorders in the synthesis of coagulation factors or from their accelerated breakdown. (1, 3, 5, 6, 10, 13−16)

In liver disease, procoagulation and anticoagulation factors are generally decreased to the same extent, so that haemostasis is kept in balance, albeit at a pathological level. Thus the clinical significance of haemostatic changes may be less serious than laboratory findings would seem to indicate. This pathological "equilibrium" is, however, extremely vulnerable and may be quickly destroyed by diagnostic or invasive procedures as well as by biochemical or toxic effects.

### 1.5.1 Synthesis disorders

The synthesis of almost all coagulation factors takes place in the liver. In liver disease, several factors, especially the vitamin K-dependent factors II, VII, IX and X, are affected differently, depending on the severity of the illness. Synthesis of non-functional coagulation factors, particularly fibrinogen (dysfibrinogenaemia), may also occur. Defects in factor activity become clinically manifest quite rapidly due to their short plasma half-lives. (s. tab. 5.12) This is where Quick's value, the Colombi index and the AT III value, among others, play their part as accepted clinical parameters of impaired liver function. (s. p. 105) A decrease in fibrinogen is observed only in severe liver damage, in consumptive disease processes or in consumption coagulopathy. Plasminogen and factors XI, XII and XIII are likewise reduced in cases of severe loss of liver function.

### 1.5.2 Clearance function disorders

The liver has the unique ability to differentiate between inactive and active coagulation factors and to remove the latter, along with plasminogen activators, from the bloodstream. Cirrhosis greatly interferes with the clearance of t-PA. The fibrinogen-fibrin degradation products, which act as thrombin inhibitors, are likewise eliminated by a healthy liver. In severe liver disease, obstructive gall-bladder disorders, cholestasis or biliary cirrhosis, the clearance function of the liver (s. p. 65) as well as the elimination of coagulation factors (especially factor XIII) and fibrin degradation products can be seriously impaired. This disrupts the haemostasis system, and fibrinolysis increases.

### 1.5.3 Increase in consumption

An increased consumption of coagulation factors is found in extensive disseminated intravascular coagulopathy. Secondary hyperfibrinolysis evolves. Simultaneous activation of the coagulation cascade or fibrinolysis system leads to the consumption of coagulation factors as well as inhibitors.

▶ Haemostatic disturbances result in *hypocoagulopathy with a bleeding tendency* (= haemorrhagic diathesis) seen as manifest haemorrhage or in *hypercoagulopathy with a tendency to thrombosis* (= thrombophilia) seen as

manifest thrombosis. An imbalance in the physiological equilibrium of the procoagulation and anticoagulation factors of the coagulation and fibrinolytic systems is invariably present.

## 1.6 Consumptive coagulopathy

### 1.6.1 Definition

*Disseminated intravascular coagulopathy (DIC) is due to enhanced formation of thrombi following an activation disorder in either the extrinsic or intrinsic coagulation cascades. Fibrin clots form in the small blood vessels and capillaries. In response, fibrinolysis increases, thus allowing large amounts of fibrin degradation products to reach the bloodstream. In the case of highly activated coagulation, platelets and coagulation factors are consumed in such large amounts that they cannot be adequately replaced. • DIC may develop into consumptive coagulopathy.*

*Aetiology:* This coagulation disorder may occur in the course of a variety of diseases and clinical conditions. Aetiopathological possibilities include infections, toxins, endotoxins, dehydration, acidosis, antigen-antibody complexes or stasis of the blood flow as well as the tumour necrosis factor.

▶ Disseminated intravascular coagulopathy does not present a clinical picture in its own right, but constitutes a severe pathological manifestation of an **altered haemostasis system.** Blood vessels, thrombocytes and endothelial cells, the coagulation system, fibrinolysis, inhibitors and activators as well as the kallikrein-kininogen system are all involved in this disorder. The haemostasis system is activated either exogenously by the release of tissue thromboplastin and its homologues or endogenously by direct proteolysis of one or several procoagulants. (1, 3, 6, 7, 14−15)

### 1.6.2 Clinical aspects

Clinical aspects and laboratory findings vary widely not only from patient to patient, but also during the course of DIC. Depending on the extent to which the coagulation system is activated, either an acute or chronic form develops. Furthermore, DIC may occur merely as an additional complication in an existing illness, without necessarily having serious consequences − or it may culminate in a life-threatening condition.

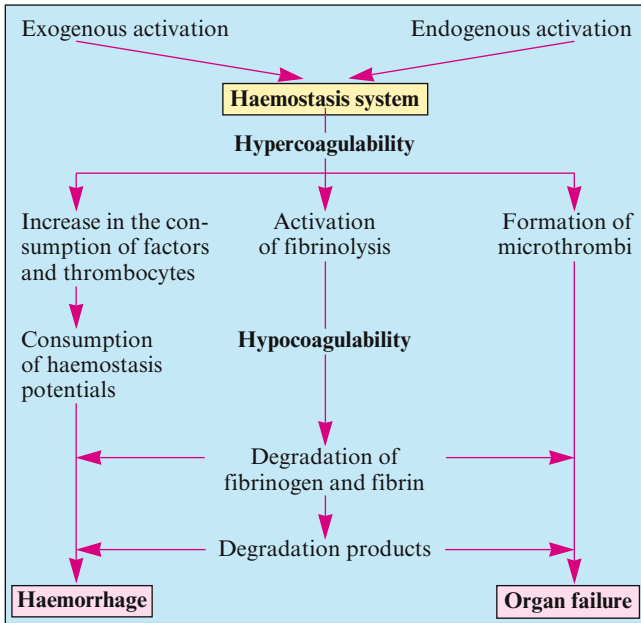
In the **initial stage** of DIC, the haemostasis system is activated via the exogenous and/or endogenous cascade. This stage is characterized by a state of hypercoagulability. There is consumption of thrombocytes and coagulation factors as well as of procoagulants and anticoagulants, with simultaneous intravascular release of thrombin. The fibrinolysis system undergoes secondary activation. (s. fig. 19.2) (s. tabs. 5.12, 5.13)


**Fig. 19.2:** Schematic course of consumptive coagulopathy

In the **second stage,** the intravascularly released thrombin begins to have an effect at various points in the pathological process. Thus (*1.*) fibrinogen and fibrin are converted into degradation products, (*2.*) factor XIII is activated, (*3.*) factors V and VIII are altered to more highly active forms with a fall in factor VIIIc, and (*4.*) aggregation of thrombin and thrombocytes occurs. The amount of monomeric fibrin rises, while the clearance capacity of the RES becomes progressively strained at the same time. Fibrin D fragments increase, as do fibrin-fibrinogen X, Y and E fragments. The monomers disintegrate into aggregates and, together with the thrombocytes, begin to form microthrombi and fibrin clots in the terminal vessels. Circulatory disorders arise with blood

stasis, hypoxia and acidosis. These result in endothelial damage, involving cell destruction to the point of organ failure. Further consumption of coagulation factors leads to a state of *hypocoagulability* with a tendency towards bleeding, which is dramatically intensified by reactive *hyperfibrinolysis* and a growing AT III deficit − a consequence of the irreversible binding to thrombin as well as to factors IXa, Xa, XIa and XIIa. (2, 4, 5, 8, 10, 12, 13−16, 18−20) (s. fig. 19.2) (s. tab. 5.13)

**Latent and compensated forms** of consumptive coagulopathy frequently occur in the course of severe acute or chronic liver disease. In 80−85% of cirrhosis patients, the values of at least one basic test (thrombocytes, Quick's value, fibrinogen, AT III, bleeding time) are pathological. In 15−30% of cases, clinically relevant haemorrhagic diathesis evolves.

It is often extremely difficult to draw up a **differential diagnosis** in a short time in order to distinguish consumptive coagulopathy from DIC; this is only possible by implementing a closely woven series of laboratory tests. Plasma thrombin time or reptilase time (in the event of concurrent heparin therapy) are appropriate parameters to determine the transition into reactive hyperfibrinolysis. (s. tab. 19.1) The diagnosis is complicated by the fact that laboratory values typical for disseminated intravascular coagulopathy might also be due to the reduced synthesis of blood-clotting factors. Likewise, evidence of fibrinogen-fibrin degradation products is not necessarily conclusive, since the diminished clearance capacity associated with the underlying liver malfunction may often preclude an adequate elimination of these substances. *It may thus prove difficult in individual cases to distinguish between a synthesis disorder and the consumption of coagulation factors as possible causes of haemorrhagic diathesis or haemorrhage.*

| | Normal range | Compensated /de-compensated DIC |
|---|---|---|
| Thrombocytes<br>Bleeding time | 150,000−380,000<br>2−5 min | ↓ − ↓↓<br>↑ − ↑↑ |

**Tab. 19.1:** Haemostasis parameters showing the normal range and corresponding changes in the course of hepatogenic consumption coagulopathy up to decompensation (s. tab. 5.12)

An evaluation of the dynamics of clotting disorders or the development of DIC as well as the further course of disease is only possible by monitoring the changes in the various laboratory parameters. Frequently repeated controls are far more important than determining each and every variable. (s. tab. 19.1)

The threshold between an inactive and an active coagulation system may be overcome abruptly at times by small stimuli, and haemostasis can then break down quite unexpectedly.

## 1.7 Therapy of haemostatic disorders

It is only possible to treat haemostatic disorders in liver disease *symptomatically*. In most cases, therapy also has to be adjusted to the individual patient. A causative effect on the haemostatic disorder can only be expected in the long term once liver function has improved.

### 1.7.1 Prophylactic measures

**Basic laboratory parameters** concerning the haemostatic status should exceed a minimum level before any diagnostic or therapeutic procedure is initiated. The following values may be taken as a guideline (although in certain instances, some values may lie below those given): thrombocytes > 80,000, Quick's value > 40%, fibrinogen > 1.5 g/l, AT III > 40%, normal bleeding time.

**Prevention of haemorrhage** is always of particular importance. In view of the highly unstable nature of the haemostasis system, which − even though still in equilibrium − has a generally reduced factor level, the *insertion of catheters* (e. g. stomach probe, urinary bladder) is only carried out if particularly stringent indications are given. (6) Likewise, the administration of any medication which might affect the haemostatic system (e. g. acetylsalicylic acid, certain antibiotics, antihistamines, antirheumatic agents, clofibrate, dextran, diuretics, glucocorticoids, cardiac and psychotropic drugs, nitrofurantoin and radiological contrast medium) should be carefully evaluated. Even traces of acetylsalicylic acid, which may be "hidden" in some medicaments, can severely disrupt haemostasis and precipitate the collapse of the painstakingly maintained equilibrium. Application of $H_2$-*receptor antagonists* or *omeprazole* may prove to be a helpful preventive measure in controlling gastrointestinal haemorrhaging. *Infection-limiting measures* can also serve to prevent haemorrhage. *Intestinal cleansing* (purgation) using poorly absorbable antibiotics (e. g. neomycin, paromomycin) and/or lactulose to suppress gram-negative flora and diminish the danger from endotoxins is of vital importance. (s. pp 277, 278, 280)

If no haemorrhagic diathesis is present or when no invasive measures or techniques which might possibly distress the patient are planned, coagulation disorders generally **require no treatment.** *The equilibrium between haemostasis and fibrinolysis, which is based on lower clotting factor levels, is indeed somewhat unstable, yet it does not normally lead to spontaneous haemorrhaging.*

Should **substitution** of haemostatic factors become necessary prior or subsequent to invasive procedures, *fresh plasma* is the agent of choice, since it contains not only a balanced mixture of procoagulant and anticoagulant factors, but also fibronectin, which serves to reinforce RES clearance. However, relatively large quantities of fresh plasma are required, and it is important that individual volume limits are adhered to for haemodynamic reasons. Preventive administration of *vitamin K* (10 mg/week), subcutaneously injected if oral application is considered inefficient or an intramuscular injection appears too risky, is recommended in the case of suspected vitamin K deficiency. This measure can also be used prior to treatment with cephalosporins, in particular β-lactam antibiotics, or if the intestinal flora is affected.

### 1.7.2 Pharmacological therapy

The **treatment** of haemostasis disorders is indicated in cases of acute liver failure or when a necrotic episode occurs during the course of cirrhosis, even if no haemorrhagic complications have been observed. There are *two reasons* for this: (*1*.) an elevated risk of haemorrhage must be anticipated in the event of acute liver dysfunction and (*2*.) extensive liver necrosis leads to the release of thromboplastic compounds, accompanied by a deterioration in the microcirculation and additional haemostatic disturbances. In this situation, an early and optimized correction of the coagulation and fibrinolysis parameters is thus essential. (1, 9−11, 13, 17) (s. tab. 19.2)

▶ Haemorrhage-related lethality of 20−30% (and more) has to be expected in the event that acute liver failure leads to **acute haemostasis disorders.** The following courses of treatment are recommended:

(*1*.) *Fresh frozen plasma* (FFP)*: 250 ml at six-hour intervals (10−20 ml/kg BW = 1,000−1,500 ml/day). Administration of 10 ml/kg BW (about 600−1,200 ml) serves to elevate the concentrations of coagulation factors and inhibitors by 15−20%. The half-life of factor VII is only 6 hours, which is why dosage intervals of 6 to 12 hours must be maintained. IgA deficiency is a known contraindication. Adverse transfusion reactions may occur with a frequency of 1−5% of cases. Improvement in coagulopathy generally lasts 1 to 2 days. • Caution is called for, since accentuated coagulation entails the danger of thrombosis (if necessary, AT III replacement of up to 60−80%), and an overload of the intra-

vascular volume must be avoided (monitoring of CVP!). (21)

(*2.*) *Antithrombin III concentrate**: 1,000−2,000 U/day until the plasma AT III value exceeds 70%.

(*3.*) *Desmopressin acetate**: This vasopressin derivative (DDAVP) acts as an antidiuretic and antihaemorrhagic agent. It increases the turnover of factors VII, VIII, IX and XII and also shortens the bleeding time. The recommended dosage is 0.3−0.4 μg/kg BW as an i.v. infusion. This substance is contraindicated in the case of a thrombotic status. Further contraindications include ischaemic heart disease, cardiac arrhythmias and seizure disorders.

(*4.*) *Vitamin K**: 10 mg, subcutaneous administration, to be repeated for 3 to 7 days until the prothrombin time has been corrected. Be careful when using the intravenous route due to the risk of anaphylaxis and hypotension. Onset of action is within 6−12 hours, full impact is at 24 hours, subsequently lasting up to 7 days. An overdose should be avoided as it can cause a (sudden and dangerous) drop in Quick's value resulting from the formation of vitamin K oxide.

(*5.*) *Heparin**: Heparin was recommended as early as 1963 for the *prevention* of consumptive coagulopathy in cirrhosis patients. The interruption of intravascular thrombin coagulation by heparin has been confirmed in animal experiments. Soluble, circulating fibrin aggregates into microthrombi (within a few hours of the coagulation system being activated); heparin, however, cannot prevent this. The efficacy of heparin is dependent on normal AT III values.
• *Heparin is no longer recommended as a prophylactic or therapeutic agent for DIC.*

(*6.*) *PPSB**: Should Quick's value remain below 20% after treatment with fresh plasma, administration of 1,000−3,000 U/day is indicated (1 unit PPSB activates coagulation by 1−2%). This treatment should always be carried out in combination with fresh plasma and AT III concentrate to avoid the danger of thrombosis or the manifestation of DIC. It must also be borne in mind that PPSB (prothrombin [II]/proconvertin [VII]/Stuart-Prower factor [VIII]/antihaemophilic globulin B) may induce an increase in intravascular consumption in the presence of hypercoagulability, and indeed trigger haemorrhaging.

▶ Treatment of **haemorrhagic complications** in acute or chronic liver disease initially focuses on the site of bleeding, i.e. in the upper or lower gastrointestinal tract. Mechanical, thermal and sclerotic measures are of prime importance.

Systemic clotting dysfunction is a potential contributory factor in more than 30% of cirrhotic patients with gastrointestinal bleeding. The seriousness of the haemorrhage depends to a great extent on the severity of the haemostatic disorder. Localized treatment must therefore be supplemented by additional corrective therapeutic measures, especially since a deterioration of the haemostatic potential in a haemorrhagic patient may occur rapidly and with serious consequences. The preparations listed above are also of value here, depending on the respective individual findings. (s. tab. 19.2)

(*1.*) *Thrombocyte concentrates**: Administration of thrombocyte concentrates may be advisable when values lower than 30,000/μl are present, but this must be specifically indicated (e.g. thrombocyte deficit due to sequestration in the spleen, increase in consumptive coagulopathy, potential antibody formation).

(*2.*) *Fibrinogen**: Doses of 2−4 g (i.v.) at six to eight-hour intervals are recommended. Where haemorrhaging occurs, simultaneous administration of even small amounts of heparin is strongly contraindicated, particularly as the patient's heparin sensitivity may be highly elevated in this condition as well as after the administration of AT III. The use of heparin in such a situation thus involves very high risks. (s. tab. 19.2)

(*3.*) *Factor XIII**: The administration of *factor XIII* for fibrin stabilization (1,250 U, i.v. until cessation of bleeding) is worthy of consideration.

| |

| − fibrinogen |
| − fresh plasma/fresh blood |
| − thrombocyte or erythrocyte concentrate |
| − vitamin K |

*Tab. 19.2:* Therapy of haemostasis disorders

*) The manufacturer's recommendations regarding application and dosage must be followed.

▶ It is not possible to draw up a "treatment schedule", since each individual case, including the financial status, calls for careful and critical evaluation of the respective measures. • The potentially deleterious countereffects produced by the haemostatic and fibrinolytic systems must be considered before administering any medication.

# 2 Upper gastrointestinal haemorrhage

## 2.1 Definition

Upper gastrointestinal (GI) haemorrhages comprise any bleeding occurring between the nasopharynx and the duodenojejunal fold (Treitz's arch), i.e. proximal to the duodenojejunal flexure. • *Such haemorrhages are especially problematic in cases where liver disease is also present.*

## 2.2 Forms

Acute gastrointestinal haemorrhage is the most frequent life-threatening emergency situation in gastroenterology. Incidence is as high as 50−100/100,000 population. In 85−90% of cases, upper gastrointestinal bleeding is involved. (31, 44) Differentiation can be made by applying various criteria relating to the haemorrhage, such as its course, extent, type and localization, as well as by classifying the bleeding activity. (s. tab. 19.3)

| |
|---|
| **1. Course of haemorrhage**<br>  − acute or chronic<br>**2. Extent of haemorrhage**<br>  − severe or slight bleeding<br>  − seeping bleeding<br>**3. Type of haemorrhage**<br>  − arterial, venous or capillary<br>**4. Source of haemorrhage**<br>  − petechiae, bleeding erosions, mucosal fissures,<br>    ulcer, variceal bleeding<br>**5. **Tab. 19.3:** Forms and classification of upper gastrointestinal haemorrhage

## 2.3 Causes

Gastroduodenal ulcers account for 45−55% of cases of upper gastrointestinal bleeding, gastric or duodenal erosions for 25−35%, and oesophageal or fundus varices for the remaining 15−25%. Portal hypertensive gastropathy is frequently found together with portal hypertension. (24, 33, 39−41, 43, 49−51) Extensive haemorrhaging can often be observed in cases where a clotting dysfunction occurs simultaneously. • The spectrum of possible causes is exceptionally wide, particularly since manifest bleeding may originate from a combination of various (subthreshold) factors in individual cases. • Actually, ca. 5% of all cases of upper gastrointestinal haemorrhage remain aetiologically unresolved. (s. figs. 19.3−19.5) (s. tab. 19.4)

## 2.4 Diagnostics

Upper gastrointestinal bleeding may be either chronic or acute. It becomes manifest as severe or slight haemorrhages of arterial, venous or capillary origin. (s. tab. 19.3) Elimination of the blood is effected by vomiting or in the stool.

| |
|---|
| 1. **Oesophageal, gastric and duodenal varices** (18−25%) |
| 2. Angiodysplasia (1%) (s. fig. 19.5)<br>3. Boerhaave's syndrome<br>4. Bouveret's syndrome (34)<br>5. Clotting defects (s. fig. 19.4)<br>6. Dieulafoy's bleeding<br>7. Duodenal ulcer (25−30%)<br>8. **Tab. 19.4:** Causes of upper gastrointestinal bleeding (with some references and frequencies)

**Fig. 19.3:** Haemorrhagic erosions in the stomach as the cause of bleeding

**Fig. 19.4:** Haemorrhagic gastritis in thrombopenia

**Haematemesis:** If bloody vomiting occurs immediately upon the onset of bleeding or if there is a deficiency of gastric hydrochloric acid or insufficient time for the formation of haematin, the vomited blood appears

*Fig. 19.5:* Angiodysplasia in the duodenum

bright red and is not foamy. After somewhat longer periods in the stomach, the blood becomes dark red to brown or black (so-called coffee ground vomitus).

**Melaena:** A recognizable elimination of blood from the intestine takes place when more than $60-70$ ml have accumulated in the lower intestine. As a result of bacterial and chemical action (lasting several hours), the stool becomes black in colour, so that a so-called tarry stool is observed. As a rule, the source of bleeding lies above the duodenojejunal flexure (ca. 90%). Melaena (s. p. 366) may, however, also arise from bleeding in the ileum or right colon − as could be demonstrated by the collection of blood in the caecum during appendectomy. The presence of larger amounts of blood in the intestine leads to an accelerated passage with diarrhoeal elimination.

**Occult blood:** Blood volumes of $< 50$ ml are not generally recognizable by discolouration of the stool, but must be demonstrated by special testing (e. g. test strips). (s. p. 366)

**Diagnostic goals:** The diagnostic procedure for upper gastrointestinal bleeding is largely standardized and has three main aims:

1. Estimation of the haemorrhagic activity
2. Quantification of the blood loss
3. Identification of the source of bleeding

**Circulatory parameters:** The determination of circulatory parameters allows a rough calculation of the amount of blood already lost as well as optimizing the subsequent diagnostic and therapeutic measures. Loss of more than $800-900$ ml blood (or less in older patients and in cases of anaemia) causes *circulatory symptoms:* tachycardia, fall in blood pressure, decrease in both cardiac output and venous return to the heart. A central venous pressure (CVP) of $< 5$ cm $H_2O$ suggests an unfavourable prognosis. The *Allgoewer-Burri index* has proved to be a useful, objective parameter:

**Allgoewer-Burri index**
*heart rate : systolic RR = index*

*index:*  0.5 = normal; 1.0 to 1.5 = impending shock with circulating blood decreased by about 30%; exceeding 1.5 = circulating blood decreased by about 50%

**Venous entries:** Venous access points (one or possibly two) must be created as quickly as possible and kept open. Circulatory stabilization by means of *volume substitution*, at best with monitoring of the central venous pressure, is crucial. Diagnostic or therapeutic endoscopy is only possible once the circulation has been adequately stabilized and any necessary *fresh blood* has been administered.

**Loss of blood:** The blood loss should be quantified by repeated determination of the *haemoglobin* and *haematocrit values*, because − depending on the severity of the bleeding − significant changes in these (and other) values only become evident after 2 to 4 hours due to the gradual flow of tissue fluid into the circulatory system.

**Laboratory parameters:** Once the initial blood sample has been taken to assess the blood loss, the following values must be determined immediately: *blood group, thrombocyte count, Quick's value, electrolyte profile* and *creatinine* as well as *fibrinogen* and *AT III levels.*

**Endoscopy:** It is essential that an endoscopic examination of the oesophagus, stomach and duodenum is carried out *as quickly as possible* under intensive care conditions with monitoring and pulsoximetry. The term "emergency endoscopy" is in fact misleading because upper gastrointestinal bleeding always constitutes an emergency and calls for immediate hospitalization and rapid diagnostic clarification.

▶ The **primary objectives** of initial endoscopy are: (*1.*) accurate identification of the location of the bleeding, (*2.*) evaluation of the bleeding activity, (*3.*) assessment of the danger of recurrent bleeding, and (*4.*) collection of coexisting findings. Endoscopy is 90−95% reliable in clarifying these questions (if necessary, repeated within a period of 12 to 24 hours). The **secondary objective** is to decide on the therapeutic consequences, such as conservative and/or local treatment, or surgical intervention. To this end, the use of endoscopy with the possibility of simultaneous therapy is the method of choice, for which there is no viable alternative.

The grounds for the **primary use of endoscopy** to clarify upper (and lower) gastrointestinal bleeding are: (*1.*) endoscopy is acknowledged as the procedure which reveals the most conclusive information; (*2.*) this diagnostic procedure also provides the opportunity of using various endoscopic techniques to effect local haemostasis; (*3.*) endoscopic techniques are more likely to be readily available than scintigraphy or selective angiography; (*4.*) endoscopy is significantly more economical in terms of time and cost than scintigraphy or arteriography; (*5.*) endoscopy is less stressful for the patient and less invasive than angiography.

**Complications** cannot be attributed to endoscopy itself, but to the pre-existing conditions: localized perforations, risks associated with aspiration, cardiac problems, lowered blood pressure, etc. Premedication may therefore be inappropriate in individual cases, and endotracheal intubation or endotracheal anaesthesia is then indicated.

349

**Stomach tube:** Use of a double-lumen stomach tube may be justified by several factors: (*1*.) detection of blood in the stomach, (*2*.) assessment of haemostasis, (*3*.) irrigation of the stomach to improve visibility during subsequent endoscopy, and (*4*.) permanent drip for clearing blood residues from the intestine to prevent the development of hepatic encephalopathy. (s. p. 277)

**Scintillation scanning:** In cases of intermittent haemorrhagic lesions or subacute bleeding, valuable diagnostic data are yielded within a period of 24−36 hours by the use of scintillation scanning, employing ⁹⁹ᵐtechnetium-labelled erythrocytes. The sensitivity of detection of bleeding is 93%, the specificity 95%, with an overall accuracy of 94%. Verification of bleeding by scintillation scanning is thus not only more reliable than arteriography, but is also far less invasive. (23)

**Angiography:** Selective angiography (coeliac artery, superior mesenteric artery) may be attempted if the haemorrhage site could not be localized by means of endoscopy and scintillation scanning. Angiography is also of intraoperative benefit. However, it is only possible to draw diagnostic conclusions with bleeding rates exceeding 0.5 ml/min. In individual cases, the administration of vasoconstrictor substances or an attempt at therapeutic embolization are rendered possible by using an in-situ angiography catheter.

## 2.5 Prognosis

**Spontaneous haemostasis:** Some 60−80% of all upper gastrointestinal haemorrhages cease spontaneously. Early diagnosis with simultaneous stabilization of the circulation facilitates such spontaneous haemostasis without further therapeutic measures being called for. In 10−15% of cases, the bleeding persists.

**Risk factors:** Several risk factors have a decisively negative influence on the prognosis. High-risk patients require particularly close observation. The necessity for surgical intervention may arise rapidly and often unexpectedly in such patients. Treatment is thus also directed at maintaining the patient in a permanent condition of operability. A new endoscopic index might possibly predict first bleeding from the upper gastrointestinal tract in patients with cirrhosis. (52) There is an almost linear correlation between the risk factors (s. tab. 19.5) and a negative prognosis or lethality. Larger vascular stumps at the base of ulcers (Forrest IIa, IIb) also show a tendency towards recurrent bleeding within 48 hours in 50% of cases. The risk remaining subsequent to the cessation of bleeding drops to less than 5% after 3 days and less than 1% after 7 days. (30, 35, 44, 45, 52)

**Surgical measures:** Surgical intervention is necessary in 5−25% of cases.

**Lethality:** Figures for lethality rates vary between 5−8% (and up to 30%). When no blood transfusion is necessary, the rate lies below 4%; when more than 6 units of blood have to be transfused, it rises to 50%.

Decisive factors influencing the **prognosis** of acute GI bleeding include: (*1*.) immediate stabilization of circulation, (*2*.) prevention of aspiration, (*3*.) type of bleeding (varicose, arterial, diffuse), (*4*.) intensity of bleeding and blood loss, (*5*.) age and possible comorbidity of the patient, (*6*.) success of the treatment, and (*7*.) recurrent bleeding. (s. tab. 19.5)

| |
|---|
| 1. State of shock in the hospitalized patient |
| 2. Initial Hb value <7 g/dl or haematocrit <30% |
| 3. Forrest state Ib/II |
| 4. Insufficient circulatory stabilization despite optimal volume replacement |
| 5. Consumption of >6 units of blood per 24 hours |
| 6. Advanced age of patient, depending on biological aging |
| 7. Concomitant illness: chronic liver, cardiac, pulmonary or kidney disease; diabetes mellitus; *etc.* |
| 8. Short-term recurrence of bleeding |
| 9. Ulcer patients after unsuccessful conservative therapy, possibly over an extensive period of time, and now requiring subsequent surgery |

**Tab. 19.5:** Significant negative prognostic risk factors in upper gastrointestinal bleeding

▶ In extensive bleeding from the larger arteries (e. g. gastroduodenal artery), surgery should be carried out immediately as opposed to losing valuable time with pointless endoscopic treatment.

## 2.6 Therapy

With the coexistence of liver disease, upper gastrointestinal bleeding poses special problems, either due to haemorrhagic complications or existing haemostatic disorders. • Therapy is initially determined by the *form, location* and *classification* of the bleeding. (s. tab. 19.3) The *causes* of bleeding will also have a substantial influence on the therapy to be implemented − depending on the respective underlying disorder. (s. tab. 19.4) *Risk factors* that have a negative effect on the prognosis will likewise have to be considered in any decision regarding therapy, which is why standard therapeutic procedures are justifiably varied in individual cases. A bacterial infection is another important risk factor, so that the administration of antibiotics (e.g. norfloxacin) is recommended. (s. tab. 19.5) (s. fig. 19.12)

### 2.6.1 Basic therapy

**Volume replacement:** Adequate volume replacement, when possible through *two venous entry points*, is initially of utmost importance. A central vein entry point is strongly recommended to facilitate the constant monitoring of pressure changes (CVP).

(*1*.) *Crystalloid i.v. solutions*, such as Ringer's solution, should only be used if the blood loss is relatively small (< 1 litre), since only 25−30% of the crystalloid i.v. solution has an effect on the volume. If administered in excessive amounts, this can lead to an undesired decrease in the colloidal pressure of the plasma. Crystalloid i.v. solutions, often containing *glucose* as a principal

energy source, also serve as carriers for any medicaments which may have to be added to the drip infusion. HES is an acceptable plasma substitute. • *The use of fructose, xylose and lipid solutions, high concentration glucose (= rise in portal pressure) or dextran products (= inhibition of thrombocyte aggregation) is generally not advisable.*

(*2*.) *Human albumin solution* has proved extremely reliable, especially when used in conjunction with crystalloid infusions. (Synthetic iso-oncotic colloids should be avoided as far as possible because of their negative effects on coagulation and kidney function.)

(*3*.) *Packed red blood cells* are indicated when the blood loss is >25% (Hb < 7−8 g/dl). In this event, at least 3 or 4 units of blood should be readily available, and sufficient reserves must be on hand. An Hb value of 10−11 g/dl is considered to be an adequate transfusion target. Degradation of the citrate normally present in conserved blood is delayed in the case of cirrhosis, so that a substitution of 10 ml calcium per 4 units of erythrocyte concentrate is advisable. In order to avoid transfusion acidosis (pH < 7.2), 40 mval bicarbonate are administered for every (4 or) 5 transfusions.

(*4*.) *Frozen fresh plasma* is used in cases of higher blood losses (>50%), or even earlier if necessary (e. g. in the presence of concomitant coagulation defects). (s. p. 346)

**Oxygen supply:** Supplementary oxygen supply via a nasal tube is recommended. The air passages must be kept unobstructed, if necessary by intubation.

**Gastrolavage** using a double-lumen tube may be of both diagnostic and therapeutic value in upper gastrointestinal haemorrhage. • Endobronchial intubation is strongly recommended for disturbances of consciousness.

**Bowel purgation:** In cases of gastrointestinal haemorrhage, large quantities of plasma proteins infiltrate the intestine. This results in an abundance of protein degradation products, which may cause **hepatic encephalopathy** in the presence of sustained failure regarding the detoxification function of the liver. In addition, the breakdown of intestinal blood releases a large amount of ammonia stored in the erythrocytes for systemic transport, thereby considerably accentuating the danger of HE. • *Blood must therefore be removed as rapidly as possible from the gastrointestinal tract!* To this end, a gastric tube is used (during endoscopy) to aspirate blood from the stomach. A swift and thorough intestinal purge is achieved by administering a 10% *mannitol solution* or *Golytely solution* through nasal intubation until a state of haemostasis is assured. Residual blood may also be flushed from the lower colon by additional *high enemas* with 300 ml lactulose (plus 700 ml water). This intensive intestinal purgation is followed by further treatment with lactulose. An additional infusion of *orni-*

*thine-aspartate concentrate* may be advisable for the prevention or treatment of HE. (s. p. 279)

### 2.6.2 Endoscopic haemostasis

A possible spontaneous haemostasis, which is found without active therapy in about half the cases of upper gastrointestinal bleeding, should on no account encourage the assumption of a passive approach with the postponement of suitable therapeutic procedures. There is an enormous danger of massive renewed haemorrhage as well as of the development of complications within a few hours following spontaneous haemostasis. (s. fig. 19.12)

▶ The development of effective procedures for endoscopic haemostasis − as well as the use of TIPS (48) − has significantly broadened the spectrum of treatment in cases of non-varicose, upper gastrointestinal bleeding. Endobronchial intubation is strongly recommended for disturbances of consciousness. In patients with acute upper GI bleeding, infusion of erythromycin (3 mg/kg BW over 30 minutes) before endoscopy improves the removal of blood and water from the stomach. Erythromycin is a motilin agonist and, as such, produces this favourable gastrokinetic effect. (29) These procedures have also improved the results achieved in differential therapy. In Forrest I and IIa, endoscopy is of prime importance. Three groups of **endoscopic methods** are available: (*1*.) topical procedures, (*2*.) thermal methods, and (*3*.) local injection techniques.

**1. Topical procedures:** Various compounds may be applied under endoscopic observation to the site of non-varicose bleeding or bleeding ulcerations following sclerotization. • The experience obtained with **adhesive fibrin** or **thrombin** is encouraging. This is also true of their application in *hypertensive gastropathy* and in *gastric antral vascular ectasia (GAVE)*. **Argon-plasma coagulation** (and possibly **laser** procedures) may also be used. Angiodysplasia is best managed using heat treatment, especially in the case of argon plasma coagulation.

**2. Thermal methods:** Various thermal methods may be employed successfully in clearly defined instances of non-varicose bleeding of the upper gastrointestinal tract:

(*1*.) The **heater technique** (R. L. PROTELL et al., 1978) involves the use of a plastic-coated metal probe, the tip of which is heated by means of a wire. Definitive haemostasis may be attained in 90−95% of cases. The heater probe has proved easy to operate and is free of complications. (27, 37)

> Whereas the heat of the heater probe is directly transferred to the site of bleeding, in the following types of probes, the electrical energy is transferred by high frequency diathermy.

(*2*.) The **monopolar probe** (C. R. YOUMANS et al., 1970) has a small differential electrode inside a catheter, which may be routed to the site of bleeding through the endoscope. At the same time, the non-differential electrode surface is fastened to one of the patient's extremities. Highly concentrated electrical energy is emitted from the probe and effects deep tissue coagulation. Primary haemostasis was achieved in 79−91% of the reported cases; recurrent bleeding only occurred in 6−8%. (30)

(*3*.) The **bipolar probe** (D. C. AUTH et al., 1980) has no non-differential electrode, both electrodes being built into the tip. In the most

widely used **BICAP** (= bipolar circumactive probe), a circular arrangement of several adjacent electrode pairs is incorporated into the probe tip. This limits the depth to which the electrical pulse penetrates the tissue. (30, 36, 46)

(*4.*) The **electrohydrothermoprobe** (EHT) (W. Matek et al., 1983) is a refinement of the monopolar probe. It allows a stream of water to be directed through the probe: the site of bleeding can thus be irrigated and rendered more easily visible, and at the same time, charring of the tissue in contact with the probe is prevented. In 92% of reported cases, definitive haemostasis was achieved, with recurrent bleeding in 11% of patients.

(*5.*) The high energy **neodymium YAG laser** (yttrium-aluminium garnet) has been used to treat bleeding gastrointestinal lesions (G. Nath et al., 1976). This method ensures deep tissue penetration of the energy, yet entails the disadvantage of a greater risk of perforation or ulceration. As with the monopolar probe, the tangential approach to the site of bleeding raises technical problems. On average, primary haemostasis was achieved in 90% (87−100%) of patients and definitive haemostasis in 43−90%. Complication rates of up to 4% have been reported. (42, 46)

Analysis of the literature reveals no significant differences between electrocoagulation and (very expensive) laser treatment procedures in terms of primary or definitive haemostasis. With laser therapy, the complication rate (0−4%) lies above that of electrocoagulation (0%). Heat and bipolar probes may be regarded as the most "tissue-friendly", an inference supported by the results of animal experiments, while laser and monopolar probe methods are more "aggressive". The electrohydrothermal probe offers a compromise. An additional consideration is that electrocoagulation and EHT procedures are technically uncomplicated, locally applicable and lower in cost compared to laser methods.

**3. Local injection techniques:** Differentiation must be made between the use of local injections in the therapy of non-varicose bleeding in the upper gastrointestinal tract and the treatment of bleeding oesophageal varices. (26, 30, 32, 42, 47)

Local injection treatment methods for non-varicose bleeding have proved uncomplicated, quick to carry out, independent of location, extremely reasonable in terms of cost and also very successful. • Absolute alcohol, adrenaline, polidocanol and hypertonic sodium solution are among the **active substances** used. (26) A combination of suprarenin and polidocanol has meanwhile been established as first choice: adrenaline (0.005−0.01%) is injected into the mucous membrane surrounding the lesion in order to induce vasoconstriction. Directly afterwards, polidocanol (1%) or a hypertonic NaCl solution may be injected at the edges of the lesion, resulting in local oedema with vascular compression and thrombosis. The reported effectiveness of this method for primary haemostasis is 83−100%, and definitive haemostasis is attained in 91−94% of cases. The *complication rate* is <1%.

If a blood clot is found at the bleeding site, it should be removed with the help of a probe or loop. This is followed by endoscopic therapy. In this way, the risk of rebleeding can be markedly reduced.

The spectrum of local injection treatment in gastrointestinal bleeding has been expanded and the results improved by the introduction of **N-butyl-2-cyanoacrylate** (J.P. Gotlib et al., 1981). This "fluid tissue glue" polymerizes instantly on contact with blood and rapidly forms an embolus-like occlusion at the site of bleeding. (s. p. 356) In addition, *fundus* and *stomach* as well as *duodenal varices* (K. Ota et al., 1998), which cannot be adequately assessed using standard sclerotization techniques, have become easier to treat. Tissue glue is still a possible therapy option.

**4. Haemoclips:** Employment of clips in cases of bleeding ulcers can be problematic, since precise application is often unsuccessful in the presence of severe bleeding or when the ulcer has undergone deformation through scarring. Nevertheless, clips are nowadays regarded as the first-choice alternative if other forms of therapy fail.

Good results have meanwhile been achieved using haemoclips: recurrent bleeding was reduced to <10%. When this technique was combined with subcutaneous injection of hypertonic sodium solution or adrenaline, the rate of recurrent bleeding dropped to <3%. (32) The clips do not destroy the tissue, and the ulcer healing process is not impaired. If the ulcer base is too firm, it becomes more difficult to attach the clips and it may not be possible to use them at all. They are particularly suitable for dealing with Mallory-Weiss bleeding and Dieulafoy's ulcer. It should be mentioned that such clips are still relatively expensive. (26, 27, 32, 37)

### 2.6.3 Drug-controlled haemostasis

The use of particular substances may be considered in concordance with the existing haemorrhage situation. (s. tabs. 19.3−19.5) These may constitute either an adjuvant therapy to endoscopic haemostasis or be used when endoscopic or surgical measures are not indicated or not possible. (22, 25, 28, 29, 40, 43, 51)

Application of pharmacological substances in existing portal hypertension is aimed at reducing both the portal pressure and the hyperdynamic circulatory status as well as improving the microcirculation in the gastrointestinal mucosa. • It also opens the door to the possibility of correcting the secretory and motor function status of the gastrointestinal tract in order to diminish the overall vulnerability of the gastric mucosa. • The instability of the clotting system is controlled by the administration of fresh plasma. These measures improve primary and definitive haemostasis as well as reducing the probability of any complications or recurrence of bleeding.

- Proton pump inhibitors
- Sucralfate
- Antacids, $H_2$-receptor antagonists
- Propranolol and its derivatives
- Vasopressin derivatives
- Somatostatin or octreotide
- Fresh plasma

# 3 Bleeding oesophageal varices

## 3.1 Oesophageal varices as collateral circulation

A serious **consequence of portal hypertension** is the formation of *collateral circulatory systems* with characteristic *haemodynamic circulation*. (s. pp 253, 737) An awareness of these possibilities heightens the understanding of the typical complications and provides grounds for the application of medicinal or invasive therapy for portal hypertension in the presence or absence of a haemorrhage. Enhanced inflow of blood from the splanchnic area into the portal vein or decreased resistance in the arterial splanchnic circulation (e. g. due to glucagon) will, however, increase portal hypertension. (s. p. 244) (s. tab. 14.8) (s. fig. 14.6)

► **Oesophageal varices,** like **cardia varices** and **fundus varices,** arise from a regional stasis of submucosal perioesophageal and paraoesophageal veins. • These varices are supplied by the left gastric vein and posterior gastric vein, while stomach varices are additionally served by the branches of the splenic vein and short gastric veins. Fundus varices may also receive a direct supply via a.v. shunts in the stomach wall. Neither the formation nor the presence of oesophageal varices shows any clinical signs. The development of Cruveilhier-von Baumgarten syndrome may protect cirrhotic patients from the risk of oesophageal varices forming and bleeding. (75) • *Elevated portal pressure is usually responsible for the formation of oesophageal varices.* (s. figs. 14.8−14.10)

## 3.2 Frequency and risks

Approximately 60−80% of all patients with portal hypertension develop oesophageal varices at some stage of their lives, half of them within 2 years and up to 90% within 10 years of the initial diagnosis. Retrogression or spontaneous disappearance of oesophageal varices has been observed in less than 1% of patients within one year, mostly in the wake of extended and strict abstinence in cases of alcoholic cirrhosis. In 90−95% of cases, the varices are localized in the middle and lower third of the oesophagus ("junction zone", i.e. in the area 2−6 cm above the oesophagogastric junction), and in 5−10% of cases, they are found in the area of the stomach fundus. Approximately 15% of patients have both oesophageal and stomach varices; these patients are particularly at risk with regard to haemorrhaging.

About 30−50% of oesophageal varix patients suffer from variceal bleeding during the course of their lives. • The risk of *initial haemorrhage* in a control group of untreated cirrhosis patients is approx. 20% per year (about 30% within three years). Most episodes of bleeding occur within the first year; altogether 70−90% occur within the first two years of observation. Some 20−30% cease spontaneously. The rate of *recurrent bleeding* (without prophylactic measures) is about 70% after the initial haemorrhage; the probability of a relapse is highest during the first week (75%), but is still relatively high after 3 months (30%). The prognosis is very poor in the event of early recurrent bleeding (more than twice within 2 days). (146, 190)

Primary oesophageal bleeding proves fatal in 30−40% of cases, despite adequate conservative treatment or emergency intervention. In general, 60−80% of patients survive longer than one year. Some 20−25% of all cirrhosis patients die as a direct result of bleeding oesophageal varices. • The lethality rate for each haemorrhage episode varies among the Child groups (A = 10%, B = 30−40%, C > 70%).

## 3.3 Predictive haemorrhagic factors

The *timing, degree of severity* and *frequency* of haemorrhage depend on numerous predisposing factors, which cannot, however, be used either as sole criteria or in individual cases to predict the respective risk of bleeding. Full awareness of such established risk factors (s. tab. 19.6) would be an important aid in defining previously non-haemorrhaging risk groups, affording the possibility of primary prophylactic measures. Severe splenomegaly and thrombopenia are also considered as risk factors. This aim has not become reality as yet. (137, 146, 147, 170)

► Bleeding oesophageal varices may be triggered by **three pathogenetic mechanisms:** (*1.*) critical pressure increase in the varices, especially when it is sudden (= *explosion hypothesis*), (*2.*) occurrence of flow turbulences with bidirectional blood flow in the varices (= *circulation hypothesis*), and (*3.*) inflammatory lesion at the varix surface with the formation of thin spots (= *erosion hypothesis*).

### 3.3.1 Increase in pressure

Oesophageal varices do not occur when the portal pressure lies below 10−12 mm Hg. It has been established that the risk of bleeding increases significantly in accordance with (*1.*) *size of the portohepatic pressure gradient*, (*2.*) *rise in the oesophageal varix pressure* (62, 148), and (*3.*) *subsequent growth in size of the varices*. The danger of recurrent bleeding also rises in relation to the variceal radius. A temporary elevation of the intravaricose pressure and the resulting increase in vessel wall tension may derive from one of several factors: the circadian rhythms (increase in nocturnal/early morning pressure), food intake, intra-abdominal pressure increase (from coughing, lifting heavy loads, choking, etc.) and even deep breathing as well as forceful respiratory movement. These may cause a sudden variceal rupture in isolated cases. (93, 144, 149, 162, 167, 169, 196) • An *upright posture* helps to limit the blood flow to oesophageal varices and hence reduces the risk of haemorrhage (110).

The **pressure gradient** (HVPG) between the portal vein and the inferior vena cava (measured as the difference between WHVP and FHVP) is regarded as a more meaningful criterion than the simple portal pressure, which may be influenced by a variety of factors. • (Portal vein pressure [P] = portal blood flow rate [F] x transhepatic vascular resistance [R]) • Measurement of the blood flow in the **azygous vein** by means of thermodilution reveals a strong correlation between the oesophageal varix pressure and the varix size, but no correlation with the risk of bleeding. The verification of a **hepatofugal blood flow** in the portal vein, splenic vein or superior mesenteric vein by duplex sonography predicts a limited risk of haemorrhage. The sonographic determination of a **hepatopetal blood flow** in the coronary veins correlates with a decreased tendency towards haemorrhaging. (219)

### 3.3.2 Endoscopic evaluation

In view of the methodological difficulties involved in the (direct or indirect) identification of relevant indicator

levels, endoscopy is the only proven method available for identifying meaningful parameters concerning varices and hence for estimating the risk of haemorrhage. • The **various criteria** to be assessed in each endoscopy may also be of individual relevance for prognosis:

1. **Size of varices:** The determination of the size of varices is of fundamental significance in assessing the haemorrhage risk. This has to be done according to different criteria: *grade I* = 1−3 mm (small), visible, or visible under strain; *grade II* = 3−5 mm, visible (medium-sized) twisted, solitary or corkscrew-like; *grade III* = 6−10 mm (large), lumen-occluding; *grade IV* = >10 mm (very large), lumen-occluding, red patches, thin spots.

2. **Localization of varices:** The identification of their location may likewise be useful for evaluation purposes: those in the lower oesophagus and in the cardia area are more likely to rupture. The simultaneous presence of *oesophageal* and *fundus varices* (10−15%) carries an increased risk of haemorrhage.

3. **Surface of varices:** An assessment of the appearance of the variceal surface provides valuable criteria. The colour may be classified on a scale from (connective tissue-like) white to (blood clot-like) blue. Occasionally, there may be circumscribed red patches or stripes, corresponding to blocked and dilated vessels in the mucosa or submucosa. These are accompanied by an abnormal elevation of oesophageal varix pressure. They may be classified as small, *cherry-red spots* (A. E. DAGRADI et al., 1966), *red wall markings* in the form of stripes or *haemocystic spots* of over 4 mm in size resembling blood-filled blisters (K. BEPPU et al., 1981). *Diffuse red areas* may signify thin patches on the varical wall. • *Under conditions of elevated pressure in the varices, the growing increase in wall tension and decrease in wall thickness culminate in the formation of so-called* **thin spots,** *which are significant indicators of the risk of haemorrhage.* Varices with red-coloured signs are subject on average to about 40% more pressure than those without such signs, and haemorrhage occurs two or three times more frequently in such cases.

▶ The **site of bleeding** can be located with precision in about 90% of cases. Haemorrhage may occur as seeping bleeding or as bright-red, spurting bleeding; there is often a "pulsation", synchronous with respiration. An inactive haemorrhage site may occasionally be observed in the form of a coagulate or as a whitish thrombocytic embolus located at the point of rupture.

**White nipple sign:** No confirmation could be given of the findings reported by R. S. CHUNG et al. (1984) that a white nipple sign (= fibrin embolus) on a varicose node (= *Mount St. Helen's sign*) pointed to an unfavourable prognosis and recurrent haemorrhage. (195)

### 3.3.3 Sonographic evaluation

*Endosonography* may be regarded as a diagnostic improvement over sonography. (147, 155, 167, 184) (s. fig.

19.6) The recognition, diagnosis and sclerosing of varices is more reliably achieved by endosonography than by conventional endoscopy. (227) • A better evaluation of the risk of recurrent haemorrhage is also afforded by *duplex sonography.* (186)

**Fig. 19.6:** Endosonographic detection of fundus varices

### 3.3.4 Child-Pugh criteria

Child-Pugh stage C (ascites, icterus, encephalopathy, albumin deficiency, drop in Quick's value) and regular alcohol abuse increase the frequency of haemorrhage and worsen the prognosis. *Coagulopathy* and *hyperfibrinolysis* are also considered to be additional risk factors, especially since higher fibrinolytic activity has been demonstrated in the mucosa of oesophageal varices. A correlation between the appearance of large *spider naevi* (>15 mm in diameter) on the skin surface and the onset of bleeding oesophageal varices was established by B. VARELA FUNTES et al. (1950). • A change in body position (e.g. bending over, lying down), cardia insufficiency, oesophagitis and gastro-oesophageal reflux have *no influence* on the tendency towards variceal bleeding.

### 3.3.5 CT and MRI

In some cases, it may be helpful to use CT with gastric varices (183, 224) or MRI with oesophageal varices (140), portal biliopathy (78) and bleeding of gall-bladder varices. (79)

## 3.4 Clinical aspects

**Haematemesis:** Oesophageal bleeding usually begins unexpectedly and without any characteristic preliminary signs. The onset is frequently in the evening, during the night or in the morning − possibly relating to the circadian rhythm of the portal pressure increase, vascular tone or clotting factors. (93, 144, 196) The haemorrhage often presents as surging haematemesis, and volumes of 500−1,000 ml of blood are vomited. The renewed accumulation of blood in the stomach may give rise to further surging haematemesis after a certain "pause in bleeding".

► **Endoscopic findings:** An endoscopic diagnosis of the haemorrhaging should be undertaken as a matter of priority as quickly as possible after the circulation has been sufficiently stabilized. This has *three objectives*: (*1*.) exact localization of the source of bleeding, (*2*.) determination of the haemorrhage criteria, and (*3*.) assessment of coexistent findings. Additional, nonvariceal sources of haemorrhage occur in up to 30% of cases in the presence (and even absence) of varices. (s. fig. 19.7) *Decisive therapeutic consequences can be derived from this.*

**Fig. 19.7:** Fresh bleeding of the oesophageal varices (first bleeding)

In the evaluation of the various **risk factors** hitherto discussed, which have also been expressed as quantifiable *scores* (NIEC score, München score), a simplified and practicable scheme may prove useful. (s. tab. 19.6)

| Parameter | Low risk / I | High risk / III |
|---|---|---|
| 1. **Varix size** | small (3−5 mm) | large (> 6 mm) |
| 2. **Fundus varices** | absent | present |
| 3. **Red-coloured signs** | slight | strong |
| 4. **Variceal pressure** | < 15 mm Hg | > 16 mm Hg |
| 5. **Localization** | mid-oesophagus | lower oesophagus |
| 6. **Alcohol** | abstinent | habitual user |
| 7. **Hyperfibrinolysis** | no | yes |
| 8. **Thrombopenia** | no / slight | strong |
| 9. **Splenomegaly** | slight | strong |
| 10. **Child-Pugh stage** | A ⟶ B | C |

**Tab. 19.6:** Relevant parameters as distinct risk factors for assessing the haemorrhagic tendency of oesophageal varices

**Circulatory disturbance:** There is great variation in the effects of oesophageal bleeding on the circulation, depending on individual circumstances. Sometimes, only slight tachycardia and hypotension are presented despite extensive bleeding, whereas in other cases, a critical state of shock is rapidly induced, often leading to death. Sudden, unexpected transitions from an apparently compensated circulatory condition to a deleterious haemorrhagic shock must always be anticipated. The monitoring and evaluation of *circulatory parameters* are thus of utmost importance. (s. p. 349)

**Complications:** The possible outcome of oesophageal haemorrhage can take the following forms: (*1*.) haemorrhagic shock, (*2*.) acute liver or kidney failure, (*3*.) hepatic encephalopathy (culminating in hepatic coma), (*4*.) consumptive coagulopathy, and (*5*.) aspiration pneumonia.

## 3.5 Conservative therapy

### 3.5.1 Basic therapy

The basic treatment of bleeding oesophageal varices is carried out under intensive care conditions. It essentially corresponds to the procedures for upper gastrointestinal haemorrhage. (s. pp 350, 351) The therapy has **three main objectives:**

1. *Volume replacement* for circulatory stabilization
2. *Gastrointestinal irrigation* to prevent hepatic encephalopathy
3. *Monitoring of haemostasis* to prevent coagulopathy

*Volume replacement* should not increase the CVP beyond 4−5 cm $H_2O$ or the haematocrit beyond 35%, since there is a danger of recurrent bleeding from the oesophageal varices in the event of overcompensation. *Haemostasis parameters* (e.g. thrombocyte count, Quick's value, fibrinogen, AT III) must be continually monitored, so that any need for volume replacement is recognized immediately. • A *torsade de pointes* (special form of ventricular tachycardia) may arise in the case of an electrolyte imbalance combined with vasopressin and neuroleptics. (88) (s. fig. 19.8)

### 3.5.2 Sclerotherapy

► The sclerosing of bleeding oesophageal varices was first carried out by C. CRAFOORD et al. (1939). They injected the agent quinine-uretan (used at that time to sclerose haemorrhoids) into the varices (82) via an oesophagoscope applying their own customized needle. This method was taken up by E. WODAK in 1958 and subsequently recommended for the periodic treatment of bleeding oesophageal varices. Positive clinical results employing a paravaricose sclerosing technique were likewise reported by H. DENK (1963).

**Primary haemostasis:** According to many publications, this highly effective method has a success rate of 80−90% (60−100%) for establishing primary haemostasis in all patients.

**Definitive haemostasis:** Definitive haemostasis can only be considered as "certain" after the complete sclerosing of oesophageal varices carried out during several (in general 4 to 6) days of treatment within a period of 6 to 8 weeks.

The sclerosing of oesophageal varices has become standardized routine procedure over the past 20 years.

**Methods:** Many technical modifications in the field of sclerotherapy have been reported and evaluated in a variety of publications. Variations in method include the range of instruments, injection technique, amount and concentration of the sclerosant per punc-

ture as well as over the whole treatment period, needle gauge and time lapse between treatments. The results achieved are nonetheless largely identical. The method selected ultimately depends on the experience of the physician involved and, in individual cases, on the particular clinical picture. (181, 199)

▶ Endoscopic sclerosing is normally carried out under i.v. sedation, employing **flexible instruments** with a wide suction channel. General anaesthesia is recommended in difficult cases of severe bleeding. • The use of a **rigid oesophagoscope** may be advantageous for endotracheal anaesthesia in special circumstances (compression of strongly bleeding varices, localized focusing on varicose nodes within the endoscope aperture, improved aspiration of blood). Such a technique is, however, in itself more difficult. *Adequate experience in "rigid" methods is without doubt extremely advantageous in intensive care situations.*

▶ Intravascular, paravascular (submucosal) or combined **injection techniques** may be employed. • An *intravaricose injection* results in immediate thrombosis and subsequent fibrosis of the varices. • The *paravaricose technique* facilitates first the compression of the haemorrhaging varices and then the (submucosal) formation of coarse scar tissue, which prevents variceal rupture and maintains the collateral integrity of the venous lumen at the same time. Replacement of the entire oesophageal mucosa by a connective tissue lining may be necessary to allow the complete eradication of varices. Paravascular injection often results in the sclerosing of varices. No significant differences between the efficacy of each of the two methods have been demonstrated. Moreover, the usual "free-hand" nature of clinical treatment renders any strict differentiation between intra- and paravascular methods very difficult. • Preference is thus given to the *combined injection technique* (N. SOEHENDRA et al., 1981), especially since the sclerosing of varices is more rapidly achieved by this method and rebleedings or the appearance of new varices are more seldom. • It is important for successful treatment that sclerosing begins at the gastro-oesophageal junction and proceeds proximally.

▶ The following **sclerosants** are generally applied: polidocanol (0.5%−3.0%), ethanolamine oleate (5%), sodium morrhuate (2.5−5.0%), aqueous phenol solution (3%), sodium tetradecylsulphate (1−3%), ceplacolin (95%), phenolic almond oil (5%) and ethyl alcohol (45%). • **Polidocanol** (hydroxypolyethoxydodecane) is the most frequently used. The higher the concentration of the sclerosing agent, the greater is the frequency of side effects. However, the sclerosing impact is far more reliable, including the "desired" local inflammation with scar formation. The most effective sclerosant (within ca. 20 seconds) is **N-butyl-2-cyanoacrylate** (0.5 ml + 0.7 ml lipiodol), which may only be injected into the varicose vein! (198) It is already used widely as a method of choice. Technical speaking, an endoscopic operation is time-consuming and calls for perfect teamwork if tissue damage and clogging of the instrument are to be avoided. Possible risks for the patient include mediastinitis, local ulcerations and systemic embolisms. (86, 90, 133, 151) (s. p. 352) • The combined use of butylcyanoacrylate and ethanolamine oleate has also been reported. (207)

**Injection volumes** of 1−2 ml per paravascular technique and 3−5 ml per intravascular technique are recommended, with a maximum of 30 ml per day. A total of ten injections may be required for each treatment session.

A **one-week interval** between treatment sessions (about 3 to 7 days for paravascular injection, at least 7 days for intravascular injection) has proved to be effective for obliteration of varices by means of repeated sclerosing (usually a total of 5 to 6 sessions).

**Advantages:** There are obvious advantages in using sclerotherapy: (*1.*) high effectiveness, (*2.*) low complication rate, (*3.*) no deleterious effects on haemodynamics or liver function, (*4.*) simplicity of use, (*5.*) patient acceptance, and (*6.*) well-balanced cost-benefit ratio.

**Complications:** The frequency of complications fluctuates considerably, and thought must be given to the great differences between the various haemorrhage patients. Generally, complicative developments can be anticipated in 10−20% of cases (when flexible instruments are used). Serious complications occur in 1−3% of cases. Lethality has been reduced to 1%. (60, 118, 135, 143, 187) • Approximately *40 different types of complications* have been reported: radiologically demonstrable thoracic findings (80−85%) (189), oesophageal strictures (10−15%) (127), thrombosis of the subclavian vein, bleeding from sclerosing ulceration (5−10%) (188, 226), perforation of the oesophagus (1−2%), broncho-oesophageal fistula, mediastinitis, infection or bacteraemia (105, 175) including pyogenic meningitis and cerebral abscess (222), formation of haematoma (179), gastro-oesophageal reflux (see below) (121), pleural effusion (59), chylothorax (73) and other pleuropulmonary complications (189), pericarditis or pericardial effusion (124), arrhythmias and myocardial ischaemia, peritonitis (203), ascites, thrombosis of the portal vein (129), development of squamous cell carcinoma (68, 98, 113, 128), etc. • The use of polidocanol can lead to considerable cardiodepressive effects. The potential danger of embolism, particularly of cerebral embolism, has been mentioned in connection with butyl-cyanoacrylate application. Disseminated coagulopathy has been described following repeated injections of ethanolamine oleate. • Life-threatening ventricular arrhythmias, so-called **torsade de pointes**, have been observed subsequent to the application of neuroleptics or vasopressin as well as in the case of electrolyte imbalances. (88) (s. fig. 19.8)

*Fig. 19.8: Torsade de pointes:* The QT interval represents the phase of myocardial spread of stimulus and repolarization. Excessive QT lengthening may be caused by certain drugs or electrolyte imbalance. In addition, a U wave can occur, whereby its amplitude exceeds the T wave in $V_4-V_6$. Subsequently, a potential life-threatening arrhythmia of type torsade de pointes may develop. Clinical symptoms include vertigo and syncopes. This arrhythmia can spontaneously disappear, but also pass into ventricular fibrillation and thus end fatally

**Side effects:** Side effects such as erosions, superficial ulceration or mucosal necrosis can be expected in >80% of cases. Sucralfate, cimetidine, ranitidine and omeprazole (116) as well as fibrin adhesive have been used both for prevention and to promote healing. From a morphological viewpoint, these inflammatory tissue reactions are to a certain extent necessary to induce thrombosis and vessel wall fibrosis. Fever, leucocytosis, chest pain and tension occur as frequent yet usually insignificant concomitant reactions. Dysphagia or dysfunction of the oesophagus are of no clinical significance. The develop-

ment of a gastro-oesophageal reflux is the subject of some controversy.

**Indications:** The use of sclerosing therapy − *which has been widely replaced by banding therapy!* − is based on three indications (s. fig. 19.12):

> 1. in acute bleeding of oesophageal varices
> 2. for preventing the recurrence of bleeding
> 3. as a preventive measure against primary haemorrhage

▶ **Primary haemostasis:** *Acute sclerosing* is generally performed during the first endoscopic examination. The rate of haemostasis is 70−95(−100)%. The frequency of (early and late) recurrent bleeding has been reduced to 30−50%, most effectively after several months when all varices have been obliterated. Nevertheless, an annual risk of recurrent bleeding of 10−20% remains due to newly formed varices, especially in the stomach fundus. Inpatient mortality is about 20%. However, more ways are being found to improve the life expectancy of the patient.

If acute sclerosing is not possible or has failed due to massive haemorrhaging, the *balloon tamponade* may be used to provide temporary relief until the circulation has stabilized sufficiently. (s. p. 358) However, this is only effective (about 80%) for a limited period of time. • Adjuvant *medicinal therapy* to reduce portal pressure is helpful. (s. p. 360) • At this stage, *elective sclerosing* can generally be performed with better visibility and circulatory conditions. In approx. 70% of cases, primary haemostasis can be achieved by means of acute or elective sclerosing. It is seldom necessary to perform portal vein surgery. (58, 61, 65, 83, 90, 91, 94, 96, 97, 103, 104, 106, 115, 123, 130, 139, 143, 157, 163, 164, 190, 192, 194, 199, 200, 201, 204−207, 209, 210, 214, 216, 217, 221)

The sclerosing of acutely bleeding fundus or stomach varices is more difficult from a technical point of view. (120, 183, 198, 224) In this respect, the use of **butylcyanoacrylate** is a genuine step forward. (84, 86, 90, 133, 151) More effective haemostasis and a lower rate of late recurrent bleeding (about 8%) may also be achieved in sclerosing oesophageal varices using this substance, which is only administered intravascularly! Adverse effects include delayed rejection of the plastic-like plugs (after 6 to 8 weeks) and protracted healing of the defect. (s. p. 356) • *Pregnancy* does not preclude successful sclerotherapy. (111, 126) • *Nutrition* has no influence on the complication rate of sclerotherapy.

▶ **Interval sclerosing:** There is *recurrence of bleeding* in 30−40% of patients within the first 5 or 6 days. The prevention of a relapse is the most important consideration in the weeks following the successful treatment of primary haemorrhage. This *secondary prophylactic measure* made it possible to reduce the rate of potentially fatal recurrent bleeding from 70−80% to 30−40% over an

observation period of 1 to 4 years as compared with a control group. The importance of acute sclerosing for primary haemostasis and of interval sclerosing for the prevention of relapses as well as in a long-term prophylactic strategy is undisputed. • The next sclerosing step is performed within the first 3 to 7 days and repeated at weekly intervals until the varices have been completely obliterated. Interval sclerosing, each time lasting 1 or 2 days, is undertaken during a hospitalization period. Endoscopic follow-up is carried out at 2 to 3-month intervals, with further sclerosing in the event of any recurrence of varices. • During the **bleeding interval,** the following procedures are available: (*1*.) programmed *sclerosing* or *ligature treatment*, (*2*.) supplementary *drug therapy*, and (*3*.) portosystemic *shunting*. These three procedures must be employed consistently in accordance with the specific conditions of each case.

**Prognosis:** The *renewed formation* of collateral varicose lesions appears in 40−60% of patients within 2 years following the eradication of varices, although these patients tend to suffer fewer relapses of bleeding than those without these new shunts. Fundus varices are found in 2−7% of cases. The question of a prognosis *quoad vitam* cannot be resolved simply in terms of the technical success of sclerosing, but is also substantially influenced by the prevailing liver function and by portal hypertension. In the first year, the survival rate in the Child A group proved to be significantly higher (80−95%) than in the Child C group (40%). Meta-analyses confirm the superiority of acute and interval sclerosing over non-endoscopic procedures not only with respect to primary haemostasis and the prevention of bleeding, but also regarding the improvement of survival time. The prognosis for fundus varices, which are physically less accessible to therapeutic measures, is generally not so favourable. (77, 101, 106, 178, 201, 220)

**Gastric varices** are found in the fundus or in the region of the cardia. They have a lower rate of bleeding than oesophageal varices (5−10% of all acute variceal bleeding), but a higher lethality. Due to their deeper location in the submucosa in comparison to oesophageal varices, common sclerotherapy or banding is generally ineffective and may even aggravate the bleeding. Isolated gastric varices are mainly found in splenic vein thrombosis. Therapy is based on direct injection of N-butyl-2-cyanoacrylate into the lumen of the varices (56, 84, 86, 120, 133, 151, 183, 224), balloon tamponade (156) or balloon-occluded retrograde transvenous obliteration. (122, 191) (s. fig. 19.9)

**Duodenal varices** are rare. Consequently, their frequency is poorly documented. They are present predominantly in patients with prehepatic portal hypertension. Possible therapy options include banding and medication (terlipressin, octreotide, later on β-blockers, etc.) or placement of a TIPS (provided there is no portal thrombosis). (63, 117)
*Fig. 19.9:* Large varix in the gastric fundus with erosion

### 3.5.3 Endoscopic variceal ligation

▶ Following the propagation of rubber band ligation for haemorrhoids by J. Barron (1963), oesophageal varix ligation was later introduced by G. Van Stiegmann et al. in 1986.

**Method:** After sucking a varicose cord into a chamber at the tip of the endoscope, a rubber ring is applied around the respective varix in order to strangulate the bleeding varicose nodule. Between 6 and 10 varices can be ligated during one session (= speedband). An application set is available for clinical use. The multiligator top can carry as many as 6 to 8 rings. As a rule, 4 or 5 sessions are held at weekly intervals. • A rare *complication*, with lethal outcome in one case, is oesophageal perforation. This event can presumably be attributed to the entrapment of the oesophageal mucosa in the 6 mm aperture between endoscope and conductor, with subsequent rupturing upon further penetration of the piloting tube. Another rare complication is cerebral artery air embolism.

The reported **advantages** over sclerotherapy are (*1.*) lower rate of complications (2% vs. 22%), (*2.*) reduced occurrence of strictures or oesophageal dysphagia, (*3.*) swift and efficacious placement, (*4.*) lower frequency of recurrent bleeding (36% vs. 48%), (*5.*) ligation-related ulcerations are flatter and their healing is more rapid, (*6.*) fewer sessions are required, and (*7.*) mortality rate is lower (28% vs. 45%). The prerequisite is that the method is applied in such a way as to ensure precise placement. *This form of therapy has proved successful and even superior to sclerotherapy.* The ligation set, however, reduces the field of vision by about 30%, and aspiration of blood is hence rendered more difficult. At the Child A stage, this method is very efficient; in Child B, it is only indicated under certain conditions. This applies both to the treatment of acute variceal bleeding and secondary prophylactic strategy. • *After many years of experience, rubber-ring ligation has become the method of choice.* However, an initial rubber-ring ligature followed by sclerotherapy is also recommended. Mean success rate is 90−92%. (96, 97, 103, 106, 130, 133, 134, 139, 160, 162, 177, 182, 185, 190, 194, 202, 204, 214, 218, 225, 226)

### 3.5.4 Balloon tamponade

Massive bleeding can be effectively controlled by mechanical compression of bleeding oesophageal or fundus varices, yet only for a limited period of time. Unless the bleeding is life-threatening, it is necessary to carry out a preliminary endoscopic examination in order to localize the source of bleeding for ensuring accuracy in the selection and placement of the tube. (s. fig. 19.12)

The use of balloon tamponades in the form of the *Sengstaken-Blakemore tube* or *Linton-Nachlas tube* constitutes rapid and highly effective **emergency treatment**; this technique is initially necessary in some 10−15% of cases of acute bleeding. It guarantees primary haemostasis in about 80% (75−100%) of cases. Care should be taken in choosing a suitable balloon tube for each individual case. This method is indicated in cases of massive bleeding where no specific sclerotherapy or rubber-ring ligation is feasible because of greatly impaired visibility. The balloon tube may also be indicated in massive bleeding to bridge the time span until the circulation has been stabilized and the planned measures can be applied (even during transportation of the patient). It should also be possible to insert a balloon tamponade under intensive care conditions as and when required. As regards other causes of upper gastrointestinal bleeding, the balloon tamponade method is not appropriate, except under special circumstances. (92, 114, 156, 157)

The **Sengstaken-Blakemore tube** (s. fig. 19.10) is the most widely used type. It comprises *4 channels*: gastric tube, gastric balloon tube, oesophageal balloon tube, and tube for aspiration from the oesophagus via the tamponade. The tube is lubricated (by means of glycerine or liquid paraffin) and introduced through the nose (or if necessary through the mouth). The correct position of the tube in the stomach can be checked by auscultation when blowing air is blown through the lumen or by X-ray. The gastric balloon is inflated with 150−250 ml air (secured with 2 clamps) and carefully fixed to the nose (or the mouth). It is not recommendable to weight down the tube. After the balloon has been appropriately positioned in the fundus, the oesophageal tube is inflated under manometric control to a pressure of about 40 mm Hg (generally, the oesophageal varix pressure does not exceed 30 mm Hg). At intervals of approximately 2 hours, the tube should be unblocked for 10 to 15 minutes to maintain the mucosal blood flow. It is imperative to keep the patient and the endoscopic technique under continuous surveillance. Should the aspiration controls via the gastric and oesophageal tubes indicate a satisfactory degree of haemostasis, the oesophageal balloon is deflated, while leaving the gastric balloon inflated in the same position. After a further period of 6 to 8 hours without recurrence of bleeding, the gastric balloon is likewise unblocked and the Sengstaken tube removed. The patient is kept in a head-up position throughout the whole procedure. • A different model, known as the **Minnesota tube**, is equipped with an additional feature to allow aspiration of the oesophageal contents above the balloon.

The **Linton-Nachlas tube** (s. fig. 19.11) has *3 channels*: gastric tube with several lateral openings, tube for the pear-shaped gastric balloon, and oesophageal tube with lateral openings for aspiration. The gastric balloon is inflated with 350−500 ml air (depending on the physical stature of the patient) and drawn into the fundus and cardia area as well as into the lower oesophageal section by weight traction (500−750 g). This ensures good compression of the varices. As a rule, the tamponade can be maintained for 36 hours,
*Fig. 19.10:* Sengstaken-Blakemore tube (R.W. Sengstaken, A.H. Blakemore, 1950): 1. oesophageal tube, 2. gastric tube, 3. gastric balloon tube, 4. oesophageal balloon tube

*Fig. 19.11:* Linton-Nachlas tube (R.R. Linton, 1953; M.M. Nachlas, 1955; L. Bertrand, H. Michel, 1969): 1. oesophageal tube, 2. gastric tube, 3. balloon tube

with no intermittent unblocking. After this period of time, the weight for traction is removed, yet the position of the tube remains unchanged for a further period of 12 hours. Hourly lavage and aspiration yield reliable information on the therapeutic results. In order to prevent nasal ulcers, pressure and rubbing should be avoided as far as possible. It is imperative for the patient to maintain a supine position with the head raised and secured by means of sandbags. • *The tube currently in use was developed by L. Bertrand and H. Michel (1969).*

**Complications:** In 15−20% of patients, aspiration pneumonia, ulceration, oesophageal rupture or asphyxia occur as a result of the dislocation of the tube. Therefore, the *range of indications for endotracheal intubation* should be kept narrow. The overall duration should not exceed 6 to 12 (to 24) hours. The use of the tube is rather unpleasant for the patient. Care of the patient as well as medicotechnical measures are rendered difficult by the indwelling tubes. After the balloon tube has been removed, **recurrent bleeding** can be expected in 30−50% of cases. This may necessitate another tamponade; alternatively, endoscopic procedures or medication for haemostasis might now be employed. • *In cases of adequate therapeutic success, further measures for a definitive haemostasis of bleeding oesophageal varices must now be initiated without delay.*

### 3.5.5 Prevention of primary bleeding

K.J. Paquet (1982) suggested the **sclerosing of varices** as a preventive measure and put forward a system of grading to assess risk patients for primary prophylactic procedures. Even though the size of the varix (degrees III and IV) generally correlates with the risk of bleeding, the *compiling of a prognostic index* proved unreliable, since it is virtually impossible to estimate the danger of haemorrhaging in the individual. This applies especially to the risk associated with prophylactic sclerotherapy and shunt operations. The results made available in the meantime have proved to be variable and controversial, for which reason primary sclerosing is not recommended as a preventive measure. Nevertheless, according to a meta-analysis, primary prophylactic measures using polidocanol were significantly more effective in improving the survival time when compared to a reference group, particularly in patients with a greater risk of bleeding. (54, 89, 136, 176, 180, 182, 213, 215) • Preventive **variceal ligation** is as effective and safe in patients with Child-Pugh A and B, especially in combination with nadolol, and in fact offers a greater chance of survival than do β-blockers. (108)

**Prophylactic medication** consists of *β-blocking agents* (propranolol, timolol, nadolol). (s. p. 323) The risk of primary bleeding could be reduced by about 50%. (69, 80, 145, 165, 168, 176) • Parallel treatment with *isosorbide mononitrate, molsidomine* and *spironolactone* is recommendable from a pharmacological point of view. Portal venous pressure should be 20−30% lower. • Previous studies have shown that all patients with cirrhosis and oesophageal varices should be given primary prophylactic medication.

Alcohol, acetylsalicylic acid and NSAIDs should be avoided. There is no advantage to be gained from not consuming certain foods (such as spices) or from the long-term intake of $H_2$ blockers.

### 3.5.6 Medicinal treatment

> In bleeding oesophageal varices, **adjuvant medication therapy** is advisable for reducing portal hypertension. This can be achieved by (*1.*) lowering vascular resistance with the help of vasodilators, (*2.*) cutting down the blood flow into the oesophageal collaterals with the help of substances which restrict the arterial splanchnic circulation, or (*3.*) applying a combination of these two therapeutic procedures. (61, 83, 100, 150, 160, 190)

In 1956 **vasopressin** was recommended for the first time to treat bleeding oesophageal varices (J. H. KEHNE et al.). Acute bleeding is temporarily arrested within a few hours in 50(−70)% of patients (0.4−0.8 U/min, i.v.). In addition to the pressure reduction in the splanchnic vascular bed (20−30%) and in the varices (ca. 15%), there are, however, also occurrences of coronary spasms, ventricular arrhythmia (88), hypertension, colicky abdominal pain and ischaemic organ lesions. By combining vasopressin with **glyceryl trinitrate** (0.4 mg, sublingually or i.v.), the frequency of side effects can be reduced (31%) and the elevated portal pressure lowered. Vasopressin has largely been replaced by its synthetic derivative terlipressin.

▶ **Terlipressin** has been used for bleeding oesophageal varices since 1975 (K. F. ARONSEN et al.). This "prodrug" is converted by enzymatic splitting off of the three glycine residues into active lysovasopressin, which results in an even distribution in the plasma and a prolonged effect (half-life of 3 or 4 hours). Terlipressin is administered at 4 to 6 hour intervals (1−2 mg in 10 ml isotonic NaCl solution). Following a bolus injection of 2 mg, the intravaricose pressure is reduced by about 30% within 2 minutes, and HVP is significantly reduced over a period of 4 hours. Haemostasis was achieved in 60−90% of cases. Terlipressin can be successfully combined with a **nitrovasodilator,** whereby the side effects of the vasoconstrictors are decreased. The combination of terlipressin and nitrates is the most beneficial drug regimen for bleeding oesophageal varices. Comparative studies on balloon tamponade, sclerotherapy and somatostatin have also demonstrated the efficacy of terlipressin. (57, 85, 91, 92, 109, 161, 193, 197) (s. p. 863)

▶ **Somatostatin** has been recommended as medication for bleeding oesophageal varices since 1979 (L. THULIN et al.). It lowers the elevated portal pressure and reduces the blood flow in the azygous vein. The ideal dosage is 250 µg as an i.v. bolus administered immediately after emergency admission, followed by 250 (−500) µg/hour as i.v. infusion. The arterial splanchnic blood flow is decreased by 20−30% with unchanged systemic pressure. This facilitates sclerotherapy and at the same time improves therapeutic efficacy. In the presence of diabetes mellitus, it is advisable to check the blood glucose levels repeatedly, since there may initially be a reduction and

later an increase in blood glucose. Somatostatin probably antagonizes the effect of glucagon. The haemostatic effect of somatostatin is well documented (64% vs. 41%) (72, 99); the drug has proved to be almost equivalent to terlipressin, but superior as vasopressin. Comparative studies with balloon tamponade or sclerotherapy also indicated that the results achieved with somatostatin were virtually identical in terms of primary haemostasis in 80% of cases. (58, 72, 114, 164, 192) Somatostatin may also be indicated as concomitant treatment after sclerotherapy and ligation for 5 to 7 days, since the danger of recurrent bleeding is particularly great during this period of time. (65, 115, 161) (s. p. 863) • The synthetic derivative **octreotide** has a good effect (reduction in mesenteric perfusion, HVWP, blood supply into the azygous vein and intravaricose pressure) in 80−85% of cases and possesses a much longer half-life than somatostatin (1−2 hours vs. 2 minutes). A dosage of 25−50 µg/hr is recommended as a continuous i.v. infusion. Octreotide has only few side effects. Recent results favour octreotide over vasopressin/ terlipressin. (81)

| | Initial bolus | Maintenance dose | Duration of therapy |
|---|---|---|---|
| **Terlipressin\*)** **Somatostatin** **Octreotide** | **2 mg i.v.** **250 µg i.v.** **50 µg i.v.** | **1−2 mg/4 hr i.v.** **250 µg/hr i.v.** **25−50 µg/hr i.v.** | **2 days** **5 days** **5 days** |
| \*) in combination with glyceryl trinitrate (20 mg/24 hr transdermally, or 40−70 µg/min i.v.) | | | |

▶ **Losartan** is an antagonist of angiotensin-II receptor. With oral administration (25 mg/day), portal hypertension could be significantly reduced. Side effects were not observed.

▶ **Metoclopramide** reduces the intravaricose pressure by restoring the normal tone to the lower oesophageal sphincter. The use of metoclopramide for the prevention and treatment of oesophageal varix bleeding is thus another pharmacological alternative. The haemodynamic effects of portal hypertension are not influenced.

▶ **Nitrates** were used to produce a favourable effect on portal hypertension: isosorbide dinitrate, isosorbide mononitrate (55, 69, 134, 136, 145, 217, 218) and glyceryl trinitrate (92, 149). *Glyceryl trinitrate* can easily be controlled owing to its short half-life of 5 minutes. It is also effective upon transdermal application (10 mg/day).

**Molsidomine** (L. R. DEL ARBOL et al., 1989) diminished the hepatic venous wedged pressure and the hepatic venous pressure gradient as a acute effect. Furthermore, in long-term oral treatment (3 to 6 months), the variceal pressure decreased by 28% and the hepatic venous pressure gradient by 25%, with a simultaneous reduction in the size of varices of about 17%. (107) A dose of 2 mg proved adequate. Orally applied molsidomine can thus be recommended for long-term prophylactic medication. • In fur-

ther studies, octreotide or the balloon tamponade were found to be superior to the combined application of nitroglycerin + terlipressin or nitroglycerin + vasopressin. (193) • The combination of *nitrates with β-blockers* has proved to be more effective than monotherapy in reducing portal hypertension. (217)

▶ **Propranolol** was used for the first time as a *β-blocking agent* for prophylactic measures with regard to bleeding oesophageal varices (D. LEBREC et al., 1980). By dilating the splanchnic vessels, it leads to a lower blood flow into the portal vein and thus a decrease in portal hypertension of 20−30%. This effect is only maintained when the intake is regular, although careful monitoring of the cardiac and circulatory function is still necessary, with particular attention being paid to a potential reduction in the cardiac output. In some patients, portal pressure cannot be diminished even with an adequate dosage of propranolol (non-responders). The frequency of *side effects* (such as hypotension, dizziness, Raynaud's syndrome, bradycardia, bronchoconstriction, impotence) can be kept well below 20%. • Propranolol can be used successfully as a prophylaxis for both oesophageal and fundus varices. The dosage (twice daily) should be continued until the pulse rate is reduced by approx. 25% of the initial value (generally down to 55−60/min); the blood pressure should not fall below 90 mm Hg. (100, 168) • According to previous experience, the risk of primary bleeding seems lower when propranolol is applied as a primary prophylactic measure in patients with medium-sized or large varices and "red-coloured signs". (54, 80, 165) • *Long-term treatment* with propranolol may be successful in certain situations as a secondary prophylactic measure in order to prevent recurrent bleeding. (64, 136, 206, 216) This is particularly true of simultaneous interval sclerotherapy. (182, 185) The gastric mucosal blood flow was slowed down in portal hypertensive gastropathy; the serum gastrin level remained unaffected. • A combination of propranolol and molsidomine is considered to be efficient. • **Nadolol** has also been used with success as a β-blocking agent − in combination with nitrate − for the prevention of primary bleeding and relapses. It is only administered once daily; its elimination is predominantly renal. Side effects are markedly fewer (< 5%) than with propranolol. (69, 134, 145, 217, 218)

### 3.5.7 Bacteraemia

Clinically relevant bacteraemia is seen in 5−15% of patients who undergo emergency sclerosing of oesophageal varices. Prophylactic treatment with poorly absorbable antibiotics led to a reduction in the frequency of bacteraemia and infections. The risk of rebleeding is increased above all by a bacterial infection. *Thus it was possible to reduce the frequency of rebleeding significantly by administering an antibiotic prophylaxis for a period of 3−7 days.* In this connection, the use of norfloxacin (2 × 400 mg/day for about 1 week) or ofloxacin proved beneficial. (67, 105, 166, 175) (s. p. 304)

**Synopsis**

**Primary prophylactic measures** such as the administration of propranolol or nadolol and, if necessary, combined with isosorbide mononitrate, molsidomine and spironolactone as well as sclerotherapy (54, 89, 166, 180, 213) or banding ligation (108, 136, 182) may be indicated in cirrhosis patients who present *major risk factors* for primary oesophageal bleeding. (s. tab. 19.12)

The various **conservative methods** used in the treatment of bleeding oesophageal varices have been investigated in a number of clinical studies. It might well be difficult to assess the results − often varying and occasionally controversial − since the individual findings within the frequently heterogeneous patient groups rarely permit any comparability between the studies. • Subsequent to the endoscopic confirmation of the diagnosis − which may only be omitted under exceptional circumstances − the decision must not only focus on the treatment procedures to be implemented, but on a flexible, sequentially structured process. This means using suitable, clinically well established procedures which have been selected from the entire scope of conservative treatment.

For **primary haemostasis,** *sclerotherapy* or *varix ligation* are considered to be the methods of choice. • Should sclerotherapy or ligation not be feasible (as yet) for primary haemostasis, *medication therapy* (first priority) with terlipressin and octreotide may be applied as an alternative − with the aim of carrying out subsequent sclerosing or ligation as soon as possible. • Should it be imperative to control massive bleeding without delay, the *balloon tamponade* method can be applied for a limited period of time. Here, too, the aim must be early sclerotherapy or ligation.

As a **secondary prophylactic step** against recurrent bleeding, eradicating sclerotherapy or ligation are the methods of choice. At the same time, β-blocking agents and nitrates may be given both as *adjuvant treatment* and subsequent *long-term therapy*. Furthermore, spironolactone and/or molsidomine are also suitable in such cases.

The question concerning the use of **semi-invasive** or **surgical measures** arises once definitive haemostasis has been achieved. This depends on the liver function in each case and a careful review of the individual risk factors and behaviour as well as an assessment of the indications. • Variceal bleeding that has proved to be unresponsive to haemostatic efforts over a period of time exceeding 2 days (with a daily application of more than four units of packed red blood cells) in spite of all conservative measures must be subjected to semi-invasive or surgical therapy. This also applies to an early recurrence of bleeding.

## 3.6 Semi-invasive treatment

### 3.6.1 Transhepatic embolization

The transhepatic embolization of bleeding oesophageal varices, which was first used by A. LUNDERQUIST et al. (1974), is only of minor clinical importance today. With this procedure, a vascular catheter is introduced via the percutaneous transhepatic route into the portal system, and the convolute of varices is selectively thrombosed. (87)

### 3.6.2 TIPS

From a haemodynamic point of view, the transjugular intrahepatic portosystemic stent shunt (TIPS) constitutes a portacaval side-to-side anastomosis in the form of a nonsurgical link between the portal vein and the hepatic vein. The TIPS can be closely compared with the portacaval interposition shunt, because the pressure reduction also depends on the shunt lumen. Stent placement leads to a permanent *decrease in portal pressure*; in 60−70% of cases, it was possible to achieve the desired reduction in pressure to almost 12 mm Hg. In addition, the splanchnic blood pool decreased, the cardiac output increased, the RAAS was deactivated and renal function improved. (70) (s. pp 259, 314, 329)

► This procedure, which is well documented in animal experiments, was introduced into clinical practice by R. F. COLAPINTO et al. in 1983. A self-expanding *Wall stent* with a width of 8 to 10 mm or a *Palmaz metal stent* (J.C. PALMAZ et al., 1985), which can be expanded up to a maximum of 16 mm, is applied. The latter was first used in clinical practice in 1989 (G. M. RICHTER et al.). • With this method, a catheter is inserted into a right liver vein through the internal jugular vein. The portal vein is punctured near the bifurcation by means of a needle inserted through the catheter, and a guide wire is introduced to an adequate extent into the portal branch. The liver tissue between the liver vein and the portal vein is predilated by means of a balloon catheter via the guide wire, and the Palmaz stent is subsequently inserted. • The problem of stenosis or re-stenosis of the stent can be largely prevented with the help of a newly developed stent type. (s. fig. 16.15)

**Indications:** The indications are: (*1.*) bleeding from oesophageal or gastric varices (acute, non-controllable bleeding, prophylactic measures against rebleeding, variceal embolization) (48, 63, 66, 94, 95, 117, 138, 142, 185), (*2.*) relapsing haemorrhage in hypertensive gastropathy, (*3.*) refractory ascites, (*4.*) Budd-Chiari syndrome, (*5.*) hepatogenic hydrothorax, (*6.*) hepatorenal syndrome, (*7.*) portal thrombosis, and (*8.*) bridging the period of time preceding liver transplantation. (70, 172, 174, 211)

**Results:** The results of this semi-invasive procedure are convincing: successful insertion of a TIPS by an experienced team could be achieved in 88−100% of cases, with a survival rate of 85% after 1 year and 78% after 2 years. The frequency of rebleeding was lowered to about 10%. The functionality of the TIPS could be maintained for 4 years. (138, 142, 211, 223)

**Mortality:** Mortality during the application of TIPS is 1%, early mortality within the first 4 weeks amounts to approximately 2%, and in the case of an emergency TIPS, the rate is about 20%.

**Complications:** The application of a stent rapidly effects the formation of pseudointima. Through increased thrombosis development, this may even culminate in stent occlusion (4−22%), which could cause rebleeding. However, there is the possibility of placing a new stent. The reported frequency of hepatic encephalopathy is 20−30%. Haemobilia was observed in 4−5% and liver haematoma in 4% of cases. In view of such a high rate of hepatic encephalopathy, the subclinical stage should also be diagnosed (s. pp 203, 275) and systematically treated until the time is appropriate for the implementation of a TIPS. (s. p. 278) During the following period, all possible dietary and medicinal measures should be taken to avert the frequent, albeit unexpected occurrence of serious hepatic encephalopathy.

The first **liver transplantations** after the positioning of a TIPS were performed by E.J. RING et al. (1992). (172) Meanwhile, other good results have also been presented. (138, 173) For transplantation purposes, a preceding TIPS is of decisive advantage as compared to a conventional shunt operation, since the extrahepatic vessels and the liver hilus remain intact. Therefore, TIPS is the method of choice when the time period preceding a transplantation has to be bridged for patients with stages Child B and C. (s. fig. 19.12)

## 3.7 Surgical treatment

As long ago as 1874, G. BANTI attempted for the first time to reduce the portal volume by means of splenectomy. In 1894 he developed this procedure further by carrying out the simultaneous resection of the short gastric veins in order to cut off the blood flow into the oesophageal collaterals. During the course of the past 100 years, countless surgical procedures and modifications for the treatment of portal hypertension and bleeding oesophageal varices have been published.

► The **tabular list** presented here consisting of more than 50 surgical procedures cannot be considered as complete or even totally accurate. • *These multiple and ingenious efforts undertaken by surgeons to control the most frequent and most life-threatening bleeding event − bleeding from oesophageal varices with portal hypertension − are worthy of admiration and respect.* • The diversity of the methods might, however, also reflect critical dissatisfaction on the part of the individual surgeon with the clinical results hitherto achieved. • *It is very interesting to compare this tabular overview of the surgical treatment of* **bleeding oesophageal varices** *(s. tab. 19.7) with the list of operative approaches for eliminating* **refractory ascites.** *(s. tab. 16.18)*

### 3.7.1 Indications

Should it be necessary to consider surgical treatment for acute gastrointestinal bleeding, the decision depends on (*1.*) *cause of bleeding* in each case, (*2.*) *bleeding intensity*, and (*3.*) possibility of surgical elimination of the *source of*

*bleeding*. The decision for operative intervention is taken in line with the following **criteria:**

1. Spurting arterial bleeding (Forrest Ia)
2. Volume replacement of >2 litres/day without definitive circulatory stabilization
3. Consumption of >5−6 units of blood/day without definitive haemostasis
4. Unfeasibility and inefficacy of conservative therapeutic measures in bleeding oesophageal varices or in hypertensive gastroenteropathy
5. Elective surgery for the elimination of persistent recurrent bleeding from oesophageal and fundus varices (with strict adherence to the selection criteria)
6. Ulcer patients with risk factors (initial Hb value <7 g/dl, Forrest stages Ib/II, signs of recurrent bleeding)
7. Secondary prophylactic measure at the request of the patient following objective presentation and discussion of the prevailing findings

Close cooperation with the surgeon is imperative for optimum treatment results in gastrointestinal bleeding. (s. fig. 19.12)

### 3.7.2 Surgical methods

Of the many surgical methods used in the treatment of bleeding oesophageal varices, only two groups are of relevance: (*1.*) block surgery and (*2.*) pressure-reducing shunt procedures. (s. tab. 19.7)

**I. Nonsurgical methods**

1. **Local haemostatic methods**
   - Varicosclerosation (CRAFOORD, C., 1939)
   - Tamponade with gauze and thrombin (BARNETT, C.B., 1949)
   - Sclerosing of the oesophageal wall (WODAK, E., 1956)
   - Transhepatic sclerosing (LUNDERQUIST, A., 1974)

**II. Surgical methods**

1. **Mediastinal tamponade**
   - upper and lower mediastinal tamponades (SOM, 1947)
   - gauze tamponade (HARLOCK, 1950)
2. **Varicotomy**
   - total oesophagogastrectomy (PHEMISTER, D.B., 1949)
   - subtotal oesophagogastrectomy (BARANOFSKY, I.D., 1949)
   - total small intestinal interposition (MEREDINO, K.A., 1950)
   - total prosthetic interposition (NACHLAS, M.M., 1956)
   - total colon interposition (KOOP, 1959)
3. **Purse-string ligation of varices**
   - abdominal/thoracic/subdiaphragmatic (HENSCHEL, C., 1938)
   - laparogastroscopic varicosclerosation (LUND, 1939)
   - transthoracic/transoesophageal (BOEREMA, I., 1949)
   - transabdominal (WELCH, C.S., 1953)
   - transthoracic/perioesophageal (NISSEN, R., 1954)
   - oesophageal dissection ligation (VOSSSCHULTE, K., 1957)
   - transthoracic/oesophageal (HARTENBACH, W., 1963)
   - oesophageal dissection ligation (BOEREMA, I., 1967)

4. **Provocation of additional collaterals**
   - omentopexy (TALMA, S., 1898)
   - displacement of the spleen into the abdominal wall (HOLMAN, 1950)
   - splenopneumopexy (NYLANDER, E.E., 1950)
   - hepatopexy (ROUSSELOT, L.M., 1959)
   - transthoracic displacement of the spleen and pole resection (BOURGEON, 1961)
5. **Reduction in portal venous volume**
   - splenectomy (BANTI, G., 1874)
   - ligation of the left gastric artery and right gastro-epiploic artery (FLEROW, 1926)
   - ligation of the hepatic artery (BERMAN, E.J., 1950)
   - ligation of the splenic artery (BLAIN, A.W., 1950)
   - small intestine resection (LAUFMANN, 1954)
   - thoracic lymph fistula (DUMONT, A.E., 1964)
   - laterolateral lymphovenous anastomosis (DEFNI, M., 1965)
   - terminolateral cervical lymphovenous anastomosis (SCHREIBER, H.W., 1968)
6. **Interruption of afferent collaterals**
   - resection of the short gastric veins by splenectomy (BANTI, G., 1894)
   - ligation and resection of the coronary vein of the stomach (ROWNTREE, G., 1929)
   - subcardia gastric dissection (TANNER, N.C., 1950)
   - subtotal oesophageal resection (COOLEY, D.H., 1954)
   - oesophageal transsection (WALKER, R.M., 1960)
   - cardia reimplantation (SCHMITT, W., 1963)
   - submucosal transsection (STELZNER, F., 1963)
   - circular subcardia gastric dissection (SCHREIBER, H.W., 1964)
   - decongestion of the oesophagus and stomach (HASSAB, M.A., 1967)
   - two-stage oesophageal dissection (SUGIURA, M., 1973)
   - fundectomy (HUNT, H.A., 1964; STELZNER, F., 1975)
   - subcardia staple suture (RINECKER, H., 1975)
7. **Shunt operations**
   - Portacaval anastomosis
     - end-to-side (VIDAL, M., 1903; WHIPPLE, A.O., 1945)
     - side-to-side (ROSENSTEIN, P., 1912)
     - crossed (double end-to-side) form (McDERMOTT, W.V., 1960)
     - interposition shunt (SARFEH, I.J., 1986)
   - Splenorenal anastomosis
     - mesentericocaval side-to-end anastomosis (MARION, P., 1953; VALDONI, P., 1954)
     - laterolateral form (COOLEY, D.A., 1954)
     - distal form (WARREN, W.D., 1967)
     - end-to-end anastomosis (HIVET, M., 1967)
     - proximal (central) form (LINTON, R.R., 1974)
   - Coronariocaval anastomosis (GÜTGEMANN, A., 1961)
   - Renomesenteric renosplenic anastomosis (ERLICK, D., 1964)
   - Saphenoumbilical anastomosis (PICCONE, V.A., 1967)
   - Mesentericocaval side-to-side anastomosis (MAILLARD, J.N., 1970; MOREAUX, J., 1972)
   - Mesentericocaval interposition shunt (REYNOLDS, T.B., 1951; DRAPANAS, T., 1972)
   - Splenocaval side-to-end shunt (PEIPER, H.J., 1973)

***Tab. 19.7:*** An overview of semi-invasive and surgical procedures for bleeding oesophageal varices and portal hypertension in chronological order (1874−1994). For reasons of simplification, only the first authors are named in each case. *(s. also tab. 16.18!)*

1. **Block surgery:** This surgical measure stops the venous flow to the bleeding oesophageal collaterals. The **disadvantage** is that portal hypertension is not influenced, so that there is a possibility of

the collaterals and varices reforming and hence a danger of recurrent bleeding (40−60%). However, block surgery also has major **advantages:** (*1.*) it ensures rapid haemostasis, (*2.*) the duration of surgery is relatively short, (*3.*) the strain imposed on the patient by surgery is limited, (*4.*) the procedure is technically simple when using a stapler suture, (*5.*) liver perfusion is maintained, and (*6.*) there are no surgical problems with a subsequent shunt operation or liver transplantation. • Consequently, block surgery is performed as an emergency measure, particularly in cases of portal thrombosis. This intervention is sometimes combined with splenectomy. (s. tab. 19.7)

Oesophageal transsection, as with the two-stage technique (Sugiura), and devascularization (Hassab, Paquet) have proved to be most valuable in cases of severe oesophageal bleeding which cannot be controlled by conservative measures. This is particularly true of high-risk patients. Haemostasis is guaranteed, recurrent bleeding is rare, and the frequency of encephalopathy is lower. Block surgery must be followed by systematic prophylactic measures against relapse. The indication for an elective shunt operation should be considered during the bleeding-free interval. Omeprazole and sucralfate have been used successfully in treating postoperative ulceration. (102, 141, 153, 210)

2. **Shunt operations:** Anastomoses are created in the portosystemic vascular area by way of this surgical method; they lead to a distinct and persistent reduction in pressure in the total portal system. An operative shunt is therefore the most effective method for attaining haemostasis and for the prevention of recurrent bleeding. However, mortality is high: regarding the selective shunt, surgical lethality is 4−16% and late lethality 21−52%, whereas the respective rates for the total shunt are 4−13% and 18−69%. Before performing a shunt operation, indirect splenoportography and CT portography are the major examination methods. No shunt operation should be performed with a Quick's value of <40%. (119, 154, 158, 159, 212)

> The classical form is the **portacaval end-to-side anastomosis** (laterolateral), applied for the first time in a dog by N. W. von Eck in 1877. Nevertheless, this was still a long way from clinical applicability. Not until 1901 was a clinical attempt made by R. Lenoir, yet without success. A renewed attempt to use this (end-to-side) shunt procedure undertaken by M. Vidal (1903) proved to be satisfactory. The first successful portacaval (side-to-side) anastomosis was reported by P. Rosenstein in 1912. Extensive clinical use of the portacaval shunt was encouraged by the studies of A.O. Whipple and A.H. Blakemore (1945). • The following years saw the development of a large number of varying shunt techniques and their modifications. (s. tab. 19.7)

▶ The **complete shunt** involves a total bypassing of the portosystemic circulation. The liver blood flow is confined to the hepatic artery. This category includes the *portacaval end-to-side shunt*.

▶ The **incomplete shunt** only effects a moderate reduction in pressure in the portal system, but residual mesentericoportal hepatic perfusion is generally maintained, which can be seen as a great advantage. This type of shunt includes: (*1.*) *portacaval side-to-side*, indicated particularly in ascites, (*2.*) *mesentericocaval interposition*, (*3.*) *portacaval interposition*, (*4.*) *laterolateral (proximal) splenorenal side-to-side*, and (*5.*) *proximal splenorenal end-to-side*, with splenic extirpation.

Deterioration of liver perfusion may possibly be prevented by **arterialization** of the portal vein stump (A.H. Hunt, 1952). Various arterialization techniques, including those which are pressure-

adapted, have been tried out (D. Burlui et al., 1968; J.N. Maillard et al., 1970; U. Matzander, 1974; and others). • The technical advantages of a **mesentericocaval anastomosis** can be seen in the simplified access to the superior mesenteric vein and the easier decompensation of the anastomosis in a liver transplantation later on.

▶ Disadvantages include the twofold anastomosis and the use of a plastic vascular prosthesis with the associated higher rate of thrombosis of 15−30%.

A selective decrease in pressure coupled with the simultaneous maintenance of portal liver perfusion permits a **distal splenorenal anastomosis** (Warren shunt). Decompression is then selectively limited to the gastrosplenic tract. Yet, this low-pressure area can only be maintained with an extensive surgical uncoupling of the circulation area of the splenic vein from the portal vein. Complete splenopancreatic disconnection comprising the left and right gastric veins as well as the epiploic veins is therefore necessary. Benefits include the much improved hepatic haemodynamics and the preserved clearance function. However, this shunt is technically more difficult and more time-consuming to implement, widelumen vessels are required, and the rate of thrombosis can be as high as 50%. Moreover, due to the use of new venous links to the gastrosplenic area, the selectivity of the shunt is not guaranteed in the long term. **Splenoadrenal shunt** utilizing a left adrenal vein is deemed to be an excellent option in selected cases.

From a *haemodynamic point of view*, both the complete and incomplete shunts are regarded as "complete shunts" because they lower portal pressure and decrease liver perfusion, albeit to varying degrees − depending on the technique and on subsequent structural changes to the liver or portal system. The portal perfusion rate in cirrhosis is reduced on average to approximately 30%, generally with arterial compensation and increased cardiac output. Cirrhosis patients show a stagnating or retrograde portal flow in 8−30% of cases. Shunt-associated *deficiency of the hepatic blood flow* would entail less serious consequences than total (or near total) failure of the liver as the major *clearance organ*.

### 3.7.3 Timing of shunt operation

When considering the ideal time point for a shunt operation, a distinction is made between (*1.*) emergency shunt, (*2.*) early elective shunt, and (*3.*) elective shunt.

▶ The **emergency shunt** may be indicated in variceal bleeding that cannot be controlled by conservative measures. It is either performed as an **immediate shunt,** i.e. without previously attempted sclerosing, or as a **rescue shunt,** i.e. after unsuccessful sclerotherapy or ligation. Owing to the high rate of surgery-associated lethality (approx. 40%), the emergency shunt is generally used as a rescue shunt. With respect to this, the *portacaval end-to-side shunt* is the most appropriate shunt form by virtue of its benefits: (*1.*) it is technically more simple to perform, (*2.*) the duration of the operation is relatively short (60−90 minutes), (*3.*) haemostasis is achieved rapidly, reliably and definitively, (*4.*) portal pressure is lowered swiftly and persistently, and (*5.*) with regard to the emergency situation, the surgical procedure is relatively well tolerated by the patient. Perioperative mortality is about 10% in Child A, 20−30% in Child B and over 50% in Child C. Moreover, this shunt entails the haemodynamic and functional late sequelae of a total shunt. The selective *distal splenorenal shunt* has also proved useful as an emergency measure, although the technique is more difficult and time-consuming, with greater operative lethality. If these emergency shunts are not feasible angiologically or for reasons pertaining to surgical techniques, a machine-performed block

operation or oesophagogastric decongestion with splenectomy should be considered. (76, 112, 119, 125, 131, 152, 171, 200, 205, 212)

▶ An **early elective shunt** is created after initial haemostasis within one or two days if there are major grounds for immediate operative procedures. In principle, sclerotherapy or ligation should be continued for as long as possible, and thus early elective shunts are only rarely indicated.

▶ An **elective shunt** should be considered in situations where no definitive haemostasis was achieved (20−30% of cases) despite a sufficiently long sclerotherapy period and where there is still a danger of severe rebleeding. Here the choice of the most favourable shunt procedure should be made with due consideration of the individual case; there is no real answer to this issue, particularly as regards the decision in favour of a total or selective shunt, since the study data available can hardly be generalized (and are barely comparable). However, preference is given to the distal renosplenic shunt and the mesentericocaval interposition shunt. (53, 74, 131, 132, 154, 158, 159, 208, 212, 221)

### 3.7.4 Prognosis

The frequency of recurrent bleeding is 0−19% with elective shunts and 53−75% with sclerotherapy. Yet it is not possible to come to a universal decision in favour of a specific procedure. *As a matter of principle, all possibilities to prevent relapse that are afforded by conservative procedures should be fully exhausted.* (95, 104, 123, 163, 200)

*Operative lethality* can be reduced to about 10% and the rate of recurrent bleeding to <10%. With careful internal treatment, the frequency of encephalopathy can be substantially diminished to 5−10% (from the previous rate of 20−30%). The *survival rate* (between 2 and 10 years) is 80−40% and can be decisively influenced by the patient's lifestyle, particularly as regards alcohol abstinence. Important *selective criteria* include: (*1*.) liver blood flow between 1,000 and 2,500 ml, (*2*.) selective portal blood flow of 15−40%, and (*3*.) timing of operation during the bleeding-free interval (elective) with careful pre- and aftertreatment.

## 3.8 Liver transplantation

Liver transplantation is the only way of ensuring the elimination of the underlying liver disease with portal hypertension − and thus also the eradication of the pre-

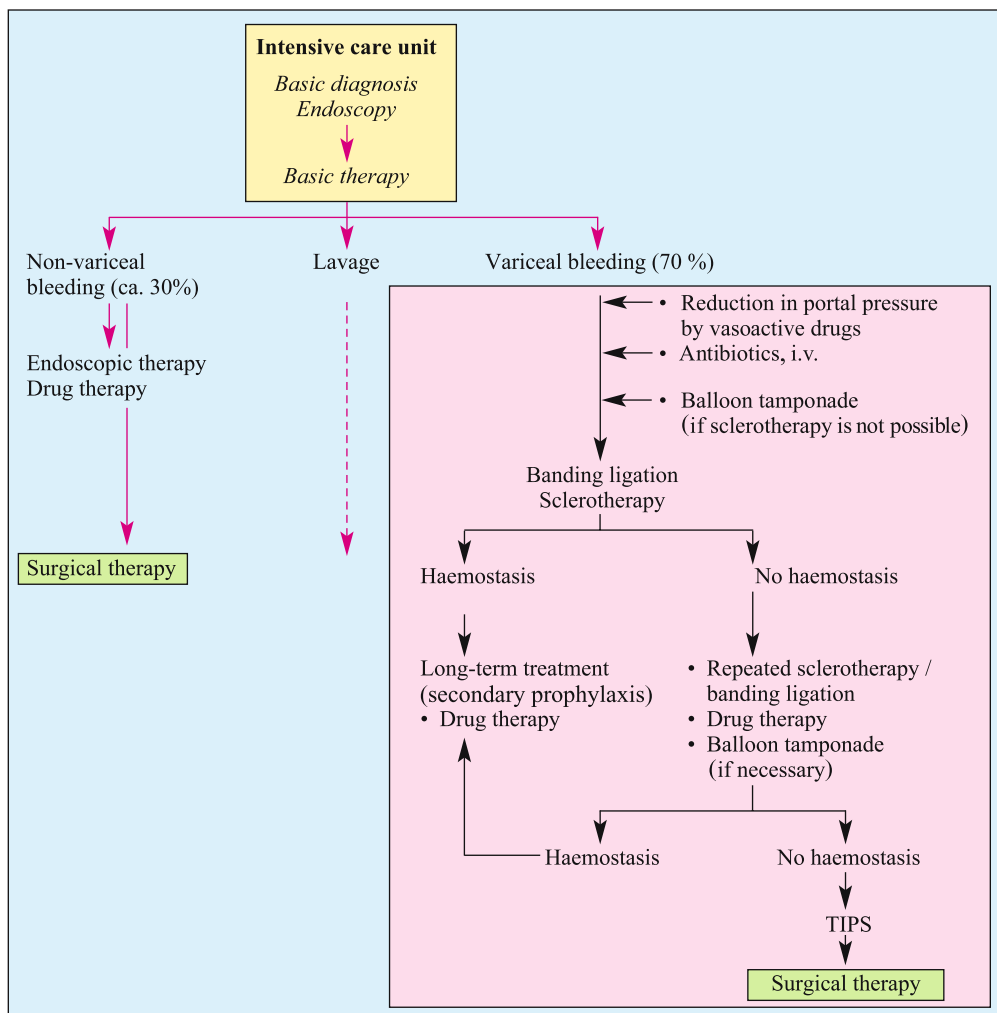

*Fig. 19.12:* Flow diagram: therapeutic spectrum for acute upper gastrointestinal bleeding, including bleeding oesophageal and gastric varices

dominant and life-threatening complex of collateral circulation with its recurrent incidences of bleeding. A transplant operation is technically feasible both after a TIPS and following block surgery. A mesentericocaval shunt is the surgical procedure of choice when a transplantation is planned at a later date. By contrast, the distal splenorenal shunt entails problems with operative techniques as well as haemodynamic difficulties. The four-year survival rate of patients who merely underwent sclerotherapy was 17%, whereas with an additional transplantation at a later date, a frequency of 73% was recorded. In appropriate cases, liver transplantation is a well-established therapeutic measure, equally suitable for the management of bleeding oesophageal varices. (119, 173)

# 4  Lower gastrointestinal haemorrhage

Lower gastrointestinal haemorrhage shows a frequency of $10-15\%$; some $3-5\%$ develop in the small bowel. Intestinal bleeding as a result of liver disease is rare. The initial problem consists in the fact that (*1.*) numerous and different causes of bleeding must be clarified by differential diagnosis and (*2.*) severe blood loss together with a concurrent liver disease is always particularly hazardous.

## 4.1  Definition

In lower gastrointestinal haemorrhage, the bleeding site is distal to the duodenojejunal ligament (Treitz's ligament) or the duodenojejunal recessus (i. e. the passage of the duodenum retroperitoneally and its transition to the intraperitoneal jejunum).

## 4.2  Forms

Lower gastrointestinal bleeding is subdivided into the same *forms* as upper gastrointestinal bleeding: acute or chronic bleeding, minor or major bleeding, arterial or venous bleeding. (s. tab. 19.4) The *intensity of bleeding* may vary between acute or even life-threatening bleeding and chronic or occult loss of blood in the stools. Acute bleeding lasts < 3 days. Occult bleeding is the most common form − in fact, the screening of symptom-free elderly people for occult blood in stools yielded positive results in 3% of cases. As regards the *nature of bleeding*, distinction must be made between melaena, reddish-brown stool, haemochezia and occult bleeding.

**Melaena** (tarry stool) (s. p. 349) is defined as tarry, sticky stools resulting from the decomposition of blood by intestinal bacteria. The occurrence of melaena depends on the amount of blood and the time of gastrointestinal passage. Usually, melaena is only to be expected in lower gastrointestinal bleeding with a bleed-

ing site in the upper part of the transverse colon. However, it may also be observed in the case of massive bleeding from the upper gastrointestinal area. • Melaena may likewise be simulated by the intake of iron (iron preparations, black pudding), charcoal tablets, bismuth, liquorice, blueberries, etc.

**Reddish-brown stool** is generally encountered in chronic recurrent lower gastrointestinal bleeding, mostly below the right part of the colon.

**Haemochezia** (bloody faeces) is defined as the discharge of fresh blood or small blood clots in the stools. This may be recognized as *blood on the surface* of a formed stool (especially with bleeding from the rectal or anal area) or *admixture of blood* in the stool (generally with a bleeding site in the upper sections of the colon). Major amounts of blood may greatly accelerate the gastrointestinal passage, which is why massive oesophageal or gastric bleeding can appear as a form of haemochezia.

**Occult blood** is defined as traces of blood in the stool which are not perceptible to the naked eye. Usually, the passage of blood into the intestinal contents amounts to around 2 ml/day. Proof of occult blood is obtained by *chemical testing* (e. g. peroxidase reaction), although it is only possible to detect amounts of blood in excess of $1.5-2.0$ ml/100 ml stool or to demonstrate them by means of an *immunological rapid diagnostic test* with a specificity of virtually 100%. The test usually comprises three specimens collected at different points in time. (s. p. 349)

## 4.3  Diagnosis

Lower gastrointestinal bleeding is less frequent than upper gastrointestinal bleeding ($15-20\%$ vs. $80-85\%$). Consequently, the presence of upper gastrointestinal bleeding has to be excluded first − even in the case of severe anal passage of blood and/or in cases of haemochezia. (230, 238, 240, 247, 254)

**Inspection:** Inspection of the stool facilitates an initial rough assessment of the nature of the gastrointestinal bleeding.

**Laboratory parameters:** Like in the upper GIB, certain parameters are initially important, such as haemogram, haematocrit, blood group, coagulation values, electrolytes, plasma urea, creatinine, Allgöwer-Burri index. (s. p. 349)

**Rectal examination:** Rectal examination by way of inspection and palpation of the anus and rectum (especially after straining) is imperative. The presence of haemorrhoids should not be accepted as a potential source of bleeding without further diagnostic clarification.

**Endoscopy:** Fundamentally, we consider intestinal endoscopy (rectosigmoidoscopy, coloscopy, enteroscopy) to

be the examination method of choice. With a massive passage of blood, the examination is naturally very difficult; it requires optimum intestinal cleansing before and during the examination as well as expertise in managing the required techniques. Due to the multiplicity of the potential causes of bleeding, endoscopy should always be used as a primary diagnostic method. With the help of **push enteroscopy,** it is possible to assess about 60 cm of the proximal jejunum. In this way, previously undetected sources of bleeding can be localized. (233) The so-called **wireless capsule endoscopy** will improve endoscopic diagnosis of the small bowel considerably. The use of this capsule is currently limited to clarifying cases of intermittent bleeding. (228, 229)

***Fig. 19.13:*** Colonic varices in alcohol-toxic cirrhosis

**Scintigraphy:** Scintigraphy (e.g. with $^{99m}$Tc-labelled erythrocytes) is the method of choice if endoscopy fails because of severe discharge of blood or due to technical difficulties, or if it yields no diagnosis. Amounts of blood exceeding $0.05-0.12$ ml/min. are demonstrable. With an accuracy rate of 94%, the overall reliability is higher than for angiography. One disadvantage is the imprecise localization of the bleeding source. (230, 238, 254)

**Angiography:** Strong lower gastrointestinal bleeding can also be confirmed and possibly localized (in up to 70% of cases) by selective angiography of either the coeliac trunk or the (superior or inferior) mesenteric artery. A prerequisite condition for this is a bleeding rate in excess of 0.5 ml/min. By using anticoagulants to provoke bleeding, it was possible to raise the positive bleeding rate from 32% to 65%. (239) Arteriography may also contribute to the differential diagnosis of lower gastrointestinal bleeding (e.g. diverticular bleeding, vascular anomaly, tumour). (230, 236, 238, 247, 254)

**X-ray examination:** An antegrade contrast-medium enema into the small intestine might be indicated in the case of suspected bleeding in this area. • A contrast X-ray of the colon using barium is only indicated in isolated cases.

All these diagnostic measures, when implemented specifically and step-by-step, yield a reliability of over 90% in lower gastrointestinal haemorrhage.

## 4.4 Aetiology

Numerous diseases of the lower gastrointestinal tract may be accompanied by bleeding. The **aetiological spectrum** is wide; the percentage frequency depends on the age distribution of the respective patients. Men are more frequently affected than women. At an advanced age, diverticulosis (overall frequency of bleedings about 50%, in old age about 40%) and angiodysplasia (overall frequency $1-3\%$, in old age about 30%) as well as haemorrhoids are the primary causes of bleeding. Furthermore, anal fissures, enterocolitis, polyps as well as benign and malignant tumours are worthy of mention. • Among the rare causes observed were proctitis, infections, parasitoses, endometriosis, collagenoses, congenital diseases (e.g. Meckel's diverticula, Osler-Rendu-Weber's disease) and mesenteric infarction. Some $80-85\%$ of cases cease spontaneously. Lethality is $2-3\%$. (230, 247, 255)

Lower gastrointestinal bleeding due to *liver disease* is very rare. The sources of bleeding develop in the course of portal hypertension. Intestinal erosions constitute the predominant mucosal changes in **portal hypertensive vasculopathy** in the gastrointestinal tract. They are usually responsible for the frequency of occult intestinal bleeding in cirrhosis patients. (232, 245)

During portal hypertension accompanied by the development of collaterals, **varices** also occur in the area of the duodenum, small intestine, colon (242, 243, 245, 248) and rectum. (231, 232, 234−236, 241, 250, 251) Very severe, even life-threatening variceal bleeding may appear. (234, 237, 242, 249, 251, 252)

## 4.5 Therapy

The therapeutic measures for lower gastrointestinal bleeding correlate with the **basic therapy** for upper gastrointestinal bleeding with respect to volume replacement, circulatory stabilization, restoration of the electrolyte balance and intestinal cleansing.

Depending on the respective findings, endoscopic **sclerotherapy**, the **banding ligation** of varices or the **clip technique** (225) is carried out. (240, 251, 253, 255) The presence of portal hypertension is generally an indication for drug-induced **pressure reduction.** This may be necessary as a situation-related primary measure as well as in the form of adjuvant treatment with endoscopic techniques or the performance of **TIPS.** (231, 244, 246)

In the case of bleeding due to benign or malignant proliferation as well as in upper gastrointestinal bleeding, **thermic haemostatic procedures** are indicated.

**Medicinal therapy** is similar to that used for upper GIB, e.g. vasopressin, FFP, PPSB, fibrinogen (s. p. 351) and octreotide. (248)

In cases of bleeding which cannot be stopped endoscopically or conservatively, interventional radiology is indicated before any surgical measures can be taken. Exact localization of the source of bleeding is absolutely essential.

# Symptoms and Syndromes

## 20 Acute and chronic liver insufficiency

# 20 Acute and chronic liver insufficiency

## 1 Definition

> The term "liver insufficiency" denotes a breakdown in the functions of the liver. The syndrome of functional liver failure covers a wide spectrum of clinical, biochemical and neurophysiological changes. In principle, liver insufficiency can occur without previous liver damage as well as with already existing liver disease. It is characterized by a deterioration in the synthesizing, regulatory and detoxifying function of the liver. This final stage of liver disease terminates in hepatic coma.

## 2 Systematics

### 2.1 Partial and global insufficiency

Serious liver disease can affect the 12 main metabolic functions of the liver, with their 60–70 even more important partial functions, to widely differing degrees. (s. tab. 3.1) The result is either *global insufficiency* or *partial insufficiency*, each with very varied clinical and biochemical symptoms. The failure of certain metabolic functions is responsible to a greater or lesser extent for the development and intensity of liver insufficiency. Impairments in the functions of detoxification and protein metabolism are particularly significant in this respect.

### 2.2 Compensation and decompensation

The **compensated stage** does not usually display any signs of liver insufficiency (except possibly jaundice), nor are there any typical ailments. Functional parameters that can be quantified in routine laboratory tests (such as cholinesterase, albumin, Quick's value, bile acids) may still be normal or only minimally impaired in the individual instance. In contrast, liver tolerance tests (galactose, indocyanine green, etc.) demonstrate a reduction of liver function which is already quite considerable.

The **decompensated stage**, i.e. manifest liver insufficiency, can present as *cellular decompensation* (e.g. in the case of acute liver failure due to toxic or inflammatory mass necrosis) or be expressed only in the form of *portal decompensation* (e.g. in cases of postsinusoidal intrahepatic portal hypertension). • As a rule, chronic liver insufficiency is accompanied by a *combined decompensation* with a loss in function of the liver cells and, at the same time, the sequelae of portal decompensation (collateral varicosis, encephalopathy, ascites, hepatorenal syndrome, variceal bleeding). *(see chapters 15–19 and 35)*

### 2.3 Acuteness and chronicity

Depending on the time period involved in the course of the disease, **acute liver failure** without pre-existing liver disease can initially be differentiated by massive liver cell disintegration due to a variety of causes. • In contrast, **chronic liver insufficiency** with pre-existing liver disease is mostly found in advanced liver cirrhosis with a progressive loss of function. • A *sudden necrotising episode* is also able to precipitate the change from chronic and still compensated liver insufficiency into acute liver failure ("acute on chronic") in the same way that acute liver failure which has been overcome can develop into chronic liver insufficiency.

### 2.4 Hepatic coma

Hepatic coma can be subdivided according to its aetiology as follows: (*1.*) *hepatocyte disintegration coma* (= endogenous coma as a result of the loss of parenchyma), (*2.*) *liver cell failure coma* (= exogenous coma as a result of metabolic disorders, almost always in the presence of cirrhosis), (*3.*) *electrolyte coma* (= so-called "false" coma due to dyselectrolytaemia, almost always iatrogenic), and (*4.*) *mixed forms of coma.* (s. pp 214, 276, 381) (s. tab. 15.5)

## 3 Acute liver insufficiency

> ► J. W. MORGAGNI (1761) was probably the first to describe acute yellow atrophy of the liver, i.e. hepatic coma. Acute liver failure can be seen as identical to the "acute yellow atrophy" described by K. ROKITANSKY in 1842. This acute and severe clinical picture was subsequently termed "bilious dyscrasia" (P. J. HORACZEK, 1844), "icterus gravis" (C. OZANAM, 1849), "acholia" (F. TH. FRERICHS, 1858), "hepatolysis" (R. EHRMANN, 1922), "hepatodystrophy" (G. HERXHEIMER, 1935) or "liver dystrophy" (R. BÖHMIG, 1949). The terms "hepatargia" (H. I. QUINCKE, 1899) and "hepatic coma" were used to denote the final stage, which usually sets in at the end of acute or chronic liver failure. • Acute liver failure in the course of acute viral hepatitis was termed "fulminant hepatitis" by W. LUCKÉ et al. (1946), who also defined a subacute form with a less severe course. (35)

### 3.1 Definition

> Acute liver failure (ALF) is defined as an acute clinical picture with *jaundice* due to a most severe disorder in the liver function and/or massive liver cell necrosis which, without any pre-existing liver disease, culminates in *hepatic coma* (= endogenous coma) within 8 weeks. Potentially, the condition is fully reversible (C. TREY et al., 1970). • In addition, *coagulopathy* must also be present (D. F. SCHAFER et al., 1989).

## Courses of disease

Clinically, there are three different courses of disease following the onset of **jaundice:** (*1*.) fulminant or *hyper-acute liver failure* (= occurrence of hepatic encephalopathy in the 1st week), (*2*.) *acute liver failure* (= occurrence of hepatic encephalopathy between the 2nd and 4th week), and (*3*.) *subacute liver failure* (= occurrence of hepatic encephalopathy between the 5th and 8th week). • Surprisingly, however, it could be shown that 30−40% of the hyperacute forms survived in spite of the development of hepatic coma and cerebral oedema. As opposed to this, the subacute forms displayed a survival rate of only 10−20%, despite a lower frequency of cerebral oedema and better liver function. (s. tab. 20.1)

| | **Hyperacute liver failure** | **Acute liver failure** | **Subacute liver failure** |
|---|---|---|---|
| Encephalopathy | ++ | ++ | ++ |
| Duration of icterus in days | 0−7 | 8−28 | 29−72 |
| Cerebral oedema | ++ | ++ | (+) |
| Quick's value | ↓ | ↓↓ | ↓ |
| Bilirubin | N-↑ | ↑↑ | ↑↑ |
| Prognosis | favourable | poor | poor |
| Survival rate | 30−40% | 5−10% | 10−20% |

**Tab. 20.1:** Characteristics and prognosis of acute liver failure and its subtypes (modified according to J.G. O'GRADY et al., 1993) (N = normal)

## 3.2 Morphology

In the **pathological-anatomical context,** *hepatomegaly* due to hyperaemia is often found at the outset. During the further course of disease, this can develop into *liver atrophy* as a result of parenchymal loss.

▶ **Histologically,** acute liver failure shows a wide range of uncharacteristic changes. (*1*.) Depending on the underlying cause, the morphological picture of **acute necrotizing hepatitis** can be witnessed with extensive confluent cellular destruction. The extent of necrosis, measured by way of the morphologically evidenced hepatic volume fraction of the still functioning liver parenchyma, yields relatively reliable information on the chance of survival (J. SCOTTO et al., 1973). Given a normal value of 85% **hepatic volume fraction** (HVF) of intact liver cells for each volume unit of the total liver, a decrease to < 30% (threshold 28−35%) would possibly mean that the patient is unlikely to survive. (*2*.) In acute liver failure caused by toxins or hypoxia, **massive fatty degeneration** of the hepatocytes can vary substantially. In diffuse fatty degeneration featuring minute vacuoles and damage to the organelles, liver cell necrosis cannot, as a rule, be detected (e. g. acute fatty liver during pregnancy, Reye's syndrome, in association with tetracycline or valproic acid). (*3*.) Between these two "classical" morphological manifestations, there are also **compound forms,** i. e. courses of disease with a variety of histological changes of different intensities and combinations. On occasions, it is also possible to identify histological findings which point to a certain cause of the disease. (40, 57)

From a morphological point of view, acute liver failure is potentially reversible, so that even **complete regeneration** can be attained. Precursory cellular necrosis is hence less of a determinant than the capacity to regenerate.

There have been reports on the transition from virus-induced acute liver failure to **chronic hepatitis.** As the final stage of fulminant viral hepatitis (also known as acute liver dystrophy or submassive hepatitic necrosis), a **postdystrophic scarred liver** ("potato liver") can develop. (s. fig. 35.14) Cicatricial distortions with a continuing effect, regenerative processes, intrahepatic vascular disorders and hypoxia-related damage lead to the conclusion that a *posthepatitic, postdystrophic scarred liver may well be a special form of cirrhosis.*

> Neither the functional state of liver insufficiency nor hepatic coma can be recognized histologically.

## 3.3 Pathogenesis

The common target structures for the various causes of acute liver failure are usually the cellular and subcellular biomembranes of the hepatocytes. Among other things, any damage to these biomembranes causes a massive inflow of calcium into the liver cells, which results in a severe disorder of the cell milieu and ultimately in cell death.

In cases of **oxygen deficiency,** the oxidative stress is mainly localized in the extracellular spaces. This is where the Kupffer cells and neutrophils are involved in complex self-stimulating mechanisms, which can lead to the formation of inflammatory mediator and cytotoxic substances. • An important pathogenetic aspect is the extent of the "priming effect", which generally results in the increased production of oxygen radicals. The complex process of **lipid peroxidation** likewise effects massive liver cell damage in the form of self-perpetuation. • Excessive **immunological reactions,** which occur in acute liver failure due to viral hepatitis, halothane hepatitis, etc., are of great significance. There are also isolated cases in which **biotoxometabolites** are produced and may act as neo-antigens. (s. fig. 3.11)

▶ Consequently, severe damage to liver cells and widespread necrosis are usually the result of a network of altered cellular and humoral reactions, which for their part are often the initial cause of acute liver failure due to their synergistic and interactive effects (H. POPPER et al., 1986). Systemic reactions are responsible for the fact that other organs and functional sequences are equally affected, thus creating a wide spectrum of clinical findings and complications.

## 3.4 Frequency and causes

Acute liver failure is a rare occurrence. It is estimated that approx. 5 cases are found out of 6,000 hospital admissions (in the USA a total of ca. 2000 patients per year, in Germany ca. 150). However, there can be wide variations in frequency due to the effect of regional differences on the individual aetiology of this disease. The causes of acute liver failure are numerous and multiform. Diabetes mellitus is an extremely high risk factor

in this respect. • Primary or secondary hepatitis viruses are deemed to be a frequent cause, although there are regional and individual variations (e. g. drug dependence, pregnancy) with regard to the predominant virus type. • A further common cause (ca. 20%) are medicaments (particularly paracetamol often taken with suicidal intent, and halothane), followed by mycotoxins, alcohol and carbon tetrachloride (such as can be found in cleaning agents or solvents, and also with "glue sniffers"), heat-stroke (up to 10% of cases), Ecstasy, and vascular diseases. (8, 13, 66, 77) (s. tab. 20.2)

1. **Primary hepatotropic viruses**
   HAV (0.2−0.3%) (6, 37), HBV (1−2%) (6, 39, 59, 65, 81), HCV (ca. 1%) (30, 65, 67, 80), HDV superinfection (ca. 20%), HEV (10−20%) (6, 30), HBV mutants, HCV + HAV (30−40%) (70)
2. **Secondary hepatotropic viruses**
   adenoviruses, Coxsackie (73), cytomegaloviruses, Epstein-Barr (20), herpes simplex (type 1,2) (69), herpesvirus-6 (1), parainfluenza virus, paramyxoviruses, parvovirus B19, varicella zoster virus, yellow fever, dengue fever
3. **Bacteria and parasites**
   leptospira, listeria (68), malaria, M. tuberculosis (25, 29), rickettsia
4. **Chemical substances**
   carbon tetrachloride (52), chloroform, nitropropane (26), trinitrotoluene, yellow phosphorus (s. tab. 30.3)
5. **Fungal poisons**
   Amanita phalloides (27, 48, 109, 120), lepiota (49)
6. **Toxins**
   B. cereus emetic toxin, microcystins of cyanobacteria
7. **Medicinal agents**
   allopurinol, amiodarone, antiretroviral agents, carbamazepine, cotrimoxazole (3), cyproterone, dapsone, didanosine, disulfiram, Ecstasy (110, 113), enflurane, flutamide, glitazone, gold, halothane, hydroxychloroquine, interferon, isoflurane, isoniazid, kava-kava, ketoconazole, lisinopril, methotrexate, methyldopa, mono-amine oxidase inhibitor, nilutamide, nimesulide, ofloxacin, omeprazole, paracetamol, phenhydane, phenothiazine, phenytoin, pirprofen, propylthiouracil, rifampicin, sulphasalazine, tetracycline, valproic acid. (s. tab. 29.4)
8. **Alcohol**
9. **Metabolic causes**
   acute fatty liver in pregnancy (44), $\alpha_1$-antitrypsin deficiency, erythropoietic protoporphyria, hereditary fructose intolerance, galactosaemia, HELLP syndrome, Reye's syndrome, tyrosinaemia, Wilson's disease
10. **Ischaemia**
    Budd-Chiari syndrome, heatstroke, ligature of the hepatic artery, shock liver, veno-occlusive disease
11. **Malignant infiltration**
    leukaemia (4), massive formation of metastases, Hodgkin's disease (16), melanoma, non-Hodgkin's lymphoma (5, 54, 78), renal cell carcinoma (19), hepatocellular carcinoma (36)
12. **Autoimmune hepatitis** (43)
13. **Septic cholangitis**
14. **Heart failure** (75)
15. **Jejuno-ileal bypass** (12)

*Tab. 20.2:* Various causes of acute liver failure (with some references)

**Paracetamol:** The first report on acute liver failure due to paracetamol poisoning was published in 1966 (D. G. D. DAVIDSON et al.). Due to induced CYP II E2, paracetamol is metabolized to the extremely reactive molecule N-acetyl-p-benzoquinone-imine (NAPQI). This binds covalently to cellular proteins. A small amount of NAPQI is neutralized by glutathione; however, with a larger quantity of NAPQI (following an intake of >10 g paracetamol), the hepatic glutathione supplies are used up, so that the NAPQI becomes highly toxic. (s. fig. 20.3) There is hence a direct correlation between the degree of glutathione consumption and the severity of liver cell damage. The loss of glutathione can be compensated by i.v. administration of the glutathione precursor N-acetylcysteine. (s. p. 383)

**Amanita phalloides:** Mycotoxins, especially $\alpha$-amatoxin, are extremely hepatotoxic as a result of the inhibition of mRNA polymerase B and the blocking of RNA synthesis. The lethal dose is approx. 0.1 mg amatoxin/kg BW (1−3 fungi = 10−50 g), depending on the patient's age and state of health as well as the respective degree of intestinal absorption and diffusion in the tissue. The heat-resistant mycotoxins (amanitines) are capable of enterohepatic recirculation. (s. pp 383, 571)

## 3.5 Clinical findings

The overall picture of acute liver failure is first and foremost determined by the clinical findings. The symptoms are dramatic and subject to swift change. The course of disease can advance within a matter of days or, in a subacute form, take several weeks. (7, 8, 13, 56, 60, 66, 77)

**General symptoms:** The acute clinical picture develops swiftly with conspicuous symptoms, such as fatigability, loss of appetite, nausea, weakness, lassitude, meteorism, apathy and disruption of the circadian rhythm.

**Encephalopathy:** Rapidly, often within 1 or 2 days, there is evidence of dysarthria, muscle tremor, finger tremor, lack of concentration and asterixis. Restlessness, hyperkinesis and hallucinatory experiences are evident. Even screaming attacks have been observed. These symptoms, which can still be classified under stages I and II, are fully reversible. Nevertheless, lethality of 30−35% must be anticipated in stage II. In contrast, stage III is clearly less reversible. Somnolence, stupor with confusion, deviant behaviour, hyperreflexia, Babinski's reflex, clonus and spasticity as well as nystagmus are now observed. There is usually still a response to acoustic stimuli. The EEG shows a slowing down of basic activity (0.5−3.0/sec.) together with mainly biphasic and triphasic potentials. Lethality rises to over 50%. In stage IV, the patient is in a deep coma. There is evidence of areflexia, an absence of any corneal reflex and loss of tonicity; the brain waves flatten out to an isoelectric line. Irrespective of therapy, lethality is 80−90%. (s. tab. 15.5)

**Cerebral oedema:** As from coma stage III, cerebral pressure can increase (75−80% of cases) owing to water retention and/or vasodilation with hyperaemia, yet with a subsequent reduction in cerebral perfusion and hypoxia. Intracranial cerebral compression is > 20 mm Hg. Cerebral oedema is vasogenetic and/or cytotoxic, the latter feature appearing to predominate. Clinical symptoms include disorders in the respiratory rhythm (in particular tachypnoea), hypertension and bradycardia as well as increased muscular tonus. Singultus suggests damage to and impending constriction of the brain stem. The pupils are dilated due to the pressure on the oculomotor nerve. Occasionally, chemosis develops, which is a fatal prognostic sign. (2) Intracranial blood circulation sinks rapidly. In 30−60% of cases, cerebral oedema is fatal. (10, 11, 38, 62, 64, 74, 76)

**Jaundice:** With the foudroyant disintegration of liver cells, a comatose condition can set in within a few hours, even before jaundice is identified. In most cases, however, jaundice is already present. The intensity and time of onset vary. Severe jaundice (> 20 mg/dl) is considered to be a poor prognostic sign.

**Hepatic foetor:** The sweet aromatic smell of the exhaled breath (mercaptan derivatives) is accepted as a reliable sign of acute liver failure, but it is not always present. The administration of poorly absorbable antibiotics (e. g. paromomycin) usually improves the condition of hepatic foetor or even eliminates it temporarily. (s. pp 87, 267)

**Fever:** Fever often occurs; for the most part, it remains at 38 °C, but septic temperatures are possible. • In some cases, this may well be a question of *aetiocholanolone fever*, whereby aetiocholanolone can also be quantified in the serum. • *Bacterial infections* are likewise a cause of fever and require appropriate treatment. *Toxins* may also be responsible for the febrile condition (tissue toxins, endotoxins). (s. p. 738)

**Liver size:** The liver may have normal size or it can be enlarged due to hyperaemia or massive fatty infiltration. A rapid shrinking of the liver to less than 1000 ml in volume ("dystrophy", "acute atrophy") − requiring sonographic or CT monitoring at the bedside − is deemed to be a poor prognostic sign.

## 3.6 Laboratory parameters

At present, there is no specific laboratory investigation which facilitates the diagnosis of acute liver failure. In view of the severity of this clinical picture, there are, however, a number of laboratory parameters which show marked pathological changes and thus require full diagnostic clarification. Activin A serum levels were elevated, especially in patients with acute liver failure, due to a paracetamol overdose. This did not affect the final outcome, but was possibly a factor in the inhibition of

liver regeneration. Serum follistatin was also increased in patients with fulminant liver disease. (28) Furthermore, the laboratory values allow an assessment of the complications involved and an evaluation of the prognosis. (7, 8, 13, 14, 56, 60, 66, 77)

▶ Various laboratory values are indicative of severe complications and thus considered to be **criteria** pointing to a poor prognosis. (s. tab. 20.3)

| | |
|---|---|
| Decrease in cholinesterase | < 500 U/l |
| Decrease in factor V | < 20% |
| Fall in Quick's value | < 20% |
| Group-specific component protein | < 34 µg/ml |
| Hyperkalaemia | due to renal failure |
| Hypoalbuminaemia | < 2.5 g/dl |
| Hypocalcaemia | due to pancreatitis |
| Hyponatraemia | < 120 mval/l |
| Hyponatriuria | < 10 mmol/l |
| Lactatacidosis | > 3.5 mmol/l |
| Phosphataemia | > 2.5 mg/dl |
| Rapid drop in transaminases | subnormal values |
| Rise in bilirubin | over 20 mg/dl |

*Tab. 20.3:* Criteria for a poor prognosis in acute liver insufficiency

1. **GPT, GOT, GDH, LDH:** These enzymes are greatly elevated in accordance with cell destruction (GOT ≫ GPT). A decrease in enzyme values during the further course of disease can be a sign of regressing cell necrosis, marked parenchymal loss or a disorder in enzyme synthesis. A rapid drop in the initially elevated enzyme values is considered to be an unfavourable prognostic sign.

2. **Bilirubin:** Serum bilirubin shows a pronounced and varied increase, although the conjugated bilirubin does not rise at all, or only minimally, since uptake and conjugation remain intact for a considerable period of time.

3. **Quick's value:** A drop in the coagulation factors II, V, VII, IX and X is a reliable indicator of the still remaining liver function. Factor VIII increases. With massive liver cell destruction, a dangerous decrease in factors V and VII is witnessed within 1 or 2 days (corresponding to the half-life of the factors) together with a reduction in Quick's value and Colombi's index (< 60−80%). (45, 47, 71) (s. p. 105)

4. **Cholinesterase:** During the further course of disease, cholinesterase decreases in relation to its longer half-life and likewise allows a reliable assessment to be made of the remaining liver function. (s. p. 103)

5. **Electrolytes:** There is evidence of *hyponatraemia* (= dilutional hyponatraemia or reinforced natriuresis) as well as *hypokalaemia* (= inadequate supply, intensified kaliuresis, outflow of potassium into the body cells due to i.v. glucose infusions). The serum values of *magnesium, phosphate* and *zinc* are also lower as a rule.

6. **Group-specific component protein:** This substance (= $\alpha_2$-globulin) is synthesized in the liver and binds actin. GCP is released upon hepatocyte decay; its pronounced reduction in the serum results from the decrease in synthesis in acute liver failure.

## 3.7 Complications

▶ The course taken by acute liver failure varies in each case as a result of the respective complications, which also decidedly worsen the prognosis. Close-meshed and targeted laboratory investigations can usually identify

complications early enough, so that successful therapy might still be possible.

**Coagulation disorders:** Some 35−55% of patients with acute liver failure are in danger of suffering from serious gastrointestinal bleeding. Extensive cutaneous haemorrhages also occur frequently. In addition, disseminated intravascular coagulation (DIC) sometimes develops. As a result, bleeding and coagulation disorders number among the most frequent causes of death (20−25%). Pathophysiology is based on the diminished synthesis of coagulation and fibrinolysis factors and inhibitors as well as a decrease in the breakdown of activated factors, a functional disorder of thrombocytes or thrombopenia, and latent consumptive coagulopathy. It is of great help to determine PTT and factor V. A high level of the thrombin-antithrombin III complex (TAT) points to a poor prognosis. The simultaneous development of portal hypertension in individual cases promotes a tendency towards nasopharyngeal and gastrointestinal bleeding. (47, 71)

**Renal failure:** In about 50% of patients with acute liver failure, renal insufficiency develops. This can be expressed in three forms: (1.) *prerenal kidney failure* due to hypovolaemia, (2.) *acute tubular necrosis*, mainly secondary as a result of circulatory hypotension with cylindruria, a higher concentration of sodium in the urine (50−70 mmol/l) and a reduced urine creatinine/serum creatinine quotient (<20) or urine urea/serum urea quotient (<3), or (3.) *hepatorenal syndrome*. (41) (s. tab. 17.3)

**Respiratory insufficiency:** In general, respiratory alkalosis (pCO$_2$ < 30 mm Hg, pH > 7.5) is initially present, triggered by intensified respiration and tachypnoea. Despite this hyperventilation, there is evidence of hypoxia, which is largely due to a disorder in oxygen diffusion. The causes for this are microthromboses, interstitial formation of oedema and increased peripheral vasotonia. Central biochemical mechanisms together with an inadequate cerebral blood circulation as a result of a reduction in pCO$_2$ reinforce the respiratory insufficiency. Approximately 80% of patients in coma stages III and IV require artificial respiration. A total collapse of the pulmonary function can be occasioned by pneumonia (ca. 50% of cases) as well as by the leakage of fluid and/or bleeding in the lung area.

**Acid-base disorders:** Initial metabolic alkalosis (resulting from decreased urea synthesis with reduced bicarbonate consumption) may be superimposed by respiratory alkalosis as an outcome of disorders in lung function. During the further course, metabolic acidosis (with renal insufficiency) and respiratory acidosis (with pulmonary insufficiency) can be expected. In advanced or severe stages of the disease, lactate acidosis may develop in some 50% of all comatose patients owing to restricted gluconeogenesis.

**Circulatory disorders:** In general, acute liver failure is initially accompanied by hyperdynamic circulation. During the further course, approx. 80% of patients develop hypotension, which above all results in a considerable reduction in hepatic, cerebral and renal perfusion. At the same time, peripheral vasodilation is usually witnessed. Bradycardia, generally resulting from cerebral oedema, worsens the cardiovascular conditions and is considered to be a poor prognostic sign. Ultimately, the patient does not respond to volume expansion and catecholamines.

**Hypoglycaemia:** In 25−40% of cases, hypoglycaemia develops and can all too easily be overlooked. The cause is seen to be a reduced glycogen content in the liver, diminished glycogen synthesis and gluconeogenesis as well as hyperinsulinaemia due to reduced degradation of insulin in the liver. (21) It is often difficult to eliminate such hypoglycaemia, even with i.v. glucose infusions. • Furthermore, there is a danger of **hypokalaemia** and even **hypophosphataemia,** necessitating phosphate substitution with continuous monitoring of the serum values of phosphate and calcium (reactive hypocalcaemia is dangerous).

**Pancreatitis:** The frequency of hyperamylasaemia is reported to be 55% of patients with acute liver failure; in 20−30% of cases, pancreatitis could be identified clinically and sonographically. The cause is multifactorial.

**Infections:** Because of their greater susceptibility, about 80% of patients with acute liver failure are subject to the threat of bacterial infection, which in 10% of cases is also the reason for their death. The typical signs of an infection, such as fever or leucocytosis, are often absent. However, increased levels of *procalcitonin* (>0.58 ng/ml) are deemed to be a valid marker of bacterial infection. The respiratory tract and the urinary passages are most frequently affected. Regular bacteriological examinations (sputum or urine as well as catheter after removal) should therefore be carried out. Haemocultures have to be checked for both aerobians and anaerobians. Multiple serological tests may be necessary for aetiological clarification. There is also a risk of fungal infections. (50)

## 3.8 Prognosis

The survival rate in acute liver failure is given as 10−40%. This rate varies widely owing to a number of reasons. There is a *better prognosis* for poisoning from paracetamol or Amanita phalloides, for example, since successful therapy procedures have already been established for these forms of intoxication. Younger patients (10 to 40 years of age) generally have a better prognosis. This also applies to HAV infection. A *poor outcome* can be expected in Wilson's disease or Budd-Chiari syndrome and in coma stages III and IV (lethality over 80%) due to the development of complications (in particular bleeding, renal or respiratory insufficiency, infection) − especially with younger (<10 years) or older patients (>40 years). Acute liver failure which is due to halothane, the application of various medicaments or viral hepatitis (delta superinfection, HEV in pregnancy) likewise has a less favourable prognosis. • *Laboratory parameters* such as serum bilirubin, coagulation factors (PTT, factor V, Quick's value), galactose test and cholinesterase have proved to be most helpful in assessing the course of disease, the liver function and hence the prognosis. (14, 18, 23, 42, 45, 57, 60, 77)

## 3.9 Regeneration

The regenerative ability of the liver is of utmost importance for overcoming such a severe disease. (40) After a regeneration period, an intact cell mass (hepatic volume fraction) of >45% is required for survival. (40) Various factors are indicative of good regeneration: rising values of $\alpha_1$-foetoprotein (and also $\gamma$GT), HGF, EGF, THF$\alpha$, TNF$\alpha$ and interleukin-6 as well as a decline in serum phosphorous levels. (14) It was possible to improve *regeneration* by means of hepatotropic substances, such as *insulin* and *glucagon* (G. Starzl et al., 1975), so that these substances are also referred to as "goodies" for the liver (S. Sherlock, 1976). Subsequent investigations proved to be contradictory. (24, 79) An increase in the regeneration rate of the liver cells can possibly be achieved either by hepatic arterial infusion of PGE$_1$ (55) or by *silymarin* through

stimulation of RNA synthesis (J. Sonnenbichler et al., 1976). (s. pp 40, 867) (s. fig. 3.5)

# 4 Chronic liver insufficiency

## 4.1 Definition

*Chronic liver insufficiency is due to the progression of an already existing chronic liver disease.* This generally tends to be advanced cirrhosis of varied aetiology. Basically, however, any liver disease can be a potential cause of chronic liver insufficiency. Alcohol and infections as well as certain medicaments are also deemed to be common causes. A great number of substances and events can trigger liver insufficiency.

The clinical picture of chronic liver insufficiency comprises both a **compensated** and **decompensated** form. These two stages of manifest chronic liver insufficiency affect the hepatocellular area or the portal system either exclusively or predominantly (= **cellular** or **portal** compensation or decompensation); mostly they occur as a *combined form* of disease. The resulting spectrum of clinical and laboratory findings will reflect either a **global** or **partial** insufficiency of the liver. (s. p. 376)

## 4.2 Clinical findings

**General manifestations of the disease:** The clinical picture of chronic liver insufficiency is characterized by general symptoms such as fatigue, apathy, lack of appetite, lack of concentration, infirmity, sensation of repletion and meteorism.

**Clinical findings:** Organ-related so-called "minor signs" of liver insufficiency can be observed over a certain period of time. (s. tab. 20.4)

1. **Gastrointestinal tract**
   − meteorism
2. **Dermis and mucosa**
   − itching
   − skin stigmata of liver disease
   − tendency to "bruise"
   − nasal haemorrhage and ulorrhagia
   − tongue changes
3. **Stools**
   − intermittent acholic stool
4. **Urine**
   − intermittent dark urine
5. **Changes in the blood count**
   − anaemia          − thrombopenia
   − leucopenia       − macrocytosis
6. **Fever**
7. **Splenomegaly**
8. **Endocrine disorders**

*Tab. 20.4:* So-called "minor signs" of chronic liver insufficiency

▶ Increasing and constant *meteorism* ("first the wind and then the rain") and intermittent characteristic changes in the colour of *stools* and *urine* are distinct signs of impending insufficiency. The "blossoming" of *spider naevi* or an intensification of *palmar erythema* as well as *tongue changes* (e.g. the transition of the moist "scarlet tongue" into a dry "raspberry tongue") are often observed. Obvious features of the blood count are: *anaemia* (due to bleeding of the skin or mucosa, folic acid deficiency, reduced erythrocyte survival time) and *thrombopenia* (due to consumptive coagulopathy, dilutional thrombopenia with plasma dilution, immunothrombopenia, sequestration in splenomegaly and toxic inhibition of the bone marrow).

## 4.3 Decompensation

Decompensation in chronic liver insufficiency is characterized by the development of severe, life-threatening **complications:**

1. **Ascites and oedema**
2. **Coagulopathy and bleeding**
3. **Hepatic encephalopathy**
4. **Hepatorenal syndrome**
5. **Hepatopulmonary syndrome**
6. **Reduction in liver functions**

### 4.3.1 Reduction in liver functions

Of particular significance is the serious impairment of essential tasks performed by the liver such as the **detoxification function** (ammonia detoxification, biotransformation, radical scavenger function, clearance abilities of the RES, etc.), the **synthesis** of vital proteins and the **regulation** of biochemical systems and substances − these are considered to be precursors of complicative developments. Any insufficiency of bilirubin metabolism is reflected in increasing **jaundice**, likewise deemed to be an unfavourable sign with respect to prognosis.

### 4.3.2 Hepatic encephalopathy

The term **hepatic encephalopathy** (HE) describes the entire field of neuropsychiatric symptoms which can be found in patients suffering from acute or chronic liver disease. The term **portosystemic encephalopathy** (PSE) stresses the presence of portosystemic shunts, which are as a rule associated with liver cirrhosis. • **Hepatic coma** (in stages III and IV) is the ultimate and total loss of consciousness (coma = deep, sound sleep). In clinical terms, 4 (or 5) stages can be defined, but the latent or subclinical stage as well as stages I and II may progress so rapidly that only the comatose final stage is actually witnessed. Generally, chronic liver insufficiency is seen as a liver failure coma, i.e. exogenous coma. Recurrent hepatic encephalopathy points to the existence of a chronic liver disease, particularly liver cirrhosis. Serum levels of TNF correlates positively with the severity of HE. *(see chapter 15)*

### 4.3.3 Ascites and oedema

*Ascites* and *oedema* are also found in severe hepatic diseases, pointing to serious disorders in the water and electrolyte metabolism. These complications are signs of decompensation in liver cirrhosis or chronic liver insufficiency. At the same time, *pleural effusion* may also be evident. Cirrhosis-related pleural effusion without concomitant ascites has been described as a rarity. *(see chapter 16)*

### 4.3.4 Hepatorenal syndrome

All liver diseases resulting in liver insufficiency can also give rise to the hepatorenal syndrome. This syndrome is most frequently found in decompensated liver cirrhosis ("renal insufficiency in the terminal stage of cirrhosis"). It involves massive vasoconstriction of the renal cortical vessels with a critical drop in the glomerular filtration rate (urine production < 500 ml/day, possibly developing into anuresis). At the same time, systemic vasodilation and hyperdynamic cardiac function are generally witnessed. The survival time is very short. Lethality is approx. 95%. *(see chapter 17)*

### 4.3.5 Coagulopathy and haemorrhage

In 15−30% of patients with liver cirrhosis, coagulopathy leads to clinically relevant haemorrhagic diathesis. Dangerous and considerable *bleeding* may occur (nasal, gingival), and there may well be pronounced cutaneous haemorrhages; the latter occasionally occur as sugillations, ecchymoses and petechial haemorrhages (s. fig. 20.1) or as disseminated petechiae, especially around postoperative scars. (s. fig. 20.2) Gastrointestinal bleeding can be assigned to the upper gastrointestinal area in 80−85% and to the lower intestinal area in 15−20% of cases. *(see chapter 19)*

*Fig. 20.1:* Sugillations, ecchymoses and petechial haemorrhages in liver cirrhosis (with "paper money skin" and white nails)

*Fig. 20.2:* Extensive purpura in the abdominal area with bleeding into the cholecystectomy scar

### 4.4 Acute-on-chronic liver insufficiency

This condition describes acute liver failure in cases of hitherto well-compensated liver disease. The result is a sudden deterioration in clinical status accompanied by jaundice as well as hepatic encephalopathy and/or the hepatorenal syndrome.

There are a number of *causes* including (*1.*) well-known hepatotoxic factors (e. g. superimposed viral infection, alcohol consumption, hepatotoxic drugs, intoxication) and (*2.*) endogenous factors (e. g. sepsis, variceal bleeding, gastrointestinal haemorrhage, diarrhoea, hypoxia). Acute liver failure is frequently the result of a chain of damaging events, like a vicious circle.

The clinical and laboratory *findings* of this sudden deterioration largely correspond to those of acute liver failure (see above). This also applies to potential *complications* such as coagulopathy, HE, ascites and/or HRS.

## 5 Therapy

Except for the treatment of, for example, paracetamol intoxication and Amanita phalloides poisoning, there is no causal therapy for liver insufficiency. All conservative treatment measures are based on **four principles:**

> 1. Prevention and treatment of complications
> 2. Substitution of substances which cannot be adequately produced in the liver as a result of hepatic synthesis disorders
> 3. Bridging the period of time until toxins have been eliminated, liver functions and regenerative processes have improved or liver transplantation can be carried out
> 4. Promotion of liver regeneration

► **Intensive care:** Patients with ALF or with decompensated chronic liver insufficiency (such as coma stages II−IV, refractory ascites, hepatorenal syndrome, disseminated intravascular coagulation, gastrointestinal bleeding) require monitoring and treatment in an intensive care unit, preferably in a transplantation centre. (7, 13, 60, 66, 77)

### 5.1 General therapeutic measures

Intensive care involves monitoring the *cardiovascular system* (blood pressure, pulse, ECG) and *respiratory frequency*. The patient's *temperature* and *urine excretion* have to be recorded every hour. The *body weight* is documented every day using a weighing bed. The water equilibrium should be carefully monitored. Consistent *preventive measures against infection* must be guaranteed for those patients who are particularly at risk. Regular physical measures for the *prevention of pneumonia* are a necessity. A moderate *head-up position* (30−40°) is recommended. • A *central venous catheter* (monitoring central venous pressure, parenteral feeding), a *nasogastral tube* and a *suprapubic bladder catheter* are positioned for supply and monitoring purposes. *Nasal oxy-*

*gen supply* is advisable. The insertion of an epidural *intracranial pressure probe* is essential for early identification of cerebral oedema.

Provided the patient does not have a paralytic ileus, **enteral feeding** via a nasogastral tube is advisable to prevent villous atrophy and thus reduce the risk of bacterial translocation. • **Parenteral feeding** (1,600–2,000 kcal/day) consists of a continuous intravenous supply of glucose and fat emulsions (MCT). Hypertriglyceridaemia may, in the case of lipid infusions for example, point to a lipid metabolism disorder, but it can also be due to increased glucose intake, which results in fatty degeneration of the hepatocytes and a corresponding reduction in liver function. Fructose, sorbitol and xylitol must be avoided! The supply of either liver-adapted amino acids or branched-chain amino acids (BCAA) is generally recommended for chronic liver insufficiency – but not advisable in cases of acute liver insufficiency, because almost all amino acids are elevated in the serum in endogenous hepatic coma. A high daily dosage of water-soluble vitamins (possibly divided into two doses) is important. Administration of zinc is recommended.

**Electrolytes** (Na, K, Ca, Mg) and **blood sugar** must be carefully monitored, and any deviation from the norm should be corrected immediately. The risk of **hypophosphataemia** must be eliminated by early parenteral substitution. During refractory episodes, such as those involving the acid-base equilibrium and **hyperhydration,** haemodialysis is usually indicated. In **hypoalbuminaemia,** substitution with salt-free albumin is necessary. • With about 75% of patients, **artificial respiration** is called for, the aim being controlled hyperventilation.

**N-acetylcysteine** is believed to promote the supply of oxygen to the tissues. (72) As a result, this substance, which is free from side effects, was also recommended for cases of $CCl_4$ intoxication (52) and is even considered helpful in acute liver failure with a different aetiology.

As a **prophylaxis** against bleeding in the upper gastrointestinal area, *H₂ antagonists* and omeprazole are recommended. • The timely and repeated administration of *fresh plasma* (FFB) as well as of antithrombin III has proved to be the most effective measure for balancing plasmatic coagulation disorders.

**Bacterial infections** are extremely common as a result of serious impairment of the cellular and humoral resistance (ca. 80%). Close-meshed bacteriological investigations are required in the frequent absence of clinical signs of infection. This leads to early antibiotic therapy based on an antibiotic sensitivity test. Although an antibiotic prophylaxis is not actually recommended, it should nevertheless be considered in the individual case, since the spreading of an infection has a decidedly negative impact on prognosis. Administration of **selenite** (i.v.) may be advisable. Around 30% of patients develop a fungus infection, with a mortality rate of 50%. The

administration of amphotericin B or fluconazol is an effective prophylactic measure. • Bacterial or fungal infection can also be effectively suppressed by *intestinal restimulating of the bacterial flora* or **intestinal sterilisation** by means of neomycin (or paromomycin), a combination of nystatin and gentamicin, or lactulose. (50, 53) (s. pp 277, 280, 304)

**EPL:** In a pilot study, it was possible to achieve recompensation and lasting stabilization in 9 out of 10 patients suffering from severe liver insufficiency by i.v. administration of a new galenic form of polyenylphosphatidylcholine. (32) • This clinical result might be supported by the finding that a considerable deterioration in liver function was associated with a deficit of essential phospholipids (= EPL). (15) (s. p. 865)

## 5.2 Specific therapeutic measures

**Paracetamol intoxication:** Liver damage due to paracetamol (> 10 g) becomes manifest within ca. 48 hours after intake. (s. p. 378) For this reason, it is essential first of all to remove the non-absorbed fractions by *gastric lavage* and *intestinal cleansing*. As medicinal treatment, i.v. administration of the glutathione precursor *N-acetylcysteine* is the therapy of choice (L. F. Prescott et al., 1977). Dosage is 150 mg/kg BW with glucose as a rapid i.v. infusion (15–20 minutes), followed by 50 mg/kg BW over 4 hours and finally 100 mg/kg BW during the next 16 hours (= about 300 mg/kg BW within 20 hours). This therapy has to be commenced as soon as possible (no later than 12–15 hours after intoxication), even though a hepatoprotective effect can still be achieved up to 36 hours later. A serum concentration of < 200 μg/ml within 4 hours or < 60 μg/ml within 12 hours after intake can be considered prognostically favourable. (s. fig. 20.3)

***Fig. 20.3:*** Centrilobular, two-week-old liver cell necrosis resulting from paracetamol intoxication (HE)

**Amanita phalloides poisoning:** After a symptom-free latent period of about 12 hours, the gastroenteric phase sets in. (s. pp 378, 571) In this type of intoxication, it is imperative to carry out *gastric lavage* and *intestinal cleansing* as soon as possible with the help of saline agents using a nasogastral tube. The intestinal administration of medicinal charcoal is recommended. *Diuresis* must be enhanced by the administration of frusemide, if necessary with simultaneous volume substitution (CVP of about 10 cm $H_2O$). After another low-symptom period of about 1 day, the hepatorenal phase sets in. The uptake of Amanita phalloides poison into the liver is inhibited by *penicillin* (1 mega unit/kg BW/day as i.v. solution over 3 days). The therapeutic efficacy of silymarin and *silibinin*

was first detected in animal experiments in 1975 (G. Vogel et al.) and subsequently confirmed by a number of clinical studies. The recommended dose of silibinin is 30 (−50) mg/kg BW/day, administered in 4 separate doses in i.v. glucose infusions, each lasting 2 hours, over a period of 3 to 4 days. Penicillin and silibinin can (and should) be applied in combination. There is no specific antidote for Amanita toxins. Given timely and appropriate therapy, morbidity and mortality are surprisingly low. • In cases of therapy failure or a critical course of disease, liver transplantation may be indicated.

**Cerebral oedema:** *Mannitol* (0.5 g/kg BW or 100 ml, each as 20% solution) is used to treat the dreaded cerebral oedema. If renal function is sufficient, this course of therapy can be repeated every 1 to 4 hours, as required. Serum osmolality should not exceed 320 mosm/l, and intracranial pressure should not go above 20 mmHg. When renal function is restricted, dehydration should only be effected by means of haemofiltration. *Artificial respiration* is required (often as PEEP ventilation). Continuous monitoring of the intracranial pressure by means of an epidural *intracerebral pressure probe* is extremely helpful. Frequently, there is increased susceptibility to cerebral convulsibility; therefore, phenytoin should be administered at an early stage. Therapeutic application of *thiopental* (A. Forbes et al., 1989) as i.v. solution (up to 150 mg/hour) calls for intracranial pressure probe monitoring. (22) Other means of lowering the intracerebral pressure include the use of aminophylline, ranitidine, luxus oxygenation and semirecumbent positioning. (9, 17, 22, 34, 63) A prophylactic reduction in $pCO_2$ down to 25−35 mm Hg through **hyperventilation** can be advantageous in the initial stage of a brain oedema. (17, 63) Moderate **hypothermia** (core temperature down to 32−33°C, for 10−12 hours) may be useful in reducing the intracerebral pressure and cerebral blood flow as well as the cerebral uptake of ammonia. (31)

**Ornithine aspartate** (40 g/8 hours as intravenous infusion) (51) and **flumazenil** are advisable for the treatment of hepatic precoma and coma.

**Dopamine** (2 to 4 μg/kg BW/hr) should be administered at an early stage to stabilize the circulation and the renal blood flow. • **N-acetylcysteine** can be applied during oxygenation due to its positive effect on stabilizing the blood circulation and improving the serum coagulation factors. • **Indomethacine** reduces cerebral ammonia uptake.

**Prostaglandin:** The positive results achieved by the application of PGE₁ were reported in 1987 (M. Abacassis et al.). According to a subsequent prospective study, 71% of patients with fulminant and subfulminant hepatitis survived. (55, 61) The effect is attributed to improved arterial flow and regeneration of the liver (0.1 to 0.6 μg/kg BW/hr by means of perfusor for up to 18 hours, with the dosage gradually being phased out). • *Beware of hypotension!*

**Glucocorticoids** were first administered with some success in acute liver failure by H. Ducci et al. in 1952. Good results were also achieved in the treatment of severe alcoholic hepatitis with liver insufficiency (R. A. Helman et al., 1971). The application of glucocorticoids in autoimmune hepatitis with acute liver failure did not prove successful. (43) • The first report containing good results after treating fulminant viral hepatitis B with **anti-HBs plasma** was published in 1971 (D. J. Gocke). • The treatment of fulminant hepatitis B with **interferon alpha** did not progress beyond initial attempts (S. Levin et al., 1989).

**Lamivudine** (100 mg/day) proved to be effective: it was possible to achieve a lasting improvement in liver function and to avoid liver transplantation. No side effects were observed.

In view of the loss of complex biochemical liver functions, drug intervention in the metabolic processes of the liver should be as varied as possible − even the use of therapeutic agents which are not clinically controlled may be biochemically or pharmacologically justified.

▶ For a detailed description of **treatment measures** see: *hepatic encephalopathy* (chapter 15.9), *ascites* (chapter 16.9), *hepatorenal syndrome* (chapter 17.5), *coagulopathy and bleeding* (chapters 19.1.7 and 19.2.6).

## 5.3 Liver support systems

The most important survival factor in acute liver failure is the **patient's age**. In the 15 to 25-year age group, 30−50% of patients survive, whereas those older than 30 years have hardly any chance of survival. It would appear that the good regenerative ability of the liver in young people is the best guarantee for survival. • An attempt must be made at **bridging the decompensatory phase** by means of optimum intensive care and monitoring of the cerebral pressure as well as by applying clinically proven or indeed new therapeutic procedures or medication until the liver has adequately regenerated or until liver transplantation can be carried out. • Basically, there are **three techniques** available for bridging the compensatory phase: (*1.*) extracorporeal systems (*2.*) biosynthetic artificial livers or hybrid organs, and (*3.*) transplantation of hepatocytes. (85, 95, 96, 106)

### 5.3.1 Extracorporeal systems

1. **Exchange transfusion** (C. Lee et al., 1958): This method was used to fractionate and repeatedly exchange the entire circulatory blood of a patient. However, based on the results of subsequent studies (G. Baltzer et al., 1971; A. G. Redeker et al., 1973), this procedure can no longer be recommended.

2. **Haemoperfusion:** The removal of both water-soluble and protein-bound substances from the plasma was first attempted by means of a haemoperfusion circuit, using a column filled with activated charcoal (D. C. Schechter et al., 1958; H. Yatzidis et al., 1964). Both the unwanted binding of corpuscular components and the danger of embolization from charcoal particles could largely be eliminated by coating the activated charcoal with a biocompatible membrane, i.e. microencapsulation (T. M. S. Chang et al., 1964). Because of the greater aggregation of thrombocytes, however, thrombopenia often ensues. This event can generally be prevented by the administration of prostacyclin (C. A. E. Gimson et al., 1980). Unfortunately, however, this procedure causes a loss of insulin and other hormones. (88)

3. **Cross-circulation:** *Homologous* cross-circulation with healthy volunteers was first attempted by J. M. Burnell et al. in 1965. • Due to multiple problems, S. C. W. Bosman et al. introduced *heterologous* cross-circulation using a baboon in 1968; baboons are the only animal species which can tolerate human blood for 5 to 7 days.

4. **Plasmapheresis:** This procedure is a further development of blood exchange (M. J. Lepore et al., 1967). The patient's plasma is separated by centrifugation or other appropriate techniques and discarded, so that the protein-bound and fat-soluble toxins circulating in the plasma are removed. This plasma volume is replaced by fresh plasma. At the same time, the separated corpuscular components of the patient's blood are reinfused. Serious complications may arise from the transmission of viral hepatitis and the occurrence of transfusion-related lung disorders (ARDS). Nevertheless, the method involved is simple and has been carried out successfully in individual cases (87, 91) even as plasma exchange with the administration of a high plasma volume (1.3 l/hr over 8 hours). • It has proved to be much more successful when the serum (ca. 3 l

fresh frozen plasma/day) is infused into the femoral artery rather than into the vein (G. Brunner et al., 1991).

5. **Plasma perfusion:** In 1974 patient plasma separated by plasmapheresis was for the first time passed through activated charcoal and artificial resin in order to absorb toxins. In this way, the patient's own purified plasma is reinfused together with the solid components of the blood. This procedure produces fewer side effects and is easy to carry out.

6. **Total body wash-out:** This technique is a modification of exchange transfusion. The circulatory system is washed out with electrolyte solutions and then refilled with donor blood whilst the patient is in a state of hypothermia (G. Klebanoff et al., 1972).

7. **Haemodialysis:** In 1968 temporary improvement could be achieved for the first time by means of haemodialysis in a patient presenting with fulminant hepatic failure (W. M. Keynes); this was repeated later in 1977 (R. Oules et al.). The procedure, however, is not generally recommended. It may be indicated in renal failure, acid-base disorders or with hyperhydration. Following haemodialysis, substitution of reduced amino acids is necessary.

8. **Haemofiltration:** This procedure turned out to be of more value than haemodialysis. No dialysate fluid is required. Instead, a solution containing buffered bicarbonate is used to replace the ultrafiltrate. In fulminant hepatic failure, continuous venovenous haemofiltration is recommended because of its advantages for the circulation and metabolism. Heparin or prostacyclin can be used as anticoagulants (C. A. E. Gimson et al., 1980).

9. **Haemodiabsorption:** The BiologicDT system is a combination of haemodialysis and haemoadsorption (S. R. Ash et al. 1992). (82) Plasma separation was subsequently added to this system (S. R. Ash et al., 1998). (83) This newly developed BiologicDTPF facilitates direct plasma contact with the haemodiadsorber. The system, which makes use of both a charcoal and a cation exchanger, dialyzes blood across a parallel plate dialyzer with a cellulose membrane. So far, results have been disappointing − only lactate, creatinine and bilirubin were reduced.

10. **Albumin dialysis:** The aim of albumin dialysis is to remove both soluble metabolites and albumin-bound substances (ABS) from the blood of patients with acute liver failure. (s. tab. 20.5)

| | |
|---|---|
| benzodiazepines | fatty acids |
| bile acids | phenylalanin |
| bilirubin | several peptides |
| carbon hybrids | tryptophan |
| copper | *etc.* |

*Tab. 20.5:* Albumin-bound substances (ABS) relevant in acute liver failure

**SPAD:** **S**ingle-**p**ass **a**lbumin **d**ialysis was the first method to be developed. The blood of the patient is extracorporeally dialyzed through an albumin-impermeable membrane against albumin in the secondary circuit. The loaded albumin is discarded.
