Finally, Hayes-Skelton and colleagues (2013) very recently conducted a well-done RCT comparing ABBT and applied relaxation in a sample of 81 individuals with GAD. Patients in both treatment conditions received 16 sessions of treatment and were followed for 6 months after treatment. Unlike the results found by Dugas and colleagues (2010) and Wells and colleagues (2010), ABBT and relaxation exhibited comparably strong outcomes at posttreatment, with 70.0% of those in the ABBT group being classified as responders to treatment in comparison with 78.8% of those in the relaxation group. At a 6- month follow-up, the treatment gains were maintained: 76.0% of the ABBT individuals were classified as responders versus 71.4% of those in the relaxation group. However, the relaxation training performed particularly strongly in this trial compared to what was observed by Wells and colleagues (2010).

Translational Research (Effectiveness Studies)

Surveys reveal that people with anxiety difficulties are prevalent in primary care settings, suggesting a need for the development of brief, cost-effective treatments (Barlow, Lerner, & Esler, 1996). Along these lines, Rollman and colleagues (2005) compared the effectiveness of a telephone-based managed care intervention with treatment as usual for 191 patients diagnosed with either PD or GAD (although 90% of the full sample carried a GAD diagnosis). Patients were randomly assigned to one of the two interventions. Those assigned to the telephone-based managed care condition were offered any combination of three intervention components: (a) a workbook designed to assist with self-management of anxiety with follow-up contact from a care manager (Craske, Barlow, & O'Leary, 1992), (b) a trial of pharmacotherapy, or (c) a referral to a community mental health care provider. Of note, the vast majority of patients (80%) chose the self-management workbook. At the 12-month follow-up, although the intervention was less successful in reducing anxiety symptoms for patients with GAD only as compared to PD, all patients who received an intervention showed significant improvements in anxiety symptoms, quality of life, the number of hours worked, and the number of days absent from work compared with those who received usual care. These data suggest that treatment in a primary care setting is not only feasible and acceptable to patients with GAD but also successful in reducing symptoms that may lead to reductions in health care costs. In an era of rising health care costs, developing brief, cost-effective, and perhaps self-directed treatments with proven efficacy for the treatment of GAD in primary care offices will be an important step for future research in the area.

Future Directions

The more we learn about the nature of GAD, the more we should be able to improve our psychotherapeutic treatments. Additional dismantling studies should assist in determining the specific mechanisms of action in successful therapy. At this time, CBT approaches are one of the most widely evaluated types of psychotherapy for GAD. In fact, a recent meta-analysis by Hanrahan, Field, Jones, and Davey (2013) found CBT was superior to nontherapy controls (d = 1.81) and non-CBT therapy (d = .63). The magnitude of effect for recent studies comparing CBT to non-CBT treatments was larger than previously found, possibly suggesting increased efficacy of newer forms of CBT. The results of studies comparing CBT to other treatments or a waitlist are summarized in Table 14.4 (adapted and updated from Barlow & Lehman, 1996).

Until recently, most studies have not demonstrated differential rates of efficacy for active treatment techniques. However, most studies have shown that active treatments are superior to nondirective approaches and uniformly superior to no treatment. Hence, the most recent NICE (2011) guidelines recommend both CBT and applied relaxation as treatment options if less intense treatments such as self-help or psychoeducational groups are not beneficial. Although more research in this area is warranted, substantial progress is evident during the past decade, particularly in the past several years. Promising new CBT approaches, such as ABBT, metacognitive therapy, and Dugas and colleagues' CBT focusing on intolerance of uncertainty, have been shown to be superior or equivalent to other active treatments (Dugas et al., 2010; Hayes-Skelton et al., 2013; Wells et al., 2010). Future

TABLE 14.3 (continued)

Study	Length of Follow-Up (Months)	Treatment (N)	Percentage Clinical Improvement of Completers (If Available)	Significant Comparison (Percentage Clinical Improvement)	
				Other Treatments (Yes/No)	Waitlist (Yes/No)
Hayes-Skelton et al. (2013)	6	ABBT(N = 40)	70	No: AR = 79%	
van der Heiden et al. (2012)		MCT(N = 61)	77	Yes: CBT = 63%	Yes

ABBT = acceptance-based behavioral therapy; AMT = anxiety management training; AP = analytic psychotherapy; APL = attention placebo; AR = applied relaxation; BT = behavior therapy; CBT = cognitive-behavioral therapy; CBT-G = cognitive-behavioral therapy-group format; CT = cognitive therapy; DZ = diazepam; FU = follow-up; I = intervention (either self-management workbook, trial of pharmacotherapy, or referral to mental health care provider); MCT = metacognitive therapy; ND = nondirective therapy; PL = pill placebo; PR = progressive relaxation; PT = posttreatment; SCD = self-control desensitization; UC = usual care.

[a]Intent-to-treat.

[b]Study comparison included patients with diagnosis of GAD, although it was not designated whether GAD was assigned as principal.

Compiled and adapted from Barlow, D. H., & Lehman, C. (1996). Advances in the psychosocial treatment of anxiety disorders: Implications for national health care. *Archives of General Psychiatry*, 53, 727–735; and Borkovec, T. D., & Whisman, M. A. (1996). Psychosocial treatment for generalized anxiety disorder. In M. Mavissakalian & R. Prien (Eds.), *Long-term treatments of anxiety disorders* (pp. 171–199). Washington, DC: American Psychiatric Press.

research will need to be conducted to further establish the efficacy of these recently developed interventions and to explore whether any of these treatments perform consistently better than other CBT approaches for GAD. Also important will be analyses of how these treatments may have similar core components and mechanisms of action. In addition, more research needs to be conducted examining the effectiveness of treatments for GAD in primary care and community settings.

TRANSDIAGNOSTIC TREATMENT

Thus far, we have reviewed a number of CBT approaches that have been developed and rigorously evaluated for PD, agoraphobia, specific phobia, SAD, and GAD. Although these interventions have shown efficacy (and, for some, effectiveness) in treating these disorders, limitations posed by the proliferation of these diagnosis-specific treatments have been increasingly acknowledged in recent years. One criticism of these approaches is the reliance on multiple manuals and clinicians skilled in delivering the protocols in all of these manuals. Thus, the development of these often complex protocols has resulted in problems with dissemination and a paucity of adequately trained professionals. Research conducted over the past several decades has also resulted in strong evidence for considerable overlap among the anxiety and mood disorders (e.g., Barlow, 2004; Barlow, Sauer-Zavala, Carl, Bullis, & Ellard, 2014b; Moses & Barlow, 2006), which may be explained by shared underlying commonalities (e.g., increased emotional reactivity, attempts to alter or avoid emotional responding; Barlow, 2002; Brown, 2007; Brown & Barlow, 2009). There is also research suggesting that CBT for one anxiety disorder often leads to simultaneous improvement in co-occurring conditions (e.g., Borkovec, Abel, & Newman, 1995; Brown & Barlow, 1995; Craske et al., 2007), although effects may not be durable for nontargeted disorders (Brown & Barlow, 1995). Collectively, these areas of research have set the stage for more parsimonious approaches to treating the anxiety disorders.

To meet this need, several programs containing core CBT strategies used to treat all anxiety and related disorders (transdiagnostic) have been developed and tested (e.g., Barlow, Allen, & Choate, 2004; Norton, 2008). One such intervention that has garnered the interest of researchers and clinicians alike is the Unified Protocol for Transdiagnostic Treatment of Emotional Disorders (UP; Barlow et al., 2011a, 2011b; Payne, Ellard, Farchione, Fairholme, & Barlow, 2014). Briefly, the major components of this treatment involve fostering present-focused,

nonjudgmental emotion awareness, altering cognitive reappraisals, preventing emotional avoidance, increasing tolerance of physical sensations associated with anxiety and distress, and facilitating action tendencies not associated with dysregulated emotions (Payne et al., 2014; Wilamowska et al., 2010). Some treatment components are almost identical to those commonly employed in evidence-based CBT protocols for specific anxiety disorders; however, the UP modules are designed to be applicable across anxiety and mood disorders, as well as other disorders characterized by intense negative and dysregulated emotions (e.g., somatic symptom disorders). The UP also extends traditional CBT strategies by including a more explicit focus on the interaction of thoughts, feelings, and behaviors, emphasizing the functional nature of emotions, and encouraging greater tolerance of emotions (Ellard et al., 2010).

The UP has been subjected to empirical testing in a number of trials to date. In the first (type 2) pilot study, 18 diagnostically heterogeneous participants began a 15-session course of individual treatment (Ellard et al., 2010). This trial used an earlier version of the protocol, which comprised psychoeducation about emotions, alteration of antecedent cognitive misappraisals, prevention of emotion avoidance, and modification of emotion-driven behaviors (Allen, McHugh, & Barlow, 2008). Principal diagnoses included PD with agoraphobia, SAD, GAD, obsessive-compulsive disorder, posttraumatic stress disorder, major depressive disorder, and hypochondriasis. Results showed significant, yet modest, pretreatment-to-posttreatment effects across principal and comorbid disorders, suggesting that there was a need for continued development and refinement of the treatment manual. After making further modifications to the protocol (e.g., increasing emphasis on present-focused, nonjudgmental emotion awareness), a second open trial of the UP was conducted in a sample of 15 similarly diagnostically heterogeneous patients (Ellard et al., 2010). Findings showed that 73% of patients met responder status, and 60% achieved high end-state functioning for their principal disorder(s). With regard to comorbid disorders, 64% of patients attained both responder status and high end-state functioning. At the 6-month follow-up, results were even more promising, with 85% of patients achieving responder status on their principal diagnosis and 69% meeting criteria for high end-state functioning. In terms of comorbid disorders, 80% of patients achieved responder status, and 50% of the total sample attained high end-state functioning at follow-up.

More recently, the first RCT of the UP was conducted. Farchione and colleagues (2012) randomly assigned 37 patients with a principal anxiety disorder (PD with agoraphobia, SAD, GAD, obsessive-compulsive disorder, anxiety disorder not otherwise specified, and/or posttraumatic stress disorder) to receive 16 sessions of the UP (n = 26) or a waitlist control condition (n = 11). The protocol used in this trial followed that employed in the second pilot study by Ellard and colleagues (2010), with the addition of a motivational enhancement module and greater emphasis on increasing positive emotions (Barlow et al., 2011a; Payne et al., 2014). At posttreatment, 50% of patients in the UP condition met subclinical status (and achieved high end-state functioning) on their principal diagnoses (vs. 0% of the waitlist) and 45% of UP patients no longer met criteria for any clinical diagnoses (vs. 0% of the waitlist). Also at posttreatment, 50% of patients in the UP condition no longer met criteria for any comorbid diagnoses (vs. 17% of the waitlist; this difference did not reach statistical significance). Individuals with different principal anxiety disorder diagnoses who received the UP responded similarly, with all but one effect size estimate for diagnosis-specific measures in the very large range at the end of treatment and at the 6-month follow-up. The UP also showed strong response rates at the follow-up assessment, with 71% of UP patients achieving subclinical status on their principal diagnosis and 64% on all clinical diagnoses.

Taken together, findings from these initial studies provide preliminary support for the efficacy of UP as a transdiagnostic treatment for anxiety disorders, including those reviewed in this chapter. Results also show that the UP has moderate to large effects on measures of negative and positive affectivity, which is consistent with the treatment's overall emphasis on affective processing. A large-scale noninferiority study is under way at our center in Boston to examine the efficacy of the UP in comparison to established single-diagnosis CBT protocols. This initiative, and other upcoming work to identify the specific mechanisms by which the UP obtains its effects, has the potential to establish the UP as a more efficient, and perhaps more effective, approach to the treatment of anxiety and related disorders than "gold-standard" single-disorder treatments.

Similarly promising results have been observed for other transdiagnostic treatments. For example, in 2012, Norton and Barrera published findings from a type 1 trial comparing the efficacy of a transdiagnostic CBT group protocol to diagnosis-specific CBT protocols. Patients (N = 46) with a principal diagnosis of PD, SAD, or GAD were randomly assigned to 12 weekly 2-hour group sessions of the transdiagnostic or diagnosis-specific treatment. Session-by-session analyses indicated that transdiagnostic CBT had noninferior outcomes in comparison to diagnosis-specific CBT. At posttreatment, no significant differences between conditions were observed; for instance, the percentage of patients classified as responders in the transdiagnostic versus diagnosis-specific condition (64.7% vs. 69.2%, respectively) was similar. In addition to studies that include a control condition and employ larger, more diverse samples and follow-up assessments, future research should aim to determine whether this and other transdiagnostic interventions (e.g., Barlow et al., 2011) facilitate significant advances in dissemination and training.

Transdiagnostic treatments for anxiety disorders can also be offered through Internet sources. This approach may be particularly well suited to reducing barriers to dissemination, as the advantages of transdiagnostic strategies are combined with increased accessibility and convenience for patients and clinicians, as well as ensured treatment fidelity (Andrews et al., 2010). To date, several electronic or Internet-based transdiagnostic interventions have been developed and evaluated, including the Coordinated Anxiety Learning and Management (CALM) intervention (Craske et al., 2011) and the Wellbeing Program (Titov et al., 2011). Generally, studies in this area provide support for the efficacy of transdiagnostic computerized CBT, thereby suggesting the potential of this innovative approach (e.g., Dear et al., 2011; Roy-Byrne et al., 2010).

For example, one recent, large-scale study examined the effectiveness of an evidence-based intervention comprising CBT and/or pharmacotherapy recommendations compared to usual care in 17 primary care clinics (Craske et al., 2011). The CALM intervention is a computer-assisted CBT program that addresses the four most common anxiety disorders in primary care settings (panic, GAD, SAD, and posttraumatic stress disorder). CALM contains eight modules; cognitive restructuring and exposure modules are tailored to each of the four anxiety disorders through branching systems, whereas the other modules are mostly generic (Craske et al., 2009). In this trial, 1,004 patients meeting diagnostic criteria for a principal anxiety disorder (262 with panic, 132 with SAD, 549 with GAD, and 61 with posttraumatic stress disorder) were randomly assigned to receive CALM or usual care for up to 12 months. Those randomized to CALM could select a combination of CBT and medication management, or medication management only; between 46% and 65% of patients (depending on principal diagnosis) in the intervention condition chose CBT plus medication, while only 9% chose medication alone. At 6 months, CALM was superior to usual care in reducing symptoms of GAD, SAD, and panic, as well as showing higher response rates for GAD and SAD. At 12 months, CALM was also superior to usual care in remission rates for PD. For comorbid disorders, effect sizes favored the intervention, but there were no statistically significant differences. These findings suggest that providers with little or no training in mental health can deliver effective CBT treatment with the aid of a computerized guide, combined with medication recommendations, to diverse patient populations in primary care settings. These data also indicate that computer-assisted, transdiagnostic CBT can affect not only general outcome measures of anxiety but also disorder-specific outcomes.

Given the significant implications for dissemination and training posed by computer-based, transdiagnostic treatments, key unanswered questions for future research include the optimal length of these programs, the ideal balance of clinician contact, the most important treatment elements, and the relative short- and long-term efficacy and cost-effectiveness compared to disorder-specific approaches. Combining Internet-based, modular formats (e.g., Carlbring et al., 2011) with a transdiagnostic approach may also represent an important area for future work in this area, as individually tailored treatment may prove more acceptable, efficient, and/or efficacious than one-size-fits-all methods.

CONCLUSIONS

It is clear that a multitude of efficacious psychological treatments for a variety of anxiety disorders exist; however, there is still considerable room for continued testing and refinement. For one, we are only

beginning to explore the effectiveness of these procedures outside of research trials. In addition to questions about the generality of effectiveness across patients, settings, and therapists of differing skills and abilities, criticisms have also been raised about the feasibility of these treatments, as well as their cost-effectiveness. Many of these issues are outlined succinctly in the template for psychological intervention guidelines referred to above (APA, 2002; American Psychological Association Task Force on Psychological Intervention Guidelines, 1995), which provides a road map for future research. Emerging findings suggest that many of these procedures are just as effective or more effective when applied in a variety of practice settings as they are in the clinical research settings where they were developed (Barlow, 1996; Barlow & Barlow, 1995), but further research in this area is necessary.

As we have emphasized, we must improve efforts to disseminate these treatments to the variety of practice settings in which they should prove useful, many of them primary care settings, to meet the demands of many patients with these disorders who desire brief, effective treatment. Evidence indicates that effective psychological treatments are much less readily available than pharmacological interventions in most settings and are often suboptimally delivered (Barlow, Levitt, & Bufka, 1999; Craske et al., 2011). Thus, it is not enough simply to develop these treatments and report on their efficacy or effectiveness. Rather, it is the responsibility of those involved in treatment development to continue evaluating methods of training and dissemination, such as those that incorporate innovative technologies and/or transdiagnostic approaches applicable across diverse patient presentations, to ensure that these treatments reach the greatest number of people who need them.

Pharmacological Treatments for Panic Disorder, Generalized Anxiety Disorder, Specific Phobia, and Social Anxiety Disorder

Ryan J. Kimmel
Peter P. Roy-Byrne
Deborah S. Cowley

Selective serotonin reuptake inhibitors (SSRIs) are now considered the first-line pharmacological treatment for panic disorder (PD) based on their low rate of side effects, lack of dietary restrictions, and absence of tolerance. Similarly, SSRIs and venlafaxine are attractive first-line treatments for social anxiety disorder (SAD). The pharmacological treatments of choice for generalized anxiety disorder (GAD) are buspirone and antidepressants, including SSRIs and SNRIs. Benzodiazepines, although effective for all these disorders, lack efficacy for comorbid depression. Moreover, benzodiazepines carry with them the risk of physiological dependence and withdrawal symptoms. Their greatest utility at present seems to be as an initial or adjunctive medication for patients with disabling symptoms requiring rapid relief and for those unable to tolerate other medications. Chronic treatment with benzodiazepines is generally safe and effective but should probably be reserved for patients who are nonresponsive or intolerant to other agents. Larger trials are necessary to determine whether pharmacological agents might be useful as monotherapies, or as adjuncts to exposure psychotherapy sessions, for specific phobia.

INTRODUCTION

Since the early 1980s, when the third edition of the *Diagnostic & Statistical Manual of Mental Disorders* (DSM-III; American Psychiatric Association [APA], 1980) subdivided neuroses into the separated domains of panic, generalized anxiety, and phobias, we have seen a growing appreciation of the important role of pharmacotherapy in the treatment of these syndromes and an accumulating body of evidence documenting the efficacy of specific classes of medication for specific anxiety disorders. This chapter reviews the clinical characteristics and pharmacotherapy of four major anxiety disorders: PD, GAD, SAD, and specific phobia. Selected literature will largely focus on the most rigorously designed studies. Other levels of evidence will be cited only to address key clinical issues not yet studied in randomized controlled trials (RCTs).

PANIC DISORDER

Panic attacks are sudden, unexpected bursts of extreme anxiety accompanied by at least four cardiorespiratory,

gastrointestinal, otoneurological, autonomic, or cognitive symptoms. PD is characterized by the presence of recurrent panic attacks, at least some of which are spontaneous (i.e., unexpected), followed by a month of persistent anxiety about having attacks, concern about the implications of attacks (often marked by hypochondriacal preoccupations), or avoidance of situations that the individual feels will bring on attacks. *DSM-5* (APA, 2013) has removed the *DSM-IV*'s specifications about PD in the presence or absence of agoraphobia. In the *DSM-5* system, agoraphobia is its own separate diagnosis. Because virtually all medication trials have included patients with PD complicated by phobic avoidance, the studies in the following review of antipanic agents are likely applicable to these individuals.

Although one in seven people will experience a panic attack in their lifetime, the diagnosis of PD involves recurrent attacks along with preoccupation or behavioral changes and has prevalences in the general population of 1.5% (1 month; Eaton, Kessler, Wittchen, & Magee, 1994), 2.3% to 2.7% (12 months; Kessler, Chiu, Demler, Merikangas, & Walters, 2005c), and 3.5% to 4.7% (lifetime; Kessler et al., 2005a). Twice as many women as men are affected, with peak age of onset typically in the late teens and early 20s (Eaton et al., 1994). There are a wide range of prospective genes and gene–environment interactions that may contribute to a risk for PD (Battaglia, 2013; Hamilton, 2009). In addition, stressful life events occur at an increased rate around the time of panic onset (P. P. Roy-Byrne, Geraci, & Uhde, 1986). Interoceptive conditioning and an increased tendency to amplify body sensations, as well as an anxious experience via catastrophic and other cognitive distortions (D. H. Barlow, 2002; Bouton, Mineka, & Barlow, 2001), constitute psychological factors that maintain panic. Hence, PD is likely to involve a heritable biological vulnerability and a series of stressful triggers modulated perhaps by a cognitive style that may have both innate and learned origins.

PD has a high rate of comorbidity with major depressive disorder and vice versa. Indeed, the antidepressant imipramine has been the target of antipanic efficacy studies since the early 1960s. Despite subsequent studies showing the efficacy of benzodiazepines and behavioral treatment in the 1980s, as well as the more recent demonstration of SSRI and serotonin–norepinephrine reuptake inhibitor (SNRI) antipanic efficacy, evidence-based treatment for PD has been poorly integrated into clinical practice. The surprisingly high utilization rate of nonspecific psychotherapy and ineffective medication regimens observed in the 1980s (Taylor et al., 1989) has been improved only modestly in both psychiatric (Goisman, Warshaw, & Keller, 1999), and primary care settings (P. Roy-Byrne et al., 2002; M. B. Stein et al., 2011) with rates of adequate medication (30% to 50%) and cognitive-behavioral treatment (CBT; 10% to 30%) still quite low in these settings. Even among providers who say that they are doing "CBT," the ambiguity of this term, the absence of some core CBT components in their practice, and the inclusion of noncompatible techniques raise questions about how frequently evidence-based guidelines are being followed (Hipol & Deacon, 2013).

The mainstays of pharmacological treatment of PD have been, in order of historical and chronological development, tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) in the 1960s and 1970s, high-potency benzodiazepines in the 1980s, SSRIs in the 1990s, and SNRIs in the new millennium. Currently, two benzodiazepines (alprazolam and clonazepam), three SSRIs (paroxetine, fluoxetine, and sertraline), and one SNRI (venlafaxine) have U.S. Food and Drug Administration (FDA) approval for PD. However, other SSRI, heterocyclic, and MAOI antidepressants are also effective, highlighting the fact that there is, in general, poor concordance between established efficacy and approved indication for PD, as well as other anxiety disorders. A large meta-analysis found no difference in the effect sizes between benzodiazepines, TCAs, and SSRIs for panic disorder (Mitte, 2005).

Selective Serotonin Reuptake Inhibitors

Extensive evidence supports the efficacy of SSRIs in the treatment of PD, with a number needed to treat (NNT) of 5 to 8 for the acute phase of treatment (Kumar & Malone, 2008). These agents have replaced benzodiazepines as first-line medication for panic in the judgment of numerous experts (Papp et al., 1997; P. P. Roy-Byrne, Craske, & Stein, 2006; Uhlenhuth, Balter, Ban, & Yang, 1998).

Currently, three SSRIs (paroxetine, sertraline, and fluoxetine) are approved by the FDA for treatment of PD. Type 1, double-blind, placebo-controlled studies, using both flexible and fixed doses, support the

short-term (8 to 12 weeks) antipanic efficacy of paroxetine (Ballenger, Wheadon, Steiner, Bushnell, & Gergel, 1998c; Kampman, Keijsers, Hoogduin, & Hendriks, 2002; Lecrubier, Bakker, Dunbar, & Judge, 1997; Oehrberg et al., 1995; M. Pollack et al., 2007; M. H. Pollack et al., 2007; Sheehan, Burnham, Iyengar, & Perera, 2005; Wedekind et al., 2010), sertraline (Kamijima et al., 2005; Londborg et al., 1998; R. B. Pohl, Wolkow, & Clary, 1998; Pollack, Otto, Worthington, Manfro, & Wolkow, 1998), and fluoxetine (Michelson et al., 1998, 2001). Seven double-blind, placebo-controlled studies have shown efficacy for the now infrequently prescribed SSRI fluvoxamine (Asnis et al., 2001; Black, Wesner, Bowers, & Gabel, 1993; de Beurs, van Balkom, Lange, Koele, & van Dyck, 1995; Den Boer & Westenberg, 1988; Hoehn-Saric, McLeod, & Hipsley, 1993; Nair et al., 1996; Sandmann et al., 1998). Two double-blind, placebo-controlled trials have demonstrated antipanic efficacy for citalopram (Leinonen et al., 2000; Wade, Lepola, Koponen, Pedersen, & Pedersen, 1997), and several trials have shown benefit from the S-isomer of citalopram, escitalopram (Bandelow, Stein, Dolberg, Andersen, & Baldwin, 2007; Stahl, Gergel, & Li, 2003). These SSRI studies have shown effects on symptomatic components of PD, including panic frequency, generalized anxiety, disability, and phobic avoidance, although not all studies measured all of these components.

Continued efficacy over the long term has been demonstrated in placebo-controlled discontinuation designs following acute placebo-controlled trials, for paroxetine over 36 weeks following a 12-week trial (Lecrubier & Judge, 1997), for sertraline over 28 weeks following a 1-year-long open-label extension after a 10-week acute trial (Rapaport et al., 2001), for fluoxetine over 24 weeks following a 10-week trial (Michelson et al., 1999), and for citalopram over 52 weeks following an 8-week trial (U. M. Lepola et al., 1998). In most of these trials, patients who had seen initial benefit continued to improve over the longer term.

There is some controversy about whether PD requires higher SSRI dosing compared to the treatment of depression or just more patience in awaiting efficacy from moderate dosing. Studies have shown that doses of 40 mg paroxetine, 100 to 200 mg sertraline, 10 to 20 mg fluoxetine, 100 to 200 mg fluvoxamine, and 20 to 30 mg of citalopram are effective. Early studies suggested higher doses may be beneficial for paroxetine (Ballenger et al., 1998c) and fluoxetine (Michelson et al., 2001) and perhaps counterproductive for sertraline at the 200-mg dose (Londborg et al., 1998). In a more recent study, sertraline (maximum dose 100 mg) or escitalopram (maximum dose 15 mg) was employed in a 6-week, open-label trial. Patients with continued panic symptoms were enrolled in a 6-week RCT wherein half of the patients were allowed dose increases of up to 200 mg sertraline or 30 mg escitalopram and half of the patients were continued on the initial dosing paradigm. Increased dose did not increase efficacy (Simon et al., 2009).

In some of the earliest studies of imipramine for panic, it was noted that the response rate at 6 months was higher than the response rate at 3 months (Zitrin, 1983). Similarly, the time course of effect for SSRIS has been shown to be delayed. In the various studies, superiority to placebo has emerged, depending on the specific outcome being measured, as early as 2 weeks (Pollack et al., 1998) and as late as 4 weeks (Ballenger et al., 1998c), with some patients responding later, at 9 to 12 weeks (Michelson et al., 2001; Oehrberg et al., 1995). Early improvement does seem to predict more complete response—that is, remission—at the end of the acute trial (Pollack et al., 2002).

Early overstimulation was noted with fluoxetine in open reports (Schneier et al., 1990), prompting recommendations for low (5-mg) starting doses, although other trials began at 10 mg with fewer problems (Michelson et al., 2001). Such effects have been infrequently noted with the other SSRIs. For example, only 2 of 80 sertraline patients experienced overstimulation in one study (R. B. Pohl et al., 1998).

The side effect burden with SSRIs has been much less severe, with higher percentages of patients completing treatment (82%), than in studies of TCAs (69%) (Bakker, van Balkom, & Spinhoven, 2002). However, abrupt withdrawal of SSRIs has been associated with a withdrawal syndrome marked by irritability, nausea, dizziness, and headache in the case of both fluvoxamine (Black, Wesner, & Gabel, 1993) and paroxetine (Oehrberg et al., 1995). This is probably due to their relatively shorter half-life compared with fluoxetine and sertraline, although similar but milder symptoms have been observed with sertraline discontinuation (Rapaport et al., 2001). The common practice of switching patients to the longer-acting fluoxetine before discontinuation has not been tested in a controlled trial. Patients taking SSRIs for PD also demonstrate statistically significant

increases in body weight and rates of sexual dysfunction (Dannon et al., 2007).

One interesting meta-analysis showed a greater effect size for serotonergic antidepressants than for both TCAs and benzodiazepines (W. Boyer, 1995), with the effect reduced, but still maintained, when only studies using high-dose imipramine or alprazolam were compared. However, other meta-analyses have failed to show a clear efficacy advantage of antidepressants over benzodiazepines (den Boer, 1998), or for SSRIs over TCAs (Bakker et al., 2002; Mitte, 2005), although three studies using direct comparisons have shown SSRI superiority to noradrenergic heterocyclics (fluvoxamine vs. maprotiline, Den Boer & Westenberg, 1990; zimelidine vs. imipramine, L. Evans, Kenardy, Schneider, & Hoey, 1986; and clomipramine vs. desipramine, Sasson et al., 1999). These findings suggest, but do not conclusively demonstrate, that serotonergic antidepressants may have an advantage as antipanic agents.

Serotonin–Norepinephrine Reuptake Inhibitor

Venlafaxine (mean dose 166 mg) proved effective in uncomplicated PD in two placebo- controlled trials (Bradweijn, Stein, Salinas, Emlien, & Whitaker, 2005; Pollack et al., 1996) and garnered FDA approval for PD. Pollack's follow-up work on venlafaxine extended-release added more weight to the evidence (M. Pollack et al., 2007) Not every trial of venlafaxine has demonstrated a statistically significant reduction in the number of panic-free patients, although beneficial effects on other panic measures were still demonstrated (Bradweijn et al., 2005; Liebowitz, Asnis, Mangano, & Tzanis, 2009). There exist no placebo-controlled trials in PD for duloxetine, desvenlafaxine, or levomilnacipran.

Tricyclic (Heterocyclic) Antidepressants

Extensive evidence supports the efficacy of TCAs, including the predominantly serotonergic TCA clomipramine, in PD. Their effect size is equal to that of SSRIs (Mitte, 2005). The initial demonstration of reduction in panic attacks, but more variable and sometimes less robust effects on anticipatory anxiety and phobic avoidance, with imipramine compared with a placebo has been replicated many times since the 1960s (D. F. Klein, 1964). Designs have varied in duration (6 weeks to 9 months), dosage (i.e., whether minimally effective doses of 150 mg have been used), breadth of symptoms measured (panic, phobia, disability), sample size, proportion of sample with comorbid phobia and depression, and use of additional behavioral therapies. Sixteen placebo-controlled trials have conclusively shown that TCAs are superior to a placebo for reduction of panic attacks and associated anxious and phobic symptomatology, 11 for imipramine (D. H. Barlow, Gorman, Shear, & Woods, 2000; Cross-National Collaborative Panic Study, Second Phase Investigators, 1992; M. Mavissakalian & Michelson, 1986; M. R. Mavissakalian & Perel, 1995; Nair et al., 1996; Schweizer, Rickels, Weiss, & Zavodnick, 1993b; Sheehan, Ballenger, & Jacobsen, 1980; Taylor et al., 1990; Uhlenhuth, Matuzas, Glass, & Easton, 1989; Zitrin, Klein, & Woerner, 1978; Zitrin, Klein, Woerner, & Ross, 1983) and 5 for the nonselective serotonin-reuptake inhibitor clomipramine (Broocks et al., 1998; Caillard, Rouillon, Viel, & Markabi, 1999; Fahy, O'Rourke, Brophy, Schazmann, & Sciascia, 1992; Johnston, Troyer, & Whitsett, 1988; Modigh, Westberg, & Eriksson, 1992). One study actually showed clomipramine superiority to imipramine at 12 weeks (Modigh et al., 1992). For imipramine, use of higher doses was more likely to show beneficial effects, and some studies also showed a clear dose–response relationship, with daily doses of 1.5 mg/kg or greater yielding beneficial effects. More recent data have suggested that therapeutic plasma levels are lower for phobia than for panic, explaining the occasionally observed dissociation between effects on these two different measures and further documenting the need for approximately 1.5 to 2.0 mg/kg of imipramine for phobia and 2.0 to 2.5 mg/kg for panic (M. R. Mavissakalian & Perel, 1995). Studies suggesting that lower doses of clomipramine (e.g., 75 mg) could also be effective did not include comparisons with higher doses as in the above imipramine studies.

Time course of effect can only be estimated from reported mean values, which are the average of numerous, somewhat variable, individual time-course profiles. Nonetheless, most studies do not show drug–placebo response differences until week 4, with maximal responses continuing for many measures to the trial's end (usually week 8). Earlier studies actually showed significant continuing improvement in phobic avoidance between weeks 14 and 26, reinforcing Klein's original hypothesis that panic improves before

phobia (Zitrin et al., 1983). Experts reviewing open trial data maintain that peak effects on panic, phobia, and anxiety measures may be delayed until 10 to 12 weeks in many patients, consistent with effects for SSRIs (Lydiard & Ballenger, 1987; Oehrberg et al., 1995). In general, antipanic effects of TCAs may, in some patients, take as long as, if not longer than, traditionally reported antidepressant effects.

Many studies show that TCAs are less well tolerated than, for example, benzodiazepines, with many patients dropping out of clinical trials both early (30% in the large Cross-National Study; more than 50% in some smaller studies) and late (e.g., 20% during maintenance treatment) in one study (D. H. Barlow et al., 2000). A direct comparison showed that imipramine was more poorly tolerated than the SSRI fluvoxamine (Bakish et al., 1996). Even in PD study completers, the side-effect profile advantage of sertraline over imipramine is evident (M. R. Mavissakalian, 2003). Although these trials do not provide clear indications of the reasons, open studies suggest that the most common reason for early discontinuation is overstimulation/jitteriness, and for later discontinuation it is weight gain (Noyes, Garvey, Cook, & Samuelson, 1989). Low initial doses, slower titration, and use of adjunctive benzodiazepines or beta-blockers may attenuate early overstimulation. Elevated heart rate and blood pressure with imipramine may be a problem in older patients or those with cardiac conditions (Taylor et al., 1990).

Few other heterocyclic agents have been studied. Desipramine was superior to a placebo for anxiety and phobia, but not for panic attack frequency reduction, at a mean dose of 177 mg/day in the only study of this agent performed (Lydiard et al., 1993). Based on SSRI class effects, as well as open trials of these other tricyclic agents, it is likely that other TCAs are also effective. Nortriptyline's lower rate of postural hypotension and anticholinergic effects may improve tolerability in some patients. Of other antidepressants in this class, lesser efficacy is suggested for trazodone (than for imipramine and alprazolam) and maprotiline (than for fluvoxamine) (Charney et al., 1986; Den Boer & Westenberg, 1988). Unfortunately, these two studies were not placebo-controlled.

Benzodiazepines

The availability of high-potency benzodiazepines with the introduction of alprazolam in the mid-1980s reversed a prior tendency to view this class of medications as ineffective for PD. Eight placebo-controlled, double-blind trials have found alprazolam to be superior to placebo in the treatment of panic attacks, with 55% to 75% of patients free of attacks at the end point of the study (Ballenger et al., 1988; Chouinard, Annable, Fontaine, & Solyom, 1982; Cross-National Collaborative Panic Study, Second Phase Investigators, 1992; Lydiard et al., 1992; Munjack et al., 1989; Schweizer, Patterson, Rickels, & Rosenthal, 1993a; Sheehan, Raj, Harnett-Sheehan, Soto, & Knapp, 1993; Uhlenhuth et al., 1989). Completer analyses showed less striking and sometimes nonsignificant differences because of the high placebo dropout rate. Alprazolam showed similar robust effects on phobic avoidance (six of seven studies), disability (five of five studies), anticipatory anxiety (three of three studies), and generalized anxiety (seven of eight studies). Although daily mean doses of 5 to 6 mg were used in these studies, two studies of lower, 2-mg fixed doses (Lydiard et al., 1992; Uhlenhuth et al., 1989) also showed superiority to a placebo, although panic-free rates were lower than with higher doses (25% to 50% vs. 55% to 75%). An extended-release formulation of alprazolam, given once or twice daily, has been shown to be comparably effective to the immediate-release compound (Schweizer et al., 1993a).

The time course of effect with alprazolam is much more rapid than with antidepressants, with superiority to a placebo generally evident in the first week or two of treatment. While some experts suggest a superiority of these agents for phobia and anticipatory anxiety, panic attacks still appear to improve before phobia with benzodiazepines (Lydiard & Ballenger, 1987). While patients with significant primary major depression were excluded in most trials, patients meeting criteria for major depression judged secondary to PD were included in some studies (mean Hamilton Depression Rating Scale around 15) and in general fared as well as those without a major depression diagnosis (Ballenger et al., 1988).

The tolerability of alprazolam was in general superior to that of imipramine, with greater retention in studies looking at head-to-head comparisons (Cross-National Collaborative Panic Study, Second Phase Investigators, 1992; Schweizer et al., 1993a; Uhlenhuth et al., 1989). The most common adverse effects of alprazolam were sedation or drowsiness, reported in 38% to 75% of patients, and memory

impairment, reported in up to 15% of patients. The frequent lack of patient awareness of memory effects suggests that caution should be used when prescribing these agents in older patients or those needing to perform complex cognitive tasks.

Four placebo-controlled trials have also supported the efficacy of clonazepam for PD and demonstrated a similar rapid time course, spectrum of anxiolytic action, and side-effect profile, with 1 mg being the minimal effective dose (Beauclair, Fontaine, Annable, Holobow, & Chouinard, 1994; Moroz & Rosenbaum, 1999; Rosenbaum, Moroz, & Bowden, 1997; Tesar et al., 1991). A randomized, open, naturalistic trial comparing clonazepam to paroxetine found that clonazepam worked faster, but there was no significant difference in efficacy between the medications by week 8. Although no patients withdrew due to adverse events, the paroxetine group had significantly more adverse events (Nardi et al., 2011). In a 34-month follow-up study, this same group followed patients who had had good results and had opted to continue treatment. They demonstrated a very small, but statistically significant, reduction in the number of monthly panic attacks in the group receiving clonazepam (mean dose 1.9 mg/day) compared to the group receiving paroxetine (mean dose 38.4 mg/day) during the extension period. The paroxetine group continued to have more side effects (Nardi et al., 2012).

One study demonstrated antipanic efficacy for diazepam, and head-to-head comparisons with alprazolam in other non–placebo-controlled studies have shown uniform equivalence with lorazepam (Charney & Woods, 1989; Dunner, Ishiki, Avery, Wilson, & Hyde, 1986; Schweizer, Fox, Case, & Rickels, 1988). One double-blind discontinuation study has documented longer-term efficacy of alprazolam over the course of a year (Dager et al., 1992), and numerous other open naturalistic follow-ups, without a placebo comparison, suggest longer-term efficacy for this and other benzodiazepines.

The main public health concern regarding benzodiazepines has focused on their abuse potential, even though panic patients on long-term treatment do not escalate their doses over time (in fact, their doses go down) and abuse of these drugs does not occur in patients without comorbid alcohol or substance abuse (Garvey & Tollefson, 1986; Nagy, Krystal, Woods, & Charney, 1989). There is also no evidence of tolerance to the therapeutic effects of benzodiazepines in the several long-term studies that have been done. However, virtually all studies show that discontinuation of alprazolam in PD patients is associated with withdrawal symptoms, recurrent panic attacks, and failure to complete the taper in 25% to 50% of patients after as little as 6 to 8 weeks of treatment (J. C. Pecknold, Swinson, Kuch, & Lewis, 1988; P. P. Roy-Byrne, Dager, Cowley, Vitaliano, & Dunner, 1989). The use of a fairly rapid taper (several weeks) in all these studies fails to mirror the current clinical practice of a long, gradual taper, shown to reduce the incidence of withdrawal in one series to 7% (J. Pecknold, 1990). A 1999 study with clonazepam used a longer (although still too rapid) 7-week taper and found symptomatic worsening but no deterioration beyond the original baseline symptom level (i.e., "rebound anxiety"), in contrast to the rebound anxiety noted in all alprazolam studies in at least a portion (approximately 20%) of patients (Moroz & Rosenbaum, 1999). Direct comparisons of alprazolam with imipramine indicate greater taper difficulty and symptom recrudescence over the short term (1 month) with alprazolam (A. J. Fyer, Liebowitz, & Gorman, 1989; Rickels, Schweizer, Weiss, & Zavodnick, 1993b). However, studies showing that relapse rates after imipramine discontinuation gradually increase over 6 months suggest that this difference in short-term (1-month) relapse rates may merely reflect the mirror image of the time course in initial response (i.e., alprazolam more rapid, 1 to 2 weeks, and imipramine more slowly, 1 to 3 months) (Cross-National Collaborative Panic Study, Second Phase Investigators, 1992; M. Mavissakalian & Perel, 1992). This suggests that much withdrawal may in fact be symptom reemergence/relapse, although this relapse is perhaps fueled by bona fide withdrawal reactions.

Monoamine Oxidase Inhibitors

In six double-blind, placebo-controlled studies, classic mixed MAOIs (phenelzine, $N = 5$; iproniazid, $N = 1$) have been shown to be superior to placebo for overall syndrome improvement (panic, anxiety, and phobia) (Lipsedge et al., 1973; Mountjoy, Roth, Garside, & Leitch, 1977; Sheehan et al., 1980; C. Solyom, Solyom, LaPierre, Pecknold, & Morton, 1981; L. Solyom et al., 1973; Tyrer, Candy, & Kelly, 1973). Of note, all of these studies predate the *DSM-III*. Patients were not selected to meet diagnostic criteria

for panic, there were no separate measures of panic frequency obtained, and measures of phobic avoidance or anxiety employed were different from those used in later panic studies. Of the studies, three of the six employed adjunctive exposure treatment or supportive psychotherapy, and one employed adjunctive diazepam. All these studies employed relatively low doses (usually 45 mg phenelzine). Although higher doses are now recommended by most experts, there are limited data to support this. The one modern study that corroborates this idea is a blinded, randomized, 36-patient comparison of tranycylpromine 30 mg/day versus 60 mg/day in patients with comorbid PD and SAD, wherein the higher dose yielded reduced panic attack frequency (Nardi et al., 2010).

The lone study comparing phenelzine to imipramine suggested that phenelzine was superior for phobic avoidance, providing the only empirical evidence to support the impression of many clinicians that this class of medications may have special efficacy for treatment-resistant patients (Sheehan et al., 1980). A number of active drug comparisons, but without placebo, have shown that the selective MAO-A inhibitors brofaromine and meclobamide were equivalent to standard serotonin reuptake inhibitors (fluvoxamine, fluoxetine, and clomipramine), although the only placebo-controlled study failed to show efficacy for meclobamide (Kruger & Dahl, 1999; Loerch et al., 1999; van Vliet, den Boer, Westenberg, & Slaap, 1996).

The time course of MAOI effect is more difficult to estimate precisely from these older studies. Delayed effects are suggested by superior effects at 8 weeks compared with 4 weeks. Of the two studies that lasted 12 weeks, one showed greater efficacy at 12 weeks than at 6 weeks (Sheehan et al., 1980). In general, the time course of effect is likely to be comparable to that seen for other antidepressants.

These medications are well tolerated in the short term due to the absence of early overstimulation effects. However, weight gain, insomnia with paradoxical daytime sedation, sexual dysfunction, and the need to follow a special low-monoamine diet limit their acceptability for some patients. A placebo-controlled study showed that the selective and reversible MAOI brofaromine, which does not require a special diet, is effective for panic, with a 70% response rate, confirming both open trials and a blind comparative trial showing equivalence to clomipramine (Bakish, Saxena, Bowen, & D'Souza, 1993; Garcia-Borreguero et al., 1992; van Vliet, Westenberg, & Den Boer, 1993). However, brofaromine is not available in the United States. No studies have been reported of the selective MAOI selegiline for the treatment of PD.

Other Antidepressants

Nefazodone has been shown to be effective in depression accompanied by panic attacks in a subanalysis of one controlled depression trial (Zajecka, 1996). Mirtazapine has been reported to be effective in two studies, although both were open-label and neither used primary outcomes that were as rigorous as some other PD trials (Boshuisen, Slaap, Vester-Blokland, & den Boer, 2001; Carpenter, Leon, Yasmin, & Price, 1999). A head-to-head, flexible-dose, double-blind trial that compared mirtazapine to fluoxetine noted good efficacy and no difference between the two in several measures, although a measurement of patient global evaluation of phobic anxiety significantly favored mirtazapine. Interestingly, mean doses were low (mirtazapine 18.3 mg and fluoxetine 14 mg). Not surprisingly, there was significantly more weight gain in the mirtazapine group and significant more paresthesias in the fluoxetine group (Ribeiro et al., 2001). The lone placebo-controlled trial of bupropion demonstrated no benefit (Sheehan, Davidson, Manschreck, & Van Wyck Fleet, 1983). Vilazodone and vortioxetine have not been the subject of trials for PD.

Other Agents

Although treatment-resistant PD occurs, it is relatively uncommon when adequate doses of the above medication classes have been tried, especially in conjunction with skilled CBT. Moreover, treatment resistance is much less common than persistent PD due to treatment delivery failure (i.e., failure to access, receive, tolerate, or adhere to appropriate treatment). Few additional classes of medication are effective. Anticonvulsants have been frequently reported effective in open trials, but only gabapentin (Pande et al., 2000), in a secondary analysis focusing on high-severity panic, and valproate, in a small crossover study (Lum, fontaine, Elie, & Ontiveros, 1990), have been shown effective in placebo-controlled designs. In contrast, carbamazepine has been shown to be ineffective in a placebo-controlled design (Uhde, Stein, & Post, 1988). There have been no published,

placebo-controlled trials of pregabalin or second generation (atypical) antipsychotic monotherapy for PD. One small placebo-controlled trial showed that the calcium channel blocker verapamil was an effective antipanic agent (E. Klein & Uhde, 1988), although curiously no other open reports have followed up on this preliminary finding. In placebo-controlled studies, clonidine has not been found to be effective (Uhde et al., 1989), nor has propranolol (Munjack et al., 1989) or buspirone (R. Pohl, Balon, Yeragani, & Gershon, 1989; Schweizer & Rickels, 1988; Sheehan, Raj, Sheehan, & Soto, 1990).

Combined augmentation treatment using multiple agents has been infrequently studied. Early addition of a benzodiazepine to an antidepressant, with withdrawal after 4 to 6 weeks, to speed initial response has been shown to be effective for clonazepam added to sertraline (Goddard et al., 2001) and for alprazolam added to imipramine (Woods et al., 1992). Subsequent discontinuation of the benzodiazepine worsened symptoms in the alprazolam study, probably because of the short half-life of the drug and consequent more severe withdrawal. In a more recent, randomized trial that employed clonazepam augmentation versus CBT augmentation for SSRI nonresponders, only 1 of 9 patients in the clonazepam arm went on to achieve remission (Simon et al., 2009). A small, open-label trial of olanzapine augmentation in the setting of SSRI-resistant panic disorder suggested some benefit (Sepede et al., 2006), but there exist no placebo-controlled trials of second generation (atypical) antipsychotic augmentation for PD. Despite an intriguing study demonstrating that the beta-blocker and serotonin 1A receptor antagonist pindolol, when added to fluoxetine in nonresponsive patients, is superior to placebo (Hirschmann et al., 2000), this strategy is not widely used in clinical practice.

Duration of Treatment/Chronic Treatment

As previously noted, all classes of agents described have been shown to retain their effectiveness over 8 to 12 months (Dager et al., 1992; Lecrubier & Judge, 1997; Michelson et al., 1999; Schweizer et al., 1993b). However, questions remain about the optimal duration of treatment following remission of panic attacks. Current consensus recommendations for treatment duration are 1 to 2 years, based on limited controlled data (APA Work Group on Panic Disorder, 1998; Ballenger et al., 1998a). Many naturalistic studies have shown relapse rates between 30% and 90% following medication discontinuation after 6 to 12 months of treatment (P. P. Roy-Byrne & Cowley, 1995). Relapse in these studies appears strongly related to illness characteristics, specifically Axis I (depression and phobic avoidance) and Axis II comorbidity.

Numerous studies have examined relapse in treatment responders using placebo-controlled discontinuation designs. Among the TCAs, relapse rates were 45% and 65% with imipramine and clomipramine discontinuation after 10 weeks of single-blind placebo substitution (Gentil et al., 1993), 38% within 3 months of placebo substitution of imipramine (M. Mavissakalian & Perel, 1992), and 37% within a year of imipramine discontinuation (M. R. Mavissakalian & Perel, 1999). A meta-analysis of four SSRI trials and two SNRI trials, with follow-up duration of 8 to 52 weeks, documented relapse 8% to 50% of the time with placebo, compared to 3% to 22% of the time with antidepressant continuation. These differences in favor of antidepressant maintenance were statistically significant (Donovan, Glue, Kolluri, & Emir, 2010).

A study of performance on cognitive and behavioral tests in patients with anxiety disorders on long-term benzodiazepine therapy, compared to matched anxious patients not on benzodiazepines, found no meaningful differences (Lucki, Rickels, & Geller, 1986).

Combined Treatment

The impact on speed of improvement when combining CBT and antidepressant is debatable, with no effect seen in acute management in one meta-analysis (Furukawa, Watanabe, & Churchill, 2006) but distinct benefit noted in the acute phase in a 2010 study of SSRI plus CBT (van Apeldoorn et al., 2010). There is ongoing work on the use of D-cycloserine (DCS) to enhance the response to CBT, with a 31-patient, double-blind, placebo-controlled trial demonstrating benefit when 50 mg DCS was given 1 hour prior to the last three sessions of a five-session, exposure-based, CBT sequence (Otto et al., 2010), In contrast, a 39-patient placebo-controlled, randomized trial for patients with agoraphobia and PD engaged in

an 11-session CBT course that included exposure (flooding) sessions found no significant benefit from augmentation with 50 mg DCS (Siegmund et al., 2011).

GENERALIZED ANXIETY DISORDER

GAD is characterized by excessive, frequent, difficult-to-control worry in several life areas, accompanied by significant distress or functional impairment, as well as by at least three of the following six symptoms: restlessness or feeling on edge, easy fatigability, concentration difficulties, irritability, muscle tension, and sleep disturbance. Since its original definition in 1980, GAD has been a problematic diagnosis with changing diagnostic criteria, poor interrater reliability (Di Nardo, Moras, Barlow, Rapee, & Brown, 1993), and high rates of psychiatric comorbidity (Brawman-Mintzer et al., 1993; Breslau & Davis, 1985). Up to 90% of patients with GAD have a lifetime history, and up to 60% a current history, of at least one other psychiatric disorder. The most common comorbidities are SAD, specific phobias, depression, dysthymia, PD, and substance abuse or dependence (Brawman-Mintzer et al., 1993; Wittchen, Zhao, Kessler, & Eaton, 1994). However, there does exist a group of patients with primary or isolated, severe, generalized anxiety associated with significant functional impairment (Kessler, Dupont, Berglund, & Wittchen, 1999). Unlike the earlier variability, the diagnostic criteria remained stable between the *DSM-IV* and *DSM-5*.

GAD usually begins in the teens or early adulthood and is twice as common in women as in men. In the National Comorbidity Survey, GAD had a 12-month prevalence of 3.1% and a lifetime prevalence of 5.7% (Kessler et al., 2005a, 2005c). However, episodes only lasting 1 to 5 months are associated with impairment and comorbidity similar to episodes lasting 6 months (Kessler et al., 2005b), and individuals meeting all criteria except for excessive worry, despite a milder presentation, show substantial impairment, comorbidity, and rates of treatment seeking (Ruscio et al., 2005), suggesting that there is a larger percentage of the population with clinically significant generalized anxiety than these prevalence figures would indicate.

GAD shows significant familial aggregation, with a meta-analysis of family and twin studies yielding an overall heritability of 0.32 (Hettema, Neale, & Kendler, 2001). Stressful life events, especially those involving loss and danger, are associated with the onset of GAD (Kendler, Hettema, Butera, Gardner, & Prescott, 2003).

The high rate of comorbidity, changes associated with successive *DSM* iterations, and the wide range of apparent receptor targets have made it challenging to construct meta-analyses to compare different treatment modalities. Historically, generalized anxiety has been treated with barbiturates, methaqualone, or, since the 1960s and 1970s, benzodiazepines. Since the early 1990s, buspirone and antidepressants have been used for GAD. More recently, second generation (atypical) antipsychotic and pregabalin have been the subjects of placebo-controlled trials. In addition, effective CBT approaches specific for GAD have been developed.

Benzodiazepines

Numerous double-blind, controlled trials have examined the efficacy of benzodiazepines in the treatment of generalized anxiety. For example, in 1978, Solomon and Hart reviewed 78 double-blind studies, concluding that benzodiazepines had not been shown to be superior to a placebo in the treatment of "neurotic anxiety" (Solomon & Hart, 1978).

In 1988, Barlow reviewed eight double-blind 2- to 6-week trials performed between 1978 and 1983 and, using the Hamilton Anxiety Rating Scale (HAM-A) as the outcome measure, found 22% to 62% reductions in score in benzodiazepine-treated patients with generalized anxiety versus 18% to 48% decreases in placebo groups (D. H. Barlow, 1988). He concluded that the effects of benzodiazepines were marginal. However, dropout rates were substantially higher in placebo groups in five of six studies supplying this information, perhaps reflecting lack of efficacy. Two studies performed in the early 1980s suggested that patients with *DSM-III* GAD seen in primary care settings responded equally well to diazepam and a placebo after the first week or two of treatment (Catalan, Gath, Edmonds, & Ennis, 1984; Shapiro, Struening, Shapiro, & Milcarek, 1982). However, diazepam was superior to a placebo for those with the most severe anxiety (Shapiro et al., 1982).

With the evolution of diagnostic criteria for GAD that required both persistent, hard-to-control worrying and a 6-month duration, benzodiazepines were found

to be superior to a placebo in acute (4- to 6-week) double-blind treatment of GAD in most (Borison, Albrecht, & Diamond, 1990; W. F. Boyer & Feighner, 1993; Cutler et al., 1993; Enkelmann, 1991; Laakmann et al., 1998; Rickels, Downing, Schweizer, & Hassman, 1993a; Rickels, Schweizer, Csanalosi, Case, & Chung, 1988b; Rickels, Schweizer, DeMartinis, Mandos, & Mercer, 1997), but not all (J. C. Pecknold et al., 1989; Ross & Matas, 1987), studies. All benzodiazepines appear equally effective (Shader & Greenblatt, 1993). About two thirds of patients experience moderate to marked improvement of anxiety symptoms (usually assessed using HAM-A and Clinical Global Impression [CGI] rating scales) with these medications, with therapeutic effects evident rapidly, within the first 1 to 2 weeks. Doses are lower by approximately half than those used in treating PD (usually the equivalent of 10 to 25 mg/day of diazepam). Benzodiazepines appear particularly effective for somatic anxiety symptoms (Rickels et al., 1982). Patients with minor depressive symptoms respond more poorly to most of these agents (Rickels et al., 1993a), with the possible exception of alprazolam, and both high- and low-anxiety volunteers given lorazepam demonstrated increases in negative emotions and decreases in positive emotions (Garcia et al., 2000).

Side effects of benzodiazepines in GAD are similar to those in PD and include sedation, psychomotor impairment, anterograde amnesia (Lucki et al., 1986), and tolerance, although GAD patients may be less vulnerable than panic patients to discontinuation symptoms, due in part to less severe nature of the anxiety that returns when the benzodiazepine dose is reduced (Ehud Klein, Colin, Stolk, & Lenox, 1994). Of note, as with panic, dose escalation is rare in GAD patients without a history of substance abuse. For example, no dosage increases were observed in 119 anxious patients taking benzodiazepines for an average of 8 years (Rickels, Case, Schweizer, Swenson, & Fridman, 1986).

Azapirones

Buspirone, an azapirone anxiolytic and 5HT-1A receptor partial agonist, was approved in the *DSM-III* era for GAD. Buspirone has been shown in several double-blind studies to be comparable to benzodiazepines, including diazepam, lorazepam, clorazepate, oxazepam, and alprazolam, for the acute treatment of GAD, yielding 30% to 50% reductions in HAM-A scores in 2- to 6-week trials (Ansseau, Papart, Gerard, von Frenckell, & Franck, 1990; Cohn, Bowden, Fisher, & Rodos, 1986; Enkelmann, 1991; Feighner, Merideth, & Hendrickson, 1982; Laakmann et al., 1998; Murphy, Owen, & Tyrer, 1989; Petracca et al., 1990; Rickels, Fox, Greenblatt, Sandler, & Schless, 1988a; Rickels et al., 1982; Strand et al., 1990). Other azapirones, including ipsapirone and gepirone, have also proved effective in placebo-controlled, double-blind trials but are not available in the United States (Borison et al., 1990; W. F. Boyer & Feighner, 1993; Cutler et al., 1993; Rickels et al., 1997).

In comparison with benzodiazepines, buspirone has a delayed (2- to 4-week) onset of action, may affect psychic anxiety symptoms to a greater extent than physical symptoms, and has the advantage of being nonsedating and without evidence of tolerance or withdrawal symptoms (Feighner & Cohn, 1989; Rickels et al., 1982). Common side effects of buspirone include nausea, dizziness, and headaches. Average therapeutic doses are 20 to 45 mg/day, although doses of up to 60 mg/day may be necessary. It should also be noted that busprione has a 2- to 3-hour half-life, necessitating TID dosing in some patients. Buspirone displays antidepressant effects in patients with comorbid depression, usually at higher doses of 45 to 60 mg/day (Gammans et al., 1992).

In general, patients on chronic benzodiazepine treatment do not respond well when switched to buspirone (DeMartinis, Rynn, Rickels, & Mandos, 2000; M. Lader & Olajide, 1987). For example, in a reanalysis of treatment results in 735 patients with GAD treated with buspirone, a benzodiazepine, or a placebo, clinical improvement was similar with buspirone versus benzodiazepine treatment in those patients with no prior history of benzodiazepine treatment and in those whose benzodiazepine treatment had ended a month or more prior to the study. In those with recent benzodiazepine treatment (within the past month), there was greater attrition with buspirone treatment due to lack of efficacy and less clinical improvement than with benzodiazepine treatment (DeMartinis et al., 2000). A double-blind study of 44 GAD patients switched to buspirone versus a placebo after 5 weeks of lorazepam treatment, with lorazepam tapered during the first 2 weeks of buspirone-versus-placebo treatment, was more

promising and showed that buspirone was superior to a placebo and comparable to lorazepam in anxiolytic effects (Delle Chiaie et al., 1995). There was no evidence of benzodiazepine withdrawal symptoms. However, the duration of lorazepam treatment was quite short. In a study examining imipramine versus buspirone versus placebo for treatment of 107 patients with GAD who had used benzodiazepines for an average of 8.5 years, the success rate of the 4- to 6-week benzodiazepine taper was significantly higher with imipramine (82.6%) than with buspirone (67.9%) or placebo (37.5%) (Rickels et al., 2000a).

A meta-analysis in the *DSM-IV* era noted buspirone to have an effect size equal to that of venlafaxine for GAD (Mitte, 2005). Similarly, a *DSM-IV*–era Cochrane Database review of azapirones for GAD noted a NNT of 4.4 (Chessick et al., 2006).

Antidepressants

When PD and GAD initially were described as distinct anxiety disorders, PD was postulated to differ from GAD in responding to antidepressant treatment. However, since the mid-1980s, a number of antidepressants, including venlafaxine, duloxetine, imipramine, trazodone, paroxetine, escitalopram, and sertraline, have been shown in double-blind trials to be effective in treating GAD (Allgulander et al., 2008; J. R. Davidson, DuPont, Hedges, & Haskins, 1999; Gelenberg et al., 2000; Haskins, Rudolph, Pallay, & Derivan, 1998; Hoehn-Saric, McLeod, & Zimmerli, 1988; Kahn et al., 1986; Montgomery, Tobias, Zornberg, Kasper, & Pande, 2006; Rickels et al., 1993a; Rickels, Pollack, Sheehan, & Haskins, 2000b; Rocca, Fonzo, Scotta, Zanalda, & Ravizza, 1997). Venlafaxine, duloxetine, paroxetine, and escitalopram are now approved by the FDA for treatment of this disorder.

In an early double-blind trial, Kahn and colleagues (1986) reported the then-surprising result that imipramine performed better than chlordiazepoxide in the treatment of nondepressed outpatients retrospectively diagnosed as having GAD. Following up on this, Hoehn-Saric and colleagues (1988), in a study of nondepressed patients with GAD, found that imipramine was comparable to alprazolam after the first 2 weeks of treatment. Imipramine was more effective in reducing psychic anxiety symptoms such as obsessionality, dysphoria, negative anticipatory thinking, and interpersonal sensitivity; alprazolam was superior in alleviating cardiovascular and autonomic symptoms.

Rickels and colleagues (1993a) compared imipramine (mean dose 143 mg/day), trazodone (mean dose 255 mg/day), diazepam (mean dose 26 mg/day), and a placebo in 230 patients with GAD treated for 8 weeks. Although all active treatments were superior to the placebo, diazepam yielded the most improvement in anxiety ratings for the first 2 weeks and imipramine was the most effective treatment thereafter, with 73% of patients moderately or markedly improved compared with 69% on trazodone, 66% on diazepam, and 47% on the placebo. Once more, antidepressants reduced psychic anxiety symptoms to a greater extent than did diazepam. Patients on antidepressants also reported more side effects.

Rocca and colleagues (1997) compared paroxetine, imipramine, and 2′-chlordesmethyl-diazepam in 81 patients with GAD. All three treatment conditions resulted in significant clinical improvement in about two thirds of patients. As in prior studies, the benzodiazepine resulted in more rapid improvement, but the antidepressants resulted in more improvement by week 4. In addition, paroxetine and imipramine were most effective for psychic anxiety symptoms, whereas 2′-chlordesmethyl-diazepam was superior for somatic symptoms. Imipramine's NNT for GAD has been subsequently calculated as 4 (Kapczinski, Lima, Souza, & Schmitt, 2003).

A number of controlled studies have now demonstrated the efficacy of SSRIs, and the combined serotonin and norepinephrine reuptake inhibitors, duloxetine and venlafaxine, in the treatment of GAD. Promising observations in double-blind trials that venlafaxine was more effective than placebo in treating symptoms of anxiety in depressed outpatients (Feighner, Entsuah, & McPherson, 1998; Khan, Upton, Rudolph, Entsuah, & Leventer, 1998) then led to type 1 double-blind, placebo-controlled trials, which established the efficacy of this agent in nondepressed patients with GAD (J. R. Davidson et al., 1999; Gelenberg et al., 2000; Haskins et al., 1998; Rickels et al., 2000b). Venlafaxine extended-release, in doses of 75 to 225 mg/day, yielded significantly greater decreases in anxiety than placebo within the first 2 to 3 weeks of treatment. Davidson and colleagues found that venlafaxine extended-release (75 or 150 mg/day) was more effective than buspirone (30 mg/day) throughout their 8-week study (J. R. Davidson et al., 1999), and Gelenberg and colleagues (2000) showed

persistent treatment gains over 28 weeks of treatment, with response rates (defined as a 40% decreases in HAM-A score or CGI of 1 or 2) at weeks 6 from 28% to 69% with venlafaxine extended-release 75 to 225 mg/day compared with 42% to 46% in the placebo group. This efficacy was replicated in a more recent, placebo-controlled trial as well (Montgomery et al., 2006). Patients treated in venlafaxine efficacy studies showed decreases in both psychic and somatic anxiety symptoms, although, consistent with prior antidepressant trials, effects on psychic anxiety were more pronounced (Meoni, Hackett, & Lader, 2004). Duloxetine, which also obtained FDA approval for GAD in the *DSM-IV* era, appears to have equal tolerability and efficacy compared to venlafaxine (Allgulander et al., 2008).

Eight- to twelve-week trials have demonstrated efficacy of paroxetine 20 to 50 mg/day (Pollack et al., 2001; Rickels et al., 2003), sertraline 50 to 150 mg/day (Allgulander et al., 2004a; Ball, Kuhn, Wall, Shekhar, & Goddard, 2005), and escitalopram 10 to 20 mg/day (J.R. Davidson, Bose, Korotzer, & Zheng, 2004; Goodman, Bose, & Wang, 2005), with response rates of 50% to 70% compared with 30% to 40% on placebo. Paroxetine significantly reduced the HAM-A anxious mood item compared with placebo as early as week 1, produced greater reductions in disability than placebo, and was equally effective at 20-mg/day and 40-mg/day doses (Pollack et al., 2001; Rickels et al., 2003). Pooled paroxetine data that included 1,800 patients demonstrated a NNT of 10 for GAD, with a mean dose of 24.3 mg/day (Rickels, Rynn, Iyengar, & Duff, 2006).

Escitalopram, in pooled results from three double-blind, placebo-controlled trials, differed significantly from placebo in total HAM-A score and in psychic anxiety by week 1 at a dose of 10 mg/day (Goodman et al., 2005) and was associated with improved quality of life (D. J. Stein, Andersen, & Goodman, 2005). Escitalopram's efficacy at 20 mg/day (Coric et al., 2010) and its positive impact on quality of life in pooled data (Demyttenaere, Andersen, & Reines, 2008) continue to be evident in more recent studies.

Escitalopram failed to demonstrate statistical, intent-to-treat, significance due to a high dropout rate in a recent study of patients over 60 years old (Lenze et al., 2009). Interestingly, citalopram also failed to demonstrate statistical significance for remission in another, small study of patients over the age of 60 with GAD (Lenze et al., 2005).

In one study sertraline treatment significantly decreased both psychic and somatic anxiety scores, although its effect on psychic anxiety was more pronounced (Dahl et al., 2005). Other placebo-controlled trials have demonstrated sertraline's efficacy at an average of 95 mg/day (Allgulander et al., 2004a) and 149 mg/day (Brawman-Mintzer, Knapp, Rynn, Carter, & Rickels, 2006).

A controlled 8-week study directly comparing paroxetine and sertraline demonstrated similar efficacy and tolerability for both agents (Ball et al., 2005), whereas a 24-week comparison of escitalopram and paroxetine demonstrated similar reductions in HAM-A scores but a significantly higher rate of discontinuation due to adverse events with paroxetine (22.6%) versus escitalopram (6.6%) (Bielski, Bose, & Chang, 2005). A meta-analysis of venlafaxine extended-release trials, a paroxetine trial, and a fluoxetine trial demonstrated no difference between venlafaxine and the SSRIs (Mitte, 2005). This result was reaffirmed in a meta-analysis of escitalopram, paroxetine, sertraline, fluvoxamine, and venlafaxine extended-release (Hidalgo, Tupler, & Davidson, 2007).

Other antidepressants show promise as treatments for GAD. For example, an open, 12-week trial of mirtazapine 30 mg/day in 44 outpatients with GAD yielded a response (defined, as in most of the SSRI trials described above, as a 50% or greater decrease in HAM-A score and a CGI improvement score of 1 or 2) in 79.5% of patients (Gambi et al., 2005). Bupropion extended-release demonstrated comparable efficacy to escitalopram in a small, double-blind study (Bystritsky, Kerwin, Feusner, & Vapnik, 2008), but there are no placebo-controlled trials of bupropion.

Although the SSRIs and SNRIs are associated with gastrointestinal side effects, weight gain, and sexual side effects, their favorable tolerability in comparison to TCAs (Brambilla, Cipriani, Hotopf, & Barbui, 2005), their efficacy for comorbid depression, and the lack of risk of tolerance and dependence make them first-line treatments for this condition.

Other Medications

About one third of patients with GAD remain symptomatic despite treatment. Thus, studies have attempted to find pharmacological treatments with novel mechanisms of action and augmentation

strategies to improve our ability to help treatment-resistant patients.

Studies performed prior to 1980 showed no efficacy of beta-blockers for the treatment of generalized anxiety (Hayes & Schulz, 1987). Another double-blind, placebo-controlled trial was more promising (Meibach, Mullane, & Binstok, 1987). This 3-week, multicenter study of propranolol (average maximum dose 189 mg/day) versus chlordiazepoxide (average dose 50 mg/day) versus a placebo in 417 outpatients with "anxiety sufficiently severe to warrant treatment with an anxiolytic agent" showed the superiority of both active drugs but fewer side effects with propranolol than with chlordiazepoxide. Surprisingly, propranolol was particularly effective in reducing psychic symptoms of anxiety. Open trials of betaxolol, a long-acting beta-blocker that enters the central nervous system, in 18 inpatients and 13 outpatients with anxiety disorders (including 16 inpatients and 11 outpatients with GAD) showed marked improvement in anxiety ratings in most patients (Swartz, 1998). Nevertheless, most experts continue to feel that beta-blockers are not an effective primary treatment for GAD and should be reserved for use as an adjunct, particularly in patients with prominent autonomic symptoms.

A multicenter, double-blind, 4-week trial of hydroxyzine (50 mg/day) versus a placebo in 133 GAD patients displayed significantly greater reductions in anxiety in the hydroxyzine group, although side effects were more common than in the placebo group (Ferreri, Hantouche, & Billardon, 1994). Similarly, both hydroxyzine (50 mg/day) and buspirone (20 mg/day) were superior to placebo in a double-blind, multicenter, 4-week trial in a total of 244 GAD patients (M. Lader & Scotto, 1998). A 12-week study comparing hydroxyzine (50 mg/day), bromazepam (6 mg/day), and placebo in 334 patients with GAD demonstrated significantly higher response and remission rates with both active drugs than with placebo (Llorca et al., 2002; Pande et al., 2003).

A meta-analysis of seven placebo-controlled trials of pregabalin suggested small effect sizes of 0.35 for psychic anxiety and 0.24 for somatic anxiety symptoms in GAD (Boschen, 2011). Dosing in placebo-controlled studies of pregabalin has ranged from 150 to 600 mg/day. Several studies have found no efficacy with dosing at the 150-mg end (Feltner et al., 2003; Pande et al., 2003), whereas a review of six double-blind, placebo-controlled trials suggested that the efficacy of pregabalin plateaus at 300 mg/day (Lydiard, Rickels, Herman, & Feltner, 2010).

Some trials have sought to compare pregabalin to benzodiazepines. In one, patients with GAD were treated for 4 weeks with alprazolam 1.5 mg/day, placebo, or one of three doses of pregabalin (300, 450, or 600 mg/day). Both alprazolam and pregabalin were superior to placebo in decreasing psychic and somatic anxiety symptoms, and the 300-mg/day dose of pregabalin was superior to both placebo and alprazolam at treatment end point. At 300 mg/day, the discontinuation rate due to side effects in this study was 3%, with the most common being somnolence, dizziness, and dry mouth (Rickels et al., 2005). Pregabalin's superiority to benzodiazepines has not been universal, however. For example, pregabalin did not significantly beat lorazepam 2 mg TID in the aforementioned studies by Pande and colleagues (2003) and Feltner and colleagues (2003). A placebo-controlled trial employing pregabalin while attempting a gradual benzodiazepine taper in patients with GAD was hampered by a high dropout rate, although some benefits were suggested (Hadley, Mandel, & Schweizer, 2012).

Two trials have compared the efficacy of venlafaxine to pregabalin. The first randomized patients to placebo, venlafaxine 75 mg/day, pregabalin 400 mg/day, or pregabalin 600 mg/day. Only the pregabalin 400-mg/day dose demonstrated efficacy on all primary and secondary measures, with venlafaxine 75 mg/day failing to show efficacy for somatic symptoms of anxiety compared to placebo. The authors note, however, that the low dose and the 6-week duration of the study may have affected venlafaxine's efficacy (Montgomery et al., 2006). The second trial, compared flexibly dosed venlafaxine extended-release (mean maximal daily dose 155 ± 60 mg) to flexibly dosed pregabalin (mean maximal daily dose 424 ± 118 mg) and placebo. Pregabalin, but not venlafaxine extended-release, significantly beat placebo on the HAM-A at the end of the 8-week trial. Venlafaxine-treated patients were significantly more likely to report a severe adverse event (20%) than patients on placebo (7.8%). Only 9.1% of patients on pregabalin reported a severe adverse side effect (Kasper et al., 2009).

Finally, an 8-week, double-blind, placebo-controlled trial of refractory GAD employed pregabalin as an adjunct to open-label treatment with venlafaxine extended-release, escitalopram, or paroxetine. By the end of the 8-week study, with mean daily pregabalin dose reaching 496 mg, HAM-A

responder, but not remission, criteria were statistically significant (Rickels et al., 2012).

Of 18 patients in an 8-week open trial of riluzole, an antiglutaminergic agent, 15 completed the trial, 12 responded, and 8 remitted (Mathew et al., 2005). Two other, similar, small, open-label trials have suggested some efficacy (Abdallah et al., 2013; Mathew et al., 2008).

A review of three double-blind, placebo-controlled studies of the GABA reuptake inhibitor tiagabine noted that the drug failed to separate from placebo on the primary measure (Pollack, Tiller, Xie, & Trivedi, 2008). An 80-patient, randomized, placebo-controlled study of valproate 500 mg TID found benefit in a 6-week study (Aliyev & Aliyev, 2008). Ocinaplon, an anxioselective GABA receptor ligand, produced greater reductions in anxiety than placebo in a 2-week trial (Lippa et al., 2005). A more recent, 60-patient, placebo-controlled trial (Czobor, Skolnick, Beer, & Lippa, 2010) of ocinaplon also demonstrated a significant HAM-A reduction, although this study was also notable for one case of a serious adverse event (icterus following transaminase elevation) that was deemed possibly related to the medication.

Deramciclane, a camphor derivative and 5-HT2A/2C receptor antagonist, was superior to placebo in an 8-week trial, especially in reducing psychic anxiety symptoms, and was well tolerated, with the most common adverse event being headache (Naukkarinen et al., 2005). Opipramol, a tricyclic compound and D2-, 5-HT2-, and H1-antagonist with high affinity for sigma receptors, was superior to placebo and equivalent to alprazolam in a 4-week controlled trial of 307 patients with GAD (Moller, Volz, Reimann, & Stoll, 2001).

Kava kava, an extract of the plant *Piper methysticum*, used in the South Pacific to induce relaxation and sleep, has a recent positive, placebo-controlled trial for generalized anxiety (Sarris et al., 2013). A review of three other placebo-controlled trials, however, found no benefit (Connor, Payne, & Davidson, 2006). Concerns about hepatotoxicity with kava kava have limited the clinical use of this agent. Passionflower (*Passiflora incarnate*) was equal in effectiveness to oxazepam in one 4-week trial (Akhondzadeh et al., 2001).

A review of three, pooled, quetiapine trials, with dosing ranging from 50 to 300 mg/day, yielded a small effect size of 0.30 in one analysis (Maher et al., 2011) Another review that included four, quetiapine monotherapy, placebo-controlled trials calculated significant odds ratios for both response (2.21) and remission (1.83) in favor of quetiapine (Depping, Komossa, Kissling, & Leucht, 2010). Evidence for quetiapine monotherapy has continued to accumulate, with recent, placebo-controlled trials demonstrating efficacy in the acute phase (Endicott, Svedsater, & Locklear, 2012; Khan et al., 2011), for long-term functioning and sleep quality in maintenance studies of quetiapine responders (Sheehan, Svedsater, Locklear, & Eriksson, 2013), and in patients over 66 years old (Mezhebovsky, Magi, She, Datto, & Eriksson, 2013). The most common side effects of quetiapine in these studies include dry mouth, somnolence, sedation, nausea, dizziness, and headache. A placebo-controlled, active-controlled (escitalopram) study found similar efficacy, although the clinically important adverse impact of quetiapine on weight, glucose, triglycerides, total cholesterol, and LDL-cholesterol was also noted (Merideth, Cutler, She, & Eriksson, 2012). In a 52-week trial of quetiapine extended-release for GAD, 17.4% of patients in the quetiapine group moved from less than two metabolic risk factors to more than three metabolic risk factors, compared to just 7.9% of placebo patients making the same transition (Katzman et al., 2011). Despite quetiapine's evidence of benefit, the metabolic side effects of this drug prevented FDA approval for GAD.

Weight gain was noted in a study of olanzapine (mean dose 8.7 mg/day) versus placebo augmentation for nonresponders to fluoxetine 20 mg/day. This study yielded a greater proportion of responders and a trend toward more remitters in a small sample of 26 patients (Pollack et al., 2006). In 40 patients continuing to experience GAD symptoms despite 4 weeks of treatment with a wide variety of anxiolytics and/or antidepressants, augmentation with risperidone 0.5 to 1.5 mg/day versus placebo in a double-blind, 5-week study led to significantly greater reductions in total and psychic anxiety scores (Brawman-Mintzer, Knapp, & Nietert, 2005). Ziprasidone's lone, placebo-controlled, double-blind study in GAD did not demonstrate statistical significance (Lohoff, Etemad, Mandos, Gallop, & Rickels, 2010). Two small open-label trials of aripiprazole augmentation of an antidepressant suggested some benefit (Hoge et al., 2008; Menza, Dobkin, & Marin, 2007).

Duration of Treatment/Chronic Treatment

Although there is extensive literature regarding acute treatment of generalized anxiety, there is less

information available regarding the long-term efficacy or the optimal duration of treatment.

Few studies have examined results of benzodiazepine treatment beyond the first 6 weeks. Cutler and colleagues (1993) found lorazepam more effective than a placebo after 6 weeks, but not after 8 weeks, of treatment, primarily due to continued improvement in the placebo group. Both alprazolam and lorazepam remained superior to a placebo after 16 weeks in another study (Cohn & Wilcox, 1984). In a study of 101 GAD patients treated with CBT, a placebo, or diazepam for 10 weeks, the greatest improvement was seen in patients receiving a combination of CBT and diazepam, and diazepam alone was more effective than placebo alone (Power, Simpson, Swanson, & Wallace, 1990). Rickels and colleagues (1988a) showed the continued efficacy of clorazepate over a 6-month trial, with no tolerance to anxiolytic effects, but there was no placebo comparison.

Thus, benzodiazepines seem to have continued anxiolytic effects for up to 6 months, but the paucity of longer term placebo-controlled studies leaves us without a clear answer to the question of whether benzodiazepines are superior to a placebo after the initial phase of treatment. Buspirone has shown continued efficacy over a treatment period of 3 to 6 months (Feighner, 1987; Murphy et al., 1989; Rickels et al., 1988b). Long-term treatment with antidepressants has been examined in 6-month trials of venlafaxine and paroxetine, a 24- to 76-week trial of escitalopram, and a 6-month comparison of escitalopram and paroxetine (Allgulander, Florea, & Huusom, 2006; Bielski et al., 2005; Gelenberg et al., 2000; Stocchi et al., 2003). All these studies support the ongoing efficacy of antidepressants for GAD with longer-term treatment. Two (Allgulander et al., 2006; Stocchi et al., 2003) specifically address the issue of relapse using placebo-controlled SSRI discontinuation trials. In a 6-month study of 566 patients with GAD who had responded to 8 weeks of paroxetine, those randomized to long-term placebo treatment were significantly more likely to relapse than those maintained on active medication (39.9% vs. 10.9%), and those on paroxetine were twice as likely to achieve remission (Stocchi et al., 2003). A similar study of 375 responders to acute treatment with escitalopram randomized to double-blind continuation treatment with escitalopram versus placebo showed a 56% relapse rate in patients on placebo versus 19% in those on escitalopram; the rate of discontinuation due to adverse events was similar in the two groups (7% with escitalopram vs. 8% with placebo) (Allgulander et al., 2006).

Longer-term antidepressant treatment is significantly favored ($p < 0.00001$) for relapse prevention in a meta-analysis of SSRI and SNRI studies (Donovan et al., 2010). In this review of treatment responders (two SSRI studies and one SNRI study), the relapse rate over 6 months after switch to placebo was as high as 60%, versus 14% with antidepressant continuation. Similar to the antidepressant data, a 52-week, placebo-controlled maintenance trial for quetiapine monotherapy responders found a 10.2% recurrence of anxiety symptoms with quetiapine continuation versus 38.9% with placebo (Katzman et al., 2011).

Two other studies have addressed the issue of optimal duration of treatment by following patients after discontinuation of effective treatment. Rickels, Case, Downing, and Winokur (1983) found that 50% of patients treated with diazepam for 6 weeks relapsed within 3 months following benzodiazepine discontinuation, and 63% relapsed within a year following discontinuation. In another trial performed by the same group (Rickels et al., 1988b), 45 patients with GAD who responded to 6 months of treatment with clorazepate or buspirone were reevaluated 6 and 40 months after the end of the study. At 6 months, 55% of clorazepate-treated patients and 38% of those treated with buspirone reported moderate to marked anxiety. At 40 months, 34 patients were contacted, and 57% of clorazepate-treated versus 25% of buspirone-treated subjects reported moderate to severe anxiety. These data suggest that for many people, GAD is a chronic illness requiring treatment for longer than 6 months. The apparently better outcome with initial buspirone treatment is interesting but may be attributable to the higher dropout rate in the buspirone group during the initial treatment period, with only the most treatment-responsive patients remaining in the study.

Combined Treatment

CBT has been proved to be an effective treatment for GAD. Given the substantial rate of nonresponse in medication trials, combining psychotherapy and pharmacotherapy seems a promising strategy. A 10-week trial of diazepam, CBT, and combined treatment showed the greatest improvement in the diazepam-plus-CBT group, although similar proportions of patients from each group were taking psychotropic

medications at 6-month follow-up (Power et al., 1990). In a study by Lader and Bond, 60 patients with GAD were randomized to buspirone plus anxiety management, buspirone and nondirective therapy, placebo and anxiety management, or placebo and nondirective therapy (M. H. Lader & Bond, 1998). All treatment groups improved, with no significant differences between groups. More recently, a study of patients more than 60 years old found that combined escitalopram and CBT led to improvement on some, but not all, of the anxiety measures compared to escitalopram alone (Wetherell et al., 2013). In a randomized, but not placebo-controlled, study of patients enrolled in a long-term venlafaxine extended-release study, those who were offered and agreed to receive an 11-sesssion course of CBT did not demonstrate improvement over those who were either not offered or who did not accept the offer of CBT (Crits-Christoph et al., 2011). This type of study has also been tried in reverse. CBT completers who had residual, clinically significant symptoms were randomized to be offered or not offered escitalopram. Of those who were both offered and accepted escitalopram, there was a trend toward improvement in GAD (Schneier, Belzer, Kishon, Amsel, & Simpson, 2010).

SPECIFIC PHOBIA

Specific (formerly simple) phobias are fears and avoidance of discrete objects or situations (e.g., heights, animals, insects, water). These fears are almost always provoked by the specific stressor, are out of proportion to the actual danger, and cause significant impairment, anxiety, or avoidance. Specific phobias are common, with 12-month and lifetime prevalences of 8.7% and 12.5%, respectively (Kessler et al., 2005c, 2005c). Similar to other anxiety disorders, studies suggest some level of genetic contribution for specific phobia (Van Houtem et al., 2013).

The treatment of choice for specific phobias is behavior therapy, specifically systematic desensitization. In a meta-analysis of 33 randomized, psychotherapy trials for specific phobia, most of which included an exposure-based treatment, a moderate to large effect size was demonstrated (Wolitzky-Taylor, Horowitz, Powers, & Telch, 2008).

Pharmacotherapy data are extremely limited. A small, double-blind, placebo-controlled 4-week pilot study examining the efficacy of paroxetine up to 20 mg/day versus placebo for specific phobias showed significant superiority of paroxetine in reducing phobia scores on the Fear Questionnaire and Hamilton Anxiety scale (Benjamin, Ben-Zion, Karbofsky, & Dannon, 2000). A placebo-controlled study of escitalopram suggested benefit, but the sample size was too small to demonstrate statistical significance (Alamy, Wei, Varia, Davidson, & Connor, 2008). It is not known whether the inclusion of a variety of specific phobias, from claustrophobia to odontophobia to acrophobia, in these studies affected the outcomes. Thus, specific therapy trials published in the past few years have tended to focus on a single, specific phobia. For example, a placebo-controlled study of quetiapine enrolled only patients with arachnophobia. A single dose of quetiapine was used during a virtual reality spider challenge. There was no statistically significant benefit seen in the primary outcome measure, although some benefit was seen for somatic anxiety symptoms (Diemer et al., 2013).

There is interest in understanding how medications may interact with the associative learning processes underlying desensitization. There is controlled evidence indicating that use of benzodiazepines may reduce therapeutic effects of exposure treatment for specific phobia (Wilhelm & Roth, 1997). On the other hand, attempts have been made to enhance extinction learning in patients with specific phobia during behavior therapy. A randomized, placebo-controlled study employing yohimbine, a noradrenaline agonist, given 1 hour prior to exposure sessions did not demonstrate benefit (Meyerbroeker, Powers, van Stegeren, & Emmelkamp, 2012). Several placebo-controlled studies have sought to determine whether DCS, given after an exposure session, has merit. However, the results for this strategy in specific phobia have been mixed (Guastella, Dadds, Lovibond, Mitchell, & Richardson, 2007; Nave, Tolin, & Stevens, 2012; Ressler et al., 2004). A recent small but intriguing reanalysis of data from another trial with a null result (Tart et al., 2013) noted that DCS may be beneficial when given to acrophobic patients whose fear was low at the end of an exposure session, but less effective, or even detrimental, when given to patients whose fear was still high at the end of the exposure session (Smits et al., 2013b). This finding may affect the design of future DCS studies in anxiety disorders. Adjunctive DCS, delivered before virtual reality exposure sessions for acrophobia, also has some placebo-controlled evidence (Ressler et al., 2004).

SOCIAL ANXIETY DISORDER

SAD disorder (previously social phobia) is defined as a fear of social or performance situations due to fears of scrutiny and negative evaluation by others. Feared social situations are avoided or endured with distress, causing significant functional impairment. Recent formulations have separated out performance anxiety as a subtype while continuing to view SAD as a spectrum that varies by number and severity of fears (Bogels et al., 2010). Reflecting the most common "specific" form, the *DSM-5* drops the "generalized" specifier and includes a "performance only" specifier. There has also been discussion about whether generalized SAD is distinguishable from avoidant personality disorder (Widiger, 1992), although some cases of avoidant personality seem to align more closely with the schizophrenia spectrum (Bogels et al., 2010). Observations such as these led *DSM-5* authors to continue to include a distinct, avoidant personality disorder diagnosis.

Most of the placebo-controlled, antidepressant trials for SAD took place in the *DSM-IV* era. As mentioned previously, the *DSM-IV* contained a specifier for the "generalized" subtype of SAD. However, even in the *DSM-IV* era, not every SAD medication trial listed the participant subtypes. Even when the subtypes were listed, not every trial sought to exclusively enroll one subtype or the other. In trials that noted and enrolled both subtypes, no consistent difference in medication efficacy was noted.

SAD is common, with a 12-month prevalence of 6.8% and a lifetime prevalence of 12.1% (Kessler et al., 2005a, 2005c). It has an early age of onset, with a peak in childhood and the teenage years (Schneier, Johnson, Hornig, Liebowitz, & Weissman, 1992); it is more common in women than in men (Bourdon et al., 1988); and it is associated with significant disability, with 22% of those with uncomplicated SAD receiving public assistance and more than 50% of social phobics reporting at least moderate functional impairment due to social anxiety (Schneier et al., 1994). In up to 70% of cases, SAD is accompanied by, and commonly precedes, other significant comorbid psychiatric disorders, such as depression, other anxiety disorders, and alcohol abuse and dependence (Schneier et al., 1992).

Behavioral inhibition, characterized by autonomic arousal in response to novelty, increased salivary cortisol, and high norepinephrine activity starting in infancy, and shyness and introversion as a toddler, is strongly associated with later SAD, suggesting an underlying inborn vulnerability in many individuals (Rosenbaum et al., 1991). In addition, family and twin studies suggest that SAD is familial and has a modest heritable component (A. J. Fyer, Mannuzza, Chapman, Liebowitz, & Klein, 1993; Kendler, Neale, Kessler, Heath, & Eaves, 1992; Mosing et al., 2009).

Since the mid-1980s, behavioral and cognitive-behavioral techniques have proven effective in the treatment of SAD (Otto, 1999), and a number of double-blind, placebo-controlled studies have examined the efficacy of psychopharmacological treatments (Muller, Koen, Seedat, & Stein, 2005). Liebowitz and colleagues published the first open and then controlled trials of medication treatment for SAD patients (Liebowitz, Fyer, Gorman, Campeas, & Levin, 1986; Liebowitz et al., 1992). These trials used the beta-blocker atenolol, based on prior reports of the utility of beta-blockers in treating performance anxiety; and the MAOI phenelzine, based on the efficacy of this medication in treating mixed agoraphobia and SAD and its success in treating atypical depression, which shares with SAD the prominent symptom of interpersonal sensitivity. Since these early trials, controlled studies have examined the efficacy of both reversible and irreversible MAOIs, benzodiazepines, serotonin reuptake inhibitors, venlafaxine, pregabalin, gabapentin, and beta-blockers. Several meta-analyses have found moderate to large effect sizes for these medication classes in the acute treatment of SAD (Black et al., 2004; Canton, Scott, & Glue, 2012).

Currently, the SSRIs and venlafaxine are considered the first-line pharmacological treatments, based on their established efficacy for both SAD and common comorbid conditions, in addition to their tolerability, safety, and lack of dietary restrictions or risk of tolerance and withdrawal. Despite this, as in GAD, benzodiazepines remain the most commonly prescribed psychotropic medications for SAD in clinical practice, and most patients remain on them in the long term (Benitez et al., 2008; Vasile, Bruce, Goisman, Pagano, & Keller, 2005).

Serotonin Reuptake Inhibitors

Twenty-five double-blind, placebo-controlled trials of SSRIs for SAD were reviewed in 2000 (van der

Linden, Stein, & van Balkom, 2000), with NNTs ranging from 1.6 to 4.2. Two other meta-analyses, both examining 15 placebo-controlled trials, although one also included venlafaxine, affirmed the efficacy of second-generation antidepressants over placebo (Hansen et al., 2008; Hedges, Brown, Shwalb, Godfrey, & Larcher, 2007).

Paroxetine and sertraline are approved by the FDA for the treatment of SAD, while fluvoxamine and escitalopram have been proven effective in double-blind trials. Citalopram was superior to placebo in a small, 4-week controlled study comparing citalopram, a neurokinin-1 receptor antagonist, and placebo (Furmark et al., 2005). The efficacy of fluoxetine has been examined in three double-blind studies (Kobak, Greist, Jefferson, & Katzelnick, 2002). In one of these, fluoxetine failed to separate from placebo over 14 weeks, but the placebo response rate was high (Kobak et al., 2002). In another comparison of cognitive therapy, fluoxetine plus self-exposure, and placebo plus self-exposure for 16 weeks, cognitive therapy was superior to both of the other groups, which did not differ significantly from each other (Clark et al., 2003). In a third, 14-week trial studying fluoxetine, cognitive-behavioral group therapy (CBGT), and combined treatment, all active treatments yielded significantly higher response rates than placebo at end point and did not differ from each other (Davidson et al., 2004) Response rates were 50.9% for fluoxetine and 31.7% for placebo, providing some support for the efficacy of fluoxetine in SAD. Fluoxetine has also been reported to relieve symptoms of social anxiety emerging during clozapine treatment in one small open trial involving patients with schizophrenia (Pallanti, Quercioli, Rossi, & Pazzagli, 1999).

Paroxetine has demonstrated efficacy for SAD at doses of 20 to 50 mg/day, with significant decreases in Liebowitz Social Anxiety Scale scores as early as week 2, significant reductions in social avoidance and social disability, and overall response rates of 55% to 66% versus 24% to 36% for placebo-treated patients after 11 to 12 weeks (Allgulander, 1999; Allgulander et al., 2004b; Baldwin, Bobes, Stein, Scharwachter, & Faure, 1999; Lepola, Bergtholdt, St Lambert, Davy, & Ruggiero, 2004; Liebowitz, Gelenberg, & Munjack, 2005; Liebowitz et al., 2002; D. J. Stein et al., 1999; M. B. Stein et al., 1998). Pooled data from these eight trials, plus an additional, placebo-controlled study that used paroxetine as an active comparator (Lader, Stender, Burger, & Nil, 2004), yielded an odds ratio for response of 3.41 (Canton et al., 2012). Of note, although some patients responded early, an analysis of three paroxetine trials demonstrated that 46 of 166 patients who were nonresponders at week 8 (27.7%) were responders at week 12, arguing for at least 12-week treatment trials in many patients (D. J. Stein, Stein, Pitts, Kumar, & Hunter, 2002a).

Sertraline trials for 10 to 24 weeks have shown superiority to placebo at doses of 50 to 200 mg/day (Blomhoff et al., 2001; Katzelnick et al., 1995; Liebowitz et al., 2003; Van Ameringen et al., 2001). Four 12-week trials of fluvoxamine, at 100 to 300 mg/day of the regular or controlled-release formulation, have demonstrated superiority of drug over placebo (Davidson et al., 2004; M. B. Stein, Fyer, Davidson, Pollack, & Wiita, 1999; van Vliet, den Boer, & Westenberg, 1994; Westenberg, Stein, Yang, Li, & Barbato, 2004). Finally, in two 12-week studies, escitalopram at 5 to 20 mg/day produced significant reductions in social anxiety scores and disability (Kasper, Stein, Loft, & Nil, 2005; Lader et al., 2004). Response rates with these agents were comparable to those seen with paroxetine and, when reported, ranged from 40% to 55% for the SSRI and 7% to 30% for placebo.

These studies clearly establish that paroxetine, fluvoxamine, sertraline, and escitalopram are effective in the treatment of SAD. It seems likely that other SSRIs also are effective, and that the mixed results for fluoxetine reviewed above may be more a product of study design and sample characteristics than a fundamentally different action of the drug on social anxiety.

Venlafaxine

Extended-release venlafaxine (venlafaxine ER) is FDA approved for SAD. Double-blind, placebo-controlled trials of 75 to 225 mg/day have demonstrated the efficacy of this agent for generalized SAD (Allgulander et al., 2004b; Liebowitz et al., 2005; March, Entusah, Rynn, Albano, & Tourian, 2007; Rickels, Mangano, & Khan, 2004). Venlafaxine treatment, versus placebo, was associated with significantly greater decreases in social anxiety and social and work disability, with reductions in social anxiety occurring as early as week 1 or 2 in one study (Liebowitz et al., 2005). Two studies used paroxetine as an active comparator and showed similar efficacy and rates of adverse events with these two medications (Allgulander et al., 2004b;

Liebowitz et al., 2005). The most common adverse events noted in these two studies were nausea, asthenia, somnolence, and insomnia.

Monoamine Oxidase Inhibitors

Liebowitz and colleagues (1986) reported that 7 of 11 patients with *DSM-III* social phobia showed a "marked" response to phenelzine and the other 4 had "moderate" improvement. Since then, four double-blind, randomized trials have supported the efficacy of phenelzine for SAD (Gelernter et al., 1991; Heimberg et al., 1998; Liebowitz et al., 1992; Versiani et al., 1992). Liebowitz and colleagues (1992) treated 74 patients with SAD with phenelzine (mean dose, 75.7 mg/day), atenolol (mean dose, 97.6 mg/day), or a placebo; by week 8, "response" rates (much or very much improved as assessed by an independent rater) were 64% for phenelzine, 30% for atenolol, and 23% for the placebo.

Gelernter and colleagues (1991), in a study of 65 social phobics (most with specific social phobia) given phenelzine, alprazolam, a placebo, or CBGT, found that all groups improved, perhaps because all patients were encouraged to expose themselves to feared situations. Nevertheless, patients taking phenelzine were more likely than those in the other groups to display functional improvement and to fall below the mean score for the general population on the social phobia subscale of the Fear Questionnaire at the end of 12 weeks. Versiani and colleagues (1992) completed a double-blind trial of phenelzine, the reversible MAOI moclobemide, and placebo. After 8 weeks, phenelzine and moclobemide were both significantly more effective than the placebo, and these gains were maintained for a further 8 weeks. Responders were then maintained on active medication or changed to a placebo. Those switched to the placebo demonstrated significant increases in symptomatology that persisted for at least 5 weeks, a finding suggesting a high rate of relapse. Finally, Heimberg and colleagues (1998) compared 12 weeks of phenelzine, pill placebo, CBGT, and an educational supportive group in 133 patients with social anxiety disorder. Both CBGT and phenelzine were superior to the control conditions, although response for phenelzine was more marked than for CBGT response at 6 weeks.

Thus, double-blind trials support the efficacy of phenelzine in the treatment of SAD. Interestingly, isolated case reports suggest that phenelzine may also be effective in the treatment of conditions related to SAD, such as elective mutism (Golwyn & Weinstock, 1990) and social anxiety secondary to physical disfigurement (Oberlander, Schneier, & Liebowitz, 1994). Other irreversible MAOIs have not been studied in double-blind trials. However, an open trial of tranylcypromine yielded 20 "marked responders" among 29 subjects (Versiani, Mundim, Nardi, & Liebowitz, 1988).

Irreversible MAOIs such as phenelzine have significant side effects, most notably hypertensive crisis, insomnia, weight gain, and sexual dysfunction. Reversible MAOIs, such as moclobemide and brofaramine, bind reversibly, are selective for the A isoenzyme of monoamine oxidase, and have fewer side effects, including a much lower rate of hypertensive crisis. The efficacy of reversible MAOIs in social phobia has been demonstrated in five double-blind, placebo-controlled trials of moclobemide (International Multicenter Clinical Trial Group, 1997; Noyes et al., 1997; Prasko et al., 2006; Schneier et al., 1998; Versiani et al., 1992) and three of brofaramine (Fahlen, Nilsson, Borg, Humble, & Pauli, 1995; Lott et al., 1997; van Vliet et al., 1993), and an open trial suggests that moclobemide is similar in efficacy to the SSRI citalopram (Atmaca, Kuloglu, Tezcan, & Unal, 2002). Unfortunately, despite the promise of the reversible MAOIs moclobemide and brofaromine for social anxiety disorder, these medications are unavailable in the United States. Of note, selegiline, which is a reversible MAOI in low doses, has been reported to be effective for SAD (Simpson et al., 1998b).

Beta-Blockers

Despite an early, promising open study of atenolol for social phobia (Gorman, Liebowitz, Fyer, Campeas, & Klein, 1985) and several studies demonstrating the efficacy of single doses of beta-blockers for treating performance anxiety in nonclinical groups such as musicians and public speakers (Jefferson, 1995), beta-blockers have not proved effective in double-blind trials with patients with different subtypes of SAD. For example, in the comparison of phenelzine, atenolol, and placebo by Liebowitz and colleagues (1992) mentioned above, atenolol was not significantly more effective than a placebo.

Behavior therapy, primarily flooding, was superior to both a placebo and atenolol in one study (Turner, Beidel, & Jacob, 1994), and propranolol showed no advantage over a placebo in a study in which subjects also received social skills training (Falloon, Lloyd, & Harpin, 1981). Pindolol 5 mg TID was studied as a possible augmentation of paroxetine for generalized SAD in a 4-week double-blind trial but was no more effective than placebo (M. B. Stein, Sareen, Hami, & Chao, 2001).

Beta-blockers (e.g., propranolol 10 to 40 mg taken as needed 45 to 60 minutes before a performance) have been shown to reduce autonomic symptoms such as tremor, sweating, and tachycardia in individuals with performance anxiety who do not necessarily meet criteria for SAD (reviewed in Muller et al., 2005). Individuals whose performance anxiety is not characterized by these autonomic symptoms are unlikely to be helped by beta-blockers.

Benzodiazepines

In open trials, both alprazolam, at doses of 3 to 8 mg/day, and clonazepam, 1 to 6 mg/day, have been effective in the treatment of SAD (Davidson, Tupler, & Potts, 1994). The only double-blind, placebo-controlled trial of alprazolam was that by Gelernter and colleagues (1991). Although alprazolam (mean dose, 4.2 mg/day) was not superior to a placebo, this study was complicated by the inclusion of self-directed exposure in all treatment groups. Clonazepam, at an average dose of 2.4 mg/day, decreased social anxiety, interpersonal sensitivity, phobic avoidance, and disability in a 10-week double-blind study of 75 patients with SAD (Davidson et al., 1993). Response rates were 78.3% for clonazepam and 20% for a placebo. Clonazepam was similar in efficacy to CBGT in a 12-week trial (Otto et al., 2000). Clonazepam, at 1 to 3 mg/day, has also been compared to placebo as an adjunctive treatment to paroxetine 20 to 40 mg/day in a randomized, double-blind, 10-week trial (Seedat & Stein, 2004). At 10 weeks, the paroxetine-plus-clonazepam group had a 79% response rate, compared with a 43% response rate for the paroxetine-plus-placebo group, although given the small sample size (19 completers), this difference was significant only at a trend level ($p < 0.06$).

In the most recent study, 181 patients who had an inadequate response to 10 weeks of sertraline were randomized to a 3-month trial of augmentation with clonazepam (up to 3 mg/day), a switch to venlafaxine (mean dose 168 mg), or sertraline plus placebo. The additional 3 months of sertraline yielded a response rate of 17%. The switch to venlafaxine yielded a numerically greater response rate (19%) than sertraline plus placebo. Clonazepam augmentation, however, yielded a response rate of 27%, which was significantly better than the sertraline-plus-placebo group (Pollack et al., 2014).

Use of benzodiazepines for SAD is complicated both by their side effects and by the high rate of comorbid alcohol abuse or dependence in this patient population (Schneier et al., 1992), which may put patients at an increased risk for benzodiazepine abuse and dependence.

Other Medications

Surprisingly, there have been no controlled trials of TCAs for patients with SAD. Although isolated case reports suggest that they may be effective (Benca, Matuzas, & Al-Sadir, 1986), and a large sample of 765 patients with agoraphobia or social phobia responded well to open-label clomipramine (Beaumont, 1977), other anecdotal evidence has been cited suggesting that TCAs are inferior to MAOIs (Liebowitz et al., 1986; Versiani et al., 1988), and an open trial of imipramine (Simpson et al., 1998a) indicated both lack of efficacy and a high dropout rate due to side effects.

Two double-blind trials using buspirone showed no significant improvement with doses averaging 32 mg/day in musicians seeking treatment for performance anxiety (Clark & Agras, 1991) and no difference between buspirone 30 mg/day and placebo in 30 patients with SAD (van Vliet, den Boer, Westenberg, & Pian, 1997). However, an open trial suggests that buspirone may be an effective augmentation agent in partial responders to SSRIs (Van Ameringen, Mancini, & Wilson, 1996).

A randomized, double-blind, placebo-controlled 14-week trial using flexible doses of gabapentin (900 to 3,600 mg/day in three divided doses; mean dose, 2,100 mg/day) in 69 patients with SAD yielded response rates (CGI of 1 or 2) of 32% with gabapentin versus 14% with placebo (Pande et al., 1999). Side effects of gabapentin included dizziness, dry mouth, somnolence, nausea, flatulence, and decreased libido. Pregabalin 600 mg/day, but not lower doses,

was superior to placebo in two double-blind trials in patients with SAD, with the most frequent side effects being somnolence and dizziness (Feltner, Liu-Dumaw, Schweizer, & Bielski, 2011; Pande et al., 2004).

In 16 patients treated with levetiracetam versus placebo, there was a moderate effect size (0.50) for Liebowitz Social Anxiety Scale scores after 7 weeks (Zhang, Connor, & Davidson, 2005). However, in a much larger, 217-patient, placebo-controlled trial, levetiracetam failed to separate from placebo for patients with SAD, generalized type (M. B. Stein et al., 2010).

Based on encouraging open-label studies (Dunlop et al., 2007; Evans et al., 2009), a very small, short, non–placebo-controlled, double-blind crossover study found similar response rates to gabapentin and tiagabine (Urbano et al., 2009).

A placebo-controlled trial of atomoxetine in patients with SAD, but without attention-deficit/hyperactivity disorder, demonstrated no benefit (Ravindran, Kim, Letamendi, & Stein, 2009).

A 16-week, open trial of flexibly dosed topiramate (maximum dose, 400 mg/day) in 23 patients with SAD resulted in rates of remission and response of 26% and 48%, respectively (Van Ameringen, Mancini, Pipe, Oakman, & Bennett, 2004).

Successful treatment of SAD with bupropion (Emmanuel, Lydiard, & Ballenger, 1991), valproic acid (Kinrys et al., 2003), clonidine (Goldstein, 1987), and the dopamine agonist pergolide (Villarreal, Johnson, Rubey, Lydiard, & Ballanger, 2000) has been reported.

A placebo-controlled trial of nefazodone failed to demonstrate statistical significance (Van Ameringen et al., 2007). Mirtazapine monotherapy has a positive placebo-controlled trial (Muehlbacher et al., 2005) and a trial where no benefit over placebo was seen (Schutters, Van Megen, Van Veen, Denys, & Westenberg, 2010). The nonresponsive patients, both those on mirtazapine and those on placebo, of the second trial were then augmented with paroxetine, although the combination of active agents showed no benefit over paroxetine plus placebo (Schutters, van Megen, Van Veen, Schruers, & Westenberg, 2011). Reboxetine (Atmaca, Tezcan, & Kuloglu, 2003) may have some utility in the treatment of SAD.

Olanzapine 5 to 20 mg/day was superior to placebo in a small, double-blind, 8-week trial, with the most common side effects being drowsiness and dry mouth (Barnett, Kramer, Casat, Connor, & Davidson, 2002). A placebo-controlled trial of sulpiride demonstrated no benefit (Bell et al., 2013). A placebo-controlled trial of quetiapine in advance of a public-speaking exposure session for patients with SAD demonstrated no benefit (Donahue et al., 2009). Another small trial of daily quetiapine for SAD also failed to separate from placebo for the primary outcome measures, although some facets of this trial would suggest that a larger study is needed to more clearly define quetiapine's impact (Vaishnavi, Alamy, Zhang, Connor, & Davidson, 2007).

Duration of Treatment/Chronic Treatment

SAD is frequently a chronic illness requiring long-term treatment (Reich, Goldenberg, Vasile, Goisman, & Keller, 1994). Several studies have found continued efficacy of serotonin reuptake inhibitors, venlafaxine, clonazepam, phenelzine, and selective MAOIs with treatment for 5 months or more. For example, sertraline was well tolerated and effective in a 20-week controlled trial (Van Ameringen et al., 2001). In the recent study by Pollack and colleagues (2014), 17% of patients who had an inadequate response to sertraline during an initial 10-week trial went on to demonstrate a response when sertraline was continued for another 10 weeks. Escitalopram was well tolerated and produced further improvement versus placebo between 12 and 24 weeks of treatment at 5 to 20 mg/day (Lader et al., 2004); fluvoxamine controlled-release (CR) 100 to 300 mg/day continued to yield gains in symptomatic improvement and reduction of disability between 12 and 24 weeks of treatment (D. J. Stein, Westenberg, Yang, Li, & Barbato, 2003); and venlafaxine XR at a low dose (75 mg/day) or a high dose (150 to 225 mg/day) was effective throughout a 28-week trial, with no significant differences in outcome between the low- and high-dose groups (M. B. Stein, Pollack, Bystritsky, Kelsey, & Mangano, 2005). In 26 patients with SAD treated with clonazepam for an average of 11.3 months (range, 1 to 29 months), clonazepam was well tolerated; 20 patients were able to reduce their dose and 5 discontinued their medication (Davidson, Ford, Smith, & Potts, 1991b). A trial comparing a placebo and brofaromine followed responders for 9 months (Fahlen et al., 1995). Those on brofaromine showed further symptomatic improvement over this period.

A number of longer-term trials have examined the issue of optimal treatment duration by studying relapse rates with discontinuation of medication at various time points. Connor and colleagues (1998) assigned patients who had responded to 6 months of clonazepam treatment to continued treatment or to a gradual taper (0.25 mg every 2 weeks) with double-blind placebo substitution for 5 months; relapse rates were 0% in the continued-treatment group and 21% in the taper group. However, currently this taper would probably be performed more gradually. In the 9-month brofaromine trial, 6 of 10 placebo-treated patients relapsed, versus none of 22 maintained on brofaromine (Fahlen et al., 1995).

Versiani, Amrein, and Montgomery (1997) reported that, of 59 patients who responded to moclobemide and were continued on treatment for 2 years, 88% deteriorated when the medication was then discontinued. Reinstitution of moclobemide restored the therapeutic response. After another 2 years following the same cohort, medication was discontinued, and up to 6 to 24 months later, 63% of patients had no or mild symptoms, suggesting that longer duration of treatment may reduce relapse after discontinuation. Alcohol abuse was the strongest predictor of negative treatment outcome. In a later follow-up study of patients originally treated acutely with phenelzine or CBGT (Heimberg et al., 1998; Liebowitz et al., 1999), responders were maintained on treatment for 6 months and then followed for a 6-month treatment-free phase. Most patients maintained their gains during the maintenance phase, but relapse rates were higher in phenelzine-treated patients than in the CBGT group once treatment was discontinued.

Four studies have examined relapse rates in patients with SAD who responded to acute treatment with an SSRI and then entered a double-blind phase in which they were maintained on active medication or switched to placebo (Montgomery, Nil, Durr-Pal, Loft, & Boulenger, 2005; D. J. Stein, Versiani, Hair, & Kumar, 2002b; M. B. Stein et al., 1996; Walker et al., 2000). Sixteen paroxetine responders after 11 weeks were randomized to an additional 12 weeks of paroxetine versus placebo in the first of these studies (M. B. Stein et al., 1996). One of eight patients on paroxetine relapsed, compared with five of eight on placebo. Fifty sertraline responders after a 20-week trial were switched to double-blind sertraline versus placebo for an additional 24 weeks and had a relapse rate of 4% on continued sertraline versus 36% on placebo (Walker et al., 2000). Of 323 patients responding to acute treatment with paroxetine, significantly fewer patients relapsed when maintained on 24 weeks of active medication than when switched to placebo (14% vs. 39%; D. J. Stein et al., 2002b). Finally, 371 responders to escitalopram showed a 2.8 times greater risk of relapse when treated with placebo versus medication for another 24 weeks (Montgomery et al., 2005).

Patients who responded to a 10-week, fixed-dose (450 mg) trial of pregabalin were enrolled in a 36-week, double-blind, placebo-controlled continuation trial. Although an administrative issue unrelated to efficacy or safety reasons shut down this study prematurely, the data still significantly favored pregabalin continuation (Greist, Liu-Dumaw, Schweizer, & Feltner, 2011).

Overall, these data suggest that many patients with SAD benefit from continued treatment beyond the acute phase of clinical trials. The optimal duration of treatment remains unclear but appears to be longer than 6 months after acute treatment for a substantial number of people. The World Federation of Societies of Biological Psychiatry and the International Consensus Group on Depression and Anxiety recommend that patients with SAD remain on effective treatment at therapeutic dosages for at least 1 year (Ballenger et al., 1998b; Bandelow, Zohar, Hollander, Kasper, & Moller, 2002).

Combined Treatment

CBT yields large effect sizes in the treatment of SAD (Butler, Chapman, Forman, & Beck, 2006). A confounder in evaluating CBT is the variety of techniques, elements, treatment settings, and group-versus-individual format in the various trials. There are randomized trials that favorably compare CBT to psychodynamic therapy (Leichsenring et al., 2013) and interpersonal therapy (Stangier, Schramm, Heidenreich, Berger, & Clark, 2011).

Two major studies have examined combining CBT with SSRIs to boost response rates. Blomhoff and colleagues (2001) randomized 387 patients with generalized SAD in a primary care setting to sertraline, placebo, sertraline plus exposure therapy, or placebo plus exposure therapy for 24 weeks. Exposure therapy was provided by primary care physicians.

Response rates for both sertraline groups were significantly higher than that of the placebo group, and there was a trend for enhanced efficacy in the sertraline-plus-placebo group. Another study by Davidson and colleagues (2004) compared 14 weeks of fluoxetine, CBGT, CBGT plus fluoxetine, CBGT plus placebo, and placebo in 295 patients with generalized SAD. All active treatments were superior to placebo but similar to each other, with no advantage seen with combined treatment (response rate 54.2% for combined treatment vs. 51.7% with CBGT and 50.9% with fluoxetine). Clearly, further studies of combined treatment are needed.

Two studies have examined the combination of a MAOI and CBGT for SAD. Blanco and colleagues (2010) randomized 128 patients to receive phenelzine, CBGT, CBGT plus phenelzine, or pill placebo. Although both phenelzine and combined treatment significantly beat placebo in certain outcome measures, combined treatment was superior to each monotherapy taken individually, as well as the monotherapies taken as a pool.

Knijnik and colleagues (2008) engaged in a 12-week randomized, but not placebo-controlled, trial of clonazepam with or without psychodynamic group therapy. This 57-patient trial demonstrated benefit for the combined treatment in the Clinical Global Impression-Improvement scale but not the Liebowitz Social Anxiety Scale.

As with specific phobia, DCS has been studied as augmentation to exposure sessions in CBT for SAD. Although an earlier, smaller study by the same group had demonstrated statistically significant benefit for DCS augmentation (Hofmann et al., 2006), a 169-patient trial found no benefit over placebo in either response or remission when DCS was delivered 1 hour in advance of 5 exposure sessions that were part of a larger, 12-session, CBT group treatment (Hofmann et al., 2013). On the other hand, a medium effect size was noted in a similar, but smaller, placebo-controlled trial of DCS 50 mg given prior to exposure therapy sessions (Guastella et al., 2008). As they did with a previously mentioned specific phobia study, Smits and colleagues (2013a) reanalyzed data from the above trial by Hoffman and colleagues and noted a benefit of DCS over placebo for patients reporting low fear at the end of an exposure session, but a detriment compared to placebo in patients who reported high fear at the end of an exposure session. As was the case with specific phobias, this is an emerging intervention that merits further study before more confident conclusions can be made.

SUMMARY

Since the early 1980s, a number of pharmacological treatments have been shown to be effective for PD, GAD, and SAD. SSRIs are now considered by most experts to be the first-line pharmacological treatment for PD based on their low rate of side effects, lack of dietary restrictions, and absence of tolerance and withdrawal symptoms. Similarly, SSRIs and venlafaxine are attractive first-line treatments for SAD. It is important to bear in mind, however, that SSRIs and SNRIs do carry significant adverse side-effect burdens of their own, including weight gain, sexual dysfunction, withdrawal syndromes, the syndrome of inappropriate secretion of antidiuretic syndrome (SIADH), and sleep disturbance. This needs to be considered when deciding whether to recommend pharmacotherapy or CBT as the first intervention. The pharmacological treatments of choice for GAD are buspirone and antidepressants, including SSRIs and venlafaxine. Benzodiazepines, although effective for all these disorders, carry with them the risk of physiological dependence and withdrawal symptoms and ineffectiveness for comorbid depression. Their greatest utility at present seems to be as an initial or adjunctive medication for patients with disabling symptoms requiring rapid relief and for those unable to tolerate other medications. Chronic treatment with benzodiazepines is generally safe and effective but should probably be reserved for patients who are nonresponsive to initial SSRI trials or intolerant to other agents. Controlled trials are necessary to determine whether patients with specific phobias respond to pharmacological agents, particularly serotonin reuptake inhibitors and DCS, as an adjunct to exposure treatments.

Overall, little is known regarding the optimal duration of treatment or long-term outcome of the conditions discussed in this chapter. However, all four disorders begin early in life, often in childhood or adolescence, and follow a chronic or waxing-and-waning course in many people. Thus, further study of treatment of anxiety disorders in children and of long-term management of PD, GAD, specific phobia, and SAD is very important. The major challenges in acute treatment of all of these disorders are to determine the most effective and also cost-effective initial combination

of pharmacological and nonpharmacological treatments and to develop new anxiolytic agents with a rapid onset of action but without the risks of tolerance and withdrawal. For existing agents, particular subtypes of these disorders or types of comorbidity may respond better to some agents than to others, and studies of combination treatments may enhance efficacy, especially in patients who are unresponsive to or only minimally improved with single agents.

Combination Pharmacotherapy and Psychotherapy for the Treatment of Major Depressive and Anxiety Disorders

Cindy J. Aaronson
Gary Katzman
Rachel L. Moster

Clinical wisdom and intuition suggest that when treating major depression and/or anxiety disorders, combining two documented efficacious treatments such as antidepressants and psychotherapy would improve outcome. However, the data do not completely support this conclusion. In this chapter we review randomized clinical trials (RCTs) comparing combined pharmacotherapy and psychotherapy with monotherapy for the treatment of major depressive disorder (MDD), panic disorder (PD), obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), generalized anxiety disorder (GAD), and social anxiety disorder (SAD) in adults. Although the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (fifth ed.; *DSM-V*) no longer categorizes PTSD and OCD as anxiety disorders, we have elected to continue to include them in this chapter.

MAJOR DEPRESSIVE DISORDER

The research literature on MDD is divided into three types of studies: acute treatment of nonspecific MDD, acute treatment of specific groups such as the chronically depressed or the elderly, and relapse prevention or maintenance therapy. There have been four review articles of RCTs of combined treatment for MDD since 1997 (Arnow & Constantino, 2003; Hegerl, Plattner, & Möller, 2004; Pampallona, Bollini, Tibaldi, Kupelnick, & Munizza, 2004; Segal, Vincent, & Levitt, 2002) and two meta-analyses (Thase et al., 1997, 2012), which conclude that combined treatment is superior to monotherapy for severely and chronically depressed patients, but not for those with milder forms.

Acute Treatment for Unspecified Depression

Tricyclic Antidepressants

An acute treatment study for nonspecific MDD was conducted by Hollan and colleagues (1992) on 107 outpatients. They compared imipramine with cognitive-behavioral therapy (CBT) and their combination for 12 weeks. All groups showed significant symptom reduction on the Hamilton Rating Scale for Depression (HRSD), but there were no differences in response between combination and each single treatment. It is difficult to interpret these results because only 64 of the 107 subjects completed the treatment, and no intent-to-treat analysis was performed. The overall attrition rate was 40%, without any mention

of breakdown by group. Perhaps the high attrition rate was due to the side effects of imipramine.

In a European trial comparing amitriptyline with clinical management, CBT alone, and the combination of CBT and amitriptyline for 8 weeks, Hautzinger, de Jong-Meyer, and Treiber (1996) studied 191 inpatients and outpatients. Their results were based on an intent-to-treat analysis with a 30% dropout rate; dropout was seen more frequently in the amitriptyline-only group. Dropouts occurred least frequently in the CBT-alone group, significantly later in the study (during the follow-up period) than in the combination group. Hautzinger's group only found a trend toward combination treatment demonstrating a higher response than either single modality alone. Possibly this trend may be accounted for by the inclusion of inpatients, who typically are more severely depressed than outpatients.

Selective Serotonin Reuptake Inhibitors

An Amsterdam study (Dekker et al., 2005) randomized 103 depressed outpatients to one of two conditions: medication and 8 or 16 weeks of psychodynamic supportive psychotherapy. The medication treatment included fluoxetine (20 mg/day) that could then be changed to nortriptyline (50 mg/day up to 150 mg/day) if fluoxetine was not tolerated or was ineffective. A further medication switch was allowed to mirtazapine (15 mg/day up to 45 mg/day) if nortriptyline was either intolerable or ineffective. All medications were maintained for 6 months. The short-term psychotherapy was based on treatment guidelines. Adherence was measured by review of audiotape sessions.

Measures used to determine outcome were the HRSD, the Clinical Global Impression (CGI), the Symptom Checklist (SCL-90), and the Quality of Life Depression Scale. All subjects were moderately depressed with a history of previous depressive episodes, and no current episode lasting longer than 2 years. Although the results showed that both treatments were effective in reducing symptoms over 6 months, the 8-session group achieved remission faster than the 16-session group. There are several limitations to this study, but the most important one is the lack of a control group. Both groups received medication and the same type of psychotherapy, only varying in the duration of treatment. It is difficult to determine how much improvement would be accounted for by the medication and how much by the psychotherapy, since medications were changed for efficacy or intolerance. This study was included in this review because the flexibility of medication treatment more closely resembles clinical practice than usual RCTs and may provide some usefulness to clinicians.

Acute Treatment for Chronic Depression

One of the premier trials included in all the above reviews was conducted by Keller and colleagues (2000), who compared nefazodone, a hybrid serotonin antagonist/reuptake inhibitor, alone; a form of CBT called cognitive-behavioral analysis system of psychotherapy (CBASP); and their combination. For the 12-week trial the researchers recruited 681 outpatients with either MDD for 2 years or longer, current MDD superimposed on dysthymia, or partially remitted recurrent MDD in a current episode. From that initial sample, 519 completed the multicenter study. History of seizures or abnormal EEG findings, severe head trauma, or stroke, suicidality, psychosis, bipolarity, eating disorders, substance use disorders, or severe personality disorders were exclusion criteria. History of nonresponse to nefazodone, CBASP, electroconvulsive therapy, or adequate trials of two different classes of antidepressants were also criteria for exclusion.

CBASP, developed for chronic MDD, is based on aspects of cognitive, behavioral, and interpersonal treatment techniques but is more directive and structured than interpersonal psychotherapy (IPT). The treatment emphasizes social problem-solving methods for dealing with interpersonal problems, and the cognitive work focuses more attention on thoughts about interpersonal interactions, including those with the therapist. The goal of CBASP is to understand how maladaptive patterns of interactions with others foster interpersonal problems. Sessions occurred twice a week during the first 4 weeks, then weekly for 8 weeks. If deemed necessary, the twice-weekly meeting schedule could be continued until week 8.

All patients receiving medication were seen for 15 to 20 minutes weekly, and clinical management was manualized. Pharmacotherapists inquired about symptoms, side effects, and other medication use but did not make any psychotherapeutic interventions. The initial dose of nefazodone was 200 mg/day for

week 1, increased to 300 mg/day at week 2 with subsequent incremental increases of 100 mg/day to a maximum dose of 600 mg/day. A dose of at least 300 mg/day by week 3 was required to stay in the trial.

After randomization of the 681 patients, 226 were assigned to the nefazodone-only group, 228 to the CBASP-only group, and 227 to the combined group. The groups did not differ on demographic and baseline measures. Outcome was measured by the 24-item HRSD; response was defined as a 50% reduction in HRSD score from baseline at weeks 10 and 12, and remission was defined as a score of 8 or less at both weeks 10 and 12.

After 12 weeks, results showed significant reduction in HRSD scores both in the completers and in the intent-to-treat analysis. Using both completer and intent-to-treat analysis, the combined treatment group had a significantly higher response rate than either of the monotherapy groups. The intent-to-treat response rates were 73% for the combined group, 48% for the CBASP group, and 48% for the nefazodone group. The completer response rates were 85% for the combined group, 52% for the CBASP group, and 55% for the nefazodone group. The dropout rate was 24%, with no significant differences among groups. In summary, for chronic depression, combined nefazodone and CBASP was significantly better for achieving response than either therapy alone.

Several additional analyses have been reported using data from this study. Thase and colleagues (2002) looked specifically at symptoms of insomnia and found that nefazodone, in combination and alone, was superior to CBASP at all time points, but the combined treatment was superior to nefazodone alone at the end of 12 weeks of treatment. Psychosocial functioning independent of depressive symptoms was assessed by Hirschfeld and colleagues (2002). Before treatment, the patients demonstrated very low or impaired psychosocial functioning in comparison to community norms. After treatment there was substantial improvement, yet some impairment remained independent of depressive symptoms. Combined treatment had a greater impact on psychosocial improvement than either treatment alone.

Lastly, sexual functioning and satisfaction were considered before and after treatment (Zajecka et al., 2002). At baseline, 65% of the men and 48% of the women had experienced some sexual dysfunction. After treatment, all patients experienced significant improvement in sexual interest and satisfaction, but the combined treatment group demonstrated significantly greater improvement in sexual interest and satisfaction than the CBASP-only group, but not compared to the nefazodone-only group.

The REVAMP trial (Kocsis et al., 2009) was an eight-site study to test the effectiveness of adjunctive CBASP or brief supportive psychotherapy to antidepressant medication compared to continued optimized pharmacotherapy alone for 12 weeks. This two phase trial uniquely treated 808 patients aged 18 to 75 with open-label, stepped pharmacotherapy. The usual exclusionary criteria were followed: bipolar disorders, psychotic disorders, dementia, eating disorders, primary PTSD or OCD, severe personality disorders, and substance dependence. They did allow substance abuse on the condition that participants attend either self-help groups or treatment.

During phase 1 (12 weeks), treatment followed an empirically derived algorithm: sertraline first (if the patient had never failed two adequate trials of selective serotonin reuptake inhibitor [SSRI] and never failed on sertraline); escitalopram (if the patient had failed on sertraline in the past and never failed two adequate trials of SSRI); bupropion (if two failures on SSRI and never failed on bupropion); venlafaxine extended-release (if two failures on SSRI and bupropion); and lastly mirtazapine if all the above had failed. Midway in phase 1, intolerance to any of the treatments moved the patient to the next option in the sequence. If mirtazapine was not tolerated, patients exited the study.

Phase 2 involved augmenting treatment. For partial responders to any of the phase 1 treatments, augmentation was with bupropion or venlafaxine if bupropion was used. For nonresponders to phase 1 treatments, the next step intervention was instituted (from sertraline to escitalopram, escitalopram to bupropion, bupropion to venlafaxine, venlafaxine to mirtazapine). For partial responders and nonresponders on mirtazapine, lithium was added. The second step of phase 2 involved randomizing patients to augmentation of CBASP, brief supportive psychotherapy, or medication only.

Remission in this trial was defined as at least a 60% decrease in HRSD score plus less than 8 on the 24-item version and no longer meeting criteria for MDD for 2 consecutive weeks. Any participants at week 12 who did not meet remission criteria were then eligible to enter phase 2. The medication-only group was seen every other week and visits were based

on the manual used in the Treatment of Depression Collaborative Research study.

Brief supportive psychotherapy (manualized) included reflective listening, empathy, evoking affect, therapeutic optimism, and acknowledgment of patients' assets, but no other interventions using interpersonal, cognitive-behavioral, or psychodynamic approaches were allowed. Both psychotherapy groups received 16 to 20 sessions over 12 weeks.

Of the 808 who entered phase 1, 491 completed 12 weeks and were either partial responders or nonresponders and were randomly assigned to one of three groups (n = 96 medication only; n = 200 CBASP; n = 195 brief supportive therapy). Remission at phase 2 was defined as a 50% decrease in HRSD, a score of less than 8, and Clinical Global Impressions Improvement (CGI-I) of 1 or 2 for two consecutive visits. Partial response was defined as an HRSD score of 8 to 16 but a 50% decrease from baseline and CGI-I of 1 or 2 for two weeks but not consecutively.

The results did not support the hypothesis that CBASP would significantly improve outcome compared to brief supportive psychotherapy or medication alone. Although there was significant improvement in all participants, there was no difference among groups. The authors suggest that the reason for this lack of differentiation, which had been supported in the earlier study (Keller et al, 2000), was due to the optimal use of pharmacotherapy in this trial, mirroring clinical practice. In addition, the participants in this trial were guaranteed medication, not psychotherapy, so perhaps the design selected for those with a preference for medication rather than psychotherapy. The authors also speculate that patients may have had less motivation for entering psychotherapy due to all the medication changes during the stepped treatment.

The researchers tested social problem-solving ability (a major focus of CBASP) to determine whether this differentiated treatment modality. Although the CBASP group experienced significantly greater improvement in social problem solving, this did not predict greater improvement in depressive symptomatology over time.

Chaput and colleagues (2008) randomized 22 of a potential 31 depressed participants who had been treated with an antidepressant plus lithium augmentation for 3 weeks and were considered nonresponders [Hamilton Rating Scale for Depression (HAM-D) score > 18] to either CBT plus quetiapine or CBT plus placebo. This Canadian study was conducted at two sites, with a balanced gender sample (73% female in each group) a mean age of 43.7 and a mean onset of illness of 22.7. Both groups had similar baseline HAM-D, Montgomery Asburg Depression Rating Scale (MADRS), and CGI scores.

Thirty-one patients were enrolled in the first phase of the study; one withdrew before lithium augmentation and another after augmentation. Of the 29 remaining, 5 responded to the lithium and were not continued to the CBT phase, while 2 dropped out, leaving the 22 who were randomized to CBT plus quetiapine or placebo.

CBT treatment was conducted weekly for 12 weeks, with each session lasting 60 minutes, and was based on Beck's model incorporating cognitive restructuring, behavioral techniques, social skills training, and applied relaxation training. Quetiapine was administered with a starting dose of 12.5 mg twice daily. Within the first 14 days, titration to a maximum dose of 200 mg twice a day was instituted in flexible dosing for a stable dose until study completion.

Response was defined as at least a 40% drop in HAM-D or a score less than 18. In this sample, the quetiapine-plus-CBT group significantly improved compared to the placebo-plus-CBT group based on HAM-D. The placebo group experienced more dropouts (only 5 completed 12 sessions) than the quetiapine group (10 completed the 12 sessions), which explains the poor results for the placebo group in the intent-to-treat analysis. When the completer analysis was performed, the CBT-plus-placebo group demonstrated a significant improvement from baseline. The CGI ratings for both improvement and severity demonstrated no significant difference between groups.

In this small sample of 11 patients per group, the combination treatment was more effective than CBT plus placebo based on HAM-D ratings in the intent-to-treat analysis but not compared to those who completed the full course of CBT. The authors explained that their low response rate and the low lithium response rate experienced earlier in the study (only 17%) may have been due to suboptimal treatment duration—only 12 weeks of CBT—while others have used 16 weeks of CBT and at least 3 weeks of lithium treatment. The limited evidence of superiority for combined treatment in this study supports the conclusion that in severely depressed individuals, combined treatment is more effective than monotherapy.

One meta-analysis of studies that included combination treatment for MDD (Thase et al., 1997) lasting 16 weeks compared CBT alone, IPT alone, and both combined with antidepressant medication (imipramine or nortriptyline). The analysis included 595 subjects from six protocols with unipolar depression and was based on a semistructured assessment using *DSM-III* or *DSM-III-R* criteria. All six studies were conducted at the authors' research center between 1982 and 1992. One was a maintenance study of recurrent MDD, a second was a maintenance study for late-life MDD, and the others focused on a specific area such as psychobiology or social factors. Three of the studies included chronically depressed patients whose episode duration lasted 2 or more years. The researchers concluded that combined therapy was superior to psychotherapy alone for recurrent, severe MDD (43% recovery for combined treatment vs. 25% for psychotherapy alone), but there was no difference in less severe depression (48% recovery for combination treatment vs. 37% for psychotherapy alone). In recurrently depressed patients, a shorter duration of illness (time to remission) resulted from combination treatment.

We are including a clinical trial testing cognitive therapy or IPT with and without medication (Peeters et al., 2012) even though it does not qualify as a RCT (no control group) because this points to the issue of treatment choice as a factor in treatment response. This Dutch study allowed MDD patients to choose which treatment they preferred in collaboration with the clinician. The 174 participants (aged 18 to 65) sought treatment from a mood disorders clinic and were diagnosed with a structured interview (SCID) and symptoms were rated using the Beck Depression Inventory (BDI). Inclusion criteria were primary MDD without bipolarity and low suicidality. Primary substance use disorders and psychotic disorder were excluded, but other comorbidity was acceptable.

Treatment sessions (cognitive therapy and IPT) lasted 50 minutes and were conducted weekly for up to 26 weeks. Those participants who also received pharmacotherapy were seen for about 15 minutes to adjust dose and monitor side effects, with no other interventions offered. Typically SSRIs were first-line treatment, followed by switching to another SSRI if needed or to venlafaxine, or a tricyclic with augmentation of lithium in nonresponders.

The 174 participants predominantly chose therapy without medication (cognitive therapy, $n = 63$; IPT, $n = 56$; cognitive therapy plus pharmacotherapy, $n = 34$; IPT plus pharmacotherapy, $n = 21$). The sample was 59% female, mean age 42.4 (SD = 11.1); 36% had chronic depression (lasting more than 2 years) and 53% had another Axis I disorder. At 26-week follow-up 76% of the sample was still available for assessment; there was no significant difference in attrition among groups. At 8 weeks, only 20% remitted, but by 26 weeks 35% remitted. In this study, there was no significant difference in effectiveness between the psychotherapies nor between monotherapy and combined therapy. Effect sizes on the BDI were quite robust (1.3 cognitive therapy; 1.0 cognitive therapy plus pharmacotherapy; 1.5 IPT; 1.0 IPT plus pharmacotherapy). The cognitive therapy group demonstrated a more rapid drop in BDI score than the cognitive-therapy-plus-pharmacotherapy group, but by the end of treatment this difference disappeared. The IPT and IPT-plus-pharmacotherapy groups evidenced parallel drops in the BDI score.

This study applies more realistically to clinical practice settings where patients can choose whether they want medication alone, psychotherapy alone, or the combination. Since less severe pathology was excluded, it is also more realistic to what patients experience in the real world of practice. Treatment duration of up to 26 weeks appears to increase response and remission in patients with chronic and severe MDD with and without comorbidity. Again, although combined treatment is not significantly more effective than monotherapy, it is an effective treatment, as demonstrated by the effect size of 1.0.

Acute Treatment of Major Depressive Disorder in Primary Care

One RCT of MDD in primary care (Mynors-Wallis, Gath, Day, & Baker, 2000) was conducted in England, where 151 subjects were randomized into four treatment groups. The patients in the first group ($n = 39$) were treated by research medical practitioners using a problem-solving technique, those in the second group ($n = 41$) were treated by research nurses using a problem-solving technique, those in the third group ($n = 36$) were treated by research medical practitioners with an SSRI, and those in the fourth group ($n = 25$) were treated by research medical practitioners with medication and by the research nurse, with a problem-solving technique.

The problem-solving treatment was based on the premise that depressive symptoms may be associated with psychosocial problems and that resolving those problems will improve the depressive symptoms. There are six stages to this technique: (a) clarification and problem definition, (b) choice of achievable goals, (c) generation of solutions, (d) choice of solution preference, (e) implementation of chosen solutions, and (f) evaluation. The SSRIs chosen were first fluvoxamine and then paroxetine; dosage was flexible. The medication treatment followed manualized guidelines and did not include any psychological interventions. The monotherapy groups met six times over 12 weeks, weekly for the first 3 weeks (sessions 1 through 3), then intermittently (weeks 5, 7, and 11) for the next 9 weeks. The combined therapy group met with each therapist on the same day. Any patient could receive an extra session if necessary. All treatment occurred in the local health center or in the patient's home.

Outcome was measured by HRSD and the BDI, with clinical interviews and assessments conducted before treatment and at 6 weeks, 12 weeks, and 1 year by blinded raters. In this study, there was no significant difference among treatment groups in outcome at any time point. Only 77% of patients completed treatment, but the investigators managed to collect 12-week data on patients who did not complete treatment. The problem-solving-only group experienced the most dropouts ($n = 14$), while the medication-only and combined treatment groups experienced the fewest dropouts ($n = 6$). At 12 weeks, the response rates ranged between 51% and 67%, perhaps a slightly lower overall response rate than found in other studies using CBT or IPT in combination with medication.

A recent British multicenter study of treatment-resistant depression in primary care, the CoBalT study, tested the addition of CBT to pharmacotherapy (Wiles et al., 2013). Adults, aged 18 to 75, recruited through medical records or direct referral from physicians with MDD, were eligible if they had taken an adequate dosage of antidepressants for 6 weeks and had a BDI score of 14 or more. Bipolar disorder, psychotic disorders, and current substance abuse problems were excluded as well as current or recent CBT treatment. Patients ($n = 469$) were randomized to either CBT or usual care with the expectation that medication use would continue for both groups.

The CBT group received 12 sessions with the option of up to an additional 6 sessions at the discretion of the therapist. Patients in the usual care group might be referred for psychotherapy (counseling or CBT) when the primary care physician deemed it appropriate. CBT followed the manual developed by Aaron Beck for the treatment of depression.

The primary outcome measure was the BDI at 6 months (assessments were also completed at 9 and 12 months). Response criteria were a 50% decrease in BDI score from baseline, while a score of less than 10 was considered remission. The 3-month follow-up assessment included 222 patients in the CBT group and 219 in the usual care group. At 6-month follow-up, 206 in the CBT and 213 in the usual care group completed the BDI.

The mean BDI at baseline was 31.8 and 88% of patients had a previous episode of MDD. There were 94 dropouts from CBT (20 did not attend any sessions, 74 withdrew or were discontinued). By 6 months, median number of sessions attended was 11, with 144 (62%) receiving at least 9 sessions. The results were significant: 46% ($n = 95$) of the CBT group were responders at 6 months compared to 22% ($n = 46$) of the usual care group. The odds ratio for response in the CBT group compared to the usual care group was 3.26. There was also a significant difference in remission between the two groups: 28% of the CBT group compared to 15% of the usual treatment group achieved remission. There was also a significant difference in anxiety as measured by the GAD-7: the patients in the CBT group demonstrated less anxiety as well as less panic. Almost all of the sample was taking medication (93%) at the 6-month follow-up.

At 12 months, significant improvement in the CBT group continued, with 55% ($n = 109$) achieving response and 40% ($n = 78$) achieving remission. In comparison, 31% ($n = 62$) of the usual care group achieved response and 18% ($n = 36$) remitted.

This study demonstrates the effectiveness of adding CBT to pharmacotherapy in patients who do not respond to pharmacotherapy alone after adequate treatment.

Acute Treatment with Adolescents

Prior to the Treatment for Adolescents with Depression Study (TADS, 2004), there were few data testing the efficacy of combined CBT and medication for depressed adolescents. This large RCT conducted at 13 academic and community centers

treated 439 adolescents aged 12 to 17 who met criteria for *DSM-IV* MDD and did not meet criteria for bipolar, conduct, substance, thought, or pervasive developmental disorders. Current use of any antidepressant, failure to respond to two SSRIs, poor past response to CBT for MDD, and intolerance of fluoxetine were exclusion criteria for study participation. In addition, medical conditions that would interfere with safe administration of fluoxetine, high risk for suicide, and inability to speak English were exclusion criteria. Current treatment with psychostimulants for attention-deficit/hyperactivity disorder (ADHD) was allowed if the dosages remained stable throughout the study.

Participants who screened positive and gave consent (n = 439) were randomized to one of four treatment groups: fluoxetine alone (n = 109), CBT alone (n = 111), combined CBT and fluoxetine (n = 107), and placebo (n = 112). Clinicians and patients were blind in both the fluoxetine-alone and placebo groups, and all knew that the combined and CBT-only groups involved active treatments. Assessments were made by blind independent evaluators, and outcome was measured by the Children's Depression Rating Scale and CGI-I.

Pharmacotherapy was manualized and monitored; it consisted of six sessions of 20 to 30 minutes spread over 12 weeks. Pharmacotherapists used a flexible dose of fluoxetine or placebo beginning at 10 mg, increasing to 20 mg after 1 week to a maximum dose of 40 mg by week 8. CBT consisted of 15 sessions of 50 to 60 minutes over 12 weeks with the adolescents alone, adolescents with parents and family, or parents alone. Beginning sessions (1 through 6) covered psychoeducation about depression, monitoring of mood, setting of goals, increasing participation in pleasurable activities, cognitive restructuring, and problem solving of social concerns. The second half of treatment focused on improving social skills (e.g., problems in social engagement, communication, negotiation, compromise, or assertiveness). Combined treatment was conducted by two clinicians, each following the manual for the treatment as conducted in monotherapy, but was integrated for partial response and dose increases.

Of the 439 participants who began the trial, 359 completed the 12 weeks of treatment, although the outcome data were based on the 351 participants who were assessed at the end of the treatment period (80% of the total). There were no significant differences among groups for dropouts or early terminators. There were no significant differences among the groups on any baseline characteristics, including demographics and illness severity. The sample was representative of the general depressed adolescent population in clinical practice, with a mean illness severity of moderate to severe.

Outcome results using the Children's Depression Rating Scale showed that combined treatment of fluoxetine and CBT was superior to placebo (p = 0.001) and to either monotherapy (p = 0.02 for fluoxetine alone and p = 0.01 for CBT alone). Fluoxetine alone was superior to CBT alone (p = 0.01). The completer response rate for combined treatment was 71% compared with 60.6% for fluoxetine alone, and 43.2% for CBT alone. The placebo response rate was 34.8%. The intent-to-treat analysis yielded the same findings: Combined treatment was superior to all other groups, and fluoxetine alone was superior to CBT alone. In this sample, CBT was not superior to placebo. However, the authors suggest that their sample may have been a more severely ill group both in MDD severity and in comorbidity, which may account for the poorer outcome in the CBT-alone group. The data from this study are consistent with findings on adult populations: Combined treatment is more effective than monotherapy in more severely depressed patients.

Maintenance Treatment

How long should therapy continue after an episode of MDD and what type of treatment best prevents relapse are important questions. Stangier and colleagues (2013) conducted a multicenter RCT to answer those questions. They compared a maintenance CBT and a manualized psychoeducation both combined with treatment as usual, which consisted of antidepressant medication, in 180 participants with remitted MDD. Inclusion for this study required current remission from *DSM-IV* MDD, HAM-D score of 9 or less, plus three or more past depressive episodes in adults between 18 and 65. Subjects were excluded if they were psychotic, suicidal, abusing substances, or medically unstable or had received CBT in the previous year. All participants were treated with maintenance antidepressant medication on an individual basis and doses were changed as needed. The experimental treatment included 8 months of either 16 50-minute sessions of CBT (weekly for several

months, gradually decreasing to monthly), or 20-minute manualized psychoeducation sessions.

The psychoeducation focused on symptoms and course of depression; the biopsychosocial model of etiology; medication side effects, complications, and compliance; signs of recurrence; and management of recurrence. Therapists were allowed to give advice, listened to patients' concerns, and reinforced patients' skills and resources but were not allowed to use any specific psychotherapeutic technique such as problem solving, cognitive restructuring, or skills training. CBT included cognitive case conceptualization, mindfulness meditation, cognitive restructuring, behavioral activation, and behavioral experiments.

Outcome (time to relapse) was measured using the Longitudinal Interval Follow-up Evaluation (LIFE). At the end of the 1-year follow-up period, 25.6% of participants dropped out (15 from the CBT group vs. 31 from the psychoeducation group, a significant difference). Although dropouts occurred during the treatment phase, 80% of the sample completed at least 12 sessions (n = 144); significantly more of the CBT group (n = 78) were completers. There were no differences between the two groups on demographic variables, nor were there significant differences in either time to relapse or risk status. What was significant was the number of previous episodes of MDD. Those who had five or more past episodes and received maintenance CBT (50%) relapsed less than those who received psychoeducation (73.2%), indicating a hazard ratio of 38% reduction in relapse risk. Participants with less than five episodes demonstrated no difference in relapse rate regardless of group. No other variables were significantly related to relapse. This study confirms that maintenance CBT protects against relapse in the most at-risk patients.

Frank and colleagues (1990) conducted a continuation treatment study of recurrently depressed patients aged 21 to 65 who had experienced at least three episodes of MDD, the prior episode lasting no longer than 2.5 years. Initially, 230 patients were treated with imipramine (150 to 300 mg) and weekly IPT for 12 weeks. For the next 8 weeks, patients were seen biweekly, then treated monthly until response was achieved (HRSD score of 7 or lower and a Raskin Severity of Depression score of at least 7). All patients continued in treatment for an additional 17 weeks at the same dosage (n = 157). To be entered into the maintenance protocol, patients were required to maintain a HRSD score of 7 or lower. Of the 230 who entered the acute treatment phase, 128 patients (30 males, 98 females) were randomized to one of five maintenance conditions—imipramine plus clinic visits (n = 28), IPT plus imipramine (n = 25), placebo plus clinic visits (n = 23), IPT alone (n = 26), and IPT plus placebo (n = 26), for 3 years.

The maintenance IPT involved monthly sessions conducted by a social worker, psychologist, or nurse practitioner. IPT therapists were highly trained and supervised by clinicians who had developed IPT (Bruce Rounsaville, Eve Chevron, Gerald Klerman, and Myrna Weissman). The imipramine dose averaged 200 mg and was administered by a psychiatrist who met with patients monthly. For those patients receiving placebo or IPT alone, medication was withdrawn over 3 weeks.

The attrition rate of the maintenance phase was 17% (n = 22), leaving 106 patients who completed the 3-year trial. Fifteen of the 22 dropped out due to noncompliance with the protocol, but only 4 reported side effects as the reason. The others who dropped out did so due to medical problems that interfered with continuation of treatment, moving out of the area, or other reasons.

The research showed that the likelihood of experiencing recurrence among those not receiving imipramine was great (OR = 4.9), whereas the likelihood of experiencing recurrence among those not receiving IPT was less (OR = 1.7) in the 3-year period following successful treatment of recurrent depression. Imipramine and clinic visits were as effective in preventing recurrence as combined imipramine and IPT, although both were more effective than IPT alone, IPT and placebo, and placebo with clinic visits. As a means of recurrence prevention, imipramine was the most effective treatment, more than combined treatment in this recurrently depressed sample. IPT alone had significant benefit in preventing recurrence.

Acute and Maintenance Treatment in the Elderly

Reynolds and colleagues (1996) reported on separate acute and continuation trials of combined therapy in elderly and midlife patients with recurrent MDD. The goal of these studies was to achieve the maximum number of remitted patients to be eligible for inclusion in an RCT of maintenance treatment. The first study involved 148 depressed patients aged 60 and over, considered the elderly group. During

the acute treatment phase, patients were treated with nortriptyline and weekly IPT modified for the needs of the elderly. Acute treatment lasted until the patient achieved a score of 10 or lower on the HRSD for 3 weeks, a remission score consistent with other studies of the elderly. The remission rate was 78.4% (n = 116). The number of dropouts was low, 12.2% (n = 18). After acute treatment, remitters entered continuation treatment for 16 weeks consisting of pharmacotherapy (same dose) and biweekly IPT to ensure complete remission and prevent relapse.

The midlife study included 214 recurrently depressed patients aged 21 to 59 (mean age, 38.5) who were treated with imipramine and IPT. Acute treatment in this group lasted until an HRSD score of 7 or lower was maintained for 3 weeks. The midlife remission rate was 69.6% (n = 149) with a dropout rate of 11.2% (n = 24). In the midlife group, remitters entered continuation treatment for 20 weeks, also consisting of same-dose pharmacotherapy and biweekly IPT. There were no significant differences in remission rates between the elderly and midlife groups for acute treatment.

The researchers analyzed the temporal course of response to treatment in both groups and found that the two groups were similar in that both showed a significant reduction in HRSD scores at 8 weeks. However, midlife patients experienced a faster reduction than the elderly patients.

There was a significant difference in relapse rates, with 15.5% of the elderly group (n = 18) and 6.7% of the midlife group (n = 10) relapsing while on combined treatment during the continuation phase. In addition, the elderly group experienced a shorter time to relapse than the midlife group (7.4 weeks in the elderly group and 16.6 weeks in the midlife group). Due to the uneven length of continuation treatment, the researchers reanalyzed the data, eliminating any midlife subjects who relapsed after the 16th week, and found that 3.4% (n = 5) of the midlife group relapsed during the first 16 weeks of continuation treatment. In comparison, 13.8% of the elderly group relapsed during the 16 weeks (n = 16), a significant difference. At the end of the study, 66.2% (n = 98) of the elderly patients and 57% (n = 122) of the midlife patients were eligible to enter the maintenance therapy condition. The maintenance data were not reported in this manuscript.

This study is included here even though it did not employ a monotherapy or placebo group because there are few data on outcomes using combined treatment with the elderly. In addition, there is value in comparing treatment results in the elderly with those in a younger population, especially one in which much research information has been collected.

Reynolds and colleagues (1999) conducted a maintenance trial on 187 recurrently depressed patients aged 59 or older. These patients were not demented, had a mean number of previous episodes of 5.3, and had no period of remission longer than 3 years.

Acute treatment included open-label nortriptyline combined with weekly IPT for 9 weeks (50% received some adjunctive pharmacotherapy). After the 9-week acute treatment period, those who were responders were continued on the combined nortriptyline and IPT treatment every other week for an additional 16 weeks to ensure stability of remission. Those able to sustain remission for 6 months were randomized for maintenance treatment. The 107 such patients were placed in one of four groups: monthly clinic visits with full-dose nortriptyline, placebo with clinical management, monthly maintenance IPT with pill placebo, and monthly maintenance IPT with nortriptyline. Maintenance therapy lasted for 3 years, but relapse or recurrence of MDD symptoms caused subjects to be dropped from the study.

Results of the maintenance trial showed that all active treatments were superior to placebo. The combined nortriptyline plus IPT was superior to IPT plus placebo, with a recurrence rate of only 20%. The combined treatment showed a trend toward significance (p = 0.06) over nortriptyline plus clinical management, with a 43% recurrence rate. The recurrence rate for IPT plus pill placebo was 64%, and the recurrence rate for pill placebo plus clinical management was 90%. The authors point out that 53% of the recurrences were associated with medication noncompliance. The strength of this study is the inclusion of a placebo arm. In addition, open-label treatment and the allowance of adjunctive medications make the results more generalizable to clinical practice.

Blackburn and Moore (1997) conducted both an acute and a maintenance treatment study of 75 recurrently depressed outpatients to determine whether cognitive therapy would be more effective than medication when used for maintenance treatment. Technically, this trial did not combine the two treatments at the same time. Rather, it used a crossover-type design, but it is included in this chapter because it is often cited and presents some important findings.

The MDD patients were randomized into one of three groups for 16 weeks of acute treatment followed by 2 years of maintenance treatment: antidepressants alone (n = 26), antidepressant first followed by cognitive therapy (n = 22), and cognitive therapy alone (n = 27). Medication treatment, conducted by general practitioners or psychiatrists, was determined by the clinician's choice, prescribed at or above the therapeutic dose and changed as needed. Meetings occurred once every 3 weeks for 30 minutes during acute treatment, but maintenance therapy meeting times were not mentioned. Cognitive therapy was conducted by trained clinicians weekly during the 16-week acute treatment and less frequently during maintenance (three sessions during month 1, two sessions during month 2, and once per month throughout the 2-year period).

Measures used were the HRSD and BDI. There were no significant differences between the three treatment groups on demographic variables, baseline HRSD and BDI measures, number of past depressive episodes, or number of hospitalizations or suicide attempts. The only significant difference was that the group that received antidepressants first followed by cognitive therapy had lower functioning prior to entering the study than the other two groups.

Thirteen patients were dropped from the acute phase analysis (11 who dropped out and 2 who received inadequate medication dosages). Of the 65 who completed acute treatment, there was significant improvement for all groups; 24% of the medication groups achieved remission, and 33% of the cognitive therapy group remitted. There was no difference among the three groups on HRSD scores. In addition, the authors analyzed whether depression severity accounted for any treatment differences in their sample and found that it did not, contrary to other findings.

After 24 months of maintenance treatment, although all patients continued to improve, there was no significant difference among the groups on either outcome measure. It should be noted that only 20 patients were assessed at 24 months. The relapse rates during the 2-year period were significant, with the cognitive-therapy-only group demonstrating the lowest rates (24%) compared with the medication-only group (31%) and the medication-first-then-cognitive-therapy group (36%). When the cognitive therapy maintenance groups were combined, the relapse rate was 26%, compared with 31% for the medication-only group.

We are including one more study that focused on the symptom of insomnia using CBT while treating the mood symptoms with escitalopram. This pilot RCT conducted at Stanford (Manber et al., 2008) recruited 30 individuals aged 18 to 75 with MDD and insomnia (defined as 2 consecutive weeks of at least 30 minutes of difficulty falling asleep and/or awakening after sleeping for three or more nights per week and less than 6.5 hours total sleep per night for three more nights per week). They excluded suicidality, psychosis, recent electroconvulsive therapy, seasonal affective disorder, past treatment with escitalopram, and having failed two SSRI treatments. No other sleep medication or treatment was allowed.

All participants were treated with escitalopram for 12 weeks (10 mg but up to 20 mg based on clinical response) in a standard protocol and randomly assigned to CBT-Insomnia (CBT-I) or a control treatment for seven sessions (five weekly, then two biweekly). CBT-I included an education component about normal sleep, circadian rhythms during depression, and effect of substances on sleep; sleep restriction and stimulus control instructions; stress, cognitive, and somatic arousal management as well as cognitive restructuring; sleep schedule adjustment; and relapse prevention. The control intervention included a quasi-desensitization procedure, education about sleep, and sleep hygiene, but no other intervention.

Depression was measured using HRSD and sleep was measured through diary and a recording device called an actigraph, which is the size of a watch. Results demonstrated significantly improved sleep in the CBT-I-plus-escitalopram group compared to the control-plus-escitalopram group. Remission of MDD was considered a score of less than 8 on the HRSD excluding the three sleep items, and the CBT-I group experienced 61.5% remission compared to 33.3% in the control group. However, this did not translate to a significant difference, probably because of small sample size. This pilot study suggests that augmenting antidepressant treatment with a psychosocial intervention for sleep in those with comorbid MDD and insomnia may be beneficial.

Summary

The main finding from these studies of treatment for depression is that combined treatment is superior to medication monotherapy when used to treat chronic

or severe major depression. Combined treatment is effective but not necessarily more effective than a stepped pharmacotherapy course. Relapse prevention is most effective when medication is combined with psychotherapy (CBT or IPT) for those who have had five or more episodes of MDD. Sequential treatment—adding an effective psychotherapy to medication treatment in those who did not previously respond to medication alone—has been shown to be efficacious. Patients with milder severity or a first episode of depression seem to benefit from either treatment alone at about the same rate, but one advantage of combining psychosocial treatment with medication may be in improved treatment adherence. Attrition rates are often higher in the medication-only groups (de Jonghe et al., 2001; Hautzinger et al., 1996); patients may drop out due to side effects or dissatisfaction with taking medication, although this is less frequent when medication is changed during the treatment course.

Most of the combined treatment studies that included an evidence-based treatment (CBT or IPT) used a tricyclic or a monoamine oxidase inhibitor rather than an SSRI, with the exception of the TADS trial in adolescents, which employed fluoxetine and CBT, with the result that combined treatment was more effective than monotherapy. It was suggested that the participants in the TADS were more severely ill, thus the higher response rate with combined treatment. Since SSRIs are more frequently prescribed in clinical practice, more RCTs using SSRIs in combination with CBT or IPT in MDD are needed.

In the primary care study (Mynors-Wallis et al., 2000), combined treatment did employ SSRI medication, but the psychosocial treatment chosen was problem-solving therapy, not CBT or IPT. The problem-solving therapy was not well received by patients (highest attrition rate), nor has it been demonstrated as particularly effective. In this study, combined treatment was no more effective than medication alone or the problem-solving therapy alone.

One last issue to consider when evaluating the results of clinical trials for MDD that use the HRSD as the primary outcome measure is rater training and reliability testing. Some of the older studies did not describe training of raters, and reliability tests were not mentioned. The HRSD, in its original format, has very few probes for each item, leaving it to the interviewer to know what to ask in order to rate the item. Frequently, independent raters are not highly experienced clinicians and are not necessarily familiar with scoring guidelines and rules of administration (Lipsitz et al., 2004). Williams (1988) developed the Structured Interview Guide for Hamilton Depression Scale (SIGH-D), where gate and follow-up questions are provided so that interviewers systematically gather the same material over time, increasing the reliability of the data. Use of such structured guides and attention to rater training could significantly affect the results of treatment trials (Lipsitz et al., 2004).

PANIC DISORDER

There have been many RCTs of treatments for PD, but almost all have compared medication alone to psychotherapy alone, and both to placebo; little has been conducted on combined treatment.

The gold-standard RCT for PD was a multicenter study conducted by Barlow, Gorman, Shear, and Woods (2000). This four-site study (Boston, New York, Pittsburgh, and New Haven) compared imipramine plus medical management, CBT alone, their combination, placebo plus CBT, and placebo plus clinical management in the treatment of 312 patients with PD. There were three phases to the study: acute treatment, maintenance treatment, and follow-up.

All patients met criteria for PD using the Anxiety Disorders Interview Schedule Revised and had experienced at least one full or limited panic attack in the 2 weeks prior to starting treatment. Most Axis I disorders were excluded except major depression, and some agoraphobia (mild) was acceptable. After passing the screening procedures, 326 PD patients without agoraphobia were randomized to one of the five acute treatment groups: CBT alone (n = 77), imipramine alone (n = 83), placebo alone (n = 24), CBT plus imipramine (n = 65), or CBT plus placebo (n = 63).

In the acute phase, patients were seen weekly for 12 weeks. The CBT used in this study is called Panic Control Therapy, developed by Barlow and Craske, and focuses on psychoeducation, breathing retraining, relaxation exercises, cognitive restructuring, interoceptive exposure (exposure to bodily sensations that are similar to those experienced during a panic attack), and situational exposure. Imipramine and placebo were both double-blind administered in a fixed, flexible dose beginning at 10 mg titrated by 10 mg up to 50 mg in 4 to 5 days, then increasing more

rapidly to 200 mg by week 5, with a maximum dose of 300 mg. Medical management involved monitoring adverse effects, clinical state, and symptoms with a goal of increased compliance with medication use. It should be noted that patients were allowed some benzodiazepine use through the acute treatment phase.

Those administering CBT and pharmacotherapy were well trained, experienced clinicians, and each conducted treatment according to a manual, with adherence monitored regularly. All assessments were conducted by independent evaluators. Primary outcome measures included Panic Disorder Severity Scale (PDSS), a seven-item, clinician-administered scale that measures panic frequency, severity, anticipatory anxiety, avoidance, and impairment; and the CGI-I. Response was calculated by a 40% decrease in PDSS score from baseline and a CGI-I of 1 or 2 (much improved).

Ninety-nine participants dropped out after randomization, with no significant difference in attrition rates among the five groups. At the end of the acute phase, all four treatment groups were superior to placebo but not different from each other. Improvement was faster for patients treated with medication. The PDSS response rate for those who completed treatment in the imipramine group was 74.5%, whereas the CBT-only group's response rate was 67.3%. The imipramine-plus-CBT group had a response rate of 84.4%, and the CBT-plus-placebo group's response rate was 80%. The placebo-only group's response rate was 38.5%. Using an intent-to-treat analysis, the PDSS response rates for the five groups were as follows: CBT alone 48.7%, imipramine alone 45.8%, CBT plus imipramine 60.3%, CBT plus placebo 57.1%, and placebo alone 21.7%. There was no evidence that combination therapy was better than monotherapy.

In the maintenance phase, responders to acute therapy (including placebo responders) were continued on the original treatment assigned, still under blinded conditions, and seen monthly for the next 6 months ($N = 170$). Imipramine- and placebo-treated patients continued on medication, and CBT-treated patients were given monthly booster sessions. The results showed that placebo-treated patients who had responded to placebo during acute treatment had a poor outcome during the maintenance phase. Patients assigned to CBT alone, imipramine alone, and combination therapy continued to be responders. The maintenance-phase PDSS response rates by group were as follows for completers: CBT alone 73.2%, imipramine alone 79.5%, CBT plus imipramine 90%, CBT plus placebo 76.3%, and placebo only 37.5%. The intent-to-treat PDSS response rates were CBT alone 39.5%, imipramine alone 37.8%, CBT plus imipramine 57.1%, CBT plus placebo 46.8%, and placebo only 13%.

In this phase combined treatment was significantly better than monotherapy. The PDSS response rate was significantly higher in the combined group when compared with each individual treatment (CBT plus imipramine vs. CBT, $p = 0.04$; CBT plus imipramine vs. imipramine, $p = 0.03$).

The last phase of this study was the follow-up phase, lasting 6 months after treatment was completed. The number of patients who were assessed during follow-up was 116. The PDSS completer response rate was 85.2% for the CBT-only group, 60% for the imipramine-only group, 50% for the CBT-plus-imipramine group, 83.3% for the CBT-plus-placebo group, and 100% for the placebo-alone group (there were only three participants in the placebo group after this phase). The intent-to-treat response rates were CBT only 32.4%, imipramine only 19.7%, CBT plus imipramine 25%, CBT plus placebo 41%, and placebo only 9.1%. The CBT-without-imipramine groups had fewer patients relapse than the imipramine-alone and combined treatment groups.

This study demonstrates the effectiveness of imipramine, CBT, and their combination for acute treatment of PD. Medication (imipramine) works more quickly than CBT but is not tolerated as well, and at the end of treatment, both are quite effective. The combined treatment was not as durable as CBT alone in the follow-up period; in fact, the relapse rates were about the same as for imipramine alone. The authors concluded that in the long term medication may interfere with CBT efficacy.

Another RCT involving combined treatment for PD was conducted by de Beurs, van Balkom, Lange, Koele, and van Dyck (1995) in Amsterdam comparing fluvoxamine and exposure therapy, monotherapy, and placebo in PD with agoraphobia. After screening for panic disorder using the Anxiety Disorders Interview Schedule, 96 PD patients with moderate or severe agoraphobia, who were between the ages of 18 and 65, were medically healthy, and did not have any history of psychosis, organic mental disorder, or substance use disorder, were randomized to one of four treatment groups ($n = 24$ per group). All psychoactive

medications except benzodiazepines were discontinued before subjects entered the protocol.

The four treatment groups were fluvoxamine plus exposure therapy, placebo plus exposure therapy, psychological panic management plus exposure therapy, and exposure therapy alone. The fluvoxamine and placebo treatments began at 50 mg, administered by a psychiatrist or psychiatric resident over 12 weekly sessions, and were titrated to 100 mg in week 2 and 150 mg in week 3. Patients were told about the effects of fluvoxamine and the serotonergic pathways in the brain of PD patients. Their medication dose was kept stable at 150 mg unless side effects necessitated a reduction. No exposure therapy was conducted until after 6 weeks of medication treatment, and patients were told to avoid exposing themselves to feared situations until the medication started working.

Psychological panic management was conducted by clinicians experienced in behavior therapy. Sessions were held weekly and focused on psychoeducation about panic, the hyperventilation process (its role in panic attacks), and the cognitive process whereby bodily sensations provoke fear thoughts and fear thoughts further provoke bodily sensations. Patients were then encouraged to bring on panic-like sensations by hyperventilation, first in the session and then later at home. Patients were trained to breathe into a paper bag to counteract the hyperventilation process and later to breathe from the abdomen.

The exposure therapy (in vivo) began after 6 weeks of treatment (fluvoxamine, placebo, or panic management). The therapists conducting exposure therapy were the same as the panic management therapists. Patients were told to practice their techniques (those in panic management) in situations that they feared or avoided and were encouraged to gradually expose themselves to those situations. During the sessions they constructed a hierarchy of agoraphobic situations. Homework was then assigned to practice going into those situations for at least 90 minutes, three times per week.

Measures were self-report scales including the Fear Questionnaire (FQ), the Mobility Inventory (MI), the Agoraphobia Cognitions Questionnaire, the Bodily Sensations Questionnaire, the SCL-90, the BDI, and the Depression Adjective Checklist. The authors created a composite score from subscales of these instruments that measure the same construct. The agoraphobia composite score combined the agoraphobia subscales of the FQ, the SCL-90, and the MI avoidance when alone scale. The composite for depression combined the BDI, the Depression Adjective Checklist, and the SCL-90. The last composite score measured bodily sensations and combined the Bodily Sensations Questionnaire and a subscale of the Agoraphobia Cognitions Questionnaire. All composite scores ranged from 1 to 10, with the higher score reflective of more symptomatology.

All patients underwent a behavioral avoidance test that included three tasks: walking 3 miles from the clinic toward town, supermarket shopping, and riding on a crowded streetcar, for a short period of time. Evaluations of the patients' ability to perform the tasks and the amount of anxiety experienced during the tasks were rated and averaged to yield one score from 1 to 10, with the higher score indicating poor performance.

Before being assigned to a treatment group, each patient was interviewed by an independent evaluator who devised four treatment goals for the patient. Using a 5-point scale, these goals were reformulated into a goal attainment scale and became another measure of treatment outcome. During the treatment, patients were asked to monitor their panic attacks on a registration form.

Of the 96 patients who began treatment, only 76 completed the full course. Six patients dropped out due to treatment-related problems and six due to other reasons. There were no significant differences between the dropouts and the completers.

The authors tested whether blindness or the use of benzodiazepines affected the results, and neither was found to be significant. All treatment groups experienced significant improvement on the three composite scores from baseline to end of treatment. The fluvoxamine-plus-exposure group experienced superior effects compared with the other three groups. There were no significant differences among the placebo-plus-exposure group, the psychological-panic-management-plus-exposure group, and the exposure-alone group. On the behavioral avoidance test, all patients experienced significant improvement on performance after treatment. The intent-to-treat analysis did not yield different results from the completer analysis.

Using the panic attack registers, the researchers analyzed panic-free status as well as increase in panic in the four groups over time. The participants in the psychological panic management group had poorer

outcome than the other three groups, who were not different from each other.

Effect sizes for the four groups on each composite score were calculated. For agoraphobia, fluvoxamine plus exposure was 2.00, placebo plus exposure was 1.29, psychological panic management plus exposure was 0.99, and exposure alone was 1.32. For depression, fluvoxamine plus exposure was 1.28, placebo plus exposure was 0.75, psychological panic management plus exposure was 0.24, and exposure alone was 0.66. For bodily sensations, fluvoxamine plus exposure was 1.22, placebo plus exposure was 0.82, psychological panic management plus exposure was 0.73, and exposure alone was 0.75.

The conclusion drawn from this study is that combined treatment of fluvoxamine plus exposure therapy was more effective than exposure alone (with or without placebo). The psychological panic management was not very effective in decreasing panic attacks. This is not surprising, since breathing retraining alone is not very effective in preventing panic attacks (Schmidt et al., 2000). It is important to note that this study did not measure response with a particular criteria set, such as CGI, making the data difficult to compare with those from other trials. Combined treatment may have been superior to the other treatments, but not all patients were panic-free.

Loerch and colleagues (1999) used moclobemide and CBT to treat patients with PD with agoraphobia for 8 weeks. They randomized 55 patients to three conditions: placebo plus CBT, moclobemide plus clinical management (psychological placebo), and placebo plus clinical management. In this trial, moclobemide plus clinical management was not more effective than placebo, so it is not surprising that the combination of moclobemide and CBT was not superior to CBT plus placebo.

A study of combined medication and CBT for PD in primary care was conducted by Roy-Byrne and colleagues (2005) in six academic medical centers in Seattle, San Diego, and Los Angeles. The Collaborative Care for Anxiety and Panic study aimed to determine whether evidence-based treatments could be generalized to primary care. Patients met study criteria if they had PD and had experienced a panic attack in the week prior to study entry, spoke English, and were willing to take medication in addition to receiving CBT treatment. After intensive screening procedures (diagnostic evaluation was determined by use of the Composite International Diagnostic Interview), 232 panic patients were enrolled and randomly assigned to the intervention group (n = 119) or usual care (n = 113).

The intervention consisted of six sessions of CBT in person over a 3-month period and six telephone contacts lasting between 15 and 30 minutes every 6 to 12 weeks over the next year. The CBT was conducted by the "behavioral health specialist" (a master's-level or recent doctoral-level individual with little previous CBT experience). An instructional videotape explaining about PD and the treatment was also given to patients. Medication was administered by the primary care physician (PCP) under the supervision of a psychiatrist. The PCPs had received an hour-long didactic training on medication treatment for panic. SSRIs were given first if there was no history of two previous failed trials; otherwise the PCP could choose a different antidepressant such as a tricyclic, nefazodone, or mirtazapine for 6 weeks. Clinical care was managed by the behavioral health specialist who was in contact with the PCP regularly via telephone, fax, or e-mail.

Measures included diagnostic assessment (Composite International Diagnostic Interview), panic frequency and severity, agoraphobic avoidance, other fears and anxiety using the FQ, the Anxiety Sensitivity Index (ASI), and assessment of pharmacological and psychotherapeutic help received (amount and type), all administered at baseline and every 3 months throughout participation in the study. Outcome was measured by a subscale of the World Health Organization Disability Scale, the Global Physical and Mental Health Scale short form (SF-12), the Center for Epidemiologic Studies-Depression Scale, and ASI. Response criteria or "high end-state functioning" was based on a composite score of the above measures: no panic attacks in the previous month, minimal anticipatory anxiety about having a panic attack (one or less on a 0- to 3-point scale), and a score of less than 10 on an agoraphobia subscale.

There were no significant differences between the two treatment groups at baseline. The sample was primarily female (67%), with a mean age of 41.2, mostly educated (76% graduated high school, 39% had some college or more) and predominantly Caucasian (65.5%; Hispanic, 13%; African American, 13.8%). Comorbidity of a medical condition occurred in almost two thirds of the sample; 55.6% had comorbid MDD, 45.7% had GAD, 29.3% had PTSD, and 39.7% had SAD. Very few had received two or more sessions of CBT-type treatment previously (3.5%), and

only 28% had received any antipanic medication for at least 6 weeks before entering the trial.

Of those who were assigned to the CBT intervention group ($N = 119$), 81 (68%) received four to six sessions of CBT, 24 (20.1%) received one to three sessions, and 14 (11.8%) received no sessions. Adherence to the treatment was measured by independent clinical raters employing the same method as used in Barlow and colleagues' multicenter study (2000), resulting in adequate adherence to the treatment manual. The study investigators were concerned that a "spillover" effect might occur. Since some PCPs had patients in the intervention group and others in usual care, they might use the knowledge gained from the intervention training to influence their treatment in usual care. However, there were no differences found between the PCPs who had patients in both groups and the PCPs who had patients only in the usual care group.

Attrition from the study was as follows: At the 3-month assessment only 1 participant had dropped out (from the intervention group); at the 6-month assessment there were 2 dropouts from the usual care group and 8 dropouts from the intervention group; at the 9-month follow-up there were 4 dropouts from the usual care group and 10 dropouts from the intervention group; and at the final 12-month follow-up assessment there were 5 dropouts from the usual care group and 11 dropouts from the intervention group.

Although 6 months of CBT treatment (consisting of six sessions encompassing all seven techniques) was offered to the intervention group, only 63% actually received three or more sessions consisting of four of the seven techniques at the 3-month assessment and only 17% at the 6-month assessment. In the usual treatment group, 14% had received three or more sessions consisting of four of seven techniques at the 3-month assessment, and 9% had at the 6-month assessment, a highly significant difference between groups in the amount of CBT received. At the 9-month assessment, there was no difference between the groups, but significance was found at the 12-month assessment period, with 6% of the intervention group and 11% of the usual care group having received three or more sessions of four of seven CBT techniques.

In the intervention group, 44% actually received appropriate antipanic medication at the 3-month assessment, and 40% of the usual care group received appropriate antipanic medication. The number of participants who actually received appropriate antipanic medication throughout the follow-up period was about the same for both groups: 42% at 6 months, 41% at 9 months, and 41% at 12 months in the intervention group; and 39% at 6 months, 39% at 9 months, and 39% at 12 months in the usual care group.

The difference between the two groups becomes clear when looking at high end-state functioning as the outcome. The intervention group demonstrated a superior proportion of patients who achieved high end-state functioning at all assessment points. At the 3-month assessment, 20% of the intervention group was considered remitted, whereas only 12% of the usual care group remitted. At the 12-month assessment, 29% of the intervention group and 16% of the usual care group were responders. Using the ASI as the outcome measure, 66% of the intervention group versus 38% of the usual care group were responders at the 12-month assessment period. The study showed trends toward significance in dose response for both CBT and antipanic medication. Those who received at least four CBT technique components while attending at least six sessions showed a better response than those who received at least four CBT components while attending three to five sessions (56% vs. 40%). Those who took appropriate medication for 3 months showed a better response than those who took appropriate medication for 6 to 11 weeks (35% vs. 29%). The power was limited in these analyses, contributing to the lack of significance.

One other measure of importance showed significant improvement between the two groups. At all assessment points, the usual care group demonstrated more improvement in depression (23%) than the intervention group (19%).

In this trial, conducted in the primary care setting, the combination of CBT and medication delivered by PCPs and behavior specialists was superior to usual care in achieving high end-state functioning and response in PD patients. Since the medication component of the treatment did not differ between the two groups, the CBT treatment accounts for most of the added improvement experienced by the patients. Only 40% of the intervention group actually completed the entire course of CBT, whereas 72% in Barlow and colleagues' (2000) trial completed 11 sessions of CBT. This study did not exclude subjects who failed to continue treatment, as usually is the case in clinical trials. There was no placebo group for comparison of the efficacy of combined treatment, but

the utility of including this trial here is to demonstrate treatment effectiveness in the primary care setting.

The only other combined treatment RCT in PD was conducted by Marks and colleagues (1993) in London and Toronto using alprazolam, placebo, situational exposure, and relaxation therapy. The 154 panic patients were randomly assigned to one of four groups: alprazolam plus situational exposure (considered the combined treatment group, $n = 40$), alprazolam plus relaxation therapy (considered a medication plus psychological placebo, $n = 37$), placebo plus situational exposure (considered placebo plus psychological treatment, $n = 38$), and placebo plus relaxation therapy (considered a double placebo, $n = 39$).

All participants were screened using the SCID for *DSM-III;* they were adults between the ages of 18 and 65 who had PD, had experienced some attacks in the previous 4 weeks, did not have other Axis I disorders, and were not on any medication when entered into the protocol. In addition, patients underwent a physical examination and laboratory tests to determine medical status.

For the medication groups, the beginning dose of alprazolam was 1 mg, then titrated to a maximum dose of 10 mg, with a mean dose of 6 mg. All patients before randomization met with an evaluator who assessed which situations were feared and/or avoided. The exposure therapy involved first reading a chapter from the manual *Living With Fear.* With the therapist, the patient planned exposures to situations that had been listed with the evaluator. The therapist accompanied the patient for the first two sessions. During the exposures, the patient rated his or her level of anxiety every 30 minutes of the two exercises. The relaxation therapy involved giving patients audiotapes of instructions to be used at home for 1 hour daily. During sessions, the therapist reviewed the patients' weekly diaries and checked progress. No instructions for exposure were given, and patients were told to "do whatever you wish" if they asked about exposure. All treatment lasted for 8 weeks.

Measures for outcome were ratings on the phobia list (0 to 8) by the patient and the independent evaluator, Phobia Questionnaire (PQ), Attack and Anticipatory Anxiety Scale, HRSD, BDI, and CGI-I. Ratings occurred at baseline, 4 weeks, and 8 weeks (posttreatment), and at 43 weeks for follow-up.

There were no significant differences among the four groups at baseline and no differences between the two sites, so all the results were pooled. Results for the alprazolam groups showed that patients improved during the first 4 weeks on a measure of panic attack frequency but remained steady until week 8. The exposure groups improved by week 2 and continued to steadily improve until week 8. Using the CGI data at 8 weeks, the percentage of patients who were considered improved (rating of 1 or 2) by group were 71% in the alprazolam-plus-exposure group, 71% in the placebo-plus-exposure group, 51% in the alprazolam-plus-relaxation group, and 25% in the placebo-plus-relaxation group. After medication taper, only 36% of the alprazolam-plus-exposure group, 29% of the alprazolam-plus-relaxation group, and 18% of the placebo-plus-relaxation group stayed well, and 62% of the placebo-plus-exposure group stayed well.

The combination treatment was only slightly better than the other treatments at the end of the 8 weeks. The alprazolam groups relapsed more frequently than the exposure therapy group, so that exposure alone was the most effective treatment after medication was discontinued. Some of the difficulty in this trial with relapse after medication discontinuation may be attributed to the very rapid withdrawal of alprazolam, which may have produced severe withdrawal symptoms in the patients.

In summary, there is no advantage to combined treatment in PD. The use of imipramine combined with CBT is no more effective than imipramine alone. The combination of a benzodiazepine and CBT is also no more effective than either treatment alone and may even be relatively contraindicated, with data suggesting poor long-term outcome when compared to CBT alone.

OBSESSIVE-COMPULSIVE DISORDER

The growing research literature on the combined treatment of pharmacotherapy and psychotherapy for the treatment of OCD lends itself nicely to being grouped into three main categories: acute treatment, long-term outcome/maintenance, and treatment discontinuation. Combination treatment studies are included when delivered concomitantly as well as sequentially.

Acute Concomitant Combined Treatment

Foa and colleagues (2005) conducted a randomized, placebo-controlled trial comparing clomipramine,

exposure and response prevention, and their combination in the treatment of OCD. Patients were randomized to one of four conditions: clomipramine alone ($n = 47$), exposure and response (ritual) prevention alone ($n = 37$), exposure and response prevention plus clomipramine ($n = 33$), and pill placebo ($n = 32$). The exposure sessions were 2 hours daily for the first 3 weeks, followed by 45-minute sessions weekly for 8 weeks. In the clomipramine-alone group, the mean dose at the end of the study was 196 mg (SD 82) for those subjects who completed at least one therapy session and 235 mg (SD 23) for those who completed the trial. In the clomipramine-plus-placebo group, the mean dose was 163 mg (SD 65), or 194 mg (SD 48) when only counting those who completed the study.

After 12 weeks, the results showed that exposure and response prevention were superior to clomipramine and to pill placebo on all measures. Addition of clomipramine to exposure and response prevention did not improve outcomes. The authors suggest that the combination treatment may have failed to show superiority to the exposure and response prevention alone group because the intensive phase of exposure and response prevention (the first 3 weeks of the study) was over by the time the clomipramine would have generated an effect. The exposure and response prevention was so successful it may have left little room for further improvement by the addition of clomipramine.

Cottraux and colleagues (1990) compared the combinations of fluvoxamine plus exposure therapy, pill placebo plus exposure therapy, and fluvoxamine with antiexposure therapy. There was no pill placebo-plus-antiexposure group, which was considered to be an unethical control group. Twenty patients were randomized to each of the three groups. The fluvoxamine-plus-antiexposure group was single-blind; the other two groups were double-blind. Over this 24-week study, patients met with the psychiatrist nine times. Patients were permitted "occasional use" of the benzodiazepine bromazepam. Exposure sessions consisted of 8 weeks of exposure homework assignments, followed by 16 weeks of guided exposure and response prevention. The sessions were not standardized and for some patients included couples counseling, cognitive restructuring, and/or assertiveness training. Antiexposure instructions involved avoiding fearful stimuli and engaging in ritualized behaviors to relieve anxiety.

Results showed that all three groups improved on measures of rituals and depression, at weeks 24 and 48. There was a small but nonsignificant superiority for combined treatment up to week 24. The sample size in each group was somewhat small, and there is no indication that an intent-to-treat analysis was used. The high baseline levels of depression, the possible confounding use of a benzodiazepine, the loosely standardized exposure therapy sessions, and the very high noncompliance rate in the antiexposure group make it difficult to draw conclusions from this study. However, the data do not seem to point toward superiority for combined treatment.

As D-cycloserine (DCS) has showed promise in other disorders, it has been studied in OCD with somewhat mixed results. DCS is a partial agonist at the *N*-methyl-D-aspartate glutamate receptor (NMDAR) that has been effective in treating other anxiety disorders that involve exposure-based treatments.

Kushner and colleagues (2007) looked at adding DCS to exposure and response prevention. A total of 32 participants enrolled in the study and completed at least one exposure and response prevention session. Twenty-five completed the study. Psychiatric medications were continued if the dose had been stable 2 months prior to study entry, and those with hoarding or ordering as their primary ritual were excluded. All subjects underwent 10 sessions of twice-weekly exposure and response prevention and were randomized to either 125 mg DCS or placebo to be taken 2 hours prior to psychotherapy. Although at the end of the study there were no between-group differences, the authors point out that the DCS group tended to improve faster and had more study completers.

Storch and colleagues (2007) enrolled 24 participants and randomized them to exposure and response prevention plus DCS taken 250 mg 4 hours prior to psychotherapy or placebo. Subjects were allowed to continue psychotropic medications as long as the doses were stable 12 weeks prior to study entry. Similar to the results of the Kushner study, no overall differences were found between the groups, but there was a trend toward a lower symptom burden in the DCS group in weeks 4 to 6 of this 12-week study.

Wilhelm and colleagues (2008) randomized 23 subjects on stable medication doses to 10 twice-weekly exposure and response prevention sessions plus DCS 100 mg or placebo given 1 hour prior to the session.

A similar conclusion was drawn here: The DCS group had lower OCD symptoms scores at the middle of treatment but not at the end of the study. The authors point out that DCS may, in fact, be quite helpful in the treatment of OCD because the faster response rate may decrease the number of treatment dropouts. Chasson and colleagues (2010) looked at the slope of change in the Wilhelm study and concluded that the subjects in the DCS group got better 2.3 times faster than the placebo group.

Overall, DCS shows some promise in the treatment of OCD, particularly in that it appears to decrease the time to symptomatic improvement when combined with exposure and response prevention. Still, the studies conducted have been small and few. More research is required in this area before firm conclusions can be drawn.

Acute Sequentially Combined Treatment

Van Balkom and colleagues (1998) examined the sequential combination of fluvoxamine with CBT in the treatment of OCD, compared with CBT alone. Patients were randomized to one of five groups: cognitive therapy alone, exposure and response prevention alone, 8 weeks of fluvoxamine followed by 8 weeks of cognitive therapy, 8 weeks of fluvoxamine followed by 8 weeks of exposure and response prevention, or a waitlist control for 8 weeks. At 8 weeks, both the cognitive therapy and the exposure and response prevention groups did significantly better than the waitlist control group. At week 16, the sequential combination of fluvoxamine plus exposure and response prevention did not show any significant difference from the CBT-alone treatments on all measures. The same results were obtained with an intent-to-treat analysis of the data.

The participants in this study were not blind to their respective groups at randomization, which may have influenced their outcome. One possible explanation for the combination groups' failure to demonstrate better outcome than the CBT-alone groups may be due to the combination groups' having received 8 weeks less CBT than did the CBT-alone groups. Since there was no fluvoxamine-alone group, this study does not allow us to make inferences about the efficacy of combination treatment compared with fluvoxamine alone.

Hohagen and colleagues (1998) studied the interaction of CBT plus fluvoxamine compared with CBT plus placebo. They also looked at treatment outcome of OCD symptoms after treatment of secondary depressive symptoms. In this multicenter study conducted in Germany, 60 patients were randomized to receive CBT plus fluvoxamine or CBT plus placebo. Because the groups differed significantly in terms of baseline symptom severity, outliers were dropped, and the sample was reduced to 49 patients. In this study, participants received either fluvoxamine or placebo for 3 weeks, followed by CBT during weeks 4 to 8.

Both groups showed significant response. Obsessions but not compulsions were significantly reduced in those receiving CBT plus fluvoxamine, as compared with CBT plus pill placebo. However, no significant differences were noted with regard to compulsions. The lack of therapeutic efficacy in treating compulsions with CBT in this study may reflect the techniques used. We now know that although often difficult to treat, obsessions are amenable to a variety of techniques in the CBT armamentarium. The treatment of OCD symptoms in patients who had comorbid depression was enhanced by the addition of fluvoxamine to CBT.

There have been several small and uncontrolled trials examining the addition of either psychotherapy to medication or vice versa in subjects who did not respond to the initial intervention. Simpson, Gorfinkle, and Liebowitz (1999) added exposure and response prevention to six out of seven eligible patients who had not responded to an adequate dose of an SSRI after 12 weeks of treatment and found that all six responded, with a mean decrease on the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) of 49%, despite the fact that only five completed the study.

Kampman and colleagues (2002) added 12 weeks of CBT in 14 patients drawn from a pool of 56 initially enrolled in a study examining the effectiveness of fluoxetine in OCD. Patients who had not responded to 12 weeks of fluoxetine were eligible for the CBT phase of the study. Nine participants completed the 12 weeks of CBT, and seven of the nine had a large reduction in symptoms (mean decrease in Y-BOCS 41%). Again, the results are promising for the addition of CBT to SSRI nonresponders, but it is difficult to draw conclusions from such a small and uncontrolled trial.

Tolin and colleagues (2004) examined a sample they determined to be a medication-refractory (failure of at least two adequate SRI trials) and clinically challenging sample (having a comorbid Axis

I or Axis II diagnosis). Participants were enrolled in a waitlist-controlled open trial. The authors indicate that the participants were required to be on stable doses of medications for at least 2 months prior to study entry and were continued on these medications throughout the study. Individuals with bipolar disorder, pervasive developmental disorder, mental retardation, psychotic disorder, current substance use disorder, or serious suicidal or homicidal ideation were excluded from the study. Patients enrolled were initially put on a 1-month waiting list and then underwent 15 psychotherapy sessions, which could be administered anywhere from one to five times weekly. There were a total of 15 completers.

As measured by the Y-BOCS, there was a 29.6% reduction of symptoms in intent-to-treat analysis. The gains, however, did decrease over time; compared to baseline there was a 26.64%, 23.36%, and 22.65% decrease in symptoms at 1, 3, and 6 months after treatment, respectively. The authors argue that although symptoms had increased at the 6-month follow-up, overall symptom burden still tended to be lower than it had been at study entry. There remains a possibility that treatment response could continue to decline over time, but the study's follow-up was limited to 6 months.

Tundo and colleagues (2007) enrolled 36 subjects who were nonresponders to at least one adequate SRI trial in a naturalistic study. Subjects were continued on current medications and were assigned to CBT, the course of which was determined by individual therapists and subjects both in terms of contact frequency and number of sessions. Overall, 28 completed 6 months of follow-up and 25 completed 1 year of follow-up, with a mean Y-BOCS reduction of 19%, which was statistically significant. The authors point out that the results are generally consistent with the studies by Simpson and colleagues (1999), Kampman and colleagues (2002), and Tolin and colleagues (2004) in that CBT supplementation appeared successful in patients who had not responded to medications. However, the mean reduction in symptoms was less than in the previous studies, with a smaller percentage of improved patients (present study 42%, Simpson et al. 86%, Kampman et al. 77%, Tolin et al. 66%); the authors argue that their sample consisted of patients who had generally failed more medication trials and had higher baseline Y-BOCS scores (28.2 in present study, 23.8 in Simpson et al., 25.7 in Kampman et al., and 25.1 in Tolin et al.), resulting in decreased treatment effectiveness.

Tenneiji and colleagues (2005) examined the addition of psychotherapy to paroxetine and venlafaxine in 96 participants with OCD (from a total of 150) who had a partial response to medication in a double-blind trial. Those who had at least a 25% reduction in symptoms as measured by the Y-BOCS after 3 months of drug treatment were given the option of randomization to continuing drug treatment alone or drug treatment plus behavior therapy for an additional 6 months. The dropout rate was higher in the combination group than in the drug-alone group (30% and 6% respectively); however, 53% in the combination group were judged to be in remission at the end of the study as opposed to 11% in the drug-alone group. The authors argue that although the differential dropout rate could be considered a weakness of the study, it is similar to the dropout rate observed in other trials of behavioral therapy, and that a high dropout rate is expected in a real-life clinical setting.

Simpson and colleagues (2013) enrolled subjects who remained symptomatic after 12 weeks of an adequate SRI trial. Participants were randomized to addition of exposure and response prevention, risperidone, or placebo and were continued on their current SRI as well as other psychotropic medications at stable doses, except for antipsychotics. Eighty-six of the 100 patients enrolled completed the studies. The authors concluded that exposure and response prevention was superior to both risperidone and placebo; although risperidone was numerically better than placebo, the difference was not statistically significant.

Overall, this group of studies suggests that there is unlikely to be great benefit to combined treatment, except in those who have failed to adequately respond to psychotherapy or medication. It is important to note, however, that many of the studies described that have looked at this population are not controlled trials, and therefore further research is necessary to elucidate this point.

Long-Term Outcome

There is a dearth of data investigating the long-term outcome of combined pharmacology and psychotherapy for the treatment of OCD. The available studies have been uncontrolled and naturalistic in design, with relatively small sample sizes, but they still provide valuable insight.

The results of naturalistic 6-month and 5-year follow-ups, with pooled data from van Balkom and colleagues' (1998) RCT and from another psychotherapy-only RCT (van Oppen et al., 1995) comparing cognitive therapy with exposure-based therapy and fluvoxamine, were published by de Haan and colleagues (1997) and van Oppen, van Balkom, de Haan, and van Dyck (2005), respectively. The two original studies, from which the data were pooled, used the same inclusion and exclusion criteria and identical treatment protocols, therapists, clinics, assessment methods, and measurement intervals.

Results of the 6-month follow-up showed that 17 of the 45 nonresponders in the original studies became responders. The 5-year follow-up showed no significant difference in clinical outcome among the cognitive therapy, exposure with response prevention, and fluvoxamine in combination with the CBT groups.

It is important to note that, as naturalistic studies, there were no control conditions for the treatments during the follow-up periods, and most of the patients who responded by 6 months had received further treatment after the initial study period.

O'Sullivan and colleagues (1991) conducted a 6-year follow-up of 34 of 40 subjects who had received 3 or 6 weeks of exposure therapy and clomipramine or placebo for 36 weeks. They found that there was no difference between the clomipramine and placebo groups but that outcomes were improved with longer duration of psychotherapy. Rufer and colleagues (2004) followed 30 subjects 6 to 8 years after an initial study of 37 inpatients randomized to CBT plus fluvoxamine or placebo. Again, combination therapy was found to be no better than CBT alone.

Cottraux, Mollard, Bouvard, and Marks (1993) conducted a 1-year naturalistic follow-up of Cottraux and colleagues' (1990) RCT discussed above. Fifty-five percent of the patients who began the initial study were available for testing at the 1-year follow-up period. The results suggest that all patients, regardless of treatment, were improved at the 1-year follow-up; however, those who received exposure therapy were less likely to have reported antidepressant treatment.

Treatment Discontinuation

Few studies have examined the effects of treatment discontinuation in those who have responded to OCD treatment. Simpson and colleagues (2004) published data from the discontinuation phase of Foa and colleagues' (2005) RCT, discussed above, which compared exposure with response prevention, clomipramine, their combination, and pill placebo. Those who were treatment responders in the acute phase were eligible to enter the discontinuation phase.

During the discontinuation phase, which lasted 12 weeks, the exposure with response prevention was stopped and the medication was tapered off. Patients still continued to see their therapist or pharmacotherapist for supportive/evaluative meetings, lasting up to 20 minutes each, at regular intervals. Those who relapsed were removed from the study and offered open treatment.

Of the 87 patients who completed phase 1 of the initial trial, 48 were responders and were eligible to enter the discontinuation phase of the study. All but 2 of the responders actually participated in the discontinuation phase. Nine of the participants relapsed during the discontinuation phase.

Although the sample size was small in the 12-week discontinuation phase, and there was no randomization or control group, the following trends were highly suggestive. Responders who originally received either CBT alone or in combination with clomipramine had less severe OCD symptoms at the beginning of the discontinuation phase, were less likely to relapse during the discontinuation phase compared to patients who had received medication alone, and, if they did relapse, had a longer time to relapse following treatment discontinuation. This study suggests that combined treatment may have an important advantage in mitigating adverse effects of medication discontinuation.

Special Populations

One third to one half of adults with OCD develop the disorder during childhood or adolescence. The Pediatric OCD Treatment Study (POTS) Team published the first RCT exploring treatment efficacy of combined treatment in child and adolescent OCD patients (March et al., 2004). The multicenter study included 112 patients, aged 7 through 17, who were randomized to CBT, sertraline, combined treatment, or pill placebo groups for 12 weeks. Results showed that patients in the combined treatment group did better than either the CBT- or sertraline-alone groups, which did not differ from each other. Remission

rates were 54% in the combined group, 39% in the CBT-alone group, 21% in the sertraline-alone group, and 4% in the pill placebo group. The difference between the combined and CBT-alone groups did not reach statistical significance.

The POTS II study (Franklin et al., 2011) examined 124 patients aged 7 to 17 who had a partial response to an adequate SRI trial. Participants were randomized to three groups: (1) medication continuation only, (2) medication plus exposure and response prevention, and (3) medication plus "instruction in CBT," which involved pharmacotherapist delivery of truncated CBT sessions during the medication management sessions. The study found that augmentation with exposure and response prevention was effective, as was instruction in CBT; however, the gains made with instruction in CBT were minimal and not statistically significant. Reported response rates were 68.6% in the exposure and response prevention group, 34% in the instructions group, and 30% in the medication-alone group.

Storch and colleagues (2010) administered DCS in children and adolescents aged 8 to 17 who had been on stable medication doses at the time of study entry. Subjects underwent 10 60-minute CBT sessions and were given DCS at a dose of 0.7 mg/kg (based on a 50-mg dose for a 70-kg adult) or placebo 1 hour prior to the session. Although DCS appeared to improve outcomes, the difference from placebo failed to reach statistical significance.

Foa, Kozak, Steketee, and McCarthy (1992) sought to determine whether behavior therapy (exposure and response prevention) for the treatment of OCD was enhanced by prior treatment of comorbid depression. Patients ($N = 38$) were divided into highly depressed (BDI > 21) and mildly depressed (BDI < 20) groups, then randomly assigned to imipramine or pill placebo. Patients received medication for 6 weeks, which was continued while they began the behavior therapy sessions. These daily sessions were 2 hours each, lasting 3 weeks. Patients then had two home visits, each of 4 hours' duration. Participants then received 12 weekly, 45-minute supportive behavior therapy sessions. Medication was discontinued at 22 weeks. The results showed that imipramine did decrease depressive symptoms but did not seem to increase the likelihood of successful behavior therapy for OCD.

The consensus at present seems to advocate for either combined CBT with medication management or CBT alone for the treatment of OCD. There are data that suggest that combination therapy is somewhat better than CBT alone in children and adolescents, and likely in those who have failed to respond to the initial treatment approach. In a general adult sample, there is little evidence that the addition of pharmacotherapy is superior to CBT alone, but there is no evidence that combined treatment has any negative effects (e.g., no greater likelihood of relapse after discontinuation). More research is needed to determine whether there are individuals who would be better suited to psychotherapy alone, medication alone, or combined treatment.

POSTTRAUMATIC STRESS DISORDER

While there have been numerous studies showing the efficacy of both pharmacological and psychosocial therapies in the treatment of PTSD, the few studies examining the efficacy of the combination have been small and fraught with methodological limitations. However, expert recommendations and common practice often espouse the usefulness of this combination.

Otto and colleagues (2003) conducted one of the earliest of these small studies in 2003, comparing the combination of sertraline plus CBT to treatment with sertraline alone in 10 female Cambodian refugees. All subjects had previously failed to respond to treatment with an SSRI other than sertraline plus clonazepam. Although inclusion and exclusion criteria were not clear, it appears that the two groups had similar and significant psychiatric comorbidity. Enrolled subjects were continued on clonazepam and started on open-label dosing of sertraline. Group CBT was conducted with five of the study participants. The results of this pilot study suggest that the women in the CBT group improved more than the women in the sertraline-alone group, particularly on measures of misinterpretation of culturally relevant somatic stimuli.

Rothbaum and colleagues (2006) compared sertraline alone and sertraline combined with prolonged exposure therapy in sertraline responders in a two-phase study where 88 subjects entered a 10-week, open-label sertraline trial and were required to demonstrate at least 20% improvement in PTSD severity to move on to phase 2. The 65 subjects who met this criterion were randomized to either 5

weeks of continued sertraline alone or sertraline with prolonged exposure therapy. Those randomized to the sertraline-only group demonstrated no further improvement. Sertraline plus exposure did result in some further reduction in symptom severity, but the results failed to reach statistical significance. In a secondary analysis, the authors examined two different groups, which they labeled as partial medication responders and excellent medication responders. In this analysis, they found that the partial medication responders derived more substantial benefit from exposure therapy than did the excellent medication responders.

Simon and colleagues (2008) compared prolonged exposure therapy alone or in combination with paroxetine in a two-phase trial. A total of 68 participants entered the first phase of this study, in which all received eight 90- to 120-minute exposure sessions. Those still symptomatic after seven sessions were randomized to paroxetine or placebo along with five addition exposure sessions. Of the 68 subjects who entered the trial, 25 were eligible for randomization to paroxetine or placebo, and 23 went on to enter the second phase of the study. The addition of paroxetine did not confer any benefit over exposure alone in this study.

Schneier and colleagues (2012) also studied 37 participants who were randomly assigned to 10 weeks of prolonged exposure therapy with either paroxetine or placebo in survivors of the September 11 attacks. There was a 12-week continuation phase of paroxetine or placebo but no exposure therapy. For the duration of the combined treatment phase, paroxetine plus exposure was superior to placebo plus exposure, with a number needed to treat of 3 (i.e., three patients needed to be treated with combined treatment in order to realize one remission that would not have also occurred with placebo plus exposure), although the placebo group also had clinically meaningful improvements. Unlike the initial combined therapy phase, results of the 12-week continuation phase did not demonstrate a significant between-group difference. The authors suggest that the study does show a benefit of addition of paroxetine, with the remission rate in the paroxetine group being double that of the placebo group. They postulate that if the study had been adequately powered, a significant difference would have been uncovered. They point out that this study differs from Simon and colleagues' study in that all subjects were randomized to paroxetine or placebo, rather than purely a sample with an inadequate response to exposure therapy alone.

Only one study has examined combined medication and psychotherapy in adolescents. Cohen and colleagues (2007) studied trauma-focused CBT alone or combined with sertraline in subjects aged 10 to 17 who had experienced sexual abuse. The initial study design planned to include 40 participants in each group; however, there was significant difficulty in recruitment, which the authors attribute to the black box warning placed on SSRIs in 2004. Ultimately, 22 participants were randomly assigned to each treatment group. The study did not demonstrate a benefit of combining CBT with sertraline instead of with placebo.

Although expert opinion continues to encourage the combination of medication and psychotherapy for the treatment of PTSD, there is little evidence to support this recommendation. In fact, in 2010, a Cochrane report (Hetrick, Purcell, Garner, & Parslow, 2010) including four studies (Cohen et al., 2007; Otto et al., 2003; Rothbaum et al., 2006; Simon et al., 2008) concluded that there is not enough evidence to support or refute the combination of psychotherapy and medication in the treatment of PTSD.

Another approach that has been used in the treatment of PTSD is the addition of medications administered at the time of psychotherapy to enhance its effectiveness. Three studies have combined psychotherapy with DCS. De Kleine and colleagues (2012) administered 50 mg of DCS or placebo 1 hour prior to exposure sessions in 67 subjects and failed to find a difference in outcome between the two groups. However, the study did allow early completers; if both the subject and the therapist felt the patient was better, he or she did not have to finish all planned psychotherapy sessions. A secondary analysis revealed that DCS did enhance outcomes in the group that completed all therapy sessions, leading to the conclusion that DCS may be helpful in those who do not have as robust a response to psychotherapy. The study had a high dropout rate ($n = 22$); 45 participants completed the study, and 8 who dropped out prior to receiving any exposure session were not included in the final analysis.

Litz and colleagues (2012) studied DCS in 26 Iraq and Afghanistan veterans with combat-related PTSD who underwent six 60- to 90-minute exposure therapy sessions. They were given 50 mg DCS or placebo prior to sessions 2 through 5, which involved

imaginal exposure. Participants could continue non–exposure-based psychotherapy as well as psychotropic medications as long as the dose was stable for 2 months prior to study entry. The DCS group had a poorer outcome than the placebo group; the authors speculate that DCS might have inadvertently reconsolidated frightening memories evoked by the therapy itself. They also point out that the sample size was small, making it difficult to draw firm conclusions.

In sum, study results involving DCS have been disappointing. Methodological difficulties including sample size and lack of clarity regarding the timing of DCS dosing may have contributed to the results. There is currently no evidence that DCS enhances outcomes in PTSD patients, but further research in this area with larger and more robust studies could lead to alternative conclusions.

Another intervention, 3,4-methylenedioxy-N-methylamphetamine (MDMA), was classified as a Schedule I drug in 1985, but prior to this there were case reports of it augmenting psychotherapy, decreasing fear, and enhancing alertness. Mithoefer and colleagues (2011) randomized 20 subjects to MDMA or placebo to enhance psychotherapy. Participants in this study were required to have treatment-resistant PTSD (failed to respond to 3 months of SSRI or SNRI treatment plus 6 months of psychotherapy). The study was also limited to individuals with crime- or war-related trauma. All participants were tapered off psychotropic medications prior to study entry, with the exception of sedatives and hypnotics taken on an as-needed basis for anxiety or insomnia.

Subjects underwent two 8-hour psychotherapy sessions with MDMA or placebo 3 to 5 weeks apart. These sessions followed a manualized psychotherapy developed specifically for this study. Patients were also offered weekly standard psychotherapy sessions in between MDMA-assisted sessions. A 125-mg dose of MDMA was administered at the beginning of psychotherapy followed by an optional supplemental 62.5-mg dose given 2 to 2.5 hours later. The session lasted the entire day, and the subjects remained overnight. Zolpidem was available for insomnia.

Following the two sessions, the blind was broken, and the placebo group was offered a crossover. Seven of the eight subjects initially randomized to placebo chose to go on to the crossover phase. Ten out of 12 participants initially randomized to MDMA no longer met criteria for PTSD at the end of the study compared with 2 out of 8 in the placebo group. In the crossover phase, all seven subjects had a response to MDMA-assisted psychotherapy. In addition to the small sample size, the authors point out that there was difficulty with blinding in this study and that most of the participants correctly guessed their treatment assignment.

Mithoefer and colleagues (2013) followed up (17 to 74 months, with an average of follow-up time of 3.5 years) on 19 of the subjects in the initial study. Sixteen of the 19 completed the follow-up phase. The improvements were durable; only two subjects relapsed in this group. No neurocognitive decline or new-onset substance abuse was observed, as had been feared with the use of this Schedule I drug. As this was a naturalistic study, the authors make the argument that all the subjects had treatment-refractory PTSD upon entering the study and were unlikely to have achieved sustained remission from interventions during the follow-up period.

Oehen, Traber, Widmer, and Schnyder (2013) enrolled 12 participants with treatment-resistant PTSD in a study that compared full-dose versus low-dose MDMA, which was administered as an active placebo to enhance the study blind. Participants underwent three MDMA-assisted, day-long psychotherapy sessions with overnight stay, similar to the psychotherapy design of Mithoefer and colleagues' study. Participants were defined as treatment-resistant if they had failed to respond to 6 months of psychotherapy or 3 months of SSRI. All psychotropic medications (other than gabapentin used for pain control) were tapered. Existing psychotherapy could be continued as long as no changes were made.

Eleven subjects completed the study. Eight were randomized to full-dose MDMA, 125 mg at the start of psychotherapy plus 62.5 mg 2.5 hours later. Four were randomized to active placebo consisting of low-dose (25-mg) MDMA at the start of psychotherapy and 12.5 mg given 2.5 hours later. After the three initial sessions were complete, the active placebo group was given full-dose MDMA in a crossover phase. After an initial analysis, two more psychotherapy sessions were added because many were judged to have had an insufficient response. At the end of the study, four of the participants in the MDMA group were improved but still met criteria for PTSD, while no patients in the placebo group responded. The between-group difference did not reach statistical significance. Even with the use of an active placebo, many participants and investigators accurately guessed randomization.

Both studies involving MDMA-assisted psychotherapy were very small and considered to be pilot studies. The results suggest some promise of using MDMA in certain PTSD patients, but risks that may be associated with longer-term use of this drug with a potential for abuse will have to be carefully considered. Similar to results in OCD, there is yet insufficient evidence to support or refute combined medication and psychotherapy for PTSD.

GENERALIZED ANXIETY DISORDER

In the years since the previous edition of this text, there have been few new RCTs comparing combined treatment with monotherapy in GAD. Benzodiazepines have been commonly prescribed for anxiety, but few studies were conducted to test their effectiveness in combination with a psychosocial treatment such as CBT. Powers and colleagues (1990) compared diazepam alone, placebo alone, CBT alone, diazepam plus CBT, and placebo plus CBT for 8 weeks in 113 subjects (double-blind). The dose of diazepam in any treatment group was 5 mg taken three times daily. Outcome measures were the Hamilton Rating Scale for Anxiety (HRSA), General Health Questionnaire (GHQ), and a self-report measure of change. Although the results demonstrated that CBT plus diazepam and CBT plus placebo as well as CBT alone were effective, and there were no differences among the CBT groups, the study did not use a structured interview for diagnosis, and diagnostic criteria was based on *DSM-III*, which limits its comparison to newer studies.

Buspirone was tested on 60 patients with GAD (Bond, Wingrove, Curran, & Lader, 2002) randomized to one of four treatment conditions: buspirone and anxiety management training, buspirone and nondirective therapy, placebo and anxiety management training, and placebo and nondirective therapy, for 8 weeks.

Nondirective therapy involved the patients talking freely with the therapist, acknowledging and reflecting back feelings discussed, using open-ended questions in a nonjudgmental manner. Anxiety management training incorporated some elements of CBT: psychoeducation, progressive muscle relaxation, and homework assignments. In addition, avoidance behaviors and anxiety triggers were explored, as well as the relationship among thoughts, feelings, and symptoms. Negative thoughts were recorded and challenged, possibly in a similar manner to cognitive therapy, but no further elaboration of the technique was presented. Both types of psychotherapy continued weekly, consisting of 45-minute sessions for 7 weeks.

The medication and placebo used flexible dosing, beginning at 5 mg in three daily capsules increased to six capsules if necessary for 8 weeks. Whether the clinicians and patients were blind to placebo versus buspirone was not mentioned. Outcome was measured using the HRSA, administered by a blind evaluator. Self-reports included the Hospital Anxiety and Depression Scale, the Zung Self Rating Anxiety Scale, the GHQ, the Cognitive Checklist, and the Mood Rating Scale.

Results showed that in 44 of 60 participants who completed the trial, there was no significant difference in outcome among the groups; all showed a 50% reduction on HRSA, indicating some improvement. When comparing the completer analysis to the intent-to-treat analysis, similar results occurred.

This study makes the case that psychotherapy is helpful in the treatment of GAD with or without the addition of buspirone. It is difficult to compare the results of this research to other studies of GAD using CBT, since only improvement on HRSA and self-reports were measured. Most other studies institute remission or response criteria and measure rate of response. Many clinicians also agree that dosages of 30 mg or less per day of buspirone, such as used in this study, are grossly subtherapeutic.

The duration of treatment in this trial was rather short (only 8 weeks), whereas other studies using CBT have been conducted for a minimum of 12 weeks (Borkovec, Newman, Pincus, & Lytle, 2002). The major hallmark of GAD is uncontrollable worry. The HRSA measures worry but not exclusively; rather, the items combine anxious mood, worry, fearful anticipation, and irritability. Other instruments have been used that focus primarily on worry (e.g., Penn State Worry Questionnaire [PSWQ]; Meyer, Miller, Metzger, & Borkovec, 1990) and make comparisons between studies easier.

Antidepressants have also been used to treat GAD. Crits-Christoph and colleagues (2011) tested the effectiveness of combining venlafaxine extended-release with CBT in a primary care sample of patients with GAD. This sample consisted of 77 patients randomly chosen from a total of 334 who had enrolled in a medication-only trial of venlafaxine extended-release.

What is unique in this sample is that participants were invited to enroll rather than being treatment-seeking for CBT. From the 77 invited, only 29 agreed to participate, while only 26 attended at least one session. Outcome measures included HRSA, GHQ, PSWQ. CBT treatment lasted for 12 sessions.

The outcome measures compared the CBT-plus-venlafaxine-extended-release group (randomly offered this treatment) to those patients who received venlafaxine extended-release alone (never offered CBT). Based on HRSA measures, there was no significant difference between the two groups (intent-to-treat), nor were there any significant differences on any other outcome measures. In this study sample of primary care patients who were medication-seeking, adding CBT to medication (venlafaxine extended-release) did not significantly improve the outcome. It should be noted that patients in this sample were excluded if they had comorbid major depression or any episode of MDD in the past 6 months. In addition, CBT lasted only 12 sessions. Other CBT treatment studies for GAD have extended the duration to 16 sessions to increase the likelihood of treatment response.

GAD is common among older adults, and pathological worry in this group may be more difficult to treat. Wetherell and colleagues (2013) recruited 73 adults over age 60 with GAD from three clinics (Pittsburgh, St. Louis, San Diego), all receiving 12 weeks of open-label escitalopram, and randomly assigned them to one of four conditions: 16 weeks of escitalopram plus modular CBT followed by maintenance escitalopram for 28 weeks, escitalopram alone followed by maintenance citalopram, escitalopram plus CBT followed by pill placebo, and escitalopram alone followed by pill placebo. Measures included HRSA and PSWQ. Depressive comorbidity was not excluded, but psychosis, suicidality, and severe cognitive impairment were exclusion criteria.

Modular CBT was a 16-week, manualized protocol targeting worry and anxiety. Modules included psychoeducation, self-monitoring, relaxation exercises, cognitive restructuring, and problem solving. In addition, family members were invited to attend one session and were taught about GAD. Those participants who were depressed (score of 3 or 4 on HAM-A depression item for two consecutive assessments) were also administered a behavioral activation module. For participants who had a comorbid anxiety disorder, an exposure module was administered. Participants with insomnia (score of 3 or 4 on HAM-A sleep item for two consecutive assessments) received a sleep hygiene module.

Participants began with escitalopram treatment, then entered the augmentation phase, where those in the CBT group received 16 sessions. During the maintenance phase, those on escitalopram who were to receive pill placebo were tapered off and started on placebo while the continuation group stayed on the same dose. Those participants who received CBT were eligible for up to three booster sessions of CBT during the maintenance phase.

Relapse in this trial was based on two consecutive assessments and defined as an HAM-A score 14 or higher or at least 5 points greater than the lowest score rated during the augmentation phase, and meeting *DSM-IV* criteria for GAD (without duration criterion). Automatically meeting the criteria for MDD was also considered relapse regardless of the HAM-A score.

Results were favorable for the patients receiving escitalopram plus CBT augmentation; they showed lower PSWQ scores (improvement in pathological worry) than the escitalopram-only group. HAM-A scores were not significantly different between groups, but when the authors analyzed only those whose score was greater than 14 at the time of augmentation, results showed a preference in the CBT group, since 52.6% were considered responders while only 26.7% of the other group achieved response.

The results of maintenance treatment demonstrated greater relapse in the placebo group (46%) than the escitalopram group (2.7). Because the effect of maintenance escitalopram was so large, the authors analyzed the placebo group to determine the effects of CBT on relapse and found a significant difference. Those participants on placebo who received CBT augmentation relapsed less often (only 25%) compared to the placebo-only group (66.4%). There was no significant difference in relapse rates between the escitalopram-only group and the CBT-plus-placebo group.

In summary, maintenance SSRI medication augmented with CBT in this older adult population was not only effective in reducing worry but also protective of relapse. From these data, we can conclude that adding CBT to an SSRI is an effective treatment option.

Although GAD is frequently comorbid with MDD (62% of individuals with GAD have had a history of MDD; Wittchen et al., 1994), there are almost

no RCTs combining psychotherapy with medication for this comorbid group. One study (Aaronson, Terranova, Pievsky & Hirschowitz, unpublished manuscript), randomly treated 62 adults with GAD and MDD, aged 18 to 65, with either CBT plus quetiapine extended-release or CBT plus placebo. Participants had to meet full criteria for both disorders on a structured interview (Mini International Neuropsychiatric Interview [MINI]) and in a psychiatric evaluation and had no history of bipolar disorder, any psychotic disorder or psychosis, eating disorder, or current substance use disorder. Any unstable medical condition in which taking quetiapine was contraindicated was also an exclusion criterion.

Treatment lasted 16 weeks (although 16 sessions of CBT may have taken more than 16 weeks to complete) and patients were seen weekly. Depression symptoms were measured by the MADRS weekly and anxiety was measured using the HRSA. CGI for improvement and severity were also measured weekly. Worry and mood were also measured by self-report at baseline and at 4, 8, 12 and 16 weeks.

CBT included psychoeducation about anxiety and depression, deep breathing, progressive muscle relaxation exercise, cognitive restructuring of rumination and worry, behavioral activation for amotivation in depression, situational exposure for phobic avoidance, and affect exposure (emotions that are typically avoided through worry). Quetiapine extended-release dosing started at 50 mg per week with a target of 150 mg by week 3. If patients did not tolerate the increase in dose, they were decreased to the lower dose, with a minimum of 50 mg throughout the study. Study researchers tried to make the dose as flexible as possible both to accommodate patients and to reflect clinical practice, yet keep the necessary rigor of a clinical trial.

Of the 62 participants randomized, 7 dropped out before beginning any treatment. The attrition rate in this trial was high—17 dropped out or were exited—due to fears about taking an antipsychotic medication and its side effects, or time commitment (no evening appointments). Response was measured by at least a 50% decrease in both MADRS and HRSA from baseline and a CGI score of 1 or 2 (for both improvement and severity).

When the total sample was included, there was no significant difference in response between the two treatment groups, although there was significant improvement in all participants. In the completer sample, there was a significant difference in outcome. In the combined group, 81% responded while 47% of the CBT-plus-placebo group responded.

The small sample size is a major limitation, but this suggests a potentially effective treatment for a subgroup of patients who typically do not have good outcomes in usual treatment.

Clearly, more research is needed for efficacy testing of combined treatment of GAD, especially involving SSRIs as well as other novel pharmacotherapies and a full course of CBT that includes cognitive restructuring, worry reduction, exposure (to emotions, thoughts, and situations), mindfulness, and progressive muscle relaxation techniques.

Generalized Anxiety Disorder and Social Anxiety Disorder in Children

The Child-Adolescent Anxiety Multimodal Study (CAMS) was a multicenter, two-phase RCT for children and adolescents aged 7 to 17 with separation anxiety disorder, GAD, or SAD. Phase I, which lasted 12 weeks, recruited children from six sites and compared CBT, sertraline, CBT plus sertraline, and placebo (Walkup et al., 2008). Phase II lasted 6 months, extending treatment for those who responded in phase I.

Inclusion criteria were meeting full *DSM-IV-TR* criteria for GAD, SAD, or separation anxiety disorder with impairment and an IQ of at least 80. Additional diagnoses of ADHD, OCD, PTSD, oppositional defiant disorder, and conduct disorder were allowed if less severe than the target disorders. Exclusion criteria included significant school refusal due to anxiety, unstable medical conditions, and failed response to two adequate trials of SSRI or CBT treatment. Current substance use disorder and major depression requiring medication treatment were also exclusionary.

Of the 524 eligible subjects, 488 were randomized and 57 stopped treatment (11.7%), with participants in the CBT group less likely to drop out. There were 140 children in the combination group, 133 in the sertraline group, 139 in the CBT group, and 76 in the placebo group.

The CBT treatment was conducted weekly for 14 sessions lasting 60 minutes (two of those sessions were parent-only sessions). The interventions used the Coping CAT manual and included anxiety management skills and exposure. The sertraline or placebo

was administered in a fixed-flexible schedule, with a starting dose of 25 mg adjusted to a maximum of 200 mg by week 8; sessions occurred weekly for 30 to 60 minutes, where anxiety was rated and side effects were discussed. The combination therapy group whenever possible met on the same day for CBT and medication visits.

Outcome measures were CGI-I, Pediatric Anxiety Rating Scale, and Children's Global Assessment Scale administered at 4, 8, and 12 weeks, and response was defined as a 1 or 2 on the CGI. In this study, the combined treatment group demonstrated the greatest response, 80.7%, significantly better than the monotherapies. While the other groups demonstrated significant improvement over placebo, the CBT group had a response of 59.7%, sertraline 54.9%, and placebo, 23.7%; the two monotherapies were equally as effective. The sertraline group did not experience any more suicidal or homicidal ideation than the placebo group but experienced more insomnia, fatigue, sedation, and restlessness than the CBT group.

Phase II of the CAMS study involved 6 months of maintenance treatment followed by a 24-week and a 36-week assessment (Piacentini et al., 2014). Maintenance CBT involved monthly sessions where no new material was added, but new or worsening symptoms were addressed using techniques learned in acute treatment. Medication maintenance visits were also monthly, with the dosage remaining constant unless side effects emerged, in which case the dosage was decreased. Again, the combined treatment group continued in the same manner as the monotherapy groups, meeting monthly for both medical visits and CBT booster sessions on the same day.

The same response criteria held for phase II: a CGI-I of 1 or 2. In addition, an excellent treatment response category was defined as a CGI-I of 1. Remission was defined as a CGI-S as 1 or 2 or no longer meeting Anxiety Diagnostic Interview Schedule, child version criteria.

Of the 370 participants who completed acute treatment, 322 (78.2%) completed the assessment at week 24 and 325 (78.9%) completed the week 36 assessment. The combined group remained about the same from 12 weeks to 24 and 36 weeks (81% to 82% responders), while the sertraline and CBT groups continued to improve in outcome so that at 36 weeks, there was no statistically significant difference among the groups. When considering excellent response, combined treatment was significantly better than CBT at 12 weeks, it just missed significance at 24 weeks ($p = 0.055$), and it was not significant at 36 weeks. Using remission status based on diagnosis, there was a significant difference; the combined group experienced greater remission than either monotherapy, and the monotherapies did not differ from each other. Using the CGI-S remission criteria, there was a trend toward significance for the combined group ($p = 0.01$), but that disappeared at 36 weeks.

In summary, for socially anxious, generally anxious, and separation anxious children and adolescents, the combination of sertraline and CBT was most efficacious at the 12-week acute treatment point, but with continued maintenance treatment, the monotherapies caught up at 24 and 36 weeks.

SOCIAL ANXIETY DISORDER

There is a paucity of RCTs for SAD comparing medication, psychotherapy, and their combination, whereas the number of such trials for monotherapy comparisons abound. Of the four RCTs that were conducted since 1990, three were conducted in an academic psychiatric setting employing trained clinicians; the other was conducted in a primary care setting with medical practitioners.

One early study by Clark and Agras (1991) compared the effectiveness of buspirone alone, placebo alone, CBT plus buspirone, and CBT plus placebo for 6 weeks in 34 musicians with performance anxiety, aged 18 to 60. The CBT was delivered in a group format of five or six participants and included cognitive restructuring, coping models, and exposure. Buspirone was administered in 5-mg doses, three times per day, and increased as needed up to 12 pills per day. Outcome was measured through subjective anxiety ratings and heart rate during laboratory performance. Results showed significantly greater improvement in the CBT-plus-placebo group over not only the buspirone-only or placebo-only groups, but also the CBT-plus-buspirone group. Buspirone was not effective at all in performance anxiety in musicians.

Davidson and colleagues (2004) conducted a large RCT for generalized SAD using fluoxetine, CBT, their combination, and placebo at two sites, randomizing 295 adults to 14 weeks of treatment in one of five groups: fluoxetine alone ($n = 57$), comprehensive group CBT alone ($n = 60$), fluoxetine and comprehensive group CBT combined ($n = 59$), placebo

plus comprehensive group CBT (n = 59), and placebo alone (n = 60). Exclusion criteria were similar to those for other RCTs for anxiety disorders: schizophrenia, bipolar disorder, current substance use disorder, cognitive impairment or organic brain syndrome, any unstable medical condition, MDD within the past 6 months, and another primary anxiety disorder.

Fluoxetine treatment and placebo, both administered double-blind by a psychiatrist following a manual, were initiated at 10 mg and increased to 20 mg on day 8, to 30 mg on day 15, and to 40 mg on day 29 (the target dose). If patients failed to achieve response at 40 mg, the dose was raised to 50 mg on day 43 and to 60 mg on day 57. Patients were seen weekly for 4 weeks, then every other week for the rest of the 10 weeks. The comprehensive group CBT involved psychoeducation, social skills training, cognitive restructuring, and in vivo exposure during the 14 weekly sessions. This type of CBT differs in the addition of social skills training and two sessions in which the patients were taught how to begin a conversation with a stranger and how to make eye contact. Group sessions were led by two extensively trained therapists and comprised five or six patients; the length of group sessions was not discussed.

Outcome was measured using the Brief Social Phobia Scale and the CGI, both rated by an independent evaluator. A videotaped role-play test of social skills was conducted before and after treatment and served as a secondary outcome measure. Of the 295 randomized patients, 211 (72%) completed the 14 weeks of treatment, with 5% (n = 16) dropping out before treatment began. In pairwise comparisons, the placebo-only group experienced more dropouts than the group receiving comprehensive group CBT only and the group receiving comprehensive group CBT plus placebo.

Based on CGI scores as the response criterion, the intent-to-treat response rates were 50.9% for fluoxetine alone, 51.7% for comprehensive group CBT alone, 54.2% for combined fluoxetine and comprehensive group CBT, 50.8% for comprehensive group CBT plus placebo, and 31.7% for placebo only, demonstrating only a trend for significance (p = 0.09). When pairwise comparisons were tested, all treatments were significantly more effective than placebo, with combined treatment demonstrating slightly greater statistical significance (p = 0.01; p = 0.03 for all other comparisons). The completer response rates were higher: fluoxetine 64.1%, comprehensive group CBT 64.6%, combined treatment 66.7%, comprehensive group CBT plus placebo 59.6%, and placebo 40.5%. Again, overall, there was a trend toward significance (p = 0.09), but the pairwise comparisons demonstrated that active treatment was more effective than placebo except for the patients receiving comprehensive group CBT plus placebo; this group only showed a trend toward significance (p = 0.08). The combined treatment group demonstrated the greatest statistical significance (p = 0.01), with comprehensive group CBT next (p = 0.02), and fluoxetine alone last (p = 0.03).

The two phobia measures demonstrated a significant difference in outcome between the active treatments and placebo, but in pairwise comparisons, fluoxetine alone followed by comprehensive group CBT alone demonstrated the fastest onset of action. In this very-well-conducted RCT, there was no significant benefit to combined CBT and medication for SAD.

The second RCT for SAD was conducted by Clark and colleagues (2003) in England. Patients aged 18 to 60 with generalized SAD of at least 6 months' duration without current MDD, bipolar disorder, psychosis, or substance use disorder were included. No participants were accepted if they had previous treatment experience with cognitive or exposure therapy or an SSRI.

The 60 SAD patients were evenly randomized to one of three treatment conditions: cognitive therapy alone, fluoxetine plus self-exposure, and placebo plus self-exposure. Acute treatment lasted for 16 weeks, followed by a 3-month maintenance period. All patients were assessed at 12 months for follow-up.

The cognitive treatment, based on the model of Clark and Wells, focused on the ways that social phobia is maintained through thoughts and safety behaviors. One of the treatment components involved helping patients change their self-focus (constant monitoring of their own sensations and worry about how others perceive them) to an external one (e.g., the social situation in which they are engaged). The treatment also incorporated videotape feedback to correct distorted self-images frequently held by socially phobic patients. In addition to receiving exposure therapy, patients were prepared in advance for what they feared would occur and then were tested for whether the feared event actually occurred. Cognitive restructuring was implemented to change dysfunctional assumptions.

Pharmacotherapists were psychiatrists with experience using SSRIs but with little formal CBT training. The fluoxetine or placebo treatment groups received 20-mg capsules, with the first dosage increase to 40 mg at week 2 or 3, increasing to a maximum of 60 mg if needed. Patients were told that fluoxetine would make them more confident in social situations by correcting a neurochemical disturbance and were advised to systematically expose themselves to social situations to derive maximum benefit from the medication.

Measures of social anxiety in this study were the Social Phobia Scale, the Social Interaction Anxiety Scale, the Liebowitz Social Anxiety Scale (LSAS), the Fear Questionnaire Social Phobia subscale, the Fear of Negative Evaluation Scale, and the Social Phobia Weekly Summary Scale (a self-report of social anxiety, social avoidance, self-focused vs. external attention, anticipatory processing, and post-event rumination). The Beck Anxiety Index and the BDI were used to assess mood.

The sample was 52% female; 43% met criteria for avoidant personality disorder. There were no significant differences between the treatment groups on demographic variables. Six patients did not complete the treatment phase. Of the 54 completers, 20 received cognitive therapy, 17 received fluoxetine plus exposure, and 17 received placebo plus exposure.

At the end of the 16-week treatment phase, cognitive therapy was significantly more effective on a composite measure of social anxiety than either combined treatment or placebo. Fluoxetine plus exposure was not significantly different than placebo plus exposure on this composite measure. All three treatment groups demonstrated a significant decrease in all measures, composite and individual, from baseline to posttreatment. All three treatment groups demonstrated significant improvement in mood measures from baseline to posttreatment, but there was no difference among the groups. These results are based on an intent-to-treat analysis.

Patients in the cognitive-therapy-only group and the fluoxetine-plus-exposure group were entered into the maintenance phase after the acute-treatment phase. The placebo-plus-exposure patients were withdrawn from the study. During the maintenance treatment, cognitive therapy patients received three monthly booster sessions. The fluoxetine-plus-exposure patients continued for 3 months on their full dose, which was then gradually tapered over 3 to 6 weeks. Measurements were again taken, and the results showed that the cognitive therapy patients maintained their treatment gains, and the fluoxetine-plus-exposure patients continued to improve. The cognitive therapy group continued to demonstrate significantly better outcome after the maintenance phase. These differences were also found at the 12-month follow-up: Cognitive therapy was superior to fluoxetine plus exposure on both composite and individual social anxiety measures.

The study authors also calculated effect sizes at posttreatment for the treatment groups: 2.14 for the cognitive therapy group, 0.92 for the fluoxetine group, and 0.56 for the placebo group. The maintenance phase effect size was 2.57 for the cognitive therapy group and 1.14 for the fluoxetine group. The 12-month follow-up effect size was 2.53 for the cognitive therapy group and 1.36 for the fluoxetine group.

In this trial, combined treatment was not better than monotherapy (cognitive therapy) in the treatment of generalized SAD, although significant improvement was demonstrated. Cognitive therapy was substantially more effective than self-directed exposure with or without fluoxetine.

The most recent study combining medication and CBT for generalized SAD was conducted by Blanco and colleagues (2010), who followed up on previous work using phenelzine alone and in combination with group CBT. The two-site study (conducted in New York and Philadelphia) randomized 166 adults aged 18 to 65 with SAD without a history of schizophrenia, bipolar disorder, current MDD or substance use disorder, previous treatment failure with phenelzine, and/or six or more CBT sessions. One hundred twenty-eight patients (New York, $n = 84$; Philadelphia, $n = 44$) were randomly assigned to one of four conditions: phenelzine alone ($n = 35$); group CBT alone ($n = 34$); combined phenelzine plus group CBT ($n = 32$); or pill placebo alone ($n = 27$). This four-phase trial included a 12-week acute-treatment phase, a 12-week intensive continuation phase, a 28-week maintenance phase, and a 12-month naturalistic follow-up phase.

The group CBT was conducted with four to six participants meeting weekly in 2.5-hour sessions led by two therapists for 12 weeks. Treatment included cognitive restructuring (awareness of relationship between anxiety and automatic thoughts and the rational alternatives) and role-playing of exposure to feared situations, followed by in vivo exposures. The

pharmacotherapy began with 15 mg of phenelzine or placebo per day for 3 days increased to 30 mg/day for 4 days, to 45 mg/day for week 2, up to 60 mg/day for weeks 3 and 4. If necessary for clinical progress, doses up to 75 mg/day for week 5 and as high as 90 mg/day for weeks 6 to 12 were permitted. All medication participants were told to expose themselves to feared situations, and that the medication would make that easier, but no specific instructions for practicing exposure were given. The patients receiving phenelzine and group CBT began medication and therapy at the same time. Both clinicians in that group were blind as to any other treatment, nor could clinicians discuss treatment with each other.

Measures for outcome included LSAS, CGI modified for SAD and HRSD as well as self-reports (FQ, Social Phobia Scale, Social Interaction Anxiety Scale, and Sheehan Disability Scale) collected at baseline and at weeks 6, 12, and 24. Response was defined as CGI score of 1 or 2 at week 12, while remission was defined as CGI score of 1 or 2 plus LSAS score of 30 or less.

There were no significant differences between groups at baseline except for the combined treatment group, which demonstrated less severity of SAD on several measures. Although there were some site differences in the demographic variables, these did not affect treatment outcome. There were also no significant differences among groups in the number of withdrawn subjects or for any demographic variables between those who continued and those who withdrew.

All primary and secondary outcome results demonstrated significant improvement in the phenelzine group and the combined group compared to placebo. The group CBT group was not significantly different from placebo. The odds ratio demonstrated that the combined group was 5.1 times more likely to improve compared to placebo, while the other three groups did not demonstrate significant odds of improving.

In the combined group 46.9% achieved remission based on CGI, while 22.1% of the phenelzine group, 8.8% of the group CBT group, and 7.4% of the placebo group remitted (the latter three groups were not significantly different from each other). Using the LSAS as outcome, the remission rates were as follows: combined group 59.4%; phenelzine 20%; group CBT 20.6%; and placebo 11.1%. The combined group was significantly better then the monotherapies which were not better than placebo or from each other. In this study, acute combined treatment was superior, followed by phenelzine alone, then group CBT, and then placebo. These same remission and response rates remained after the 12-week continuation phase.

The primary care RCT for SAD was conducted by Blomhoff and colleagues (2001) in Norway and Sweden. They randomly treated 387 socially anxious patients with sertraline or placebo. Half of those patients were randomly assigned to exposure therapy or general medical care. There were 98 patients in the sertraline-plus-exposure-therapy group, 98 in the placebo-plus-exposure-therapy group, 96 in the sertraline-plus-general-care group, and 95 in the placebo-plus-general-care group. All treatment was provided by medical practitioners who received training in diagnostic interviewing and exposure therapy.

One hundred thirty-five subjects from the sample had a comorbid diagnosis, but only 2% had comorbid dysthymia. Excluded diagnoses were history of bipolar disorder, psychosis, or panic disorder that began before social phobia, as well as current MDD, any other anxiety disorder, eating disorder, or substance use disorder.

Measures used to determine outcome were the SPS, the Clinical Global Impression-Social Phobia Scale (CGI-SP), and the MADRS. Diagnosis was assessed using the MINI. Clinicians in this study included 50 physicians who underwent a 30-hour training program to conduct the MINI and other rating scales, to make a reliable diagnosis of social phobia, and to conduct the exposure therapy component of the treatment. Training involved lectures, videotapes, manuals, and group supervision.

The sertraline treatment or placebo began with one pill daily (50-mg dose) for 4 weeks, and then the dosage was increased to 100 mg daily (two pills). At weeks 8 and 12, the dosage was again increased to a maximum of 150 mg if needed. The 12-week dosage was maintained through week 16 if tolerated. Patients were seen for nine visits over the 16 weeks of the study. Pharmacotherapy adherence was evaluated regularly through blood levels, as well as through pill counts.

The general medical care component of the study was based on NIMH guidelines for clinical management of mood disorders: general therapeutic support, reassurance and encouragement with some advice, and allowing the patient to express fears and concerns. No interpretations of patient behavior or specific behavioral instructions were allowed.

The exposure therapy component, conducted during eight 15- to 20-minute sessions over the first 12 weeks of the study, consisted of psychoeducation, with explanations of the treatment and the identified problems, and homework assignments and instructions for the patient to gradually expose himself or herself to feared situations outside the session meeting, using rating scales to measure the level of anxiety. The goal was for the patient to slowly decrease his or her anxiety as each exposure occurred. The physician's role throughout the 12 weeks of exposure therapy was to identify goals, to explore new coping strategies, and to support self-exposure.

Outcome was measured on three levels (responder, partial responder, and nonresponder) based on the CGI-SP and the SPS (self-report). Ratings were made at weeks 4, 8, 12, 16, and 24. Response criteria were a 50% reduction on SPS from baseline, a CGI-SP severity rating of 1 or 2, and a CGI-SP improvement rating of 1 or 2. Nonresponse criteria were less than a 25% reduction on SPS from baseline and a CGI-SP improvement rating of no change or worse (4 or higher). Partial response criteria were scores between response and nonresponse.

The protocol called for treatment withdrawal after 16 weeks if nonresponse occurred, and 44 (11%) patients were withdrawn. The intent-to-treat group consisted of 354 patients. There was a significant difference in response between those patients receiving sertraline and those receiving placebo, but only a trend toward significance between patients in the exposure group compared with the general care group ($p = 0.08$). The combined sertraline and exposure group had an intent-to-treat response rate of 40.8% ($n = 40$) and a completer response rate of 45.5%. The sertraline-only group had an intent-to-treat response rate of 36.4% and a completer response rate of 40.2%. The intent-to-treat response rate for both sertraline groups was 38.6%, and the completer response rate was 48.4%. The exposure-only intent-to-treat response rate was 30.6%, and the completer response rate was 33%. The combined treatment group had a trend toward significance compared with the exposure-only group ($p = 0.059$). In this primary care trial, sertraline, with or without exposure therapy, was effective in treating generalized SAD, and combined treatment was not more effective than sertraline alone.

Haug and colleagues conducted a 1-year follow-up after the termination of the 24-week treatment (2003). Of the 354 patients who were assessed at the 24-week period, 328 were evaluated 1 year later, 83 in the sertraline-plus-exposure group, 85 in the sertraline-plus-general-care group, 78 in the exposure-only group, and 82 in the placebo-plus-general-care group. All groups demonstrated a significant decrease from their baseline measures at the 1-year follow-up. The exposure-only group continued to improve from the 24-week assessment to the 1-year follow-up, with a significant change on the CGI-SP. The placebo group also showed improvement from the 24-week period to the 1-year follow-up on the CGI-SP. For the sertraline-plus-exposure and the sertraline-plus-general-care groups, there was a nonsignificant worsening on the CGI-SP at follow-up. On individual scales measuring aspects of social fear and avoidance, the exposure-only group also demonstrated continued improvement from the end of treatment to the 1-year follow-up. In addition, the placebo group demonstrated some of the same improvement, whereas there was again slight deterioration in the sertraline groups (nonsignificant).

One very important note must be considered when evaluating these data: 66 patients (20.5% of the sample) received some SSRI during the follow-up period, including those who had been assigned to a no-active-medication group. There were 13 (15.5%) in the sertraline-plus-exposure group, 18 (21.6%) in the sertraline-plus-general-care group, 14 (19.2%) in the exposure-only group, and 21 (19.5%) in the placebo group. This may account for the high rate of improvement in the placebo group and the lack of statistical significance in decreased improvement in the sertraline groups.

This RCT of generalized SAD in primary care demonstrated no greater efficacy for combined treatment than for monotherapy. There are some limitations to this research. The design did not allow for blinded evaluations of outcome; therefore, there may be some rater bias given the fact that the clinicians who conducted the treatments also made the response determinations. The exposure therapy, as conducted by physicians, differs somewhat from that conducted by trained psychiatric clinicians—the physicians directed the patients to do the exposures on their own, whereas psychiatric clinicians generally accompany the patients on many or at least some exposures, offering support and encouragement throughout the process. This often facilitates further exposures, many of which are self-directed in between

sessions. This may have accounted for the modest efficacy of exposure only.

The Blomhoff and Davidson data did not support the hypothesis that combined treatment was more effective than monotherapy in SAD, yet the Blanco study did. This difference may be attributable to the analytical method used by Blanco, an ordering or gradation of response from placebo to monotherapies to combined treatment using a linear-by-linear test. It might also be the use of a monoamine oxidase inhibitor versus an SSRI. In the Blanco study, group CBT was less efficacious than in other studies comparing monotherapies, with much lower remission rates than in the Hofmann trial described next. This lack of efficacy for group CBT is difficult to explain.

Hofmann and colleagues (2013) augmented CBT for SAD with DCS in an RCT with 169 participants at three sites, two in Boston and one in Dallas. Adults with generalized social anxiety with no history of bipolarity, psychosis, OCD, current eating disorder, substance use disorder, or PTSD were included. CBT was conducted in a group format for 12 sessions each lasting 2.5 hours. At session 3, participants were randomly assigned to 50 mg of DCS orally ($N = 87$) or pill placebo ($N = 82$) to be taken 1 hour in advance of the session. There were five exposure sessions augmented with DCS or placebo.

Measures included CGI and LSAS; response was defined as 1 or 2 on CGI-I, and remission was considered 1 or 2 on CGI plus LSAS score below 30. The response rates were 79.3% in the active group compared to 73.2% in the placebo group. The remission rates were 34.5% in the DCS group and 24.4% in the placebo group. Neither of these differences was significant. Although there was some evidence that DCS accelerated the response, by the end of treatment, there was no increased benefit for DCS in generalized SAD.

SUMMARY

According to an analysis of the national trends for outpatient treatment of anxiety disorders (Olfson, Marcus, Wan, & Geissler, 2004), the community rate of combined medication and psychotherapy treatment for any anxiety disorder was 27%, whereas the rate of combined antidepressant and psychotherapy treatment was 21%. For the most part, there is little evidence that combined psychosocial and medication therapy is superior to either alone in the treatment of mood and anxiety disorders over time. Exceptions to this are in MDD for adolescents and for those with five or more recurrent moderate to severe episodes as well as augmentation of CBT or IPT in partial responders and nonresponders.

In fact, in the case of PD and the study by Barlow and colleagues (2000), there was even evidence that adding medication to CBT impeded the success of CBT. One possible explanation for this is that long-term administration of antidepressant medication impairs learning, which interferes with the mechanism of action of CBT. This is consistent with some animal studies in which an SSRI interfered with extinction of conditioned fear learning (Burghardt et al., 2013).

Another explanation for the lack of superiority of combined treatments was suggested by Otto (2002), who postulated that medication forms a context in which learning occurs. In this case, the learning involves the gradual exposure to bodily sensations (interoceptive exposure) whereby the patient learns to be less fearful of these sensations. When the context is withdrawn, the benefit of what was learned may be diminished as well.

Although more research in the area of combined treatment for mood and anxiety disorders is surely needed, our review suggests that most patients with these disorders should be offered an evidence-based psychosocial intervention first, as these have been shown to be, for the most part, of at least equal efficacy and to have fewer adverse side effects than medication intervention. Medication would be a first-line therapy only in cases in which the patient prefers it to psychotherapy, qualified therapists are unavailable, or the severity of illness is such that more rapid onset of effect is needed. Finally, combined therapy would be used when a full course of evidence-based monotherapy is unsuccessful.

Treatments for Obsessive-Compulsive Disorder

Darin D. Dougherty
Scott L. Rauch
Michael A. Jenike

There is overwhelming evidence of the most rigorous type supporting the efficacy of serotonin reuptake inhibitors (SRIs) in the treatment of obsessive-compulsive disorder (OCD). Along with SRIs, behavior therapy must be considered a viable first-line therapy. The best available data suggest that behavior therapy, and perhaps cognitive therapy, is at least as effective as medication in some instances, and may be superior with respect to risks, costs, and enduring benefits. A variety of second-line medication treatments for OCD have been studied in a controlled or systematic fashion. Augmentation of SRIs with antipsychotics, buspirone, or clonazepam is provisionally recommended based on the available data. Other monotherapies and augmentation strategies find very limited support at present.

DIAGNOSTIC CRITERIA AND CLINICAL CHARACTERISTICS

OCD is a common condition, with lifetime prevalence estimates of approximately 2% to 3% in the United States and up to 5.5% worldwide (Angst, 1994; Karno, Golding, Sorenson, & Burnam, 1988; Rasmussen & Eisen, 1994). The hallmark signs and symptoms of OCD include intrusive unwanted thoughts (i.e., obsessions) and repetitive behaviors (i.e., compulsions; American Psychiatric Association [APA], 2013). Classic obsessions include violent, religious, or sexual themes, as well as preoccupations with contamination, pathological doubting or uncertainty, concerns with symmetry, and a general sense that something bad will happen if a particular ritual is not performed in precisely the right manner. Classic compulsions include washing, cleaning, counting, checking, repeating, and arranging behaviors. For most, the disease manifests itself as multiple obsessions and multiple compulsions (Rasmussen & Eisen, 1994). Experiencing occasional unwanted thoughts, performing repetitive or ritualistic behaviors, and having transient feelings of anxiety are all part of normal human experience. However, to meet the criteria for OCD, the symptoms must be sufficiently intense or frequent to cause marked distress or impair functioning. In fact, people with OCD are often severely impaired by the symptoms of their disease. Unlike psychosis, OCD is characterized by intact insight; because people with OCD recognize that their thoughts and behaviors are extreme or nonsensical, they are often embarrassed or ashamed of their condition and frightened that they may be "going crazy." In severe cases of OCD, insight can become tenuous as obsessions progress to overvalued ideas.

The differential diagnosis of OCD includes other psychiatric disorders that are characterized by repetitive thoughts or behaviors. For instance, the obsessions of OCD are to be distinguished from the ruminations

of major depression, the racing thoughts of mania, the psychotic thoughts of schizophrenia, and the preoccupation with food and body image associated with eating disorders. Likewise, the compulsions of OCD are to be distinguished from the tics of Tourette syndrome, the ritualized self-injurious behaviors of borderline personality disorder, the rhythmic movements that can present in autism or mental retardation, and the stereotypes of complex partial seizures. By definition, the diagnosis of OCD should not be made if the symptoms can be attributed to another disorder or are the consequence of substance use (APA, 2013).

A variety of disorders within *Diagnostic and Statistical Manual of Mental Disorders* (APA, 2013) are also characterized by repetitive symptoms (Hollander, 1993, Hollander et al., 1996; McElroy, Phillips, & Keck, 1994). The classification "OCD and Related Disorders" within DSM-5 has been coined to reflect the notion that a family of similar disorders may exist that share some common phenomenological, etiological, and perhaps pathophysiological characteristics. Such related disorders include Tourette syndrome (characterized by intrusive sensations and urges, as well as a drive to perform motor and vocal tics), hair pulling disorder/trichotillomania (characterized by compulsive hair pulling), skin picking disorder (characterized by compulsive skin picking), hoarding disorder (characterized by excessive accumulation of items), and body dysmorphic disorder (characterized by a preoccupation with certain aspects of one's own appearance). Comorbidity among the related disorders with OCD is common; in addition to other related disorders, frequently coexisting conditions include major affective disorders, anxiety disorders, and substance use disorders (Karno et al., 1988; Rasmussen & Eisen, 1994).

ETIOLOGY AND NEUROBIOLOGY

Although the cause of OCD remains unknown, family genetic studies suggest that OCD is a familial disorder (e.g., Black et al., 1992; Hettema et al., 2001; Nestadt et al., 2000; Pauls et al., 1995). Specifically, family genetic studies indicate that in some cases OCD seems to arise sporadically, whereas in others there exists an apparent familial relationship. A review of OCD twin studies (van Grootheest et al., 2005) concluded that OCD is heritable, with genetic influences ranging from 45% to 65% in children and from 27% to 47% in adults. Contemporary neurobiological models implicate dysfunction in one or another of several segregated corticostriatal pathways (Dougherty, Rauch, & Greenberg, 2010; Rauch, Whalen, Dougherty, & Jenike, 1998). OCD seems to involve subtle structural abnormalities in the caudate nucleus, as well as functional dysregulation of neural circuits comprising orbitofrontal cortex, cingulate cortex, and the caudate. Some research suggests that autoimmune processes, precipitated in some cases by beta-hemolytic streptococcal infection, may cause damage to striatal neurons in occasional sporadic childhood-onset cases of OCD and Tourette syndrome (Allen, Leonard, & Swedo, 1995; Swedo 1994; Swedo, Leonard, & Kiessling, 1994; Swedo et al., 1998). Neurochemically, serotonergic systems have been implicated in OCD (Rauch et al., 1998). Of note, however, some recent imaging studies have also implicated the dopaminergic system in OCD (Denys, van der Wee, Janssen, De Geus, & Westenberg, 2004b; Denys, Zohar, & Westenberg, 2004c), which resonates with emerging evidence supporting augmentation therapy with dopaminergic antagonist medications for OCD (e.g., Denys, de Geus, van Megen, & Westenberg, 2004a; McDougle, Epperson, Pelton, Wasylink, & Price, 2000).

HISTORICAL PERSPECTIVE

Descriptions of probable OCD date back to the 15th century, and up through the 1700s the malady was conceptualized in religious or supernatural terms (Hunter & Macalpine, 1982; Pitman, 1994). Treatments such as exorcism notwithstanding, clinical reports and attempts to medically or scientifically characterize OCD did not emerge until the late 1800s, when neurologists, including Georges Gilles de la Tourette (1885), described OCD symptoms in the context of movement disorders. In the early 1900s, other clinicians contributed eloquent phenomenological descriptions of obsessive-compulsive symptoms (Janet, 1903; Meige & Feindel, 1907), but little progress was made toward effective treatment of OCD. Freud's case of the Rat Man (1909/1924) introduced the application of psychodynamic principles in attempts to both understand and relieve what he termed *obsessional neurosis*.

It was not until 1967 that the tricyclic antidepressant clomipramine, the first available SRI, emerged

as an effective treatment for OCD (Fernandez & Lopez-Ibor, 1967). Contemporaneously, behavioral therapy for OCD was emerging as a viable treatment modality and the object of formal study (Rachman, Hodgson, & Marks, 1971). Interestingly, it was also in the 1960s that Ballantine and colleagues began their pioneering efforts to systematically study the safety and efficacy of anterior cingulotomy, a neurosurgical treatment for severe treatment-refractory OCD and other psychiatric illnesses (Ballantine, Bouckoms, Thomas, & Giriunas, 1987).

The subsequent quarter-century has seen great development in the assessment and treatment of OCD. Several educational and self-help books written for lay audiences (e.g., Baer, 1991; Rapoport, 1989), articles appearing in the general medical literature (Jenike, 1989), and the birth of an advocacy group (International OCD Foundation; http://www.ocfoundation.org) all contributed to a growing awareness of OCD. Whereas it had still been believed that OCD was a relatively rare disorder (approximately 0.1% lifetime prevalence), publication of the Epidemiological Catchment Area study results (Karno et al., 1988) surprised much of the psychiatric and public health community by suggesting that OCD had a lifetime prevalence of 2.6%, ranking it as the fourth most common psychiatric illness in the United States. In 1989, a collaborative group of investigators from Yale University and Brown University published studies reporting on the validation of a scale for quantifying the severity of OCD symptoms (Goodman et al., 1989b, 1989c). The Yale-Brown Obsessive Compulsive Scale (Y-BOCS) became the gold-standard measure for many of the clinical trials that followed. During this same era the pharmaceutical industry produced a new class of compounds known as *selective serotonergic reuptake inhibitors* (SSRIs) that, like clomipramine, acted by blocking serotonergic reuptake sites. Unlike clomipramine, however, these new SSRIs had much lower affinities for adrenergic and cholinergic receptors, presumably conferring upon them a more favorable side-effect profile. Investigators in psychopharmacology proceeded to systematically study these new agents, as well as other novel compounds, while their psychotherapist counterparts conducted investigations of cognitive and behavioral treatments. During the 1990s alone, there were more than 1,500 reports about drug treatments and OCD published in medical sources. Moreover, neuroscience advances have brought us closer to understanding the etiology and pathophysiology of OCD and related disorders.

CONTEMPORARY TREATMENT

Numerous reviews have been written regarding treatment recommendations for OCD (e.g., Dominguez & Mestre, 1994; Dougherty, Rauch, & Jenike, 2004, 2012; Goodman, McDougle, & Price, 1992; Jenike 1993a, 1993b, 1998; Jenike & Rauch, 1994; Montgomery 1994; Rauch & Jenike, 1994; Table 17.1). There is broad agreement among experts in the field that first-line treatments for OCD include SRIs (clomipramine or SSRIs) and/or behavior therapy. When these first-line interventions fail, second-line pharmacological approaches include augmentation of SRIs with additional medications or trials of alternative medications as monotherapies in place of SRIs. Third-line treatments may include experimental treatments such as unproven augmentation therapies or intravenous clomipramine if available (Fallon et al., 1992, 1998; Koran, Sallee, & Pallanti, 1997; Warneke, 1989). Finally, other nonpharmacological treatments, including deep brain stimulation (DBS), neurosurgery, and electroconvulsive therapy (ECT), have remained more controversial and are reserved for particular clinical situations or as treatments of last resort. In the following section, the scientific evidentiary basis for these various treatment recommendations is reviewed. Although the focus in this chapter is on psychopharmacology, the authors wish to explicitly emphasize that most experts view behavior therapy as a critical and effective first-line treatment for OCD, and that this brand of treatment is all too often overlooked or unavailable.

Measures of Symptom Severity and Treatment Response

Before reviewing the extensive database on clinical trials in OCD, it is worth considering the instruments available for measuring the severity of symptoms and clinical improvement. The tools for quantifying the dependent variables in these studies as well as the thresholds that are adopted to operationalize "treatment response" profoundly affect the results and interpretations of clinical research.

TABLE 17.1 Sample Treatment Recommendations for Obsessive-Compulsive Disorder

Treatment	*Dosage*	*Time Course*
First Line		
Behavior therapy		
Exposure and response prevention		At least 20 hours
Medication: Serial SRI trials (consider at least two SSRI trials and one of CMI)		
CMI	150–250 mg/day	12 weeks
Fluoxetine	40–80 mg/day	12 weeks
Sertraline	50–200 mg/day	12 weeks
Fluvoxamine	200–300 mg/day	12 weeks
Paroxetine	40–60 mg/day	12 weeks
Citalopram	40 mg/day	12 weeks
Escitalopram	20–30 mg/day	12 weeks
Second Line		
Modifications to behavior therapy		
Consider inpatient sessions; home visits or other in situ sessions; or cognitive therapy		
Medication: SRI augmentation		
Clonazepam	0.5–5 mg/day	4 weeks
Buspirone	15–60 mg/day	8 weeks
Antipsychotics		
Pimozide	1–3 mg/day	4 weeks
Haloperidol	0.5–10 mg/day	4 weeks
Risperidone	0.5–6 mg/day	4 weeks
Olanzapine	2.5–15 mg/day	4 weeks
Quetiapine	200-600 mg/day	4 weeks
Medication: Alternative monotherapies		
Clonazepam	0.5–5 mg/day	4 weeks
Buspirone	30–60 mg/day	6 weeks
Phenelzine	60–90 mg/day	10 weeks
Venlafaxine	To 375 mg/day	12 weeks
Duloxetine	To 120 mg/day	12 weeks
Third Line		
Alternative monotherapies without controlled data		
Alternative augmentation strategies without controlled data		
Fourth Line		
DBS		
Consider neurosurgery (only if OCD is longstanding, severe, debilitating, and unresponsive to an exhaustive array of other treatments)		

CMI = clomipramine; OCD = obsessive-compulsive disorder; SRI = serotonin reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

As noted above, the gold-standard instrument for quantifying OCD symptom severity is the Y-BOCS (Goodman et al., 1989b, 1989c), a rater-administered scale scored from 0 to 40, with high values reflecting more severe symptoms. The Y-BOCS comprises 10 elements, 5 elements about obsessions and 5 about compulsions (i.e., frequency/time consumed, interference, distress, resistance, and control over symptoms). Each element is rated from 0 to 4. Alternative contemporary rater-administered instruments include unidimensional global scales (Pato, Eisen, & Pato, 1994). The National Institute of Mental Health Global Obsessive Compulsive Scale (NIMH-GOCS; Insel et al., 1983) is a 15-point scale that has been shown to correlate with the Y-BOCS, although the descriptive anchor points of the NIMH-GOCS tend to emphasize elements of interference and resistance. Clinical Global Improvement (CGI; see Pato et al., 1994) scales represent another type of unidimensional rater-administered instruments that are commonly used in clinical trials, such as the 7-point CGI, with anchor points including 1 = very much improved, 4 = no change, and 7 = very much worse. The rater-administered CGI has also been shown to correlate well with the Y-BOCS and NIMH-GOCS; modified versions of the CGI can be self-administered by patients. Other self-administered instruments include the Leyton Obsessional Inventory (LOI; Cooper 1970) and the Maudsley Obsessive Compulsive Inventory (MOCI; Sternberger & Burns, 1990). As inventories, both consist of symptom-related and/or trait-related questions with binary response options (i.e., yes/no or true/false). Self-ratings can be particularly problematic in OCD, which, together with the fact that these scales are limited to specific symptom sets, makes them suboptimal for characterizing symptom severity or gauging clinical improvement in treatment trials (see Kim, Dysken, & Kuskowski, 1990; Pato et al., 1994).

Typically, for studies that report a percentage of responders, criteria for response might include decrease in Y-BOCS of at least 25% or 35%, and/or a CGI of 1 or 2. Therefore, it is important to appreciate that a substantial proportion of "responders" in these studies remain symptomatic and meaningfully affected by their residual illness.

First-Line Pharmacotherapy: Serotonin Reuptake Inhibitors

Currently, the SRIs are the first-line treatment for OCD (Dougherty & Rauch, 1997; Dougherty, Rauch, & Jenike, 2012). There is overwhelming evidence from multiple randomized, double-blind, placebo-controlled studies supporting the efficacy of SRIs in the treatment of OCD (Table 17.2). Specifically, in adults, well-designed and well-controlled trials have demonstrated the relative efficacy of clomipramine versus placebo, as well as the relative efficacy of SSRIs, including fluoxetine, sertraline, paroxetine, and fluvoxamine, versus placebo. Moreover, SRIs have been shown to be significantly more effective than non-SRI tricyclic antidepressants (TCAs) in placebo-controlled as well as non–placebo-controlled studies (Table 17.3). In the only randomized, double-blind, placebo-controlled study involving non-SRI TCAs, nortriptyline was not shown to be significantly more effective than placebo (Thoren, Asberg, Cronholm, Jornestedt, & Traskman, 1980; see Table 17.2), supporting the view that non-SRI TCAs are not an effective monotherapy for OCD.

Despite a wide range of observed SRI response rates, large-scale studies have generally yielded approximately 40% to 60% responders, with mean improvement in the active treatment group of approximately 20% to 40% (see Greist et al., 1995b). In terms of the relative efficacy among SRIs, a large-scale meta-analysis of multicenter trials of SRIs was performed by Greist and colleagues (1995c) in which clomipramine (n = 520), fluoxetine (n = 355), sertraline (n = 325), and fluvoxamine (n = 320) were all shown to be significantly superior to placebo. This meta-analysis further indicated that clomipramine might have superior efficacy over SSRIs. Although the meta-analysis by Greist and colleagues had many strengths, including that all studies used comparable parameters and were conducted at essentially the same centers, the results should be interpreted with caution. Since there was a serial progression in the availability of these agents and in the performance of these trials, clomipramine was studied on an SRI-naïve population, whereas each successive agent was undoubtedly tried on a cohort comprising a larger subpopulation of patients with histories of past SRI unresponsiveness. Consequently, each successive trial might well have been conducted on a more treatment-resistant population, biasing the efficacy in favor of agents studied in earlier years (i.e., clomipramine). In fact, a growing number of studies (see Table 17.3) and a comprehensive literature review (Pigott & Seay, 1999) suggest that the SRIs all have comparable efficacy. However, despite these group data, any single individual may respond very

TABLE 17.2 Placebo-Controlled Trials of Serotonin Reuptake Inhibitor Therapy for Obsessive-Compulsive Disorder (Adults)

Treatment Conditions	*N*	*Comments*	*Study*
CMI vs. placebo	20	CMI significantly superior to placebo	Karabanow (1977)
CMI vs. placebo crossover	14	CMI significantly superior to placebo	Montgomery (1980)
CMI vs. nortriptyline vs. placebo	24	CMI, but not nortriptyline, superior to placebo	Thoren et al. (1980)
CMI vs. placebo	12	CMI significantly superior to placebo	Mavissakalian et al. (1985)
CMI vs. placebo	27	CMI significantly superior to placebo	Jenike et al. (1989)
CMI vs. placebo	32	73% improved on CMI; 6% improved on placebo	Greist et al. (1990)
CMI vs. placebo	239	38% average decrease in symptoms with CMI 3% average decrease in symptoms with placebo	CMI collaborative group (1991)
CMI vs. placebo	281	44% average decrease in symptoms with CMI 5% average decrease in symptoms with placebo	CMI collaborative group (1991)
CMI vs. placebo	36	CMI significantly superior to placebo	Foa et al. (2005)
CMI vs. venlafaxine	47/26	50% CMI responders; 36% venlafaxine responders; no statistically significant difference	Albert et al. (2002)
CMI vs. fluvoxamine	227	Both effective with no statistically significant difference	Mundo et al. (2001)
CMI vs. fluvoxamine	65/68	Both effective with no statistically significant difference	Mundo et al. (2000)
Sertraline vs. placebo	87	Sertraline significantly superior to placebo	Chouinard et al. (1990)
Sertraline vs. placebo	19	Sertraline significantly superior to placebo	Jenike et al. (1990a)
Sertraline vs. placebo	325	Sertraline significantly superior to placebo	Greist et al. (1995a)
Sertraline vs. placebo	167	Sertraline significantly superior to placebo	Kronig et al. (1999)
Sertraline vs. fluoxetine	77/73	Equivalent improvement on Y-BOCS; higher proportion of remission with sertraline	Bergeron et al. (2002)
Sertraline vs. desipramine	166	Sertraline significantly superior to desipramine	Hoehn-Saric et al. (2000)
Fluvoxamine vs. placebo	16	Fluvoxamine significantly superior to placebo	Perse et al. (1987)
Fluvoxamine vs. placebo	42	Fluvoxamine significantly superior to placebo	Goodman et al. (1989a)
Fluvoxamine vs. placebo	38	Fluvoxamine significantly superior to placebo	Jenike et al. (1990b)
Fluvoxamine vs. placebo	160	Fluvoxamine significantly superior to placebo	Goodman et al. (1996)
Fluvoxamine vs. BT vs. placebo	31	BT superior to fluvoxamine, which was superior to placebo	Nakatani et al. (2005)
Fluvoxamine CR vs. placebo	153	Fluvoxamine controlled release (CR) significantly superior to placebo	Hollander et al. (2003e)
Fluoxetine vs. placebo	355	Fluoxetine (20, 40, 60 mg) significantly superior to placebo Fluoxetine (40, 60 mg) significantly superior to placebo; 20-mg effects equal to placebo	Tollefson et al. (1994b)

TABLE 17.2 (continued)

Treatment Conditions	*N*	*Comments*	*Study*
Fluoxetine vs. placebo	217	Paroxetine (40, 60 mg) significantly superior to placebo; 20-mg effects	Montgomery et al. (1993)
Paroxetine vs. placebo	348	equal to placebo	Wheadon et al. (1993)
Paroxetine vs. venlafaxine	75/75	Equally efficacious	Denys et al. (2003)
Citalopram vs. placebo	401	Citalopram (20, 40, 60 mg) significantly superior to placebo	Montgomery et al. (2001)
Escitalopram vs. paroxetine vs. placebo	466	Escitolpram (20 mg, 10 mg) & paroxetine (40 mg) significantly superior to placebo	Stein et al. (2007)

BT = behavior therapy; CMI = clomipramine.

well to one or two agents of the SRI medications and not the others. Thus, serial trials of each agent may be required to determine which drug is best.

Data regarding duration of treatment, optimal dose, and adverse side effects are also plentiful but difficult to interpret with confidence because studies were often not designed to specifically answer these questions. The collective wisdom, purportedly supported by the data from the multicenter trials as well as anecdotal clinical experience, has been that response to SRIs is typically delayed such that an adequate trial of an SRI requires at least 10 weeks' duration. Indeed, a meaningful proportion of responders continue to emerge past the 8-week mark in these studies, as well as in anecdotal clinical experience. Experts also suggest that optimal doses of SRIs for OCD may exceed those typically used for major depression (e.g., Montgomery et al., 1993), although the dose-comparison studies of OCD have not always shown significant dose-dependent responses across the OCD study population (e.g., Greist et al., 1995a). As for adverse side effects, although the meta-analysis by Greist and colleagues (1995c) did not find any significant difference between medication groups regarding dropout rates due to adverse side effects, this is a relatively insensitive measure of adverse side-effect profile. Also, the aforementioned cohort effects apply for adverse side effects as well; subjects participating in the early clomipramine trials may have viewed that agent as the only available course of treatment, whereas subjects in later SSRI trials may have been aware of the wider variety of available treatments, making them less willing to endure nuisance adverse side effects. Clearly, as with other TCAs, the risks and adverse side effects mediated by anticholinergic and antiadrenergic mechanisms (e.g., constipation, cardiac conduction disturbances, orthostatic hypotension) are more commonly associated with clomipramine than with SSRIs. Furthermore, clomipramine is believed to pose a significant risk with regard to lowering seizure threshold. All SRIs can pose risks (e.g., serotonergic syndrome) and produce a variety of adverse side effects (e.g., nausea, sleep disturbances, sexual disturbances) attributable to their primary mechanism of action via serotonergic reuptake blockade (Grimsley & Jann, 1992). There is no substantive evidence that any SRI is significantly superior or inferior to any other with regard to serotonergically mediated adverse side effects.

Although many clinicians use SRIs as a long-term treatment for OCD, few controlled studies of long-term pharmacotherapy of OCD have been conducted. While most open studies have demonstrated high relapse rates of OCD symptoms within weeks of discontinuation (Pato, Zohar-Kaduch, Zohar, & Murphy, 1988; Thoren et al., 1980), one open-label study of SRI discontinuation found that only 23% of patients relapsed within 1 year (Fontaine & Chouinard, 1989). One randomized, double-blind study incorporating substitution of desipramine for clomipramine in a crossover design found that 89% of patients in the substituted group encountered relapse during a 2-month period (Leonard et al., 1991). More

TABLE 17.3 Non–Placebo-Controlled Trials of Drug Therapy for Obsessive-Compulsive Disorder (Adults)

Treatment Conditions	*N*	*Comments*	*Study*
CMI vs. amitriptyline	20	CMI significantly superior to amitriptyline	Ananth et al. (1981)
CMI vs. amitriptyline	39	95% improved on CMI 56% improved on amitriptyline	Zhao (1991)
CMI vs. clorgyline	13	CMI effective; clorgyline ineffective	Insel et al. (1983)
CMI vs. clorgyline	12	CMI superior to clorgyline	Zahn et al. (1984)
CMI vs. doxepin	32	78% markedly improved on CMI 36% markedly improved on doxepin	Cui (1986)
CMI vs. fluvoxamine	6	Comparable efficacy	Den Boer et al. (1987)
CMI vs. fluvoxamine	66	Comparable efficacy	Freeman et al. (1994)
CMI vs. fluvoxamine	79	Comparable efficacy	Koran et al. (1996)
CMI vs. fluvoxamine	26	Comparable efficacy	Milanfranchi et al. (1997)
CMI vs. fluvoxamine	133	Comparable efficacy	Mundo et al. (2000)
CMI vs. fluoxetine	11	Comparable efficacy	Pigott et al. (1990)
CMI vs. fluoxetine	55	Comparable efficacy	Lopez-Ibor et al. (1996)
CMI vs. imipramine	16	CMI superior to imipramine	Volavka et al. (1985)
CMI vs. imipramine crossover	12	CMI superior to imipramine	Lei (1986)
CMI vs. paroxetine	406	Comparable efficacy	Zohar et al. (1996)
CMI vs. sertraline	168	Comparable efficacy (fewer dropouts with sertraline)	Bisserbe et al. (1995)
Fluvoxamine vs. desipramine	40	Fluvoxamine superior to desipramine	Goodman et al (1990)
Fluvoxamine vs. paroxetine vs. citalopram	30	Comparable efficacy	Mundo et al. (1997b)
Citalopram	29	76% improved in 24-week open-label trial	Koponen et al. (1997)
Citalopram	18	14 of 18 showed reduced Y-BOCS score in open-label trial	Marazziti et al. (2001)
Venlafaxine	39	69% improved in open-label trial	Hollander et al. (2003c)

CMI = clomipramine.

recently, four placebo-controlled relapse-prevention studies have been conducted. One study assigned responders to fluoxetine to either continued treatment with fluoxetine ($n = 36$) or placebo ($n = 35$) and found 1-year relapse rates of 17.5% and 38%, respectively (Romano, Goodman, Tamura, & Gonzales, 2001). Another study assigned responders to sertraline to either continued treatment with sertraline or placebo and found relapse rates of 21% versus 59%, respectively (Koran, Hackett, Rubin, Wolkow, & Robinson, 2002). One study found that paroxetine responders assigned to continued treatment with paroxetine or placebo exhibited relapse rates of 38% versus 59%, respectively (Hollander et al., 2003a). Lastly, one study found that escitalopram responders assigned to continued treatment with escitalopram or placebo exhibited relapse rates of 23% versus 52%, respectively, at 24 weeks (Fineberg et al., 2007). Some investigators have proposed using lower doses of SRIs for OCD maintenance treatment based on open-label trials (Pato, Hill, & Murphy, 1990; Ravizza, Barzega, Bellino, Bogetto, & Maina, 1996), and two controlled studies have demonstrated the efficacy of this approach (Mundo et al., 1997a; Tollefson, Birkett, Koran, & Genduso, 1994a). Thus, the data suggest that discontinuing SRIs in patients with OCD

results in a high relapse rate, although there is still some debate regarding maintenance dosages of SRIs.

In addition to the above data regarding pharmacotherapy for OCD in adults, there are analogous studies in children and adolescents documenting the efficacy of CMI over non-SRI TCAs as well as placebo (Table 17.4). There are a number of placebo-controlled studies of SSRIs for OCD in children, which likewise support the efficacy of SRIs in treating OCD in children. A meta-analysis suggests that clomipramine may be superior to the SSRIs in treating pediatric OCD (Geller et al., 2003).

Second-Line Pharmacotherapy: Serotonin Reuptake Inhibitor Augmentation and Alternative Monotherapies

For patients who do not derive satisfactory reduction of symptoms with SRI therapy, second-line pharmacological treatments include SRI augmentation and alternative monotherapies. It is important to appreciate that only a minority of patients with OCD do not respond favorably to SRIs and that this relatively treatment-resistant group may be quite heterogeneous, including with respect to underlying pathophysiology. Therefore, specific subsequent treatments may be very effective for some subset of this population while having only modest mean efficacy for the overall cohort. Consequently, some second-line treatment trials have focused on the number or proportion of patients who meet responder criteria rather than the mean decrease in symptom severity over the entire study population. Moreover, in some instances, attention has been focused on the clinical characteristics that might distinguish responders from nonresponders.

Augmentation of Serotonin Reuptake Inhibitors

Numerous agents have been tried as augmenting agents in combination with SRIs for patients who were unresponsive or only partially responsive to SRIs alone (see Dougherty et al., 2004; Jenike, 1998; McDougle & Goodman, 1997). However, few controlled trials of such strategies have been conducted (Table 17.5). Despite numerous case reports

TABLE 17.4 Controlled Trials of Serotonin Reuptake Inhibitor Therapy for Obsessive-Compulsive Disorder (Children and Adolescents)

Treatment Conditions	*N*	*Comments*	*Study*
CMI vs. desipramine vs. placebo	8 adolescents	No significant differences crossover	Rapoport et al. (1980)
CMI vs. placebo cross-over	14 children	CMI superior to placebo	Flament et al. (1985a, 1985b)
CMI vs. desipramine	48	CMI superior to desipramine; 64% of patients relapsed when desipramine substituted for CMI	Leonard et al. (1988)
CMI substituted with desipramine in half of subjects	26	89% receiving desipramine relapsed 18% remaining on CMI relapsed	Leonard et al. (1991)
CMI vs. placebo	61	37% average decrease with CMI 8% average decrease with placebo	DeVeaugh-Geiss et al. (1992)
Fluoxetine vs. placebo	14 children	Fluoxetine superior to placebo	Riddle et al. (1992)
Sertraline vs. placebo	187	Sertraline superior to placebo	March et al. (1998)
Fluoxetine vs. placebo	43	Fluoxetine superior to placebo	Liebowitz et al. (2002)
Fluoxetine vs. placebo	103	Fluoxetine superior to placebo	Geller at al. (2001)
Sertraline, BT, combination of sertraline and BT, or placebo	112	Combined > BT = sertraline > placebo	POTS Team (2004)
Fluvoxamine vs. placebo	120	Fluvoxamine superior to placebo	Riddle et al. (2001)

CMI = clomipramine.

TABLE 17.5 Serotonin Reuptake Inhibitor Augmentation Therapies for Obsessive-Compulsive Disorder: Controlled Trials

Augmenting Agent	*SRI*	*N*	*Trial*	*Results*	*Study*
Lithium	Fluvoxamine	30	2- or 4-week double-blind placebo-controlled	Very little improvement	McDougle et al. (1991)
Lithium	CMI	9	Double-blind crossover (with T3)	None	Pigott et al. (1991)
L-triiodo-thyronine (T3)	CMI	9	Double-blind crossover (with lithium)	None	Pigott et al. (1991)
Buspirone	CMI	14	2-week placebo, then 10-weeks buspirone	4/14 (29%) improved an additional 25% on buspirone; 3/14 (21%) worsened >25% on depression scores	Pigott et al. (1992a)
Buspirone	Fluoxetine	14	Double-blind crossover with placebo; 4 weeks per treatment condition	1/14 (7%) improved significantly more with buspirone	Grady et al. (1993)
Haloperidol	Fluvoxamine	34	Double-blind placebo-controlled, with 17 per group; 4-week trial; after failing fluvoxamine alone	11/17 (65%) responded to haloperidol; 0/17 to placebo; 8/8 with tics responded to haloperidol	McDougle et al. (1994)
Clonazepam	CMI or fluoxetine	16	Placebo-controlled, crossover; 4-week trial; after 20-week stable dose on CMI or fluoxetine	Significant improvement in OCD on one of three measures for clonazepam vs. placebo; significant improvement in global anxiety as well	Rauch & Jenike (1994)
Clonazepam	Sertraline	37	Placebo-controlled,	No significant difference	Crockett et al. (2004)
Pindolol	Paroxetine	14	Double-blind, placebo-controlled, 4-week trial after ~17 weeks stable dose of paroxetine	Significant ($p<0.01$) improvement in YBOCS	Dannon et al. (2000)
Risperidone	SRI	36	Double-blind, placebo-controlled; 6-week trial after 12 weeks on SRI	50% responders; significant ($p < .001$) reduction in Y-BOCS	McDougle et al. (2000)
Risperidone	SRI	16	Double-blind, placebo-controlled; 8-week trial after at least 12 weeks on SRI	40% responders	Hollander et al. (2003b)
Risperidone	SRI	16	Double-blind, placebo-controlled; 2-week crossover trial with haloperidol	Both risperidone and haloperidol superior to placebo	Li et al. (2005)

TABLE 17.5 (continued)

Augmenting Agent	*SRI*	*N*	*Trial*	*Results*	*Study*
Olanzapine	Fluoxetine	44	Placebo controlled; 6-week trial after 8 weeks on fluoxetine	No significant difference	Shapira et al. (2004)
Olanzapine	SRI	26	Double-blind, placebo-controlled; 6-week trial	Significant improvement of Y-BOCS	Bystritsky et al. (2004)
Quetiapine	SRI	40	Double-blind, placebo-controlled; 8-week trial	Quetiapine superior to placebo	Denys et al. (2004a)
Quetiapine	SRI	42	Double-blind, placebo-controlled, 6-week trial	No significant difference between quetiapine and placebo	Carey et al. (2005)
Quetiapine	SRI	27	Single-blind, placebo-controlled; 8-week trial	9/14 in active group had 60% or greater decrease in Y-BOCS score; no improvement with placebo	Atmaca et al. (2002)
Quetiapine	SRI	76	Double-blind, placebo-controlled, 10-week trial	Quetiapine superior to placebo	Vulink et al. (2009)
Quetiapine	SRI	40	Double-blind, placebo-controlled, 12-week trial	No significant difference between quetiapine and placebo	Kordon et al. (2008)

CMI = clomipramine; SRI = serotonin reuptake inhibitor.

suggesting that lithium might be an effective augmenting agent in combination with various SRIs, the only two controlled trials of lithium, added to fluvoxamine (McDougle et al., 1991) and clomipramine (Pigott et al., 1991), respectively, speak against the efficacy of these combinations.

Similarly, the encouraging results from case series and uncontrolled trials of buspirone augmentation (see Dougherty et al., 2004; Jenike, 1998; McDougle & Goodman, 1997) were followed by only marginal success in controlled trials. In Pigott and colleagues' (1982) study of buspirone plus clomipramine, despite a 29% responder rate, there was not significant improvement over the entire cohort with respect to OCD symptoms, and 3 of 14 subjects experienced an exacerbation of more than 25% on measures of depression, for unclear reasons. In Grady and colleagues' (1993) double-blind crossover study of buspirone augmentation of fluoxetine, only 1 of 14 subjects showed improvement, which may have reflected the brief duration of treatment (only 4 weeks in each phase). Finally, McDougle and colleagues (1993b) found greater improvement with placebo than with buspirone in a double-blind, placebo-controlled study of buspirone augmentation of fluvoxamine for 6 weeks.

Contrary to a small case series reporting unimpressive results (Jenike, 1998), the use of clonazepam as an augmenting agent with clomipramine or fluoxetine has been studied in a placebo-controlled fashion, with some studies suggesting significant antiobsessional efficacy as well as a nonspecific decrease in anxiety measures (Pigott, L'Heueux, Rubenstein, Hill, & Murphy, 1992b; see Rauch & Jenike, 1994) and another study finding no significant difference when compared with placebo (Crockett, Churchill, & Davidson, 2004).

The most impressive augmentation data document the benefits of adding low doses of dopamine antagonists (both first-generation and second-generation antipsychotic medications) to SRI pharmacotherapy in patients with

treatment-refractory OCD (McDougle et al., 1990, 1994, 2000). Some data (McDougle et al., 1993a) initially suggested that OCD patients with comorbid tics may be less responsive to SRI monotherapy than OCD patients without tics. More recent studies have demonstrated the efficacy of SRI augmentation with antipsychotics in OCD patients with and without comorbid tics (McDougle et al., 2000). Although initial studies demonstrated the efficacy of SRI augmentation with first-generation antipsychotics, more recent controlled studies of augmentation with second-generation antipsychotics have yielded encouraging results as well. Three controlled trials of risperidone augmentation of an SRI (Hollander, Baldini, Rossi, Sood, & Pallanti, 2003; Li et al., 2005; McDougle et al., 2000) demonstrated efficacy. Of two controlled trials of olanzapine augmentation, one study (Bystritsky et al., 2004) yielded positive results but the other (Shapira et al., 2004) did not. Finally, three controlled studies (Atmaca, Kuloglu, Tezcan, & Gecici, 2002; Denys et al., 2004a; Vulink et al., 2009) of quetiapine augmentation yielded positive results, while two others (Carey et al., 2005; Kordon et al., 2008) did not. It is worth mentioning that, although second-generation antipsychotics are efficacious as SRI augmentation agents, they are ineffective when used as monotherapy and may even precipitate or worsen OCD symptoms when used as monotherapy (for review, see Lykouras et al., 2003)

Numerous other agents have been tried in combination with SRIs, including clonidine, tryptophan, fenfluramine, pindolol, riluzole, trazodone, and nortriptyline, as well as other antidepressants (see Dougherty et al., 2004; Jenike, 1998; McDougle & Goodman, 1997, for reviews). The small number of subjects, lack of sufficient controls, and mixed results preclude drawing even preliminary conclusions regarding the potential efficacy of such strategies. If an augmenting agent is indicated for treatment of some comorbid condition (e.g., lithium for bipolar disorder, trazodone for insomnia, or clonidine for Tourette syndrome) and no strong contraindication is present, then a trial of the agent in combination with an SRI is easily rationalized. Anecdotally, these strategies have appeared to be of tremendous benefit in some isolated cases. No studies have sought to establish the optimal dosage or duration of treatment for any of these augmentation strategies. Therefore, current guidelines reflect the parameters used in the reported successful trials, as well as anecdotal experience with OCD and other psychiatric disorders.

Alternative Monotherapies

For patients who fail to derive satisfactory response from trials of SRIs alone as well as augmentation strategies, the next recommended step is to consider alternative monotherapies in place of SRIs. In addition to uncontrolled data, positive controlled studies lend some support for trials of clonazepam, monoamine oxidase inhibitors (MAOIs), and buspirone (Table 17.6).

In the case of clonazepam, one placebo-controlled study (Hewlett, Vinogradov, & Agras, 1992) supports its efficacy in OCD, and another placebo-controlled study failed to demonstrate efficacy in OCD (Hollander, Kaplan, & Stahl, 2003). If clonazepam is used as a monotherapy for OCD, recommendations regarding dosage (i.e., 0.5 to 5 mg/day) and duration (i.e., 4 weeks or longer) have no controlled empirical basis and are simply extrapolated from clinical experience with benzodiazepines for other anxiety disorders and these few reports in OCD.

Non–placebo-controlled studies involving the MAOI clorgyline speak against its efficacy in OCD, showing no significant decrease in OCD severity (Insel et al., 1983) and inferior efficacy in comparison to SRIs (Insel et al., 1983; Zahn, Insel, & Murphy, 1984). In contrast, small case series suggested beneficial results from the MAOI phenelzine in patients with comorbid OCD and panic disorder (Jenike, Surman, Cassem, Zusky, & Anderson, 1983). A non–placebo-controlled study of phenelzine versus clomipramine suggested significant clinical improvement in both groups and no significant difference in efficacy between the two agents (Vallejo et al., 1992). The results of Vallejo and colleagues must be interpreted with caution, however, since the study was underpowered to identify a difference between clomipramine and phenelzine, and suboptimal clinical measures of improvement were employed. In fact, a subsequent placebo-controlled trial of phenelzine and fluoxetine demonstrated that patients treated with fluoxetine improved significantly more than those in the placebo or phenelzine groups (Jenike et al., 1997). This study did note that a subgroup of patients with symmetry obsessions did respond to phenelzine, however. Therefore, the efficacy of

TABLE 17.6 Alternative Medications as Monotherapies for Obsessive-Compulsive Disorder: Controlled Trials

Treatment Conditions	*N*	*Comments*	*Study*
Clorgyline vs. CMI	13	Clorgyline ineffective; CMI effective	Insel et al. (1983)
Clorgyline vs. CMI	12	Clorgyline inferior to CMI	Zahn et al. (1984)
Phenelzine vs. CMI	30	Both effective and comparable	Vallejo et al. (1992)
Clonazepam vs. CMI vs. Clonidine vs. active placebo crossover	25	35% average decrease with clonazepam; clonazepam comparable to CMI and superior to active placebo	Hewlett et al. (1992)
Clonazepam vs. placebo	27	No significant difference	Hollander et al. (2003d)
Buspirone vs. CMI crossover	20	Both effective and comparable, 20% improvement in 55% in both groups	Pato et al. (1991)
Fluoxetine vs. phenelzine vs. placebo	64	Fluoxetine group improved significantly more than phenelzine or placebo groups	Jenike et al. (1997)
Trazodone vs. placebo	21	No significant difference	Pigott et al. (1992b)

CMI = clomipramine.

phenelzine as a monotherapy for OCD should be regarded as provisional. Specific recommendations regarding dosage (i.e., phenelzine 60 to 90 mg/day) have little empirical basis, reflecting extrapolation from clinical practice with MAOIs for major depression and panic disorder; the duration of trials (i.e., 4 weeks or longer) mirrors that of SRIs for OCD. In addition to the usual low-tyramine diet and other precautions typically indicated in the context of an MAOI trial, it is critical to be cautious regarding the transition from serotonergic medications to an MAOI due to the risks of dangerous interactions, including serotonergic crisis. Current guidelines are based primarily on the half-life of the agents involved rather than direct empirical data related to adverse events per se. Conservative recommendations are washout periods of at least 2 weeks when transitioning from clomipramine or a short-half-life SSRI to an MAOI, at least 5 weeks when transitioning from fluoxetine to an MAOI, and at least 2 weeks when transitioning from phenelzine to an SRI.

Although one open trial of buspirone did not yield significant antiobsessional benefit (Jenike & Baer, 1988), a controlled trial of buspirone versus clomipramine suggested that both were comparably effective (Pato et al., 1991). The relatively short duration of the trial, the modest power for detecting a difference between treatments, and the absence of a placebo group mitigate against drawing firm conclusions from Pato and colleagues' study. Still, given the excellent tolerability of buspirone, other circumstantial evidence of possible efficacy as an augmenting agent, and its general efficacy as an anxiolytic, the clinical use of buspirone as an alternative monotherapy for cases of treatment-resistant OCD seems justified pending further information. Specific recommendations regarding dosage (i.e., up to 60 mg/day) and duration of trials (i.e., 6 weeks or longer) have little empirical basis, simply reflecting the protocol adopted in the study by Pato and colleagues.

Because the serotonin-norepinephrine reuptake inhibitors (SNRIs; venlafaxine, desvenlafaxine, and duloxetine) have serotonin reuptake inhibition properties, one would expect that the SNRIs might be efficacious in the treatment of OCD. However, no controlled studies of SNRIs for the treatment of OCD have been reported. A recent review of the literature (Dell'Osso et al., 2006) finds that the data that are available suggest that SNRIs seem to be as effective as SRIs in treating OCD. Nonetheless, controlled trials are needed.

Another exciting target for OCD pharmacology is the glutamatergic system (for review, see Pittenger et al., 2006). Some preliminary findings worthy of mention include small trials of positive results with memantine (Aboujaoude et al., 2009; Feusner et al., 2009), as well as riluzole (Pittenger et al., 2008). Agents targeting opioid receptors have shown promise as well, including a short report of tramadol (Goldsmith, Shapira, & Keck, 1999), as well as a controlled trial suggesting that oral morphine may

be effective for treating refractory OCD (Koran et al., 2005). Lastly, controlled trials have failed to demonstrate the efficacy of trazodone (Pigott et al., 1992a), clonidine (Hewlett, Vinogradov, & Agras, 1992), and diphenylhydramine (Hewlett et al., 1992) as monotherapies for OCD.

Nonpharmacological Therapies

Behavior Therapy

The gold-standard mode of behavior therapy for OCD is exposure and response prevention. This entails the patient actually being exposed to provocative stimuli (e.g., touching a "contaminated" object) and refraining from carrying out his or her usual compulsions (e.g., hand washing)—that is response prevention. It appears that in vivo exposure and response prevention represent the salient elements of effective behavior therapy regardless of setting, supervision, or addition of cognitive techniques.

There are numerous partially controlled trials of exposure and response prevention behavior therapy that have consistently shown impressive antiobsessional efficacy, with improvement in 75% to 85% of patients but with dropout rates as high as 20% to 30% (Foa, 2010; Simpson et al., 2006). Follow-up studies suggested that treatment gains were maintained for up to 1 to 5 years after discontinuation of active treatment, although these results were confounded by occasional "booster" sessions (Marks, 1981; Marks et al., 1975; Mawson, Marks, & Ramm, 1982). A meta-analysis (Christensen, Hadzi-Pavlovic, Andrews, & Mattick, 1987; Quality Assurance Project, 1985) based on data from 38 studies between 1961 and 1984 found comparable effect sizes for clomipramine (1.7) and behavior therapy (1.8) at the end of treatment; the benefits from exposure and response prevention persisted at a mean 80-week follow-up (effect size = 1.7), whereas no such follow-up data were available for clomipramine. In contrast, psychosurgery resulted in an effect size of 1.4 and dropped to 1.0 at the 60-week follow-up. In a separate study, Pato and colleagues (1988) showed that almost 90% of patients who received clomipramine for OCD relapsed after discontinuation of the medication. Thus, pending well-controlled head-to-head studies, based on partially controlled data and the limited method of meta-analysis, the implication is that in comparison with clomipramine or psychosurgery, behavior therapy may produce the highest mean effect size and the most enduring gains following discontinuation of active treatment.

Only a small number of studies directly comparing behavior therapy and medication have been reported. Rachman and colleagues (1979) found behavior therapy to significantly outperform clomipramine and did not find significant incremental benefit from the two treatments in combination. This study is limited, however, in that the clomipramine condition entailed relatively low doses (mean, 164 mg/day; maximum, 225 mg/day) as well as inadequate duration of clomipramine treatment (6 weeks). In another head-to-head comparison of behavior therapy and clomipramine, medication was found to be more effective for reducing obsessional doubt, whereas behavior therapy was more effective for reducing compulsive rituals (Solyom & Sookman, 1977). In practice, medication and behavior therapy are routinely used in concert, and experts in the field have long recommended this as an optimal treatment approach (e.g., Baer & Minichiello, 1990; Rauch & Jenike, 1994). Numerous studies (Honagen et al., 1998, Marks, Stern, Mawson, Cobb, & McDonald, 1980; Marks et al., 1988; O'Connor et al., 1999) have demonstrated that the combination of behavioral therapy and medication is more effective than either treatment alone, whereas two studies (Foa et al., 2005; van Balkom et al., 1998) found that the addition of SRIs to patients being treated with either cognitive therapy or exposure and response prevention was not superior to either cognitive therapy or exposure and response prevention used in patients not taking medication.

Beyond exposure and response prevention, limited trials of alternative behavioral methods have supported the use of imaginal flooding for checkers (Steketee, Foa, & Grayson, 1982) and "thought stopping" for patients with pure obsessions (Rimm & Masters, 1974). Moreover, cognitive therapy can also be effective for OCD (see Abramowitz, Taylor, & McKay, 2005). Finally, although controlled data are not currently available regarding cognitive-behavioral therapy for OCD in children and adolescents, preliminary findings of open trials and case reports suggest that, with age-appropriate modifications to the

regimen, results can be comparable to those in adults (Franklin et al., 1998; March, 1995; March, Mulle, & Herbel, 1994; Scahill, Vitulano, Brenner, Lynch, & King, 1996).

Deep Brain Stimulation

DBS, which uses surgically implanted electrodes that may be turned on and off to stimulate or inhibit activity in surrounding brain tissue, has been used for decades to treat neurological diseases such as Parkinson's disease and intractable pain (Devinsky, Beric, & Dogali, 1994). The first use of DBS for psychiatric illness reported that three out of four patients with intractable OCD were clinically improved following DBS in which the electrodes were directed at the same target as that used for neurosurgical anterior cingulotomy (see below), specifically in the anterior limb of the internal capsule (Nuttin et al., 1999). Subsequently, the worldwide experience regarding the efficacy of DBS for the treatment of OCD (see Greenberg et al., 2010) has been reported as the target migrated posteriorly to the current DBS target, the ventral capsule/ventral striatum (VC/VS). The worldwide data demonstrated that 67% to 75% patients with OCD who had not significantly improved with all conventional treatments did ultimately respond to DBS at the VC/VS target. These data resulted in U.S. Food and Drug Administration approval of DBS at the VC/VS target for treatment-refractory OCD in 2009.

Neurosurgery

Despite a large body of uncontrolled data reporting antiobsessional benefits from a variety of neurosurgical procedures (see Cosgrove & Rauch, 1995; Jenike, Rauch, Baer, & Rasmussen, 1998; Mindus et al., 1994, for reviews), thus far ethical factors and technical limitations have precluded the performance of sham-controlled studies to definitively establish the efficacy of these strategies. Neurosurgical treatment of OCD is reserved for patients with severe and debilitating illness who have failed to respond to an exhaustive array of other available treatment options and who provide informed consent or assent. Currently, the most commonly employed neurosurgical treatments for OCD include anterior cingulotomy, anterior capsulotomy, subcaudate tractotomy, and limbic leukotomy. In recent prospective trials of cingulotomy and capsulotomy, almost half of patients experienced symptom reduction of at least 35% (Dougherty et al., 2002; Mindus et al., 1994; Sheth et al., 2013). Studies directly comparing the relative efficacy and safety among the different neurosurgical approaches are also lacking. Adverse effects, in the context of contemporary techniques, include seizure and transient headache. Perhaps surprisingly, discernible adverse effects on cognition or personality are rare (see Corkin 1980; Jenike et al., 1998; Mindus et al., 1994). With the advent of innovative surgical devices that allow functional neurosurgery without craniotomy (e.g., by gamma knife), the performance of ethical double-blind sham-controlled trials of neurosurgery for OCD is now feasible.

Electroconvulsive Therapy

There are no controlled data regarding the efficacy of ECT for OCD. Given the high comorbidity of major affective illness in OCD, and the well-established efficacy of ECT for major depression, it is not surprising that some patients with OCD have reportedly shown clinical improvement with ECT. Several limited case series and anecdotal reports suggest that ECT may be useful in some circumstances, and such intervention would seem prudent in cases where ECT is indicated based on the presence of comorbid severe affective illness (see Jenike & Rauch, 1994). Controlled data are needed, however, before meaningful conclusions can be drawn regarding the specific antiobsessional efficacy of ECT for OCD. In this regard, important considerations include the effects of ECT on patients with OCD in the absence of major depressive disorder, the careful clinical distinction between genuine OCD versus ruminations or intrusive thoughts due to a different diagnosis, and the use of clinical instruments to tease apart antidepressant effects versus antiobsessional effects versus global improvement. Currently available data do not provide compelling support for the use of ECT in OCD without comorbid ECT-responsive conditions.

NEW HORIZONS AND FUTURE TREATMENTS

Future OCD treatment research can be divided into two categories: (a) initiatives to assess and optimize

the use of currently available treatments and (b) initiatives to develop new treatments. As documented by the above review, there is much work to be done in establishing the efficacy of various treatments, following up on preliminary data with well-controlled prospective trials. Moreover, optimal doses and durations for various treatments need to be determined empirically and in a scientifically rigorous fashion. Clinical subtyping or characterization based on symptom dimensions may uncover important predictors of treatment response (Ackerman, Greenland, Bystritsky, Morgenstern, & Katz, 1994; Mataix-Cols, Marks, Greist, Kobak, & Baer, 2002; Mataix-Cols, Rauch, Manzo, Jenike, & Baer, 1999; Ravizza, Barzega, Bellino, Bogetto, & Maina, 1995), informing patients and clinicians which treatments should be tried first or avoided in particular cases. Public policy issues regarding treatment access loom large for mental health care delivery in the United States. Education of health care consumers, as well as policymakers and clinicians, will be critical to high-quality care in the years ahead. Primary care physicians must be informed about OCD, and trends in training must be established to ensure an adequate supply of therapists with expertise in behavioral methods. Technological innovations, such as telepsychiatry, may help to provide specialized assessment and treatment to remote regions and ultimately reduce the costs of care (Baer, 1991; Baer et al., 1995).

Truly novel treatments for OCD may emerge from advances in our understanding of its pathophysiology or serendipitously. As new compounds become available that interact with the serotonergic and dopaminergic systems via specific receptor subtypes (e.g., 5HT1D, 5HT1A, or 5HT3; Swerdlow, 1995), it is likely that several will be antiobsessional candidates. Beyond monoaminergic systems, agents that modulate neuropeptidergic transmission may represent the next wave of psychopharmacological agents to be tested in OCD and related disorders. For instance, we have proposed that, based on the neurochemistry of corticostriatal pathways, substance P antagonists might serve as potent antiobsessionals (Rauch et al., 1998). Such compounds are already available within the pharmaceutical industry but currently are being studied only for other indications. The hypothalamic neuropeptide oxytocin is also the subject of intensive study because of its purported role in species-specific grooming behaviors (Leckman et al., 1994). Beyond neuropharmacology, research regarding autoimmune-mediated causes of OCD have prompted investigation of plasmapheresis to clear autoantibodies plus prophylactic antibiotic treatment to prevent subsequent infections and further damage (Allen et al., 1995; Swedo, 1994; Swedo et al., 1994). Also, transcranial magnetic stimulation, which has shown promise as an alternative treatment for major depression, is being studied for use in OCD. Finally, neuroimaging studies have documented consistent brain activity changes following successful treatment with either SRIs or behavior therapy (Baxter et al., 1992; Schwartz, Stoessel, Baxter, Martin, & Phelps, 1996). Such findings underscore the potential power of neuroimaging methods in searching for predictors of treatment responsiveness.

SUMMARY

The past 40 years have seen tremendous advances in the treatment and understanding of OCD, with a recent acceleration of progress. It is now appreciated that OCD is a common disorder, and effective treatments, including medication, behavior therapy, and neurosurgery, have emerged. There is overwhelming evidence of the most rigorous type supporting the efficacy of SRIs in the treatment of OCD. Along with SRIs, behavior therapy must be considered a viable first-line therapy. The best available data suggest that behavior therapy, and perhaps cognitive therapy, is at least as effective as medication in some instances and may be superior with respect to risks, costs, and enduring benefits. A variety of second-line medication treatments for OCD have been studied in a controlled or systematic fashion. Augmentation of SRIs with clonazepam or buspirone and augmentation with high-potency antipsychotics in cases of a comorbid tic disorder are provisionally recommended based on the marginal available data. Other augmentation strategies find very limited support at present. Alternative monotherapies, including buspirone, clonazepam, and phenelzine, have all been the subject of positive controlled or partially controlled studies. However, the quality of these data make recommendations for these strategies tentative as well, pending additional information. Beyond second-line treatments, the current database is inadequate for making difficult treatment decisions. There is now considerable clinical experience with neurosurgery for severe, debilitating,

treatment-refractory OCD. The apparent modest success rates with neurosurgery and its relative safety based on open trials would seem to pose a reasonable option for a small number of cases. Still, controlled data on neurosurgery are sorely needed. The future of OCD treatment will, we hope, entail rigorous research to more clearly establish the efficacy and safety of preexisting treatment options, as well as a refined sense of which patients might respond preferentially to which interventions, at what dose, and after how long. Furthermore, we can look forward to emerging novel treatment strategies that might include modified cognitive-behavioral therapies; new compounds acting via serotonergic, dopaminergic, or neuropeptidergic systems; and interventions that counteract autoimmune processes.

Psychosocial Treatments for Posttraumatic Stress Disorder

Lisa M. Najavits
Melissa L. Anderson

The study of psychosocial treatments for posttraumatic stress disorder (PTSD) has improved substantially in the past decade, with greater rigor, expansion of sampling, and diverse treatment models. It is clear that PTSD treatments work better than treatment as usual; average effect sizes are in the moderate to high range. A variety of treatments have been established as effective, with no one treatment having superiority, and both present-focused and past-focused models work (neither consistently outperforms the other). Areas of future direction include training, dissemination, client access to care, optimal delivery modes, and mechanisms of action. Methodological issues are also discussed, including improving research reporting, broadening study samples, and greater use of active comparison conditions.

CONTEXT

Awareness of PTSD has increased markedly. Its origins in the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* began in the first edition as "gross stress reaction" (American Psychiatric Association [APA], 1952), and it was eventually termed PTSD in the third edition (APA, 1980). First understood as a disorder primarily suffered by military personnel in wartime, it has since been understood as a disorder arising from diverse types of traumas, including natural disaster, such as hurricane or tornado; child physical and sexual abuse; domestic violence; life-threatening illness; accidents; and terrorist attacks. Most people (81.7%) experience one or more traumas in their lifetime, per the National Comorbidity Survey Replication (Sledjeski, Speisman, & Dierker, 2008). Yet, remarkably, most people who experience trauma do not go on to develop PTSD. For those who do develop PTSD after exposure to trauma, their symptoms cluster into four categories as defined by *DSM-5* (APA, 2013): (a) *intrusion symptoms* (e.g., intrusive memories, nightmares, flashbacks); (b) *avoidance symptoms* (e.g., not wanting to talk about the trauma, avoidance of reminders of the trauma); (c) *negative alterations in cognitions and mood* (e.g., distorted self-blame, estrangement from others, diminished interest in activities), and (d) *alterations in arousal and reactivity* (e.g., sleep problems, anger, exaggerated startle response). Additionally, the *dissociative* subtype of PTSD identifies symptoms such as feeling detached from one's mind or body and experiences in which the world seems unreal, dreamlike, or distorted. Persistence of symptoms for over a month and marked decline in functioning are also required. *DSM-5* PTSD differs from *DSM-IV-R* PTSD primarily in the following ways: (a) the definition of "trauma" now includes the phrase "or sexual violence," and there is no longer a requirement for "intense fear, helplessness, or horror" and (b) a new symptom cluster has

been added: "negative thoughts and mood." The 12-month prevalence rate of PTSD in the U.S. population is estimated at 3.5% and lifetime prevalence at 6.8% (Kessler et al., 2005a, 2005b). Global data suggest that similar rates of PTSD are also observed in countries outside of the United States (Kessler et al., 2009).

Most people with PTSD have one or more co-occurring psychiatric diagnoses, including disorders of mood, substance use, anxiety, and personality (Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995). Subjectively, the experience of PTSD is described as a devastating loss that "shatters assumptions" about oneself, others, the future, and the world (Janoff-Bulman, 1992) and that affects perceptions of safety, trust, power, esteem, and intimacy (McCann & Pearlman, 1990). A broad literature on PTSD exists within the professional field and also in literature (e.g., Frankl, 1963; Morrison, 1987; Wiesel, 1960) and film (e.g., *Once Were Warriors*, *Monster*, *This Boy's Life*, *Schindler's List*, *Saving Private Ryan*, *Precious*).

Historically, description of trauma arose in relation to combat, from ancient literature (the *Iliad*) through later history, with terms such as *soldier's heart* during the American Civil War, *shell shock* during World War I, and other terms such as *combat neurosis* and *war hysteria* (Weisaeth, 2002). In 1895, Freud and Breuer proposed that trauma could lead to mental disorder, an idea radical for its time (Wilson, 1994). After the Vietnam War, PTSD was formally named in the *DSM-III* (APA, 1980). The decades since then have seen enormous growth in the study of PTSD, including its epidemiology, assessment, and neurobiological substrates and the development and testing of new treatments for it.

This chapter is designed to be helpful to both clinicians and researchers. It is organized into four sections: key principles, description and empirical validation of PTSD treatments, summary of key findings, and future directions. Due to space limitations and the plentiful array of PTSD models that have arisen in recent years, we have limited this review to models with one or more type 1 studies (randomized controlled trials [RCTs]) published in the peer-reviewed literature from 2010 to February 2014, as well as retaining key type 1 studies from the earlier edition of this chapter (Najavits, 2007). This review is comprehensive in that we included all interventions and studies that met these parameters, plus the following inclusion criteria:

- *Treatments designed for PTSD* (not treatments developed for other diagnoses and applied to PTSD without adaptation)
- *Treatments intended for full PTSD* rather than a specific PTSD symptom (thus excluding Imagery Rehearsal Therapy for nightmares, for example; Casement & Swanson, 2012)
- *Behavioral therapies* (thus excluding medication trials, medication-enhanced psychotherapy, or comparisons of medication vs. psychotherapy)
- *Samples with current PTSD*. We excluded models that only had studies of clients with a history of trauma; subthreshold PTSD; or no PTSD, such as prevention studies.
- *Individual or group treatment modality*. We excluded couple and family treatments as these are less frequently practiced.
- *Adult PTSD treatments*. We cover adolescent studies if they were in addition to at least one adult RCT. For treatments specifically designed for children or children and their caregivers, the interested reader is directed to www.nctsn.org and www.nrepp.org. Examples of such treatments are Child-Parent Psychotherapy (Lieberman, Van Horn, & Ippen, 2005) and Trauma-Focused CBT (Cohen, Mannarino, & Iyengar, 2011).
- *Studies that report pretreatment to end-of-treatment PTSD outcomes*. Studies that do not provide end-of-treatment outcomes have been excluded (e.g., McGovern, Lambert-Harris, Alterman, Xie, & Meier, 2011).

In terms of our reporting, we focus solely on PTSD outcomes unless the treatment was designed to address a comorbid condition (e.g., substance use disorder [SUD]), in which case we also report on that. We do not address secondary outcomes, nor treatment dismantling results. We focus on intent-to-treat analysis, not subgroup analyses, unless intent-to-treat was not available. We also focus on differences between treatment conditions, as all studies were RCTs. We do not address follow-up periods after the end of treatment, as our goal is to prioritize the internal validity of treatment effects. References to more detailed descriptions and research reviews are provided throughout for readers who desire additional information. All models are listed in alphabetical order within sections.

KEY PRINCIPLES

Across the available literature, we note several overarching principles:

1. *PTSD treatments work, and work better than treatment as usual (TAU).* Research shows consistent evidence that treatments designed for PTSD do indeed work. This is the conclusion drawn by every major review and meta-analysis on psychosocial treatments for PTSD (e.g., Bisson, Roberts, Andrew, Cooper, & Lewis, 2013; Bradley, Greene, Russ, Dutra, & Westen, 2005; Butler, Chapman, Forman, & Beck, 2006; Powers, Halpern, Ferenschak, Gillihan, & Foa, 2010; Watts et al., 2013) and professional practice guidelines such as the International Society for Traumatic Stress Studies (Foa, Keane, Friedman, & Cohen, 2008), the Royal College of Psychiatrists and the British Psychological Society (2005), Veterans Health Administration (2004), Institute of Medicine (2008), and the Agency for Healthcare Research and Quality (Jonas et al., 2013).

   The degree of improvement is in the moderate to high range. For example, according to a meta-analysis by Bradley and colleagues (2005), 67% of clients who complete PTSD treatment no longer meet criteria for the disorder ("completer analysis"), and 56% of clients who enroll in PTSD treatment no longer meet criteria for the disorder ("intent-to-treat analysis"). Effect sizes, which reflect degree of change, are reported to average 1.43 from pretreatment to end of treatment, 1.11 when comparing PTSD treatment versus waitlist control conditions, and 0.83 when comparing PTSD treatment versus supportive therapy control condition. Consistent with these findings, another recent meta-analysis reported an average effect size of 1.14 across PTSD psychotherapy studies (Watts et al., 2013).

   Despite the overall positive outcomes for PTSD treatments, it is important to recognize several major caveats that generally receive less scrutiny. Dropout rates are a concern PTSD treatments are usually conducted in individual modality by highly trained clinicians, which add up to relatively costly treatments; and a substantial proportion of study participants had prior PTSD treatment and/or other relevant treatments during the course of studies, including medications (thus calling into question the impact of any particular episode of PTSD behavioral therapy; Najavits, 2013).
2. *The PTSD literature has achieved strong results in part by excluding more severe and complex clients.* The PTSD literature has historically and consistently excluded clients with complexities such as the following (Bradley et al., 2005; Najavits & Hien, 2013; Ronconi, Shiner, & Watts, 2014):
   - Homelessness
   - SUD (especially alcohol or drug dependence and drug use disorders generally)
   - Domestic violence
   - Suicidal or homicidal ideation
   - Serious and persistent mental illness
   - Significant medical illnesses such as HIV
   - Mandated treatment
   - Pregnancy
   - Cognitive impairment
   - Current incarceration

   Thus, the PTSD literature needs to be understood in light of such major limitations. Less positive treatment outcomes are likely when a broader range of clients are included. For example, a treatment often labeled as "gold standard" for PTSD, Prolonged Exposure, has more positive results when studied in PTSD-alone than PTSD/SUD samples (Najavits, 2012, 2013). Notably, treatment models designed for comorbid PTSD/SUD tend to have fewer exclusions in their study samples.
3. *Various treatments are effective, thus allowing clinicians and clients to choose based on their preferences.* A major advance has been the growing evidence base of many PTSD models. Thus, there is no one right way but many. It is possible to select effective treatments based on the clinician's training, the treatment context, and clients' presentation and preferences.
4. *PTSD treatments fall into two broad categories: past-focused and present-focused (or their combination).* Past-focused PTSD models ask the client to explore the trauma narrative in detail to promote "working through" or processing of painful memories and emotions of the trauma. In contrast, present-focused PTSD models focus on psychoeducation and

coping skills to improve current functioning in domains such as interpersonal, cognitive, and behavioral skills. Examples of past-focused models include Cognitive Processing Therapy (CPT), Eye Movement Desensitization and Reprocessing (EMDR), Narrative Exposure Therapy, and Prolonged Exposure. Examples of present-focused models include Cognitive Therapy for PTSD (CT-PTSD), Seeking Safety, and Stress Inoculation Training.[1]

5. *Overall, effective treatments do not differ significantly from each other.* For example, present- and past-focused models both work, and neither consistently outperforms the other (Bisson et al., 2013; Jonas et al., 2013). This is often a surprise to clinicians and clients, who typically assume that telling the trauma narrative is "more powerful" or "necessary" for healing. Similarly, within any category, treatments do not differ significantly from one another. For example, among past-focused treatments, EMDR and Prolonged Exposure both work, and neither outperforms the other (Benish, Imel, & Wampold, 2008; Bisson et al., 2013; Bradley et al., 2005; Powers et al., 2010; Watts et al., 2013).
6. *Combining effective treatments is intuitively appealing, but research so far suggests it is not needed.* Various studies have compared combinations of effective treatments (e.g., Prolonged Exposure plus Stress Inoculation Training or Cognitive Therapy), but the combined treatment consistently shows no greater efficacy than the single treatments being studied (Bryant et al., 2008; Bryant, Moulds, Guthrie, Dang, & Nixon, 2003; Foa et al., 1999, 2005; Foa, Rothbaum, Riggs, & Murdock, 1991; Glynn et al., 1999; Moser, Cahill, & Foa, 2010).
7. *The empirical base has improved greatly over the past decade.* The field now has more studies, more models, and a wider range of populations (e.g., comorbid clients, adolescents); the use of technology such as virtual reality and telehealth; and improved study methodologies.
8. *In addition to evidence-based treatments, the PTSD field has various untested treatments.* Some treatments have never been tested; others have been evaluated only in case studies or uncontrolled pilots. Such treatments may hold promise, and thus it is important to remember that "absence of evidence is not evidence of absence."
9. *Additional research is needed.* Important topics include how to improve training and dissemination of evidence-based treatments; larger sample sizes; broader populations to include more complex and severe clients; exploration of interactions between client and clinician variables in relation to treatment models; longer follow-ups; effectiveness studies; optimal timing of treatments; greater attention to external uncontrolled treatments; improvement in access to care; and further study of promising models.

DESCRIPTION AND EMPIRICAL VALIDATION OF TREATMENTS

In this section, we describe specific PTSD therapies and their RCT evidence. Models are identified as *past-* and/or *present-focused* per point 4 above. Past-focused models are reviewed first due to the larger quantity of literature on these models.

Past-Focused Treatments

The past-focused treatments listed in this section (Table 18.1) share a common strategy of asking the client to explore the past in detail. The models differ in some aspects of their approaches, including how explicitly the trauma narrative is expressed, whether nonverbal modalities are used (e.g., physical sensations), and whether other techniques are incorporated. But overall, these models have as their central goal a deep therapeutic exploration of past trauma. As such, they typically evoke intense emotions, such as rage, sadness, panic, and fear. The client is encouraged to face trauma memories and emotions fully, after which she or he is guided to return to the present by the end of the session.

In some models, the clinician guides the client to focus on "hot spots" that may be especially painful (such as the look on the face of a dying child or the smell of smoke from a fire). To increase the vividness of memories, the client may be asked to notice all senses (smell, sight, sound, touch, hearing) and speak in the present tense. The client may be asked to repeat the trauma narrative many times until it no longer holds strong emotional power. The client essentially *works through* or *processes* the trauma. If the client experienced multiple traumas, she or he

TABLE 18.1 Selection[a] of Past-Focused Posttraumatic Stress Disorder (PTSD) Treatment Models with Type 1 Randomized Controlled Trials

Treatment Model	*Modality*	*Population(s)*	*Comparison Condition(s)*
Abreactive Ego State Therapy	Individual	Mixed PTSD sample	Ochberg Counting Method
Accelerated Resolution Therapy	Individual	Mixed PTSD sample	Attention control
Cognitive Processing Therapy	Individual	Incarcerated adolescents, veterans, survivors of child sexual abuse, interpersonal trauma, military sexual trauma, sexual assault	Minimal attention, Prolonged Exposure, Present-Centered Therapy, treatment as usual, waitlist
Emotional Freedom Techniques	Individual	Mixed PTSD sample, veterans	EMDR, standard of care/waitlist
Eye Movement Desensitization and Reprocessing (EMDR)	Individual	Female sexual assault survivors, mixed PTSD sample, health maintenance organization patients, primary care patients, veterans	Biofeedback-assisted relaxation, Brief Eclectic Psychotherapy, Emotional Freedom Techniques, Prolonged Exposure, Prolonged Exposure + cognitive restructuring, relaxation, routine clinical care, waitlist
Narrative Exposure Therapy	Individual	Earthquake survivors, refugees	Psychoeducation, supportive counseling, treatment as usual, waitlist
Prolonged Exposure	Group, individual	Adolescents, female sexual assault survivors, mixed PTSD sample, Japanese civilians, female veterans and active duty military, motor vehicle accident survivors, people living with HIV, primary care patients, survivors of combat and terrorism, veterans	Cognitive Processing Therapy, Cognitive Therapy, EMDR, monitoring group, Present-Centered Group Treatment, Present-Centered Therapy, Prolonged Exposure + cognitive restructuring, relaxation, Stress Inoculation Training, supportive counseling, Time-Limited Dynamic Therapy, treatment as usual, waitlist
Structured Writing Therapy for PTSD	Individual	Comorbid PTSD/substance use disorder	Treatment as usual
Virtual Reality Exposure Therapy	Individual	Veterans	Minimal attention
Written Exposure Therapy	Individual	Motor vehicle accident survivors	Waitlist

[a] Per inclusion criteria as defined at the start of the chapter.

may be encouraged to fully process one trauma, usually the most upsetting one, and then move to others.

Among the many versions of such treatments, several have accumulated an evidence base. Such treatments represent a helpful method that may achieve results in relatively short time frames, particularly for single-incident trauma. However, such methods may be contraindicated due to the fact that intense trauma memories and emotions can be too disturbing for clients who are currently unstable, such as those who are in domestic violence relationships, who are homeless, who have SUD, or who have suicidal or homicidal ideation (Najavits, 2002; Solomon & Johnson, 2002). Also, clients may be poor candidates for these models if they lack memory for their trauma, have severe dissociation, or have major cognitive impairment (Coffey, Schumacher, Brimo, & Brady, 2005). Thus, such complex clients have been excluded from the vast majority of PTSD outcome trials, as noted earlier in this chapter.

Abreactive Ego State Therapy

Abreactive Ego State Therapy emphasizes the repeated, hypnotically activated "reliving" of the trauma event, combined with ego-strengthening techniques conducted by a co-clinician (Barabasz, Barabasz, Christensen, French, & Watkins, 2013). In recent studies of a 5- to 6-hour single session of manualized Abreactive Ego State Therapy, it outperformed a placebo comparison (the Ochberg Counting Method) in mixed PTSD samples (Barabasz et al., 2013; Christensen, Barabasz, & Barabasz, 2013).

Accelerated Resolution Therapy

Accelerated Resolution Therapy is a brief treatment developed for adults with comorbid PTSD and depression (Kip et al., 2013). It uses imaginal exposure (the client "imagines" the trauma in detail) in conjunction with the clinician oscillating the hand at the client's eye level, with the client engaging in left-to-right eye movements as a way to reduce physiological sensations related to the recall of a trauma. After this exposure to trauma material, the clinician then facilitates "voluntary image replacement" by asking the client to replace distressing images or senses with positive images. Although Accelerated Resolution Therapy is similar to EMDR (see below), it is distinct in its use of image replacement, its primary focus on processing of physiological sensations, and use of a fixed number of eye movements (Kip et al., 2013). In an RCT with survivors of military trauma, those receiving Accelerated Resolution Therapy evidenced greater reduction in PTSD symptoms than those in an attention control condition (Kip et al., 2013).

Cognitive Processing Therapy

CPT was originally developed for female rape victims (Resick & Schnicke, 1992) but has since been tested in other populations per Table 18.1. The model draws heavily on McCann and Pearlman's 1990 trauma themes of safety, trust, power, esteem, and intimacy (Solomon & Johnson, 2002). There is a strong focus on cognitive restructuring to address overly generalized beliefs ("the world is unsafe") and overly constricted beliefs ("it's all my fault"). The client typically writes a trauma narrative as homework outside of the therapy session.

In RCTs of CPT, it has outperformed minimal attention (Resick, Nishith, Weaver, Astin, & Feuer, 2002), TAU (Forbes et al., 2012), and waitlist control conditions (Ahrens & Rexford, 2002; Chard, 2005; Galovski, Blain, Mott, Elwood, & Houle, 2012; Macdonald, Monson, Doron-Lamarca, Resick, & Palfai, 2011; Monson et al., 2006). CPT has also been directly compared with Prolonged Exposure; both evidenced positive outcomes and there were no differences between them on PTSD outcomes (Resick et al., 2002). When CPT was studied in relation to Person-Centered Therapy, a present-focused model, it outperformed the latter on self-reported but not clinician-assessed PTSD symptoms (Suris, Link-Malcolm, Chard, Ahn, & North, 2013). For a review, see Koucky, Dickstein, and Chard (2013).

Emotional Freedom Techniques

The Emotional Freedom Techniques approach (Craig, 1999) assumes that PTSD is the byproduct of trauma-related disturbances in the body's energy field. The treatment uses light manual stimulation of the endpoints of traditional acupuncture meridians on the face, upper body, and hands, while the client focuses on the trauma. In an RCT with veterans, Emotional Freedom Techniques outperformed a waitlist control (Church et al., 2013). In a study comparing Emotional Freedom Techniques versus EMDR in a mixed PTSD sample, PTSD reductions were found in both conditions; however, more EMDR clients achieved clinically significant PTSD change (Karatzias et al., 2011).

Eye Movement Desensitization and Reprocessing

In EMDR therapy (Shapiro, 1995) the client focuses on trauma while engaging in bilateral (back-and-forth) eye movements by tracking the clinician's raised fingers horizontally across the visual field. The client reports thoughts, emotions, and physical sensations that emerged. Processing involves reducing negative emotions and physical sensations (e.g., chest tension); and strengthening positive beliefs (e.g., "I'm now in control"). Some clinicians use tapping or tones instead of eye movements as the essential element is believed to be dual awareness (Jeffries & Davis,

2013). Detailed descriptions of the trauma, extended exposures, and homework are not used.

Various RCTs of EMDR have been conducted (for reviews and meta-analyses, see, e.g., Bisson et al., 2013; Bradley et al., 2005; Butler et al., 2006; Verstrael, van der Wurff, & Vermetten, 2013; Watts et al., 2013). EMDR has outperformed control conditions such as waitlist (Power et al., 2002; Rothbaum, 1997; Rothbaum, Astin, & Marsteller, 2005) and routine clinical care (Carlson, Chemtob, Rusnak, Hedlund, & Muraoka, 1998; Marcus, Marquis, & Sakai, 1997), although in one study it did not outperform a relaxation control other than on one variable (Taylor et al., 2003). Compared to active treatments, it has outperformed Biofeedback-Assisted Relaxation (Carlson et al., 1998) and has resulted in faster recovery than Brief Eclectic Psychotherapy (Nijdam, Gersons, Reitsma, de Jongh, & Olff, 2012) and more clinically significant change than Emotional Freedom Techniques (Karatzias et al., 2011). It has been most studied in relation to Prolonged Exposure (Power et al., 2002; Rothbaum et al., 2005; Taylor et al., 2003). The overall finding, based on meta-analyses, is that both models work yet do not evidence differences in their outcomes or in duration of treatment (Bisson et al., 2013; Bradley et al., 2005; Powers et al., 2010; Watts et al., 2013).

Narrative Exposure Therapy

Narrative Exposure Therapy was originally developed for survivors of war and torture (Schauer, Neuner, & Elbert, 2005). It does not identify a single trauma event as the focus of therapy; rather, it guides the client to construct a detailed chronological account of his or her history, integrating the trauma narrative into a cohesive life story. In RCTs, Narrative Exposure Therapy has outperformed a waitlist control (Zang, Hunt, & Cox, 2013), TAU (Stenmark, Catani, Neuner, Elbert, & Holen, 2013), and psychoeducation and supportive counseling (Neuner, Schauer, Klaschik, Karunakara, & Elbert, 2004). For a review, see Robjant and Fazel (2010).

Prolonged Exposure

Prolonged Exposure starts with several sessions of preparation of the client, after which the client can engage in both imaginal exposure (the client "imagines" the trauma) and in vivo exposure (the client faces reminders of the trauma, such as touching clothing that was worn at the time of the trauma) (Foa, Hembree, & Rothbaum, 2007). Breathing retraining is also recommended. There is a strong focus on exposure homework, including writing or audiotaping a trauma narrative to review between sessions.

Prolonged Exposure has had various RCTs (for reviews and meta-analyses, see, e.g., Foa, 2011; McLean & Foa, 2011; Powers et al., 2010; Rauch, Eftekhari, & Ruzek, 2012). RCTs comparing Prolonged Exposure to active treatments have reported positive outcomes but no differences between Prolonged Exposure and CPT (Resick et al., 2002); Cognitive Therapy (Marks, Lovell, Noshirvani, Livanou, & Thrasher, 1998; Tarrier et al., 1999); EMDR (Rothbaum et al., 2005); Present-Centered Group Treatment (Schnurr et al., 2003); or Stress Inoculation Training (Foa et al., 1999). In a few RCTs, there have been differences between treatment conditions. For example, Prolonged Exposure has outperformed Relaxation Training (Marks et al., 1998; Taylor et al., 2003) and Time Limited Dynamic Therapy (using a developmentally adapted Prolonged Exposure therapy for adolescents; Gilboa-Schechtman et al., 2010).

Prolonged Exposure has outperformed some minimal control conditions, including a monitoring control condition (Pacella et al., 2012), TAU (Asukai, Saito, Tsuruta, Kishimoto, & Nishikawa, 2010; Nacasch et al., 2011), waitlist control (Foa et al., 2005; Glynn et al., 1999; Power et al., 2002), and supportive counseling (Bryant et al., 2003; Foa, McLean, Capaldi, & Rosenfield, 2013a; Foa et al., 1991). However, a recent RCT for clients with comorbid PTSD and SUD compared Prolonged Exposure to BRENDA (a supportive counseling model) and found that both models improved PTSD and SUD, with no difference between them at the end of treatment in either domain (Foa et al., 2013b).

Virtual Reality Exposure Therapy

Virtual Reality Exposure Therapy is a version of exposure therapy that makes use of advanced graphics, sound effects, and computer technology to immerse the client in a realistic, visually rich virtual environment. For example, one model for military veterans

has the client don headgear to view "a virtual Huey helicopter flying over a virtual Vietnam, and a clearing surrounded by jungle" (Rothbaum, Hodges, Ready, Graap, & Alarcon, 2001). As the client moves, the scene appears to move, too, via body-tracking devices.

Such technology-intensive models have become more common in recent years and are beginning to accumulate evidence that both Virtual Reality Exposure Therapy and traditional exposure therapies have positive outcomes, with no differences between them (for reviews, see Goncalves, Pedrozo, Coutinho, Figueira, & Ventura, 2012; Motraghi, Seim, Meyer, & Morissette, 2014; Rizzo et al., 2011; Rothbaum, Rizzo, & Difede, 2010). A recent study of military personnel found that Virtual Reality Exposure Therapy outperformed a minimal attention control on criterion C symptoms of PTSD (avoidance/numbing) and posttraumatic guilt (Miyahira et al., 2012).

Written Exposure Therapies

Written exposure therapies focus on processing trauma memories through writing. These approaches are derived from the early work of Pennebaker and Beall (1986), who had clients repeatedly write about their most traumatic experience with as much emotion and detail as possible. Such approaches go by a number of names (e.g., Structured Writing Therapy, Written Disclosure, Written Exposure Therapy) and have generally evidenced similar treatment effects as therapies using oral disclosure of the traumas (see Frattaroli, 2006, for a review).

For example, in an RCT of a brief, five-session Written Exposure Therapy with motor vehicle accident survivors, Written Exposure Therapy outperformed waitlist control (Sloan, Marx, Bovin, Feinstein, & Gallagher, 2012). However, a recent study in clients with comorbid PTSD and SUD found that Structured Writing Therapy did not outperform TAU on PTSD or SUD outcomes, with both conditions reducing the symptom severity of both disorders (van Dam, Ehring, Vedel, & Emmelkamp, 2013).

Present-Focused Treatments

Present-focused PTSD treatments (Table 18.2) provide psychoeducation and coping skills training. Various cognitive, behavioral, and interpersonal methods are used, such as grounding (sensory focus to recenter in the present so as to reduce upsetting

TABLE 18.2 Selection[a] of Present-Focused Posttraumatic Stress Disorder (PTSD) Treatment Models with Type 1 Randomized Controlled Trials

Treatment Model	*Modality*	*Population(s)*	*Comparison Condition(s)*
Cognitive Therapy for PTSD (CT-PTSD)	Individual	Children, mixed PTSD sample, motor vehicle accident survivors	Assessment only, emotion-focused supportive therapy, Prolonged Exposure, Prolonged Exposure + cognitive restructuring, relaxation, self-help booklet, Trauma-Focused Cognitive-Behavioral Therapy, waitlist
Seeking Safety	Group, individual	Groups with comorbid PTSD/substance use disorder: adolescent girls, homeless women veterans, incarcerated women, low-income urban women, male veterans, women	Enhanced residential services, Relapse Prevention, standard community care, treatment as usual, waitlist, Women's Health Education
Stress Inoculation Training	Individual	Female sexual assault survivors	Prolonged Exposure, supportive counseling, waitlist
Trauma Affect Regulation: Guide for Education and Therapy (TARGET)	Group, individual	Delinquent adolescent girls, incarcerated women, mothers	Present-Centered Therapy, relational supportive therapy, supportive group therapy, waitlist

[a] Per inclusion criteria as defined at the start of the chapter.

emotions), learning to ask for help, identifying and coping with PTSD triggers, rehearsing compassionate self-statements, getting out of unsafe relationships, developing a schedule of productive activities, and cognitive restructuring.

Cognitive Therapy for Posttraumatic Stress Disorder

In CT-PTSD, the goal is to help clients become aware of their maladaptive beliefs and modify them to become more adaptive. This may include, for example, correcting excessively negative assumptions about the trauma (e.g., self-blame); exploring the connection between beliefs, feelings, and behavior; and identifying inaccurate appraisal of threats in the current environment. Examples of models include those by Ehlers, Clark, Hackmann, McManus, and Fennell (2005), Foy (1992), and Tarrier and colleagues (1999). A cognitive component is also part of many of the past-focused models reviewed above, as well as many of the combination models reviewed below; however, as described here, CT-PTSD does not include a past-focused component.

Several RCTs of CT-PTSD have been conducted; see the review by Butler and colleagues (2006) and a recent meta-analysis by Ougrin (2011). In comparisons with active treatment conditions, CT-PTSD and active treatments generally reduce PTSD symptoms, with no difference between them. Examples include Prolonged Exposure (Marks et al., 1998; Tarrier et al., 1999) and Trauma-Focused Cognitive Behavioral Therapy (Nixon, Sterk, & Pearce, 2012). CT-PTSD has outperformed Relaxation Training (Marks et al., 1998), a self-help booklet (Ehlers et al., 2003), and Emotion-Focused Supportive Therapy (Ehlers et al., 2014). It has also outperformed a number of minimal control conditions, including assessment only (Ehlers et al., 2003) and waitlist (Ehlers et al., 2005, 2014).

Seeking Safety

Seeking Safety was designed to treat comorbid PTSD and SUD (Najavits, 2002). It focuses on the core theme of safety, with 25 topics that address cognitive, behavioral, and interpersonal coping skills to address both disorders at the same time (integrated therapy) from the start of treatment (first-stage therapy). Examples of topics are, for example, *asking for help*, *compassion*, *healing from anger*, *healthy relationships*, *honesty*, and *creating meaning*. It emphasizes flexibility, with skills addressed in any order the clinician chooses, and variable treatment length and pacing.

Various RCTs of Seeking Safety have been conducted. Seeking Safety is the only model thus far for comorbid PTSD and SUD that has outperformed a control condition on SUD (see Najavits & Hien, 2013, for a review). In a study of men veterans, Seeking Safety outperformed TAU on SUD (drug use disorder); PTSD and alcohol use disorder improved in both conditions, with no difference between them (Boden et al., 2012). In a study of community-based women, both Seeking Safety and Relapse Prevention (an active comparison) reduced PTSD and SUD symptoms, with no difference between them, and both treatments outperformed a nonrandomized TAU arm on PTSD and SUD (Hien, Cohen, Miele, Litt, & Capstick, 2004). In a study of adolescent girls, Seeking Safety outperformed TAU on SUD and trauma symptoms but not PTSD (Najavits, Gallop, & Weiss, 2006). In a study of partial-dose Seeking Safety using less than half the model, both Seeking Safety and Women's Health Education (an active comparison) reduced PTSD symptoms, with no difference between them (Hien et al., 2009). SUD did not decrease in either study arm, but close to half the sample was abstinent from substances at baseline. An RCT on PTSD and alcohol use disorder (AUD) compared partial-dose (12 session) Seeking Safety with the antidepressant sertraline versus Seeking Safety with placebo (Hien et al., in press). Both conditions improved in both PTSD and alcohol use severity ; moreover, the Seeking Safety plus sertraline condition had greater PTSD improvements than Seeking Safety plus placebo. This study indicates that Seeking Safety, with or without antidepressant medication, evidenced significant improvements in both disorders, even with just a partial dose.

Stress Inoculation Training

Stress Inoculation Training for PTSD is designed to help clients manage anxiety and cope better. It can include breathing exercises, relaxation, psychoeducation, thought stopping, cognitive restructuring, role playing, and guided self-dialogue (Foa et al., 1991). Compared to Prolonged Exposure, Stress Inoculation Training was superior in one study (Foa et al., 1991) but showed no difference in another (Foa et al.,

1999). Stress Inoculation Training has outperformed supportive counseling and waitlist control (Foa et al., 1991, 1999). We were unable to locate any recent RCTs on Stress Inoculation Training.

Trauma Affect Regulation: Guide for Education and Therapy

Trauma Affect Regulation: Guide for Education and Therapy (TARGET) teaches affect-regulation skills relevant to trauma (Ford & Russo, 2006). Its seven skills are summarized by "FREEDOM": "*F*ocusing the mind on one thought at a time; *R*ecognizing current triggers for emotional reactions; distinguishing dysregulated versus adaptive *E*motions; *E*valuations (thoughts), goal *D*efinitions, and behavioral *O*ptions; and self-statements affirming that taking responsibility for recovering from intense emotions is crucial not only to one's personal well-being but also to *M*aking a positive contribution to primary relationships and the community" (Ford, Steinberg, & Zhang, 2011).

In an RCT comparing TARGET to Present-Centered Therapy there were no differences between them in PTSD diagnosis or clinically significant change in PTSD symptoms, but both treatments outperformed waitlist on these variables (Ford et al., 2011). In an RCT of TARGET versus relational supportive therapy, there was no difference between them except for one variable favoring TARGET (PTSD criterion B [i.e., intrusive reexperiencing symptoms]; Ford, Steinberg, Hawke, Levine, & Zhang, 2012). Similarly, in an RCT comparing TARGET to supportive group therapy, both reduced PTSD symptoms, with no difference between them (Ford, Chang, Levine, & Zhang, 2013).

Combination Treatments (Past-Plus Present-Focused)

In this section, we review models that combine past- and present-focused treatments, an intuitively appealing attempt to create a stronger model of therapy (Table 18.3).

TABLE 18.3 Selection[a] of Combination Past- Plus Present-Focused Posttraumatic Stress Disorder (PTSD) Treatment Models with Type 1 Randomized Controlled Trials

Treatment Model	*Modality*	*Population(s)*	*Comparison Condition(s)*
Abreactive Ego State Therapy	Individual	Mixed PTSD sample	Ochberg Counting Method
Brief Eclectic Psychotherapy	Individual	Mixed PTSD sample, police officers	EMDR, minimal attention, waitlist
Concurrent Treatment of PTSD and SUD Using Prolonged Exposure (COPE)	Individual	Comorbid PTSD/ substance use disorder (SUD)	Treatment as usual
Dialectical Behavior Therapy for PTSD (DBT-PTSD)	Individual and group	Survivors of child sexual abuse	Waitlist
Integrated Cognitive-Behavioral Therapy (CBT) for PTSD and Alcohol Use Disorder	Individual	Comorbid PTSD/ alcohol use disorder	CBT for alcohol use disorder + supportive counseling
Resilience-Oriented Treatment for PTSD	Group	Veterans	Waitlist
Skills Training in Affective and Interpersonal Regulation (STAIR)/Exposure	Individual	Adult female survivors of childhood abuse	Supportive counseling + Prolonged Exposure, STAIR + supportive counseling, minimal attention waitlist
Trauma Management Therapy	Individual and group	Male veterans	Exposure therapy

[a] Per inclusion criteria as defined at the start of the chapter.

Brief Eclectic Psychotherapy

Brief Eclectic Psychotherapy is composed of two primary phases: imaginal exposure and cognitive restructuring (Gersons, Carlier, & Olff, 2004). Its core treatment components are also used in other cognitive-behavioral therapies, including psychoeducation, imaginal exposure, writing assignments, and cognitive restructuring. However, Brief Eclectic Psychotherapy is unique in its use of exposure for catharsis, inclusion of mementos and farewell rituals, and incorporation of psychodynamic elements (Schnyder, Muller, Maercker, & Wittmann, 2011).

Brief Eclectic Psychotherapy has outperformed a minimal attention control (Schnyder et al., 2011) and waitlist (Gersons, Carlier, Lamberts, & van der Kolk, 2000). It has also been directly compared with EMDR, with both evidencing positive outcomes on PTSD reduction and no differences between them (Nijdam et al., 2012).

Concurrent Treatment of Posttraumatic Stress Disorder and Substance Use Disorder Using Prolonged Exposure

Concurrent Treatment of PTSD and SUD using Prolonged Exposure (COPE) integrates existing treatment components for PTSD and SUD, including motivational enhancement and CBT for SUD; psychoeducation about PTSD/SUD; in vivo and imaginal exposure; and cognitive restructuring (Mills et al., 2012). COPE is a modified version of Concurrent Treatment of PTSD and Cocaine Dependence (Back, Dansky, Carroll, Foa, & Brady, 2001). In a recent RCT, both COPE and TAU reduced PTSD and SUD symptoms among clients with comorbid PTSD/SUD at end of treatment, with no difference between them (Mills et al., 2012).

Dialectical Behavior Therapy for Posttraumatic Stress Disorder

Dialectical Behavior Therapy for PTSD (DBT-PTSD) is an adaptation of DBT, an evidence-based treatment for borderline personality disorder that does not target trauma and has shown limited effects on PTSD (Harned et al., 2008). DBT-PTSD was developed to (1) reduce fear of trauma-related primary emotions, such as fear, disgust, and powerlessness, using exposure techniques; (2) question nonjustified secondary emotions, such as guilt, shame, and self-contempt; and (3) radically accept trauma-related facts (Bohus et al., 2013). In a recent RCT of DBT-PTSD for clients with comorbid PTSD and borderline personality in a residential treatment setting, it outperformed a TAU waitlist control on reduction of PTSD symptoms but not on symptoms of borderline personality disorder (Bohus et al., 2013).

Integrated Cognitive Behavioral Therapy for Posttraumatic Stress Disorder and Alcohol Use Disorder

Integrated Cognitive Behavioral Therapy for PTSD and Alcohol Use Disorder (ICBT-PTSD/AUD) combines CBT and motivational enhancement approaches for alcohol use disorder with exposure therapy and cognitive restructuring for PTSD (Sannibale et al., 2013). An RCT compared ICBT-PTSD/AUD to ICBT-AUD plus supportive counseling (but no PTSD component). Both conditions evidenced reductions in PTSD symptom severity and alcohol consumption, with no difference between them at the end of treatment (Sannibale et al., 2013).

Resilience-Oriented Treatment for Posttraumatic Stress Disorder

Kent, Davis, Stark, and Stewart (2011) developed "a resilience-oriented treatment for PTSD" that seeks to foster clients' resources, such as awareness of positive emotions and social connectedness. These resources are drawn on in later sessions, when group members experience PTSD symptoms or engage in trauma exposure. In a study of veterans with PTSD, the resilience-oriented treatment outperformed waitlist control (Kent et al., 2011).

Skills Training in Affect and Interpersonal Regulation/Exposure

Skills Training in Affect and Interpersonal Regulation followed by exposure therapy (STAIR/Exposure) is a phase-based model developed for adult survivors of child abuse (Cloitre, Koenen, Cohen, & Han, 2002). STAIR/Exposure divides sessions evenly between

skills training (adapted from DBT) and exposure (adapted from Prolonged Exposure). The phase-based concept derives from the work of Herman (1992) and others who identified phases of PTSD recovery, in which coping skills are established before engaging in exposure techniques.

In an RCT, STAIR/Exposure has outperformed minimal attention waitlist (Cloitre et al., 2002). Compared to active, phase-based treatments, it has outperformed supportive counseling followed by exposure therapy and performed equivalent to STAIR followed by supportive counseling (rather than exposure) (Cloitre et al., 2010). For additional discussion of STAIR/Exposure, see Landes and colleagues (2013).

Trauma Management Therapy

Trauma Management Therapy was developed for veterans with PTSD (Turner, Beidel, & Frueh, 2005). It is composed of imaginal and in vivo exposure, followed by social and emotional rehabilitation (veteran-specific training in social skills, anger management, and communication). In a recent RCT, both Trauma Management Therapy and an exposure therapy-only condition reduced PTSD symptoms, with no difference between them; however, Trauma Management Therapy outperformed exposure therapy on measures of social engagement and interpersonal functioning (Beidel, Frueh, Uhde, Wong, & Mentrikoski, 2011).

SUMMARY OF KEY FINDINGS

Effective Treatments

Various treatment approaches show positive outcomes in RCTs with TAU, minimal attention, and waitlist controls. Among the treatment approaches reviewed above, all generally outperform control conditions, with the exception of Structured Writing Therapy, which did not outperform TAU (van Dam et al., 2013). However, with regard to active treatment comparisons, effective treatments do not appear to differ significantly from each other. Within any category (i.e., past- or present-focused), results across RCTs do not indicate consistent, significant differences between active treatments. For example, among past-focused treatments, CPT, EMDR, Narrative Exposure Therapy, and Prolonged Exposure all work, with none consistently outperforming any other (Benish et al., 2008; Jonas et al., 2013; Powers et al., 2010).

Comparison of Present- versus Past-Focused Treatments

Available data indicate no demonstrable difference in outcome between present- and past-focused treatments (e.g., Bisson et al., 2013; Bradley et al., 2005; Butler et al., 2006; Marks et al., 1998; Ougrin, 2011; Schnurr et al., 2003; Watts et al., 2013). This may come as a surprise given a longstanding clinical literature suggesting that both may be needed for PTSD recovery (Herman, 1992). Indeed, some clients and clinicians believe that the "real work" in PTSD treatment is past-focused, with present-focused work merely a precursor or adjunct. In fact, both present- and past-focused PTSD models produce positive outcomes, neither outperforms the other, and both are superior, overall, to control conditions such as waitlist and TAU. Thus, client preferences and clinician training should become the ultimate determinant of which model to choose from among the various models. Indeed, a recent meta-analysis of PTSD treatments used a novel approach by addressing *complexity* of the client population as a moderator (Gerger, Munder, & Barth, 2014). Their conclusion was that specific PTSD treatments (which largely have been past-focused) are the preferential treatment only for clients with less complex clinical problems. For clients with greater complexity, both specific and nonspecific treatments (e.g., present-focused models such as relaxation and supportive counseling) are equally recommended.

Combination of Treatment Approaches

Combining effective treatments is intuitively appealing, but research indicates that it is not needed. Various studies have compared combinations of effective treatments (e.g., Prolonged Exposure plus Stress Inoculation Training or Cognitive Therapy), but the combined treatment typically shows no greater efficacy then either treatment alone (Bryant et al., 2003; Foa et al., 1991, 1999, 2005; Glynn et al., 1999;

Moser et al., 2010). For example, several studies have addressed whether Prolonged Exposure is sufficient by itself or whether adding elements of Cognitive Therapy (i.e., cognitive restructuring and/or coping skills training) improves PTSD outcomes. Several RCTs indicate that the addition of Cognitive Therapy did not improve outcomes over and above pure exposure in various samples (Bryant et al., 2003; Foa et al., 2005; Marks et al., 1998; Moser et al., 2010). Similarly, cognitive or skills models without an exposure component show no difference from those with an exposure component (Cloitre et al., 2010; see also the dismantling study by Resick et al., 2008) In sum, both exposure and cognitive therapy components produce positive outcomes but do not appear to enhance treatment effects when combined. One exception is a study that reported better PTSD outcomes for a combination of imaginal exposure, in vivo exposure, and cognitive restructuring compared to exposure alone (Bryant et al., 2008).

Treatments for Comorbid Posttraumatic Stress Disorder and Substance Use Disorder

Recent years have seen an increase in the number of treatment models developed for and tested with clients with comorbid PTSD and SUD. Indeed, SUD is the only disorder comorbid with PTSD that has received notable research attention. Similar to treatment models developed for PTSD, models developed for comorbid PTSD/SUD fall into present-focused, past-focused, or combination categories. Seeking Safety, a present-focused treatment, is the most studied evidence-based model. It is the only model thus far studied for PTSD/SUD that has outperformed a control in RCTs (see Najavits & Hien, 2013, for a review). In contrast, past-focused models, which have been studied in four recent RCTs, indicated no difference from the control on either PTSD or SUD at end of treatment. Neither Structured Writing Therapy (van Dam et al., 2013) nor COPE (Mills et al., 2012) outperformed TAU, and neither Prolonged Exposure nor ICBT-PTSD/AUD outperformed supportive counseling (Foa et al., 2013b; Sannibale et al., 2013). Additional reviews of treatments for comorbid PTSD/SUD are available (e.g., Brady, Back & Coffey, 2004; Najavits & Hien, 2013; Ouimette & Read, 2013; van Dam et al., 2013).

FUTURE DIRECTIONS

Like the proverbial glass that is both half full and half empty, PTSD treatment outcome research can be viewed in terms of its major advances over the past several years, or from the framework of all that still needs to be studied.

Improvement in Methodology

The methodology of studies investigating psychosocial treatments is much improved compared with 30 years ago. Indeed, the meta-analysis by Bradley and colleagues (2005) found that treatment effect size was positively associated with year of publication, indicating that more recent studies showed more robust effects. However, close inspection of research reports shows a level of methodological variability that is sometimes at odds with the simple "bottom-line message" conveyed in the abstracts. For example, many studies employ small sample sizes, are statistically underpowered, and collect limited follow-up data (Bisson et al., 2013). Many studies do not include or report on key issues that would be helpful for understanding their results (e.g., power analyses, end-of-treatment assessments, comorbid disorders). In the current climate, results of PTSD treatment outcome research may determine what treatments and programs are funded or discontinued; thus, adequate methodology has real-world implications for clients, clinicians, and programs.

Two excellent methods for evaluating the quality of clinical trials are provided in the 2010 Consolidated Standards of Reporting Trials statement (Schulz, Altman, & Moher, 2010) and by Moncrief (see Bisson & Andrew, 2005). Insistence on one or both of these consistently by journal editors and funding agencies could have a dramatic and rapid impact.

The Moncrief scale, for example, considers 23 different methodological criteria and assigns scores to them on a 0-to-2 scale, giving a maximum possible total of 46. The criteria included in the scale are objective and include items such as specification of main outcomes a priori, sample size, follow-up duration, power calculation, method of allocation, allocation concealment, clear description of treatment and adjunctive treatment, blinding of subjects, representative sample recruitment, use of diagnostic criteria, exclusion criteria and number of exclusions and refusals, description

of sample demographics, blinding of assessor, assessment of compliance with treatments, details of side effects, record of number and reasons for withdrawal by group, outcome measures described clearly or use of validated instruments, information on comparability and adjustment for differences in analysis, inclusion of withdrawals in analysis, presentation of results with inclusion of data for reanalysis of main outcomes, appropriate statistical analysis, conclusions justified, and declaration of interests (Bisson & Andrew, 2005, p. 4).

In addition to these could be added the need to report the rate of comorbid Axis I and Axis II diagnoses (given that most PTSD clients have one or more co-occurring disorders), clinician effects, adherence rating, clinician selection and training, method for assigning clients to clinicians, use of a treatment manual, analysis of both completer and intent-to-treat samples, and whether clients were paid to attend treatment sessions. It has also been suggested that using waitlist and TAU comparisons may be responsible for the inflation of effect sizes in RCTs of psychotherapy approaches and that, therefore, direct comparisons between effective psychotherapies are needed to avoid such inflation (Watts et al., 2013).

Broadening of Samples

Recent studies use rigorous selection of PTSD clients (rather than simply a history of trauma) and validated diagnostic tools. Also, a broader array of client populations has been studied in terms of sociodemographic characteristics and trauma type. However, continued expansion in sampling is needed. There are still relatively few studies that include complex individuals, with the most common exclusions being comorbid psychosis, SUD, bipolar disorder, and suicidal ideation (Ronconi et al., 2014). It will be essential to include these individuals in future therapy outcome research to improve the generalizability of results to real-world client populations.

Studies of Dissemination

There is a need for more effectiveness studies that evaluate how treatments fare in real-world implementation and a need to better understand issues such as client and clinician preferences for treatment, use of technology for enhancing treatment, and public health challenges such as how clients can access PTSD treatment in their communities. One such public health challenge is the cost of PTSD treatment, and additional research is needed to determine which treatments are simultaneously cost-effective and effective in reducing PTSD symptoms. For example, although studies of Virtual Reality Exposure Therapy are becoming more prevalent in the literature, these therapies are often more expensive and harder to implement than verbal or written exposure therapies. Given findings that Virtual Reality Exposure Therapy does not outperform traditional exposure therapies (Goncalves et al., 2012; Motraghi et al., 2014; Rizzo et al., 2011; Rothbaum et al., 2010), the use of such technologies may not be necessary to produce clinically significant change.

Additionally, the use of telehealth and Internet technologies to improve treatment access is the subject of a number of recent open pilots and pilot RCTs. Initial results suggest that telehealth and Internet delivery of PTSD treatment is safe and effective (Morland, Hynes, Mackintosh, Resick, & Chard, 2011; Possemato, Ouimette, & Knowlton, 2011; Strachan, Gros, Ruggiero, Lejuez, & Acierno, 2012); however, it may not be as effective as in-person treatment (Gros, Yoder, Tuerk, Lozano, & Acierno, 2011). Larger RCTs of telehealth and Internet-delivered treatments are needed before making any further conclusions about the effectiveness of these approaches.

Delivery of Treatments

Another key area is more refined study of how to deliver treatments. This might include how and when they should be combined (e.g., with other psychosocial treatments), how long to deliver them, when to determine that a treatment is not working for particular clients, outcome differences based on modality and/or pacing of treatment, whether particular clinician characteristics are necessary for effective delivery, and greater understanding of what aspects of treatments are essential.

NOTE

1. The term *trauma-focused* is often used to identify past-focused models and *non–trauma-focused* to identify present-focused models. We eschew these terms, however,

as all present-focused PTSD models directly and strongly "focus on trauma." The difference is how they approach it. Past-focused models primarily focus on the past by exploring intense trauma memories and associated feelings, thoughts, and body sensations. Present-focused models omit detailed exploration of the past, typically in the service of helping stabilize the client, and instead focus primarily on coping skills and psychoeducation. We note too that the term "non-trauma-focused treatment" to refer to such present-focused PTSD models is also problematic as it labels them solely by what they are not. It is equivalent to referring to women as "non-men" or children as "non-adults." Present-focused approaches have a rich content of coping skills and psychoeducation that is better captured by a meaningful label (Najavits & Hien, 2013).

Pharmacological Treatment of Posttraumatic Stress Disorder

Julia A. Golier
Andreas C. Michaelides
Maya Genovesi
Emily Chapman
Rachel Yehuda

Although psychotherapy is considered the first line of treatment for posttraumatic stress disorder (PTSD), there have been some advances made in the pharmacological treatment of this disorder as well. Based on numerous controlled clinical trials, antidepressants are still the first-line pharmacological treatment for this disorder. Multiple studies suggest that selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, and paroxetine) are efficacious in reducing PTSD-specific symptoms and improving global outcome. Emerging evidence also suggests efficacy for the selective serotonin/norepinephrine reuptake inhibitor venlafaxine. Other individual agents found to be efficacious include the tricyclic antidepressant (TCA) imipramine and the monoamine oxidase inhibitor (MAOI) phenelzine. Prazosin is emerging as a beneficial adjunctive agent in treating PTSD-related sleep disturbances and nightmares. Some evidence suggests that atypical antipsychotics may be efficacious against a broad range of symptoms, although their potential for causing metabolic side effects may limit their widespread use. Controlled clinical trials are needed to assess whether anticonvulsants, cortisol-based treatments, sympatholytics, or other novel, nontraditional approaches are efficacious, and how and when pharmacotherapy can supplement or enhance psychotherapy outcomes. However, these studies should occur in the context of discussion regarding the goals of pharmacotherapy in PTSD as well as the subgroups of patients or clinical presentations most likely to require or benefit from the different pharmacological interventions.

INTRODUCTION

The diagnosis of PTSD first appeared in the anxiety disorder section of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association [APA], 1980), with the intention of describing the characteristic and long-lasting symptoms that occur in individuals following exposure to extremely traumatic events. In the most recent edition, *DSM*-5, PTSD has been reclassified as a trauma- and stressor-related disorder. This new category—which also includes acute stress disorder and adjustment disorder—was developed to explain psychological symptoms that occur following

exposure. Classic explanations of anxiety disorders suggest symptoms with no immediate antecedent or reason, but for traumatic disorders the immediate precipitating factor is known. PTSD includes manifestations of fear and anxiety, fluctuations in mood and dissociative states, changes in personality, and, in its most severe form, symptoms phenotypically similar to psychosis. An important question in PTSD pharmacotherapy has been whether to target individual symptoms or to address the syndrome as a whole.

DIAGNOSTIC CRITERIA

The first diagnostic criterion (Criterion A) for PTSD is that a person must have been exposed to a trauma, currently defined as "actual or threatened death, serious injury, or sexual violence" (APA, 2013). *DSM-5* removes the person's subjective response to trauma—specifically experiencing fear, helplessness, or terror—as a subcriterion since this feature does not provide any additional diagnostic accuracy. The symptoms of PTSD are classified into four discrete clusters that constitute diagnostic Criteria B through E. Intrusive symptoms (Criterion B) include (a) having recurrent and unwanted recollections of the event; (b) having distressing dreams of the event; and (c) acting and feeling as if the event were reoccurring (e.g., dissociative flashback). Additionally, (d) psychological and (e) physiological distress following exposure to symbolic representations of the event may also occur. Avoidant symptoms (Criterion C) reflect behaviors indicative of actively trying to avoid (a) internal (e.g., memories) or (b) external (e.g., places) reminders of the trauma. Symptoms of altered mood or cognitions include (a) the inability to recall important aspects of the trauma (e.g., psychogenic amnesia); (b) negative perceptions about oneself, others, or the world; (c) distorted cognitions regarding the cause or result of the event, leading to blame of others or oneself; (d) a negative emotional state that persists; (e) markedly diminished interest in normally significant activities; (f) feelings of detachment or estrangement from others; and (g) restricted range of affect. Altered arousal and reactivity symptoms include (a) irritability or angry outbursts; (b) a pattern of destructive behavior; (c) hypervigilance; (d) an exaggerated startle response; (e) difficulties with concentration; and (f) sleep problems. Meeting diagnostic criteria for PTSD requires the concurrent presence of at least one intrusive symptom, one avoidant symptom, two altered mood and cognition symptoms, and two altered arousal and reactivity symptoms.

In addition to the above criteria, symptoms must be present for at least 1 month (Criterion F); must be accompanied by clinically significant impairment in social, occupational, or other areas of functioning (Criterion G); and are not attributed to the effects of substances or other medical conditions (Criterion H). If symptoms last for more than 3 months following the traumatic event, the diagnosis of chronic PTSD is given. The diagnosis of delayed-onset PTSD is given if symptoms begin at least 6 months after the traumatic event. PTSD may be diagnosed in any person who meets the above diagnostic criteria, regardless of other preexisting or concurrent psychopathology. To date, the bulk of the existing psychopharmacological literature has been based on the *DSM-IV* criteria, which conceptualized PTSD as being composed primarily of intrusive (Criterion B), avoidant (Criterion C), and hyperarousal (Criterion D) symptom clusters, thus omitting altered cognitions from diagnostic classification.

PREVALENCE

Epidemiological studies have demonstrated that PTSD is a common psychiatric condition, and while there is a significant range in estimations, its lifetime prevalence has been estimated to be as high as 14% in the U.S. general population (Breslau Davis, Andreski, & Peterson, 1991; J. R. Davidson, Hughes, Blazer, & George, 1991; Helzer, Robin, & McEvoy, 1987; Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995; Shore, Vollmer, & Tatum, 1989). Among U.S. military veterans, the point prevalence of PTSD has been estimated to be between 2% and 17% and the lifetime prevalence 6% to 31%. More than 80% of adults in the United States have experienced a traumatic event; estimates of the prevalence of PTSD among those exposed to Criterion A stressors range from 3% to 58% (APA, 1994). This wide range reflects the fact that some types of traumatic events are more likely to result in PTSD than others. Among those who have experienced torture, such as concentration camp survivors and prisoners of war, the prevalence of PTSD can be quite high, with estimates of 50% to 75% in such samples (Goldstein, van Kammen, Shelly, Miller, & Kammen, 1987; Kluznick, Speed, Van Valenburg, &

Magraw, 1986). Among rape victims, approximately one third develop PTSD, and rape accounts for the greatest overlap among genders in the development of the disorder. However, in individuals who have been exposed to natural disasters such as earthquakes, volcanic eruptions, and bushfires, the prevalence of lifetime PTSD is lower, with estimates ranging from 3.5% to 16% (McFarlane, 1992; Shore, Tatum, & Vollmer, 1986; Shore et al., 1989). Estimates of the prevalence of PTSD in trauma survivors may also vary depending on the amount of time that has elapsed between the traumatic event and assessment of PTSD. The few studies examining the longitudinal course of PTSD prospectively demonstrated that frequency of PTSD following a specific traumatic event declines with time (Kessler et al., 1995; McFarlane, 1989; Rothbaum et al., 1992), with symptoms for the majority of trauma survivors resolving within 2 to 3 years. However, for the minority of individuals who remain symptomatic, the symptoms of PTSD may intensify over time, as does the risk of developing secondary and chronic comorbid mood or anxiety disorder, substance abuse, and memory impairment (Freedy, Shaw, & Jarrell, 1992; Golier et al., 2002; Green, Lindy, Grace, & Leonard, 1992; Kulka et al., 1990; North, Smith, & Spitznagel, 1994).

BURDEN OF POSTTRAUMATIC STRESS DISORDER

Exposure to traumatic events and the subsequent development of PTSD can result in significant psychological, physical health, and social consequences for the individual, as well as place a considerable burden on the health care system.

PTSD is associated with a number of adverse mental health outcomes, including other psychopathology, substance use, and self-harm. For example, individuals who experience childhood trauma are at increased risk for suicide (Felitti et al., 1998). Those diagnosed with PTSD are 2 times more likely to develop a depressive disorder and 10 times more likely to develop a panic disorder compared to their counterparts without a diagnosis (Perkonigg, Kessler, Storz, & Wittchen, 2000). Among veterans, there is a greater likelihood to be diagnosed with depression and anxiety in addition to PTSD as compared to PTSD alone, PTSD with anxiety, and PTSD with depression (Ginzburg, Ein-Dor, & Solomon, 2010). Severity of PTSD symptoms is associated with an increase in illicit drug and alcohol use (Ouimette et al., 2008). Kessler, Sonnega, Bromet, Hughes, and Nelson (1995) further estimated the likelihood of being diagnosed with another mental health disorder for both men and women in the general population. Men diagnosed with PTSD are 2 times more likely to be diagnosed with alcohol abuse and dependence, are almost 7 times more likely to be diagnosed with major depressive disorder, are approximately 10 times more likely to be diagnosed with mania, and are approximately 14 times more likely to be diagnosed with three or more psychiatric disorders than their male counterparts without PTSD. In contrast, women diagnosed with PTSD are approximately two times more likely to be diagnosed with alcohol abuse and dependence, are approximately four times more likely to develop major depressive disorder or mania, and are almost eight times more likely to be diagnosed with three or more psychiatric disorders than their female counterparts without PTSD (Kessler et al., 1995). With such cross-sectional analyses it is not always possible to determine whether such diagnoses are distinct comorbid conditions as they may be preexisting vulnerabilities to PTSD or PTSD symptoms themselves. The inclusion of "persistent negative emotional state" as a diagnostic criterion may minimize some of this comorbidity.

There is also significant medical comorbidity with PTSD. Overall, PTSD is associated with an increase in physical symptoms, higher rates of health care utilization, and early-age heart disease mortality (Boscarino, 2008; Deykin et al., 2001). Individuals who experienced four or more instances of childhood trauma demonstrate a 1.5-fold increase in physical inactivity and obesity when compared to individuals without instances of childhood trauma (Felitti et al., 1998). Those diagnosed with PTSD are more likely to develop arthritis, back and neck pain, chronic pain, heart disease, ulcers, and headaches (Sledjeski, Speisman, & Diefker, 2008). These detrimental health trends apply to both veteran and nonveteran populations. Vietnam veterans with PTSD are at greater risk of developing both cardiovascular and autoimmune diseases, including hypothyroidism, rheumatoid arthritis, and psoriasis (Boscarino, 2004). Iraq war veterans with PTSD, compared to those without, report lower ratings of general health, have a greater number of missed work days, and report a higher severity of somatic symptoms (Hoge et al., 2007).

The effects of PTSD can adversely permeate relationships and family life, among other social impacts. Among veterans, 70% of those who carry a PTSD diagnosis report intimate relationship distress, compared to 30% without a PTSD diagnosis (Riggs, Byrne, Weathers, & Litz, 1998). Some estimate that veterans with PTSD are a little more than 5 times more likely to perpetrate an act of domestic violence (e.g., hitting) and 26 times more likely to commit a severe act of violence (e.g., choking) compared to veterans with relationship problems but without a PTSD diagnosis (Sherman, Sautter, Jackson, Lyons, & Han, 2006). Among veterans separated from their partners, 53.7% report that they had conflicts (e.g., shoving) with their partner and 27.6% of veterans reported that their partner was currently afraid of them (Sayers, Farrow, Ross, & Oslin, 2009).

Individuals with PTSD and traumatic experiences are also significantly more likely to engage in risk-taking behaviors (Felitti et al., 1998; Killgore et al., 2008). Those who experience four or more traumatic childhood events are more likely to have a high number of sexual intercourse partners (defined as 50 or more) over their lifetime, which increases their risk of contracting a sexually transmitted infection (Felitti et al., 1998). Additionally, Killgore and colleagues (2008) surveyed 2,244 veterans just returning home from Iraq and found that those who had greater exposure to intense human trauma, had killed someone, or had been exposed to violent combat endorsed a higher tendency to engage in risky behaviors like fast driving and consuming higher quantities of alcohol, and more often expressed aggression toward others.

The increased incidence of comorbid psychopathology and medical problems, risk-taking behaviors, and disruption to family systems among individuals with PTSD places a great burden on the mental health care system. Veterans with PTSD utilize four times more general outpatient mental health services than veterans without PTSD, in addition to PTSD specialty treatment (Possemato, Wade, Andersen, & Quimette, 2010). For global analyses the World Health Organization (WHO) uses the disability adjusted life-years (DALYs) metric to estimate the burden of a disease or disorder. Each DALY represents a healthy year lost across the globe as the result of a disease and is calculated based on specific morbidity and mortality rates. The WHO (2001) estimates that PTSD's global burden of disease is 3,230,000 DALYs, which is similar to that of oral cancer, bladder cancer, and kidney cancer (Murray et al., 2012). Moreover, estimates for PTSD-related costs for returning veterans in the first 2 years are $5,904 to $10,298 on a per-case basis (Tanielian et al., 2008). Kessler and Greenberg (2002) estimate that the total annual cost of anxiety disorders, which include PTSD, is more than $100 billion annually in the U.S. population when taking into account the impact of unemployment, underemployment, and comorbidity costs.

ETIOLOGY

By definition, exposure to a traumatic event is a requirement for the development of PTSD. However, only a minority of persons exposed to even the most severe traumas develop PTSD or another psychiatric illness. In fact, other psychiatric disorders, including substance use and mood disorders, are more strongly associated with exposure to a traumatic event (Perkonigg, Kessler, Storz, & Wittchen, 2000). Therefore, it is important to consider other risk factors that influence the development or persistence of posttraumatic stress symptoms following trauma exposure. These include the severity of the trauma (Foy, Sipprelle, Rueger, & Carroll, 1984; March, 1993; Yehuda, Southwick, & Giller, 1992); past history of stress, abuse, or trauma (Bremner, Southwick, Johnson, Yehuda, & Charney, 1993; Zaidi & Foy, 1994); history of behavioral or psychological problems (Helzer et al., 1987); premorbid psychopathology; genetic factors (True et al., 1993); family history of psychopathology (J. Davidson, Swartz, Storck, Krishnan, & Hammett, 1985); and lower IQ (Macklin et al., 1998) as well as subsequent exposure to reactivating environmental events (Goldstein et al., 1987; Kluznick et al., 1986; McFarlane, 1990; Schnurr, Friedman, & Rosenberg, 1993; Solomon & Preager, 1992; True et al., 1993; Yehuda et al., 1995). Women are also at increased risk for developing PTSD, likely as a result of a greater exposure to assault (Breslau 2002). An awareness of the risk factors can have significant implications for the treatment of this chronic, heterogeneous, and multifaceted disorder, since the associated psychopathology may not only be a direct response to a precipitating traumatic event.

PHARMACOTHERAPY IN ADULTS WITH POSTTRAUMATIC STRESS DISORDER

Rationale for the Use of Pharmacotherapy in Posttraumatic Stress Disorder

An early view of the role of pharmacotherapy in the treatment of PTSD suggested that medications should be considered primarily as adjunctive to psychotherapy by modulating anxiety and depression to facilitate therapy. Antidepressants and anxiolytics were also considered to be indicated owing to the high rates of comorbid mood and anxiety disorders in PTSD. However, as research into the biological underpinnings of PTSD progressed, it became evident that there are alterations in the catecholaminergic and serotonergic systems and in the hypothalamic-pituitary-adrenal (HPA) axis in PTSD and that these were distinct from the alterations seen in other psychiatric disorders (e.g., Charney, Deutch, Krystal, Southwick, & Davis, 1993; Yehuda, Giller, & Mason, 1993). This provided a further rationale to examine an approach to pharmacotherapy in PTSD that might reduce symptoms by acting on the neurotransmitter systems implicated by these alterations. Increasing appreciation of the prevalence, severity, and chronicity of PTSD and the availability of novel psychotropic agents on the market have also fueled the advances made in the pharmacological treatment of this disorder and supported the notion that medication can be a primary treatment for core symptoms of PTSD (J. R. Davidson, 1992; Friedman, 1988).

Assessment of the Efficacy of Pharmacotherapy in Posttraumatic Stress Disorder

Table 19.1 summarizes the open-label and controlled pharmacological trials in the acute-phase treatment of chronic PTSD. The medications studied include antidepressants, antipsychotics, benzodiazepines, hypnotic agents, anticonvulsants and mood stabilizers, and sympatholytics as well as other medications that are emerging as potential treatments (e.g., cortisol-based treatments).

The medications are listed by category, and for each drug the studies are ranked according to their type (type 1 through type 4). To facilitate comparisons among the studies, the table includes information regarding the sample size and gender distribution, treatment population, the percentage changes in total PTSD symptoms from baseline to treatment end point, and the scales used to measure these changes. Additionally, the rate of treatment response is provided, as well as information regarding whether there were beneficial effects on specific symptoms (intrusive, avoidant, or hyperarousal symptoms, depression, or sleep).

The earliest studies used measures of depression or anxiety as primary outcome measures (e.g., the Hamilton Rating Scale for Depression; Hamilton, 1960) before validated scales for PTSD were available. Others have relied on self-report instruments of PTSD symptoms such as the Impact of Events Scale (Horowitz, Wilner, & Alvarez, 1979) and the Mississippi Scale for PTSD (Keane, Caddell, & Taylor, 1988). Over time, studies have increasingly relied on validated clinician-rated instruments such as the Clinician Administered PTSD Scale (CAPS; Blake Weathers et al., 1990), the Treatment of PTSD scale (TOP-8; J. R. Davidson & Colket, 1997), and the Structured Interview for PTSD (SIP; J. R. Davidson, Malik, & Travers, 1997). For more global measures of outcome, the Clinical Global Impression-severity (CGI-S) and Clinical Global Impression-improvement (CGI-I) scales (Guy, 1976) are used. Responder status in PTSD studies is often defined as subjects having been "much improved" or "very much improved" on the CGI. Other definitions are based on categorical levels of symptom improvement—most often defined as a 30% reduction in PTSD symptom severity—which are used alone or in combination with the CGI-I score. Less often, remission rates are reported, defined as the patient no longer meets criteria for the diagnosis or has a CAPS score of 20 or lower, which is indicative of only mild symptoms.

Table 19.1 summarizes acute-phase treatment of PTSD, referring to the initiation of a course of treatment. It does not refer to acute PTSD; for the majority of studies, the illness had been present for years to decades prior to the treatment trial, which often was not the first treatment trial. Details of the duration of illness, time since trauma exposure, and extent of treatment history could not be provided for each study but are mentioned for some of the most influential studies or when such information was particularly germane (e.g., studies of PTSD resistant to SSRIs). The extent of psychiatric comorbidity is also not explicitly summarized in the table, but most studies had high rates of comorbid disorders. Major depression was

almost always the most common comorbid condition. Generalized anxiety disorder, dysthymia, social phobia, panic disorder, agoraphobia, and a lifetime history of alcohol or substance abuse/dependence were also common comorbid conditions. Primary psychotic disorders and active substance abuse were almost always exclusionary.

The trials were most typically completed on relatively stabilized outpatients. Thus for many studies, there were likely earlier clinical interventions related to establishing stability, assessing safety and dangerousness, engaging the trauma survivor in treatment, forming a therapeutic alliance, and treating active substance abuse that may have preceded the initiation of the treatment trials but are not specifically addressed in the studies under review.

Acute-Phase Treatment

Monoamine Oxidase Inhibitors

MAOIs were among the first medications to be systematically studied in the treatment of PTSD. An open trial of phenelzine published in 1981 noted a

dramatic reduction in traumatic dreams, flashbacks, and violent outbursts in five veterans with traumatic war neurosis (Hogben & Cornfield, 1981). Subsequent studies supported this pattern of reduction in intrusive symptoms in open trials in U.S. combat veterans with PTSD (J. Davidson, Walker, & Kilts, 1987; Milanes et al., 1984). To date there have been two controlled trials of phenelzine. In a randomized, double-blind, crossover trial of 13 patients with PTSD of mixed trauma type, 4 weeks of phenelzine was not efficacious (Shestatzky, Greenberg, & Lerer, 1988). In an 8-week double-blind, placebo-controlled trial, veterans were randomized to phenelzine (60 to 75 mg/day), imipramine (200 to 300 mg/day), or placebo. Active medication was associated with significant decreases in PTSD symptoms as measured by the Impact of Events Scale (IES), particularly intrusive symptoms. The magnitude of effect was largest in the phenelzine-treated group, which experienced 68% global improvement, compared with 45% improvement with imipramine and 28% improvement with placebo. Improvement was evident in the absence of a medication effect on anxiety or depression. Thus, this was one of the first studies to demonstrate that

medications can improve PTSD symptoms independent of their antidepressant efficacy.

A disadvantage with the use of MAOIs is the necessity for diet restrictions and the risk of hypertensive crisis from tyramine-containing foods and other medications. This drawback to MAOIs has been obviated with the development of reversible inhibitors of monoamine oxidase A that do not interact with normal dietary quantities of tyramine and have a more favorable side-effect profile. Among these are moclobemide and brofaromine. In a 12-week open-label study of moclobemide in 20 patients with PTSD, significant improvement was evident in total PTSD symptoms, depression, anxiety, and overall functioning. The effect sizes were quite large, and 55% of the subjects no longer met criteria for PTSD, by far the highest remission rate reported in a medication trial in PTSD. In contrast, a controlled trial of brofaromine was negative. In a large ($N = 118$) multicenter, double-blind, parallel trial, the maximum improvement in total CAPS scores over 12 weeks was 33% in the brofaromine group and 31% in the placebo group. Of note, moclobemide is not available in the United States, and brofaromine was withdrawn from the market in 1994. Together, the data do not provide uniform support for the use of MAOIs as a class of drug in PTSD, but they do support the use of phenelzine and moclobemide in particular in the treatment of chronic PTSD.

Tricyclic and Tetracyclic Antidepressants

Prior to the introduction of SSRIs, TCAs were the most studied class of medications in PTSD. In addition to multiple positive retrospective reviews and case reports (Birkhimer, DeVane, & Muniz, 1985; Blake, 1986; Bleich, Siegel, Garb, & Lerer, 1986; Burstein et al., 1988; Falcon et al., 1985; Shen & Park, 1983; Turchan, Holmes, & Wasserman, 1992), there have been three randomized clinical trials (RCTs) of TCAs, one trial each for imipramine (Kosten, Frank, Dan, McDougle, & Giller, 1991), desipramine (Reist et al., 1989), and amitriptyline (J. R. Davidson et al., 1990).

A 4-week, double-blind, crossover study of desipramine (200 mg/day) versus placebo was conducted with 18 U.S. veterans. Desipramine treatment was associated with significant improvement in depression, but IES scores were virtually unchanged after desipramine or placebo (Reist et al., 1989). Given that it subsequently became clear that 8 weeks is the minimum duration of a treatment trial in PTSD and that there are other methodological limitations (absence of clinician-rated PTSD scales, small sample size), this negative controlled study should be considered preliminary. In the previously mentioned trial of phenelzine and imipramine (Kosten et al., 1991), 8 weeks of imipramine (200 to 300 mg/day) was superior to placebo in combat veterans with PTSD, with reduction in overall PTSD symptoms and intrusive symptoms. An 8-week trial of amitriptyline (150 to 300 mg/day) was conducted in veterans from World War II, the Korean War, or the Vietnam War with PTSD who were also receiving supportive psychotherapy (J. R. Davidson et al., 1990). Among study completers there were significant reductions in measures of anxiety and depression but no significant effect on the IES. There was a significant difference in some measures of clinical response (e.g., 50% of the amitriptyline group had a final CGI of 2 or less as compared with 16.6% of the placebo group), but not those dependent on PTSD symptom reduction (27.2% of the amitriptyline group had a greater than 50% drop in PTSD symptom score as compared with 16.6% of the placebo group). Thus, amitriptyline appears to improve clinical outcomes in PTSD, but the effect is not mediated primarily by reduction in PTSD-specific symptoms.

Several small, open-label studies have suggested that the tetracyclic antidepressant mirtazapine may be efficacious in PTSD. In six outpatients with both PTSD and major depression treated for 8 weeks, 33% showed clinical response on the CGI-I scale (Connor, Davidson, Weisler, & Ahearn, 1999). An Australian study treating 13 participants diagnosed with combat-related PTSD using a flexible mirtazapine dose (15 to 45 mg) demonstrated significant improvement assessed by both clinician- and self- administered PTSD symptom rating scales. In another, 15 patients were treated with a flexible dose of mirtazapine with significant reductions in PTSD symptoms (Bahk et al., 2002). One double-blind, placebo-controlled trial has been reported (J. R. Davidson et al., 2003). Twenty-nine patients with chronic PTSD secondary to a variety of trauma types were randomized to a fixed dose of mirtazapine (45 mg/day) for 8 weeks. The results were positive for some but not all primary outcome measures. Significantly higher response rates were found for mirtazapine than for placebo based on the global improvement measure of the Short PTSD

Rating Interview (65% vs. 22%); however, there were not significant group differences in reduction of total symptoms on this same measure. Mirtazapine was associated with greater symptom improvement in some secondary measures (Structured Interview for PTSD, Hospital Anxiety Scale) but not others (Davidson Trauma Scale, Hospital Depression Scale).

Selective Serotonin Reuptake Inhibitors

The largest type 1 studies of pharmacotherapy in PTSD have examined the efficacy of SSRIs, including fluoxetine, sertraline, and paroxetine. The first controlled trial of fluoxetine in PTSD was conducted at two different sites, an outpatient trauma clinic and a Veterans Administration (VA) outpatient clinic (van der Kolk et al., 1994). Sixty-four subjects, nearly half of whom were combat veterans, were randomized to 5 weeks of double-blind treatment with placebo or fluoxetine. For the sample as a whole, fluoxetine was superior to placebo in reducing overall PTSD symptoms. Improvement was also noted in numbing and hyperarousal symptoms but not avoidance and intrusive symptoms. The subsample from the trauma clinic had notably greater improvement than the veteran sample. In the veteran subsample, fluoxetine did not have a statistically significant effect on PTSD symptoms but did have a significant effect on depressive symptoms.

Although numerous open-label studies had suggested fluoxetine is efficacious in combat-related PTSD (Burdon, Sutker, Foulks, Crane, & Thompson, 1991; Dow & Kline, 1997; McDougle, Southwick, Charney, & James, 1991; Nagy, Morgan, Southwick, & Charney, 1993; Shay, 1992), a subsequent small, double-blind trial appeared to confirm the lack of efficacy in combat-related PTSD reported in the van der Kolk study. Twelve male Vietnam veterans were randomized to receive fluoxetine (10 to 60 mg/day; mean 48 mg/day) or placebo for 12 weeks (Hertzberg, Feldman, Beckham, Kudler, & Davidson, 2000). The response rate in the fluoxetine group was 17% as compared with 33% in the placebo group, and there were no significant fluoxetine-related differences in PTSD symptom severity measures.

Subsequent studies in civilian PTSD found fluoxetine efficacious. In a predominantly female (91%) and Caucasian (93%) sample of subjects with chronic PTSD, primarily secondary to sexual or physical assault, 12 weeks of fluoxetine was associated with significantly greater reduction in total PTSD symptom severity, evident as early as 2 weeks (Connor, Sutherland, Tupler, Malik, & Davidson, 1999). The response rate in the fluoxetine group was nonsignificantly higher than in the placebo group (85% vs. 62%), and the fluoxetine-treated group had higher end-state functioning. Another placebo-controlled trial in civilian PTSD similarly found that fluoxetine improved quality of life (Malik et al., 1999).

It was unclear whether the discrepancies in the outcome of fluoxetine treatment in civilian versus combat PTSD reflected differences in responsiveness based on trauma type or based on other factors relevant to many long-term VA patients. These include chronicity of illness, high rates of comorbid psychiatric illness and substance abuse, and even benefits and compensation seeking. A large (N = 301) double-blind, placebo-controlled trial of fluoxetine was conducted in a sample of PTSD subjects who were predominantly male (81%) and Caucasian (91%); 48% had experienced a combat-related trauma. Unlike the previous fluoxetine studies, it was not performed by the U.S. Department of Veterans Affairs but rather at sites in Belgium, Croatia, Israel, South Africa, and Yugoslavia (Martenyi et al., 2002a) in subjects who had been exposed to combat, were victims of or witnesses to war, or had witnessed another person's death. In this 12-week, flexible-dose (20 to 60 mg/day) study, the response rate in the fluoxetine group (defined as 50% or greater decrease in TOP-8 total score and a CGI-I score of much or very much improved) was 59.9%, significantly higher than the rate of 43.8% in the placebo group. The fluoxetine-treated group also had a significantly greater reduction in total PTSD symptom severity, and in particular in intrusive and hyperarousal symptoms, depression, and anxiety.

In the authors' subgroup analysis, statistically greater improvements compared with placebo were apparent in white subjects compared with nonwhite subjects, in those with combat-related PTSD compared with those with other traumas, in those with multiple traumas as compared with those with a single trauma, and in those without dissociative symptoms. The most robust effect sizes were for those without dissociative symptoms (1.20) and for those with combat-related trauma (0.78). There was a statistically significant treatment effect for men (N = 245) but not for women (N = 56); however, the effect sizes in women and men (0.53 vs. 0.35, respectively) were in the same range. These results suggest that neither

combat exposure nor male gender is associated with poor response to fluoxetine in veterans, and that combat-related PTSD may be more responsive to fluoxetine when treated earlier.

Sertraline is one of two medications approved by the U.S. Food and Drug Administration (FDA) specifically for PTSD. There have been a few large multicenter, double-blind, placebo-controlled trials of sertraline in the acute-phase treatment of chronic PTSD. One was a 12-week trial of a flexible dose of sertraline (50 to 200 mg) versus placebo in outpatients with a *DSM-III* diagnosis of moderate to severe PTSD. A total of 187 subjects were randomized. The majority were women (73%) who had physical or sexual assault as the index trauma (61.5%). Eighty-eight percent were Caucasian, and 9% were African American. The mean age of the sertraline-treated patients was 40.2 years, the mean duration of illness was 13.1 years, and the mean time from the traumatic event was 19.9 years. The prevalence of major depression was 36%, other anxiety disorders 18%, a history of alcohol abuse/dependence 22%, and a history of substance abuse/dependence 14% in the sertraline-treated group. The sertraline and placebo groups did not differ on demographic and clinical characteristics or rates of discontinuation. Of the common side effects, insomnia was significantly greater in the sertraline than the placebo group (16.0% vs. 4.3%).

Treatment with sertraline (mean dose 133.3 ± 59.2 mg/day) yielded significantly greater efficacy than placebo (based on last-observation-carried-forward analysis) on three of four a priori outcome measures: baseline–to–end point change in total CAPS scores, CGI-S, and CGI-I. There was a trend toward significant reductions on the IES scale. There was a significantly greater response rate in the sertraline than the placebo group (53% vs. 32%; defined as a greater than 30% reduction from baseline in CAPS total severity score and CGI-I score). Additionally, sertraline was associated with significantly greater improvement in depression and on multiple measures of social and occupational functioning. Sertraline did not improve reexperiencing symptoms, a core feature of the disorder, as measured on either the CAPS or the IES.

A subsequent 12-week, multicenter, controlled trial of a flexible dose (50 to 200 mg) of sertraline was conducted in a sample that was demographically and clinically similar to that of the aforementioned study (J. R. Davidson, Rothbaum, van der Kolk, Sikes, & Farfel, 2001). Treatment with sertraline was associated with a higher response rate than placebo (60% vs. 38%) and significantly greater improvement in total CAPS score, the CGI-S, and the CGI-I. As in the study by Brady and colleagues (2002), sertraline was not associated with improvement in reexperiencing symptoms; additionally, there was no improvement in hyperarousal symptoms, anxiety, or depression or on the Pittsburgh Sleep Quality Index (PSQI), a self-rated scale that assesses sleep quality and disturbances (Buysse, Reynolds, Monk, Berman, & Kupfer, 1989).

There was a significant clinical response to sertraline in both studies and, as subsequently reported, a significantly higher rate of remission than placebo (23% vs. 14%; J. R. Davidson, 2004). Interestingly, sertraline was not associated with improvement in reexperiencing symptoms and was inconsistently associated with reductions in hyperarousal or depressive symptoms. This raises the question of which changes in symptoms account for the clinical improvement. A pooled analysis found that the most robust effects of sertraline were on the symptoms of emotional numbing (anhedonia, foreshortened future, emotional detachment, emotional numbing), anger, and hypervigilance (J. R. Davidson, Landerman, Farfel, & Clary, 2002). The least-affected symptoms were in the reexperiencing cluster; no significant effects were found for traumatic nightmares or physical distress at reminders, and only weak effects were observed for intrusive memories, flashbacks, avoiding feelings, insomnia, and startle. Sustained sertraline-related reductions in anger were evident by the first week of treatment and partly but not fully explained the subsequent treatment effects on the remaining symptoms. Thus, sertraline-related effects were most evident for psychologically mediated symptoms (e.g., anger, emotional distress, anhedonia) and least evident for somatically mediated symptoms (e.g., nightmares, insomnia, exaggerated startle, physiological distress; J. R. Davidson et al., 2002a).

An important limitation of these two initial sertraline studies is that a significant majority of the subjects were women, and separate analyses of efficacy were not done in men and women (although the absence of a gender-by-treatment interaction on the CAPS change scores was noted for the second study [J. R. Davidson et al., 2001]). These limitations were addressed in a similar study examining the efficacy of a daily flexible dose of sertraline (25 to 200 mg, mean = 135

mg) versus placebo in a 12-week, double-blind, multisite randomized trial (N = 169) composed primarily of males (79.9%) with an average age of 45.3 years. A change in CAPS-2 score from baseline to endpoint was their primary outcome measure. Most participants' PTSD was combat-related (71%) followed by as a result of physical or sexual assault (15.4%). The average duration of illness was 18.3 years. They found that sertraline treatment did not differ from placebo in any of their primary or secondary outcomes. They also attempted to explore whether any participant variables moderated their outcomes but did not find significance. These findings are consistent with an older study of Israeli military veterans with PTSD (N = 42), most of whom were middle-aged men (Zohar et al., 2002). In the Israeli study the index traumas were combat-related violence (N = 32), motor vehicle accidents (N = 8), and captivity (N = 2), and the mean duration of illness was 7.1 (7.8) years in those randomized to sertraline and 7.6 (8.3) years in those randomized to placebo. Subjects were randomly assigned to double-blind treatment with sertraline (flexible dose 50 to 200 mg) or placebo. Based on the intent-to-treat analysis, there were no significant differences in the change in mean CAPS, CGI-S, or CGI-I scores, and the rates of response using the same criteria as the previous sertraline studies were not significantly higher in the sertraline- than the placebo-treated group (41% vs. 20%). The small sample size does not appear to fully explain the absence of significant differences. This group of study subjects had higher baseline CAPS scores than in most studies of civilian PTSD, a lower response rate, and a smaller percentage improvement in symptoms, suggesting that sertraline may be less efficacious in male combat veterans than in other traumatized groups with PTSD.

A multisite study (N = 21 sites) examining the efficacy of sertraline on children and adolescents (6 to 17 years old, mean = 10.8) meeting criteria for PTSD had a similar lack of statistically significant findings. This study used the UCLA PTSD-I, a semistructured interview assessing the presence and severity of *DSM-IV* PTSD symptoms. One hundred thirty-one mostly female (59.7%) participants were randomized to either a flexible dose of sertraline (50 to 200 mg) or placebo. Sertraline treatment was not associated with any improvements in PTSD. Moreover, based on calculated endpoint scores using last observation carried forward, the placebo group displayed greater improvement in PTSD symptoms.

Paroxetine is the second medication to have received FDA approval for PTSD. A 12-week open-label trial of paroxetine in non–combat-related PTSD suggested efficacy in treating all three symptom clusters, as well as anxiety, depressive, and dissociative symptoms (Marshall et al., 1998). Two subsequent 12-week, double-blind, placebo-controlled trials have confirmed this. The first was a fixed-dose (20 mg/day and 40 mg/day of paroxetine) study (Marshall, Beebe, Oldham, & Zaninelli, 2001). A total of 355 patients, predominantly women who had experienced physical or sexual assault (mean age 41.8 years), completed this study. The average time elapsed since the index trauma was 15.7 years and the majority were diagnosed with a comorbid mood or anxiety disorder.

Based on an intent-to-treat analysis, improvement was significantly greater for the paroxetine groups compared with the placebo groups on all primary efficacy measures, including the CAPS total severity score and each of the three symptom cluster scores. Response rates, based on the CGI-I, were significantly greater in the paroxetine-treated groups (54% in the 40-mg/day group, 62% in the 20-mg/day group) than in the placebo group (37%), but a dose–response relationship was not evident. There was also evidence of functional improvement in the paroxetine-treated groups in the areas of work, social life, and family life. Both men and women showed significant drug-versus-placebo differences in total scores on the CAPS.

In the second paroxetine trial, 307 outpatients with a *DSM-IV* diagnosis of PTSD were randomized to either placebo or a flexible dose (20 to 50 mg/day) of paroxetine (Tucker et al., 2001). The subject characteristics were similar to those in the aforementioned paroxetine trial. Compared with the placebo group, the paroxetine-treated group (mean dose 27.6 [6.72] mg/day) showed significantly greater reduction in total severity of PTSD symptoms, in each of the PTSD symptom cluster scores, and in depressive symptoms, and showed greater functional improvement. Paroxetine was associated with higher rates of response (based on the CGI-I) and remission (CAPS total score of less than 20), and 58.8% of paroxetine-treated subjects responded and 29.4% remitted, as compared with 38.0% and 16.5%, respectively, of the placebo-treated subjects. In men and women, paroxetine treatment was associated with a statistically significantly greater change in symptoms, and equal proportions of men and women achieved

responder status. Lastly, Marshall and colleagues (2007) conducted a trial of paroxetine in a small sample of underrepresented minority outpatients with PTSD. In addition to a significant reduction in CAPS score, paroxetine treatment was associated with a reduction in dissociative symptoms and interpersonal problems.

Multiple open-label studies with fluvoxamine have been reported (J. R. Davidson, Weisler, Malik, & Tupler, 1998b; Escalona, Canive, Calais, & Davidson, 2002; Marmar et al., 1996; Neylan et al., 2001; Tucker et al., 2000). Included are studies of civilian and combat-related trauma. Each study reported significant improvement in symptoms from baseline, ranging from 32% to 72%. Improvements in reexperiencing and avoidance were found in all studies, and all but one (Escalona et al., 2002) reported improvement in hyperarousal.

Two studies have examined the effects of fluvoxamine on sleep in greater detail. In combat veterans, improvement was evident in all domains of subjective sleep quality, and especially in combat-related dreams (Neylan et al., 2001). In a study of civilian PTSD, the mean number of hours slept increased from 4.5 to 6.8 hours per night, and there was a significant decrease in sleep difficulties and trauma-related dreams (Tucker et al., 2000). Controlled trials are needed to examine whether fluvoxamine does indeed have efficacy for all PTSD symptom clusters and whether there are beneficial effects on sleep and nightmares, which have not been evident with other SSRIs.

Other Antidepressants

Nefazodone is a unique antidepressant that acts as a presynaptic serotonin reuptake inhibitor and a postsynaptic 5-hydroxytryptamine 2A (5HT2A) receptor antagonist. It has been of particular interest in PTSD because it has been shown to improve objective measures of sleep quality in depressed subjects (Rush et al., 1998). To date there have been five open-label studies in veterans; in all, treatment was associated with significant improvement in clinician-rated total PTSD symptoms, as well as in the three individual classes of symptoms (Davis, Nugent, Murray, Kramer, & Petty, 2000; Garfield, Fichtner, Leveroni, & Mahableshwarkar, 2001; Hertzberg, Feldman, Beckham, Moore, & Davidson, 1998; Neylan et al., 2003; Zisook et al., 2000). A similar pattern of improvement was observed in a sample of private practice patients (J. R. Davidson, Weisler, Malik, & Connor, 1998a). Based on ambulatory polysomnography, improvements in objective measures of sleep quality were observed with nefazodone treatment in Vietnam combat veterans. The improvements included increases in total sleep time and sleep maintenance and in delta sleep (Neylan et al., 2003), with corresponding improvements in subjective sleep quality (reductions in nightmares and improved scores on the PSQI).

The results of a 12-week, placebo-controlled, double-blind study in combat veterans were less encouraging. Although the nefazodone group showed greater improvement in global PTSD symptoms and depression, response rates in the nefazodone group did not differ from those in the placebo group at study end point (46% vs. 40%; Davis et al., 2004). Safety concerns limit the use of nefazodone as a first-line agent. It has a black box warning regarding an increased (but rare) risk of liver failure that has resulted in deaths and transplantation. Accordingly, it has been taken off the market in some countries.

Beneficial effects of venlafaxine have been noted in a case report (Hamner & Frueh, 1998) and case series (Smajkic et al., 2001). A 12-week, multisite, double-blind, randomized trial examined the efficacy of venlafaxine extended-release, a serotonin norepinephrine reuptake inhibitor approved by the FDA to treat major depressive disorder, generalized anxiety disorder, social anxiety disorder, and panic disorder with or without agoraphobia. The overall sample consisted of 538 males and females prescribed flexible doses of sertraline (25 to 200 mg/d), venlafaxine extended-release (37.5 to 300 mg/day), or placebo. They found significant improvement in the CAPS total score for the venlafaxine group (sertraline was not significant). Venlafaxine also significantly reduced CAPS avoidance and hyperarousal scores as well as scores on the Davidson Trauma Scale (DTS; J. R. Davidson, Tharwani, & Connor, 2002b), CGI-S, and the Hamilton Rating Scale for Depression (HAM-D). Sertraline compared to placebo was only associated with improved CAPS avoidance and CGI-S.

To date there is limited information about the efficacy of bupropion as a treatment for PTSD. However, the extant data on bupropion suggest it is not an effective pharmacological treatment approach specifically for PTSD. An open-label trial of bupropion in combat veterans with PTSD found significant improvement in depressive symptoms, but not in PTSD symptoms,

except for hyperarousal symptoms. Of the 14 study completers, 10 were classified as treatment responders (Canive, Clark, Calais, Qualls, & Tuason, 1998). A small 8-week placebo-controlled, double-blind study examining the efficacy of bupropion sustained-release on a sample of men and women (N = 30, mean age = 50), diagnosed with civilian or military PTSD, did not find any significantly different reductions in PTSD symptoms.

Antipsychotics

There are scant case reports on the use of first-generation antipsychotics in PTSD (chlorpromazine: Leber, Malek, D'Agostino, & Adelman, 1999; thioridazine: Dillard, Bendfeldt, & Jernigan, 1993) and one open-label study suggesting levomepromazine improves sleep in inpatients with PTSD (Aukst-Margetic, Margetic, Tosic, & Bilic-Prcic, 2004). Given the general impression that they are not effective against core PTSD symptoms and owing to the risk of tardive dyskinesia, their use has generally not been advocated in PTSD. However, in the past decade there have been a number of trials suggesting that second-generation antipsychotics (SGAs; atypical antipsychotics) may have a role in the treatment of chronic PTSD. Among the agents studied have been risperidone, olanzapine, quetiapine, and aripiprazole.

A primary rationale for testing the efficacy of SGAs is that many patients with PTSD do not respond to first-line psychopharmacological treatments or have residual distressing symptoms and functional impairment. Accordingly, trials of these drugs initially were conducted primarily in combat veterans, treatment-resistant patients, and those with co-occurring psychotic symptoms. Assessments of outcome generally include changes in psychotic symptoms based on scales typically used for schizophrenia, such as the Positive and Negative Symptoms of Schizophrenia Scale (PANSS; Kay, Fiszbein, & Opler, 1987) and the Brief Psychiatric Rating Scale (BPRS; Overall & Gorham, 1962). Possible sides effects, such as tardive dyskinesia, akathisia, and other extrapyramidal symptoms, are typically assessed using the Abnormal Involuntary Movement Scale (AIMS) (Guy, 1976), the Barnes Akathisia Scale (Barnes, 1989), and the Simpson-Angus Scale (SAS) (Simpson & Angus, 1970), respectively.

To date there have been two open-label (David, De Faria, Lapeyra, & Mellman, 2004; David, De Faria, & Mellman, 2006), and five double-blind placebo-controlled trials (Bartzokis, Lu, Turner, Mintz, & Saunders, 2005; Hamner et al., 2003b; Kozaric-Kovacic, Pivac, Muck-Seler, & Rothbaum, 2005; Padala et al., 2006) of risperidone in combat-related PTSD. The open-label study prescribed 12 weeks of adjunctive risperidone (1 to 3 mg/day) to treatment-resistant veterans and found a significant reduction in total CAPS score, total PANSS score (as well as PANSS measures of general psychopathology, positive symptoms, and negative symptoms), and the CGI-S. With respect to safety concerns, fasting glucose levels showed a trend-level increase from baseline to endpoint, one subject gained 25 lbs, and there were no significant extrapyramidal symptom increases. A second open-label 12-week flexible-dose trial evaluated how risperidone might improve sleep in veterans with PTSD (David, De Faria, & Mellman, 2006). Participants reported decreases in trauma-related dreams as well as a decrease in the frequency of awakening in the middle of the night in the morning log assessment, and data from the sleep log indicated a reduction in the proportion of traumatic dreams by week 6 of the study.

A 6-week trial of risperidone (2 to 4 mg/day) as monotherapy was conducted among 26 treatment-resistant inpatient combat veterans. The study excluded participants with Axis I comorbidity or a family history of psychosis (Kozaric-Kovacic et al., 2005). They found a significant decrease in the total and subscale scores of the PANSS, PTSD-I, and the CGI-S. Of note, 12% of participants gained weight during the trial and 42% developed extrapyramidal side effects. A subsequent risperidone trial was conducted over a 12-week period and compared a flexible dose of risperidone to placebo (monotherapy) in 20 females between the ages of 19 and 65 years diagnosed with chronic PTSD due to sexual assault or domestic violence (Padala et al., 2006). Participants who received risperidone were started on 0.5 mg twice daily, and the dose was titrated to 1 mg daily each week to achieve a dosage of 4 to 6 mg daily. The treatment group had a significant decrease in both the total CAPS-2 score and among the hyperarousal and intrusive subscale scores.

A longer 16-week, double-blind, placebo-controlled trial of adjunctive risperidone was conducted on 65 veterans with combat-related PTSD (Bartzokis et al.,

2005). Risperidone was associated with significant reductions in total CAPS score and the psychotic subscale of the PANSS. The treatment was well tolerated and was not associated with changes in the BAS, AIMS, or SAS, adjusted for baseline scores, or with alterations in weight, heart rate, or blood pressure. Another randomized, double-blind, 5-week trial of adjunctive risperidone (1 to 6 mg/day, mean = 2.5 mg/day) was conducted on combat-related PTSD with psychotic features in the absence of a primary psychotic disorder (Hamner et al., 2003b). Examples of psychotic symptoms included auditory or visual hallucinations pertaining to the precipitating trauma or experiencing nonspecific symptoms such as hearing whispering voices or expressing paranoid ideation. Although the risperidone group displayed a significantly greater reduction on the PANSS total and global psychopathology scores, no significant changes were discovered on the PANSS positive symptom score or on total CAPS score. While there were no treatment-associated changes on the BAS, AIMS, or SAS, one patient developed akathisia.

One small, double-blind, placebo-controlled study of adjunctive risperidone (0.5 to 8 mg/day) conducted on women with moderate to severe PTSD related to childhood abuse found that risperidone treatment was associated with significant overall PTSD symptom reduction, including reexperiencing and hyperarousal (Reich, Winternitz, Hennen, Watts, & Stanculescu, 2004). In terms of adverse side effects, risperidone was associated with an increase in prolactin and no difference in weight gain compared to placebo.

Conversely, a larger 6-week, double-blind, placebo-controlled study of adjunctive risperidone (titrated to 3 mg at bedtime), conducted on 247 veterans with PTSD recruited from 23 VA outpatient centers, found that risperidone treatment was not associated with any significant CAPS score reductions and did not reduce symptoms of anxiety or depression. Adverse events were also more common in the risperidone treatment group when compared to the placebo group, including higher rates of weight gain (15.3% vs. 2.3%) and higher rates of fatigue (13.7% vs. 0%).

Olanzapine has been studied as a monotherapeutic (Carey, Suliman, Ganesan, Seedat, & Stein, 2012; Petty et al., 2001) and adjunctive agent (Stein, Kline, & Matloff, 2002) in combat-related PTSD. Petty and colleagues (2001) treated a sample of 48 veterans with open-label olanzapine (5 to 20 mg/day) for 8 weeks as monotherapy. They found a significant reduction in total CAPS score and in each of the subscales, in the BPRS, and on measures of anxiety and depression. There were no significant changes in safety measures (BAS, AIMS, and SAS). Notably, however, among completers, the mean weight gain was 3.5 ± 3.1 kg. Olanzapine was later studied as a monotherapy in an 8-week double-blind, placebo-controlled trial of 28 males and females diagnosed with non–combat-related PTSD (Carey et al., 2012). From baseline to endpoint, the olanzapine group demonstrated a significant reduction in CAPS score compared to the placebo group. Substantial weight gain (13 to 22 lbs) was reported in the treatment group.

In an 8-week double-blind, placebo-controlled trial of adjunctive olanzapine (10 to 20 mg/day) in SSRI-resistant combat veterans with PTSD (Stein et al., 2002), olanzapine treatment was associated with significantly greater reductions in total PTSD symptoms, depressive symptoms, and sleep quality. The response rates in the olanzapine- and placebo-treated groups (30% vs. 11%) were not significantly different. Weight gain, however, was significantly greater in the olanzapine than the placebo group (+13.2 lbs vs. –3.0 lbs). A double-blind, placebo-controlled trial of olanzapine monotherapy (5 to 20 mg/day) was conducted in female veterans with PTSD, primarily stemming from sexual assault/harassment in the military (Butterfield et al., 2001). The response rate (60%), extent of PTSD symptom reduction, and functional improvement did not differ between the groups. However, the olanzapine-treated group had significantly greater weight gain than the placebo group (11.5 ± 4.43 lbs vs. 0.9 ± 0.06 lbs).

To date there have not been any controlled trials of quetiapine, but there is preliminary evidence from three open-label trials suggesting it may be efficacious in chronic PTSD. In a case series of five medication-resistant PTSD subjects, all showed improvement in flashbacks with quetiapine (Filteau, Leblanc, & Bouchard, 2003). In a 6-week open-label study in combat veterans, adjunctive quetiapine (25 to 300 mg/day; Hamner et al., 2003a) was associated with a broad spectrum of improvement, including significant reductions in total PTSD symptom severity (and in each of the three symptom clusters), PANSS composite and positive symptom score, and the HAM-D. Fifty-eight percent of subjects met criteria for response based on the CGI. No significant

changes were observed for weight or blood pressures or in the AIMS, BAS, and SAS scales. Analysis of the sleep data from this study revealed significant improvement with quetiapine on multiple measures of the PSQI, most notably sleep duration, which increased from 4.0 ± 1.0 to 6.0 ± 1.8 hours per night, and sleep quality (Robert et al., 2005).

In another open-label study, quetiapine (100 to 400 mg/day) was added to the regimen of 15 PTSD patients on stable doses of SSRIs. There was a significant reduction in total CAPS score (and in each of the subscales), as well as on multiple secondary measures including the PSQI and HAM-D. Fifty-three percent of patients had a clinical response, and one went into remission (Ahearn, Mussey, Johnson, Krohn, & Krahn, 2006). There were no reports of adverse events, movement-related disorders, or weight gain.

In an additional 8-week open-label trial of quetiapine (25 to 400 mg/daily; mean = 335.75 mg/daily), 53 male inpatient veterans diagnosed with PTSD with psychotic symptoms were treated. Significant reductions in CAPS, PANSS, and CGI-S scores were found, and improvement was evident as early as week 2. In the treatment group, sedation was the most frequently reported (39.6%) adverse event, followed by hypotension (3.8%), psychomotor agitation (9.4%), and QT prolongation (5.7%) (Kozaric-Kovacic & Pivac, 2007).

To date there have been three open-label trials of aripiprazole for the treatment of PTSD (Mello et al., 2008; Villarreal et al., 2007; Youssef et al., 2012). The first was conducted over a 12-week period; 22 veterans with PTSD received 5 to 30 mg/day (Villarreal et al., 2007). Participants demonstrated significant reductions in CAPS total score and scores on subscales as well as on measures of depression, anxiety, and psychotic symptoms. Additionally, they reported an increase in sleep duration. Among the completers, 36% were responders based on a 30% or greater reduction in total CAPS score. Somnolence (54.5%), restlessness (50%), insomnia (36.4%), and asthenia (31.8%) were the most common adverse events.

Similar findings were discovered in a 16-week open-label trial of aripiprazole (7.5 to 15 mg/daily) among 32 individuals diagnosed with PTSD (Mello et al., 2008). Overall, participants had a 38% total CAPS score reduction. More than half were considered responders and had a 30% total CAPS score. Of note is the high percentage (28%) of participants who discontinued treatment prior to the second assessment; 18.7% of these discontinuations were attributed to adverse events, which included anxiety, nausea, insomnia, and psychomotor agitation.

A third 12-week open-label pilot trial of aripiprazole (5 to 30 mg/daily) conducted on 10 veterans diagnosed with PTSD also found significant decreases in total CAPS scores and other symptom outcome measures (Youssef et al., 2012). Overall, 50% of participants responded to aripiprazole, defined as a 20% reduction in CAPS score. They also had significant improvements on the Short PTSD Rating Interview (SPRINT), TOP-8, DTS, CGI-I, and all three PANSS subscales. The most commonly reported adverse effects included weight gain, concentration difficulties, and akathisia.

Positive case reports of the effect of clozapine (Hamner, 1996) and ziprasidone (Siddiqui, Marcil, Bhatia, Ramaswamy, & Petty, 2005) on combat-related PTSD have also been published.

In summary, the effects of SGAs on core PTSD symptoms and associated symptoms are mixed, although the available evidence from studies of 6 to 16 weeks' duration suggests that there may be a role for SGAs as adjunctive medications for treatment-refractory PTSD and PTSD with psychotic symptoms. The apparent efficacy of some agents, such as olanzapine, against a broad array of PTSD-specific and associated symptoms makes them a possibly attractive option. However, they do not appear to be effective in veterans. Furthermore, side effects were evident, and weight gain was especially marked for several agents and was consistently observed with olanzapine even in these short-term studies. Given the link between SGAs, weight gain, and the metabolic syndrome, the risks of treatment with SGAs in PTSD need to be carefully balanced against the potential benefits, and careful monitoring of both therapeutic effects and adverse effects is warranted.

Despite the mixed data on efficacy and the concerns regarding adverse side effects, the use of these antipsychotic medications in clinical practice is widespread. In an observational study of veterans receiving care at a VA hospital, 9% of the 831 inpatients and 10% of the 554 outpatients with PTSD were being treated with antipsychotics. In both samples, those treated with the antipsychotics had more psychiatric and social impairment. However, outcomes at 1-year follow-up were not different between those treated with and without antipsychotics (Sernyak, Kosten,

Fontana, & Rosenheck, 2001). In a nonveteran community clinic, 17% of those with PTSD alone and 34% of those with PTSD and major depressive disorder were being treated with atypical antipsychotics (Mellman, Clark, & Peacock, 2003).In an examination of VA records of 274,297 veterans with a PTSD diagnosis in 2004, 80.4% were prescribed psychotropic medication (Mohamed & Rosenheck, 2008). Among them, 33.6% were prescribed antipsychotics. Given their widespread use and potentially serious side effects, continued study is needed to examine their efficacy, which groups may be at increased risk for harm, and how the risks can be managed and minimized.

Benzodiazepines

Benzodiazepines have generally not been recommended as a treatment for PTSD owing to concerns related to efficacy, the potential for abuse and dependence, and the potential for severe symptom exacerbation with discontinuation (Risse et al., 1990). However, they have been little studied. In a double-blind, crossover trial of 10 PTSD patients of mixed trauma type, 5 weeks of alprazolam treatment was compared with 5 weeks of placebo treatment. Alprazolam was associated with significant decreases in the Hamilton anxiety scale, but no differences were observed on clinician-rated or self-rated PTSD scales (Braun, Greenberg, Dasberg, & Lerer, 1990). A randomized, single-blind, placebo-controlled crossover study of clonazepam for sleep was conducted in a small number ($N = 6$) of combat veterans. Marginal efficacy was found for clonazepam, with mild to moderate improvements in difficulty falling or staying asleep, no change in the frequency or intensity of nightmares, and little improvement in the quality of sleep (Cates, Bishop, Davis, Lowe, & Woolley, 2004).

The paucity of studies of benzodiazepines in chronic PTSD is striking in light of the frequency with which these drugs are prescribed in clinical practice. A follow-up of 370 veterans after a brief hospitalization for PTSD showed that 45% of those without substance abuse histories and 26% of those with substance abuse histories were treated with benzodiazepines (Kosten, Fontana, Sernyak, & Rosenheck, 2000). There was no evidence that benzodiazepines had an adverse effect on 1-year outcomes. Nor was there evidence that they were associated with improvement in anxiety symptoms or functioning. However, benzodiazepine use was significantly associated with lower health care utilization (Kosten et al., 2000). Understanding the mechanisms that mediate this effect is important because PTSD is associated with significant medical morbidity and very high rates of health care utilization.

This prescribing pattern is not unique to the VA. Based on a review of Medicaid records, in a community-based sample in New Hampshire, 41% of patients with PTSD alone were prescribed benzodiazepines or other hypnotics, and 54% of patients with both MDD and PTSD were treated with benzodiazepines or related hypnotics (Mellman, Clark, & Peacock, 2003). Given this vast discrepancy between treatment guidelines and actual clinical practice, large-scale, double-blind studies are needed to evaluate whether benzodiazepines are effective, deleterious, or neither in chronic PTSD. A broader range of outcomes may be needed to capture whether there is some other aspect of mental health (e.g., sense of well-being, decreased somatization) that might explain their widespread use and their apparent impact on reducing health care utilization.

Mood Stabilizers and Anticonvulsants

The use of anticonvulsants and mood stabilizers in the treatment of PTSD has been of interest for clinical reasons, since PTSD can be associated with affective instability (Golier, Yehuda, Schmeidler, & Siever, 2001), irritability, violence and other symptoms for which mood stabilizers have previously been found to be effective. Researchers hypothesize that kindling perpetuates PTSD-related symptoms (Post, Weiss, Smith, Li, & McCann, 1997). Following trauma exposure, sensitization may occur such that limbic structures subsequently respond to less intense trauma-related stimuli. This phenomenon is thought to explain reexperiencing symptoms and increased levels of distress and physiological reactions to traumatic reminders (Post et al., 1997). Raising the neuronal threshold for arousal in limbic areas could relieve the behavioral and neurobiological sensitization of trauma survivors (Keck, McElroy, & Friedman, 1992). This notion has prompted interest in the use of mood stabilizers in this disorder, including those that act on gamma-aminobutyric acid (GABA)-A (e.g., valproate) and GABA-B (e.g., carbamazepine)

receptors resulting in neuronal hyperpolarization and stabilization.

The beneficial effects of carbamazepine or its analogue oxcarbazepine have been noted in case reports (Ford, 1996; Malek-Ahmadi & Hanretta, 2004) and in a case series in which Vietnam War veterans were noted to have improved impulse control and fewer angry outbursts (Wolf, Alavi, & Mosnaim, 1988). In an open-label trial, 10 combat veteran inpatients with PTSD were treated with carbamazepine at doses ranging from 600 to 1,000 mg/day (Lipper et al., 1986), resulting in significant reductions in total PTSD symptoms and on the BPRS, as well as reductions in somatization, hostility, psychosis, and confusion-bewilderment on self-rating scales. Seven of the 10 showed a clinical response based on the CGI-I. To date, there have not been any type 1 studies examining the use of carbamazepine as a pharmacological intervention for PTSD.

Valproate has been studied in two open-label studies of combat veterans with PTSD. In the first, improvement in hyperarousal, sleep, and avoidant symptoms was noted in a group of 16 combat veterans treated with 750 to 1,750 mg/day of valproate over a period of several months (Fesler, 1991). In another, following 8 weeks of adjunctive valproate (1,000 to 2,500 mg/day; mean = 1,356 mg) there were significant decreases in total CAPS scores (including intrusive and hyperarousal symptoms), depression, and anxiety, and 11 of 13 subjects showed a clinical response (Clark, Canive, Calais, Qualls, & Tuason, 1999). A subsequent randomized, double-blind, placebo-controlled study of 82 predominantly male combat veterans, receiving a titrated dosage of 500 mg of valproate twice daily for 8 weeks, did not report significant differences in CAPS score reductions between the placebo and control groups. This was true for both total and hyperarousal cluster symptom scores, which were the specific outcome measures for this study (Davis et al., 2008).

Several reports suggest that gabapentin, approved by the FDA for the treatment of partial complex seizures and neuropathic pain, may be efficacious, especially for intrusive symptoms. In one case report, it significantly reduced flashbacks in a woman with PTSD and MDD (Malek-Ahmadi, 2003); in another, it reduced nightmares in a man with treatment-resistant PTSD following an electrical injury (Brannon, Labbate, & Huber, 2000). In a retrospective review of Vietnam veterans with chronic PTSD, 73% of subjects were rated as moderately to much improved with the addition of gabapentin, with an improvement in insomnia and nightmares (Hamner, Brodrick, & Labbate, 2001). A small randomized double-blind placebo-controlled trial comparing propranolol (discussed in the Secondary Prevention section) and gabapentin among 48 civilians with physical injury trauma prescribed to prevent the development of mental health sequelae (within 48 hours of their trauma) did not demonstrate any significant benefits of gabapentin over placebo in any of their follow-up outcome measures (Stein et al., 2007).

Topiramate is a novel antiepileptic with a broad spectrum of pharmacological properties. In addition to its anti-kindling properties, its use in PTSD is supported by preclinical data showing that it reduces acoustic startle in animals (Khan & Liberzon, 2004) and enhances the sensitivity of the glucocorticoid receptor in PTSD patients in vitro (Yehuda et al., 2004). Not only does it have positive case reports (Berlant, 2001), but a retrospective review found that it decreased nightmares in 79% and flashbacks in 86% of patients with civilian PTSD (Berlant & van Kammen, 2002). In a prospective open-label study of 33 PTSD patients in private practice, topiramate was used primarily as an adjunctive agent over 4 weeks at a median dose of 50 mg/day. Despite the short duration of treatment, significant reductions were observed in total PTSD symptoms (and in each symptom cluster) based on the self-reported PTSD Checklist. Seventy-seven percent responded, with a 30% or greater reduction in PTSD symptoms. With respect to intrusive symptoms, 79% ceased having reexperiencing symptoms, with a mean time to full cessation of just 15 days. These encouraging initial results suggested that topiramate might have a rapid rate of response in PTSD, but subsequent and more rigorous studies have been equivocal about its efficacy. A double-blind randomized control trial on 38 mostly female outpatients did not demonstrate a statistically significant reduction of PTSD symptoms as measured by the CAPS (Tucker et al., 2007). Yet a more recent double-blind study found a significant (–57.78% vs. –32.41%) reduction of CAPS score in their sample of 35 civilians diagnosed with PTSD (Yeh et al., 2011). There appears to be a paucity of studies with large sample sizes in the current topiramate literature.

Tiagabine is a selective GABA reuptake inhibitor that increases extracellular GABA levels. In addition to a positive case report (Berigan, 2002) and case series (Taylor, 2003), an open-label study of tiagabine (mean dose 12.5 ± 4.0 mg/day) was completed in patients with chronic PTSD (Connor, Davidson, Weisler, Zhang, & Abraham, 2006). Among completers, there was significant improvement in PTSD symptom severity, anxiety, depression, sleep quality, and level of functioning. However, a subsequent type 1 study has called into question these initial promising results (J. R. Davidson et al., 2007). A 12-week double-blind, placebo-controlled continuation phase trial of 232 participants found that CAPS total score reductions from baseline to termination did not differ significantly between the treatment and placebo groups (30.7 vs. 30.2 points).

Phenytoin is an anticonvulsant that blocks the cellular responses to glutamate. Interest in phenytoin in the treatment of PTSD was prompted by observations that the deleterious effects of stress on memory performance and the hippocampus in animals are blocked by phenytoin (Hui, Guang-Yu, Chong-Tao, Quan, & Xiao-Hu, 2005; Watanabe, Gould, Cameron, Daniels, & McEwen, 1992). To the extent that PTSD symptoms or the associated neuropsychological impairments and neuroanatomical alterations (Bremner et al., 1997; Gurvits et al., 1996) are mediated by similar effects of stress on humans, phenytoin could theoretically attenuate this process (Bremner et al., 2005). In an open-label study of phenytoin as monotherapy, 9 of 12 patients completed the study. Among completers there was a 41.5% reduction in total CAPS score and a significant reduction in all three PTSD symptom clusters, in the absence of significant reduction in anxiety or depression. Social and occupational functioning also improved. RCTs are necessary to establish the certainty of phenytoin's efficacy as a pharmacological treatment of PTSD.

Information about the efficacy of lithium carbonate in the treatment of PTSD is also scant in the literature. Van der Kolk (1983) performed an open trial of lithium carbonate (therapeutic dose: 300 to 1,500 mg/day) in 14 treatment-refractory combat veterans. Eight of them improved, with noted reduction of hyperarousal symptoms. Kitchner and Greenstein (1985) reported similarly beneficial results in an open trial with five combat veterans. A recent case study found a significant reduction of acute suicidality among two female patients with PTSD treated with 3 to 4 weeks of lithium carbonate at 600 to 900 mg daily.

In summary, multiple anticonvulsants and mood stabilizers with varying neurobiological mechanisms have been tested for the treatment of PTSD and have demonstrated mixed efficacy outcomes. While these treatment approaches have been promising, there is a lack of type 1 trials to fully ascertain their utility as pharmacological interventions for PTSD.

Sympatholytic Agents

Interest in the potential use of antiadrenergic drugs in PTSD dates back to some of the earliest scientific observations regarding the pathophysiology of this illness. Beginning with Kardiner's (1941) seminal depiction of "physioneurosis" in combat veterans, there has been evidence of increased sympathetic nervous system activation in PTSD. Abundant lines of evidence support this view, including evidence of elevated levels of catecholamines (Kosten, Mason, Giller, Ostroff, & Harkness, 1987), enhanced autonomic responses to loud tones (Orr, Lasko, Shalev, & Pitman, 1995), and increased alpha-2 receptor sensitivity (Southwick et al., 1999).

The possibility that sympatholytic antihypertensives could be effective against chronic PTSD was investigated as early as 1984. Kolb, Burris, and Griffiths (1984) studied propranolol, a nonselective beta-adrenergic receptor blocker, in 12 Vietnam combat veterans. At doses of 120 to 160 mg/day there was improvement in explosiveness, nightmares, intrusive recollections, startle response, hyperalertness, and impaired sleep, as well as in self-esteem and psychosocial function. Propranolol was also noted in a case report to reduce the reemergence of PTSD symptoms following retraumatization (Taylor & Cahill, 2002). Stein and colleagues (2007) investigated the efficacy of propranolol (120 mg/daily for 14 days after trauma exposure) as a preventive intervention for PTSD (discussed in greater detail in the Secondary Prevention section). They found that propranolol was not significantly better than placebo on any of their outcome measures.

Kolb and colleagues (1984) also reported that clonidine, an alpha-2 receptor agonist, alleviated flashbacks and hyperarousal in combat veterans. Clonidine is of particular interest, since subsequent studies have demonstrated that the alpha-2 receptor antagonist yohimbine exacerbates PTSD symptoms in

the laboratory and in naturalistic settings (Southwick et al., 1997, 1999). In a pilot study, Kinzie, Sack, and Riley (1994) added clonidine to the treatment of nine Cambodian refugees with PTSD who did not improve with imipramine and followed them for 12 to 19 months. In this descriptive study the researchers noted that six of the patients had improvement in PTSD symptoms (two no longer met criteria for the disorder), six had improvement in sleep, six had improvement in depression, and seven had improvement in nightmares.

Prazosin, a centrally active adrenergic-1 antagonist, has been more extensively studied. Following up on a clinical observation, an initial case series using this sympatholytic antihypertensive in combat PTSD showed that at low doses at bedtime, prazosin improved severe and chronic combat-related nightmares (Raskind et al., 2000). In a small open-label trial in civilian PTSD, 6 weeks of prazosin was also associated with clinical improvement and reduction in nightmares (Taylor & Raskind, 2002). In a retrospective review of 58 male Vietnam and Gulf War veterans with treatment-refractory PTSD, those treated with at least 8 weeks of prazosin (mean dose = 9.6 ± 0.9 mg/day) showed a significant decrease in distressing dreams (Raskind et al., 2002). Of the few published studies of PTSD treatment in the elderly, prazosin reduced nightmares in elderly combat veterans and a Holocaust survivor (Peskind, Bonner, Hoff, & Raskind, 2003).

Treatment with prazosin was subsequently evaluated in a double-blind, placebo-controlled, crossover trial in 10 Vietnam War combat veterans with chronic PTSD and severe nightmares. For most subjects it was an adjunctive agent. Not only was improvement in sleep difficulty and recurrent distressing dreams noted, but there were significant reductions in the PTSD total score and scores on each of the three subscales. Furthermore, prazosin treatment was associated with greater clinical global improvement than placebo (Raskind et al., 2003).

Prazosin is emerging as an effective treatment for the sleep problems and nightmares associated with PTSD and may be useful for a broader range of PTSD symptomology. Indeed, appreciation of the benefit of this medication is suggested by Bernardy, Lund, Alexander, and Friedman (2012), who estimate that the prescription of prazosin among veterans has increased by 9.1% (almost seven-fold) from 1999 to 2009. A more recent double-blind randomized trial (n = 34) found significant improvement of PTSD sleep-related symptomology among male combat veterans who took the study drug for 8 weeks (Raskind et al., 2007). The study team expanded upon these initial results with a larger trial of 56 participants aimed at understanding the impact prazosin has on sleep quality in male veterans (Raskind et al., 2013). Prazosin was determined to significantly improve nightmare symptoms of PTSD, supported by reductions in both CAPS sleep questions and the PSQI. This drug is unique in targeting a specific subset of PTSD symptoms. Further research is needed to develop targeted PTSD psychopharmacological interventions for sleep and other specific distressing symptoms.

Despite the compelling scientific rationale for the use of sympatholytic agents, to date there have been no randomized, double-blind, placebo-controlled trials investigating the independent effects of clonidine on PTSD symptoms. Furthermore, neither of the two studies of guanfacine (type 1 and type 3) has demonstrated significant reduction in CAPS scores following treatment (Davis et al., 2008; Neylan et al., 2006). The need for future research of sympatholytic agents is further suggested by the promising early outcomes with prazosin. Such studies may help us to better understand whether direct modulation of the noradrenergic system in PTSD is associated with a clinically meaningful treatment response.

Sedatives and Hypnotics

Disrupted sleep, which can be characterized by difficulties initiating and maintaining sleep, distressing nightmares, and phobic avoidance secondary to nightmares, is often a chronic and distressing symptom in PTSD. Research has been devoted to better understand the unique qualities of sleep disturbances in those diagnosed with PTSD. Findings indicate a high prevalence of nightmares (compared to sleep onset and maintenance insomnia) and have been replicated across several studies (Neylan et al., 1998; True et al., 1993). Sleep quality and quantity have rarely been measured by type 1 and type 2 drug trials for PTSD. However, sleep improvements have been noted in open-label studies with fluvoxamine, nefazodone, and tiagabine (Connor et al., 2006; Neylan et al., 2001; Rush et al., 1998; Tucker et al., 2000). Additionally, quetiapine treatment was associated with significant improvement on multiple

measures of the PSQI, most notably sleep duration, which increased from 4.0 ± 1.0 to 6.0 ± 1.8 hours per night, and sleep quality (Robert et al., 2005). However, since monotherapy is rarely sufficient to improve PTSD sleep-related disturbances, sedative/hypnotics are frequently prescribed as an adjunctive agent. Despite this, few empirical data are available to guide prescribers.

Trazodone is a triazolopyridine antidepressant with sedative effects that has been evaluated in two uncontrolled trials. The larger of the two is a survey of the adjunctive use of trazodone in combat veteran inpatients ($N = 74$; Warner, Dorn, & Peabody, 2001). Nineteen percent discontinued trazodone, with the most common adverse side effects being daytime sedation and priapism (the latter occurred in 12% of subjects). Seventy-two percent of the patients who continued taking trazodone (mean dose = 212 mg/day) found that it decreased nightmares, 92% found that it aided sleep onset, and 78% reported improvement in sleep maintenance.

Zolpidem tartrate, zaleplon, and eszopiclone are nonbenzodiazepine hypnotics specifically indicated for insomnia (Ancoli-Israel, Walsh, Mangano, & Fujimori, 1999; Dieperink & Drogemuller, 1999; Pollack et al., 2011). Among these, eszopiclone is the only hypnotic that has been approved for long-term use. A type 1 efficacy study of 24 civilians found that those who were prescribed eszopiclone had significantly lower CAPS total and PSQI scores at endpoint compared to placebo (Pollack et al., 2011). It is remarkable that a sedative can lead to global improvements in PTSD symptomatology, and the mechanism requires further study. This finding raises the possibility that sleep improvement itself can lead to broader therapeutic gains, or that the medication itself has effects beyond sedation. Still, further investigation of other nonbenzodiazepine hypnotics is necessary, especially since preliminary studies, such as a clinical report on zolpidem in chronic PTSD, showed success in treating insomnia without adverse effects for as long as 20 months (Dieperink & Drogemuller, 1999).

Despite the limited study of anxiolytics and sedative/hypnotics for PTSD patients (and guidelines that discourage their use) actual use remains widespread. Approximately 61% of veterans prescribed psychotropic medications receive this drug class; prescriptions are mostly associated with a comorbid anxiety disorder diagnosis (Mohamed & Rosenheck, 2008). According to Bernardy, Lund, Alexander, and Friedman (2012), rates of prescription of nonbenzodiazepine hypnotics remained relatively stable until 2008, when there was a tripling of prescriptions, coinciding with zolpidem's placement on the national VA formulary. These prescribing trends highlight the need for more rigorous research on the potential benefits and harms of sedative/hypnotic use in PTSD.

Novel Agents

Decades of work by VA investigators and others have demonstrated that dysregulation of the HPA axis is a feature of PTSD pathophysiology and an important potential biological treatment target (discussed at length in the Secondary Prevention section). The question arises as to whether or how this knowledge can identify novel biological targets for PTSD that might reduce PTSD symptoms. Of particular interest in this regard is mifepristone (RU 486), a potent glucocorticoid receptor antagonist. This glucocorticoid receptor antagonist is hypothesized to recalibrate the HPA axis through blockade of peripheral and central GR while enhancing central glucocorticoid signaling. Mifepristone is also thought to potentially have beneficial neurocognitive-enhancing properties. Young and colleagues (2004) reported significant spatial working memory and verbal fluency improvements based on a trial of 20 participants with bipolar disorder. A mifepristone crossover trial of 32 Gulf War veterans found that low-dose mifepristone (200 mg daily) prescribed for 6 weeks significantly improved verbal learning compared to placebo (Golier et al., 2014).

There are limited studies examining the impact of mifepristone on PTSD. One pilot study explored the efficacy of mifepristone as a brief (week-long) PTSD pharmacological intervention. Mifepristone was prescribed once daily (600 mg) for 7 days via a double-blind, placebo-controlled, all-male-veteran sample ($N = 8$). At endpoint the treatment group demonstrated a statistically greater clinical response (defined as a decrease in CAPS2 total score of at least 12) than the placebo group, and one participant no longer met criteria for PTSD. These results suggest that mifepristone may have the potential to be a short-term, time-limited, pharmacological intervention for the treatment of acute and long-term PTSD symptomology (Golier et al., 2012). These results have informed a VA-sponsored multisite, double-blind, controlled trial that is under way to examine the efficacy and safety of short-term mifepristone in military PTSD.

Some researchers have hypothesized that treating glutamatergic sites in the brain may be a beneficial treatment approach for PTSD (Charney et al., 1993; Friedman, 2000; Nutt, 2000), since glutamate is implicated in learning and memory (Collingridge & Bliss, 1995) and stressful memories are associated with activation of the *N*-methyl-D-aspartic acid (NMDA) glutamate receptors (Glue et al., 1993). D-cycloserine (DCS) is a broad-spectrum antibiotic and antitubercular drug and a selective partial agonist at the glycine site on the NMDA receptor. In a double-blind, placebo-controlled, crossover study of 11 patients with PTSD, symptom improvement with DCS (25 mg bid) was not significantly better than placebo (Heresco-Levy et al., 2002).

A subsequent 6-week, double-blind, placebo-controlled crossover study used D-serine (30 mg/kg/d), an NMDA full agonist, on 22 mostly medicated outpatients with chronic PTSD and showed a similar lack of findings. Participants reported reductions in anxiety based on the HAM-A, self-reported PTSD symptoms assessed by the MISS, and a reduction on the CAPS reexperiencing cluster. This was the first study conducted on D-serine, and further research is warranted to understand the implications of potentially treating PTSD (Heresco-Levy et al., 2009).

Buspirone, a nonbenzodiazepine anxiolytic, has been reported as effective in a case study describing three combat veterans (Wells et al., 1991). Buspirone (dose range 35 to 60 mg) reduced associative symptoms of anxiety and depression, as well as insomnia and flashbacks. Finally, there are a few clinical reports in which the serotonin antagonist cyproheptadine was used successfully for the treatment of traumatic nightmares (Brophy, 1991; Harsch, 1986) in the dosage range of 4 to 28 mg/day.

Summary of the Results of Acute-Phase Treatment Trials of Chronic Posttraumatic Stress Disorder

In summary, this review of the existing literature shows that, based on type 1 and type 2 studies, monotherapy with phenelzine, imipramine, sertraline, fluoxetine, paroxetine, and olanzapine has been shown to be effective in the treatment of PTSD, as compared with placebo, based on both improvements in total PTSD symptom severity and higher response rates. Despite these results, some other studies examining the efficacy of sertraline, phenelzine, and fluoxetine have found mixed results. Despite their scant utilization, amitriptyline and mirtazapine have both been demonstrated to be superior to placebo with respect to clinical response but not total PTSD symptom reductions. Other negative controlled trials have been reported for brofaromine, desipramine, inositol, and alprazolam. The results from the brofaromine study appear to be conclusive. Results for the other three agents are not definitive, given the small sample sizes (10 to 18 subjects) and, for the latter three agents, the short trial duration (5 weeks or less).

In terms of SSRIs, paroxetine consistently demonstrated efficacy against all three PTSD symptom clusters. In contrast, sertraline is not effective in reducing reexperiencing symptoms and was associated with decreased hyperarousal and decreased depressive symptoms. For fluoxetine the pattern of efficacy for the individual symptom clusters were not consistent across studies. There are also varying results from controlled trials examining the effectiveness of anticonvulsants and sympatholytics in alleviating PTSD symptoms. While they show promise as adjunctive medications for the reduction of reexperiencing and hyperarousal symptoms, additional controlled trials with larger sample sizes are needed to fully determine their efficacy.

In general, risperidone, olanzapine, and prazosin appear to be effective adjunctive treatments in treatment-resistant or refractory patients. Recent open-label trials of aripiprazole also show promising results. All were associated with significant reductions in total PTSD symptoms. Reduction in PTSD-related psychotic symptoms was noted with the SGAs and with distressing nightmares with prazosin. However, the risk/benefit ratio of the SGAs needs to be very carefully weighed because both extrapyramidal and metabolic adverse side effects were significant even during short-term trials.

Very few of the controlled trials in PTSD specifically assessed sleep quality or quantity; however, in controlled trials prazosin and eszopiclone have been shown to be beneficial in targeting sleep (Pollack et al., 2011; Raskind et al., 2003), and there are indications that risperidone and clonazepam may improve sleep in PTSD by reducing trauma-related dreams, helping with sleep-onset problems, and improving one's ability to stay asleep (Cates et al., 2004; David, De Faria, & Mellman, 2006). Although SSRIs are considered a first-line treatment, they have not been shown to have beneficial effects on sleep quality in PTSD, and sertraline was associated with a significantly greater

occurrence of insomnia as an adverse side effect in civilian PTSD (J. R. Davidson et al., 2001).

Maintenance Treatment and Relapse Prevention

Prescribers now have available a number of pharmacological approaches to treating PTSD. Partial response is a more typical outcome than complete remission, and these treatments are not curative. Thus, the question arises as to whether efficacy is maintained or enhanced over time and whether or for how long continuation treatment is indicated. Some data are available that can begin to answer these questions.

A study of continuation treatment in PTSD was conducted with sertraline. Subjects who completed the double-blind sertraline studies were eligible to continue in the open-label continuation phase lasting 24 weeks (Londborg et al., 2001). Subjects remained blinded to the acute-phase treatment during the continuation phase; 92% of responders maintained their response during the continuation phase. Importantly, 54% of those who did not achieve responder status during the acute phase achieved it during the continuation phase. High baseline symptom severity was an important predictor of longer time to response; comorbidity, childhood trauma, depression, the number of traumas, and other demographic variables were not predictors.

The final phase of this series of studies of sertraline was designed to examine whether maintenance therapy protects PTSD patients from relapse or deterioration (J. R. Davidson et al., 2001). This type 1 double-blind, placebo-controlled discontinuation study enrolled PTSD patients who had shown sustained responses at the end of the continuation phase. Maintenance treatment was continued for 28 weeks after a previous 24-week continuation study. Sertraline demonstrated a significant advantage over placebo in prevention of relapse (5.3% vs. 26.1% participants who relapsed) and acute exacerbation of PTSD symptoms (15.8% vs. 52.2%). The sample was predominantly female, but the prophylactic benefit of sertraline was evident in both men and women. These data suggest that the efficacy of sertraline treatment is maintained, sometimes enhanced over time, and can prevent exacerbations and relapse.

In a similarly designed trial, PTSD subjects who responded to acute treatment were randomized to continue in a 24-week double-blind maintenance phase on either fluoxetine ($N = 69$) or placebo ($N = 62$; Martenyi, Brown, Zhang, Koke, & Prakash, 2002). Response was stringently defined as a 50% decrease in the TOP-8 score, a CGI-S score of 2 or lower, and not meeting the criteria for PTSD. Among those who responded to fluoxetine in the acute-phase study, the completion rate in the continuation phase was higher in subjects randomized to fluoxetine than to placebo (83% vs. 66%). In a subsequent discontinuation study, PTSD subjects were randomly assigned to double-blind treatment with either fluoxetine or placebo, after having shown at least minimal response to open-label fluoxetine treatment for 6 months (up to 60 mg/day) (J. R. Davidson et al., 2005). There were a significantly higher number of relapses in the placebo group (50%) than in the fluoxetine group (22%), and a significantly earlier time to relapse in the placebo group. However, differences in relapse rates were not noted based on self-report instruments. Thus, the results from clinician- and self-report data are not entirely consistent, but the results of the two studies suggest that continued therapy with fluoxetine appears to prevent relapse as compared with placebo when categorical criteria of relapse are used based on clinician assessments.

Open-label continuation studies also provide preliminary evidence for the benefits of maintenance treatment with other antidepressants. Multiyear follow-up was obtained in an open-label trial of nefazodone in combat-related PTSD at doses of 400 to 600 mg/day (Hertzberg, Feldman, Beckham, Moore, & Davidson, 2002). Of the 10 patients who responded at the end of the 12-week trial, 7 remained "much improved," 2 were "minimally improved," and 1 was worse. In a small, open-label study of mirtazapine in PTSD, gains made during the initial 8-week trial were maintained over the 6 months of treatment, and there was an increase in the number of responders over time (Kim, Pae, Chae, Jun, & Bahk, 2005). Taken together, these studies suggest that treatment gains in PTSD are maintained or enhanced during maintenance treatment with antidepressants, and antidepressants are indicated in the long-term management of this chronic disorder, as they are in other affective and anxiety disorders.

Nevertheless, patients with PTSD are known to have high rates of nonadherence to pharmacological treatments (Chilcoat & Breslau, 1998). Research into the reasons for this treatment obstacle is still nascent. Some preliminary findings indicate that medication adherence is related to the specific ways

that patients understand how PTSD affects them biologically and psychosocially and their perceived ability to control their symptomatology (Spoont et al., 2005). Further work is needed to determine how best to engage patients in long-term treatment and identify optimal pharmacological strategies—either alone or in combination with psychotherapy—that induce longer-lasting therapeutic effects.

Secondary Prevention of Posttraumatic Stress Disorder

Although stress and trauma are implicated as risk factors for many Axis I and II disorders, PTSD is in a unique category of trauma- and stressor-related disorders for which a traumatic event is a prerequisite. The immediate aftermath of a traumatic event represents a potential window of opportunity for early intervention to prevent the development of the full disorder. Concerns about terrorism and the effects of a number of recent natural and manmade disasters have brought the question of how to intervene clinically after a trauma into sharper focus. Educational, psychotherapeutic, and pharmacological approaches are all possible interventions that can be applied to trauma survivors at greatest risk for developing PTSD. Preliminary medication trials for the secondary prevention of PTSD have been conducted for cortisol, beta-blockers, and benzodiazepines.

Activation of the HPA axis in response to a traumatic stressor leads to the release of cortisol from the adrenal gland, which, through negative feedback inhibition, ultimately serves to constrain the stress response. There is ample evidence of HPA axis dysregulation in chronic PTSD, including elevations in corticotrophin releasing factor (Baker et al., 2005; Bremner et al., 1997), which is a potent stimulator of the stress response. However, PTSD is not typically associated with elevated serum or urinary cortisol levels. Rather, it is often, but not always, associated with reduced 24-hour cortisol levels (reviewed in Yehuda, 2002), which may cause a deficit in central negative feedback. It has been suggested that these HPA axis alterations contribute to overactivation of the HPA axis and sympathetic nervous system following stress (Yehuda., 2002). Whether HPA axis alterations are evident at the time of trauma is not known, but several prospective studies suggest that lower posttraumatic cortisol levels in the acute aftermath of trauma predict the subsequent development of PTSD (McFarlane, Atchison, & Yehuda, 1997; Resnick, Yehuda, Pitman, & Foy, 1995), whereas cortisol levels at 1 week do not (Bonne et al., 2003).

These findings raise the question of whether manipulation of the HPA axis at the time of traumatization can prevent the development of PTSD. Compelling data from studies of intensive care unit (ICU) patients suggest it can. Patients treated in the ICU provide an opportunity to study the relationship between trauma, glucocorticoids, and the subsequent development of trauma-related psychopathology, since such patients often receive exogenously administered catecholamines and glucocorticoids and have high rates of PTSD resulting from life-threatening illness and its treatment (Schelling et al., 1999). In an initial retrospective case-control comparison of septic shock patients treated in an ICU, those who had received stress doses of hydrocortisone had a lower incidence of PTSD than those who had not (5 of 27 vs. 16 of 27); they also had higher scores of emotional well-being (Schelling et al., 1999). A similar result was found in a prospective, randomized, double-blind study of the hemodynamic effects of hydrocortisone on septic shock. Development of PTSD in the group treated with stress doses of hydrocortisone (1 of 9) was significantly lower than in the placebo group (7 of 11; Schelling et al., 2001). The effect did not appear to be mediated through memory consolidation, since there were no significant group differences in the recall of categories of traumatic memories from the ICU (Schelling et al., 2001). In a randomized, double-blind, placebo-controlled pilot study of patients with acute stress symptoms, stress doses of hydrocortisone were associated with a significant reduction in the CAPS score compared with placebo, and at the 2-week follow-up assessment, 66.7% of participants as opposed to 20% of placebo group participants who were in the hydrocortisone treatment group developed acute stress reaction (Zohar et al., 2011).

This series of studies provides an interesting demonstration that direct administration of cortisol in the peritraumatic period prevents the development of PTSD secondary to life-threatening illness. Although this is a unique population and the doses of steroids used were high, the results may be more broadly applicable. In a small double-blind, crossover study of low doses of cortisol in patients with civilian PTSD, cortisol treatment effectively reduced PTSD

symptoms, especially reexperiencing symptoms (Aerni et al., 2004). Owing to the beneficial effects of hydrocortisone observed in these controlled studies, studies of the efficacy and safety of short-term cortisol treatment for the secondary and tertiary prevention of PTSD are warranted.

The use of beta-blockers in the secondary prevention of PTSD has also been explored. There is considerable evidence of overactivation of the sympathetic nervous system in PTSD and in those who are at high risk for developing PTSD after a trauma (Shalev et al., 1998; Southwick et al., 1999). Epinephrine strengthens memory consolidation, and it has been hypothesized that excessive release of epinephrine at the time of a traumatic event results in an exceptionally strong emotional memory and conditioned fear response that is ultimately manifested as symptoms of PTSD (Pitman, 1989). Propranolol, which crosses the blood–brain barrier, eliminates this memory-consolidating effect in humans (Cahill, Prins, Weber, & McGaugh, 1994) and is therefore considered a candidate for the prevention of PTSD.

To examine this hypothesis, traumatized persons at increased risk of PTSD, as reflected by a heart rate greater than 80 beats per minute at emergency room admission, were randomly assigned to a 10-day course of double-blind treatment with propranolol ($N = 18$) versus placebo ($N = 23$), 40 mg four times daily (Pitman et al., 2002). The first dose was given within hours of the event. At 1 month, the mean CAPS scores in the two groups did not differ. There was, however, one outlier with very high levels of PTSD symptoms in the propranolol group. This outlier may have obscured group differences, since the distribution of PTSD severity scores was significantly different in the two groups (Pitman et al., 2002). However, the rate of PTSD in the placebo completers was not statistically different than in the propranolol completers at 1 month (30% vs. 18%) or 3 months (13% vs. 11%).

A nonrandomized open-label study of propranolol in trauma victims was subsequently performed (Vaiva et al., 2003). Trauma survivors with tachycardia were offered treatment with propranolol 40 mg, three times a day for 7 days, and were assessed 2 months later. There was not a significant difference in the rates of PTSD in those who refused propranolol versus those who received the medication (3/8 vs. 1/11); however, PTSD symptom severity as measured by the TOP-8 was significantly lower in the propranolol than the no-propranolol group.

A double-blind randomized proof-of-concept trial of propranolol in physically injured trauma survivors was also performed (Stein, Kerridge, Dimsdale, & Hoyt, 2007). Forty-eight male (54%) and female participants with severe injuries who required emergent trauma care were randomized to receive propranolol (120 mg/day), gabapentin (1,200 mg/day) or placebo for 14 days, which included three phases: uptitration (2 days), acute treatment (8 days), and the taper phase (4 days). Participants were assessed at 1, 4, and 8 weeks following the injury. While they did not demonstrate any significant findings, of the 569 potential participants, only 8% consented to the treatment.

Thus, neither preliminary study shows that propranolol protects against the development of a diagnosis of PTSD, but it may reduce the severity of PTSD symptoms in the months following trauma. Larger controlled trials are needed to definitively answer this question, since the ability to prevent the development of PTSD has important ramifications for public health.

Finally, three studies have examined the effect of benzodiazepines in recent trauma survivors. The use of benzodiazepines in the aftermath of trauma is rooted in the idea that they reduce arousal, inhibit memory consolidation, and have antipanic properties (Gelpin et al., 1996). In a study of consecutive emergency room admissions, trauma survivors who reported excessive distress within the first week after a traumatic event were treated at the discretion of the research psychiatrist with either clonazepam or alprazolam and interviewed at successive points after the traumatic event (Gelpin et al., 1996). Their posttraumatic symptoms were compared with those of a control group drawn from an ongoing study and matched by gender and PTSD symptoms at 1 week. The benzodiazepine-treated group did not differ from the comparison group in PTSD or depressive symptoms at multiple assessments over 6 months. Thus, within the limits of a case-control design, this study does not suggest a beneficial effect of benzodiazepines on the course of PTSD; rather, the development of PTSD was higher in the benzodiazepine-treated group. Considering the nonrandom assignment to the treatment group, it cannot be concluded that benzodiazepines facilitated the development of PTSD.

In a pilot evaluation of temazepam in four subjects with acute symptoms following trauma, temazepam was administered for 5 nights, tapered for 2 nights, and then discontinued. At 1 week, sleep had

been improved and PTSD symptom severity lessened (Mellman, Byers, & Augenstein, 1998). In a subsequent randomized, placebo-controlled trial, 22 trauma survivors manifesting early symptoms of PTSD were randomly assigned to placebo or temazepam for 7 nights, beginning on average 14 days after the trauma. There was no improvement in sleep parameters in the temazepam group beyond its period of use (Mellman et al., 1998). However, 55% of the subjects in the temazepam group and 27% of subjects in the placebo group had PTSD at final assessment. None of these studies provides definitive or even suggestive evidence that the short-term use of benzodiazepines in the acute treatment of trauma is beneficial. The higher rate of PTSD development in the benzodiazepine-treated group in both the case-control and the randomized trial suggests that such treatment may in fact be deleterious. Yet a clear recommendation cannot be made on the basis of these results. Larger studies are needed to determine whether the seemingly innocuous act of prescribing a benzodiazepine in the short term to an acutely distressed trauma survivor might indeed be helpful or ultimately have adverse effects on the natural course of posttraumatic recovery.

ADJUNCTIVE DRUG THERAPY: PAIRING PHARMACOLOGICAL TREATMENTS WITH PSYCHOTHERAPY

Psychotherapeutic techniques can be equally important for the maintenance of PTSD remission, relapse prevention, and even secondary prevention in the aftermath of a traumatic event. Yet there is still a dearth of empirical evidence on how or when to combine pharmacological treatment and psychotherapy. It is unclear when or whether the combination is superior to either treatment alone or whether one treatment modality can treat residual symptoms following a course of treatment with the other modality. Recently, however, certain pharmacological agents have shown potential for short-term enhancement of psychotherapy outcomes.

Propranolol and other sympatholytic agents may be particularly efficacious in reducing the physiological symptoms of PTSD when paired with psychotherapy. One study tested propranolol on 19 civilians with mixed trauma. The participants underwent psychophysiological script-driven imagery therapy, which required them to read a script of their trauma. Immediately following this, they were administered 40 mg of short-acting propranolol followed by 60 mg of long-acting propranolol 2 hours later. One week later, they were asked to read the same script again. The researchers found that those who were given the two doses of propranolol 1 week prior to the assessment had significantly decreased physiological arousal (heart rate and skin conductance level) compared to the placebo group (Brunet et al., 2008).

Another promising agent to be used in conjunction with therapy is DCS (discussed earlier in the section on novel agents), a partial NMDA receptor agonist that has been implicated with improved extinction of fear in animal studies (Walker, Ressler, Lu, & Davis, 2002). While DCS has been shown to have positive outcomes with some diagnoses—such as improved outcomes in acrophobics undergoing behavioral exposure therapy (Ressler et al., 2004)—its efficacy in PTSD has been mixed. In one randomized, double-blind, placebo-controlled trial, 67 participants with military and/or civilian trauma were each given a 50-mg dose of DCS 1 hour before weekly sessions of prolonged exposure therapy (de Kleine et al., 2012). At treatment follow-up, completers showed an average CAPS total score reduction of 23% and general clinical response, but this decrease did not significantly differ from placebo. Moreover, a concurrent randomized placebo-controlled trial of 26 military veterans found that those who were prescribed placebo in conjunction with exposure therapy had greater CAPS score improvements than those who took DCS with therapy (36.4% vs. 33.3%, respectively) (Litz et al., 2012). Another recent study, conducted on 22 mostly male (76%) participants with mixed civilian trauma, demonstrated that those who received 100 mg of DCS 90 minutes before virtual reality exposure therapy differed significantly from the placebo group on mean CAPS score reduction (45.9% vs. 30.0%, respectively). This between-groups difference increased over time, with peak values at the 6-month follow-up. Clearly, further investigation is necessary into the efficacy of DCS when paired with psychotherapies, including expanding the size and enhancing the diversity of sample populations.

While investigations are still in the early pilot phase, hydrocortisone has also been implicated as a novel adjunctive pharmacological treatment for prolonged exposure therapy, particularly for the modification of trauma-related memories and learning. An

initial case report consisting of one male veteran given 300 mg of oral hydrocortisone 30 minutes before each of seven prolonged exposure sessions and another male veteran given placebo demonstrated that the treated but not the untreated participant had a significantly greater reduction in the CAPS total score (52 vs. 42 points) (Yehuda et al., 2010). Although limited by the sample size of only two participants and other metrics of study design rigor, this observation suggests the potential for cortisol treatments adjunctive to behavioral interventions for PTSD. Another concurrent double-blind, placebo-controlled study tested the impact of hydrocortisone treatment on Cluster C (cognitive and memory) PTSD symptoms. They found a significant between-groups difference (drug = 1.9 vs. placebo = 2.7) (Surís et al., 2010).

Preliminary studies suggest that the potential benefit of nontraditional approaches—such as the use of 4-methylenedioxymethamephetamine (MDMA)—in addition to psychotherapy may be efficacious in the treatment of PTSD (Mithoefer, Wagner, Mithoefer, Jerome, & Doblin, 2011; Oehen, Traber, Widmer, & Schnyder, 2013). MDMA is thought to be particularly compatible with psychotherapy since it is short-acting and produces feelings of acceptance and of being emotionally grounded (Doblin, 2002). In the first RCT of MDMA (125 mg at first dose; 62.5 mg supplemental dose) paired with psychotherapy in 20 participants with chronic treatment-resistant PTSD, there was a significant decrease in CAPS scores for the treatment group at all three time points following baseline (Mithoefer et al., 2011). Eighty-three percent of the treatment group had a significant clinical response versus 25% in the placebo group. For the entire duration of the study, no serious adverse events, adverse neurocognitive impacts, or significant increases in blood pressure were reported. In a randomized, double-blind, active-placebo controlled pilot study of MDMA-assisted psychotherapy, 12 participants with PTSD were randomized to a low-dose group (25 mg, plus 12.5 mg supplemental dose) and a full-dose group (125 mg, plus 62.5 mg supplemental dose). While the change in the CAPS score between the two groups was only marginally significant ($p = 0.066$), there were statistically significant improvements in the Posttraumatic Diagnostic Scale scores. There were also significant changes in the CAPS score observed between the second and third psychotherapy sessions in the full-dose group (Oehen et al., 2013). Still, the fate and acceptance of treatment with this low-dose psychedelic remain unknown. The possibility of acceptance is suggested by the emerging mainstream use of intravenous ketamine—an NMDA antagonist and drug of abuse (i.e., "Special K")—in depression and possibly PTSD, informed by evidence that ketamine reduces symptoms of depression and anxiety (Aan het Rot, Charney, & Mathew, 2008; Berman et al., 2000; Clinicaltrials.gov, 2012; Zarate et al., 2006) and suicidality (Price, Nock, Charney, & Mathew, 2009). McGhee, Maani, Garza, Gaylord, and Black (2007) found that ketamine, given to Operation Enduring Freedom/Operation Iraqi Freedom veterans prior to surgery, was related to a lower rate of the subsequent development of PTSD. Most recently, Feder and colleagues (2014) compared intravenous ketamine infusions (0.5 mg/kg) to infusions of an active control, the benzodiazepine midazolam (0.045 mg/kg), in 45 veterans with PTSD. They reported that ketamine produced a greater reduction in symptoms measured by the IES-R scale than midazolam 24 hours after the infusions. Furthermore, with the relaxation of laws prohibiting marijuana use, it is likely that medical marijuana will be explored as a potential PTSD treatment. In an open-label clinical trial of synthetic cannabinoid in the management of PTSD, 72% of participants reported a reduction in the intensity and frequency of nightmares (Fraser, 2009). Further research into cannabinoid use for the treatment of PTSD is under way in several countries.

Fortunately, the pace of PTSD treatment advances over the past 5 to 10 years is promising and will likely continue to yield more effective (and novel) treatments for this disorder in the coming years.

PRESCRIBING TRENDS AND FUTURE DIRECTIONS

The numerous type 1 and type 2 studies in PTSD completed in recent years support the view that pharmacotherapy can be a primary treatment for chronic PTSD. Evidence from such studies suggests that multiple antidepressants from different classes are effective first-line agents in the acute phase and maintenance treatment of PTSD, especially but not only SSRIs and serotonin/norepinephrine reuptake inhibitors. Some SGAs are also effective adjunctive treatments for a broad range of symptoms in treatment-refractory PTSD, although the benefits need be measured against the risks.

As new information becomes available, and as providers develop their own body of experience treating PTSD, prescribing practices change. An analysis of the change in prescribing of different classes of medications in the VA (Bernardy, Lund, Alexander, & Friedman, 2012) from 2004 to 2009 highlights some of these trends. While there was only a small change in overall antidepressant use (net absolute change in frequency of use of +2.7%), there were significant shifts in the types of agents prescribed. There was a significant increase in use of SSRIs or serotonin/norepinephrine reuptake inhibitors (+9.3%) as well as an increase in the use of mirtazapine (+7.4%) and bupropion (+5.6%) and significant decreases in the use of the TCAs (–10.0%) and nefazodone (–11.7%).

In contrast, overall antipsychotic use decreased significantly during this period. The reduction was driven primarily by decreased use of first-generation antipsychotics (–7.5%) and little change in overall use of SGAs. A notable exception to this latter trend was a significant increase in prescriptions for low-dose quetiapine (+9.1%). Benzodiazepine use decreased (–6.1%), but this change was accompanied by increased use of prescriptions to aid sleep, namely marked increases in the use of nonbenzodiazepine hypnotics (+9.1%) after zolpidem was placed on the national formulary, a dramatic increase in prazosin use (+7.7%), and the aforementioned increase in quetiapine, which is sometimes used clinically for sleep enhancement in PTSD.

These data reflect both a trend toward prescribing informed by the literature on efficacy as well as an openness to prescribe medications off-label for symptoms for which effective treatments are under studied or still needed (e.g., insomnia). Despite the substantial gains made, much more needs to be done to expand the pharmacological options available to treat this potentially chronic and disabling disorder.

While drug treatment for acute-phase PTSD is certainly critical, there is increasing appreciation about the chronicity of this disorder for some trauma survivors and the associated burdens. There is therefore a need to develop and test pharmacological and other strategies for sustained management and diminution of chronic PTSD symptoms. Additional studies are also needed to determine ways to maximize the efficacy of existing treatments, whether through determination of optimal dosing and duration of treatment or by combining different agents. Much more information is needed on predictors of response to different agents to facilitate treatment matching for this heterogeneous disorder. Future studies also need to address the clinical needs of subjects not included in these studies, including geriatric patients, PTSD patients with active substance abuse, and patients with severe mental illness in whom PTSD may be a secondary but distressing condition.

Finally, almost all the agents shown to be effective in PTSD were developed and marketed for other illnesses and have secondarily been demonstrated to be useful in the treatment of PTSD. To profit from the advances made in the psychobiology of PTSD, it is important to conduct rigorous trials of medications whose use is supported by a strong theoretical basis from either preclinical or human biological studies.

Treatments for Eating Disorders

Kathleen M. Pike
Loren M. Gianini
Katharine L. Loeb
Daniel Le Grange

Substantial progress in advancing evidence-based treatments for eating disorders has been made, although significant gaps in knowledge remain that require further attention. Many well-designed type 1 and type 2 studies provide cumulative support for cognitive-behavioral therapy (CBT) as the treatment of choice for bulimia nervosa (BN). A significant body of research also supports the utility of Interpersonal psychotherapy (IPT) and pharmacotherapy in the treatment of BN; they are considered appropriate alternative treatments for BN in cases where CBT has not been effective or is contraindicated. While CBT, IPT, and pharmacotherapy often produce significant reductions in binge eating and compensatory behaviors, there remains a need to improve upon these treatment outcomes to help more individuals achieve full and lasting recovery. In the treatment of binge eating disorder (BED), CBT and IPT have been shown to be the most efficacious in reducing symptoms and improving psychological outcomes. Weight loss is often an additional goal of those entering treatment for BED; however, existing treatments have generally been unsuccessful in producing significant maintainable weight loss. Anorexia nervosa (AN) remains extremely challenging to treat. However, initial studies suggest that CBT may be associated with improved outcome both in the acute and maintenance phases of treatment. Recent findings also suggest that adapting CBT and Specialist Supportive Clinical Management (SSCM) for severe and enduring AN can result in better engagement in treatment and significant clinical improvement. Additional, methodologically rigorous studies are needed to more fully inform treatment guidelines for adults with AN. Family-based treatment employing the Maudsley Model has shown promising results for adolescents with a relatively short-term duration of illness.

INTRODUCTION

Eating disorders are prevalent psychiatric conditions that are associated with life-threatening medical complications, comorbid psychiatric disorders, role impairment, and suicidality (Crow et al., 2009; Swanson et al., 2011). In particular, AN has the highest mortality rate of any psychiatric disorder. These disorders typically begin in adolescence or early adulthood and, when untreated, often follow a severe and enduring course (Wonderlich et al., 2012). Over the past decades, an enormous amount of clinical research has been conducted that provides important data to guide treatment across the spectrum of eating disorders. At the same time, significant gaps exist in terms of developing evidence-based guidelines for the range of eating disorders, and more clinical research is necessary to address essential questions of clinical care and treatment.

This chapter begins with a diagnostic update that highlights the changes brought about by the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM-5*). This material is followed by a detailed review of available evidence for both pharmacotherapy and psychotherapy for the main eating disorders: AN, BN, and BED. The clinical implications of the available treatments for each of these diagnoses are summarized.

DIAGNOSTIC UPDATE

Anorexia Nervosa

AN typically begins in adolescence or young adulthood and predominantly affects females (about 10% of cases are male). AN is less common than either BN or BED; the 12-month prevalence among young females is approximately 0.4% (Hoek, 2006).

DSM-IV criteria for AN were widely viewed as overly restrictive and, as such, diagnostic criteria for *DSM-5* have been broadened to capture common variations in case presentation. In the revised diagnostic criteria of *DSM-5*, the diagnosis of AN is made if individuals restrict their energy intake such that they achieve a "significantly low weight" in relation to what would be expected for individuals of the same age, sex, developmental trajectory, and physical health. A body mass index (BMI) of 18.5 kg/m^2 or below is provided as a general guideline for "significantly low weight" among adults; however, it is possible for individuals to have a higher BMI and still meet criteria for AN, particularly if the individual's starting weight was especially high. For children and adolescents, there is no hard-and-fast delineation of what constitutes "significantly low weight." However, the Centers for Disease Control and Prevention defines "significantly low weight" as a BMI that falls below the fifth percentile for age (Centers for Disease Control and Prevention, 2011). In addition to low weight, individuals with AN typically demonstrate an intense fear of gaining weight or becoming fat. In addition, *DSM-5* AN includes individuals with persistent behaviors that interfere with weight gain even if they do not describe overt fear of weight gain or fat. These individuals are often referred to as having "non-fat-phobic anorexia." The allowance of behavioral indicators of the psychological features of AN renders the criteria more developmentally sensitive, as verbal endorsement of such symptoms is often absent in children and adolescents. This change is critical for early case identification and intervention in light of the age-of-onset data noted above.

Individuals with AN place undue importance on shape and weight while experiencing body image disturbance, and they often fail to appreciate the seriousness of maintaining a dangerously low weight. Given the importance of a thin shape and low weight in the self-evaluation of individuals with AN, the significantly low weight they have been able to achieve and the restrictive behaviors that maintain this weight are often viewed as ego-syntonic. As such, many individuals with AN do not pursue treatment of their own accord, and they may be resistant when concerned family or friends attempt to persuade them to attend treatment. Finally, the *DSM-5* eliminated amenorrhea as a diagnostic criterion for postmenarcheal females, given its narrow clinical applicability and poor predictive utility. Individuals with AN may be classified as either restricting or binge/purge subtypes. Severity specifiers of mild, moderate, severe, and extreme have now been added and are based upon BMI, such that lower BMI ranges connote heightened severity of illness. AN is associated with an elevated mortality rate, with the crude mortality rate being approximately 5% per decade (Smink et al., 2012). The majority of deaths are due to medical complications of the eating disorder or suicide (Arcelus et al, 2011).

Bulimia Nervosa

BN typically emerges slightly later than AN but still predominantly affects adolescents and young adult women. BN is also more common than AN, with a 12-month point prevalence of approximately of 1% to 1.5% in young females (Hoek, 2006). BN is characterized by binge eating episodes in which the individual eats an objectively large amount of food within a discrete period of time (usually less than 2 hours) *and* experiences a sense of loss of control while engaged in this behavior. These binge episodes are followed by some type of compensatory behavior, which is most often self-induced vomiting or the misuse of laxatives, but may also include use of diuretics, enemas, diet pills, excessive exercise, or fasting. When not engaged in binge eating, most individuals with BN attempt to restrict food intake in pursuit of weight loss to achieve a thin beauty ideal. Weight and shape are extremely

important to the sense of self-worth for individuals with BN, and body dissatisfaction is typically elevated. By diagnostic distinction, individuals with BN are normal weight or higher; underweight individuals who binge eat and/or purge would be characterized as having AN, binge/purge type. BN is associated with an elevated mortality rate, with the crude mortality rate being approximately 2% per decade; suicide risk is elevated in this group as well (Crow et al., 2009; Smink et al., 2012).

In *DSM-IV*, the diagnostic criteria for BN required that individuals engage in binge eating followed by inappropriate compensatory behaviors at least an average of twice a week for 3 months. This criterion has been modified in *DSM-5* such that binge eating and subsequent inappropriate compensatory behaviors must occur on average at least once a week for 3 months. This revision was made as a result of research demonstrating that the functional impairment and overvaluation of weight and shape among individuals engaging in binge/purge episodes at this lower frequency did not differ significantly from those engaging in these behaviors more frequently (Wilson & Sysko, 2009). *DSM-5* has eliminated the subtype specification of "purging type" and "nonpurging type" and has added severity specifiers of mild, moderate, severe, and extreme, which are based upon the frequency of inappropriate compensatory behaviors. The validity and utility of these severity specifiers have yet to be examined empirically.

Binge Eating Disorder

In *DSM-IV*, BED was ascribed research diagnostic criteria and classified under the umbrella diagnosis of "eating disorder not otherwise specified." There have been numerous studies since 1994 confirming that BED is deserving of its own diagnostic category; as such, BED is now a distinct diagnosis in *DSM-5*.

The hallmark feature of BED is binge eating without regular compensatory behavior (e.g., absence of vomiting, over-exercise, or laxative abuse). Binge eating occurs an average of at least once per week for at least 3 months, and individuals with BED experience distress because of their binge eating. While many individuals with BED have tried dieting on numerous occasions, the dietary restriction observed in AN and BN is not typically seen in this group. It is common for individuals with BED to be overweight or obese, particularly in clinical settings. Unlike AN and BN, the gender ratio in BED is much less skewed and the 12-month prevalence of BED is 1.6% in females and 0.8% in males (Hudson et al., 2007). The prevalence of BED is greater among obese adults (estimates range from 8% to 28%; Hudson et al., 2007) and it is greater still in obesity treatment facilities and clinics (Johnson et al., 2001; Wilfley et al., 2003). While BED may begin in adolescence and young adulthood for many, it is not uncommon to encounter many BED patients in mid- to late adulthood.

Avoidant/Restrictive Food Intake Disorder

In *DSM-5*, avoidant/restrictive food intake disorder has replaced the *DSM-IV* diagnosis of "feeding disorder of infancy and early childhood," which was rarely used in practice. These diagnoses are fairly similar; however, *DSM-5* has broadened the diagnostic criteria, thus increasing the number of identified cases and reducing the number of cases relegated to an unspecified eating disorder category. Avoidant/restrictive food intake disorder is characterized by a feeding or eating disturbance such that an individual fails to meet appropriate caloric or nutritional needs, may be dependent on tube feeding or nutritional supplements, and/or has markedly impaired psychosocial functioning, such as an inability to eat in front of others. In contrast to AN and BN, there is no evidence of significant shape and weight concerns.

Individuals with avoidant/restrictive food intake disorder may experience a lack of interest in food or an aversion to sensory qualities of foods, such as certain types of food textures, colors, or smells. These difficulties most commonly develop in infancy or early childhood and may or may not persist into adulthood (Wildes et al., 2012). Other individuals with avoidant/restrictive food intake disorder may avoid eating due to fear of aversive consequences, such as choking or vomiting. This type of food avoidance may be prompted by a traumatic event such as choking or a medical procedure such as esophagoscopy. The course of avoidant/restrictive food intake disorder is unknown, although there is some evidence that sensory-based food aversions may be lifelong (Mascola, Bryson, & Agras, 2010). It is also unclear what the relationship is between avoidant/restrictive food intake disorder and other eating disorders.

Rumination Disorder

The hallmark feature of rumination disorder is repeated regurgitation of food for at least 1 month. Once regurgitated, the food may then be rechewed, reswallowed, or spit out. The regurgitation should not be due to a medical condition, and it cannot occur exclusively in the context of another eating disorder. Onset of rumination disorder can occur at any time throughout the lifespan. Prevalence rates are unknown, but it is thought to occur more frequently in individuals with intellectual disability (Olden, 2001).

Pica

Pica is defined by the eating of nonnutritive, nonfood substances for at least 1 month. This behavior should be inappropriate to developmental level, and it is recommended that pica not be diagnosed in children younger than 2 years of age, given that it may be developmentally normal for infants to mouth nonfood objects and ingest them. If this behavior occurs in the context of another disorder, such as an intellectual disability or an autism spectrum disorder, it should be severe enough to warrant additional independent clinical attention. Childhood onset is most common, but pica can begin at any time throughout the lifespan. Although pica is occasionally related to a nutritional deficiency, this is not the case in most individuals. The general prevalence of pica is unknown; however, among individuals with an intellectual disability, the prevalence tends to increase as severity of intellectual disability increases (American Psychiatric Association, 2013). Pica can be dangerous and sometimes fatal when an individual ingests a poisonous or otherwise injurious substance.

Other Specified Feeding or Eating Disorder and Unspecified Feeding or Eating Disorder

In *DSM-5*, "other specified feeding or eating disorder" and "unspecified feeding or eating disorder" diagnoses replace the *DSM-IV* diagnosis of eating disorder not otherwise specified. "Other specified feeding or eating disorder" is intended to capture eating disorders that do not meet full criteria for the other eating disorders in this diagnostic class; they allow the clinician to describe the specific reason why it does not fit into one of these other diagnoses. One example of a presentation that would warrant a diagnosis of other specified feeding or eating disorder would be "atypical anorexia nervosa," wherein an individual meets all criteria for AN but, despite significant weight loss, still is in the normal weight range. Other common variants of other specified feeding or eating disorder are purging disorder, wherein an individual purges in an attempt to influence shape or weight but does not engage in binge eating, and night eating syndrome, wherein an individual eats excessively after his or her evening meal or after awakening from sleep during the night. A diagnosis of unspecified feeding or eating disorder should be used when the clinician chooses not to or cannot give further detail as to the nature of the eating disturbance but can confirm that the disorder causes significant distress or impairment. The prevalence of these disorders is unknown since they are new additions to the *DSM-5*.

TREATMENTS FOR ANOREXIA NERVOSA

There are several important treatment targets in AN. Of paramount importance is that patients gain weight and begin engaging in a sustainable regimen of regular, healthy eating. Relapse is common in AN, so it is also important for treatment to address the factors that put an individual at greatest risk for reactivating eating disorder behaviors, keeping in mind that cognitive symptoms often persist until full and sustained weight restoration is achieved. While there have been many studies of different treatments for AN and many more are in progress, there have been few randomized controlled trials (RCTs) and fewer conclusive answers as to best practices in treatment with this patient group.

Medically fragile and severely ill patients with AN are often treated in hospital, inpatient, or residential settings. There are a number of ethical concerns regarding randomizing these patients to conditions wherein they might receive placebos, inactive, nonspecific treatments, or be placed on a waiting list (Watson & Bulik, 2012). As such, best practices for these chronic and severe patients are typically derived from expert clinical experience and opinion rather than RCTs and often involve inpatient hospitalization.

Pharmacotherapy

Since the publication of the third edition of this volume, several RCTs have examined the impact of atypical antipsychotic medications on weight gain and eating disorder psychopathology in AN (Attia et al., 2011; Bissada, Tasca, Barber, & Bradwejn, 2008; Brambilla et al., 2007; Kafantaris et al., 2011; Mondraty et al., 2005). Among these atypical antipsychotics, olanzapine has been the most commonly studied. Taken together, the results of these studies demonstrate that the impact of atypical antipsychotics on weight gain and psychological symptoms has been mixed, inconsistent, and small in the studies in which benefits have been found.

Studies have also examined the effectiveness of fluoxetine following weight restoration in AN. A small study by Kaye and colleagues (2001) suggested that outcome may improve with use of fluoxetine. However, a larger, well-controlled RCT conducted by Walsh and colleagues (2006) found that fluoxetine did not have an impact on time to relapse, weight gain or loss, or core eating disorder pathology above and beyond CBT, and there was no evidence that it was superior to placebo. Thus, at the current time, no psychotropic medication has proven efficacy for AN treatment.

Psychotherapy

Family-Based Therapy

Family-Based Therapy (FBT; sometimes referred to as the Maudsley Method) is a manualized treatment conducted on an outpatient basis, typically spanning approximately 20 sessions over the course of 12 months (Lock & Le Grange, 2012). As part of this treatment, parents are charged with helping their child restore weight by managing their child's caloric intake throughout the day. Once weight restoration is well under way, treatment focuses on gradually transferring control over eating back to the patient, who in most studies of FBT is an adolescent. While there have been a number of open trials and clinical case series examining the utility of FBT in AN, there are few RCTs comparing FBT with another active treatment. Given the low base rate of treatment-seeking individuals with AN, it can be difficult to recruit adequate numbers of participants, and sample sizes in studies are often quite small. Furthermore, while RCTs are viewed as the most rigorous means of determining the efficacy and effectiveness of treatments, they too are imperfect. Given this caveat, we will review the RCTs of FBT below in some detail.

In the first major RCT of FBT for AN, Russell and colleagues compared the effects of 1 year of FBT versus individual therapy on maintaining weight restoration achieved in a hospital setting (1987). This research team found that FBT was superior to individual therapy at 1 year in achieving a "good" outcome, marked by maintaining at least 85% ideal body weight, and reduced eating disorder psychopathology in the subset of patients with AN who were ill for 3 years or less, and had their onset of AN at or before age 18. FBT was not superior to individual treatment in patients who had been ill for more than 3 years or who had their onset of AN at age 19 or later. The group in which a significant differential effect of treatment was found (ill for less than 3 years, onset age at or before age 18) comprised 21 patients, 11 of whom received FBT. The superiority of FBT in this subset of patients was maintained 5 years later (Eisler et al., 1997).

The second RCT comparing a family treatment similar to FBT (Behavioral Family Systems Therapy [BFST]) with an individual "ego-oriented" therapy was conducted in a sample of adolescents between the ages of 12 and 19 who had been ill for 12 months or less and were at least at 75% of ideal body weight (Robin et al., 1999). Of the 37 patients, 19 were assigned to BFST and 18 were assigned to individual "ego-oriented" therapy. BFST patients entered treatment at a lower BMI than participants in individual "ego-oriented" therapy (15.2 vs. 16.6, respectively). Treatment was 12 to 18 months in duration, and by the end of the study both intervention groups had gained a significant amount of weight. Although those in BFST gained more than those in individual "ego-oriented" therapy, at both end of treatment and at the 1-year follow-up, BFST and individual "ego-oriented" therapy did not differ significantly with regards to number of participants reaching either 50th percentile BMI or 25th percentile BMI.

More recently, Lock and colleagues (2010) conducted a significantly larger two-site RCT comparing 24 sessions of FBT to 32 sessions of Adolescent Focused Therapy (akin to individual "ego-oriented" therapy). Treatments were equivalent in therapy contact hours delivered over the course of a year in a sample of 121 adolescents aged 12 to 18 years. The

researchers defined remission as reaching at least 95% of expected body weight and having eating pathology scores within one standard deviation of community norms on the Eating Disorder Examination (EDE). At the end of treatment, remission was reached in 42% of participants in FBT and 23% in those assigned to Adolescent Focused Therapy, although this difference did not reach statistical significance. At the 6-month follow-up, remission rates were 40% and 18%, respectively, and at the 12-month follow-up they were 49% and 23%, respectively, with both differences being statistically significant. Additionally, a significantly greater number of Adolescent Focused Therapy participants were hospitalized during treatment in comparison to FBT participants (32 vs. 9), although mean number of days in the hospital and mean weight gain in the hospital did not differ by treatment group.

Several studies have compared different delivery formats for FBT. Eisler and colleagues (2000) compared conjoint family therapy, wherein the parents and the child are seen together, with separate family therapy, wherein the parents and the child are seen separately, in a sample of 40 adolescent patients with AN. Average age of patients was 15.5 years and average duration of illness was 12.9 months. There were no significant differences between these two treatment formats from pre-treatment to posttreatment in terms of percentage ideal weight, BMI, and weight change. Of note, separate therapy was significantly better than conjoint therapy in families with high expressed emotion (hostile, critical forms of communication). This advantage was sustained at the 5-year follow-up (Eisler, Simic, Russell, & Dare, 2007), with patients from families with high expressed emotion assigned to separate therapy continuing to gain weight and patients from families with high expressed emotion assigned to conjoint therapy demonstrating no significant weight changes. Le Grange and colleagues (1992) found a similar lack of overall difference in outcomes between conjoint and separate family therapy in a sample of 18 adolescents with AN.

Lock and colleagues (2005) compared two different treatment doses of FBT: 10 sessions over 6 months versus 20 sessions over 1 year. The sample comprised 86 adolescents with a mean duration of illness of approximately 12 months and a mean initial BMI of 17.1. There were no observed differences in outcome at 12 months after randomization, although patients with higher levels of eating-related obsessive-compulsive symptoms and nonintact families fared better with the longer intervention.

In sum, FBT focuses on early intervention and is particularly useful for young patients with a short duration of AN. FBT has been most widely studied in adolescents, and the literature demonstrates that it is as effective or better than other treatments. The caution and challenge for the field is to recognize that the FBT trials have been conducted by a small team of researchers, and it will be important to replicate the demonstrated utility of FBT among independent investigators and clinicians. Furthermore, the preliminary data regarding conjoint (parent and child) versus separate (parent only) treatment outcomes suggest that the format of family-based therapy interventions may need to be adjusted depending on the level of expressed emotion in the family.

Individual Psychotherapy

A number of RCTs comparing individual therapy approaches in samples of adults and adolescents with AN have been reported, although the results have not revealed a clear advantage of one treatment over another. Several small studies have compared CBT, behavior therapy, nutritional counseling, cognitive analytic therapy, and low-contact control conditions in various permutations (Channon, De Silva, Helmsley, & Perkins, 1989; Crisp et al., 1991; Hall & Crisp, 1987; Serfaty, Turkington, Heap, Ledsham, & Jolley, 1999; Treasure et al., 1995). No significant findings have emerged from these studies.

A larger study (n = 84) comparing focal psychoanalytic psychotherapy, cognitive analytic therapy, FBT, and routine outpatient treatment involving brief sessions found no significant differences in outcome between the three active treatments, although all three were superior to routine outpatient treatment (Dare, Eisler, Russell, Treasure, & Dodge, 2001). These participants were older (mean age = 26.3 years), and the mean duration of illness was 6.3 years. "Good" outcomes were achieved in only 13.8% of the sample, which is significantly worse than outcomes in many studies among the cohort of younger patients with a shorter duration of illness.

McIntosh and colleagues (2005) studied 56 adult women with AN (diagnosed without applying the *DSM-IV* amenorrhea criterion) plus 23 with subthreshold AN (BMI 17.5 to 19.0) by randomizing

them to 20 sessions of CBT, IPT, or SSCM. Results showed that SSCM was superior to IPT; CBT fell between SSCM and IPT and was not statistically different from either of the other two treatments. This sample was evaluated again approximately 7 years later; at that point all three treatment groups were equivalent on physical, cognitive, and behavioral measures of AN (Carter et al., 2011). Overall, 49% of the sample had a good outcome.

A multisite trial comparing CBT, fluoxetine, and their combination randomized 122 patients with AN; however, only 37% completed the 1-year study (Halmi et al., 2005). Notably, 73% of patients in the fluoxetine-alone condition did not complete the treatment, and the low completion rates overall did not allow the authors to assess and compare outcomes. The retention challenges in this study call attention to the difficult nature of studying and treating AN.

More recently Schmidt and colleagues (2012) developed a treatment for adult AN (Maudsley Model of Anorexia Nervosa Treatment for Adults [MANTRA]). MANTRA focuses on the health risks inherent in AN, the often-present rigid cognitive style, the function of AN in the patient's life, and behavioral experiments to address socioemotional difficulties. MANTRA was compared to SSCM in an RCT with 72 outpatients with AN or eating disorder not otherwise specified. Recovery was defined in three ways: (A) eating pathology within one standard deviation of community norms on the EDE, (B) BMI above 18.5, and (C) both A and B. The proportion of MANTRA patients meeting criterion A at posttreatment and at the 6-month follow-up was 43% and 59%, respectively, compared to 45% and 73% in the SSCM group. The proportion of MANTRA patients meeting criterion B at posttreatment and at the 6-month follow-up was 18% and 27%, respectively, compared to 21% and 26% in the SSCM group. Finally, the proportion of MANTRA patients with both normal EDE scores and BMI above 18.5 at posttreatment and at the 6-month follow-up was 7% and 14%, respectively, compared to 13% and 19% in the SSCM group. There were no statistically significant differences between the two treatment outcomes.

The largest RCT to date in adults with AN randomized 242 individuals to focal psychodynamic psychotherapy, enhanced CBT, or treatment as usual (Zipfel et al., 2014). The treatment-as-usual condition is notable in that it was conducted within the context of the German health care system and participants were given the names of experienced eating disorder therapists, with sessions typically being covered by health insurance. These treatment-as-usual patients also met with a medical provider to have regular weights and blood tests. By the end of treatment, 22% of patients had dropped out, and by the 12-month follow-up a total of 30% had dropped out. While BMI did increase across all treatment groups and eating pathology decreased at both end of treatment and again at the 12-month follow-up, no significant differences emerged across the treatment conditions.

Relapse Prevention and Severe and Enduring Anorexia Nervosa

There have been a small number of studies examining the effects of psychological treatment on weight-restored patients after hospitalization. As reported above, Russell and colleagues (1987) compared the impact of FBT and supportive psychotherapy in a sample of adolescents and adults with AN after weight restoration in hospital. As noted, the young, short-duration cases fared better if they received FBT; however, the older patients with a longer duration of illness did poorly across conditions. There have been two studies evaluating the impact of CBT versus an active comparison treatment after hospitalization. In the first study, 33 patients were randomized to either 12 months of CBT or nutritional counseling (Pike, Walsh, Vitousek, Wilson, & Bauer, 2003). In the CBT group, 44.4% achieved an adapted Morgan Russell outcome of "good" (BMI ≥ 18.5 for 8 consecutive weeks, cyclical menses, but some disturbance in weight concern, restraint, or binge/purge behaviors) compared with 6.7% of the participants in the nutritional counseling group ($p < 0.02$). There was a trend for more CBT participants to achieve full recovery compared with nutritional counseling (16.7% vs. 0%, $p < 0.097$). The second study compared CBT and maintenance treatment as usual in a sample of 88 patients with AN in a nonrandomized clinical trial (Carter et al., 2009). Within maintenance treatment as usual, participants were encouraged to seek follow-up care, with the most common option chosen by patients being individual psychotherapy and an aftercare group provided by the study's authors. Only 2.9% of the patients receiving maintenance treatment as usual received no treatment at all. At the 1-year follow-up, 26 of 46 CBT patients had completed

the full year of CBT treatment compared to 30 of 42 patients receiving maintenance treatment as usual. Relapse was operationalized in two ways: (a) BMI ≤ 17.5 for three consecutive months and (b) an average of two or more episodes per week of bingeing and/or purging for 3 months. By the 1-year follow-up, 65% of the CBT group and 34% of the group receiving maintenance treatment as usual had avoided relapse.

Touyz and colleagues (2013) conducted a study comparing CBT for AN with SSCM for 63 individuals with severe and enduring AN, which was defined as having at least a 7-year illness history of AN. This was a multisite RCT of 30 outpatient visits spread over 8 months in which individuals received either CBT for AN or SSCM, both modified for severe and enduring AN. Participants were assessed at baseline, at the end of treatment, and at 6- and 12-month post-treatment follow-ups. The focus of this study was to improve engagement in treatment and quality of life; primary outcome measures assessed quality of life, mood, and social adjustment. Weight and eating disorder psychopathology were secondary outcomes.

The study achieved a remarkable retention rate of 85% by the end of the study, and both groups showed significant and comparable improvements. The CBT for AN group had higher scores on the Weissman Social Adjustment Scale ($p = 0.038$) at the 6-month follow-up. At 12 months, the CBT group had lower EDE global scores ($p = 0.004$) and higher readiness for recovery ($p = 0.013$) compared to the SSCM group.

Clinical Implications

Taken together, this review of treatment research in AN suggests that adolescent patients can do well in psychotherapy, while adults do not fare nearly as well. Adolescents are typically ill for a shorter duration than adults with AN, and many adults have had multiple treatment series. It is hypothesized, although not yet confirmed, that there may be some fundamental difference between those who respond to early intervention efforts and those who do not, and this may help explain the relative success of some treatment modalities that focus on adolescents. In this group of young, shorter-duration cases, FBT should be considered. Family interventions that directly address the eating disorder should be offered to children and adolescents with AN according to National Institute for Clinical Excellence (NICE) guidelines. Among adults, there is no clear psychotherapy of choice that appears to be most helpful in acute care, although treatment does provide significant improvements over baseline functioning. In the case of relapse prevention, there is limited evidence supporting CBT. Finally, at the current time, pharmacotherapy does not seem to be indicated for the specific treatment of eating disorder symptoms such as low weight and overvaluation of shape and weight. There are many ongoing RCTs for AN (see Watson & Bulik, 2012, for a description) that explore both pharmacological and innovative psychotherapeutic approaches, such as cognitive remediation therapy and exposure therapy, and it is likely these will yield important information to further improve upon treatment response in both adolescent and adult patients.

TREATMENT OF BULIMIA NERVOSA

Pharmacotherapy

Many types of antidepressant medications have been studied in the treatment of BN, including monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs), and selective serotonin reuptake inhibitors (SSRIs). In a meta-analysis of nine double-blind, placebo-controlled trials of antidepressant medication, Whittal and colleagues (1999) examined 870 patients on four outcome measures: frequency of binge eating, frequency of purging, depression, and "eating attitudes" (concerns about shape and weight, self-reported dietary restraint). The overall effect sizes were 0.66 for binge eating, 0.39 for purging, 0.73 for depression, and 0.71 for eating attitudes. A review of RCTs comparing MAOIs, TCAs, and SSRIs to placebo concluded that all three of these types of medication were superior to placebo in reducing binge eating (Flament, Bissada, & Spettigue, 2012). There have been no head-to-head comparisons of different classes of drugs within a single study. However, given that both MAOIs and TCAs have a number of unpleasant side effects, and the potential for fatal overdose, they are not recommended as a first-line treatment for BN.

Of the SSRIs, fluoxetine has been the most studied in BN. The Fluoxetine Bulimia Nervosa Collaborative Study Group (1992) compared 60 mg/day with 20 mg/day with placebo in 387 women with BN for

8 weeks. The 60-mg dose was superior to placebo in reducing both binge eating (67% vs. 33%) and vomiting (56% vs. 5%). The 20-mg dose had an intermediate effect, with median reductions in binge eating and vomiting at 45% and 29%, respectively. The 60-mg dosage of fluoxetine was also associated with reduced depression and improved eating attitudes. In comparing 60 mg of fluoxetine to placebo over a 16-week period, Goldstein and colleagues (1995) found similar results regarding reductions in bingeing and vomiting. Given these data, 60 mg of fluoxetine is generally viewed as the medication treatment and dosage of choice for patients with BN.

Dropout rates are high in trials of longer-term medication use (Romano, Halmi, Sarkar, Koke, & Lee, 2002; Walsh et al., 1991). Furthermore, the long-term efficacy of antidepressant medications in BN is relatively unknown and the optimal length of treatment with medication is also unknown. Importantly, the use of bupropion is contraindicated in the treatment of BN due to an increased risk of seizures in this population (Horne et al., 1988).

The NICE (2004) guidelines provide treatment recommendations for numerous mental health conditions. These guidelines are based upon a standardized evaluation of the research evidence, and treatment recommendations are graded from A (support derived from RCTs) to C (support derived from expert opinion). The NICE guidelines rated the level of empirical support for antidepressant medication in BN as B, meaning that support is derived from well-conducted clinical studies but not necessarily RCTs.

Psychotherapy

CBT for BN has been manualized by Fairburn, Marcus, and Wilson (1993b) and targets bingeing, purging, dietary restriction, and overvaluation of weight and shape through various structured cognitive and behavioral interventions such as self-monitoring, stimulus control, and establishing regular eating patterns. The most recent meta-analysis examining the efficacy of psychological treatments for BN included 26 studies using CBT, with a total of 460 patients (Whittal, Agras, & Gould, 1999). CBT was compared to no treatment, delayed treatment, or another active psychotherapy. Seventeen of these trials reported outcomes related to binge frequency, and the effect size was 1.28. Twenty-four trials reported purge frequency outcomes with an effect size of 1.22, 19 reported depression outcomes with an effect size of 1.31, and 15 trials reported on improvements of eating attitudes with an effect size of 1.35. The authors also determined that CBT was superior to medication on each of these four outcomes.

A Cochrane Library review of psychotherapy outcomes for BN (Hay, Bacaltchuk, Stefano, & Kashyap, 2009) examined 31 controlled studies of BN. In 18 of these studies, participants were only of the purging subtype of BN, and in 3 studies participants were non-purging subtype only. This review examined binge eating and depression outcomes in studies comparing CBT to no treatment, delayed treatment, another active psychotherapy, or guided and pure self-help forms of CBT. CBT was found to be superior to delayed treatment and other psychotherapies with regards to binge eating remission. CBT was also significantly superior to delayed treatment with regards to reductions in binge eating, and it approached statistical significance in comparison to other active psychotherapy comparators. CBT approached statistical significance compared to other psychotherapies in demonstrating reductions in depression. This Cochrane Library review is a rigorous, systematic evaluation of the research; however, it is notable that data on purging and eating attitudes were not analyzed or reported.

In a recent study researchers were able to determine that CBT was more effective than psychoanalytic psychotherapy in reducing bingeing, purging, and eating-disordered cognitions even though CBT patients were treated for far fewer sessions over a much shorter period of time (Poulsen et al., 2014). Specifically, patients in the CBT condition received 20 sessions of treatment over the course of 5 months, while patients in the psychoanalytic psychotherapy condition attended an average of 72 sessions of treatment over the course of 2 years. All patients were assessed twice: at 5 months and at 2 years. After 5 months, 42% of the CBT patients were abstinent from bingeing and purging, compared with 6% in the psychoanalytic psychotherapy condition, and CBT patients had significantly lower levels of depression, eating-disordered cognitions, and interpersonal problems compared to those receiving psychoanalytic psychotherapy. At 2 years, 44% of the CBT patients were abstinent from bingeing and purging, compared with 15% in the psychoanalytic psychotherapy condition, although those in the psychoanalytic psychotherapy

condition had now experienced improvements in depression, eating-disordered cognitions, and interpersonal problems on par with those in the CBT condition. Overall, the results indicated that CBT was significantly more effective in reducing bulimic symptomatology, and it was able to achieve these results fairly quickly. These results are even more striking given the large difference in quantity and duration of treatment between the two treatment conditions.

Overall, CBT has been demonstrated to completely eliminate binge eating and purging in 30% to 50% of cases. Many other patients experience significant improvement of symptoms, and these results are often sustained long term. Furthermore, there is evidence that dietary restraint, eating, weight, and shape concerns all improve significantly over the course of treatment and in long-term follow-up, with nearly three quarters of patients demonstrating EDE global scores within one standard deviation of community norms at a 5.8-year follow-up (Fairburn et al., 1995). The NICE guidelines have given CBT a grade of A for the treatment of adults with BN, and it is the treatment of choice for this condition.

More recently, CBT for BN has been elaborated to address additional potential perpetuating factors of the eating disorder, such as low self-esteem, perfectionism, and interpersonal problems. This version of CBT is called CBT-Enhanced (Fairburn et al., 2003). There are good indications that CBT-Enhanced works well in transdiagnostic groups of participants with eating disorders, but it does not appear to be superior to CBT (Fairburn et al., 2009). As such, it appears that the active components of the treatment may be those core modules that address the eating disorder in a more focused way.

Interpersonal Psychotherapy

IPT was originally developed as a treatment for depression (Klerman, Weissman, Rounsaville, & Chevron, 1984). It is brief and time-limited and focuses on improvements in interpersonal functioning, which is known to be problematic in individuals with eating disorders (Wilfley, Stein, & Welch, 2005). Notably, IPT need not address the eating disorder, although it can be focused such that interpersonal problems are specifically linked to the maintenance of the eating disorder (Tanofsky-Kraff & Wilfley, 2010). In controlled trials comparing IPT to CBT, CBT has been found to be superior to IPT in reducing bulimic symptoms at posttreatment (Agras et al., 2000; Fairburn et al., 1991). However, at follow-up time points 1 year and 6 years later, efficacy rates do not significantly differ between the two treatments (Agras et al., 2000; Fairburn et al., 1993a, 1995). Specifically, in follow-up reports from a trial comparing CBT, IPT, and behavior therapy, 1-year remission rates of bingeing and purging were 36%, 44%, and 20%, respectively (Fairburn et al., 1993a). By the 5.8-year follow-up, remission rates were 63%, 72%, and 14%, respectively (Fairburn et al., 1995). In a large, multisite trial comparing CBT and IPT for BN (n = 220), remission rates in those completing treatment were 45% and 8% at posttreatment, with CBT being superior (Agras et al., 2000). At the 12-month follow-up, remission rates among completers were 40% in CBT and 27% in IPT, which was not a statistically significant difference. The NICE (2004) guidelines give IPT for BN the treatment recommendation of B. These guidelines note that IPT may be considered as an alternative treatment to CBT; however, the time to full improvement is significantly longer than that of CBT (approximately 8 to 12 months).

Guided Self-Help and Pure Self-Help Approaches

Pure self-help is typically in the form of a treatment book or CD-ROM given to a patient, with minimal guidance or interaction with a clinician. Guided self-help typically involves a treatment book or CD-ROM in conjunction with brief meetings with a therapist who helps the patient implement the treatment. At present the majority of studies examining self-help approaches have compared its efficacy with a waitlist control group in open trials (Sysko & Walsh, 2008). Compared to waitlist control, self-help approaches are associated with significantly greater improvement in bulimic symptoms (Bara-Carril et al., 2004; Bell & Newns, 2002; Cooper, Coker, & Fleming, 1996; Pritchard, Bergin, & Wade, 2004; Schmidt, Tiller, & Treasure, 1993). In these open trials, remission rates from binge eating ranged from 12.8% to 47%, while remission rates from purging ranged from 27% to 65.2%. Remission rates from both binge eating and vomiting ranged from 26.8% to 50%. In comparison to other active treatments, studies have been few, results have been inconsistent, and

there is evidence to suggest that self-help is less potent than in-person treatment (see Sysko & Walsh, 2008). Evidence-based self-help approaches as a first step in the treatment of BN have received a grade of B from the NICE guidelines (2004).

Clinical Implications

Taken together, the research suggests that CBT should be considered the treatment of choice in BN because it appears to be the most efficacious treatment with the quickest rate of response and the most enduring effect. However, RCTs examining IPT and antidepressants also show significant therapeutic benefit, although they do not have the same speed of impact on symptoms and endurance of treatment response as CBT. Therefore, if competent CBT clinicians are not available, or if CBT does not produce meaningful improvement, IPT and/or antidepressant medication should be considered. Finally, if individual therapy or antidepressants are not available, self-help approaches may be recommended as a first step.

TREATMENT OF BINGE EATING DISORDER

Pharmacotherapy

Weight Loss Medication

Three drugs are currently approved by the U.S. Food and Drug Administration for treating obesity: orlistat, lorcaserin, and phentermine-topiramate. Of these, only orlistat (a lipase inhibitor) has been studied as a treatment for obese individuals with BED, although topiramate (without phentermine) has also been examined. In a 24-week RCT comparing orlistat plus a low-calorie diet to placebo plus a low-calorie diet, Golay and colleagues (2005) found no significant differences between the two treatment arms with regards to reductions in binge eating; however, participants taking orlistat did lose significantly more weight than those in the placebo condition. Grilo, Masheb, and Salant (2005a) compared CBT with guided self-help plus either orlistat or placebo over 12 weeks and at a 3-month follow-up. Intent-to-treat analysis showed that binge remission rates (no binges in the past 28 days) were significantly higher at posttreatment in the group receiving orlistat (64% vs. 36%); however, by the 3-month follow-up there were no significant differences between the treatment arms, with both groups demonstrating a 52% binge remission rate. More recently, Grilo and White (2013) examined behavioral weight loss treatment plus either orlistat or placebo in an obese sample of Spanish-speaking adults. Forty participants were diagnosed with BED and 39 were not. Results for the subset of patients with BED showed that, following 4 months of treatment, binge remission rates did not differ significantly between the treatment groups (60% in the group receiving behavioral weight loss treatment and orlistat, 70% in the group receiving behavioral weight loss treatment plus placebo), nor did the groups differ on reductions in eating disorder psychopathology, depression, or BMI. At the 6-month follow-up, both treatment groups had binge remission rates of 50%.

The anticonvulsant topiramate has been examined in individuals with BED in three trials (Claudino et al., 2007; McElroy et al., 2003, 2007b). In the first of these studies, patients at a single site were randomized to receive either topiramate or placebo for 14 weeks (McElroy et al., 2003). Intent-to-treat analysis showed a binge eating remission rate of 64% in the topiramate group versus 30% in the placebo group. Individuals in the topiramate group also lost significantly more weight than those in the placebo group (5.9 kg vs. 1.2 kg, respectively). McElroy and colleagues (2007b) then conducted a large multisite RCT in which 195 patients with BED received topiramate and 199 received placebo for 16 weeks. At the end of treatment, 58% of patients on topiramate and 29% of patients on placebo attained remission from binge eating. Individuals on topiramate also lost significantly more weight than those on placebo. Finally, Claudino and colleagues (2007) compared topiramate plus CBT versus placebo plus CBT in a 21-week trial. In this sample, 37 patients were in the group receiving topiramate and 36 were in the placebo group. In intent-to-treat analysis, the binge eating remission rate was 83.8% in the topiramate group compared with 61.1% in the group receiving placebo.

Antidepressant Medication

In a 2008 meta-analysis of the effects of antidepressants in BED, Stefano and colleagues analyzed seven studies in which either TCAs (imipramine) or SSRIs (fluoxetine, fluvoxamine, sertraline, citalopram) were

used for short-term treatment (6 to 16 weeks) either in conjunction with psychotherapy or alone. Overall, binge remission rates were significantly higher at the end of treatment in the active medication treatments versus placebo (40.50% vs. 22.22%). However, these periods of treatment were relatively short (average of 8 weeks), and the study with the longest duration (16 weeks; Grilo et al., 2005b) did not find a significant difference between fluoxetine and placebo groups. Furthermore, there were no significant differences in weight change between active antidepressant medication and placebo groups.

Other Medications

Atomoxetine is a selective norepinephrine reuptake inhibitor that is FDA approved for the treatment of ADHD. McElroy and colleagues (2007a) compared atomoxetine to placebo in a 10-week RCT of adults with BED. Intent-to-treat analysis revealed that 70% of participants in the atomoxetine treatment arm achieved binge remission compared to 32% in the placebo condition. Mean weight loss in the group receiving atomoxetine was 2.7 kg compared to 0 kg in the placebo group.

Psychotherapy

Cognitive-Behavioral Therapy

There is a strong body of evidence supporting the use of CBT in the treatment of BED. CBT has been shown to be effective in significantly reducing binge eating and general eating psychopathology both directly following treatment and after longer-term follow-up. CBT produces higher binge abstinence rates than no treatment and behavioral weight loss treatment (Grilo & Masheb, 2005; Munsch et al., 2007; Schlup et al., 2009). Grilo and colleagues (2011) compared (a) 16 sessions of CBT with (b) 16 sessions of behavioral weight loss treatment and (c) 16 sessions of CBT followed by 16 sessions of behavioral weight loss treatment in an RCT of 125 obese individuals with BED. CBT was superior to behavioral weight loss treatment with regards to binge eating abstinence at posttreatment and continuing through a 12-month follow-up (51% in the CBT group, 36% in the behavioral weight loss treatment group, and 40% in the combined treatment group). While behavioral weight loss treatment produced significantly greater reductions in BMI by posttreatment, there were no significant group differences in weight loss by the 12-month follow-up. CBT also appears to be superior to pharmacological treatment of BED. In a 12-month follow-up of an RCT of obese binge eaters, Grilo and colleagues (2012) found that adding fluoxetine to CBT treatment did not add significantly to the efficacy of CBT on its own.

Less intensive guided self-help versions of CBT have also been examined in the treatment of BED. An early, small RCT (Loeb, Wilson, Gilbert, & Labouvie, 2000) compared guided and unguided CBT self-help conditions in an adult binge eating sample and showed an advantage for therapist guidance. Wilson and colleagues (2010) conducted an RCT of 205 overweight and obese individuals with BED who were randomized to either 20 sessions of behavioral weight loss treatment or IPT or 10 sessions of guided CBT self-help over the course of 6 months. At a 2-year follow-up, both IPT and guided CBT self-help were shown to produce significantly higher rates of binge remission (65% and 67% respectively) compared to behavioral weight loss treatmen (47%). The efficacy of IPT and guided CBT self-help did not differ significantly, although guided CBT self-help was less effective than IPT among patients with low self-esteem and high eating pathology scores as measured by the EDE. In a study of binge eating within a primary care sample, Striegel-Moore and colleagues (2010) compared guided CBT self-help to treatment as usual. Eighty-nine percent of this sample had either full or subclinical BED, while the remaining 11% had been diagnosed with BN. At the 12-month follow-up, CBT was associated with higher binge abstinence rates than treatment as usual (64% vs. 45%) and greater reductions in eating disorder pathology.

Interestingly, while CBT has been shown to be superior to IPT in the treatment of BN, the two treatments appear to be equally efficacious in the treatment of BED. In a large RCT comparing CBT with IPT in the treatment of adults with BED, binge eating abstinence rates were 79% and 73%, respectively, at posttreatment and 59% and 62% at a 1-year follow-up (Wilfley et al., 2002). At the 4-year follow-up there were still no significant differences between the groups (Hilbert et al., 2012). Although there have been fewer studies of treatment of BED using IPT as compared to CBT, the existing evidence does suggest it is efficacious.

Behavioral Weight Loss

Behavioral weight loss has been studied as a nonspecialist treatment for BED. As noted above, results indicate that individuals receiving behavioral weight loss treatment achieve binge abstinence at a significantly lower rate than specialist BED treatments such as CBT and IPT (Grilo et al., 2011; Wilson et al., 2010). In addition to the studies previously discussed in this chapter, Devlin and colleagues (2005) compared 20 sessions of (a) behavioral weight loss treatment plus CBT and either fluoxetine or placebo with (b) behavioral weight loss treatment with fluoxetine or placebo. All iterations of treatment involving CBT had significantly higher binge remission rates (62%) than those involving behavioral weight loss treatment with only fluoxetine or placebo (33%). This pattern of results was maintained at the 2-year follow-up (Devlin et al., 2007).

Dialectical Behavior Therapy

Dialectical Behavior Therapy (DBT), which has shown to be a well-validated and effective treatment for those with impaired emotion regulation, has been adapted for BED (Linehan, 1993). At present there are few RCTs comparing DBT for BED to either waitlist control or other active treatments. However, the results of the few trials that have been done suggest that it is worthy of further investigation. A trial comparing DBT to waitlist demonstrated that DBT led to a significantly greater reduction in eating pathology and binge eating (Telch, Agras, & Linehan, 2001). More recently, DBT was compared to an active comparison group therapy in 101 adults with BED over the course of 20 group sessions (Safer, Robinson, & Jo, 2010). At posttreatment, significantly more patients in the DBT group had attained binge remission (64%) compared to active comparison group therapy (36%). By the 12-month follow-up these group differences had disappeared, with abstinence rates being 64% vs. 56%, respectively.

CONCLUSIONS

Eating disorders, particularly AN, have been notoriously challenging to treat. The psychological and pharmacological intervention outcome literature emerging over the past 20 years or so reviewed here provides valuable research data to inform best clinical practices; this body of literature also highlights the need for multiple areas of further study. Specifically, for AN, while promising treatment strategies exist for children and adolescents, there is a dearth of significant findings to guide intervention for acute care for low-weight adults with AN. CBT shows promise in terms of relapse prevention for those adults who respond to earlier treatment interventions that focus on weight gain and stabilization. Retention challenges among adult studies compromise both research and clinical efforts to alleviate suffering in this pernicious disorder. In BN, CBT is the clear treatment of choice for achieving rapid and sustained benefits, with additional interventions (IPT and pharmacotherapy) as viable alternatives; however, there is significant room for improvement in terms of achieving full remission, the optimal outcome for any psychiatric disorder. For BED, psychological, behavioral, and pharmacological treatment modalities, and many specific interventions within each of these categories, result in significant reductions in binge eating. In contrast, weight loss, an additional treatment goal in this often overweight or obese patient population, is rarely seen as a secondary benefit. Given the number of efficacy trials under way for AN, the next two decades are likely to bring more information to shape effective clinical practice in eating disorders, informed by the advances in risk factors research to guide prevention strategies.

Treatment of Sleep Disorders

Deepa Burman
Daniel J. Buysse
Charles F. Reynolds, III

This chapter provides an evidence-based review of the seven categories of *DSM-5* sleep-wake disorders. Specific sleep-wake disorders vary widely in their clinical manifestations, etiologies, treatment, and the level of evidence supporting those treatments. Sleep-wake disorders are prevalent, increase the risk of many common mental and substance use disorders, and exacerbate these disorders, with which they typically co-occur. Unless properly treated in their own right, sleep-wake disorders can impair treatment response and worsen the long-term course of mental disorders. Thus, it is important for psychiatrists and other mental health practitioners to understand the diagnosis and treatment of sleep-wake disorders and when to refer the patient for consultation with a sleep medicine specialist.

INTRODUCTION

Traditionally, psychiatrists have considered sleep disorders/problems to be symptoms of psychiatric disorders. Chronic sleep problems affect 50% to 80% of patients in a typical psychiatric practice, compared with 10% to 18% of adults in the general U.S. population. Similarly psychiatric morbidity is high in patients seen in the sleep disorders clinic. In reality, the relationship between sleep and psychiatric disorders is found to be bidirectional, such that each can amplify the disability and suffering of the other. Moreover, sleep disturbances such as insomnia disorder are potent risk factors for the onset of common mental disorders. For example, Baglioni and colleagues (2011) found that nondepressed people with insomnia have a twofold risk of developing depression (Roth et al., 2006).

Understanding sleep disorders is thus critical for the management of psychiatric patients. According to the *DSM-5* classification of sleep-wake disorders there are 10 disorder groups: insomnia disorder, hypersomnolence disorder, narcolepsy, breathing-related sleep disorders, circadian rhythm sleep-wake disorders, non–rapid-eye-movement (NREM) sleep arousal disorders, nightmare disorder, rapid eye movement sleep behavior disorder, restless legs syndrome, and substance/medication-induced sleep disorder. Impairment of daytime function is a critical feature of all these disorders. The goal of this chapter is to review evidence-based treatment for *DSM-5*-defined sleep-wake disorders and to provide guidance to the nonspecialist about when to consider referral to a sleep specialist for further assessment and management of patients. In each section below, we provide citations to clinically useful reviews of treatment. Further details on the features and pathophysiology of individual sleep disorders can be found in other sources such as "Clinical Pharmacology of Other Drugs Used as Hypnotics" by Buysse and colleagues (2010), in Principles and Practice of Sleep Medicine, edited by Kryger and colleagues.

INSOMNIA DISORDER

Overview and Diagnosis

Insomnia is a significant health problem because of its high prevalence, treatment challenges, and high socioeconomic burden. It is characterized by difficulty in falling or staying asleep or returning to sleep after a middle-of-the-night awakening. An essential feature of insomnia disorder is dissatisfaction with sleep quality or quantity. It is the most prevalent of all sleep disorders, with a higher female preponderance compared to males. *DSM-5* consolidated various insomnia disorders from *DSM-IV* into a single diagnosis because of the difficulty in discriminating "primary" and "secondary" forms and the reality of high comorbidity. To warrant an insomnia disorder diagnosis, the sleep difficulty should occur at least 3 nights a week for at least 3 months despite adequate opportunity for sleep. This distinguishes it from sleep deprivation. Nonrestorative sleep is no longer a feature of insomnia in *DSM-5*.

A detailed and careful 24-hour sleep-wake history is crucial for the diagnosis and management of insomnia disorder. Evaluation using a 1- or 2-week sleep-wake diary should be considered whenever possible. An example of a sleep-wake diary can be seen in Figure 21.1. Polysomnography is not usually indicated for insomnia disorder unless there is concern about other coexisting sleep disorders based on history.

Patients should be reassessed every few weeks or monthly until symptoms are stable or have resolved. Because of the high relapse rate, regular follow-ups every 6 months or annually should be considered. "Sleep hygiene" measures should be combined with other forms of insomnia treatment, but sleep hygiene alone has not been found to be effective for treatment of chronic insomnia.

Management

Insomnia treatments aim to improve the amount and quality of sleep and also to enhance daytime function. Ideally, short-term pharmacological treatment should be supplemented with behavioral and cognitive strategies. Whenever medications are prescribed, treatment goals and expectations should be discussed along with safety, side effects, potential for dose escalation, and rebound insomnia. Long-term medication treatment should be accompanied by consistent follow-up and ongoing monitoring for efficacy, side effects, and newly developed comorbid conditions.

Psychological and Behavioral Treatments

Psychological and behavioral treatments for insomnia have been evaluated in many randomized controlled trials (RCTs) and meta-analyses. In general, these treatments aim to reduce sleep latency and improve sleep consolidation by changing behaviors, habits, and cognitions that interfere with sleep. The best evidence for efficacy among the various approaches is for multicomponent cognitive-behavioral treatment of insomnia (CBT-I), stimulus control therapy, and sleep restriction therapy. Behavioral approaches are comparable to medications in efficacy and are found to be more durable. Currently there is insufficient evidence to recommend sleep hygiene education, imagery training, or cognitive therapy as monotherapies.

Table 21.1 summarizes the major components of behavioral and psychological treatments for insomnia that can be administered individually or in a group.

CBT-I combines cognitive therapy with behavioral techniques and is typically delivered over six to eight individual treatments. It relies on the patient being an active participant in his or her own treatment. The behavioral component may include stimulus control therapy and/or sleep restriction therapy with or without use of relaxation therapy. Cognitive therapy aims at changing the patient's beliefs and attitudes about insomnia. It uses a psychotherapeutic method to reconstruct cognitive pathways with positive and appropriate concepts about sleep and its effects (Hauri, 1991b; Jacobs, Pace-Schott, Stickgold, & Otto, 2004; Spielman, Saskin, & Thorpy, 1987).

Cognitive-behavioral approaches use sleep diaries for assessment and monitoring of treatment outcomes. They require patients to work on bedtimes and wake times, thereby using voluntary waking behaviors to influence sleep. The generic applicability of the behavioral/psychological approaches rests with their basis in the two-process model of sleep regulation along with an understanding that stimulus-linked conditions or sleep-related beliefs that foster wakefulness are often good targets for modification. Substantial data support the process of sleep propensity being normally governed by the length of time a person is

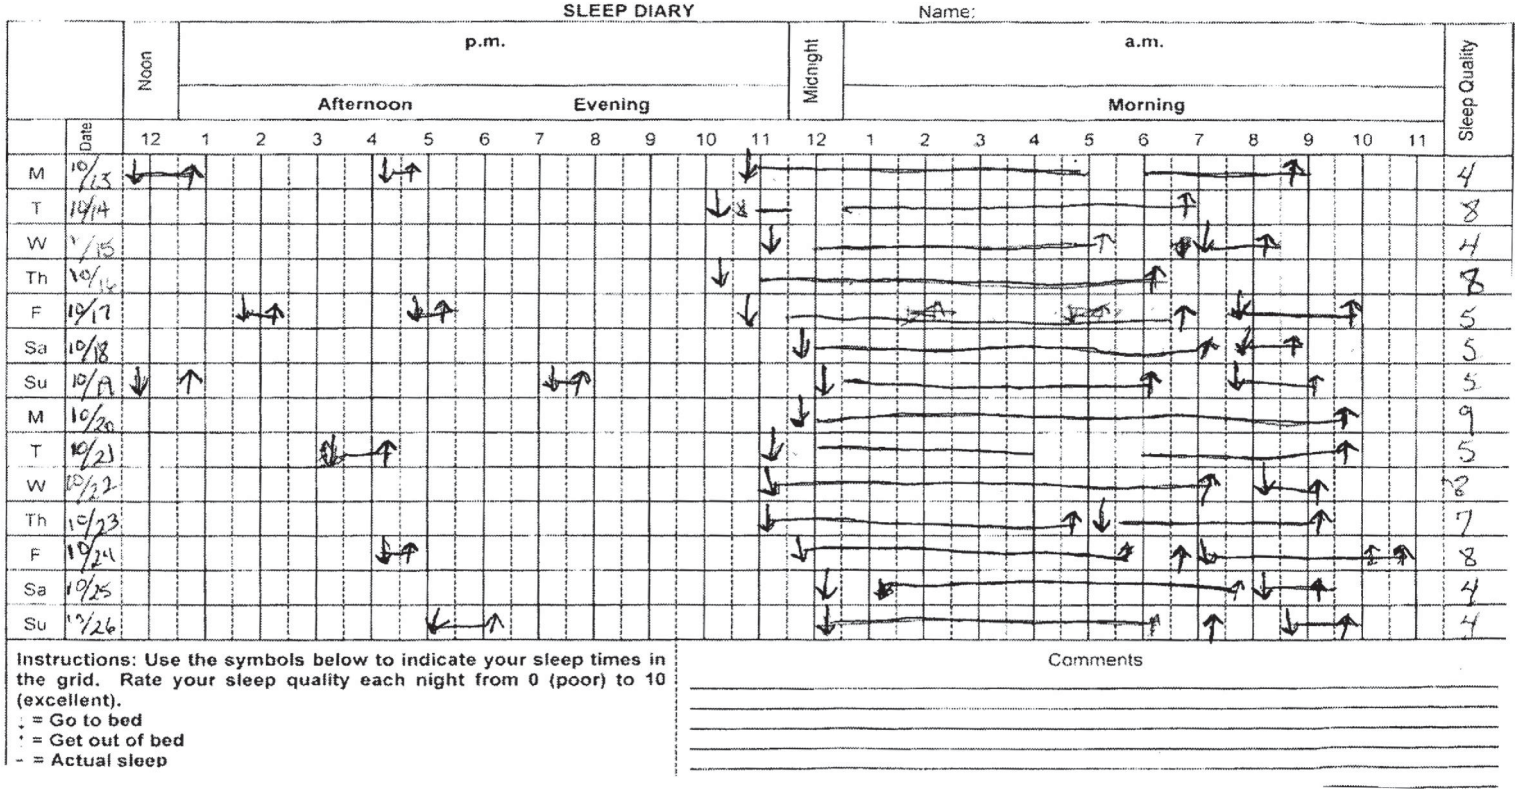

FIGURE 21.1 Sleep diary. A sleep diary (log) is a visual record designed to gather information about a patient's sleep patterns. It should be completed within an hour of getting out of bed, and the best estimate of sleep wake timing should be recorded. (Adapted from the American Academy of Sleep Medicine.)

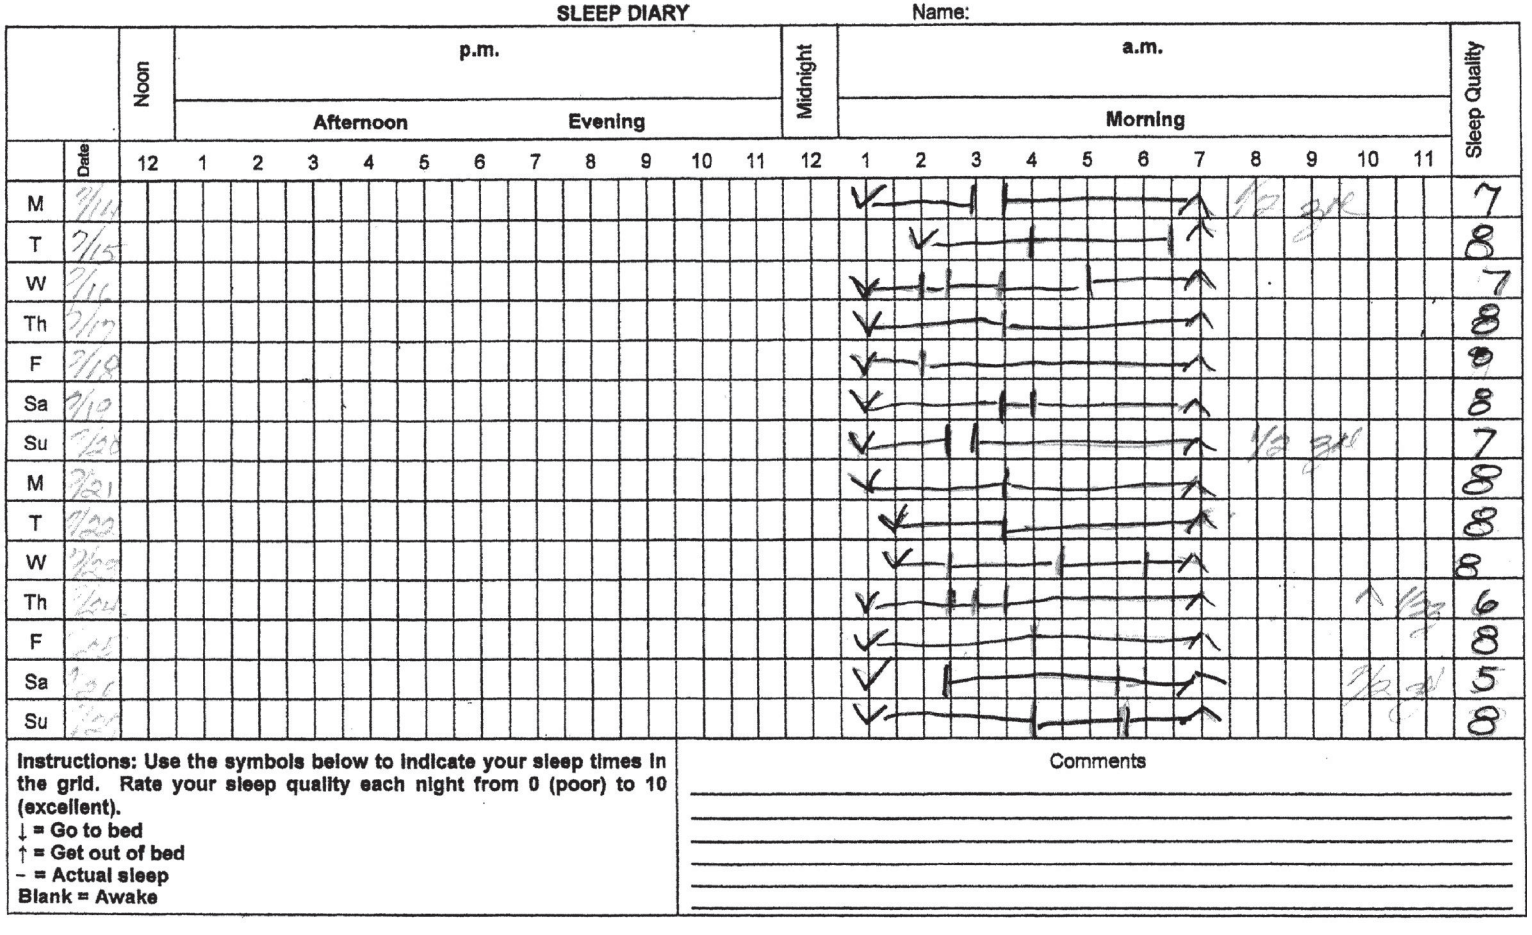

FIGURE 21.1 Continued

TABLE 21.1 Psychosocial Treatments of Insomnia

Type of Treatment	*Description*	*Key Elements*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
CBT-I	Multimodal treatment that combines cognitive therapy with behavioral interventions.	Sleep education Stimulus control techniques Sleep restriction techniques Cognitive therapy techniques May include relaxation training.	Based on various meta-analyses, systematic review, and clinical trials. The findings indicate that nonpharmacological therapies produce reliable and durable changes in several sleep parameters of chronic insomnia patients. The data indicate that between 70% and 80% of patients treated with nonpharmacological interventions benefit from treatment.	Type 1 & 2 studies	Hofmann, Asnaani, Vonk, Sawyer, & Fang, 2012 C. M. Morin, Culbert, & Schwartz, 1994 Montgomery & Dennis, 2003 Morin et al., 2006 Okajima, Komada, & Inoue, 2011
Stimulus control	Based on operant and classical conditioning principles: nonsleep activities and the bedroom environment can serve as stimuli that interfere with sleep. Treatment prescribes behaviors that strengthen associations between the environment and sleep.	Go to bed only when sleepy. Use the bed and bedroom for sleep only. Do not read, watch television, talk on the phone, worry, or plan activities in the bedroom. If unable to fall asleep within 10–20 min, leave the bed and the bedroom. Return only when feeling sleepy again. Set the alarm and wake up at a regular time every day. Do not use the snooze button on the alarm. Do not nap during the day.	Based on at least 2 between-group design studies demonstrating efficacy in more than one way. Stimulus control was as effective as sleep education plus relaxation and more effective than a waitlist control. Stimulus control treatment produced significant improvements on most sleep parameters relative to no additional treatment.	Type 1–3 studies	Riedel, Lichstein, & Peterson, 1998 Lacks, Bertelson, Sugerman, & Kunkel, 1983 Morin et al., 1994 Smith, Perlis, Park, & Smith, 2002 Baillargeon & Demers, 1998

(*continued*)

TABLE 21.1 (continued)

Type of Treatment	*Description*	*Key Elements*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Relaxation techniques	Muscular tension and cognitive arousal are incompatible with sleep. Relaxation decreases waking arousal and facilitates sleep at night.	Specific techniques may include progressive muscle relaxation, guided imagery, paced breathing.	Clinical trials. Studies contrasting relaxation-based interventions to a control condition found relaxation more effective than waitlist, placebo, or no treatment. Relaxation was more effective for sleep onset.	Type 2 & 3 studies	Friedman, Bliwise, & Yesavage, 1991 Means, Lichstein, & Epperson, 2000 Lichstein, Riedel, & Wilson, 2001
Biofeedback	Three types of biofeedback have been specifically tested for the treatment of insomnia: EMG, theta EEG, and sensorimotor rhythm EEG.	Visual or auditory feedback to patients helps them control physiological parameters and reduce somatic arousal.	Very few studies with effects of biofeedback for treating insomnia. All studies available show that it is an effective modality for treatment of insomnia, but it takes longer than other forms of relaxation therapy with little appreciable advantage.	Type 3 & 6 studies	Nicassio & Boylan, 1982 Freedman & Papsdorf, 1976 VanderPlate & Eno, 1983 Cortoos, de Valck, Arns, & Breteler, 2010
Sleep restriction	Based on experimental evidence that sleep is regulated by circadian and homeostatic processes. Treatment increases homeostatic sleep drive by reducing time in bed and maintaining a consistent wake time in the morning to reinforce circadian rhythms.	Restrict time awake in bed by setting strict bedtime and rising schedules limited to the average number of hours of actual sleep reported in 1 night. Keep a fixed wake-up time, regardless of actual sleep duration. If after 10 d sleep efficiency is lower than 85%, further restrict bedtime by 15–30 min. Increase time in bed by advancing bedtime by 15–30 min when the time spent asleep is at least 85% of time in bed.	Based on clinical trials and meta-analysis. Reduction in wake time after sleep onset, increased sleep efficiency and total sleep time. Also noted to have improvement in subjective assessment.	Type 2–4 studies	Vincent, Lewycky, & Finnegan, 2008 Wohlgemuth & Edinger, 2000 Morin, Hauri, Espie, & Spielman, 1999 Spielman, Saskin, & Thorpy, 1987 Morin et al., 1994

Sleep hygiene	Recommendations promoting behaviors that help sleep, discouraging behaviors that interfere with sleep	Specific recommendations vary across studies. Typical recommendations include: Do not try to sleep if not sleepy. Avoid stimulants (caffeine, nicotine). Limit alcohol intake. Maintain a regular sleep schedule 7 nights per wk. Avoid naps. Get regular exercise at least 6 h prior to sleep. Keep the bedroom dark and quiet.	Insufficient evidence to be an option as a single therapy. Whether this therapy is effective when added to other specific approaches could not be determined from available data.	Type 2–5 studies	Jefferson, Drake, Scofield, & Myers, 2005 Stepanski & Wyatt, 2003 Schoicket, Bertelson, & Lacks, 1988 Hauri, 1991a
Cognitive therapy	Identify, challenge, and replace dysfunctional beliefs and attitudes regarding sleep and sleep loss. These beliefs increase arousal and tension, which impede sleep and further reinforce the dysfunctional beliefs.	Challenge unhelpful beliefs and fears about sleep (e.g., overestimation of numbers of hours of sleep necessary to be rested; apprehensive expectation that sleep cannot be controlled; fear of missing opportunities for sleep). Thought journaling to reduce rumination. Design behavioral "experiments" to test beliefs about sleep.	Ongoing research to be an option as a single therapy. Extensive evidence for effectiveness when used with other therapies.	Type 3 studies	Belanger, Savard, & Morin, 2006 Harvey, 2002 Harvey et al., 2007 Okajima et al., 2011 Yook, Lee, Ryu, Kim, & Choi, 2008

continuously (i.e., not napping) awake ("Process S") *and* by the biological time of day as set by the suprachiasmatic nuclei of the hypothalamus governing the body's circadian rhythms ("Process C"). It is Process C that makes it more difficult to remain awake between 3 and 5 a.m. (Fig. 21.2).

Based on these principles, CBT-I includes restricting time in bed to match actual sleep time, setting a regular sleep-wake time regardless of the duration of sleep the night before. New treatment modalities are being investigated to disseminate these treatments and reduce patient burden and costs; they include home-based treatment (Espie, Inglis, Tessier, & Harvey, 2001), telephone interventions, Internet-based interventions (Morin, Stone, Trinkle, Mercer, & Remsberg, 1993), and self-help material (Mimeault & Morin, 1999).

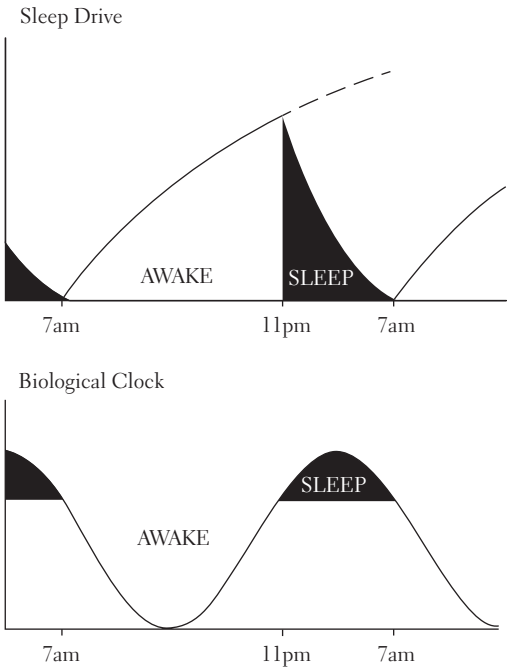

FIGURE 21.2 The two-process model. Alertness level is determined by the interaction between two regulatory processes. The sleep homeostatic drive (Process S) promotes sleep and builds up during extended wakefulness, reaching a maximum in the late evening (near the usual sleep time). The circadian rhythm system (Process C) promotes wakefulness during the day. It is biphasic and tends to dip in the midafternoon. Process C also reaches its peak in the evening to counterbalance the accumulation of homeostatic drive that has built up throughout the day, and it begins to fall just before the usual bedtime. This system promotes wakefulness during the day and consolidates sleep at night (Borbely, 1982).

Pharmacological Treatments

Hypnotic therapy should be considered for insomnia when the patient is significantly distressed by disturbed sleep, when the sleep disturbance is deleterious to the patient's overall safety or health, when cognitive-behavioral approaches are unavailable or unsuccessful, or when the patient is unwilling or unable to engage in CBT. Benzodiazepine receptor agonists are the mainstay of pharmacological treatment for insomnia, although many agents other than benzodiazepine receptor agonists are also used in the treatment of insomnia; these include agents classified as antidepressants, antipsychotics, antihistamines, anticonvulsants, melatonin agonists, and herbals as well as chloral hydrate and sodium oxybate (Bertisch, Herzig, Winkelman, & Buettner, 2014).

Among the many medications used to treat insomnia, a much smaller number are approved by the U.S. Food and Drug Administration (FDA) for this indication. Currently approved drugs include benzodiazepine receptor agonists, one tricyclic drug, one melatonin receptor agonist, antihistamines, barbiturates (Krystal, 2009; Walsh 2004) and an orexin receptor antagonist.

Table 21.2 summarizes various pharmacological treatment methods for insomnia and Table 21.3 summarizes herbal and over-the-counter treatments.

There is considerable evidence indicating that the benzodiazepine receptor agonists are efficacious in the treatment of insomnia, whether primary or comorbid, chronic or transient. They have a wide margin of safety as commonly used in clinical practice. Meta-analyses have demonstrated the they are efficacious in the treatment of chronic insomnia (Holbrook, Crowther, Lotter, & Endeshaw, 2001; Soldatos, Dikeos, & Whitehead, 1999) on self-reported outcomes of sleep latency, sleep duration, number of awakenings, and sleep quality. Effects are comparable in magnitude to those of CBT (Smith, Fogg, & Eastman, 2009).

The 2005 National Institutes of Health state-of-the-science report on the management of chronic insomnia concluded that the benzodiazepine receptor agonists are the only medications with an established

TABLE 21.2 Pharmacological Treatments

Medications	*Key Clinical Points*	*Main Side Effects*	*Relative Contraindications*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Benzodiazepine receptor agonists (nonbenzodiazepines)	First-line hypnotics. Margin of safety or therapeutic index is wide.	Sedation, anterograde amnesia, ataxia, sleep walking, sleep violence or sleep related eating disorders, respiratory depression. Rebound insomnia, tolerance and abuse may occur.	Concomitant illnesses such as obstructive sleep apnea, substance use disorder, or advanced liver disease.	RCTs of benzodiazepine receptor agonist hypnotics Adults younger than 65 years N = 1894 Moderate effect sizes (d = 0.56–0.71) for self-reported outcomes of sleep latency, total sleep time, number of awakenings, sleep quality Z scores for effect sizes range from 0.71 to 0.76	Type 1 studies	Buysse, 2013 Roehrs & Roth, 2012 Schutte-Rodin, Broch, & Buysse, 2008 Riemann & Perlis, 2009 Walsh & Roth, 2011

TABLE 21.2 (continued)

Medications	*Key Clinical Points*	*Main Side Effects*	*Relative Contraindications*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Benzodiazepines	Agonists at benzodiazepine receptor GABA-A site. Different medications have different durations of action.	Sedation, ataxia, anterograde amnesia, ataxia, sleep walking, sleep violence or sleep related eating disorders, respiratory depression. Rebound insomnia, tolerance and abuse may occur.	Concomitant illnesses such as obstructive sleep apnea, substance use disorder, or advanced liver disease.	RCTs of benzodiazepine hypnotics compared to placebo or other active treatments N = 2,672 Self-report outcomes: Significant difference favoring benzodiazepines vs. placebo for sleep latency, total sleep time Polysomnography outcomes: Significant difference favoring benzodiazepines vs. placebo for total sleep time Side effects (drowsiness, dizziness, lightheadedness): Significantly more likely in patients taking benzodiazepines vs. placebo. Reduce time to sleep onset, prolonged stage 2, prolonged total sleep time and some reduction in REM sleep.	Type 1 & 2 studies	Holbrook et al., 2001 Holbrook, Crowther, & Lotter, 2000 Nowell, Mazumdar, Buysse, & Dew, 1997

	Sedative antidepressants (e.g., doxepin, trazodone)	Sedative nature due to central anticholinergic or antihistaminergic activity. There is also possible effect of serotonin 5HT2 receptor antagonism and alpha 1 antagonism. Helpful in patients with concomitant depression. Doxepin is FDA approved for sleep maintenance insomnia.	Somnolence, headache, dizziness and nausea. Priapism is a relatively uncommon side effect of trazodone.	Hypersensitivity and use of MAO inhibitors within 14 days. Dry mouth, constipation, narrow-angle glaucoma, and urinary retention with doxepin. Trazodone to be used with caution in those at risk of falls because of orthostatic hypotension.	RCTs of benzodiazepine receptor agonists and antidepressant drugs in chronic insomnia Antidepressants: Significant effects on polysomnographic wake after sleep onset, sleep efficiency, total sleep time; and on sleep diary rating of sleep quality Adverse events significantly greater for benzodiazepine receptor agonists and antidepressants vs. placebo	Type 1–3 studies	Krystal, Lankford, Durrence, & Ludington, 2011 Richey & Krystal, 2011 Wiegand, 2008 Buscemi, Vandermeer, Friesen, & Bialy, 2007 Glass, Sproule, Herrmann, & Busto, 2008 Mendelson, 2005
	Ramelteon	First melatonin receptor agonist for treatment of insomnia	Headache, dizziness, somnolence, fatigue, nausea	History of angioedema with ramelteon and concurrent use of fluvoxamine. Use in severe liver failure.	8 placebo-controlled RCTs of ramelteon in chronic insomnia. Sleep latency reduced in patients 18–64 years old. No difference in percentage of REM on polysomnography between ramelteon and placebo. Well tolerated without major side effects. No dose–response relationship observed. No next-day residual daytime sedation.	Type 1 & 2 studies	Mayer, Wang-Weigand, & Roth-Schechter, 2009 Reynoldson & Elliott, 2008 Sateia, Kirby-Long, & Taylor, 2008 Miyamoto, 2009 Ferguson, Rajaratnam, & Dawson, 2010 Kuriyama, Honda, & Hayashino, 2014

TABLE 21.2 (continued)

Medications	*Key Clinical Points*	*Main Side Effects*	*Relative Contraindications*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Mirtazapine	Sedating effects diminish in doses greater than 30 mg due to adrenergic effects. Antagonizes adrenergic, serotonergic and histaminergic receptors.	Increased appetite and weight gain. Dry mouth and constipation.	Used with in caution in patients with bipolar disorder, obesity, liver disease and kidney disease	Clinical trials and open-label studies. Improves sleep continuity in depressed patients with poor sleep quality. Decreased sleep latency, increased total sleep time and sleep efficiency. No effect on REM sleep.	Type 3–6 studies	Winokur et al., 2000 Wichniak, Wierzbicka, & Jernajczyk, 2012
Sedative antipsychotics: quetiapine, olanzapine	Used in doses lower than typically used in their FDA-approved indications. Antagonize dopamine, histamine, serotonin, muscarinic, cholinergic, and adrenergic receptors. Improves sleep primarily in patients with mood disorders.	Orthostatic hypotension, dizziness, dry mouth, constipation, blurred vision, urinary retention, weight gain and sedation. Can lead to extrapyramidal side effects, which are less common in newer agents. Olanzapine associated with cognitive impairment, glucose intolerance, elevated risk of mortality among patients with dementia.	Used with caution in patients with myocardial infarction, ischemia or conduction abnormalities, closed-angle glaucoma, decreased gastrointestinal motility, urinary retention, or hypotension.	Clinical studies demonstrate decrease in sleep latency, increased sleep efficiency and improved subjective sleep quality.	Type 3, 5, & 6 studies	Monti & Monti, 2004 Anderson & Griend, 2014 Wiegand et al., 2008 Wine, Sanda, & Caballero, 2009 Cohrs et al., 2004

TABLE 21.3 Over-the-Counter Medications for Insomnia

Medications	*Key Clinical Points*	*Main Side Effects*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Melatonin	Used both as a hypnotic and as a chronobiotic to phase shift circadian rhythms. Studied in adults and children.	Daytime somnolence	Crossover studies and clinical trials, Associated with reduced sleep latency and improved quality of sleep. Less consistent effects on sleep maintenance. Dose–response effect has not been established.	Type 2, 3, 4, 5 studies	Smits, Nagtegaal, van der Heijden, Coenen, & Kerkhof, 2001 Ferracioli-Oda, Qawasmi, & Bloch, 2013
Valerian root	One of the 10 most popular herbal products sold in the United States	Hepatotoxic	Meta-analysis of 18 studies found that valerian decreased objective sleep latency by less than 1 minute compared to placebo.	Type 2, 3, 4, 5 studies	Nunes & Sousa, 2011 Sarris & Byrne, 2011 Balderer & Borbély, 1985 Fernández-San-Martín et al., 2010
Antihistamines (e.g., diphenhydramine and doxylamine)	Antagonizes H1 histamine receptors	Closed-angle glaucoma, decreased gastrointestinal motility, urinary retention, asthma, chronic obstructive pulmonary disease, and severe liver disease. There have been reports of coma and rhabdomyolysis occasionally occurring with doxylamine.	Sleep-enhancing effects of diphenhydramine noted in placebo-controlled trials of sleep disturbance in a mixed group of psychiatric patients. Effects on sleep maintenance more consistent than sleep onset. No studies with doxylamine.	Type 2, 3, 5 studies	Glass et al., 2008 Griend & Anderson, 2012 Smith & Smith, 1985

scientific basis (i.e., clearly defined risk and benefit by dose) for use for insomnia. Thus, for most patients with chronic insomnia, pharmacotherapy should be initiated with a benzodiazepine receptor agonist at the lowest effective dose for the shortest clinically necessary period of time.

Benzodiazepine receptor agonists act at a specific recognition site on the GABA-A receptor that is distinct from the actual GABA binding site. They increase the affinity for GABA binding, thereby promoting the inhibitory actions of this neurotransmitter. Significant differences in pharmacokinetic profiles exist among the benzodiazepine receptor agonists, thereby providing physicians with therapeutic options that have differing durations of action, with half-lives varying from 1 hour to greater than 100 hours. Half-life and duration of action can help to guide the clinician on the choice of a particular drug. For instance, a patient with primarily sleep-onset difficulties may benefit from a short-acting hypnotic, whereas a patient who has trouble staying asleep may benefit from a longer-acting agent (Kryger, Roth, & Dement, 2010; Mendelson, 2011).

The primary contraindications to the use of benzodiazepine receptor agonists are concomitant illnesses, such as obstructive sleep apnea, substance abuse disorder, or advanced liver disease. However, these cases represent relative rather than absolute contraindications.

Although they are generally well tolerated, benzodiazepine receptor agonists can cause adverse effects, including sedation, memory impairment, impaired balance, impaired driving performance the day after dosing, and complex sleep-related behaviors. The latter may include eating, walking, and sexual activity while ostensibly asleep. Abrupt discontinuation of benzodiazepine receptor agonists can be associated with rebound insomnia and withdrawal symptoms.

Doxepin is a tricyclic antidepressant approved as a hypnotic agent. At low doses (3 to 6 mg) it has been approved as a hypnotic. It reduces wakefulness across the night and improves sleep efficiency (Krystal et al., 2011). At hypnotic doses, doxepin has antihistamine (H1) effects and very few effects on serotonin, norepinephrine, or dopamine neurotransmission. This accounts for sedation and without some of the toxicity and side effects associated with anticholinergic properties at high doses. Although not formally approved, low-dose trazodone and mirtazapine are commonly used to treat insomnia. Melatonin and a melatonin receptor agonist, ramelteon, have been used as hypnotics, and ramelteon is FDA approved for this purpose. Both have been shown to decrease subjective sleep latency. They have fewer side effects compared to benzodiazepine receptor agonists (Buysse, Bate, & Kirkpatrick, 2005; Erman, Seiden, Zammit, Sainati, & Zhang, 2006). Antihistamines are another class of commonly used over-the-counter agents to treat insomnia. Their efficacy and side effects have not been rigorously evaluated. Most promising use has been shown in insomnia associated with allergy symptoms.

Other drugs used in the treatment of insomnia include valerian, gabapentin and pregabalin, and sedating antipsychotic drugs. Very limited evidence supports the efficacy and safety of these drugs for treating insomnia.

In 2014 the FDA approved the orexin receptor antagonist suvorexant for the treatment of insomnia, the first drug its class.

HYPERSOMNOLENCE DISORDER AND NARCOLEPSY

Overview and Diagnosis

The essential feature of hypersomnolence disorder and narcolepsy is excessive daytime sleepiness that is not due to disturbed nocturnal sleep, occurring at least three times a week for at least 3 months. In narcolepsy, irresistible sleep occurs intermittently during waking hours. In addition, the patient must have at least one of the following: cataplexy episodes, defined by brief episodes of sudden bilateral loss of muscle tone precipitated by strong emotions but preserved consciousness; hypocretin deficiency in cerebrospinal fluid; or nocturnal polysomnography findings of REM latency less than 15 minutes or mean sleep latency of less than 8 minutes with two episodes of REM sleep during a mean sleep latency test. The mean sleep latency test is the key test for diagnosis of narcolepsy, in which the patient is required to take five naps during the day. The mean time to sleep onset and the presence of REM sleep are measured. For improved validity of the mean sleep latency test, it should be interpreted in the context of the patient's clinical findings.

In hypersomnolence disorder, excessive sleepiness occurs despite a main sleep period of at least 7 hours. Nighttime sleep is of long duration with good sleep continuity but is nonrestorative.

A careful history must be obtained in all cases. Because of its importance in the diagnosis of narcolepsy, cataplexy should be assessed in detail. Possible substance abuse must be elicited as well. The Epworth Sleepiness Scale, an eight-item self-report instrument that assesses the tendency to doze in various scenarios, is commonly used to assess sleepiness in hypersomnolence disorder, narcolepsy, and other sleep disorders. The total score ranges from 0 to 24, with a score of 10 or more suggesting pathological sleepiness. Sleep logs and/or actigraphy can be helpful to rule out sleep deprivation/restriction. Narcolepsy is associated with deficiency of the peptide neurotransmitter hypocretin (orexin) and loss of orexin-containing cells in the lateral hypothalamus. Projections from the lateral hypothalamus innervate arousal centers of the brain stem and posterior hypothalamus, and loss of orexinergic cells is associated with instability of sleep-wake states. Levels of hypocretin-1 in cerebrospinal fluid can be measured; low levels are found in most cases of narcolepsy. Because of difficulty in performing lumbar punctures and the absence of routine clinical laboratories for assays, its use is reserved for complex cases.

Although driving and working can be impaired in untreated cases, once hypersomnolence disorder or narcolepsy is controlled, patients can consider driving with caution. In addition to medical and behavioral management, referral to support groups is often helpful for social support.

Management

Since no cure of hypersomnolence or narcolepsy currently exists, treatment is aimed at symptom control to allow patients to live a full personal and professional life. Treatment of hypersomnolence is very similar to that of narcolepsy. The mainstay of treatment is pharmacological, although adjunctive behavioral therapy plays a role in adapting to the situation. Treatment aims at reducing excessive daytime sleepiness, improving nighttime sleep, and managing cataplexy symptoms if present. Since the medications are used on a long-term basis and have considerable adverse effects, treatment must balance maintaining an active life with avoiding adverse effects and developing tolerance to medications.

Table 21.4 summarizes various pharmacological treatment options based on symptoms of narcolepsy, and Table 21.5 gives an overview of medications used for narcolepsy.

Stimulants

Stimulants are indicated in the treatment of excessive daytime sleepiness. They produce substantial improvement in daytime alertness in a dose-dependent manner. Amphetamines and related drugs, which include methylphenidate, dextroamphetamine, and mixed amphetamine salts, are most commonly used. They increase dopaminergic and noradrenergic neurotransmission by blocking reuptake of these neurotransmitters via the dopamine reuptake transporter and by increasing presynaptic dopamine release (Riddle, Fleckenstein, & Hanson, 2005).

Stimulants are available in immediate-release and sustained-release forms. The usual duration of effect of immediate-release preparations is 3 to 6 hours. A combination of the two forms often provides the best balance between acute effects and sustained alertness. The optimal combination, timing, and dose to provide maximal efficacy vary on an individual basis. Patients may report "peaks" and "crashes" associated with the onset and offset of drug effects with short-acting preparations alone. Side effects may include increased heart rate and blood pressure and symptoms of anxiety, nervousness, and tremor. There have also been reports of methylphenidate causing an increased risk of sudden cardiac death, but Schelleman and colleagues found a lack of dose–response relationship, suggesting there may not be a causal association. Nocturnal sleep disruption can result from doses taken in the late afternoon and early evening. In some cases patients may experience psychotic symptoms such as hallucinations and paranoid delusions. Tolerance, dependence, and abuse can also occur. If tolerance develops, medication class can be switched or the patient can take periodic "drug holidays;" the latter may help to preserve the efficacy of stimulant medications.

Modafinil and armodafinil are wake-promoting agents comparable in efficacy to traditional stimulants in promoting alertness. Their exact mechanism of action is unknown but appears to involve local effects in the hypothalamus or effects on the dopamine transporter (U.S. Modafinil in Narcolepsy Multicenter Study Group, 2000). The effect of modafinil lasts relatively long due to its half-life of 12 to 15 hours.

TABLE 21.4 Hypersomnolence Disorders: Narcolepsy Treatment Based on Symptoms

Symptoms Addressed	*Key Clinical Points*	*Medications Used*	*Key References*
Excessive daytime sleepiness	Continuous daytime sleepiness with sleep attacks, usually the first symptom and present in 100% of the patients. Treatment includes conservative measures and medications.	Modafinil (standard) Sodium oxybate (standard) Amphetamine (guideline) Methamphetamine (guideline) Dextroamphetamine (guideline) Methylphenidate (guideline) Selegiline (option)	Littner et al., 2001 Wise, Arand, Auger, Brooks, & Watson, 2007
Cataplexy	Sudden usually bilateral, partial or complete loss of muscle tone provoked by emotional stimuli. Most accurate marker of the disease.	Sodium oxybate (option) Tricyclic antidepressants (option) Selective serotonin reuptake inhibitors (option)	Houghton, Scammell, & Thorpy, 2004 Dauvilliers, Arnulf, & Mignot, 2007 Lopez & Dauvilliers, 2013 Dauvilliers, Billiard, & Montplaisir, 2003
Sleep paralysis	Inability to move limbs or head or to speak or breathe normally either at sleep onset or awakening despite being mentally awake. May be associated with hypnagogic hallucinations.	Sodium oxybate (standard) Tricyclic antidepressants (guideline) Selective serotonin reuptake inhibitors (guideline) Venlafaxine (guideline) Selegiline (option)	Dauvilliers et al., 2003 La Herrán-Arita & García-García, 2013

The efficacy of modafinil has been evaluated extensively in excessive daytime sleepiness due to narcolepsy, idiopathic hypersomnia, and sleep apnea (La Herrán-Arita & García-García, 2013). Side effects include headache, nervousness, and small increases in blood pressure. Modafinil inhibits hepatic enzymes and can reduce the effectiveness of oral contraceptives (La Herrán-Arita & García-García, 2013; Littner et al., 2001).

Lisdexamfetamine is a pro-drug of d-amphetamine that has been used in children with attention-deficit/hyperactivity disorder. It provides a more gradual increase in brain drug concentrations, reducing pleasurable effects of the d-amphetamine. Increasing its dose enhances its efficacy but also delays its time of peak effect. This makes it less favorable for abuse and diversion purposes (Heal, Smith, Gosden, & Nutt, 2013). There have not been studies evaluating lisdexamfetamine specifically for narcolepsy, and it is not FDA approved for this indication but has been used as an "off-label" drug for treatment of narcolepsy.

Sodium oxybate can also enhance alertness in narcolepsy (Mamelak, Black, Montplaisir, & Ristanovic, 2004), but it is primarily used for the treatment of cataplexy. Atomoxetine and bupropion are other agents

TABLE 21.5 Medications for Narcolepsy

Medication/Medication Class	*Key Clinical Points*	*Main Side Effects*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Nonamphetamine stimulants; for example modafinil (100–400 mg once daily or in divided doses) and armodafinil	For treatment of excessive daytime sleepiness. Mechanism of action is unknown but hypothesized to selectively activate wake-generating sites in the hypothalamus.	Headache, nausea, dizziness, insomnia	Results from many multicenter studies indicate significant impact of modafinil on sleepiness.	Type 1 and 2 studies	La Herrán-Arita & García-García, 2013 Golicki, Bala, Niewada, & Wierzbicka, 2010 Wisor & Eriksson, 2005, 2010
Amphetamine-like stimulants: Amphetamines 5–60 mg divided doses Methylphenidate 5–60 mg divided doses	Helpful in excessive daytime sleepiness. Increase dopamine transmission. Tolerance may develop requiring escalating doses. Effectiveness may be restored by "drug holiday."	Nervousness, headache, loss of appetite, palpitations, irritability, tremors	Currently available stimulants have not been tested parallel to placebo control or with each other in narcolepsy patients.	Type 2 and 3 studies	Mignot, 2012 Wisor et al., 2001 Heal et al., 2013 Mitler, Erman, & Hajdukovic,1993
Sodium oxybate 6–9 g of liquid solution divided nightly	Useful for cataplexy and excessive sleepiness in narcolepsy. Can cause rapid sedation and amnesia. Available only from a single central pharmacy.	Sedation, enuresis, respiratory suppression	Based on RCTs and case series	Type 1 & 3 studies	Anon., 2003 Mayer, 2012 Black & Houghton, 2006 Black, Pardi, Hornfeldt, & Inhaber, 2010
Selective serotonin reuptake inhibitors	Used for treatment of cataplexy. Less efficacious but better side effect profile compared to tricyclics.	CNS excitation, nausea, sexual difficulties	Based on case series and case reports	Type 4–6 studies	Lopez & Dauvilliers, 2013 Vignatelli, D'Alessandro, & Candelise, 2008 Frey & Darbonne, 1994 Langdon, Shindler, Parkes, & Bandak, 1986
Tricyclic antidepressants	Were the first medications to treat cataplexy; currently used as the last resort.	Dry mouth, urinary retention, constipation	-	Type 3 studies	Campos-Rodriguez et al., 2012 La Herrán-Arita & García-García, 2013 Schmidt, Clark, & Hyman, 1977 Roth, 2007
Norepinephrine and serotonin uptake inhibitors	Effective for cataplexy, sleep paralysis and hypnagogic hallucinations. Venlafaxine has been used in both adults and children. Atomoxetine is a highly specific noradrenergic reuptake inhibitor and tried in cases of resistant cataplexy after failure of fluoxetine, venlafaxine, and other serotonin reuptake inhibitors.	Nausea, dry mouth, elevated blood pressure, insomnia, withdrawal syndrome	Based on case series	Type 3 & 6 studies	Lopez & Dauvilliers, 2013 Møller & Østergaard, 2009 Ratkiewicz & Splaingard, 2013 Houghton et al., 2004

used in patients with hypersomnolence, but their efficacy has not been formally evaluated.

Anticataplectic Drugs

First-line treatment for cataplexy consists of antidepressants, mainly venlafaxine, desmethylvenlafaxine, duloxetine, or fluoxetine (Morgenthaler et al., 2007a).

Sodium oxybate (gamma hydroxybutyrate) is also a very effective treatment for cataplexy, with additional positive effects on daytime sleepiness (Anonymous, 2002, 2003). Sodium oxybate is administered in gram doses so it is given as a liquid at the beginning of the night and in the middle of the night. Two doses through the night are required because of its very short elimination half-life, ranging from 20 to 70 minutes. Although the half-life is very short, it exerts longer-lasting physiological effects through unknown mechanisms (Pardi & Black, 2006). It increases slow-wave sleep and REM sleep. Sodium oxybate is strictly controlled by the U.S. Drug Enforcement Agency because of its abuse potential and the possibility of diversion to other individuals. Side effects include profound sleepiness, sleepwalking, amnestic behaviors, and respiratory suppression in large doses.

BREATHING-RELATED SLEEP DISORDERS

Overview and Diagnosis

Breathing-related sleep disorders include three distinct disorders: obstructive sleep apnea hypopnea, central sleep apnea, and sleep-related hypoventilation. All of these are associated with impaired ventilation during sleep, resulting in sleep disruption and daytime fatigue or sleepiness. Effective treatment can have a positive impact on quality of life and morbidity of psychiatric patients. These disorders are also important to recognize in patients with psychiatric conditions because of symptom overlap, such as disrupted sleep, sleepiness, irritability, and depression (Harris, Glozier, Ratnavadivel, & Grunstein, 2009).

A careful history of symptoms followed by in-lab or at-home diagnostic polysomnography is warranted. A sleep study (polysomnogram) records breathing patterns in addition to other parameters. Two types of breathing events are typically identified: hypopneas, characterized by reduction in airflow by 30% with oxygen desaturation of at least 3%, and apneas, characterized by cessation of airflow for at least 10 seconds. The number of apneas and hypopneas per hour of sleep is known as the apnea-hypopnea index, which is a measure of severity of obstructive sleep apnea hypopnea and central sleep apnea. More than five events in one hour are considered abnormal in adults. Sleep-related hypoventilation may or may not be associated with an increased apnea-hypopnea index but is characterized by low oxygen saturation (hypoxemia) or carbon dioxide retention (hypercapnia).

Management

The goals of treatment for patients with obstructive sleep apnea syndrome are correcting the breathing disturbance, controlling symptoms, and reducing comorbidities associated with sleep apnea to improve quality of life. Table 21.6 summarizes treatments for obstructive sleep apnea.

Somatic Treatments

Positive Airway Pressure Therapy

Positive airway pressure therapy helps to passively open the upper airway during sleep and acts as a pneumatic splint. In addition, it may also increase upper airway size and stiffen the upper airway walls, likely due to "tracheal tug"—the downward pull on upper airway structures during lung expansion (Alex, Aronson, Onal, & Lopata, 1987).

RCTs have also shown positive airway pressure to improve sleepiness, quality of life, and blood pressure. Observational studies have shown reduction in cardiovascular mortality. Optimal adherence to therapy is a major limiting factor in reducing effectiveness (Campos-Rodriguez et al., 2012).

Various modes of positive pressure therapy delivery include continuous positive airway pressure, bilevel positive airway pressure, autotitrating positive pressure devices, and devices with a backup rate. Table 21.7 lists these devices and gives brief descriptions.

Oral Appliance Therapy

Oral appliances are devices that are inserted into the mouth for treatment of snoring and sleep apnea.

TABLE 21.6 Breathing-Related Sleep Disorders: Obstructive Sleep Apnea

Treatment Modality	*Key Elements*	*Evidence for Efficacy*	*Evidence Grade*	*AASM Grade*	*Key References*
Positive pressure therapy	First-line treatment. Main limitation is willingness to accept therapy and remain adherent. Many variants available, such as continuous, bilevel, or autoadjusting positive pressure therapy. Splints open airway while sleeping.	Based on various RCTs with strong evidence. Many studies have intention-to-treat designs. Studies to assess and validate a mechanical device such as continuous positive airway pressure are difficult to design.	Type 1–3 and 3 studies	Gold standard in moderate to severe cases and option in mild cases	McDaid et al., 2009 Epstein et al., 2009 Pagel, 2007 Campos-Rodriguez et al., 2012
Oral appliance	Device inserted in the mouth. Tongue retaining and mandibular repositioning. Minimum of 6–10 teeth in each arch is needed. Not recommended as first line in patients with severe obstructive sleep apnea, but may be considered if unable to tolerate positive airway pressure therapy or failed surgery.	Various RCTs have demonstrated efficacy of oral appliance in mild to severe cases. Better tolerated than positive pressure in some cases. Need to establish uniform definition of treatment success and patient characteristics associated with treatment success need to be determined.	Type 1, 4, 5 studies	Standard for primary snoring. Guideline for patients with mild to moderate obstructive sleep apnea who prefer or are not candidates for continuous positive airway pressure or cannot tolerate continuous positive airway pressure.	Ferguson et al., 2006 Hoffstein, 2007 Ngiam et al., 2013 Pliska & Almeida, 2012 Doff et al., 2013
Surgery	Tracheostomy was the first treatment option available. Evaluation of patients includes fiberoptic evaluation of upper airway. Various options available like maxillary mandibular advancement, uvulopalatopharyngoplasty, palatal implants or multilevel or stepwise approach.	Few systematic reviews and a very small number of RCTs. There is lack of high-level controlled studies and absence of standardized criteria to describe "surgical success."	Type 3–6 studies	Option as an adjunct to treatment of obstructive sleep apnea in obese patients. It can be used as first line in mild to moderate cases.	Aurora et al., 2010a Caples et al., 2010 Sommer, Maurer, Hörmann, & Stuck, 2012

(*continued*)

TABLE 21.6 (continued)

Treatment Modality	*Key Elements*	*Evidence for Efficacy*	*Evidence Grade*	*AASM Grade*	*Key References*
Medical management	Weight loss, modafinil for residual sleepiness, topical nasal corticosteroids for rhinitis, positional therapy	Few RCTs have evaluated adjunct treatments for obstructive sleep apnea. Weight loss has been well documented to have a positive impact on obstructive sleep apnea. Several studies documenting sleep position influencing severity of sleep apnea. Modafinil has been shown to improve residual sleepiness after treatment of sleep apnea in patients who do not have an identifiable cause of hypersomnolence based on few studies with variable level of evidence.	Type 1–6 studies	Option as an adjunct to primary treatment	Dixon et al., 2012 Sarkhosh et al., 2013 Neill, Angus, Sajkov, & McEvoy, 1997 Chapman et al., 2014 Darwish et al., 2010 Keating & Raffin, 2005 Schwartz, Hirshkowitz, Erman, & Schmidt-Nowara, 2003
Oxygen therapy	Oxygen therapy has not been proved to improve outcomes in obstructive sleep apnea. May be useful in treatment of severe hypoxemia untreated by positive pressure therapy.	Level 2 and level 3 studies, few of which were based on special-population patients. The evidence suggests that providing supplemental oxygen during sleep is not sufficiently effective in reducing apnea frequency and increasing daytime alertness to stand alone as therapy for most patients.	Type 2 and 5	Not recommended as primary treatment	Mehta, Vasu, Phillips, & Chung, 2013 Owens, 2013

TABLE 21.7 Positive Airway Pressure Delivery

Mode	*Mechanism of Pressure Delivery*
Continuous positive airway pressure (CPAP)	Continuous pressure during exhalation and inhalation
Bilevel positive airway pressure (BPAP)	Separate pressures during exhalation (lower) and inhalation (higher). Can be with or without a backup rate. Backup rate is helpful in patients who cannot generate effective breathing effort.
Autotitrating positive airway pressure	Minimum and maximum pressure fluctuates between set limits. Can be AutoCPAP or AutoBPAP.

Two main types are the tongue retaining device and mandibular repositioning appliances, also known as mandibular advancement devices. They are typically used in mild to moderate sleep apnea when patients cannot tolerate positive pressure therapy.

RCTs have demonstrated improvement in the apnea-hypopnea index, sleepiness, quality of life, and 24-hour blood pressure. Higher adherence to mandibular advancement devices is likely the cause of improved effectiveness compared to continuous positive airway pressure, despite lower efficacy. The most common minor and temporary side effects of therapy include temporomandibular joint pain, myofascial pain, tooth pain, salivation, dry mouth, gum irritation, and morning-after occlusion (Ferguson, Cartwright, Rogers, & Schmidt-Nowara, 2006; Pliska & Almeida, 2012).

Surgery

Various surgical procedures are available for management of upper airway obstruction. One of the most common is uvulopalatopharyngoplasty, but recent low-level evidence has shown that this procedure alone does not reliably normalize the apnea-hyponea index when treating moderate to severe sleep apnea. Low-level evidence has also shown another technique, maxillomandibular advancement, to be effective in the treatment of severe obstructive sleep apnea. Prior evidence has shown tracheostomy to be an effective single intervention to treat obstructive sleep apnea; however, concerns about patient safety, autonomy, and quality of life preclude its routine use, and it is considered only when deemed necessary by clinical urgency in cases of life-threatening obstructive sleep apnea and recurrent severe hypercapnic respiratory failure (Aurora et al., 2010a; Camacho et al., 2014; Caples et al., 2010).

Medical Management

Clinical trials have shown long-term improvements in sleep-disordered breathing and sleep quality from lifestyle interventions aimed at weight loss that include dietary modification and aerobic exercise, especially when combined with a primary treatment for obstructive sleep apnea (Dixon et al., 2012). In addition to dietary weight loss, bariatric surgery can be considered as an adjunctive treatment, especially in cases of morbid obesity. Positional therapy (avoiding the supine position) and reduction in alcohol use should be also considered as helpful measures in some patients.

The use of topical nasal steroids is recommended in patients with obstructive sleep apnea and concurrent rhinitis. Modafinil is recommended for treatment of residual excessive daytime sleepiness in patients with obstructive sleep apnea after effective positive airway pressure treatment has been provided and when no other identifiable causes of sleepiness have been identified (Morgenthaler et al., 2006).

CIRCADIAN RHYTHM SLEEP-WAKE DISORDERS

Overview and Diagnosis

In humans, many physiological and behavioral processes occur roughly on a 24-hour or circadian cycle. The suprachiasmatic nucleus in the anterior hypothalamus is the master circadian pacemaker in mammals. External stimuli called *zeitgebers* entrain the nucleus to the light-dark cycle. Misalignment

between endogenous circadian rhythm and exogenous factors results in a variety of disorders, classified in *DSM-5* as circadian rhythm sleep-wake disorders. An essential feature for diagnosis is a persistent or recurrent pattern of sleep-wake disturbance resulting in a mismatch between endogenous rhythm and personal or societal demands. *DSM-5* distinguishes the following types of disorders.

Delayed sleep phase type is characterized by delayed sleep onset and awakening. Sleep duration and quality are normal when patients are allowed to sleep during their own "biological night." Advanced sleep phase type is characterized by a sleep cycle that is advanced compared to conventional societal norms. Irregular sleep-wake type occurs when the sleep-wake pattern is disorganized and variable throughout the 24-hour period; this type is commonly seen in neurodegenerative disorders and institutionalized elderly persons (Sack et al., 2007; Zee & Vitiello, 2009). Non-24-hour sleep-wake type is defined by a sleep pattern that is entrained to an endogenous circadian rhythm that is usually slightly more than 24 hours, accompanied by a daily drift usually to later times. It occurs commonly in blind individuals. Shift work type is associated with an unconventional shift work schedule, with insomnia during the time allotted for rest and/or excessive sleepiness while at work.

Diagnosis of these disorders is based on clinical presentation and thorough history. Sleep-wake logs are a useful tool to assess the sleep-wake pattern. Actigraphy can provide objective verification of activity and resting patterns. Polysomnography may be useful to rule out other sleep disorders, like obstructive sleep disorder or periodic limb movement disorder.

Management

Improved daytime function, nighttime sleep, and quality of life are the major treatment goals for circadian rhythm sleep wake disorders. The main approach in treatment is to realign the timing of the endogenous circadian rhythm with the required sleep-wake schedule. Bright light and melatonin can reset the circadian clock in a time-of-day–dependent manner when given at specific times. Bright light in the morning advances rhythms and in the evening delays them. Melatonin in the evening advances rhythm and in the morning (theoretically) delays rhythm. The "switch point" between advances and delays for both bright light and melatonin occurs at the time of core body temperature minimum, about 2 to 3 hours before habitual wake time. Consequently, bright light or melatonin close to the time of core body temperature minimum can have large and unpredictable effects on circadian rhythm timing.

Table 21.8 gives an overview of common treatments used in circadian rhythm sleep disorders. A treatment outline for specific disorders is given below.

Delayed Sleep Phase Syndrome

Treatment includes slowly advancing the circadian rhythm and avoiding bright light in the evening. Melatonin (0.5 to 5 mg) can be used to advance the sleep cycle when given 6 to 9 hours before the dim-light melatonin onset (~1 to 3 hours before sleep onset) (Mundey, Benloucif, Harsanyi, Dubocovich, & Zee, 2005). Bright light in the morning hours, near the time of usual awakening, also helps to advance circadian rhythms. Combination therapy with morning bright light and evening melatonin can improve subjective sleepiness, fatigue, and cognitive function (Wilhelmsen-Langeland et al., 2013). Good sleep hygiene is an essential component of treatment (see Table 21.3).

Advanced Sleep Phase Syndrome

Similar to delayed sleep phase syndrome, appropriately timed bright light and melatonin are used to treat advanced sleep phase. Bright light between 7 and 9 p.m. is used to delay the natural sleep-wake window and other circadian rhythms. Bright light should be avoided in the early morning to minimize phase-advancing effects. No published studies currently validate the effectiveness of morning melatonin in this disorder (Lack & Wright, 1993; Lack, Wright, Kemp, & Gibbon, 2005), and concerns about a direct sedating effect with morning administration weigh against this treatment.

Irregular Sleep-Wake Disorder and Non-24-Hour Sleep-Wake Disorder

Treatment of irregular sleep-wake cycle and non-24-hour sleep-wake cycle depends on whether a person has light perception. It mainly entails consolidating

TABLE 21.8 Circadian Rhythm Disorders

Treatment Modality	*Key Elements*	*Type of Disorder Addressed*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Light therapy	Timed light exposure can shift circadian phase and increase objectively determined alertness. Exposure to bright light at the wrong circadian time can perpetuate or exacerbate changes in sleep-wake period.	Best evidence in delayed sleep phase syndrome but may be considered as an option in other circadian rhythm disorders	Cohort, case control studies, and case series	Type 2, 3, 4 studies	Morgenthaler et al., 2007b Wilhelmsen-Langeland et al., 2013
Melatonin	Important modulator of circadian rhythms. In addition to phase-resetting properties, evidence supports role in sleep modulation by increasing evening sleep propensity and reducing core body temperature.	Shift work, jet lag. Effective for entraining circadian rhythms in blind people with free-running sleep-wake cycles.	RCTs, cohort and case control studies	Type 2 & 3 studies	Morgenthaler et al., 2007b Wilhelmsen-Langeland et al., 2013 Weingarten & Collop, 2013 Cajochen, Kräuchi, & Wirz-Justice, 2003 Herxheimer & Petrie, 2001
Hypnotics	Can increase duration of daytime sleep but have not shown to improve alertness in early morning hours during shift work	Jet lag, shift work	RCTs, cohort and case control studies	Type 2 & 3 studies	Morgenthaler et al., 2007b Buxton, Copinschi, van Onderbergen, Karrison, & van Cauter, 2000 Walsh, Sugerman, Muehlbach, & Schweitzer, 1988
Chronotherapy	Successful delay of sleep times by 3 hours daily over a 5- to 6-day period until the desired sleep time is achieved. Followed by rigid adherence to a set sleep-wake schedule and good sleep hygiene practices. Light exposure at wrong time may limit effectiveness and practicality.	Delayed, advanced sleep phase disorders	Based on case reports and committee consensus	Type 3, 5, 6 studies	Morgenthaler et al., 2007b Singh, Sharma, & Malviya, 2012d
Stimulants	Modafinil and caffeine counter sleepiness and improve performance during night shift compared to placebo.	Shift Work Disorder (SWD), jet lag	Based on RCTs	Type 1, 2, 3 studies	Sack et al., 2007 Darwish, Bond, & Ezzet, 2012 Czeisler et al., 2005 Ker, Edwards, Felix, Blackhall, & Roberts, 2010

the sleep period. Melatonin, increased social cues, and bright light immediately after awakening are options for sighted individuals or blind people with intact retino-hypothalamic pathways. In blind individuals without light perception, lack of entrainment from environmental light cues is the main problem. Exogenous melatonin at a fixed time every day (dose range 0.3 to 10 mg approximately 1 hour before the desired bedtime) can help entrainment (Hack, Lockley, Arendt, & Skene, 2003). Tasimelteon, a melatonin receptor agonist, has recently been approved by the FDA, based on two trials, for the treatment of non-24-hour sleep-wake disorder in blind individuals.

Shift Work Disorder

The treatment of shift work disorder—specifically overnight shift work—includes interventions to (1) decrease sleep pressure at night (scheduled naps or hypnotics before daytime sleep), (2) increase alertness using caffeine or stimulants at the beginning of the work shift, and/or (3) minimize bright light exposure at the end of the work shift by wearing dark glasses while traveling home from work and using blackout curtains to make the bedroom as permissive for sleep as possible (Morgenthaler et al., 2007b). Bright light during the first half of the night shift may also help to delay circadian rhythms and improve shift work adaptation.

Modafinil and armodafinil are both FDA approved for use in shift workers with excessive sleepiness during work hours (Czeisler et al., 2005). On days off, night-shift workers may have regular daytime social or family responsibilities and often revert to nocturnal sleep hours. An experimental paradigm of "compromise phase position" has been promising wherein the individual goes to bed slightly earlier and does not completely invert his or her schedule on days off (Smith et al., 2009).

Jet Lag Disorder

The basic strategy for treatment includes symptom management and realigning circadian clock to the new time zone as soon as possible. American Academy of Sleep Medicine practice parameters consider timed melatonin administration as a "standard" and timed and dosed bright light as a treatment "option" for jet lag disorder. While traveling east, treatment should be started before travel. This involves gradually moving the sleep period before travel by 1 hour earlier each day and having the patient exposed to at least 1 hour of bright light in the morning. After arrival at the destination, light should be avoided in the morning, followed by exposure to high levels of light in the afternoon. Exogenous melatonin should be taken 5 hours before habitual bedtime. Hypnotics can be used at bedtime if needed at the destination. While traveling west, treatment should be started at the destination. Morning bright light should be avoided and light exposure in the evening should be maximized. Hypnotics can be taken at bedtime if needed. Good sleep hygiene and a 30-minute nap during the day are a helpful adjuncts in cases of both east and west travel.

Combination therapy with somatic and behavioral interventions, including a regular sleep schedule and good sleep hygiene, is usually beneficial for all circadian rhythm sleep-wake disorders.

PARASOMNIAS

According to *DSM-5*, the parasomnias include sleep disorders with undesirable physical events or experiences that occur at entry into sleep, during sleep, or during arousals from sleep. They include NREM sleep arousal disorders, nightmare disorders, and REM sleep behavior disorder. Many of them are benign, especially during childhood, but they can cause physical harm and poor health due to sleep disruption.

NREM Sleep Arousal Disorders

Overview and Diagnosis

NREM sleep arousal disorders include parasomnias that occur from arousals during NREM sleep, most often sleep stage N3 or slow-wave sleep. They include confusional arousals, sleep terrors, and sleepwalking. Other specific behaviors may include sleep-related eating disorder and sleep-related sexual activity. *DSM-5* defines three specific ones—NREM parasomnias, sleepwalking, and sleep terrors. Recurrent episodes of partial arousals from sleep occur usually during the first third of the night, when NREM sleep is deepest. There is typically minimal or no recall of the event, with minimal or no dream imagery.

TABLE 21.9 Nightmare Disorder

Treatment Modality	*Key Elements*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Nonpharmacological	Trauma-focused cognitive-behavioral therapy, including imagery rehearsal technique; lucid dreaming therapy; sleep dynamic therapy; relaxation; and rescripting therapy and self-exposure therapy	Based on case series and case studies. Some case control studies.	Type 3 and 6 studies	Bisson, Roberts, Andrew, Cooper, & Lewis, 2013 Bisson & Andrew, 2007 Germain, Buysse, & Nofzinger, 2008 Augedal et al., 2013
Prazosin	For nightmares associated with post-traumatic stress disorder. Postural hypotension.	Based on 3 RCT/placebo-controlled studies and some case series. Found to be moderate to strongly beneficial.	Type 2 and 3 studies	Augedal et al., 2013 Hudson, Whiteside, Lorenz, & Wargo, 2012 Aurora et al., 2010b Taylor, Freeman, & Cates, 2008
Clonidine	Nightmares associated with posttraumatic stress disorder	No RCTs. Paucity of hard data.	Type 3 studies	Alao, Selvarajah, & Razi, 2012 Aurora et al., 2010b

Sleepwalking is characterized by repeated episodes of rising from bed and walking about during sleep. During the episodes, the individual has reduced alertness and responsiveness, blank stare, and absent communication with others. There is relative unresponsiveness to efforts by others to awaken the individual, and if awakened he or she has limited recall of the episode.

Sleep terrors include repeated sudden awakenings from sleep, usually with a scream or cry. Excessive autonomic arousal and behavioral manifestations of intense fear occur. The individual is difficult to awaken or difficult to comfort during the episode. Sleep terrors are also called "night terrors" or "pavor nocturnus."

Confusional arousals are not specifically included in a part of *DSM*-5 but are considered to be related to other NREM parasomnias. Confusional arousals are brief, incomplete arousals that start in N3 sleep. During episodes, the individual usually does not leave the bed. Primary sleep disorders such as sleep apnea or periodic limb movement disorders can aggravate these conditions.

Sleep-related eating disorder is classified as a subtype of sleepwalking in *DSM*-5. It involves partial arousals from sleep in which the patient involuntarily eats and drinks. It can occur in isolation or comorbidly with restless legs syndrome, periodic limb movements, and sleep-related breathing disorders (Howell, Schenck, & Crow, 2009).

Sleep-related sexual behavior ("sexsomnia") is also classified as a subtype of sleepwalking in *DSM*-5. It consists of inappropriate sexual behaviors during sleep without conscious awareness and may have medicolegal implications. This may result in feelings of shame or guilt leading to depression (Schenck, Arnulf, & Mahowald, 2007).

Management

Treatment of NREM parasomnias is directed at reducing symptoms of self-harm or harm to others based on the frequency of events (Mahowald & Cramer Bornemann, 2005).

Somatic Treatment

Clonazepam (0.5 to 1 mg) has been successful in the long-term management of parasomnias. If the disorder is limited to the first half of the sleep period, short-acting benzodiazepine receptor agonists such as triazolam or zolpidem have been used. Dopaminergic agents, opiates, and topiramate have been used and found to be effective in sleep-related eating disorder. If nonpharmacological treatment is not enough to manage symptoms, use of pharmacotherapy may be helpful in the treatment of sleepwalking (Schenck & Mahowald, 2000, 2002).

Psychosocial and Behavioral Treatments

Reassurance about the benign nature of childhood NREM parasomnias, especially in episodic cases, is usually sufficient. For more severe episodes, nonpharmacological treatments have been found to be helpful in children. These include maintaining a regular sleep-wake schedule and reducing sleep pressure by avoiding sleep deprivation. For sleepwalking, ensuring a safe sleeping environment is crucial to management, which would include safety locks on doors. NREM parasomnia episodes may be triggered by sleep disruption due to obstructive sleep apnea or periodic limb movement disorder. These cases may benefit from treatment of the primary sleep disorder (Schenck & Mahowald, 2010).

Nightmare Disorder and REM Sleep Behavior Disorder

Overview and Diagnosis

REM sleep is characterized by increased physiological activation, atonia of muscles, and dreams or active mentation. The most common parasomnias occurring during REM sleep are REM sleep behavior disorder and nightmare disorder. REM sleep behavior disorder is characterized by loss of normal muscle tone along with dream enactment (often violent). According to *DSM-5*, the presence of atonia during REM sleep on a polysomnogram or a history suggestive of REM sleep behavior disorder, along with a diagnosis of alpha synucleinopathy (e.g., Parkinson's disease), can be used to diagnose REM sleep behavior disorder.

Nightmare disorder is characterized by recurrent disturbing dreams during REM sleep, often resulting in awakening, distress, and impairment of daytime function.

Management

Treatment of REM parasomnias is directed at reducing symptoms of self-harm or harm to others based on the frequency and bothersome nature of events. Table 21.10 lists treatment options for REM behavior disorder.

TABLE 21.10 REM Parasomnia—REM Sleep Behavior Disorder

Treatment Modality	*Key Elements*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Clonazepam	Long-acting benzodiazepine. May preferentially control phasic locomotor activity at the brain stem level without restoring atonia via a serotonergic effect. May also modify dream content in REM sleep behavior disorder.	Based on case series and case reports	Type 3 and 5 studies	Aurora et al., 2010c Fantini & Ferini-Strambi, 2012
Melatonin	Studies show success in patients with synucleonopathies, memory problems and sleep-disordered breathing. Decreased episodes of REM sleep without atonia and movement time in REM, as opposed to studies with clonazepam.	Evidence less strong than for clonazepam. Based on clinical consensus. Case series with very few subjects.	Type 2, 3, 6 studies	Aurora et al., 2010c Kunz & Mahlberg, 2010 Anderson & Shneerson, 2009 Boeve, Silber, & Ferman, 2003
Nonpharmacological	Injury-prevention techniques. Modifying sleep environment has best evidence for treatment of REM sleep behavior disorder.	Consensus-based recommendation by American Academy of Sleep Medicine	Type 6 studies	Aurora et al., 2010c Schenck, Lee, Bornemann, & Mahowald, 2009
Dopamine agonist—pramipexole	PET and SPECT scans have suggested dysfunction of dopaminergic nigrostriatal system, due to which dopamine agonists have been considered.	Efficacy studies have shown contradictory results.	Type 3 and 6 studies	Aurora et al., 2010c Sasai, Inoue, & Matsuura, 2012 Schmidt, Koshal, & Schmidt, 2006

REM Sleep Behavior Disorder

Benzodiazepine receptor agonists are the first-line treatment of REM sleep behavior disorder. Clonazepam (0.5 to 1 mg) is the most commonly used medication. Not only does it reduce the frequency of events, but it may also modify dream content in REM sleep behavior disorder. Melatonin and pramipexole have also been used with some success (Aurora et al., 2010c). Ensuring the safety of the sleep environment for the patient and his or her bed partner is an essential adjunct to treatment. Medication-induced cases usually resolve after discontinuing the offending agent (Mahowald & Schenck, 2005).

Nightmare Disorder

Prazosin has been shown to be effective in RCTs for treatment of nightmare disorder associated with posttraumatic stress disorder (Cukor, Spitalnick, Difede, Rizzo, & Rothbaum, 2009). Medications, including benzodiazepines and sedating antidepressants such as trazodone, are used to treat nightmares, but little empirical evidence supports their efficacy. Dream rehearsal therapy is useful for recurrent nightmares. This treatment involves scripting and rehearsing a new dream scenario to replace the common, distressing dreams (Augedal, Hansen, Kronhaug, Harvey, & Pallesen, 2013). Table 21.9 summarizes some treatment modalities for nightmare disorder.

RESTLESS LEGS SYNDROME

Overview and Diagnosis

Restless legs syndrome is a sensorimotor neurological disorder causing uncomfortable sensations in the leg that are described by patients as aching, burning, tingling, creeping, crawling, or "pins and needles" (Kerr, McKinon, & Bentley, 2012). *DSM-5* describes restless legs syndrome as an urge to move the legs that worsens during rest and in the evenings and is relieved by moving around. There may be associated repetitive leg jerks at night during sleep, which are called periodic limb movements (Rye & Trotti, 2012). These limb movements are characterized by rhythmic, repetitive stereotypic dorsiflexion/extension of the big toe, dorsiflexion at the ankle, and sometimes flexion at the knee and hip joints. For the leg movements to be counted as periodic limb movements, they must be 0.5 to 10 seconds in duration and have an amplitude greater than 8 μV above the resting baseline anterior tibial electromyogram level on a polysomnogram. The periodic limb movement index is defined as the number of these movements per hour of sleep. An index above 15 in adults and above 5 in children is considered diagnostic for periodic limb movement disorder in the ICSD-2 (International Classification of Sleep Disorders-2) diagnostic and coding manual.

Improvements in restless legs syndrome and periodic limb movement disorder seen with L-dopa and dopamine agonists support the hypothesis that dopamine may be involved in the pathophysiology of these disorders (Cervenka et al., 2006). Restless legs syndrome may be idiopathic (primary) or secondary. Those with an affected first-degree relative commonly have primary restless legs syndrome. Secondary causes include renal failure, pregnancy, iron deficiency, and medications. Iron is an important co-factor in the dopamine synthesis pathway. It is also necessary for intracellular mitochondrial function in dopamine-producing neurons (Yeh, Walters, & Tsuang, 2012).

Management

The goals of treatment of restless legs are to improve symptoms that result in disturbances in sleep onset or sleep maintenance, causing sleep disruption and daytime sleepiness. Treatment options are outlined in Table 21.11.

Somatic Treatment

Evaluation and treatment of reversible causes should be first attempted. A serum ferritin level less than 50 mcg/dL should be treated with iron replacement therapy. Vitamin B_{12}, folate, vitamin D, and magnesium deficiency should also be treated (Cuellar, Hanlon, & Ratcliffe, 2011).

Dopamine agonists, including pramipexole and ropinirole, are considered as first-line therapy and have been tested in controlled trials for treatment of restless legs syndrome. The most common side effects are sleepiness, nausea, and hypotension. They may be associated infrequently with compulsive gambling, spending, or sexual behavior. Rotigotine is a non-ergot dopamine receptor agonist available in a transdermal patch form (Bogan, 2014).

TABLE 21.11 Restless Legs Syndrome

Treatment Modality	*Key Elements*	*Side Effects*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Dopamine agonist—pramipexole, ropinirole	First line	Nausea, orthostatic hypotension, daytime fatigue and somnolence, compulsive or impulsive behavior, tolerance and augmentation	Based on double-blind placebo-controlled studies with long-term follow-up studies showing sustained efficacy	Type 1 & 2 studies	Aurora et al., 2012 Manconi et al., 2011 Scholz, Trenkwalder, Kohnen, Riemann, Kriston, & Hornyak, 2011a Varga et al., 2009 Zintzaras et al., 2010
Dopamine precursors (e.g., L-dopa/carbidopa)	Quick onset and short duration of action due to higher rebound	Morning rebound or augmentation in early evening, daytime somnolence	Open-label placebo-controlled studies	Type 3, 5, 6 studies	Bassetti et al., 2011 Scholz, Trenkwalder, Kohnen, Riemann, Kriston, & Hornyak, 2011b Trenkwalder et al., 2008
Opiates	Useful in severe cases, when patients are unresponsive to other agents. Useful during withdrawal from dopamine agonist after severe augmentation.	Constipation, dependence, respiratory depression at high doses. Use with caution in patients who snore and have sleep apnea.	Several open-label and controlled clinical trial	Type 2, 3, 5 studies	Walters, 2013
Benzodiazepine rector agonists	Used to improve quality of sleep and reduce periodic leg movements associated with arousals. Improves sleep continuity.	Sedation, ataxia, anterograde amnesia, sleepwalking, sleep violence or sleep-related eating disorders, respiratory depression. Rebound insomnia, tolerance, and abuse may occur.	Based on placebo-controlled crossover studies and case series	Type 2 and 6	Shinno et al., 2010 Facheris, Hicks, Pramstaller, & Pichler, 2010 Saletu et al., 2001
Anticonvulsants—Neurontin	More potent and fewer side effects than dopaminergic agonists. Useful in neuropathic restless leg syndrome.	Daytime fatigue and somnolence	Open-label and one placebo-controlled study	Type 1, 2, 6 studies	Burke & Faulkner, 2012 Yaltho & Ondo, 2010 Hayes, Lemon, & Farver, 2012 Lee et al., 2011

(*continued*)

TABLE 21.11 (continued)

Treatment Modality	*Key Elements*	*Side Effects*	*Evidence for Efficacy*	*Evidence Grade*	*Key References*
Iron supplementation	Iron deficiency and conditions involving iron deficiency such as end-stage renal disease, pregnancy, gastric surgery have been associated with secondary restless legs syndrome. Iron deficiency in substantia nigra may be associated with abnormal regulation of transferrin receptor. Most clinicians recommend achieving a ferritin level of >45 to 50 mcg/mL.	Constipation, nausea, gastrointestinal upset, dark stools	Based on RCTs	Type 1–3 studies	Hornyak et al., 2014 Mohri et al., 2012 Trotti, Bhadriraju, & Becker, 2012 .
Nonpharmacological	Good sleep hygiene; avoid alcohol use; stretching exercises and leg massages	NA	NA	Type 3 and 6 studies	Hornyak et al., 2014 Aurora et al., 2012 Romenets & Postuma, 2013

Levodopa/carbidopa is a dopaminergic medication that can also decrease restless legs syndrome symptoms and periodic limb movements. Augmentation and rebound effects are common with these medications. Augmentation is the tendency for symptoms to develop earlier in the day or to become more severe than prior to treatment and is usually treated by switching to a dopamine agonist (Cuellar et al., 2011; Romenets & Postuma, 2013; Silber, Becker, Earley, Garcia-Borreguero, & Ondo, 2013; Wilt et al., 2013).

Other medications include benzodiazepines, which can decrease arousals but do not decrease the number of movements, and opioids, which are also used for some treatment-resistant cases. Anticonvulsants such as gabapentin and carbamazepine can also be considered. Gabapentin may be useful in cases of restless legs associated with painful sensations (Silber et al., 2013).

Psychosocial and Behavioral Treatments

Nonpharmacological treatments that have been helpful include stretching exercises, massage, and hot baths. Avoiding tobacco, alcohol, caffeine, and antihistamines can also help decrease symptoms. If restless legs syndrome occurs during treatment with a selective serotonin reuptake inhibitor, switching to a different class of medication may be helpful (Hening, Buchfuhrer, & Lee, 2007).

SUMMARY

Treatment of sleep disorders can be initiated in most cases by non-sleep specialists. A significant number of patients seen in psychiatry clinics experience sleep disturbances. Most patients with insomnia can be treated by psychiatrists, especially given the coexistence of psychiatric disorders and insomnia. The close relationship that psychiatrists have with their patients provides an understanding of the biopsychosocial context in which their patients live, something that is undoubtedly important in successful treatment of sleep disorders. Referral to sleep specialists should be considered when there is evidence of coexisting multiple sleep disorders or when insomnia is complicated by evidence of other sleep disorders, such as sleep apnea or narcolepsy. Patients who do not respond to brief behavioral interventions or who fail to respond to conventional management options may also be good candidates for referral.

Pharmacotherapy and Psychotherapy for Sexual Dysfunctions

R. Taylor Segraves

Well-controlled, double-blind, multisite (type 1) investigations have demonstrated that phosphodiesterase type 5 (PDE5) inhibitors are efficacious for the treatment of erectile problems of mixed etiologies and that serotonergic antidepressants delay ejaculation in men with premature ejaculation. Similarly, studies have demonstrated the efficacy of transdermal testosterone therapy in restoring sexual function in women after oophorectomy. Both type 1 and type 2 studies have produced suggestive evidence of the efficacy of cognitive-behavioral therapy (CBT) in the treatment of sexual dysfunction in both sexes, although the number and the methodological rigor of such studies are limited and the effect sizes tend to be smaller than studies of pharmacological therapies. There is minimal evidence concerning when pharmacological, as opposed to psychological, therapies should be employed, or when combined psychotherapy and pharmacotherapy is indicated. Major changes have been made in the definitions of sexual dysfunctions and their criteria sets in *DSM*-5. Existing data concerning the efficacy of both psychological therapies and pharmacotherapy may not extend fully to the sexual dysfunctions as defined in *DSM*-5.

INTRODUCTION

Most contemporary clinicians conceptualize sexual function as being influenced by biological, psychological, and cultural factors. Many cases of sexual dysfunction are precipitated and maintained by a combination of psychological and biological factors. The response to pharmacotherapy may itself be influenced by psychological factors. Even when the sexual dysfunction has predominantly biogenic origins, the existence of the problem may then produce psychological and interpersonal consequences that then complicate treatment.

Unfortunately, research concerning biological therapies has occurred relatively independently from research concerning psychotherapy of the sexual disorders. Research on biological therapies has tended to focus primarily on the target symptom, whereas psychotherapy tends to have a broader focus. Much of the current research concerns idiopathic sexual dysfunction in heterogeneous patient populations in which it is difficult to ascertain the relative contribution of biological and psychological factors. Thus, it is often unclear how much one can generalize from the published data to a given patient. Knowing the relative contribution of etiological factors is important since one would expect the benefits of psychotherapy to be less in cases that are primarily biological in etiology. One also would expect that the type of psychotherapy indicated in cases of predominantly biological etiology would be different in content from therapy designed to treat psychogenic sexual dysfunction. Since much of the current research is on heterogeneous or poorly defined populations, it is difficult to ascertain which type of intervention should be primary or when different interventions should be combined.

The current diagnostic systems may be partially responsible. The *DSM-IV-TR* was criticized for being

imprecise and not clearly differentiating transient variations in sexual functions in response to the vicissitudes of relationships from more enduring sexual difficulties. The *DSM-5* represents a marked departure from *DSM-IV-TR* and contains clear duration and severity criteria for sexual dysfunction. In addition, the *DSM-5* clearly specifies that a diagnosis of sexual dysfunction should not be made if the problem is secondary to relationship discord or life stress. It is hoped that these more precise criteria will facilitate research that will more clearly delineate the indications and advantages of different types of therapeutic interventions.

HISTORICAL OVERVIEW OF THERAPY FOR SEXUAL PROBLEMS

Historically, the treatment of sexual dysfunctions can be divided into five eras: the psychoanalytic, the early behavioral, the Masters and Johnson, the neo–Masters and Johnson, and the current psychobiological. Prior to 1970, psychoanalytic concepts guided clinicians in their understanding and treatment of sexual problems. Sexual symptomatology was linked to discrete, unresolved, unconscious conflicts that occurred during specific developmental periods. Sexual symptoms were traced to designated constellations of conflict occurring in early childhood (Meyer, 1976). In a classical analysis, patients were seen three to five times weekly over the course of several years. Freud's revolutionary method employed free association, dream analysis, interpretation of unconscious motives, and the recapitulation of significant emotional attachments through the transference. Because of the focus on individual intrapsychic dynamics, couples treatment was rarely undertaken. The analytic literature was replete with elegant, richly detailed descriptions of individual case histories and analysis. By contemporary standards, these often fascinating reports qualify only as untested case formulations.

In the late 1950s, behavioral therapists described promising results from treating sexual disorders by using of symptom-oriented direct treatment approaches (Brady, 1966; Cooper, 1969; Haslam, 1965; Lazarus, 1963; Wolpe, 1958). These interventions were loosely modeled on classical conditioning paradigms and assumed that the dysfunction was a learned (conditioned) anxiety response. The guiding principle of behavior therapy (LoPiccolo & LoPiccolo, 1978; Marks, 1981; Obler, 1973) was to extinguish the anxiety or performance demands that interfered with normal sexual function. The most common behavioral technique, systematic desensitization, paired relaxation with a series of carefully designed, hierarchical, anxiety-provoking sexual situations, in vivo or by imagery. Like psychoanalysis, behavior therapy concentrated on individual psychotherapy and tended to ignore the dynamics of relationships. These studies, while more rigorously documented than the analytic reports, had minimal influence on clinical practice.

In 1970, Masters and Johnson published the results of a study of 790 cases employing a blend of intense daily individual and couples psychotherapy for two weeks. The ingredients of their treatment model consisted of physical examination, history taking, education, prescription of behavioral tasks, and counseling for interpersonal issues that interfered with natural sexual function. Their treatment was based on two fundamental postulates: (a) the primacy of psychogenic factors, particularly learning deficits and performance anxiety in the etiology and maintenance of sexual dysfunctions, and (b) the amenability of most sexual disorders to a brief problem-focused treatment approach (Rosen & Leiblum, 1995). Masters and Johnson's most important contribution was the emphasis given to the deleterious effects of performance anxiety and their prescription of sensate focus exercises to alleviate this troubling state. Performance anxiety, the fear of future sexual failure based on a previous failure, is a universal experience that appears in all sexual dysfunctions. Masters and Johnson provided clear descriptions of their treatment method and reported initial and 5-year-posttreatment "failure rates" for lifelong and acquired arousal, orgasm, and pain disorders. Their work revolutionized the treatment of sexual problems and generated great enthusiasm among clinicians for their novel short-term, directive treatment methods.

By present-day standards, Masters and Johnson's outcome data can be criticized on multiple grounds, for not (a) using standardized, valid, and reliable assessment measures; (b) specifying the basis for classifying cases as successes or failures; (c) employing control, waitlist, or placebo groups; and (d) blinding the investigators to the experimental conditions. In addition, it was questionable whether their results applied to typical patient populations because they studied affluent, well-educated, and highly motivated

patients. These vital concerns linger because later researchers have been unable to replicate the magnitude of the positive outcomes achieved by Masters and Johnson (Heiman & LoPiccolo, 1983; Rosen & Beck, 1988; Wright, Perreault, & Mathieu, 1977; Zilbergeld & Evans, 1980). Nonetheless, their reports revolutionized the treatment of sexual problems and generated great enthusiasm among clinicians for their treatment method.

The neo–Masters and Johnson era was heralded by the publication of Helen Singer Kaplan's widely acclaimed book *The New Sex Therapy* (1974). As a discipline, sex therapy had come of age. Kaplan integrated modifications of Masters and Johnson's treatment methods with behavioral and analytic interventions. She treated couples by addressing both partners' intrapsychic and interpersonal contributions to the initiation and maintenance of the dysfunction. She distinguished between recent and remote etiological causation, recommending direct treatment approaches for the former while reserving traditional psychodynamic methods for the latter. The more commonly seen recent etiological causes were relationship deterioration, performance anxiety, widowhood, health concerns, and aging. Examples of remote influences included pre-Oedipal separation-individuation conflicts, unresolved Oedipal struggles, paraphiliac scripts, gender identity conflicts, and adolescent masturbatory guilt. Kaplan's prolific writings did not include outcome statistics on the follow-up of her suggested treatment interventions.

Treatments for sexual dysfunction proliferated and evolved into blends of psychodynamic, behavioral, and cognitive therapies using individual, couples, and group formats (Althof, 1989; Gagnon, Rosen, & Leiblum, 1982; Leiblum, Rosen, & Pierce, 1976; Levine, 1992; McCarthy & McCarthy, 1984; Rosen & Leiblum, 1989; Scharf, 1985; Zilbergeld, 1992). As the field matured, clinical investigators began to develop more sophisticated methodologies that included control groups, placebo treatments, randomization of experimental conditions, and standardized, valid, and reliable questionnaires. However, the majority of these research reports lacked long-term follow-up.

The middle 1980s ushered in the current psychobiological era. Sophisticated studies with adequate long-term follow-up describing the efficacy and psychological impact of oral agents, intracavernosal injection, vacuum tumescence therapy, and treatment of rapid ejaculation by serotonin reuptake inhibitors began to appear in the literature (Althof, 1995a, 1995b; Althof et al., 1995; Assalian, 1988; Barada & McKimmy, 1994; Goldstein et al., 1998; Segraves, Saran, Segraves, & Maguire, 1993). These studies turned the tide toward the blending of medical and psychological treatments for male sexual dysfunction.

In March 1998, sildenafil citrate received approval by the U.S. Food and Drug Administration (FDA) for the treatment of erectile dysfunction (ED; Goldstein et al., 1998). Since its release, countless prescriptions have been written, making it one of the most prescribed medications in the United States. Subsequently, vardenafil, tadalafil, and avanafil were also approved as PDE5 inhibitors for the treatment of ED (Goldstein et al., 2012; Wylie & MacInnes, 2005). The PDE5 inhibitors transformed the treatment and research landscape. Because the oral erectogenic agents were safe and easily tolerated, the established principle of etiology guiding treatment became less meaningful. Prior to the introduction of these treatments, men diagnosed with psychogenic ED were treated by mental health professionals and those with organic dysfunction were seen primarily by urologists. After the introduction of the oral erectogenic drugs, much of the care of such patients shifted to primary care physicians. These therapies altered the traditional role of the mental health professional, which had been to (a) assess the etiology of ED, (b) offer psychotherapy to men or couples with primarily psychological dysfunction, and/or (c) treat the conspicuous psychological sequelae of organic conditions (Althof & Seftel, 1995; Levine, 1992). Once these new pharmacological interventions became available, the clinician's role was shifted to include identification and attenuation of the resistances to medical treatments for ED.

Dapoxetine, a serotonin reuptake inhibitor, has been approved in many countries for the treatment of premature ejaculation (Hoy & Scott, 2012; McMahon, 2012). As a result, treatment of premature ejaculation has become predominantly pharmacological in the past decade.

Since 1999, the medicalization of sexual dysfunction has also begun to influence treatments for female sexual dysfunction. There have been studies of sildenafil for female sexual arousal disorder, testosterone patches to enhance sexual desire, and the introduction of clitoral erection devices, gels, and

homeopathic remedies as well (Berman, Shuker, & Goldstein, 1999). Although there was minimal evidence supporting a role for sildenafil in treating sexual arousal disorders (Laan, Everaerd, & Both, 2005), numerous studies found that exogenous testosterone increased libido in women with a decrease in libido after bilateral oophorectomy (Basson et al., 2004; Buster et al., 2005; Shifren et al., 2000; Utian, Braunstein, Buster, Lucas, & Simon, 2004). Use of testosterone therapy has been approved for the treatment of sexual problems in surgically menopausal women in some European countries, and considerable off-label use of testosterone occurs worldwide (Fooladi & Davis, 2012).

NOSOLOGY

Knowledge concerning the treatment of sexual dysfunctions and interest in this area of psychobiology has grown significantly in the past 20 to 30 years. The recent emergence of this field can be appreciated by realizing that the first two *DSM* editions (American Psychiatric Association [APA], 1952, 1968) did not contain diagnostic terms for the sexual dysfunctions. *DSM-III* (APA, 1980) provided a radical departure by including a section on sexual dysfunctions. These diagnoses and their criteria sets were based on the concept of a normal sexual response cycle for men and women (Schmidt, 1995) and were strongly influenced by the works of Masters and Johnson (1966) and Helen Singer Kaplan (1974). *DSM-IV* was introduced in 1994 and added two new entities: sexual dysfunction due to a general medical condition and substance-induced sexual dysfunction. There were no significant changes to the sexual dysfunction criteria in *DSM-IV-TR* (2000). Changes in nomenclature for the psychosexual dysfunctions in the different *DSM* versions are listed in Box 22.1.

Sexual dysfunctions listed in *DSM-IV* included male hypoactive sexual desire disorder (HSDD), ED, premature (early) ejaculation, delayed ejaculation, genito-pelvic pain/penetration disorder (GPPD; new to this edition), female sexual interest/arousal disorder (new to this edition), female orgasmic disorder, and substance/medication-induced sexual dysfunction. Five *DSM-IV-TR* diagnoses were deleted in *DSM-5*: sexual aversion disorder, female arousal disorder, dyspareunia, vaginismus, and sexual dysfunction secondary to a general medical condition. There were also some name changes: Male orgasmic disorder became delayed ejaculation and premature ejaculation became premature (early) ejaculation. In *DSM-IV-TR*, HSDD and dyspareunia applied to both sexes. *DSM-5* retained male HSDD, but features of female HSDD are now classified in a new entity, female sexual interest/arousal disorder. In *DSM-5*, features of dyspareunia and vaginismus are classified as GPPD. Dyspareunia in males no longer exists as a separate coding. Specific frequency and/or duration criteria are listed for all diagnoses except substance/medication-induced sexual dysfunction. A specific

BOX 22.1 Modifications in Sexual Disorders Nomenclature in the *Diagnostic and Statistical Manuals* of the American Psychiatric Association

1. *DSM-I* was published in 1952 and did not contain diagnostic terms for the psychosexual dysfunctions.
2. *DSM-II* was published in 1968. The only diagnostic entity pertaining to psychosexual disorders was psychophysiological genitourinary disorders, which referred to disorders of micturition, menstruation, and sexual function.
3. *DSM-III* was published in 1980. It included diagnoses for the psychosexual disorders. The term *homosexuality* was deleted and the term *ego dystonic homosexuality* was added as a diagnostic entity. The term *inhibited sexual excitement* referred to both male erectile disorder and female arousal disorder.
4. *DSM-III-R* was published in 1987. The term *sexual aversion disorder* was added. The term *ego dystonic homosexuality* was deleted. The use of the term *inhibited* in diagnostic entities was deleted. The term *inhibited sexual excitement* was changed to *male erectile disorder* and *female arousal disorder*.
5. *DSM-IV* was published in 1994. Subjective criteria were dropped from definitions of male erectile disorder and female arousal disorder. The terms *sexual disorder secondary to a general medical condition* and *substance-induced sexual disorder* were added.
6. *DSM-IV-TR* was published in 2000. Sexual dysfunction diagnoses were unchanged from *DSM-IV*.
7. *DSM-5* was published in 2013. Sexual disorder secondary to a general medical disorder, sexual aversion disorder, dyspareunia, vaginismus, female arousal disorder, and hypoactive sexual arousal disorder in females were deleted. Genito-pelvic pain/penetration disorder and female sexual interest/arousal disorder were added as new diagnostic categories. Specific duration and frequency criteria were added for most diagnostic categories.

time duration after vaginal penetration is specified for the diagnosis of premature (early) ejaculation. The diagnostic entities in *DSM-IV* are listed in Box 22.2, the additional specifications in *DSM-5* are listed in Box 22.3, and the major changes from *DSM-IV-TR* are listed in Box 22.4.

There have been a number of major changes in *DSM-5*. These changes are important to note as they may influence how much one can generalize from data using *DSM-IV-TR* diagnostic criteria to the new criteria. It is hoped that the new criteria will facilitate future clinical research by defining more homogenous groups. *DSM-IV-TR* criteria were criticized for being imprecise (Waldinger & Schweitzer, 2008), for not differentiating transient variations in sexual function from persistent sexual disorders meriting medical intervention (Segraves et al., 2007), and for assuming that female patterns of sexual response follow the same patterns as that of males (Basson, 2010). *DSM-5* represents a paradigm shift in that it recognizes that male sexuality and female sexuality are different and should be classified separately. For instance, in *DSM-5* male desire and arousal (erection) difficulties are classified as separate disorders, and the *DSM-5* diagnosis of female sexual interest/arousal disorder combines elements of sexual interest/desire with elements of subjective sexual arousal. Because of the high comorbidity of HSDD and female sexual arousal disorder as defined in *DSM-IV-TR* (Brotto, 2010; Graham, 2010), one assumes that research using *DSM-IV-TR* criteria will be largely applicable to the *DSM-5* category of sexual interest/arousal disorder. Studies at multiple centers have reported difficulties differentiating cases of vaginismus from dyspareunia (Binik, 2010a, 2010b). There is a new category, GPPD, in *DSM-5*. It is unclear whether data using the *DSM-IV-TR* criteria will be applicable to the new diagnostic entity. Another major change is the use of operational criteria to define premature ejaculation as an ejaculatory latency of approximately 1 minute or less. This definition is analogous to the definition adopted by the International Society of Sexual Medicine (McMahon et al., 2008). It is possible that the efficacy of various treatment approaches for premature ejaculation may vary depending on the length of the ejaculatory latency period.

The *DSM-5* criteria have been criticized on multiple grounds. The major focus of concern appears to be changes in criteria for sexual disorders in women. Some have questioned whether there are sufficient data to justify "merging" HSDD and female sexual arousal disorder within the new entity of female sexual/interest/arousal disorder (Clayton et al., 2012; Derogatis, 2010; Fabre & Smith, 2010). Others have raised similar concerns about the merger of dyspareunia and vaginismus into one entity, GPPD (Laan et al., 2010). There has also been criticism that there are insufficient data to warrant a criterion of 60 seconds or less for premature ejaculation (Jern, 2010; Rubio-Aurioles, 2010) and the duration and frequency criteria for ED (Eardley, 2010; Nelson, 2010). The *DSM-5* task force on sexual dysfunctions addressed these criticisms (Binik et al., 2010), suggesting that all changes to criterion sets were based on empirical findings.

EPIDEMIOLOGY

The largest study of the prevalence of sexual concerns in the United States, conducted by Laumann and colleagues (1999), is known as the National Health Social Life Survey. This survey was a probability sample of U.S. adults, aged 18 to 59. The sample consisted of 2,968 adults. All were interviewed face to face with a structured interview. Sexual problems were more prevalent among women than men. Among males, the most common problems were difficulty with orgasm (8.3%), lack of interest (15.8%), rapid ejaculation (28.8%), and erectile difficulties (9.8%). Erectile difficulties were positively correlated with age. Women complained of painful coitus (14.4%), lack of interest (33.4%), inability to reach orgasm (24.1%), and difficulty with lubrication (18.8%). Feldman and colleagues (1994) studied the epidemiology of ED and its medical and psychosocial correlates in a random sample of men aged 40 to 70 who lived in cities and towns near Boston. A self-administered sexual questionnaire was used. Approximately half of the population reported at least occasional problems with erections. The prevalence of erectile problems was highly correlated with age: Only 5% of men aged 40 reported total erectile failure as compared with 15% of men aged 70. Other variables associated with erectile failure were depressive symptoms, cigarette smoking, heart disease, and hypertension. A prospective study of the same sample found that the incidence of impotence was related to various cardiovascular risk factors, as well as a submissive personality (Araujo et al., 2000;

Premature (early) ejaculation

A. A persistent or recurrent pattern of ejaculation occurring during partnered sexual activity within approximately 1 minute following vaginal penetration and before the individual wishes it (Note: Although the diagnosis of premature (early) ejaculation may be applied to individuals engaged in non-vaginal sexual activities, specific duration criteria have not been established for these activities)
B. The symptom in Criterion A must have been present for at least 6 months and must be experienced on almost all or all (approximately 75–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts)

Genito-pelvic pain/penetration disorder

A. Persistent or recurrent difficulties with one or more of the following:
   1. Having vaginal intercourse/penetration
   2. Marked vulvovaginal or pelvic pain during vaginal intercourse
   3. Marked fear or anxiety either about vulvovaginal or pelvic pain in anticipation of, during, or as a result of vaginal penetration
   4. Marked tensing or tightening of the pelvic floor muscles during attempted vaginal penetration
B. The symptoms in criterion A have persisted for a minimum duration of approximately 6 months

Female orgasmic disorder

A. Presence of either of the following symptoms and experienced on almost all or all (approximately 75–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts):
   1. Marked delay in, marked infrequency, or absence of orgasm
   2. Markedly reduced intensity of orgasmic sensation
B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months

Female sexual interest/arousal disorder

A. Lack of, or significantly reduced, sexual interest/arousal, as manifested by at least three of the following:
   1. Absent/reduced interest in sexual activities
   2. Absent/reduced sexual/erotic thought or fantasies
   3. No/reduced initiation of sexual activity, and typically unresponsive to a partner's attempts to initiate
   4. Absent/reduced sexual excitement/pleasure during sexual activity on all or almost all (approximately 75–100%) sexual encounters (in identified situational contexts or, if generalized, in all contexts)
   5. Absent/reduced sexual interest/arousal in response to any internal or external sexual/erotic cues (e.g., written, verbal, visual, etc.)
   6. Absent/reduced genital and/or non-genital sensations during sexual activity on almost all or all (approximately 75–100%) sexual encounters (in identified situational contexts or, if generalized, in all contexts)
B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months

Erectile disorder

A. At least one of the three following symptoms must be experienced on almost all or all (approximately 75–100%) occasions of sexual activity (in identified situational contexts or, if generalized, in all contexts):
   1. Marked difficulty in obtaining an erection
   2. Marked difficulty in maintaining an erection until the completion of sexual activity
   3. Marked decrease in erectile rigidity
B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months

Delayed ejaculation

A. Either of the following symptoms must be experienced on almost all or all occasions(approximately 75–100%) of partnered sexual activity (in identified situational contexts or, if generalized, in all contexts), and without the individual desiring delay:
   1. Marked delay in ejaculation
   2. Marked infrequency or absence of ejaculation
B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months

(*continued*)

BOX 22.2 (continued)

Male hypoactive sexual desire disorder

A. Persistently or recurrently deficient (or absent) sexual/erotic thoughts or fantasies and desire for sexual activity. The judgment of deficiency is made by the clinician taking into account factors that affect sexual functioning, such as age and general and sociocultural context of the individual's life.
B. The symptoms in Criterion A have persisted for a minimum duration of approximately 6 months

Substance/medication-induced sexual dysfunction

A. A clinically significant disturbance in sexual function is predominant in the clinical picture
B. There is evidence from the history, physical examination, or laboratory finding of both (1) and (2)
   1. The symptoms in Criterion A developed during or soon after substance intoxication or withdrawal or after exposure to a medication
   2. The involved substance/medication is capable of producing the symptoms in Criterion A

Note: For all disorders except substance/medication-induced sexual dysfunction, Criterion C and D are as follows: Criterion C. The symptoms in Criteria A cause clinically significant distress in the individual; Criterion D. The sexual dysfunction is not better explained by a non-sexual mental disorder or as a consequence or severe relationship distress or other significant stressors, and is not attributable to the effects of substance/medication or another medical condition.

BOX 22.3 Additional Specifications in *DSM-5*

*Specify whether**:
Lifelong: the disturbance has been present since the individual became sexually active
Acquired: the disturbance began after a period of relatively normal sexual function

*Specify whether**:
Generalized: not limited to certain types of stimulation, situations, or partners
Situational: only occurs with certain types of stimulation, situations, or partners

*Specify current severity***

Mild: evidence of mild distress over the symptoms in Criterion A
Moderate: evidence of moderate distress over the symptoms in Criterion A
Severe: evidence of severe distress over the symptoms in Criterion A

*These specifications are required for all of the sexual dysfunctions except substance/medication-induced sexual dysfunction.

**Severity specification in not required for substance/medication-induced sexual dysfunction.

The severity specification for premature (early) ejaculation differs from that of the other sexual dysfunctions is as follows: (1) Mild: ejaculation occurring within approximately 30 seconds to 1 minute of vaginal penetration; (2) Moderate: ejaculation occurring within approximately 15–30 seconds of vaginal penetration; (3) Severe: ejaculation occurring prior to sexual activity, at the start of sexual activity, or within approximately 15 seconds of vaginal penetration.

Reprinted with permission from *The Diagnostic and Statistical Manual of Mental Disorders* (5th ed., Copyright 2013). American Psychiatric Association.

BOX 22.4 Changes in *DSM-5* from *DSM-IV-TR*

1. Requirement that each of the dysfunctions causes clinically significant distress in the individual
2. Requirement that most of the sexual disorders be present on 75% or more of occasions and have been present for approximately 6 months or longer
3. Specification of an intravaginal latency time criterion for premature ejaculation
4. Inclusion of severity ratings
4. Deletion of etiological specification (subtype)
4. Deletion of sexual aversion disorder, female arousal disorder, vaginismus, dyspareunia, and sexual dysfunction due to a general medical disorder
5. Male orgasmic disorder, premature ejaculation, and substance-induced sexual dysfunction diagnoses changed to delayed ejaculation, premature (early) ejaculation, and substance/medication-induced sexual dysfunction
6. Changed hypoactive sexual desire disorder to apply only to males
7. Addition of genito-pelvic pain/penetration disorder and female sexual interest/arousal disorder

Johannes et al., 2000). Pinnock, Stapleton, and Marshall (1999) used a mailed questionnaire to study the prevalence of erectile problems in a probability sample of men over 40 in South Australia. ED was correlated with age: Only 3% of men aged 40 to 49 reported erections insufficient for coitus, compared with 64% of men aged 70 to 79. Various cardiovascular risk factors were associated with the presence of ED. Similar studies of the prevalence of ED have taken place in Thailand, Malaysia, Japan, and Italy (Parazzini et al., 2000; Shirai et al., 1999). In these studies, increasing age and cardiovascular risk factors were associated with ED. Hawton, Gath, and Day (1994) studied a community sample of middle-aged women in the Oxford area in the United Kingdom. A semistructured interview was used. Questions concerned sexual and orgasm frequency. Marital adjustment was the main predictor of sexual activity and satisfaction. In this sample, 17% of participants stated that they experienced orgasm on all coital opportunities, 16% said they never experienced orgasm, and 29% said they experienced orgasm more than 50% of the time. Two percent said they never enjoyed coitus, whereas 41% said they always enjoyed coitus. Dunn, Croft, and Hackett (1999) sent an anonymous postal questionnaire to a stratified random sample of the adult general population in the United Kingdom. More women than men had sexual problems. The most common sexual problems in women were vaginal dryness and infrequent orgasm.

A global study of the prevalence of sexual disorders surveyed 27,500 subjects from 29 countries (Laumann et al., 2005). In women the most common difficulties were lack of interest (26% to 43%), inability to reach orgasm (18% to 41%), and difficulty with lubrication (31%). In men, the most common difficulties were rapid ejaculation (24%) and erectile problems (17%). Most difficulties were more prevalent in eastern and southeastern Asia than in other parts of the world. The significance of regional differences in prevalence proved difficult to determine because different response rates and inquiry techniques were used in different countries. Despite the high prevalence of sexual problems, it is interesting that less than 18% of subjects requested help with their difficulty, and only 9% reported being asked about sexual problems by their physicians (Moreira et al., 2005). A critical review of current epidemiological research concerning sexual difficulties was recently published (Lewis et al., 2010).

Although there have been numerous studies of the prevalence of sexual concerns, the true prevalence of sexual dysfunction as defined by the *DSM-IV-TR* and *DSM-5* is unclear. The prevalence of problems meeting diagnostic criteria is much less than the studies mentioned above. King and colleagues (2007) studied the prevalence of sexual dysfunction in consecutive attendees to general practices in London. Thirty-eight percent of women received an ICD-10 diagnosis of sexual dysfunction. However, only 18% of those so diagnosed agreed that they had a problem. Most women attributed their change in sexual responsiveness to relationship and emotional difficulties. Similarly, Dennerstein and colleagues (2008), in a prospective study of Australian women, found that most aspects of sexual function declined markedly during menopause transition; however, only a minority were significantly distressed by this change in sexual function. A probability sample of 11,161 British men and women aged 16 to 44 found that sexual problems lasting 1 month or less were far more common than those lasting at least 6 months (Mercer et al., 2003). For example, 40% of the women reported problems with lack of interest in sex the previous year; however, only 10% complained of this problem lasting at least 6 months. Similarly, 5.8% of the men complained of difficulty achieving an erection, but only 0.8% complained of erectile problems lasting 6 months. In the Global Study of Sexual Problems (Laumann et al., 2005), reports of frequent problems with sexual concerns were far less common than occasional problems. For example, approximately 13% of men in Northern Europe complained of erectile problems, but less than 3% indicated that this was a frequent problem. Similar differences in prevalence according to frequency of occurrence were reported for other sexual difficulties in differing regions of the world. Surveys have reported that 28% to 30% of men complain of premature ejaculation. Studies using time estimates have found that the prevalence of men with ejaculatory latencies of 1 minute or less is less than 3% (Park et al., 2010; Serefoglu et al., 2011; Waldinger et al., 2009).

Some sexual dysfunctions may be associated with other Axis I disorders. For example, mood disorder may be associated with an increased prevalence of HSDD and male ED (Kennedy et al., 1999; Thase et al., 1999). Euthymic patients with a current diagnosis of HSDD have an increased lifetime prevalence of mood disorder (Schreiner-Engel &

Schiavi, 1986). There are also reports of decreased libido being more common in patients with schizophrenia (Aizenberg et al., 1995), anorexia nervosa (Raboch & Faltus, 1991), and anxiety disorders (Minnen & Kampman, 2000). Erectile problems appear to be common in men with posttraumatic stress disorder (Congrove et al., 2002), and patients with obsessive-compulsive disorder have been found to have multiple sexual problems, including difficulty reaching orgasm (Fontelle et al., 2007) Comorbidity between anxiety disorders including social anxiety and premature ejaculation have been found (Corretti et al., 2006; Figueira et al., 2001). However, most cases of sexual dysfunction do not have a clear relationship to another Axis I disorder. There also is minimal evidence of a relationship between sexual dysfunction and personality disorder (Segraves, 1989). Personality traits of introversion, emotional instability, and not being open to new experiences have been found to be associated with decreased orgasmic capacity. Most clinicians assume that the immediate causes of sexual dysfunction involve anxiety about performance, a cycle of demand and negative expectancies, and self-defeating cognitions (Segraves, 1989).

WHAT CONSTITUTES A SUCCESSFUL INTERVENTION?

Human sexual behavior involves a complex interplay of individual, interpersonal, cultural, and biological factors. Typically, outcome studies of biological interventions, such as the use of PDE5 inhibitors for the treatment of ED, have focused on the restoration of genital function as the primary outcome measure. Patient satisfaction and effects on interpersonal interaction are also frequently assessed and, most often, restoration of genital function has had a positive influence on both individual and interpersonal psychological factors (Seftel et al., 2009). However, since genital function has personal and interpersonal symbolic significance, this is not always the case (Wise, 1999). There is increasing evidence that interventions that focus on psychological as well as biological factors have more favorable outcomes (Althof, 1995a).

Studies of psychological interventions are difficult to design and conduct. The challenge is to design methodologically sound studies that also reflect the complexity of individual variation and are acceptable to patients. For example, many patients may not agree to be in a waitlist control group, and for those who initially agreed to be in a waitlist control group, attrition may limit a meaningful comparison of treatment versus no treatment. In pharmacological studies, one can include a placebo treatment. In psychological interventions, the inclusion of a plausible placebo treatment is extremely difficult, as both the therapist and the patient will need to believe that it is a legitimate therapy. In psychological therapies, it is also difficult to control for therapist effects: The "same" therapy delivered by two different therapists may have different outcomes.

METHODOLOGICAL PROBLEMS IN SEX THERAPY OUTCOME STUDIES

Initial studies of outcomes of psychological treatment of sexual dysfunction were criticized because they had small sample sizes, did not use experimental control groups (waitlist, alternative treatment groups), lacked random allocation to treatment, failed to provide clear-cut criteria for admission into the study, lacked long-term follow-up, and inadequately described the intervention (Spence, 1991). Some of these criticisms apply to more recent studies.

Other problems with studies of psychological interventions include the possible contamination of the study population. This is apparent in early studies of the treatment of ED, in which men whose problems had organic etiologies were incorrectly diagnosed as having psychogenic ED. Clearly, psychological interventions alone were unlikely to benefit men whose erectile problems were caused by vascular disease. Thus, these outcome studies may have been biased in a negative direction. The same may be true of current studies of psychotherapy for other sexual disorders. For example, it is likely that some of the women currently being treated psychologically for desire/arousal problems have idiopathic disorders that may subsequently be found to have biological etiologies.

PSYCHOLOGICAL TREATMENTS OF SEXUAL DYSFUNCTION: GENERAL FORMULATIONS

Masters and Johnson (1970) introduced an intensive outpatient model of sex therapy involving daily combinations of individual and couple psychotherapy,

administered by a mixed-sex co-therapy team. Their treatment model was impractical in most settings. Subsequently, therapists modified the approach to involve weekly sessions and a single therapist. Early studies found that a single therapist had similar outcomes to a mixed-sex co-therapy team and that a therapist of the same sex as the patient was not required.

Subsequent research (Hawton, 1995) identified the following variables associated with positive outcomes from psychological interventions:

1. The quality of the couple's general relationship, particularly the female partner's general assessment of the relationship (Hawton & Catalan, 1986);
2. The motivation of the partners, particularly the male partner, for treatment (Hawton & Fagg, 1991; Stephenson Rellini, & Meston, 2013);
3. Absence of serious psychiatric disorder in either partner;
4. Physical attraction between the partners;
5. Early compliance with treatment program homework assignments.

Other research studied the efficacy of individual versus group psychotherapy approaches and found minimal evidence to support one approach over the other (Duterte et al., 2007). However, the vast majority of patients preferred individual or couple therapy and not group therapy.

A limited number of more recent studies have employed waitlist controls. Studies have also investigated combined psychological and pharmacological therapy and use of the Internet to deliver psychotherapy (Althof, 2010). Psychotherapy has shifted to a cognitive-behavioral model with clear specification of different components of intervention. However, there have been very few studies investigating the individual contribution of these different treatment components.

OUTCOMES OF TREATMENTS FOR SPECIFIC SEXUAL DYSFUNCTIONS

Male Hypoactive Sexual Desire Disorder

Men report problems with desire far less frequently than women (Laumann et al., 1999), and there is minimal information available concerning the psychological treatment of desire problems in men. The major issue in treatment decision making is a careful differential diagnosis to identify etiologies with established interventions. In general, a presentation of a lifelong problem of low sexual desire or a situational pattern to the problem is suggestive of a psychological etiology. Syndromes to be considered in the differential diagnosis of acquired male HSDD include untreated depression, drug side effects, and endocrinopathies such as hypogonadism, hypothyroidism, or hyperprolactinemia (Segraves, 2008). As stated above, there is minimal evidence regarding the efficacy of psychological therapies for HSDD in men. Cognitive-behavioral treatment approaches involve helping the man to develop sensory awareness and to identify erotic cues, desensitization of anxiety, and cognitive restructuring (LoPiccolo & Friedman, 1988). Psychoanalytic approaches concentrate on the transference relationship and the internalization of exciting and rejecting objects. The only evidence supporting any of these psychological approaches consists of case reports or small clinical series.

Double-blind studies have shown that successful treatment of depression can restore libido unless the psychopharmacological agent itself has sexual side effects (Labbate, 2008). Drug side effects should be considered if the problem occurs shortly after drug initiation or dose increase. Clinical studies indicate that the addition or substitution of bupropion for an serotonergic antidepressant may alleviate selective serotonin reuptake inhibitor (SSRI)-induced sexual dysfunction (Balon, 2009). Clinical series have also suggested that the substitution of aripiprazole for prolactin-elevating antipsychotic drugs may alleviate antipsychotic drug-induced sexual dysfunction (Nunes et al., 2012).

The relationship between serum testosterone and libido within normal ranges is unclear. However, controlled trials and large clinical series have established that exogenous testosterone supplementation can restore libido in hypogonadal men (Maurice, 1999). Clinical series have shown that the use of prolactin-lowering drugs can restore sexual desire in men with frank prolactinemia. Data from clinical series indicate that thyroid hormone therapy in men with hypothyroidism may normalize libido (Maggi et al., 2013).

Female Sexual Interest/Arousal Disorder

As discussed earlier, female sexual interest/arousal disorder is a new diagnostic code in *DSM-5* that

combines elements of HSDD in *DSM-IV-TR* with elements of subjective arousal. There are strong reasons to expect that research done using HSDD criteria will be applicable to the new entity. These reasons include the following: (1) high comorbidity between measures of sexual arousal and sexual desire; (2) the finding that most women don't distinguish between desire and arousal; and (3) the fact that pharmacological interventions that affect measures of desire also affect arousal (Buster et al., 2005).

Psychological Therapies

There have been a limited number of controlled studies of the psychotherapy of HSDD in females. Most studies employed a variant of CBT administered in a group format. Some studies have attempted to decipher the efficacy of specific components of therapy. The evidence concerning the efficacy of psychotherapy of sexual disorders has been recently reviewed elsewhere (Gunzler & Berner, 2012; Ter Kuile et al., 2010). Trudel and colleagues (2001) reported a study of the efficacy of multimodal CBT for women meeting operational diagnostic criteria for HSDD in *DSM-IV-TR*. The criteria used indicate that the women in his study also met criteria for female sexual interest/arousal disorder as defined in *DSM-5*. The women were found to have various irrational, negative automatic thoughts, core irrational beliefs, antisexual attitudes, anticipatory anxiety, fears of abandonment, and corresponding negative affects before treatment. Thirty-eight couples were randomly assigned to CBT consisting of 12 weekly, 2-hour group couple therapy sessions and 36 couples to a 12-week waitlist control group. Seventy-four percent of women in treatment were improved or cured at the end of treatment, a gain that was largely maintained at the 3-month and 1-year follow-ups. At the end of treatment, 28% of the women considered themselves totally cured. Similar results were found on multiple questionnaire variables on which the treatment group demonstrated significant positive changes in comparison to the waitlist control group. Hurlbert and Apt (1995) compared the efficacy of a CBT approach administered in women-only group therapy versus in couples-only group therapy versus a waitlist control group for the treatment of HSDD in women. Nineteen patients were in each group. The treatment approach consisted of a multimodal treatment package augmented by orgasm consistency training. A previous study by Hurlbert (1993) had demonstrated the efficacy of orgasm consistency training in women with HSDD. Orgasm consistency training consists of teaching the male partner to delay ejaculation, directed masturbation exercises for the female, directing couples that the female should reach orgasm first ("the ladies come first rule"), and directing the man to shift forward during thrusting so that there is more clitoral contact during coitus ("the coital alignment technique"). Both treatment groups demonstrated significant improvement in comparison to the waitlist control group, and the couples-only group demonstrated greater improvement than the women-only group approach.

Other promising approaches include Internet-based therapies (Jones & McCabe, 2011) and approaches based on mindfulness (Brotto et al., 2008a, 2008b). To date, there are no controlled data comparing either of these interventions to a control condition in women diagnosed with either HSDD or female sexual interest/arousal disorder. Mindfulness is an approach that emphasizes present-moment nonjudgmental awareness.

Pharmacotherapy

No agents have been approved by the FDA for the treatment of desire disorders in women, although there is considerable interest in the role of testosterone in female libido. Abnormally low endogenous androgen levels have been proposed as one etiology for HSDD in females. In premenopausal women, testosterone is derived from the ovaries and adrenal glands. There is a gradual decline in serum testosterone with aging and a dramatic decline after oophorectomy. Studies have not found a consistent relationship between serum testosterone and sexual function in women (Davis, Davison, Donath, & Bell, 2005; Dennerstein, Dudley, Hopper, & Burger, 1997). Several factors may explain the lack of a correlation between testosterone levels and sexual function in women. Blood levels of testosterone may not reflect tissue concentrations as there is considerable intracellular metabolism of testosterone, and accurate measurement of testosterone at the levels present in women is difficult (Fooladi & Davis, 2012). As of 2010, there had been 35 double-blind controlled trials involving 4,768 women of adding testosterone to

conventional postmenopausal hormone therapy. The available evidence clearly indicates that adding testosterone to hormone therapy improves sexual function, measures of interest in sexual activity, and the number of satisfying sexual events (Somboonporn et al., 2010). Most of these studies involved study of the effects of adding transdermal testosterone to hormone replacement in postmenopausal women, although there is some evidence for a beneficial effect of transdermal testosterone in older premenopausal women (Davis et al., 2008). Other forms of delivery such as creams and gels have also been studied. The efficacy of testosterone cream in women has been demonstrated (El-Hage et al., 2007), whereas there have been inconsistent data concerning the efficacy of testosterone gel (Fooladi & Davis, 2012). Studies of dehydroepiandrosterone have not found significant effects on sexual desire. Similarly, studies of peripheral vasodilators such as sildenafil have not shown efficacy in the treatment of HSDD (Al-Azzawi et al., 2009).

The link between postmenopausal estrogen-progesterone therapy and breast cancer has led to concern about any form of hormone therapy. Safety data from controlled double-blind studies of transdermal testosterone suggest that there are no significant health risks in up to 2 years of therapy. As a consequence, off-label use in women of transdermal testosterone formulated for men is common in the United States. Whether there are health risks with the use of testosterone beyond 2 years is unknown.

A single-blind study found that bupropion increased various indices of libido in women with hypoactive sexual desire disorder (Segraves et al., 2001); a subsequent double-blind study found that bupropion had significant effects on questionnaire measures of sexual arousal, orgasm, and satisfaction (Segraves, Clayton, & Croft, 2004).

Other compounds are being investigated for the treatment of desire problems in women. These include flibanserin and melanocyte-stimulating hormone analogues. A preparation of testosterone combined with a PDE inhibitor is also being studied.

Erectile Disorder

Psychological Intervention

Two recent reviews of controlled studies of psychosocial interventions for ED have concluded that there is evidence that psychosocial interventions are superior to waitlist control groups and that the combination of psychosocial therapy and oral pharmacotherapy is superior to oral pharmacotherapy alone (Berner & Gunzler, 2012; Melnik et al., 2008). The available evidence consists of studies of varying quality using differing therapeutic approaches. For example, therapeutic approaches have included creative-dynamic image synthesis (Sommer et al., 2001), virtual reality methods (Optale et al., 1997), hypnotic suggestion (Aydin et al., 1997), theme-based psychotherapy (Melnik & Abdo, 2005), and CBT approaches (Andersson et al., 2011; McCabe, 2001). Differing outcome measures have been used, and some studies used such small sample sizes that one would not expect to find differences between treatment approaches. For example, one study compared five conditions, each of which included only four men (Kilmann et al., 1987). Two studies have found evidence that CBT is superior to a waitlist control group (Andersson et al., 2011; McCabe, 2001). One study did not find an advantage to combining counseling with intracavernosal injection therapy (van der Windt et al., 2002), and one study did not find a significant benefit from adding counseling to vacuum erection device therapy (Wylie et al., 2003).Three studies found that counseling combined with sildenafil therapy was superior to sildenafil therapy alone (Abdo et al., 2008; Banner & Anderson, 2007; Melnik et al., 2012; Phelps et al., 2004). One study actually found counseling to be more effective than oral sildenafil therapy (Melnik & Abdo, 2005).

Pharmacotherapy

Clearly, the most acceptable pharmacotherapy for ED is an oral medication. The introduction of the oral agent sildenafil in 1998 had a dramatic effect on the treatment of erectile problems (Goldstein et al., 1998). At this point, oral PDE inhibitors (e.g., sildenafil, vardenafil, tadalafil, and avanafil) are first-line therapies for ED. These drugs are intracellular signal amplifiers and slow the degradation of cyclic guanosine monophosphate, thus leading to a chain of events resulting in decreased intracellular calcium, relaxation of the smooth muscle of the corpus cavernosum, and thus penile erection (Tsertsvadze et al., 2009). These drugs thus enhance the ability of a man to achieve an erection given adequate psychological or physical stimulation. They do not

produce spontaneous erections or enhance libido. The efficacy of the PDE inhibitors has been demonstrated in multiple double-blind, placebo-controlled, multicenter type 1 studies (Osterloh, Eardley, Carson, & Padma-Nathan, 1999). There have been 72 parallel-group, placebo-controlled studies of sildenafil, 27 involving vardenafil and 28 involving tadalafil. Avanafil was recently introduced in the U.S. market (Goldstein et al., 2012). In all of these studies, there was a significant difference between the PDE inhibitor and placebo in the ability to obtain erections sufficient for penetration and the ability to maintain them after penetration. Increasing doses of drug were associated with increased erectile function. Scientifically sound studies have been conducted in men with hypertension, including those currently receiving medications for their disease, and the drug has also been shown to be helpful to men with type 1 and type 2 diabetes (Vardi & Nini, 2009), spinal cord injury, postradical prostatectomy (Candy et al., 2008), and depression (Albersen et al., 2012). Depending on the etiology of the dysfunction, efficacy ranges between 40% and 80%. All of the PDE5 inhibitors appear to have similar efficacy and a similar side-effect profile (Yuan et al., 2008). The primary difference between these compounds appears to be that tadalafil has a longer duration of action.

The most common side effects include headache and facial flushing, seen in 10% to 20% of men; dyspepsia, seen in 5% of men; and red/blue color vision changes or blurry vision, seen in 3% of men. The headache and facial flushing may be explained by the vasodilatory effects of sildenafil on the cerebral circulation. The dyspepsia is due to the small overlap in sildenafil activity with type 4 PDE found at the gastroesophageal sphincter, leaving the gastroesophageal sphincter open. All of the PDE inhibitors have mild effects on PDE5 located in the rod and cone photoreceptors and can cause mild reversible visual symptoms. There have also been reports of ischemic optic neuropathy associated with PDE5 use, although a causal relationship has not been established (Kerr & Danesh-Meyer, 2009).

Absolute contraindications to sildenafil use are the concomitant use of nitrate drugs. Caution has been advised in patients with retinitis pigmentosa, preexisting hypotension, and the use of multiple antihypertensive agents (American College of Cardiology and American Heart Association Consensus Group, 1999; Tomlinson, 1999). The significance of cardiac deaths is difficult to evaluate because the majority of men taking sildenafil have cardiovascular risk factors. A small number of cases of priapism have been reported with sildenafil. The primary action of sildenafil is peripheral.

Prior to sildenafil the only other oral agent for ED was yohimbine, a natural herb of an African tree bark. Yohimbine is an alpha-2 adrenergic antagonist (Morales, Surridge, & Marshall, 1987). Double-blind studies have shown that it has modest efficacy, mainly in men with psychogenic erectile problems (Reid et al., 1987; Riley, Goodman, Kellet, & Orr, 1989; Sondra, Mazo, Segraves, & Chanceler, 1990; Susset et al., 1989). There are few objective, placebo-controlled studies that validate the efficacy of yohimbine.

Three separate double-blind trials have established that subcutaneous apomorphine is effective in eliciting erections approximately 20 minutes after administration (Danjou, Alexander, Warat, Combiez, & Perch, 1988; Lal, Ackman, Thavundayil, Kieley, & Etienne, 1984; Segraves, Bari, Segraves, & Spirnak, 1991). It has been hypothesized that apomorphine acts at the level of the paraventricular nucleus of the brain (Chen, Chan, & Chang, 1999). Early data suggest a significant improvement in erectile activity over placebo (Heaton, Morales, Adams, Johnston, & el-Rashidy, 1999; Mulhall & Goldstein, 1999). The clinical utility of both subcutaneous and sublingual apomorphine has been limited by its propensity to cause nausea. Apomorphine has less efficacy than the PDE5 inhibitors and is not available in the U.S. market (Eardley, Wright, MacDonagh, Hole, & Edwards, 2004; Gontero et al., 2005; Perimenis et al., 2004).

Other pharmacotherapies for ED include transurethral systems (MUSE) and intracorporeal injection therapy. Both these methods employ different delivery systems to introduce vasoactive substances into the corpora cavernosa of the penis. Of the two approaches, intracavernosal injection therapy has a higher success rate in producing firm erections. The parameters of such therapy, dose regimens, and side effects are well established. The efficacy for psychogenic as well as organic erectile problems appears well established (Althof et al., 1991). The three most common agents used to induce erections are papaverine hydrochloride, phentolamine, and prostaglandin E1. Although they are frequently combined, each agent can be used singly (Althof & Seftel, 1995). As one might expect, there have also been a number

of reports and studies employing the triple therapy of papaverine, phentolamine, and prostaglandin El, referred to as tri-mix (Barada & McKimmy, 1994). Triple therapy appears to have superior results over the use of papaverine phentolamine combination therapy for some conditions, such as severe arteriogenic disease (McMahon, 1991). Triple therapy has also been used in patients with psychogenic impotence (Bennett, Carpenter, & Barada, 1991). Papaverine and papaverine-phentolamine injection therapy have the disadvantages of causing delayed corporeal fibrosis, variable efficacy, systemic reactions, and the risk of prolonged erections (Levine et al., 1989).

Vacuum Tumescence Devices

An alternative strategy for the man who is resistant to trying or has not benefited from psychotherapy and who finds the concept of self-injection of a substance into the penis somewhat aversive is the use of the external vacuum erection device. The vacuum device is placed over the penis, and a negative pressure facilitates blood flow into the penis, producing an erection. A tension ring (rubber band) is slipped from the base of the vacuum erection device to the base of the penis, maintaining the erection. Different studies using diverse patient populations have reported that between 70% and 100% of men will achieve erections using this device (Althof & Seftel, 1995; Turner, Althof, & Levine, 1992). Dropout rates are around 20%. Side effects are minimal, and there is no evidence of significant negative psychological effects from employing this device. However, with the introduction of effective oral erectogenic agents, the use of mechanical aids has decreased.

Premature Ejaculation

The behavioral treatment for premature ejaculation was first described by a urologist, James Semans, in 1956. He reported a high success rate using a technique that involved having the female stimulate her partner's penis until just before the point of ejaculatory inevitability, stopping, and then restarting stimulation. This intervention is repeated until the man can voluntarily delay ejaculation. Masters and Johnson (1970) reported a similar technique using a firm frenulum squeeze prior to the point of ejaculatory inevitability. Once control is achieved with manual stimulation, the couple is instructed to have coitus using the female-superior position. Again, the male is instructed to signal just prior to ejaculatory inevitability, at which point the partner ceases movement. Once he indicates that he has regained control, she begins movement again. Most contemporary clinicians employ either the start/stop or frenulum-squeeze technique as part of their treatment of premature ejaculation (Maurice, 1999; Metz & McCarthy, 2003; Rowland & Cooper, 2011). Despite the widespread adoption of this technique, there is limited evidence supporting the efficacy of the psychological treatment of premature ejaculation (Melnik et al., 2011).

One major controlled study demonstrating the efficacy of behavioral treatment of premature ejaculation was reported by DeCarufel and Trudel in 2006. This study reported that both behavioral therapy and a cognitive therapy approach in which men were taught to recognize various levels of sexual excitement were superior to a waitlist control group. Outcome measures included measurement of ejaculatory latency, sexual satisfaction, and questionnaire measures of sexual interaction. Gains were maintained at a 3-month follow-up evaluation. Three other controlled studies compared the efficacy of psychological interventions to pharmacotherapy (Abdel-Hamid et al., 2001; Li et al., 2007; Yuan et al., 2008). These studies produced mixed results. One study found that counseling plus chlorprazine was superior to drug alone (Li et al., 2007), while another study found behavior therapy to be similar in outcome to SSRI therapy (Abdel-Hamid et al., 2001).

Pharmacological Treatments

A large number of placebo-controlled, double-blind studies have demonstrated that daily treatment with fluoxetine, sertraline, clomipramine, and paroxetine can be used to delay ejaculatory latency in men with rapid ejaculation. Consistent findings have been obtained using a variety of outcome measures, including patient estimate of time between penetration and ejaculation, partner estimate, and patient or partner report of stopwatch readings. It appears that ejaculatory delay occurs only during active drug treatment and that sustained pharmacotherapy is necessary for most men to maintain a slower pattern of ejaculation. The effect is usually reported after 1 to 2 weeks of treatment. Chronic treatment with 20 to 40 mg of

paroxetine (Waldinger, Hengeveld, & Zwindman, 1994, 1997), 25 to 50 mg of clomipramine (Althof et al., 1995; Kim & Seo, 1998), 50 to 200 mg of sertraline (Biri et al., 1998; Kim & Seo, 1998; McMahon, 1998a, 1998b; Mendels, Cameram, & Sikes, 1995), or 20 mg of fluoxetine (Haensel, Klem, Hop, & Slo, 1998; Kara et al., 1996) has been shown to increase ejaculatory control in men experiencing rapid ejaculation (Giuliano & Clement, 2012). A meta-analysis of the published data indicates that paroxetine has a stronger effect in promoting ejaculatory delay than the other SSRIs (Waldinger, 2003).The effect of these drugs on ejaculatory latency dissipates when the drug is discontinued.

Some investigators have investigated the efficacy of various drugs taken as needed. The available evidence indicates that clomipramine, a serotonergic antidepressant, can be effective when taken on an as-needed basis; five double-blind controlled studies have reported these findings. Dosing is typically 25 to 50 mg taken approximately 5 hours prior to coitus. Ejaculatory latency has been reported to increase fourfold (Althof et al., 1995; Haensel & *Rowland* 1996; Segraves et al., 1993; Strassberg et al., 1999: Waldinger, 2007).

Several investigators have explored the use of SSRIs when on-demand therapy is preceded by daily treatment (Kim & Paick, 1999; McMahon & Touma, 1999). The data concerning this approach are mixed.

Dapoxetine, a serotonin reuptake inhibitor, has been studied in over 6,000 subjects and been approved for use in the treatment of premature ejaculation in many countries (although not the United States). Dapoxetine hydrocholoride is a short-acting SSRI characterized by rapid absorption and clearance. It is effective when used on demand and has been shown to be effective in men with lifelong as well as acquired premature ejaculation.

Topical anesthetic creams and sprays have also been shown to be effective in delaying ejaculation. Prilocaine-lidocaine formulations have been demonstrated to be effective (Atikeler et al., 2002; Basuto & Galindo, 2004; Berkovich et al., 1995; Dinsmore & Wyllie, 2009; Henry & Morales, 2003). Another approach is the use of creams formulated from plant products. For example, SS-cream, formulated from nine natural products, is applied to the penis 1 hour prior to coitus (Xin et al., 2000). Placebo-controlled, double-blind studies have demonstrated that this compound increases ejaculatory latency (Choi et al., 2000; Xin et al., 2000).

There have been reports that sildenafil may help in the treatment of rapid ejaculation (Chen et al., 2003: Salonia et al., 2002). However, a recent controlled study did not find evidence of efficacy of sildenafil in the treatment of premature ejaculation (McMahon et al., 2005, 2006).

Double-blind placebo-controlled studies have also found that tramadol, a mild opioid receptor agonist, can be effective in delaying ejaculation when taken on demand (Bar-Or et al., 2012; Giuliano, 2007; Salem et al., 2008). This strategy would not be recommended as a first-line therapy because of the potential of addiction with this agent.

Delayed Ejaculation

Because delayed ejaculation is one of the least commonly encountered sexual complaints in clinical practice, there is a paucity of information concerning its etiology and treatment. *DSM-5* does specify clear criteria regarding when this diagnosis should be made. It has been suggested that this diagnosis should definitely be considered in men who are unable to ejaculate after 25 to 30 minutes of sexual activity and are distressed by their inability to ejaculate sooner. Some men will simply cease sexual activity after shorter time periods because of pain and/or exhaustion (McMahon et al., 2013). The *DSM-5* recommends that the subtypes "lifelong versus acquired" and "situational versus global" be used. It has also been suggested that psychogenic etiologies be given primary consideration in cases of lifelong premature ejaculation and that organic etiologies should receive primary consideration in acquired delayed ejaculation. Similarly, psychological factors would be strongly considered when the man reports a situational pattern to his failure to ejaculate (i.e., able to ejaculate with one partner and not another) and that organic factors would be more likely in cases of acquired delayed ejaculation. Although these suggestions have face validity, there is limited empirical evidence to support these assumptions (Segraves, 2010a).

No controlled trials of psychological treatment of delayed ejaculation have been reported. Psychological treatment appears to vary mainly by the theoretical orientation of the psychotherapist. Psychoanalytically oriented therapists posit that

insight-oriented psychotherapy focusing on becoming aware of unconscious motivation (e.g., fear or anger at the partner) is the preferred intervention. Therapists with a cognitive-behavioral orientation have noted that many men with delayed ejaculation have a vigorous masturbatory style that produces much more stimulation than vaginal penetration (Perelman, 2005a,b) or have sexual fantasies during masturbation that are more arousing than sex with the partner. Interventions include vibrator stimulation, more vigorous penile thrusting, masturbatory retraining, encouraging the partner to stimulate the patient's penis vigorously during foreplay, and realigning sexual fantasies (Althof, 2012; Rowland et al., 2010). Although many of the case reports of delayed ejaculation are compelling, there are no controlled trials using any of these methods.

No pharmacological agents are approved for the treatment of delayed ejaculation. Moreover, there are no controlled double-blind studies of the efficacy of any pharmacological therapy for delayed ejaculation (McMahon et al., 2013; Waldinger & Schweitzer, 2005). Case reports suggest that drugs with dopaminergic or adrenergic activity such as amantadine, cabergoline, pseudoephrine, reboxetine, bupropion, and yohimbine may benefit some cases. There have also been case reports reporting success with oxytocin, buspirone, and cyproheptadine.

Female Orgasmic Disorder

Spence (1991) presents a cogent summary of the dilemmas to be considered in assessing the efficacy of therapy for women with orgasmic disorders. The primary issue remains unresolved: Is success predicated solely on coital orgasm, on partnered sexual activity with orgasm through any means, or by orgasm achieved by masturbation? Most contemporary therapists would consider orgasm by any means in a partnered relationship to be a treatment success, although many patients prefer orgasm during coitus. This expectation may be reinforced by the partner. Adding to the confusion is the media's constant reinforcement of unrealistic expectations from sexual encounters. Both men and women are led to believe that all women can easily and regularly achieve orgasm from intercourse alone.

Recent research indicates that orgasmic capacity has a genetic component (Dunn et al., 2005) and is related to certain normal personality traits (Harris et al., 2008). Other research indicates that (1) only about 25% of women report regularly achieving orgasm during partnered sexual activity (Lloyd, 2005); (2) many women are not distressed by absence of orgasm during sexual activity (King et al., 2007); (3) women vary widely in the type of stimulation that triggers orgasm (Meston et al., 2004); (4) orgasmic difficulties are often comorbid with anxiety, depression, and relationship difficulties (Rellini & Clifton, 2011); and (5) many women who are sexually responsive to their partners do not achieve orgasm through coitus (Laan et al., 2013).

Psychological Interventions

Recent reviews of the efficacy of psychosocial interventions for the treatment of female orgasmic disorders have concluded that CBT including directed masturbation is effective in helping women to become orgasmic (Heiman, 2002; Laan et al., 2013; Meston, 2006; Meston et al., 2004; Rellini & Clifton, 2011). Eight separate studies found that cognitive-behavioral interventions including directed masturbation were superior to a waitlist control or alternative therapy in increasing orgasmic response (Bogat et al., 1983; Delehanty, 1982; Dodge et al., 1982; Heiman & LoPiccolo, 1983; Heinrich, 1976; McMullen & Rosen, 1979, Munjack et al., 1976; Riley & Riley, 1978). Andersen (1981) did not report significant differences in orgasmic attainment between women receiving systematic desensitization therapy, directed masturbation, or a waitlist control group, although more women in the directed masturbation group became orgasmic. Follow-up at 2 months indicated that the benefits were sustained for most women. The prognosis for success in treatment for female orgasmic disorder appears more positive for women with lifelong orgasmic dysfunction than for women who acquire the dysfunction after a period of normal function. Whatever the success in achieving orgasm via masturbatory training, it begins to diminish as the woman moves from self-induced orgasm to partner-induced orgasm through manual or oral stimulation or intercourse-induced orgasm without manual stimulation. For example, one study reported that 100% of women were able to become orgasmic through masturbation, whereas only 47% of these women reported orgasm during coitus (Heinrich,

1976). Successful outcomes have been reported using a variety of treatment formats, including individual, conjoint, and group therapy and bibliotherapy. It is notable that most of these studies were performed several decades ago.

Results from other approaches including systematic desensitization were mixed. Two studies reported that "coital realignment" therapy was superior to a control group treatment (Eichel et al., 1988; Hurlbert & Apt, 1995). Coital realignment therapy involves instructing the male to position himself up and forward on his female partner to increase clitoral stimulation (Eichel et al., 1988).

Pharmacotherapy

No agent has been approved for the treatment of female orgasmic disorder in the United States; as a result, there have been few controlled trials of agents to treat female orgasmic difficulties (Ishak et al., 2010). In trials for other indications, there is evidence that certain agents facilitate orgasm, particularly in postmenopausal women. To this end, trials of testosterone therapy in postmenopausal women have found that testosterone supplementation improves various aspects of sexual function, including orgasm (Braunstein et al., 2005; Davis et al., 1995, 2006, 2008; Nathorst-Boos et al., 2006; Shifren et al., 2000). Controlled trials have also indicated that tibilone, a drug with estrogenic, progestogenic, and androgenic properties, has been found to improve measures of orgasmic capacity (Uygur et al., 2005).

Other compounds have been found to improve orgasmic function in women in controlled studies of populations selected for other indications. For example, bupropion was found to increase orgasm completion in women with HSDD (Segraves et al., 2004), and sildenafil was found to increase orgasmic response in a group of women with normal libido who came for treatment of arousal problems (Caruso et al., 2001). Other investigators have not reported benefit using sildenafil in women complaining of problems with desire and arousal (Basson & Brotto, 2003). Randomized placebo-controlled trials have indicated statistically significant benefits on various aspects of sexual function but not orgasm function from a dietary supplement marketed as ArginMax (Ito et al., 2006) and a topical botanical produce marketed as Zestra (Ferguson et al., 2010). One study did not find an effect of gingko biloba on ability to achieve orgasm (Meston et al., 2008).

Genito-Pelvic Pain/Penetration Disorder

As discussed earlier, GPPD is a new *DSM-5* diagnosis that combines elements of vaginismus and dyspareunia (Binik, 2010a, 2010b). The current cognitive-behavioral model for understanding dyspareunia is a circular one, which assumes that catastrophic memories of pain during intercourse lead to fear of pain and hypervigilance, which in turn contribute to pelvic floor muscle tone and increased pain (Ter Kuile et al., 2010). Similarly, fear of pain during vaginal penetration could provoke hypervigilance and avoidance of sexual activity (Borg et al., 2012). Given this model, one would assume that personality features of anxiety-proneness and somatization as well as certain relationship factors could be involved in the maintenance of vaginismus and sexual pain disorders. Studies have found catastrophic pain cognitions to be common in women with vaginismus (Borg et al., 2012) and indeed many treatment centers employ a multidisciplinary approach, including mental health professionals, in the treatment of pelvic pain penetration disorders (Reissing, 2012). However, it is impossible to ascertain whether the psychosocial issues identified are the result of the problem or whether they play a significant role in the genesis or maintenance of the difficulties. Since the literature before 2013 was separately reported for dyspareunia and vaginismus, this review will follow that convention.

Vaginismus can be classified as lifelong (primary) or acquired (secondary). Lifelong vaginismus is sometimes referred to as "unconsummated marriage." The usual treatment is the use of graduated vaginal dilators, a technique introduced by Sims in 1861. There is a long history of the use of graduated dilators for this condition, and many clinicians use a cognitive-behavioral approach including the gradual progression of vaginal dilators of progressively larger diameters (in vivo desensitization) as the preferred intervention. Numerous case histories and clinical series report this to be a highly effective intervention, with success rates ranging from 70% to 100% (Crowley et al., 2009). Several recent review articles have concluded that current evidence of less-than-optimal quality suggests that this approach is effective (Crowley et al., 2009; McGuire & Hawton,

2001). There are only five studies that meet minimal criteria to be reviewed as controlled studies of the psychological treatment of vaginismus (Al-Sughayir, 2005; Jarrousse & Poudat, 1986; Schnyder et al 1998; Ter Kuile et al., 2007; van Lankveld et al., 2006). Of these studies, only one used a randomized allocation to treatment or to a waitlist control group (van Lankveld et al., 2006). In this study, cognitive-behavioral group psychotherapy and bibliotherapy were both found to be superior to a waitlist control group. The 10-session, 2-hour group therapy led by a mixed-sex co-therapy team was not superior to minimum-contact bibliotherapy. Bibliotherapy consisted of a 50-page manual on the treatment of vaginismus plus a CD-ROM detailing relaxation and sexual fantasy exercises. Only 9% of the patients receiving group psychotherapy reported successful vaginal penetration at the conclusion of therapy as compared to 14% in the bibliotherapy group. This success rate was dramatically lower than those previously reported in the literature. The lack of controlled studies validating the efficacy of in vitro desensitization should not be interpreted as indicating that this type of therapy is ineffective; there have been only a handful of controlled studies of the efficacy of this treatment, in contrast to large numbers of uncontrolled trials finding this intervention to be effective. Remission rates of vaginismus without intervention appear to be quite low (Crowley et al., 2009). Although hypertonus of the pelvic floor is a possible component of the pain involved in vaginismus, there is no evidence that physical therapy of the pelvic floor is a necessary component of the treatment for vaginismus (Rosenbaum, 2007). There is, however, some evidence to suggest that botulinum neurotoxin injection into the bulbospongiosum muscle is helpful for some women with vaginismus (Pacik, 2011).

The literature concerning the treatment of dyspareunia is difficult to evaluate for multiple reasons, including (1) the high placebo response rate noted; (2) the relatively high rate of remission of symptoms without intervention; (3) uncertainty regarding whether associated psychosocial variables are simply the consequence of the disorder rather than being of etiological significance; (4) conditions of varying etiologies being similarly labeled; and (5) varying use of terminology. In *DSM-IV-TR*, dyspareunia was subtyped as lifelong or acquired, but in clinical practice, the subtype of deep or superficial is more commonly employed. Deep dyspareunia is considered almost always to be organic in etiology and often a symptom of endometriosis (Steege & Zolnoun, 2009). Most of the research concerning psychosocial correlates of dyspareunia concerns superficial dyspareunia (pain in the vaginal vestibule). Various terms have been employed to describe superficial dyspareunia: vulvodynia, vulvar vestibulitis, provoked vestibulitis, and provoked vulvodynia (Boyer et al., 2011; Fugl-Meyer et al., 2013). Although pain can be generalized and occur in multiple contexts, the most common clinical presentation is pain provoked by coitus or attempted vaginal penetration.

In many cases, the pain described seems out of proportion to any pathology identified; in many cases no clear organic etiology can be identified. This has led to the hypothesis that repetitive mild tissue injury may lead to neurogenic inflammation and lowered pain thresholds. Spasm of the pelvic floor musculature (guarding) frequently accompanies provoked vulvodynia and may contribute to the pain experienced (Rosenbaum, 2007). Some have also hypothesized that chronic subthreshold negative stimuli may also lead to central sensitization to pain stimuli. A variety of psychological variables have been reported to be associated with provoked vulvodynia, including negative attitudes toward sexuality, depression, anxiety, sexual abuse, and insecure attachment styles (Granot et al., 2011; Landry & Bergeron, 2011). In the absence of prospective studies, one cannot ascertain whether the psychological factors are the results of pain or whether they play a significant etiological role.

Evaluation of studies of efficacy of various treatment interventions should take into consideration that spontaneous remission rates of 30% (Steege & Zolnoun, 2009) and placebo-response rates of 50% have been reported (Petersen et al., 2009). Thus, the outcomes of any study that did not employ a placebo or no-treatment condition have to be regarded with skepticism. Although many centers use a biopsychosocial model of intervention (Sadownik et al., 2012; Spoelstra et al., 2011), the evidence supporting the efficacy of this approach is limited. Schultz and colleagues (1996) did not find behavior therapy plus surgery to be superior to behavior therapy alone in a study of 14 women. Bergeron and colleagues (2001, 2008) studied the relative efficacy of CBT, electromyographic feedback, and vestibulectomy in women with provoked vestibulodynia. All interventions demonstrated apparent efficacy, although the surgical intervention was statistically superior to the other interventions. None of the studies mentioned above

employed a no-treatment condition. Accordingly, one has to conclude that there is minimal evidence to date supporting cognitive-behavioral interventions for dyspareunia.

There have been reports of high success rates using surgical interventions. However, there is a paucity of randomized trials evaluating surgical approaches (Tommola et al., 2010). Randomized double-blind trials support the use of vaginal estrogens (Krychman, 2011) and intravaginal dehydroepiandrosterone (Labrie et al., 2011) to treat dyspareunia in postmenopausal women. Although botulinum toxin has been described to be effective in the treatment of dyspareunia, a double-blind study comparing botulinum injection to saline injection found no difference in outcomes between the two approaches (Petersen et al., 2009).

Substance-Induced Sexual Dysfunction

The diagnostic entity of substance-induced sexual disorders (i.e., sexual disorders associated with drug intoxication and with the use of prescribed medication) was introduced in *DSM-IV*. The name was modified in *DSM-5* to substance/medication-induced sexual dysfunction. A variety of chemical agents have been associated with sexual dysfunction. Most of the reports concern substances of abuse, antihypertensive agents, and psychiatric drugs (Segraves & Balon, 2004).

Sexual dysfunction has long been suspected to be related to chronic alcohol abuse. In particular, it has been assumed that chronic alcohol abuse in males is associated with ED (Miller & Gold, 1988; Palha & Esteves, 2008; Schiavi, 1990). Although less evidence is available concerning the effects of chronic alcohol abuse in females, it appears that chronic alcohol abuse may also be detrimental to female sexual function (Amidu et al., 2010; Rosen, 1991; Segraves, 2010b; Smith et al., 2012). There is considerable evidence that chronic alcohol abuse has deleterious effects on hypothalamic-pituitary and testicular function (Schiavi, Stimmel, Mandeli, & White, 1995). Chronic alcohol abuse is also associated with damage to the central nervous system, as manifested by dementia and Wernicke-Korsakoff syndrome. Peripheral polyneuropathy associated with myelin and axon degeneration is a common neurological complication of chronic alcoholism. Thus, there are several mechanisms by which chronic alcohol abuse could cause sexual dysfunction.

There is abundant evidence documenting the deleterious effects of nicotine on male erectile function (Palha & Esteves, 2008). The impact is related both to the average number of cigarettes smoked and number of years as a smoker. Smoking has a deleterious effect on the vascular component of penile erection. It is less clear that nicotine has a harmful effect on female sexuality.

Cannabis use is perceived by many users to have a beneficial effect on the experience of sexual pleasure, the ability to relax with a sexual partner, and the experience of sexual fantasies. However, there is some evidence that cannabis use may be associated with difficulty achieving orgasm in women (Christensen et al., 2011; Johnson et al., 2004).

Evidence concerning the effects of opioids on sexual function has been uniform and convincing. The evidence consists of anecdotal reports, surveys, and clinical studies. All the studies are consistent in finding diminished libido while the person is on narcotics (Abel, 1985). Methadone has also been found to be associated with male sexual dysfunction (Brown et al., 2005). Retrospective studies suggest that normal libido returns during drug-free periods (Segraves, Madsen, Carver, & Davis, 1985).

Cocaine and amphetamine use has been reported to cause increased libido and spontaneous erections (Abel, 1985). However, there is evidence that chronic abuse of these agents may lead to decreased libido and other sexual dysfunctions (Palha & Esteves, 2008; Siegel, 1982). It is unclear whether sexuality returns to baseline during abstinence from these agents.

Most of the antihypertensive drugs have been reported to cause erectile problems (Rosen & Leiblum, 1995; Segraves, 1988, 2010; Segraves et al., 1985). Case reports also suggest that many other agents, including antiarrhythmic agents, digoxin, and hypolipidemic agents, may be associated with erectile problems. Unfortunately, most of these reports do not include control groups or use appropriate measures of sexual function. Sildenafil appears capable of reversing erectile problems in patients with hypertensive arterial disease.

Psychiatric drugs have also been reported to cause sexual problems. This is true of almost all classes of psychiatric drugs (Segraves, 2003, 2010). Most of the evidence concerning the action of these drugs comes

from clinical reports. Most of the controlled studies are of antidepressant drugs. Benzodiazepines have been frequently reported to cause delay in orgasm. This has been reported with chlordiazepoxide, lorazepam, diazepam, and alprazolam (Segraves, 1995a, 1995b). A double-blind controlled study by Riley and Riley (1988) demonstrated a dose–response relationship between diazepam dose and orgasmic delay.

Most of the aliphatic, piperidine, and piperazine phenothizines have been reported to cause ejaculatory and erectile problems (Labbate, 2008; Segraves, 2010a). The few studies of sexual function in female patients treated with antipsychotics indicate that anorgasmia may be an unwanted side effect. Antipsychotic-induced sexual dysfunction has been reported to correlate with prolactin elevation. There has been interest in whether the newer prolactin-sparing antipsychotics would have a lower incidence of sexual dysfunction. At this point, the evidence is inconclusive, partly because of the high prevalence of sexual problems in patients with untreated schizophrenia (Aizenberg et al., 1995; Montejo et al., 1998) and partly because of methodological problems in assessment. Most reports are in agreement that risperidone causes more sexual dysfunction than olanzapine (Tran et al., 1997) and that the sexual problems with risperidone appear dose-related (Marder & Meibach, 1994). Aripiprazole also appears to have a low incidence of sexual dysfunction (Serretti & Chiesa, 2011). There have been case reports of antipsychotic-induced sexual dysfunction being reversed by sildenafil (Salerian et al., 2000; Segraves, 1999). There have been unconfirmed case reports of amantadine, bromocriptine, and cabergoline being used to reverse antipsychotic-induced sexual dysfunction.

Most of the antidepressants available in the United States have been reported to cause sexual dysfunction, with the possible exceptions of bupropion, mirtazapine, and nefazodone (Clayton & Balon, 2009; Segraves, 1995a, 1995b). This phenomenon has been confirmed in double-blind studies of many of the antidepressants (Feiger, Kiev, Shrivastava, Wisselink, & Wilcox, 1996; Harrison et al., 1985; Kowalski, Stanley, & Dennerstein, 1985; Monteiro, Noshivani, Marks, & Lelliott, 1987; Segraves, 2010a; Segraves et al., 2000). The most commonly reported sexual side effects are anorgasmia and ejaculatory delay. The incidence of sexual problems appears to be relatively similar among the SSRIs and dual reuptake inhibitors except that vilazodone and duloxetine appear to have a lower incidence of associated sexual dysfunction (Clayton & Balon, 2009). Paroxetine appears to have a higher incidence of anorgasmia than the other selective reuptake inhibitors. A variety of interventions have been suggested for antidepressant-induced sexual dysfunction. These include drug holidays, changing time of dose, lowering dose, waiting for tolerance to develop, and the use of antidotes. Numerous antidotes have been reported in case reports. These include the addition of bupropion, mirtazapine, nefazodone, yohimbine, cyprohepatadine, amphetamine, and many others (Rosen et al., 1999). The only antidotes proven effective in double-blind trials are sildenafil (Hargreave, 1998) and buspirone (Landen et al., 1999) in male sexual dysfunction and sildenafil for serotonergic antidepressant-induced anorgasmia in women (Nurnberg et al., 2008).

FUTURE DEVELOPMENTS

The past decade has witnessed extensive research on the pharmacological treatment of human sexual disorders, especially erectile disorders. Following the successful launch of the PDE5 inhibitors, there has been a search for compounds that facilitate sexual responsiveness in women. Because low sexual desire is the most common complaint in female patients, pharmacological research has focused on compounds that target the central nervous system. This research will contribute to our understanding of the neurophysiological substrate for human sexuality. Psychosocial variables appear to be more salient in female than in male sexual response. A search for effective interventions for female sexual dysfunction will undoubtedly increasingly use the biopsychosocial model. As we gain a better understanding of the relative contributions of biological and psychological influences on human sexuality, this will facilitate the development and deployment of targeted interventions.

There is a need for more controlled studies of the efficacy of psychological therapies for the sexual dysfunctions. The evidence for the efficacy of psychological therapies is weaker than that for pharmacological interventions, so we have minimal information regarding which components of CBT are essential or when this therapy is indicated. CBT for sexual dysfunctions is still in its formative stage. In the next

decade, one would expect detailed study and identification of its effective components. Similarly, one would expect the development of different models of psychotherapy for sexual problems that are predominantly psychogenic in contrast to models of therapy for problems that are predominantly biogenic.

In summary, the past decade has been an exciting time for professionals involved in the treatment of sexual dysfunctions, and the next decade has the promise to be even more engaging.

Psychosocial Treatments for Substance Use Disorders

Daniel M. Blonigen
John W. Finney
Paula L. Wilbourne
Rudolf H. Moos

Based on the findings of meta-analyses, as well as type 1 and type 2 randomized controlled trials (RCTs), the most effective psychosocial modalities for treating substance use disorders (SUDs) are cognitive-behavioral interventions, motivational interviewing (MI) and motivational enhancement therapy (MET), contingency management (CM), community reinforcement approach (CRA), behavioral couples and family therapies, and 12-Step facilitation (TSF). The foci of these interventions include substance use behavior, as well as patients' life contexts and social and personal resources. Limited evidence is available for these interventions' differential effectiveness, suggesting that they operate through common mechanisms of change. Brief interventions are highly effective in the treatment of alcohol use disorders. However, as stand-alone treatments, they are best suited for individuals with mild to moderate alcohol use problems. Regardless of modality, therapists who are interpersonally skilled, empathic, and nonconfrontational, and who develop a strong therapeutic alliance, are more effective at helping patients achieve better outcomes. Residential care should be reserved for patients with greater substance use severity, limited social resources, and/or significant psychiatric and medical comorbidities. However, an individualized approach marked by variable intensity of continuing care and ongoing monitoring is needed to address the high rate of relapse in this population. A challenge for the field is to determine how to best implement empirically supported interventions in real-world clinical settings so that they are cost-effective; reach the patient populations in most need of the intervention; produce positive outcomes; and are adopted by clinical providers, delivered as intended, and integrated into routine practice.

INTRODUCTION

SUDs are a serious global public-health problem (Rehm et al., 2009). For example, illicit drug dependence directly accounted for 20 million disability-adjusted life years lost worldwide in 2010 (Degenhardt et al., 2013). Combined with extensive indirect costs such as premature mortality, lost productivity, crime, and increased health care utilization, SUDs also impose a significant economic burden (Wickizer, 2013). For example, in 2006 the economic costs of excessive drinking in the United States were estimated to be over $223 billion (Bouchery et al., 2011). These estimates are on par with the costs of

other major health-risk behaviors, such as smoking, and have prompted the Robert Wood Johnson Foundation (2001) to declare SUDs the "number one health problem in the U.S."

Much of this toll derives from substance use that falls short of meeting diagnostic criteria for an SUD (Rossow & Romelsjö, 2006). However, even among individuals who have an SUD, the majority recover on their own without treatment (Dawson et al., 2006). Nevertheless, a sizeable portion of the total population of individuals with SUDs turns to treatment after their own attempts at change have failed. Among those with an alcohol use disorder or illicit drug use disorder in the United States in 2012, approximately 8% and 15%, respectively, sought treatment in the past year (Substance Abuse and Mental Health Services Administration, 2013), and individuals who have both a drug use disorder and a comorbid psychiatric disorder are more likely to seek treatment (Compton et al., 2007). These figures highlight the importance of research to identify treatments for SUDs that are efficacious (i.e., yield positive effects under controlled research conditions) as well as effective when delivered routinely in real-world clinical settings.

We review psychosocial interventions with the most empirical support for treating SUDs in this chapter. Pharmacological treatments, combined with or independent of psychosocial approaches, and comparative effectiveness studies of psychosocial versus pharmacological approaches are covered elsewhere in this volume. We also consider promising new psychosocial treatments with accompanying data on their efficacy and/or effectiveness in the chapter. Overall, our emphasis is on research reported since publication of the last version of this chapter in 2007. Next, we review recent evidence on potential mechanisms of change for these psychosocial treatments. Following that, we update research on (a) the role of therapist characteristics and the therapeutic alliance in treatment outcomes; (b) the linkages between the duration and amount of treatment and outcome; (c) the settings and formats in which treatments are delivered; and (d) evidence for the impact on outcome of matching patients to specific SUD treatments. We conclude the chapter by commenting on the limits of our ability to identify evidence-based treatments and summarize "what works" in the treatment of SUDs. In reporting findings from specific studies, we use the standards of Cohen (1988) to interpret the magnitude of effect sizes (i.e., small = ~0.2, medium = ~0.5, and large = ~0.8). For a more practical interpretation, however, the reader is referred to the binomial effect size display (Rosenthal & Rubin, 1982), which translates effect sizes into the "success rate" of a treatment or procedure. Based on this approach, the above-noted small, medium, and large effect sizes would translate into success rates (e.g., abstinence or significant reductions in drinking at the end of treatment or at some follow-up time point) of approximately 55%, 62%, and 69%, respectively, among participants in the treatment condition, relative to a 50% rate in a comparison group (Miller & Manuel, 2008; Randolph & Edmondson, 2005).

Treatments may be more or less effective for individuals with differing levels of substance use severity. Thus, an important consideration is the changes made to the classification of SUDs in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*-5; American Psychiatric Association [APA], 2013; see also Hasin et al., 2013). Most notably, a single diagnosis of "substance use disorder" is now listed, which combines symptoms that were previously separated between diagnoses of substance abuse and substance dependence. The former symptom of recurrent substance-related legal problems has been deleted; a new symptom, craving for one or more substances, has been added. A diagnosis of SUD can be applied to nine classes of substances (alcohol; cannabis; phencyclidine; other hallucinogens; inhalants; opioids; sedatives, hypnotics, and anxiolytics; stimulants; tobacco) and is met if 2 or more out of 11 symptoms (covering domains of impaired control, social impairment, risk use, and pharmacological criteria) are observed within a 12-month period. For classes of drugs for which there is a lack of evidence for withdrawal symptoms (i.e., phencyclidine, other hallucinogens, and inhalants), a maximum of 10 symptoms is listed. Further, new indicators for severity (mild = presence of two or three symptoms; moderate = presence of four or five symptoms; severe = presence of six or more symptoms) are specified. Based on our review, essentially all prior studies that diagnosed patients likely identified individuals who would still be diagnosed with an SUD using the new *DSM*-5 criteria. Accordingly, the overall conclusions of the literature to be reviewed likely hold for individuals diagnosed as having SUDs via *DSM*-5. As a possible exception, most studies of brief interventions have focused primarily or wholly on individuals with alcohol use "problems" of mild to moderate

severity, which may or may not meet criteria for a diagnosis in either the prior or current nomenclature.

EFFICACY/EFFECTIVENESS OF COMMON PSYCHOSOCIAL TREATMENT MODALITIES

Summarizing the empirical literature on the effectiveness of psychosocial treatment modalities for SUDs presents numerous challenges. For example, most of the relevant research has focused separately on treatment of alcohol and drug use disorders, despite the substantial overlap between these disorders among individuals in the general population (Stinson et al., 2005) as well as among those who seek treatment (Hartzler et al., 2011). Further, systematic comparisons of the effectiveness of psychosocial treatment modalities are hampered by variations across relevant studies on a range of key dimensions (e.g., characteristics of the sample, the efficacy/effectiveness of the comparison group, number of outcomes tested; time interval in which outcomes were compared; statistical power; Finney, 2000).

"Box-Score" Reviews of Psychosocial Treatments for Alcohol Use Disorders

Four quantitative syntheses have compared the effectiveness of common psychosocial treatment modalities for alcohol use disorders (Finney & Monahan, 1996; Holder et al., 1991; Miller et al., 1998, 2003). These box-score reviews entail various approaches to aggregating evidence regarding the efficacy or effectiveness of a given modality across studies of randomized (or in some cases well-matched) controlled trials. These reviews represent the only comprehensive quantitative syntheses of the comparative effectiveness of common psychosocial treatment modalities for SUDs but are dated—for instance, the most recent review by Miller and colleagues (2003) covers controlled clinical trials published only up to 2000. Consequently, the findings of these reviews serve as a starting point and require integration with more recent studies.

Holder and colleagues (1991) derived an evidence index based on the ratio of positive (i.e., a significant and favorable treatment effect on one or more outcome variables) and negative trials of common psychosocial treatment modalities for alcohol use disorders. This approach was criticized for not taking into account variability in either the methodological quality of trials or the strength of the competition to which various treatment modalities had been compared (Howard, 1993). Accordingly, Finney and Monahan (1996) adjusted the evidence index of treatment effectiveness by taking into account factors that would make it more or less likely for a study to detect a significant treatment effect (e.g., sample size, number of comparisons conducted; whether continuous or categorical outcomes were examined) as well as information on the strength of the competition against which a given modality had been pitted.

More recent reviews by Miller and colleagues (1998, 2003) went further in addressing these issues by developing sophisticated coding systems to rate studies based on the methodological quality (e.g., the method of allocating participants to groups; rate of attrition). Miller and colleagues (2003) identified a total of 381 controlled clinical trials published through 2000. They calculated a "cumulative evidence score" that ranked specific treatment modalities for alcohol use disorders.

Table 23.1 provides the rankings of 15 psychosocial treatment modalities for alcohol use disorders with three or more controlled trials that were included in each of the four box-score reviews described above. Theoretically related modalities are grouped together and the groups are ordered based on their average rankings across the reviews. Several treatment modalities were consistently highly ranked. For example, even though the study by Holder and colleagues (1991) was criticized for not accounting for methodological quality across studies, the modalities identified as having "good evidence of effect" (i.e., brief motivational counseling, social skills training; stress management training; behavioral self-control training [BSCT]; community reinforcement approach; behavioral marital therapy) were fairly consistent with many of the highly ranked modalities from the other reviews. In addition, Martin and Rehm (2012) recently summarized all systematic reviews of the effectiveness of psychosocial treatment modalities for alcohol problems in adults that have been published since 2000 and observed that the modalities with the strongest empirical support are MET, other brief interventions, and various cognitive-behavioral interventions. These conclusions are generally consistent with the rankings of the box-score reviews, which were based on studies published prior to 2000. Notably, Martin and Rehm (2012) also concluded that, when the modalities with

TABLE 23.1 Rankings by Effectiveness Indices of 15 Psychosocial Treatment Modalities Having Three or More Studies in Holder et al. (1991), Finney and Monahan (1996), Miller et al. (1998), and Miller et al. (2003)

Modality	*Holder et al. (1991)*	*Finney & Monahan (1996)*	*Miller et al. (1998)*	*Miller et al. (2003)*
Motivational				
Brief motivational counseling	3	7	1	1
Cognitive and behavioral				
Social skills training	1	2	2	4
Stress management training	5	5	11	10
Behavioral self-control training	2	10	6	3
Cognitive therapy	9.5	11	7	6
Reinforcement				
Community reinforcement	5.5	1	3	2
Marital and family				
Marital therapy, behavioral	4	3	5	5
Marital therapy, other	8	4	10	11
Aversive conditioning				
Aversion, nausea	12	6	4	8
Aversion, covert sensitization	7	8.5	8	7
Aversion, electric shock	11	8.5	9	9
Other				
Hypnosis	9.5	15	12	12
Confrontational interventions	13	13	12	13
Education (tapes/lectures/films)	14	12	15	15
General counseling	15	14	14	14

Theoretically related modalities are grouped together and the groups are ordered based on consideration of their average rankings across the four reviews. Brief interventions and motivational enhancement therapy (MET) were separated as modalities in Miller et al. (2003), with brief interventions ranking first in effectiveness among the treatment modalities that were reviewed and MET ranking second. The average of these two rankings (1.5) was the highest ranking among the 15 modalities that were included in all four reviews.

the strongest evidence have been compared to one another in well-designed clinical trials, their effectiveness is comparable.

Systematic Reviews of Psychosocial Treatments for Illicit Drug Use Disorders

We are aware of only two systematic reviews of psychosocial interventions for the treatment of illicit drug use disorders (Dutra et al., 2008; Klimas et al., 2013). Dutra and colleagues (2008) examined the effect sizes from 34 "well-controlled" clinical trials for the treatment of cannabis, cocaine, opiates, and polysubstance use, which represented the treatment of 2,340 patients. The psychosocial interventions evaluated included CM, relapse prevention, cognitive-behavioral therapy (CBT), and treatments that combined CBT and CM. The strongest effect sizes were found for CM interventions, either in

combination with CBT (1.02) or alone (0.58), followed by relapse prevention (0.32) and CBT alone (0.28). However, the effect sizes for the specific treatment modalities were not significantly different from one another.

Given the relative dearth of research on the outcome of treatment for illicit drug use disorders, the findings by Dutra and colleagues (2008) are informative; however, there are a number of limitations to this review. Most notably, there was substantial variability in the control conditions to which the target psychosocial interventions were compared. Lacking a somewhat standard control condition makes it difficult to judge the relative efficacy of the target treatment types. Further, two empirically supported psychosocial treatment modalities—MET and TSF—were used only as control conditions and no effect sizes were reported that compared these interventions to any of the target conditions. Klimas and colleagues (2013) conducted a systematic review of psychosocial interventions to reduce drinking among individuals with concurrent problems with alcohol and illicit drug use. However, this review was limited by the paucity of the data (only four studies were identified) as well as the lack of methodological rigor of the studies.

Overviews of Effective Psychosocial Treatment Modalities

Their limitations aside, these reviews suggest that the modalities with the most support for the treatment of SUDs are motivational interventions (e.g., MET; brief motivational counseling), cognitive-behavioral interventions (e.g., social skills training; self-control training), CM, the community reinforcement approach (CRA), and behaviorally oriented couples and family therapy. Notably, these modalities have been most consistently recommended for the treatment of SUDs by a number of organizations including (but not limited to) the American Psychological Association (2013), the U.S. National Institute on Drug Abuse (NIDA, 2012), and the U.S. Department of Veterans Affairs/Department of Defense (VA/DoD) clinical practice guidelines (2009). In addition, randomized trials now provide support for TSF, which combines social environment changes with cognitive and behavioral elements. Finally, brief interventions, which are distinct from brief motivational counseling and MET, were found to have the highest effectiveness score among alcohol treatment modalities with three or more studies (Miller et al., 2003).

In the sections to follow, we review each of these treatment modalities and highlight the findings of meta-analyses when available or, in lieu of meta-analyses, the most recent type 1 (e.g., random assignment to treatment conditions; adequate statistical power) and type 2 randomized controlled studies (i.e., those that did not include one or more criteria of a type 1 study but were deemed to be of adequate methodological quality overall). We highlight studies that provide new process or outcome data on these modalities.

Cognitive-Behavioral Treatments

Broadly, CBT includes a number of interventions that target intrapersonal and interpersonal triggers for relapse via functional analysis of substance use, provide coping skills and alcohol and/or drug-refusal skills training, and increase non-use-related activities. For the sake of consistency with other reviews (Magill & Ray, 2009; Martin & Rehm, 2012), we use the term "cognitive-behavioral" to describe treatment modalities that use any of these strategies. However, it should be noted that interventions with a more cognitive focus (e.g., relapse prevention) have less support than interventions that are more behavioral or skills-focused (Miller et al., 2003).

As Table 23.1 suggests, the most highly ranked cognitive-behavioral intervention is social skills training. In this approach, patients learn how to initiate social interactions, express their thoughts and feelings more effectively, and cope with high-risk social situations and interpersonal difficulties (e.g., how to respond appropriately to criticism from others or refuse offers of drugs or alcohol). Treatment is typically in a group format to facilitate role-playing, social modeling, and receipt of feedback and is effective as either a stand-alone treatment (Eriksen, Bjornstad, & Gotestam, 1986; Monti, Gulliver, & Myers, 1994) or when combined with coping skills training (Monti et al., 1997; Monti & O'Leary, 1999).

We did not find any meta-analyses on the efficacy of social skills training per se for the treatment of SUDs; however, we did identify two meta-analyses of randomized trials of CBT for SUDs. Walters (2000) reviewed 17 trials of BSCT published between 1984 and 1997. BSCT (or "behavioral self-management training")

teaches patients social and coping skills but focuses on moderation rather than abstinence and teaches patients to set limits to drinking and self-monitor drinking habits. Walters (2000) detected a moderate effect size (0.33) across studies on measures of alcohol consumption and drinking-related problems. These effects were superior to no-treatment controls and other non-abstinence-oriented interventions. Effects were larger for BSCT relative to abstinence-oriented interventions, although not significantly so, perhaps due to the small number of trials comparing BSCT with an abstinence-oriented intervention (n = 6). In the other meta-analysis, Magill and Ray (2009) reviewed 53 RCTs of CBT (i.e., cognitive-behavioral, relapse prevention, or coping skills training) among adults diagnosed with either an alcohol use disorder or an illicit drug use disorder (total N = 9,308). A small, albeit significant, effect was observed across diverse comparison conditions, including active control comparisons (0.15). However, CBT had a large effect size (0.80) relative to no-treatment control conditions. Across studies, effects were reduced at 6 and 9 months and markedly diminished at 12 months after treatment. It is worth noting that, in this review, more cognitively oriented interventions (e.g., relapse prevention) were combined with skills-focused interventions, despite the fact that the latter have shown more empirical support (Miller et al., 2003).

Motivational Interviewing/Motivational Enhancement Therapy

Brief interventions drawing on the principles of MI (Miller & Rollnick, 2002) have strong empirical support as a treatment for SUDs, particularly alcohol use disorders. However, not all brief interventions are based on MI principles. Specifically, non-MI-based brief interventions commonly used in medical settings were regarded as a distinct treatment modality in the most recent box-score review (Miller et al., 2003). Accordingly, we review the evidence-base for "brief interventions" in a subsequent section.

MI seeks to evoke and reinforce the client's motivation for change. MI uses a client-centered approach and assumes that clients have the personal resources to change. However, it is also a directive intervention that assumes that assistance from a therapist in the context of an egalitarian relationship with the client will maximize the chances of positive behavior change, whereas a confrontational approach will impede such change. Key elements of MI include (a) empathy, (b) acceptance, (c) collaborative partnership, (d) compassion, (e) direction, and (f) evocation of client motivation. This approach can incorporate normative feedback using assessments of alcohol and other drug use to provide clients with information about the discrepancy between their level of substance use and that of most other people in the general population. MI is typically delivered in four sessions or less; however, it is defined more by the style or manner of interacting with clients than by a specific number of treatment episodes. For example, it can be used as a stand-alone intervention or as a brief intervention to increase a patient's engagement in therapy prior to the initiation of a more extended treatment modality. An important aspect of MI is its emphasis on the individual's current motivation for change in each session. Forcing discussions about ambivalence with clients who are committed to change has been shown to be counterproductive (Ashton, 2005).

Several meta-analyses have been conducted on MI (e.g., Burke, Arkowitz, & Menchola, 2003; Dunn, DeRoo, & Rivara, 2001; Rubak, Sandbaek, Lauritzen & Christensen, 2005). Rubak and colleagues (2005) found that MI had reduced the amount of alcohol consumed and the resultant blood alcohol concentration. Looking across a number of problem behaviors, they also noted that the effect of MI increased at follow-ups of 1 year or more, and that two or more sessions increased the effectiveness. Hettema, Steele, and Miller (2005) reported a significant, large effect size of MI (0.77) in the short term (i.e., 1 month or less) relative to a range of comparison conditions. This effect decreased but was still in the moderate range (0.30) at follow-up time points up to 1 year. Across all follow-up points, effects sizes were comparable for studies of alcohol (0.26) and drug (0.29) abuse. Further, treatment effect sizes were largest when MI was included at the outset of an existing treatment program, suggesting that it may be most effective as an engagement strategy or adjunct to other treatments. In another meta-analysis of MI across 18 studies (Vasilaki, Hosier, & Cox, 2006), the effect size was large (0.60) at 3 months or less; among a subset of studies (n = 9) that compared MI to an active treatment condition, the effect size was moderate (0.43).

MET is a four-session intervention based on the principles of MI and normative assessment feedback. In Project MATCH, more than 1,700 individuals

with an alcohol use disorder were randomly assigned to receive four sessions of MET, 12 sessions of CBT, or 12 sessions of TSF over a 12-week period. MET was found to be as efficacious as the other two more intensive treatments on the primary outcomes of drinks per drinking day and percent days abstinence (Project MATCH Research Group, 1997). These findings align with those from a large randomized trial of individuals with alcohol problems from the United Kingdom, which found three sessions of MET to be as effective as nine sessions of social behavior and network therapy (akin to CRA-based approaches) on drinking outcomes at a 12-month follow-up (UKATT Research Team, 2005). Regarding long-term efficacy, Adamson and Sellman (2008) reported comparable rates of heavy drinking 5 years after treatment among patients from a randomized trial who received MET or one of two control conditions (nondirective reflective listening; no further counseling); however, this finding reflected the fact that patients in the control conditions had caught up to the earlier drinking gains of the MET patients.

A few recent studies have begun to identify the effective components of MI-based interventions. Individuals with substance use problems are more likely to overestimate the amount of alcohol and drugs that other people use. The normative feedback element of MET is thought to cause a reduction in substance use by correcting the client's normative beliefs about drug and alcohol use. Using a randomized design, Martens and colleagues (2013) evaluated the efficacy of two single components of a brief, in-person MI-based intervention—personalized normative feedback and protective behavioral strategies feedback—among at-risk college-student drinkers. Relative to individuals in the protective behavioral strategies feedback condition and an alcohol education condition, those in the personalized normative feedback condition were more likely to reduce their drinking at a 6-month follow-up, and these effects were mediated statistically by changes in the clients' perceived norms about drinking at the 1-month follow-up. The benefits of personalized feedback were also supported in a meta-analysis of individual-level interventions to reduce drinking among college students (Carey et al., 2007). Thus, personalized normative feedback appears to be a key component of MET. However, most of this research has been focused on college students, so generalization beyond this population is necessarily limited.

Contingency Management

In CM-based approaches, behaviors indicating better substance use outcomes (e.g., drug-free urine screenings) are reinforced by providing patients with prizes or other incentives (e.g., vouchers with monetary value that can be exchanged for goods and services). For voucher-based reinforcement, the value of these incentives typically increases gradually with each drug-free urine analysis. The reinforcement schedules in CM are usually limited to the time in which patients are in treatment, with the majority of extant CM trials using a 12-week reinforcement schedule.

The efficacy of CM—particularly for drug use disorders and as an adjunct to other treatment programs—is supported by multiple meta-analytic reviews of randomized trials. Lussier and colleagues (2006) examined 30 randomized trials of voucher-based CM for individuals with SUDs. They concluded that CM was superior to a range of control conditions on abstinence outcomes, and that effect sizes were largest for higher-value vouchers delivered immediately after a patient met a contingency (e.g., drug-free urine analysis). Similar conclusions were reached in a meta-analytic review by Prendergast and colleagues (2006), which was not limited to trials using voucher-based reinforcement. A subsequent trial by Petry and colleagues (2007) concluded that prize- and voucher-based reinforcements (relative to standard treatment) were equally effective in achieving abstinence among outpatients who were dependent on cocaine (see also Petry & Roll, 2011). In addition, the effectiveness of CM has been demonstrated in multisite trials in the community (Petry, Alessi, & Ledgerwood, 2012), and the U.S. Department of Veterans Affairs (Hagedorn et al., 2013).

An ongoing issue in the CM literature is the efficacy of the intervention after the end of treatment. Specifically, the outcomes of most CM trials have been assessed during or at the end of the intervention (Prendergast et al., 2006), and multiple randomized trials have not found CM to maintain abstinence after reinforcements have ended (e.g., Kirby et al. 2013). However, combining CM with other effective treatment modalities such as CBT (Budney, Moore, Rocha, & Higgins, 2006; Carroll et al., 2012) or CRA (Litt et al., 2007) can lead to better long-term substance use outcomes.

Community Reinforcement Approach

CRA is a comprehensive behavioral treatment package that employs social, recreational, vocational, and familial incentives to alter the environment of individuals with SUDs. The goal is to help these individuals adopt a pleasurable and sober lifestyle that is more rewarding than, and can compete with, a lifestyle marked by alcohol and drug use (Hunt & Azrin, 1973). Basic CRA includes (a) a functional analysis to identify internal and external triggers for using substances and explore the negative and positive consequences of use; (b) a therapist–client agreement to sample time-limited periods of abstinence; (c) behavioral skills training to help clients develop problem-solving, communication, and drink-refusal skills; (d) vocational skills training; (e) social and recreational counseling to identify new sources of pleasurable activity; and (f) relapse prevention to help clients identify high-risk situations for using and how to anticipate and cope with these situations. Relationship counseling and other approaches that employ the assistance of significant family members are also incorporated in some forms of CRA (e.g., Community Reinforcement And Family Training [CRAFT]). The key emphasis of CRA-based interventions is on the development of a supportive social network and the promotion of rewarding activities that can substitute for substance use.

CRA-based interventions are among the more highly ranked psychosocial modalities for the treatment of SUDs, with their efficacy/effectiveness supported by multiple randomized trials and systematic reviews (e.g., Meyers, Roozen, & Smith, 2011; Roozen et al., 2004). Most recently, a trial of CRA found individuals randomized to a "network support" condition (vs. network support plus CM or case management) yielded 20% more days of abstinence at 27 months after treatment (Litt, Kadden, Kabela-Cormier, & Petry, 2009). Other trials, however, have not identified advantages of CRA compared to other active interventions such as MET (UKATT Research Team, 2005).

Higgins and colleagues (2003) developed a model of CRA that includes a CM component, and several trials have shown that CRA plus voucher-based CM predicts better substance use outcomes than vouchers alone for a range of substance-abusing populations (Bickel et al., 2008; Budney et al, 2006; Garcia-Rodriguez et al., 2009). Finally, CRAFT was designed to engage treatment-resistant individuals with SUDs into treatment by working through family members (e.g., showing concerned significant others how to change the home environment to reward behaviors that promote sobriety and withhold rewards when the individual uses alcohol or drugs; Meyers et al., 1998). Several randomized trials have shown that this approach improves outpatient treatment engagement among initially unmotivated drug users (Meyers et al., 2002; Miller, Meyers, & Tonigan, 1999).

Behavioral Couples and Family Therapy

Behavioral Couples Therapy and other family-based therapies involve the active participation of the spouse or partner of an individual with SUDs to effect change in his or her drinking behavior. These interventions often begin with an assessment of the patient's drinking behavior as well as the relationship between the patient and the spouse/partner. The interventions address drinking through the use of behavioral contracts and agreements, while other components assist couples in improving their relationship and resolving conflicts by enhancing communication skills, encouraging more positive exchanges and caring behaviors, and planning joint recreational activities.

Multiple randomized trials and reviews support the efficacy of these interventions to improve substance use, relationship, child psychosocial, and partner violence outcomes (McCrady, Epstein, Cook, Jensen, & Hildebrandt, 2009; Vedel, Emmelkamp, & Schippers, 2008). A trial of women with alcohol use disorders compared Behavioral Couples Therapy to individual behavioral therapy and found that the women assigned to Behavioral Couples Therapy had significantly greater improvements in percent days abstinent during treatment and at 12 months after treatment (McCrady et al., 2009). In addition, a meta-analysis of 12 randomized trials (total $n = 754$) found moderate to large effect sizes for Behavioral Couples Therapy (relative to individual-based treatments) on a range of drinking and relationship outcomes (Powers et al., 2008).

12-Step Facilitation

TSF is based on the principles of Alcoholics Anonymous (AA) and the "disease model" of addiction. This model assumes that alcohol dependence is

a chronic disease and requires a lifelong commitment to abstinence. In AA and other 12-step mutual-help groups, the goals are for participants to reduce denial over their alcohol and drug use, accept that they are powerless over the substance use, and surrender control to a "higher power." Ongoing involvement in mutual-help groups after abstinence is achieved is a central tenet of the 12-step model, and multiple studies have found greater mutual-help group attendance to be linked to a greater likelihood of long-term abstinence (e.g., Witbrodt et al., 2012). Despite these benefits, most individuals who attend mutual-help groups as part of their treatment for alcohol dependence discontinue involvement in these groups at the end of their designated treatment period (Kaskutas et al., 2005).

TSF is a highly structured and manual-based approach developed to enhance ongoing involvement in 12-step mutual-help groups. Used either as a stand-alone or adjunctive intervention, TSF involves introducing clients to the principles of the 12-step model, providing clients with information on 12-step groups in their area, and encouraging clients to set goals for 12-step meeting attendance and involvement. Although the long-term goal of this intervention is abstinence, TSF is more directly aimed at encouraging client commitment to, and participation in, 12-step groups. To this end, clients attend weekly sessions in which they are asked about their drinking habits and 12-step meeting attendance and participation and are provided with AA or Narcotics Anonymous literature applicable to the step they have reached.

The efficacy of TSF is somewhat controversial. TSF was not included in several early box-score reviews (Finney & Monahan, 1996; Holder et al., 1991) and was ranked relatively low among the treatment modalities in the Mesa Grande database (Miller & Wilbourne, 2002). For example, Miller and colleagues (2003) noted that, in five out of the six studies they identified, TSF was no more effective than comparison modalities (see also Ferri et al., 2006). However, as noted by Miller and colleagues (2003), the comparison modalities in trials of TSF have typically been well-supported treatments for SUDs (e.g., CBT); thus, TSF has faced stiffer competition than many other psychosocial treatment modalities.

In their systematic review of psychosocial treatments for alcohol problems, Martin and Rehm (2012) highlighted two large, well-designed trials that suggest that TSF is more effective than its low ranking in the Mesa Grande database suggested. First, in a large, naturalistic, multisite study of inpatients from SUD treatment programs in the U.S. Department of Veterans Affairs that were either in TSF- or CBT-oriented programs, or a mixture of the two, no differences were found among the three groups on 9 of 11 outcome variables at a 1-year follow-up (Ouimette, Finney, & Moos, 1997). Further, patients in TSF-oriented programs were significantly more likely than those in CBT-oriented programs to abstain from alcohol or drugs in the 3 months prior to the follow-up, and additional analyses suggested that this effect was mediated by patients' involvement in 12-step groups (Humphreys, Huebsch, Finney, & Moos, 1999). Second, in Project MATCH, no differences emerged among TSF, CBT, or MET groups on the primary outcomes of drinks per drinking day and percent days abstinent at 1- and 3-year follow-up assessments (Project MATCH Research Group, 1998a, 1998b). Collectively, these findings, as well as those of other randomized trials (e.g., Brown, Seraganian, Tremblay, & Annis, 2002), suggest that the efficacy of TSF may be at least as strong as cognitive-behavioral interventions in the treatment of SUDs.

As with many treatment modalities, the effectiveness of TSF is dependent on the intensity of the intervention. Timko and DeBenedetti (2007) conducted an RCT comparing intensive TSF (i.e., in addition to standard TSF, counselors actively arranged AA meeting attendance and encouraged participants to keep an AA attendance journal) versus standard TSF (i.e., participants were provided psychoeducation, given an AA schedule, and only encouraged to attend sessions). At a 12-month follow-up, patients in the intensive TSF condition reported greater 12-step meeting attendance and involvement than those in the standard TSF condition, which in turn predicted significantly lower alcohol and drug use (see also Donovan et al., 2013, regarding the efficacy of a TSF-based intervention for stimulant abusers).

Brief Interventions

Due to their practicality and efficacy, brief interventions have surged in popularity over the last decade. This is particularly true in health care settings where medical providers are often constrained by lack of time. Brief interventions range from a single 5-minute

session to three or four 30-minute sessions. Moreover, the content of brief interventions can vary considerably, from simply advising patients to reduce their drinking and drug use to norm-referenced feedback and brief lifestyle counseling (Jonas et al., 2012; Kaner et al., 2013). The FRAMES model (Miller & Sanchez, 1993) outlines six elements that are common components of empirically supported brief interventions: giving *f*eedback on the risks and consequences of substance use; emphasizing personal *r*esponsibility to change substance use; giving concrete *a*dvice on how to modify substance use; offering a *m*enu of different change options; using an *e*mpathic and nonjudgmental therapeutic style; and increasing patients' *s*elf-efficacy to change their pattern of use. These components and, accordingly, many brief interventions are guided by MI principles. However, one recent study, which analyzed data from three RCTs of brief alcohol interventions, did not find consistent evidence that the therapist's "MI spirit" was related to drinking outcomes (Bertholet, Palfai, Gaume, Daeppen, & Saitz, 2013).

Multiple reviews of type 1 and type 2 trials have concluded that brief interventions are more efficacious than no treatment for individuals with mild to moderate drinking problems, are as efficacious as more intensive interventions, and are feasible and effective in medical settings (Bien, Miller, & Tonigan, 1993; Madras et al., 2009; Miller et al., 2003; Wilk et al., 1997), particularly primary care (Kaner et al., 2013; Moyer et al., 2002). The definition of "brief" (either in terms of number of sessions or the overall length of the intervention) is not uniform across studies. However, effectiveness may be more dependent on multiple contacts than the length of individual sessions (Jonas et al., 2012). Moreover, participants assigned to brief interventions sometimes received other treatments for hazardous drinking, and most brief interventions have been compared to a no-treatment control and therefore have faced limited competition relative to more intensive treatment modalities, which are typically compared to other active treatments.

Despite these caveats, considerable evidence supports the effectiveness of brief interventions. Accordingly, more recent work has begun to consider the populations and settings best suited for these interventions, and the level or intensity needed to effect positive substance use outcomes. In terms of populations, the efficacy of brief interventions is well established with patients seen in primary care (particularly middle-aged men; O'Donnell et al., 2014) with hazardous alcohol use or mild to moderate alcohol use disorders. These interventions may be less effective with medical inpatients, patients who misuse drugs other than alcohol, or patients who are severely dependent on alcohol or other drugs (Field et al., 2010; Saitz et al., 2007; but see Srisurapanont et al., 2007).

Saitz (2010) reviewed randomized trials of alcohol screening and brief interventions for patients in primary care to determine whether those identified as alcohol dependent exhibited decreases in drinking and alcohol-related problems or increased engagement in the alcohol treatment system. Out of 16 randomized trials, 14 excluded patients with "very heavy" alcohol use or dependence, and the 2 remaining studies (Burge et al., 1997; Chang et al., 1997) offered no evidence of the efficacy of brief interventions over a no-treatment control among alcohol-dependent patients (see also Moyer et al., 2002).

Stepped-care models, which provide more intensive interventions for patients who do not respond to an initial brief intervention, may be a sensible alternative for more severely dependent individuals (Breslin et al., 1997; Sobell & Sobell, 2000). There is mixed evidence for the efficacy of a stepped-care approach for initial nonresponders (Jaehne et al., 2012). However, this may be due to a lack of sufficient power to detect group differences or a lack of differentiation between low- and high-intensity interventions in extant trials. As an exception, one randomized trial found, as hypothesized, that a stepped-care intervention was of comparable effectiveness to a full-care intervention on drinking outcomes but more cost-effective (Bischoff et al., 2008).

In terms of level of intensity, multicomponent brief interventions may be no more effective than simpler, single-component approaches. For example, Kaner and colleagues (2013) conducted an RCT of three brief interventions, each of which built on the previous ones: an informational leaflet control group; 5 minutes of structured brief advice; and 20 minutes of brief lifestyle counseling. All three groups completed the AUDIT (Saunders et al. 1993) and received norm-referenced feedback on their scores. No group differences in AUDIT scores emerged at 6- and 12-month follow-ups, suggesting that adding brief advice or lifestyle counseling did not provide incremental benefit over assessment and feedback.

Consistent with this finding, Holloway and colleagues (2007) found that providing medical inpatients with a self-help booklet was as effective as a 20-minute brief intervention in reducing their drinking. Again, however, these findings may apply primarily to individuals with more mild or moderate alcohol use problems, whereas populations marked by very heavy use or dependence may require a stepped-care approach, or more intensive interventions that include pharmacotherapy (Oslin et al., 2014).

OTHER PSYCHOSOCIAL TREATMENT MODALITIES

As shown in Table 23.1, some of the most common approaches to SUD treatment in the United States (e.g., educational tapes, lectures, books, or films; general counseling; and confrontational interventions) are among the lowest-ranked modalities. General unstructured counseling is also ineffective for the treatment of SUDs and often serves as a control condition in randomized trials. In general, confrontational approaches do not help to engage individuals in SUD treatment or improve substance use outcomes (Moyers & Miller, 2013). However, confrontation may help to engage individuals in treatment if it is delivered by an interpersonally skilled therapist in the context of an empathic and egalitarian relationship (Moyers, Miller, & Hendrickson, 2005).

Milieu therapies, such as therapeutic communities, have a longstanding tradition in the treatment of SUDs (De Leon, 2000). Generally, these approaches are based on a social learning model in which patients hold jobs and other positions of responsibility and are held accountable by their peers and by staff for fulfilling their responsibilities and adhering to program rules and norms. Although a significant positive effect for therapeutic communities relative to control conditions was reported in one meta-analysis (Prendergast et al., 2002), other systematic reviews, including the most recent box-score review (Miller et al., 2003), have either found limited or mixed evidence for effectiveness (Reif et al., 2014) or concluded that these programs were no more effective than other forms of residential treatment (Smith, Gates, & Foxcroft, 2006). In one exception, men with comorbid SUDs and other mental health disorders who were randomly assigned to a modified, 12-month therapeutic community (vs. a comparison group) had significantly greater declines in alcohol and drug use at 12 months after release from prison (Sullivan et al., 2007). The reasons for the differences across reviews are unclear but may be a function of the variability in these interventions in terms of both the target population (e.g., prisoners, seriously mentally ill patients) and setting (e.g., residential, day-treatment centers).

Other treatment modalities not included in the box-score reviews, due to either limited evidence or because they were developed after these reviews, have been gaining prominence in recent years. The Matrix Model is a multimodal treatment program, combining relapse prevention, skills training, facilitation of 12-step mutual-help group involvement, and family systems and educational approaches, to help individuals who abuse stimulants engage in treatment and achieve abstinence (Rawson et al., 1995). This model uses a nonconfrontational approach and is typically delivered in a group format on an outpatient basis, but also includes individual counseling and routine screening of drug use (Obert et al., 2000). NIDA (2012) has cited this approach as an effective treatment for SUDs; however, we are aware of only one randomized trial of this intervention. Among 978 individuals addicted to methamphetamine who were randomly assigned to treatment as usual or a 16-week manual-based form of the Matrix Model, those in the Matrix Model condition stayed in treatment longer, provided more drug-free urine samples, and had longer periods of abstinence during treatment; however, no significant differences were found between these conditions after treatment (Rawson et al., 2004).

Mindfulness-based interventions have received increasing attention over the last decade. Broadly, these interventions, which include mindfulness-based stress reduction and Acceptance and Commitment Therapy (ACT), employ behavioral exercises to help patients increase their awareness of internal and external triggers to substance use. In contrast to avoidance-based coping strategies, the goal is to focus attention on the full experience of internal and external phenomena. Systematic reviews have concluded that these interventions are more effective than control conditions in reducing substance use (Zgierska et al., 2009); however, these reviews identified very few randomized trials and highlighted methodological limitations to these trials (e.g., high dropout rates in the treatment condition).

In a recent trial of ACT, Smout and colleagues (2010) reported no significant differences on

outcomes between adults dependent on methamphetamine who were randomly assigned to ACT or CBT. However, the "competition" in this case (i.e., CBT) is itself an intervention with strong support for the treatment of SUDs. Further, Luoma, Kohlenberg, Hayes, and Fletcher (2012) conducted a randomized trial to test whether a group-based ACT intervention focused on shame improved aftercare attendance and reduced substance use among patients in a residential SUD treatment program. Intent-to-treat analyses indicated that, relative to patients assigned to treatment as usual, those in the ACT condition had greater treatment attendance and fewer days of substance use at a 4-month follow-up. Mindfulness-based interventions, particularly ACT, show promise; however, the limited number of rigorous trials and mixed findings suggest caution and encourage more research on these approaches.

The past decade has also seen a rapid increase in integrated treatments for individuals with both SUDs and other psychiatric disorders. This issue is important, given the high prevalence of comorbid mental health disorders among SUD patients and their relatively poor prognosis (Nunes & Rounsaville, 2006). However, the evidence for effectiveness is mixed, and existing studies are burdened by small samples, inconsistent definitions of comorbidity, and a wide range of populations and treatments (Hunt et al., 2013; Tiet & Mausbach, 2007). Although many of these studies have employed one or more of the empirically supported treatments described here, some interventions were designed specifically as a treatment of SUDs and another mental health condition. For example, Seeking Safety was developed for the treatment of SUDs and comorbid posttraumatic stress disorder (PTSD). However, only a handful of RCTs have been conducted. In a large multisite trial of women with comorbid SUD and PTSD who were treated with either Seeking Safety or an active comparison (a health education group), no significant group differences emerged on substance use outcomes at any of three follow-up assessments (Hien et al., 2009). By contrast, in a trial of U.S. military veterans in an outpatient SUD clinic, those randomized to Seeking Safety (vs. treatment as usual) had greater treatment attendance at the end of the intervention and better drug use outcomes (but not alcohol use or PTSD outcomes) at a 6-month follow-up (Boden et al., 2012).

Finally, due to their low cost and ease of dissemination, computer- and Web-delivered interventions have received increasing attention (Cucciare et al., 2012). These are typically brief interventions with content that is largely CBT-based (e.g., moderation training akin to BSCT; Hester et al., 2009) and/or MI-based (e.g., assessment and personalized feedback; White et al., 2010). Multiple meta-analyses of type 1 and 2 trials have demonstrated the efficacy of computer- and Web-delivered interventions, although most studies have been limited to alcohol use among college students. Across eight trials identified by White and colleagues (2010), medium-sized treatment effects for several distinct drinking outcomes were observed. In their meta-analysis of the efficacy of computer-delivered interventions to reduce drinking among college students, Carey and colleagues (2009) concluded that these interventions show a small, albeit significant, treatment effect when compared to assessment-only conditions and are roughly equivalent to other alcohol-related interventions (e.g., alcohol education). Carey and colleagues (2012) also conducted a meta-analysis to determine the relative efficacy of face-to-face versus computer-delivered interventions for college drinkers. Each mode of delivery had a significant treatment effect relative to controls at short-term follow-ups (<13 weeks); however, direct comparisons conducted in four trials favored face-to-face over computer-based interventions.

These reviews provide support for the delivery of brief interventions for alcohol misuse using Web-based approaches but also suggest some caution given the small effect sizes, the heterogeneity of outcome measures and follow-up periods, and the predominant focus on college-student populations. Further, the efficacy of this mode of delivery may be limited in comparison to face-to-face interventions. On the other hand, some individuals, particularly those in rural settings, may have very limited treatment options, in which case a no-treatment control may be an appropriate comparison condition when evaluating the efficacy of Web-based interventions.

MECHANISMS OF CHANGE UNDERLYING EFFECTIVE TREATMENT MODALITIES

The last decade has seen a marked emphasis on identifying why some psychosocial treatments for SUDs are effective (Kiluk & Carroll, 2013; Longabaugh & Magill, 2011) and others are not. Identifying the "active ingredients" of effective treatments can inform

the development of brief versions of treatments that eliminate ineffective components of more intensive protocols, inform the development of newer, more theoretically anchored treatments, and facilitate implementation of empirically supported treatments into routine care. The bulk of the research literature has been limited to secondary analyses of trial data using mediational models (MacKinnon & Fairchild, 2009).

Focusing on mechanisms of change in MI, a review by Apodaca and Longabaugh (2009) identified 19 studies of MI that provided data on at least one link in a mediational causal model. Client change talk and experience of discrepancy (i.e., discomfort with how one's current behavior diverges from one's goals and values) had positive effects on outcomes. More recently, Morgenstern and colleagues (2012) conducted a trial that experimentally manipulated the active ingredients of MI and similarly concluded that client change talk is a key mediator of the effects of MI.

With respect to CBT, Morgenstern and Longabaugh (2000) reviewed 10 randomized trials that examined possible mediators of the effects of CBT and found little empirical support for any of the proposed mechanisms. However, a more recent analysis found that quality of coping skills acquired, rather than the sheer number of skills, was a significant mediator of the effects of CBT on reduced drug use after treatment (Kiluk et al, 2010). Further, in secondary analyses of data from the COMBINE trial (i.e., combined pharmacotherapy with CBT and/or medication management to treat individuals with alcohol dependence), receipt of drink-refusal training was associated with significantly fewer days of drinking during treatment and 12 months after treatment, and these effects were mediated by changes in self-efficacy (Witkiewitz, Donovan, & Hartzler, 2012).

Relative to the aforementioned modalities, studies attempting to identify the active ingredients of CM and CRA have been limited. However, Lussier and colleagues (2006) reported that improved treatment attendance (see also Hagedorn et al., 2013) and medication compliance may account for the beneficial effects of CM on patient outcomes, and Litt, Kadden, Kabela-Cormier, and Petry (2008) suggested that increased self-efficacy may be a common mechanism of behavior change for CM and treatment modalities. In addition, higher rates of abstinence 2 years after treatment among individuals in a network support intervention (analogous to CRA) was mediated by more AA attendance and involvement and greater self-efficacy and coping skills at 15 months (Litt et al., 2009).

Regarding 12-step approaches, Kelly and colleagues (2009) identified 13 studies that conducted full mediational tests of the effects of 12-step groups. They concluded that these groups help individuals recover from substance use via enhancement of self-efficacy, coping skills, and motivation, and increasing engagement in adaptive social networks (see also Kelly et al., 2011). The above-noted findings of Litt and colleagues (2009) regarding mediators of network support may also apply here, given that this intervention was also partly based on the TSF intervention from Project MATCH.

Although these studies identified significant mediators for many of the effective psychosocial treatments for SUDs, a review of research on the mechanisms of action for MI, CBT, Behavioral Couples Therapy, and TSF provided minimal support for the belief that these treatments work via unique active ingredients (Morgenstern & McKay, 2007). Rather, it has been suggested that the effectiveness of these interventions is driven by common factors that cut across these ostensibly distinct modalities (Finney et al., 1998; Kiluk & Carroll, 2013; Lussier et al., 2006). Common processes may explain the limited evidence for specific mediators of the effects of individual treatment approaches, or for the effectiveness of one modality over others in the treatment of SUDs (Dutra et al., 2008; Martin & Rehm, 2012). A prominent example of this is the Combined Behavioral Intervention from the COMBINE trial (Anton et al., 2006), which demonstrated that MET, CBT, and TSF are not mutually exclusive. A review by Moos (2007) suggested that a select number of social processes that protect against the development of SUDs (i.e., support, goal direction and structure; availability of prosocial activities and rewards to compete with substance use; a focus on abstinence-oriented norms and models; and development of coping skills and increased self-efficacy) may also be active ingredients of effective psychosocial treatments of SUDs.

An alternative conceptualization of mechanisms of change, based on neuroscience research, focuses on the cognitive, affective, and learning processes that underlie changes in substance use among treated individuals. For example, a recent review by Stanger and colleagues (2013) highlights changes in decision

making, such as delay discounting (i.e., shifting the preference for the immediate rewards of drug use to the delayed reward of abstinence), as a key mediator of SUD treatment outcomes, particularly in CM-based approaches. Further, a study of individuals who participated in an RCT of computer-assisted CBT for SUDs, which included functional MRI and neuropsychological testing before and after treatment, suggested that changes in the neural systems involved in cognitive control, impulsivity, and attention may drive the effects of behavioral therapies for SUDs (Devito et al., 2012).

ROLE OF THERAPEUTIC ALLIANCE AND THERAPIST CHARACTERISTICS

As defined by Lebow and colleagues (2006), the therapeutic alliance reflects the collaborative relationship and emotional bond between the patient and therapist, and a shared agreement regarding the specific goals and tasks of treatment. The importance of the therapeutic alliance to SUD treatment outcomes is well established. For example, a stronger working alliance was a significant predictor of better drinking outcomes across all three treatment modalities in Project MATCH. This finding held for both therapist and patient ratings of the alliance in the outpatient arm, and for therapist ratings in the aftercare arm (Connors, Carroll, DiClemente, Longabaugh, & Donovan, 1997). Similar findings have emerged for therapist and patient ratings of alliance in a study of opioid-dependent patients in methadone treatment (Belding, Iguchi, Morral, & McLellan, 1997).

In their review of the literature on therapeutic alliance and substance use outcomes, Meier and colleagues (2005) noted that early therapeutic alliance is a consistent predictor of reduced substance use during treatment, but not of posttreatment outcomes. In this regard, a key mechanism in the alliance–outcome link may be whether an early alliance enhances patients' engagement and retention in treatment. For example, a strong therapeutic alliance early in treatment is associated with a longer length of stay in treatment among patients with a drug use disorder (Simpson, Joe, & Rowan-Szal, 1997), among couples in marital therapy for drinking problems (Raytek, McCrady, Epstein, & Hirsch, 1999), and among emergency department patients with drinking problems (Baird et al., 2007).

A key contributor to the quality of the therapeutic alliance is the interpersonal style of the therapist. Indeed, therapist characteristics have a robust impact on SUD patients' outcomes that may be greater than the impact of any particular treatment modality (Luborsky et al., 1986; Najavits & Weiss, 1994). Several studies have found dramatic variations across therapists with regard to their impact on SUD treatment retention and outcomes (Najavits et al., 2000; Najavits & Weiss, 1994). For example, Najavits and colleagues (2000) found significant therapist differences in four studies of treatment retention, which ranged from 29% to 77%; in one of these studies, the average effect size among therapists on treatment outcomes ranged from 0.13 to 0.74. Further, data from large randomized trials of SUD patients have indicated that therapist variables are primarily responsible for the association between alliance and outcomes (Baldwin, Wampold, & Imel, 2007; Crits-Christoph et al., 2009; see also Laska et al., 2013).

In general, therapist differences are not attributable to level of professional training, years of clinical experience, recovery status, or the characteristics of patients being treated (Lebow et al., 2006; Najavits & Weiss, 1994). Rather, therapists who are more interpersonally skilled and empathic and less confrontational tend to have better outcomes, and in one study these therapist characteristics were associated with greater patient self-efficacy and coping skills acquisition at the end of treatment (Ritter et al., 2002). Importantly, these therapist characteristics are also congruent with the principles of MI, and various studies have concluded that the benefits of MI are maximized by a less directive (Karno & Longabaugh, 2004) and more empathic therapeutic style (Baird et al., 2007). However, all major treatment modalities reviewed here emphasize the importance of a good working alliance between the therapist and patient, and the findings of most studies are consistent across treatment modalities (Lebow et al., 2006; Najavits & Weiss, 1994). Such findings may provide another explanation for why evidence is limited regarding the differential effectiveness across these treatment modalities.

DURATION AND AMOUNT OF TREATMENT

When considering the evidence base for psychosocial treatments for SUDs, it is important to understand

the association between length of stay in residential programs and outcomes and the significance of continuing care for maintaining long-term reductions in substance use.

Length of Stay in Residential Treatment

Residential SUD treatment may be most appropriate for patients with greater substance use severity, significant psychiatric comorbidity, fewer social resources, and lower social competence (Drake et al., 2008; Finney, Moos, & Wilbourne, 2009; Rychtarik et al., 2000; Simpson, Joe, Fletcher, Hubbard, & Anglin, 1999; Tiet et al., 2007). However, the most appropriate length of stay in these programs is an issue of some debate. For example, naturalistic studies have found longer stays in residential SUD treatment programs to be associated with better patient outcomes (Moos & Moos, 1995; Simpson, Joe, & Brown, 1997), whereas type 1 and 2 trials (e.g., McCusker et al., 1997; Nemes, Wish, Messina, 1999) have tended to find that longer residential programs do not offer an incremental benefit over shorter programs (for reviews, see Mattick & Jarvis, 1994; Miller & Hester, 1986). Most recently, Harris and colleagues (2012) examined whether a longer average length of stay in SUD residential treatment programs in the U.S. Department of Veterans Affairs was associated with better substance-related outcomes. Compared to patients who were randomly selected from programs with an average length of stay of less than 90 days, those randomly selected from programs with an average length of stay greater than 90 days had a more extensive history of mental health treatment and were more likely to be homeless, but had fewer severe substance-related problems. Further, in covariate-adjusted analyses to examine outcomes after discharge, patients in programs longer than 90 days improved less on the alcohol composite of the Addiction Severity Index than patients from programs shorter than 90 days.

The discrepancy between naturalistic studies and randomized trials regarding the benefits of longer residential programs may be explained by the fact that, in naturalistic studies, certain patient characteristics are likely associated with better treatment retention (e.g., motivation to change), and that these characteristics (which are equated across groups in randomized trials) rather than the length of treatment itself lead to better outcomes. Alternatively, naturalistic studies may capture the dynamic interaction between patient characteristics and the effects of treatment that occur in real-world clinical settings; that is, patients with certain characteristics may stay in treatment longer and, as a result of receiving more treatment, may experience better outcomes. In any case, the predominantly null findings in randomized trials suggest that assigning patients to a longer planned duration of care, regardless of their level of motivation or other patient characteristics, will not lead to better outcomes. Rather, an individualized approach that considers patient preferences and allows patients to remain in treatment when they choose to and when clinically indicated is likely to lead to better outcomes.

Continuing Care Following Intensive Treatment

As defined by Blodgett and colleagues (2014), continuing care is "a period of less intensive treatment following a more intensive treatment episode" (p. 87), which is used to maintain and reinforce therapeutic gains. Due to the high rate of relapse among SUD patients, particularly within the first year after entering treatment (Jin et al., 1998), continuing care is a standard recommendation in guidelines for the treatment of SUDs (e.g., VA/DoD, 2009). The benefits of continuing care are supported by both naturalistic studies (Moos & Moos, 2003) and randomized trials (Dennis, Scott, & Funk, 2003; Sannibale et al., 2003). Further, in a number of randomized trials, telephone-based continuing care ("telephone monitoring") has been linked to improved outcomes (McKay et al., 2004, 2005, 2011; McKellar et al., 2012).

Three systematic reviews of the efficacy of continuing care have been conducted. First, McKay (2009) used a "box-score" approach to classify and count the number of trials that showed a positive (i.e., at least one significant effect on a primary substance use outcome) or negative (i.e., either no effect or a significant effect favoring the control condition) result for continuing care. A positive result was found in 10 of 20 trials, with positive results generally linked to a longer duration and greater intensity of care, as well as more active efforts to facilitate the delivery of continuing care (McKay et al., 2004, 2005). Similarly, Lenaerts and colleagues (2014) identified 20 trials of continuing care but focused on the 6 they found to be methodologically strong. The four that employed more

active interventions to empower patients seemed to have better drinking-related outcomes.

Blodgett and colleagues (2014) sought to expand upon prior box-score reviews by using meta-analytic techniques to calculate an overall effect size for the efficacy of continuing care and to conduct formal tests of potential moderators of this effect. Thirty-three controlled trials were identified, 19 of which compared continuing care to a no-treatment (or minimal-treatment) condition (total $n = 3{,}542$). In this subset of studies, a significant effect of continuing care was detected at the end of treatment (0.19), with a slightly larger effect at the last follow-up time point after the continuing care period (0.27). In terms of moderators, studies with longer planned durations of care or more sessions per week were not associated with a larger effect of continuing care at the end of treatment or at the last follow-up. CBT fared significantly better than other therapeutic modalities, although only in relation to a no-treatment control group. Studies using contracting, prompting, and social reinforcement to increase engagement in continuing care (e.g., Lash et al., 2007) did not demonstrate significantly larger effects than less active interventions; however, there was very little power to detect such effects, given the small number of such studies ($n = 3$). In addition, effect sizes in studies in which continuing care was delivered via telephone versus in-person did not differ, although it should be noted that the former approach is more cost-effective.

The findings of Blodgett and colleagues (2014) support the use of continuing care to facilitate and maintain recovery in patients with SUDs, although with some caveats. The overall effect of continuing care was relatively small and somewhat less impressive than the findings from naturalistic studies. However, this must be balanced with consideration of the advantages of naturalistic studies in terms of more accurately portraying real-world clinical settings. Further, in most studies, the amount of informal (e.g., mutual-help groups) or formal SUD care received by patients outside of the study was unclear, and in many cases participants assigned to a "no-treatment" control condition were given referrals to outside SUD care providers and mutual-help groups, which may have diluted the treatment effects for the continuing care conditions. Overall, the evidence supports an individualized approach to the provision of continuing care that relies primarily on cost-effective interventions (e.g., telephone monitoring) and considers a client's motivation, current functioning, and other resources and risk factors for relapse—all of which can be monitored through repeated assessments with validated instruments (i.e., measurement-based care; Cacciola et al., 2013; McKay, Drapkin, Goodman, & DePhilippis, 2009).

TREATMENT SETTING AND FORMAT

Due to their differences in cost, the relative effectiveness of residential and outpatient SUD treatment has been the focus of intense, but not rigorous, study (Reif et al., 2014). Finney, Hahn, and Moos (1996) conducted a box-score review of type 1 and 2 studies comparing the effectiveness of residential versus outpatient alcohol treatment. Five of 14 studies found a significant difference favoring residential care on one or more drinking outcomes, and in two other studies, day treatment was found to be superior to residential treatment. The remaining seven studies found no difference in patients' drinking outcomes as a function of setting. A meta-analysis of these studies by Finney and Moos (1996) detected a small, albeit significant, effect size at 3-month follow-ups that favored residential treatment settings; however, this effect was nonsignificant at 6- and 12-month follow-ups. Other randomized trials have observed few significant differences on drinking outcomes between patients assigned to residential versus outpatient SUD treatment (Greenwood, Woods, Guydish, & Bein, 2001; Guydish et al., 1999; Rychtarik et al., 2000; for a review, see McCarty et al., 2014) or between those assigned to day hospital versus residential programs (Witbrodt et al., 2007).

Importantly, individuals with greater SUD severity who are clinically judged to be in need of more intensive care cannot ethically be randomized to residential or outpatient treatment settings. Consequently, most studies have focused on patients who are less severely impaired and thus eligible for treatment in either setting. To address this issue, Finney and colleagues (1996) recommended a focus on large, multisite naturalistic studies to examine the relative efficacy of matching patients with greater substance use severity to more intensive residential treatment settings. In this vein, the American Society of Addiction Medicine has developed Patient Placement Criteria (Mee-Lee, 2013) to match patients to one of five levels of care: (a) early

intervention; (b) outpatient; (c) intensive outpatient/partial hospitalization; (d) residential/inpatient; and (e) medically managed inpatient treatment. Patients are matched on level of care based on ratings along six dimensions (acute intoxication or withdrawal potential; biomedical issues; emotional-behavioral issues; readiness for change; potential for relapse; and recovery environment).

Although the conceptual rationale for using these criteria appears compelling, they have received only limited empirical support (Finney, Moos, & Wilbourne, 2009; Magura et al., 2003). However, studies of patient/setting matching that did not specifically use—but were consistent with—these criteria suggest that more severely impaired patients (i.e., greater substance use severity, psychiatric severity, cognitive impairment; fewer social resources) tend to have significantly better outcomes if treated in residential settings (McKay et al., 2002; Rychtarik et al., 2000; Simpson et al., 1999; Tiet et al., 2007). Thus, a range of studies has demonstrated the value of matching patients to residential or outpatient care by considering their substance use severity, medical and psychiatric comorbidity and severity, level of cognitive functioning, and social resources and recovery environment.

Another important issue, particularly from the standpoint of cost, is the relative effectiveness of group versus individual treatment. The majority of psychosocial treatments for SUDs have used group therapy as the primary mode of delivery (Walters, Ogle, & Martin, 2002), although the efficacy of this approach relative to individual therapy has been tested in only a handful of studies. In a review by Weiss and colleagues (2004), four randomized trials were identified that focused on a specific treatment modality. In all four studies, the primary substance use outcomes showed significant reductions as a function of treatment, but the outcomes did not differ between group and individual formats. (Of note, it is unclear whether these studies accounted for the clustering of patients within groups in the analyses; see Morgan-Lopez, Cluff, & Fals-Stewart, 2009.) In addition, a recent trial of a CBT-based MI intervention found significant reductions in patients' substance use outcomes during treatment and at a 12-month follow-up, but no significant differences between the group and individual conditions in the outcomes at either time point (Sobell et al., 2009). From a cost containment standpoint, these findings suggest that health care systems may obtain the most "bang for their buck" by providing SUD treatment in a group format.

MATCHING PATIENTS TO PSYCHOSOCIAL TREATMENT MODALITIES

There is some support for matching patients with SUDs to specific psychosocial treatment modalities to maximize the effectiveness of treatment. For example, patients with chronic SUDs marked by severe psychiatric comorbidity responded better to highly structured CBT-based approaches (Rosenblum et al., 2005), whereas those with less psychiatric severity and more adaptive coping styles fared better with less structured and more facilitative interventions (Gottheil et al., 2002). Other work has suggested that patients with fewer social or personal resources improve more when they receive treatments that explicitly target those deficits. For example, relative to patients with more support from family or friends (e.g., married patients), those with an underdeveloped social support network benefit more from CRA-based approaches, which aim to augment patients' support networks (Azrin, Sisson, Meyers, & Godley, 1982). Further, CBT may be better suited than MI for patients who have trouble expressing their feelings (Rosenblum et al., 2005). However, CBT requires a moderate level of cognitive functioning, and some evidence suggests that individuals with cognitive impairments benefit less from coping skills training due to difficulties in learning and recalling new information (Maude-Griffin et al., 1998; Smith & McCrady, 1991).

Their promise notwithstanding, it is important to note that the findings of these studies were based largely on exploratory analyses. Further, a review of 54 alcohol treatment studies found that 22% of the variance in the number of significant patient/treatment interaction effects could be accounted for by the number of tests of interaction that were conducted (Moyer, Finney, Elworth, & Kraemer, 2001). These limitations emphasize the need for studies designed to test a priori matching hypotheses. To date, three such major studies have been conducted. Most notably, Project MATCH compared patients randomly assigned to CBT, MET, and TSF and tested 16 matching hypotheses that had both theoretical and empirical support. Of a total of 64 contrasts tested, only one was statistically significant (Project MATCH

Research Group, 1997). Similarly, no evidence for matching effects was detected in tests of matching hypotheses in the UKATT study of MET and social network therapy (UKATT Research Team, 2005) or in the VA Effectiveness Study of programs with a CBT and/or TSF orientation (Ouimette et al., 1999).

Although the findings of these multisite trials are not encouraging, limitations in their methodological design suggest that patient/treatment matching effects may still be present. For example, all three treatment modalities in Project MATCH were delivered in an individual format on an outpatient basis and therefore may not have been as distinct as would be preferred in a treatment-matching study. This fact is notable, given the earlier-cited evidence supporting matching patient severity to treatment settings, and other evidence supporting matching supplementary services to other concurrent needs of SUD patients (e.g., social and employment domains; Friedmann et al., 2004; McLellan et al., 1997, 1998). In addition, reexamination of Project MATCH data using growth mixture modeling provided partial support for three a priori matching hypotheses: (1) patients low on self-efficacy at baseline had better posttreatment outcomes if assigned to CBT than MET (Witkiewitz et al., 2007); (2) patients with higher network support for drinking at baseline fared better if assigned to TSF than either CBT or MET (Wu & Witkiewitz, 2008; see also Longabaugh, Wirtz, Zweben, & Stout, 1998); and (3) patients with lower motivation to change at baseline had better outcomes if assigned to MET relative to CBT (Witkiewitz et al., 2010).

More recent secondary analyses also suggest moderate support for some patient/treatment matching effects. For example, several studies by Karno and colleagues (2005a, 2005b, 2009) found significant matching effects based on patients' interpersonal style and therapist characteristics using Project MATCH data. Specifically, patients higher on anger and reactance who had more directive and structured therapists generally had poorer drinking outcomes, whereas those lower in reactance fared better with highly directive therapists. These findings were replicated in a sample of patients dependent on methamphetamine who were randomly assigned to directive and nondirective telephone aftercare (Karno et al., 2012). In addition, a recent study found that adults with SUDs who were depressed and had poor neuropsychological functioning fared better in CBT than TSF groups, possibly because they needed formal structured training to develop and use novel coping skills (Granholm et al., 2011; but see Maude-Griffin et al., 1998; Smith & McCrady, 1991).

LIMITATIONS OF EXISTING RESEARCH

Several limitations must be considered when interpreting the existing research literature. Most importantly, our conclusions regarding the SUD treatment modalities with the most empirical support are based, in part, on the results of box-score reviews, which calculate the proportion of relevant studies that have found a significant treatment effect for a given modality in comparison to some alternative condition. These reviews preceded, and were not designed to meet, the Institute of Medicine's standards of systematic reviews (National Research Council, 2011). For example, they lack a standard treatment condition against which various treatment modalities can be compared (see Finney, 2000). For example, if two highly effective psychosocial treatment modalities are frequently compared to each other, each modality would be deemed "ineffective" using a box-score review approach. Consequently, reliance on only box-score reviews can distort the evidence for the relative efficacy of a given modality (see our earlier discussions regarding TSF).

Statistical and methodological issues also pose challenges. First, variation in statistical power to detect treatment effects can distort the findings of box-score reviews as it may contribute to a null finding in studies with small samples but a statistically significant treatment effect of the same size in a larger study. Notably, Moyer, Finney, and Swearingen (2002) reported that, given the lower power of alcohol treatment trials published from 1970 to 1998, there was, on average, just over a 50-50 chance of detecting a statistically significant, medium-sized treatment effect, assuming one test of an effect. Second, most trials in the SUD treatment literature have examined multiple outcome variables assessed across multiple follow-up points, which increases the risk of type 1 error. This situation is especially problematic in box-score reviews, given that there is rarely a correction for the number of tests conducted; thus, studies that include multiple comparisons may conclude that a given treatment modality is efficacious based on a chance finding. Third, as highlighted by Baldwin, Murray, and Shadish (2005), most studies of SUD treatments administered in a group format have not accounted for violations of the

assumption of independence, which also increases the risk of type 1 error.

Despite their limitations, box-score reviews can reveal important patterns, particularly when (a) they are based on a large number of studies, (b) they address a clear question with reference to participants, interventions, comparisons, outcomes, and study design, and (c) efforts are made to quantify and adjust for the quality of the included study designs. As an alternative to box-score reviews, meta-analyses can provide effect sizes to determine not just the statistical significance of a given study but the overall magnitude of an average treatment effect across studies. Such analyses are less likely to be biased by studies of low power or multiple comparisons and also have the ability to examine moderators of treatment effects to determine the conditions under which a given treatment modality is more or less efficacious. For example, meta-analyses can examine the magnitude of a given modality's treatment effect in comparison to no-treatment controls, as well as other active control conditions (for an example, see Magill & Ray, 2009).

Beyond the limitations of box-score reviews, other factors present challenges to integrating the findings across randomized trials of psychosocial treatments for SUDs. For example, relatively little is known about the representativeness of patients who are enrolled in the existing trials. This is partly due to the fact that most studies do not report the proportion of patients screened who were eventually enrolled into a trial (Gross, Mallory, Heiat, & Krumholz, 2002). Melberg and Humphreys (2010) conducted a systematic review of 98 clinical trials from the drug dependence literature and reported that, on average, 29% of potential subjects were ineligible and an additional 29% refused to participate. These rates were even higher in larger trials, suggesting that the benefits of greater power from such studies may be offset by the possibility of bias in the sample selected. Such bias may be less relevant if the characteristics of patients who enrolled are comparable to those who are ineligible or unwilling to participate. However, only 6% of the studies Melberg and Humphreys (2010) reviewed provided such information, and they tended to lack sufficient power to detect such differences (see also Humphreys et al., 2013).

A related issue is the representativeness of patients who complete follow-up assessments in randomized trials. A recent review of 24 studies found that younger patients were less likely than older patients to be retained in clinical trials (Korte et al., 2011). To address these potential biases, greater transparency is needed about the population from which participants are recruited and how differences in retention at follow-ups across subgroups of participants may affect the interpretation of study findings. Greater adherence to the Consolidated Standards of Reporting Trials (CONSORT; Boutron et al., 2008) is one method to address this issue, as well as appropriate handling of missing data in analyses (Hallgren & Witkiewitz, 2013).

Another limitation is the variability across studies in the outcomes used to determine whether a treatment is efficacious, as well as in the most appropriate methods of assessing these outcomes. A panel of treatment and research experts recently concluded that substance use behavior should ideally be measured by a combination of self-report and biological indicators (e.g., urine analysis). However, the panel also acknowledged that the most appropriate outcome will inevitably vary as a function of a number of variables, including the specific type of intervention and its treatment goals (e.g., abstinence or harm reduction) and that a formal decision process is needed to guide researchers in the selection of the most appropriate primary and secondary outcomes and methods of assessment (Donovan et al., 2012). For clinical trials of alcohol use treatments, some consensus has emerged for use of "percent of subjects with no heavy drinking days" as an efficacy endpoint (Falk et al., 2010).

Finally, better integration of findings across randomized trials of psychosocial treatments for SUDs would be aided greatly by more consistent standards of reporting the findings from trials. The CONSORT was developed precisely for these purposes, and an analysis by Ladd and colleagues (2010) showed that the quality of reporting alcohol treatment outcomes has improved more in studies published in journals that adopted the CONSORT guidelines. Thus, efforts to enforce consistent reporting of the findings of type 1 and 2 SUD treatment trials using these guidelines may help address many of the key issues identified in methodological reviews of this literature.

WHAT WORKS IN SUBSTANCE USE DISORDER TREATMENT

Findings from meta-analyses and type 1 and type 2 RCTs indicate that the most efficacious and

effective psychosocial modalities for treating SUDs are cognitive-behavioral interventions, MI/MET, CM and CRA (particularly when combined), behavioral couples and family therapies, and TSF approaches. Limited evidence is available on the differential effectiveness of these interventions. With the exception of CM, the evidence for effectiveness is stronger for the treatment of alcohol (vs. drug) use disorders (VA/DoD, 2009). Regardless of modality, therapists who are interpersonally skilled, empathic, and less confrontational tend to establish stronger alliances with patients, which in turn lead to better patient outcomes.

These general conclusions are highly congruent with the conclusions reached in the previous version of this chapter, which was published in 2007. This may be due to the fact that systematic comparisons of psychosocial treatments for SUDs are still limited to box-score and qualitative reviews. Future efforts to systematically compare the most common psychosocial treatment modalities should conform to the recommendations of the Institute of Medicine (National Research Council, 2011). In addition, research on mechanisms of change (which has grown considerably since the last version of this chapter) suggests that effective interventions operate more or less through common social processes (i.e., increasing support, goal direction, and structure for patients; increasing engagement in activities and rewards that can substitute for alcohol and drug use; increasing exposure to abstinence-oriented norms and models; and developing patients' coping skills and increasing their self-efficacy). Thus, it may be expected that there will be fewer advances in this area in terms of identifying novel psychosocial treatments that are as effective as (or more so) than existing modalities.

These similar conclusions notwithstanding, there have been a number of important advances in this literature over the past 7 years. First, the evidence base for brief interventions has grown considerably, particularly within primary care. However, as a stand-alone intervention, the efficacy is still limited to the treatment of mild to moderate alcohol use problems; more intensive residential programs are best suited for patients with greater substance use severity, limited social resources, and significant psychiatric and medical comorbidity. Second, there are now a number of meta-analyses to support the efficacy of computer- and Web-delivered interventions. Such interventions will greatly increase the ability to provide care to individuals from rural areas; however, extant studies have been limited to treatment of hazardous drinking among college students. Third, several recent studies indicate that therapist variability is primarily responsible for alliance–outcome associations; this highlights the potential value of increased supervision and monitoring of therapists to maximize treatment outcomes. Fourth, in contrast to earlier literature on duration and amount of care, the most recent work supports an individualized approach marked by variable intensity of continuing care and ongoing monitoring of functioning and risk (i.e., measurement-based care). Fifth, although this chapter focused exclusively on psychosocial treatments for SUDs, the most recent work suggests that these modalities may be limited for individuals with more severe SUDs and should therefore be used in conjunction with pharmacotherapies (Anton et al., 2006; Oslin et al., 2014; VA/DoD, 2009).

Finally, an ongoing challenge for the field is to determine how best to implement efficacious interventions for SUDs into real-world clinical settings so that they are cost-effective; can reach the patient population in most need of the intervention; produce positive outcomes; are adopted by clinical providers; are delivered as intended or adapted in a way that does not compromise the integrity of the treatment; and are integrated into routine practice and maintained over the long term (Glasgow et al., 1999). Examining these issues should help identify factors associated with successful implementation of empirically supported treatments for SUDs (Lash et al., 2011; Manuel, Hagedorn, & Finney, 2011).

ACKNOWLEDGMENTS

Preparation of this revised chapter was supported in part by a Career Development Award-2 from the U.S. Department of Veterans Affairs, Office of Research and Development (Clinical Science Research & Development) to Dr. Blonigen, and by NIAAA Grant 008689 to Dr. Finney. The views expressed are those of the authors and do not necessarily reflect those of the Department of Veterans Affairs, the National Institute on Alcohol Abuse and Alcoholism, or any other U.S. Government entity. We thank Dr. Daniel Kivlahan for his helpful comments.

Psychopharmacological Treatments for Substance Use Disorders

James R. McKay
Henry R. Kranzler
Kyle M. Kampman
Rebecca L. Ashare
Robert A. Schnoll

The treatment of substance use disorders (SUDs) with medications is well established, although most experts agree that, to be successful, pharmacological interventions must be combined with psychosocial therapies. A large number of type 1 and type 2 controlled trials have shown that the use of nicotine replacement therapy (NRT) to induce and maintain smoking cessation significantly increases abstinence rates. Non-nicotine treatments, such as bupropion, which is also an antidepressant, and varenicline, have been found in controlled trials to significantly increase smoking abstinence rates measured at intervals up to 12 months after the beginning of treatment. The treatment of alcohol use disorder can now be enhanced by three approved medications that are based on different mechanisms of action: disulfiram, an aversive agent that works when adherence is assured; naltrexone, which reduces alcohol reward via the endogenous opioid system and results in decreased alcohol craving and reduced heavy drinking; and acamprosate, which reduces post-alcohol excitability and has been effective in European trials but not in U.S. or Australian trials. A long-acting version of naltrexone has been approved by the U.S. Food and Drug Administration (FDA) to treat alcohol and opiate dependence. It provides therapeutic blood levels for at least 30 days and may improve adherence, which is an important consideration in the treatment of SUDs. Methadone maintenance treatment has consistently shown efficacy in the treatment of opioid dependence, and the partial opioid agonist buprenorphine has substantially expanded the options for treating the disorder. Buprenorphine is available to treat opioid addiction by qualified physicians in their offices rather than being dispensed only in a highly regulated treatment program, as is required for methadone. There are as yet no FDA-approved medications to treat addiction to stimulants, which include cocaine and methamphetamine. Although double-blind, placebo-controlled clinical trials of several medications have provided initial evidence of efficacy to treat cocaine use disorder, they have not yet been shown in multisite trials to be efficacious.

INTRODUCTION

SUDs affect virtually every sector of society. As a group they are among the most common of all mental disorders. Household surveys have found a lifetime prevalence rate of 15% to 18% and a 12-month prevalence rate of 9% (Cohen, Feinn, Arias, & Kranzler, 2007; Grant et al., 2004; Kessler et al., 2005). These rates do not include nicotine addiction, one of the most devastating and difficult to treat of all the addictive disorders. Although rates of cigarette smoking in the United States have declined, smokers unable to quit on their own are among the most difficult patients presenting for treatment. Many individuals have multiple addictions; for example, alcoholics frequently are addicted to both cocaine and nicotine. There is also a good deal of overlap with other mental disorders such as anxiety and mood disorders.

There are common properties among the disorders produced by the major drugs of abuse, but there are also important differences, particularly in treatment approaches. Thus, a chapter on treatment of SUDs must consist of four distinct reviews focusing on the major drugs or drug categories: nicotine, alcohol, stimulants (cocaine, methamphetamine), and opioids (heroin and prescription opioids). Other drugs, such as cannabinoids, hallucinogens, Ecstasy, and minor tranquilizers, may also be abused, but they account for a relatively small proportion of patients needing treatment, and there are no effective medications currently available.

The features that define SUDs include compulsive use of the substance despite interference with normal activities and adverse effects on health. The recent publication of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*; American Psychiatric Association, 2013) reflects a substantial modification in the diagnosis of SUDs. In contrast to *DSM-IV*, *DSM-5* does not differentiate between abuse and dependence. Rather, based on findings that the *DSM-IV* abuse criteria aggregate with the criteria for dependence, *DSM-5* SUD criteria incorporate both abuse and dependence criteria. Specifically, there are 11 criteria: three of the four *DSM-IV* abuse criteria (legal problems having been omitted due to low frequency of endorsement), seven dependence criteria, and craving. Mild SUD is present when two or three criteria are met in a 12-month period; moderate SUD is diagnosed when four or five criteria are present; and the diagnosis of severe dependence is made when 6 to 11 criteria are met.

SUCCESS OF TREATMENT

In this chapter we define successful treatment as significant reductions in substance use and negative consequences of use, along with improvement in the ability to function according to one's societal role. Total abstinence from the addictive substance is often the accepted goal of treatment, but this is not often achieved. In the case of opioid addiction, transfer to a stable maintenance medication, albeit pharmacologically similar in many ways to heroin, is considered successful treatment provided that the person can refrain from socially and personally harmful behavior. This definition of success is commonly used for other chronic disorders such as arthritis or diabetes; it therefore is a pragmatic and medically acceptable definition based on functional capacity.

DETOXIFICATION

Detoxification is simply the removal of a drug from the body. This usually occurs because of metabolism by the liver and excretion via the kidneys. If the intake of the drug is gradually decreased, detoxification can be accomplished with little risk or discomfort as the body adapts to the absence of the drug. Detoxification is often confused with treatment, but in reality detoxification is, at best, the first step in treatment. Detoxification from sedatives such as alcohol can be dangerous because of medical complications during withdrawal, but these are readily treated in any medical facility and in the vast majority of cases on an outpatient basis. Treatment of the addiction involves a process of rehabilitation to reduce the probability of relapse and lengthen the time that the person is no longer using the drug of abuse. There is no evidence that rapid detoxification under general anesthesia is any more effective in the long term than less heroic and expensive means. Although some interesting research has been done on novel ways to achieve detoxification, for the purposes of this chapter we will emphasize long-term, relapse prevention or harm reduction treatment.

PSYCHOACTIVE AGENTS IN THE TREATMENT OF ADDICTION

One might reasonably ask whether medications are ever justified in the treatment of a disorder that involves excessive use of drugs. Although there is controversy about this on philosophical grounds, empirical studies clearly show the benefits of medications when they are indicated. In addition to the treatment of the addictive disorder itself, psychoactive medications are often indicated to treat accompanying psychiatric disorders. One school of thought that had many proponents in the past was that addicts were all more or less alike and all had to be treated by "getting at the underlying problem" and insisting on strict freedom from all drugs. In that earlier era, nicotine and caffeine were not usually thought of as drugs, but all psychoactive medications prescribed by physicians were avoided. Subsequent data, however, have demonstrated that all addicts are not alike. Even within a single drug category such as alcohol, dependent individuals have different needs that require different kinds of treatment. Heredity also has a major influence on the risk of addiction, and data indicate that treatment response is also influenced by genetic variation (Johnson et al., 2011, Kranzler et al., 2014; Oslin et al., 2003). The concept of patient/treatment matching, now referred to as personalized medicine, has become popular despite a relative paucity of replicated, empirical findings.

NICOTINE DEPENDENCE

Cessation of smoking may be very difficult even for smokers who strongly desire to quit, and subsequent resumption of smoking, despite long periods of abstinence, is common. Those who begin smoking prior to age 21 are less likely to succeed in smoking cessation programs. Most smokers are nicotine dependent and experience a variable withdrawal syndrome when regular administration of nicotine is stopped. The nicotine withdrawal syndrome consists of irritability, impatience, hostility, anxiety, dysphoric or depressed mood, difficulty concentrating, restlessness, decreased heart rate, and increased appetite or weight gain.

Nicotine administration can block these withdrawal symptoms whether given intravenously, by absorption though the mucosal membranes of the mouth (chewing gum or sucking a lozenge), by absorption through the skin (patch), via nasal spray, or by an inhaler or an electronic cigarette. Although the peak nicotine levels associated with the psychoactive effects of smoking are not achieved by chewing gum or by patch administration, their widespread availability as over-the-counter medications has enabled many smokers to avoid the serious health risks of tobacco smoke. Most smokers can then gradually reduce their nicotine dependence over several days to weeks. Craving for the psychoactive effects continues, however, and relapses to smoking over the ensuing months are common. Table 24.1 summarizes clinical trial results for NRT. Meta-analyses demonstrate efficacy for nicotine patch, gum, inhaler, lozenge, and nasal spray, and quit rates are increased with higher dose of nicotine gum, the use of combination NRTs, and the use of NRT with the non-nicotine medication bupropion (Stead et al., 2012). Despite substantial interest in electronic cigarettes, the first randomized controlled trial (RCT) showed no significant increase in cessation rates compared to nicotine patch or placebo electronic cigarette (Bullen et al., 2013).

The association of smoking and depression has led to the evaluation of several classes of antidepressants as potential treatments for nicotine dependence, including selective serotonin reuptake inhibitors and monoamine oxidase inhibitors. Meta-analyses indicate that bupropion, an atypical antidepressant, significantly improves cessation rates compared to placebo (Table 24.2; Hughes, Stead, & Lancaster, 2007), but it is not significantly more efficacious than NRT (Cahill, Stevens, Perera, & Lancaster, 2013). It is equally effective for treating nicotine addiction with or without a history of comorbid depression, but may be less effective for smokers with current depression (van der Meer, Willemsen, Smit, Cuijpers, & Schippers, 2013). In addition, the tricyclic antidepressant nortriptyline, has been found to significantly increase cessation rates compared to placebo (see Table 24.2; Cahill et al., 2013; Hughes et al., 2007), although this medication is not currently FDA approved for treating nicotine dependence.

Most recently, varenicline, a nicotinic receptor partial agonist, was approved for treating nicotine dependence by the FDA. As a partial agonist it reduces withdrawal symptoms by maintaining moderate dopamine levels, and as an antagonist it blocks the rewarding effects of smoking. Two seminal placebo-controlled studies demonstrated the efficacy of varenicline (Gonzales et al., 2006; Jorenby et al.,

TABLE 24.1 Treatment of Nicotine Use Disorder: Nicotine Replacement Therapy (NRT)

Authors	*Study Class*	*N, Number of Studies*	*Treatment Length*	*Follow-up Length*	*Results*		*Comments and Dosing*
Stead et al. (2012)	4	>50,000; 150 studies	3 weeks or longer	6 months or longer	Randomized Controlled Trials		Comprehensive review, including each NRT and a range of moderating variables.
					Treatment	Risk Ratio (95% CI)	
		19,586; 43			Nicotine patch	1.64 (1.52–1.78)	7–21 mg (depending on amount smoked) daily for 8–10 weeks starting on quit day; use patch 16–24 hours each day.
		22,581; 56			Nicotine gum	1.49 (1.40–1.60)	2 mg (if your first cigarette of the day is typically 30 minutes or more after waking) or 4 mg (if your first cigarette of the day is typically <30 minutes of waking); use at least 9 pieces per day for the first 6 weeks and then taper use; use for up to 12 weeks.
		3,405; 7			Nicotine lozenge	1.95 (1.61–2.36)	2 mg (if your first cigarette of the day is typically 30 minutes or more after waking) or 4 mg (if your first cigarette of the day is typically <30 minutes of waking); use >9 lozenges/day for 6 weeks then taper use; use for up to 12 weeks.
		976; 4			Nicotine inhaler	1.90 (1.36–2.67)	Use 6–16 cartridges/day for up to 6 months with dose taper for final 3 months.
		887; 4			Nicotine nasal spray	2.02 (1.49–2.73)	Use 8–40 doses/day for 3–6 months.
		618; 4			High-dose gum[a]	1.85 (1.36–2.50)	4 mg for 12 weeks.
		4,664; 9			Combination NRT[b]	1.34 (1.18–1.51)	See above.
		1991; 4			NRT and bupropion	1.24 (1.06–1.45)	See above and Table 24.3.
Bullen et al. (2013)	1	657; 1			E–cigarette (vs. patch; vs. placebo)	1.26 (0.68–2.34) 1.77 (0.54–5.77)	First randomized trial to compare e-cigarette to nicotine patch and placebo e-cigarette.

[a] In highly dependent smokers only; [b] Two NRTs vs. one.

TABLE 24.2 Treatment of Nicotine Use Disorder: Antidepressants

Authors	*Study Class*	*N, Number of Studies*	*Treatment Length*	*Follow-up Length*	*Results*		*Comments and Dosing*
Hughes et al. (2007)	4	>13,000; 66 studies	3 weeks or longer	6 months or longer	Randomized Controlled Trials		Comprehensive review of numerous classes of antidepressants, assessment of side effects and adverse events, and comparisons to nicotine replacement therapy and varenicline.
					Treatment	Odds Ratio (95% CI)	
		>11,000; 36			Bupropion	1.69 (1.53–1.85)	Begin dosing 1–2 weeks before quit date; 150 mg/day for days 1–3; 300 mg/day for days 4–7 and for an additional 6–11 weeks. Additional weeks may be considered for successful quitters.
		975; 6			Nortriptyline	2.03 (1.48–2.78)[a]	75–100 mg/day or titrated to pre-quit serum levels recommended for depression for 60 days to 12 weeks.
		1,622; 3			Vs. Varenicline	0.66 (0.53–0.82)[b]	See above and Table 24.3.

[a] Excluded one trial considered to have inadequate methodological rigor; [b] Trials used bupropion.

TABLE 24.3 Treatment of Nicotine Use Disorder: Nicotine Receptor Partial Agonists

Authors	*Study Class*	*N, Number of Studies*	*Treatment Length*	*Follow-up Length*	*Results*		*Comments and Dosing*
Cahill et al. (2012)	4	10,666; 24 studies	3 weeks or longer	6 months or longer	Randomized Controlled Trials		Comprehensive review, including three medications, assessment of side effects and adverse events, and comparisons to nicotine replacement therapy and bupropion.
					Treatment	Odds Ratio (95% CI)	
		6,166; 14			Varenicline	2.27 (2.02–2.55)	Begin dosing 1 week before quit date; 0.5 mg once daily on days 1–3, 0.5 mg twice daily on days 4–7, and 1 mg twice daily for 11 weeks; 12 additional weeks for successful quitters.
		2,151; 3			Cytisine	3.98 (2.01–7.87)[a]	1.5 mg/day for 20–25 days.
		1,622; 3			Vs. Bupropion	1.52 (1.22–1.88)[b]	See Table 24.2.
		1,272; 4			Low-dose varenicline	2.09 (1.56–2.78)	0.3 mg daily; 1.0 mg daily; 0.5 mg twice daily; or 0.5 mg 1–4 times per day.

[a] Excluded one trial considered to have inadequate methodological rigor; [b] Trials used varenicline.

2006). Since then, more than a dozen studies have shown that smokers taking varenicline are more than twice as likely to be abstinent at a 6-month follow-up, compared to placebo (Table 24.3; Cahill, Stead, & Lancaster, 2012). Varenicline is more efficacious than NRT and bupropion (Cahill et al., 2013), possibly by more effectively reducing craving and reinforcement from smoking (Cinciripini et al., 2013). The efficacy of varenicline at a reduced dose has also been demonstrated (Cahill et al., 2012). While the FDA labeling for varenicline includes a warning about the potential neuropsychiatric and suicide risks associated with this medication, several large studies indicate that the varenicline is a safe medication for treating nicotine dependence (Buggy et al., 2013; Gibbons & Mann, 2013).

Lastly, another nicotinic receptor partial agonist, cytisine, has been shown to be an effective treatment for nicotine dependence in two trials (Cahill et al., 2012, 2013).

Ongoing research is focused on improving the efficacy of existing treatments by identifying individual predictors of treatment response. The rate at which nicotine is metabolized by the cytochrome P450 (CYP) 2A6 enzyme has been shown to be stable across time and predictive of smoking relapse. Fast metabolizers of nicotine smoke more cigarettes, are more nicotine dependent, have more difficulty quitting, and have a worse response to nicotine patch treatment compared to slow metabolizers (Lerman et al., 2006; Schnoll et al., 2009). However, bupropion has been shown to be more effective among fast metabolizers (Patterson et al., 2008). Current clinical trials investigating the use of this biomarker of nicotine metabolism may offer an innovative approach to personalizing treatment for nicotine dependence, thereby enhancing the efficacy of these medications.

ALCOHOL USE DISORDER

Medications that have been evaluated to treat alcohol use disorder include aversive agents; serotonergic medications, including antidepressants, anxiolytic agents, and the serotonin-3 receptor (5-HT3) antagonist ondansetron; and agents that are intended to block the effects of alcohol at the neurotransmitter level, including opioid antagonists and the anticonvulsant medication topiramate (Kranzler et al. 2013). The most recent approval of medications to treat alcohol dependence in the United States was in 2006, when the FDA approved a long-acting injectable formulation of naltrexone. Studies of these agents are described in detail in a number of reviews or meta-analyses, which are cited in the sections that follow.

Aversive Medications

Aversive medications produce an unpleasant reaction when alcohol is consumed, which is intended to deter drinking. Disulfiram, the only aversive medication approved to treat alcoholism in the United States, has long been used in alcohol rehabilitation (Favazza & Martin, 1974). Consuming alcohol following the ingestion of disulfiram causes an elevated plasma concentration of acetaldehyde, resulting from disulfiram's blockade of the catabolism of acetaldehyde, a metabolite of alcohol. The intensity of the reaction varies both with the dose of disulfiram and the volume of alcohol consumed.

Overall, disulfiram is no more effective than placebo in promoting abstinence (Suh, Pettinati, Kampman, & O'Brien, 2006). The largest and most methodologically rigorous study of disulfiram was a 1-year multicenter trial in which more than 600 male veterans with alcohol dependence were randomly assigned to receive disulfiram (at a dosage of either 1 mg/day or 250 mg/day) or an inactive placebo (Fuller et al., 1986). Patients assigned to the two disulfiram groups were told they were being given the drug, but neither patients nor staff knew the dosage. Irrespective of the medication group, patients who were adherent to the medication and treatment visit regimen were more likely to remain abstinent throughout treatment. In a planned secondary analysis of patients who resumed drinking, the group that received the approved dosage of disulfiram (i.e., 250 mg/day) reported significantly fewer drinking days than patients in the other two groups. Thus, disulfiram may help to reduce the frequency of drinking in men who cannot maintain abstinence (Fuller et al., 1986).

Disulfiram may be more effective in preventing relapse when combined with efforts to enhance medication adherence (e.g., by contracting with the patient and a significant other to work together to ensure adherence, providing the patient with regular reminders and other information, incentives, and behavioral training and social support) (Allen & Litten, 1992; Brewer, Meyers, & Johnsen, 2000). Azrin

and colleagues (1982) found that disulfiram-treated patients who received a trial program of stimulus control training, role-play, communication skills training, and recreational and vocational counseling had better outcomes than those receiving placebo. Chick and colleagues (1992) randomly assigned patients to receive disulfiram 200 mg/day or placebo for 6 months as an adjunct to outpatient alcoholism treatment. The patient ingested the study medication under the supervision of an individual nominated by the patient. Disulfiram treatment significantly increased abstinent days and decreased total drinks consumed, with parallel changes in levels of the hepatic enzyme gamma-glutamyltransferase (GGT).

Disulfiram is administered orally. Because of the risk of side effects and toxic reactions, the daily dosage prescribed in the United States has been limited to 250 to 500 mg/day. However, efforts to titrate the dosage of disulfiram in combination with a challenge dose of ethanol indicate that in some patients more than 1 g/day of disulfiram is required to produce a disulfiram–ethanol reaction (Brewer, 1984).

The adverse effects of disulfiram, particularly the potential for the disulfiram–ethanol reaction, contraindicate its use in patients with a variety of medical and psychiatric conditions and in pregnant women. Prior to initiation of therapy, the potential for disulfiram to cause a reaction when combined with alcohol should be discussed openly with the patient. The disulfiram–ethanol reaction commonly includes sweating, flushing, hyperventilation, thirst, nausea, vomiting, palpitations, tachycardia, vertigo, and weakness, although more severe symptoms, including syncope and, rarely, cardiovascular collapse, have also been reported. To prevent precipitating an adverse reaction, the patient should also avoid over-the-counter preparations with alcohol, foods prepared with alcohol, and drugs that can interact with disulfiram.

The following tests are recommended by the Center for Substance Abuse Treatment (2009) before initiating disulfiram therapy: liver function tests (alanine aminotransferase, aspartate aminotransferase, GGT, alkaline phosphatase, lactate dehydrogenase, bilirubin, total protein, albumin, and prothrombin time), complete blood count, blood urea nitrogen, serum creatinine, and a pregnancy test for women of reproductive potential. Liver function tests should be repeated 10 to 14 days after beginning treatment, monthly for the first 6 months of therapy, and then at 3-month intervals thereafter, and pregnancy testing should be repeated monthly during treatment.

Serotonergic Agents

Serotonin plays an important role in the modulation of mood and impulse control and appears to influence the development and maintenance of alcohol use disorders (Kranzler & Anton, 1994). Because studies have suggested that individuals with alcohol use disorders may have low levels of serotonin (Kranzler & Anton, 1994), a number of serotonergic medications have been evaluated as treatments for alcohol dependence. The agents that have received the greatest attention are serotonin reuptake inhibitors (SRIs), such as citalopram and sertraline, and ondansetron, a 5-HT3 receptor antagonist. Although studies of SRIs indicate that these agents may lead to short-term reductions in alcohol consumption in heavy drinkers, studies in alcohol-dependent patients have yielded mixed findings (Kranzler et al., 2013). Overall, the only clear justification to use SRIs to treat alcohol dependence is in late-onset alcoholics (i.e., with onset after age 25), for which some support exists (Kranzler et al., 2011; Pettinati et al., 2000), or those with co-occurring depression, who appear to respond to sertraline treatment when combined with naltrexone (Pettinati et al., 2010), but not as monotherapy (Kranzler et al., 2006).

The efficacy of ondansetron has been examined in several studies. Johnson and colleagues (2000) showed that it reduced drinking behavior only among early-onset alcoholics (onset of problem drinking before age 25). At a dosage of 4 μg/kg twice daily—substantially lower than its antiemetic dosage—ondansetron increased the proportion of days abstinent and reduced the intensity of drinking more than placebo. In contrast, in late-onset alcoholics, ondansetron's effects on drinking behavior were no better than those of placebo.

A subsequent study by Johnson and colleagues (2011) showed that the effects of ondansetron were not moderated by the age of onset of problem drinking. Rather, in this study, the medication reduced drinking only in alcoholics homozygous for the L allele of a polymorphism (5-HTTLPR) in *SLC6A4*, the gene encoding the serotonin transporter. Further, a single nucleotide polymorphism (SNP) in the 3′ untranslated region (3′UTR) of the gene (Seneviratne

et al., 2009) interacted with the 5-HTTLPR polymorphism to moderate the response to ondansetron. Thus, ondansetron reduced drinking most in individuals with the LL genotype at 5-HTTLPR and the TT genotype of the 3′UTR SNP. Recently, Johnson and colleagues (2013), in a secondary analysis of this study, found that polymorphisms in the genes encoding the 5-HT3 receptor, *HTR3A* (rs1150226 and rs1176713) and *HTR3B* (rs17614942), also moderated the response to ondansetron. In patients selected for specific genotypes at these loci (more than one third of those originally enrolled), ondansetron exerted moderate to large effects on drinks per drinking day, the percentage of heavy drinking days, and the percentage of days abstinent. If replicated, these findings would contribute substantially to the personalization of alcohol dependence treatment by allowing medication to be selected based on genotypic information obtained prior to the initiation of treatment, thereby offering a high likelihood of a favorable treatment response.

Opioid Antagonists

Two opioid antagonists have been shown to be efficacious in the treatment of alcohol dependence (Table 24.4).

Naltrexone

In 1994, the FDA approved naltrexone to treat alcoholism based on two single-site clinical trials (O'Malley et al., 1992; Volpicelli et al., 1992). Most, but not all, subsequent placebo-controlled studies of naltrexone have shown it to be efficacious in alcohol treatment. Of note is the COMBINE study, a placebo-controlled trial that compared naltrexone, acamprosate, and the two medications combined, together with either medical management or an intensive psychotherapy, in a sample of 1,383 subjects (Anton et al., 2006). Naltrexone, when combined with medical management, modestly reduced the risk of heavy drinking and modestly increased the percent days abstinent, effects that were not enhanced by the addition of an intensive cognitive-behavioral intervention.

Meta-analyses conducted over more than a decade (Bouza et al., 2004; Kranzler & Van Kirk, 2001; Rösner et al., 2010b; Srisurapanont & Jarusuraisin, 2005) have consistently shown naltrexone to be efficacious, principally in reducing the risk of heavy drinking. The most recent of these meta-analyses (Rösner et al., 2010b) included a total of 50 RCTs with nearly 8,000 participants. It showed that naltrexone produced a modest, statistically significant reduction (~17%) in the risk of heavy drinking relative to the placebo group. Naltrexone-treated patients also showed significant reductions in heavy drinking days, the amount of alcohol consumed, and GGT levels. Naltrexone also decreased drinking days by about 4%, which was not statistically significant.

The vast majority of naltrexone studies have been 3 months or shorter in duration. In a VA multicenter study (Krystal et al., 2001), patients were treated with naltrexone for 12 or 52 weeks. Neither group showed a response that was superior to placebo on any of the outcomes examined. A study of long-acting naltrexone for alcohol dependence (discussed below), which was the basis for its approval by the FDA in 2006, was 6 months in duration (Garbutt et al., 2005).

O'Malley and colleagues (2003) used a primary-care model to treat alcohol-dependent patients initially with open-label naltrexone for 10 weeks, in combination with either cognitive-behavioral therapy (CBT) or a less intensive, supportive approach (primary care management). Although the psychosocial treatment did not moderate the response to medication treatment, patients receiving CBT had a lower risk of drinking. Responders to the initial treatment were then randomly assigned to one of two placebo-controlled, 24-week continuation studies together with either CBT or primary care management. In the primary care management group, naltrexone-treated patients had a higher response rate and lower drinking frequency than those receiving placebo. However, when combined with CBT, naltrexone was no better than placebo. Thus, the initial treatment effects of naltrexone may be maintained using either CBT or a less intensive, supportive treatment together with continued naltrexone administration.

Three main approaches have been employed to enhance the treatment effects of naltrexone in alcohol dependence. These include the use of "targeted" (i.e., as-needed) naltrexone administration in anticipation of high-risk drinking situations (Kranzler et al., 1997, 2003, 2009), long-acting injectable naltrexone formulations (Kranzler et al., 1998, 2004; Garbutt et al., 2005), and genetic moderators of treatment response (Chamorro et al., 2012; Oslin et al., 2003).

TABLE 24.4 Treatment of Alcohol Use Disorder: Meta-analysis of Opioid Antagonists

Authors	*N, Number of Studies*	*Treatment Length*	*Follow-up Length*	*Results*		*Comments*
Rösner et al. (2010b)	7,793 50 studies	4 weeks or longer	Up to 52 weeks	Randomized Controlled Trials		Comprehensive review of studies of alcohol dependence or alcohol abuse; 94% of studies were of naltrexone and 6% were of nalmefene; 88% of studies were two-arm trials; multiple outcome measures evaluated
				Treatment Outcome	Risk Ratio (RR) or Mean Difference (MD) (95% CI)	
	4,433; 28			Return to heavy drinking	RR = 0.83 (0.76, 0.90)	
	4,693; 27			Return to any drinking	RR = 0.96 (0.92, 1.00)

Targeted naltrexone may provide an alternative to daily dosing. In an 8-week, placebo-controlled trial of naltrexone 50 mg, 153 problem drinkers were randomly assigned to receive daily medication or medication targeted to situations identified by them as being high risk for heavy drinking (Kranzler et al., 2003). Patients in the targeted condition, irrespective of medication, were less likely to drink. Compared to placebo, naltrexone reduced heavy drinking by 19%. Targeted naltrexone, and to a lesser extent targeted placebo, reduced daily drinking more than daily placebo, an effect that was greater than that of daily naltrexone. A subsequent 12-week comparison of daily or targeted naltrexone with placebo was conducted in 163 problem drinkers whose goal was to reduce their drinking to safe limits (Kranzler et al., 2009). At the end of the study, targeted naltrexone had two significant effects compared to the other three groups: In men, it reduced drinks per day, and in both sexes, it reduced drinks per drinking day.

Heinälä and colleagues (2001) compared naltrexone 50 mg/day with placebo in 121 nonabstinent individuals with alcohol dependence, pairing medication with either coping skills or supportive therapy. During the first 12 weeks of treatment, naltrexone prevented relapse to heavy drinking only in combination with coping skills therapy. During a subsequent 20-week period, during which subjects used their medication in response to alcohol craving, the naltrexone group had a lower rate of relapse to heavy drinking. Together, these findings support the use of targeted naltrexone both in the initial treatment of heavy drinkers and to maintain the beneficial effects of an initial period

of daily naltrexone in alcohol-dependent individuals. This work provided the foundation for the use of as-needed nalmefene, which, as discussed below, is now approved for use in the European Union.

Long-acting, injectable formulations of naltrexone have been developed to enhance adherence with and yield more consistent plasma concentrations of the medication. In a pilot study of 20 alcohol-dependent individuals, treatment with a depot formulation of naltrexone produced by Biotek, Inc. resulted in greater reductions in the frequency of heavy drinking than placebo (Kranzler et al., 1998). Two other long-acting naltrexone formulations have also been tested for safety and efficacy in alcoholics. In a 12-week, placebo-controlled trial in 315 patients who also received motivational enhancement therapy (Kranzler et al., 2004), a long-acting naltrexone formulation produced by DrugAbuse Sciences delayed the onset of any drinking, increased the total number of days of abstinence, and doubled the likelihood of subjects remaining abstinent throughout the study (Kranzler et al., 2004). A third long-acting formulation (Garbutt et al. 2005), produced by Alkermes, was approved by the FDA to treat alcohol dependence based on a study of more than 600 alcohol-dependent patients who were randomly assigned to receive six monthly injections of long-acting naltrexone 380 mg, long-acting naltrexone 190 mg, or matching volumes of placebo. The medication and the injections were well tolerated, with injection site reactions occurring more commonly with the active formulation. Long-acting naltrexone 380 mg resulted in a 25% reduction in the rate of heavy drinking compared to placebo. The long-acting naltrexone 190-mg formulation resulted in a 17% reduction in heavy drinking, which was not significantly better than placebo.

Although there are no head-to-head comparisons of any of the long-acting formulations to oral naltrexone, adherence may be better with the Alkermes formulation than oral naltrexone (Gastfriend, 2011). Six months of treatment with long-acting naltrexone led to significant improvements in measures of quality of life, including those for mental health, social functioning, general health, and physical functioning (Pettinati, Gastfriend, Dong, Kranzler, & O'Malley, 2009). The adverse effects associated with the long-acting naltrexone formulations are similar to those of the oral formulation, including nausea, headache, and fatigue, but long-acting formulations are also associated with local reactions at the injection site.

Pharmacogenetic approaches to naltrexone treatment have focused on a polymorphism in *OPRM1*, the gene encoding the mu-opioid receptor. Carriers of a variant allele (118G or Asp40) may have a better clinical response to naltrexone than individuals homozygous for the more common A118 (or Asn40) allele (Oslin et al., 2003). A recent meta-analysis of the moderating effects of the Asn40Asp polymorphism from six published studies showed that naltrexone-treated patients with one or two copies of the Asp40 allele were more than twice as likely not to relapse to heavy drinking as Asn40-allele homozygotes, with no effect on abstinence rates. Identifying individuals with the Asp40 allele could help to differentiate a subgroup of the population that is more likely to respond to naltrexone treatment. However, the prevalence of the Asp40 allele varies widely by population (>30% in Asians, <20% in individuals of European descent, and <5% in individuals of African descent), so the effects of naltrexone could also vary substantially by population (Arias, Feinn, & Kranzler, 2006).

Nalmefene

In a pilot study (Mason et al., 1994) of nalmefene, also an opioid receptor antagonist, 40 mg/day was superior to 10 mg/day of the drug or placebo in preventing relapse to heavy drinking in a small sample of alcoholics. A subsequent study showed no difference between nalmefene 20 mg/day or 80 mg/day, and when combined, the nalmefene-treated subjects had significantly better outcomes than the placebo group on measures of heavy drinking (Mason et al., 1999). In a 12-week multisite study in recently abstinent outpatient alcoholics, no differences were found between the groups receiving nalmefene (5, 20, or 40 mg/day) versus placebo on drinking outcomes (Anton et al., 2004).

In 2013, based on three multicenter trials of 6 to 12 months in duration, the European Medicines Agency approved nalmefene 18 mg for use on an as-needed basis to reduce heavy drinking in alcohol-dependent individuals. Two of these studies (Gual et al., 2013 Mann et al., 2013) each enrolled more than 600 patients, randomly assigning them to nalmefene or placebo treatment for 6 months. In both studies, nalmefene was statistically superior to placebo in reducing heavy drinking days, with the first study, but not the second one, showing a significantly greater reduction in total alcohol consumption in the

nalmefene group than the placebo group. In the third study (van den Brink et al., 2012), which randomly assigned 665 patients to nalmefene or placebo for a total of 52 weeks of treatment, the medication reduced the number of heavy drinking days and total alcohol consumption beginning in the first month. There was a statistically significant advantage for nalmefene at most time points, including at the end of treatment, but not at the midpoint of the study. Nalmefene also significantly reduced GGT serum concentrations in two of the three studies and alanine aminotransferase serum concentrations in all three studies.

Summary

Although there is evidence supporting the use of naltrexone to treat alcohol dependence, in unselected samples of patients the medication has a small effect size (Rösner et al., 2010b). However, naltrexone may be of particular utility in subgroups of patients. The ready identification of these individuals is of great clinical interest, as is the potential utility of combining naltrexone with other medications and with specific kinds of psychotherapy. New approaches to the use of naltrexone, including targeted administration and long-acting injectable formulations, may enhance its clinical utility. The literature supporting the use of nalmefene includes three large multicenter trials that support its efficacy and have led to its approval in the European Union.

Acamprosate

Acamprosate (calcium acetylhomotaurinate) is an amino acid derivative with weak antagonist effects at NMDA receptors and at a glutamate metabotropic (mGluR5) receptor (Blednov & Harris, 2008; Mann et al., 2008). Based on this, acamprosate may reduce glutamatergic excitability following the cessation of drinking. Initially evaluated in France (Lhuintre et al., 1985), evidence of the medication's efficacy has mostly come from Europe, where some studies have shown persistent beneficial effects of the medication during posttreatment follow-up. Three European studies provided the basis for the approval in 2004 of acamprosate for clinical use in the United States (Paille et al., 1995; Pelc et al., 1997; Sass et al., 1996) (Table 24.5).

A number of meta-analyses have examined the effects of acamprosate (Bouza et al., 2004; Chick,

TABLE 24.5 Treatment of Alcohol Use Disorder: Meta-analysis of Acamprosate

[a]In days; [b]Gamma-glutamyltranspeptidase concentration in International Units/L

Lehert, Landron, & Plinius Maior Society, 2003; Kranzler & Van Kirk, 2001; Mann, 2004; Rösner et al., 2010a). The most recent meta-analysis included data from 24 RCTs with 6,915 participants. It showed that acamprosate significantly reduced the risk of any drinking and increased the cumulative abstinence duration. The authors concluded that acamprosate appeared to be a safe and effective treatment to support continuous abstinence after detoxification in patients with alcohol dependence, although the size of the treatment effects was modest (Rösner et al., 2010a).

Two large multicenter trials in the United States (Anton et al., 2006; Mason et al., 2006), a large European study (Mann et al., 2009), and an Australian study (Morley et al., 2006) showed no beneficial effects of acamprosate compared with placebo in the treatment of alcohol dependence. In the COMBINE study (Anton et al. 2006), acamprosate did not significantly alter measures of alcohol consumption irrespective of the intensity of the concomitant psychosocial treatment provided, nor did the combination of acamprosate and naltrexone significantly decrease measures of drinking.

The heterogeneity of the samples that are typically enrolled in multicenter studies may have obscured the modest therapeutic effects of the medication. In addition, the substantial difference in the results of published studies could be attributable to the greater severity of alcohol dependence in the studies showing efficacy (i.e., those from Europe).

In summary, meta-analysis of studies enrolling nearly 7,000 patients provides evidence of a beneficial effect of acamprosate in relapse prevention. However, because acamprosate failed to demonstrate efficacy in several large clinical trials, additional research is needed to identify the patient characteristics and therapeutic approaches that contribute to an optimal response to acamprosate.

Anticonvulsants

The potential utility of anticonvulsants to treat alcohol dependence has been shown in placebo-controlled studies of carbamazepine (Mueller et al., 1997), divalproex (Salloum et al., 2005), topiramate (Johnson et al., 2003, 2007; Kranzler et al., 2014), and gabapentin (Anton et al., 2011; Mason et al., 2014). In a 12-month pilot study, Mueller and colleagues (1997) found that carbamazepine reduced drinks per drinking day, time to first heavy drinking day, and consecutive days of heavy drinking more than placebo. Salloum and colleagues (2005) reported that bipolar patients with alcohol dependence treated with valproate had a significantly greater decrease in alcohol consumption than those receiving placebo. Brady and colleagues (2002) found that divalproex was no different than placebo in reducing drinking behavior in a 12-week, double-blind, placebo-controlled pilot study in alcohol-dependent individuals without bipolar disorder.

Anton and colleagues (2011) tested whether the combination of naltrexone 50 mg and gabapentin (up to 1,200 mg/day) was better than naltrexone alone or placebo during the first 6 weeks of a 16-week trial. They found that the combination of gabapentin and naltrexone improved drinking outcomes more than naltrexone alone during the first 6 weeks after the cessation of drinking. The effect did not endure once gabapentin was discontinued.

Subsequently, Mason and colleagues (2014) conducted a 12-week RCT comparing gabapentin 900 mg/day or 1,800 mg/day with placebo and concomitant manual-guided counseling. Gabapentin treatment was associated with higher rates of abstinence and no heavy drinking, evidenced by a linear dose effect. The number needed to treat (NNT) was 8 for the 1,800-mg group. The no-heavy-drinking rate also showed a significant linear dose effect, with the NNT of 5 for the high-dose gabapentin group. Similar effects were seen on measures of mood, sleep, and craving. Interpretation of the study's findings is limited, however, by the low overall rate of study completion (56.7%).

In both single-site and multisite placebo-controlled clinical trials, Johnson and colleagues (2003, 2007) found that topiramate 300 mg/day had a moderate effect in reducing drinks per day, drinks per drinking day, drinking days, heavy drinking days, and GGT concentration. In addition, topiramate treatment decreased compulsive thoughts about drinking, increased psychosocial well-being, and improved the quality of life (Johnson et al., 2008). Although in the single-site study (Johnson et al., 2003) the topiramate and placebo groups were equally likely to complete treatment, in the multicenter study (Johnson et al., 2007) topiramate-treated patients were more likely than placebo-treated patients to discontinue treatment prematurely.

Miranda and colleagues (2008) randomly assigned 61 heavy drinkers to receive treatment with topiramate

200 mg/day, topiramate 300 mg/day, or placebo. They titrated the medication to the target dosage over a 32-day period, maintaining the dosage for 1 week prior to a human laboratory study. During the titration period, the two topiramate groups reduced the frequency of heavy drinking more than placebo, with no significant difference between the two dosages of topiramate. A larger proportion of subjects receiving topiramate 300 mg than topiramate 200 mg or placebo discontinued treatment prematurely.

Recently, a placebo-controlled study conducted in 106 alcohol-dependent patients in Thailand (Likhitsathian et al., 2013) failed to show a significant advantage of topiramate 300 mg/day in reducing drinking. However, in that study, only about half of the patients completed treatment and adherence to the prescribed regimen was not evaluated, factors that limit the interpretation of the results.

In a study of heavy drinkers (the vast majority of whom were alcohol dependent) who wanted to reduce their drinking, participants were randomly assigned to treatment with topiramate 200 mg/day or placebo for 12 weeks (Kranzler et al., 2014). In intent-to-treat analyses, topiramate was significantly better than placebo in decreasing the number of heavy drinking days and increasing the number of abstinent days. Based on prior findings of genetic association to alcohol dependence (Kranzler et al., 2009), rs2832407, a SNP in *GRIK1*, which encodes the GluK1 kainate receptor subunit, was examined as a moderator of topiramate's efficacy in the 128 patients who were of European ancestry. There was a significant interaction of genotype by medication, such that in the CC genotype group but not in the A-allele carrier group, topiramate-treated patients reduced their heavy drinking more than placebo-treated patients.

Topiramate affects multiple neurotransmitter and enzyme systems, so in addition to its effects on drinking behavior, it produces a variety of side effects, the most frequent of which are paresthesia, anorexia and weight loss, difficulty with memory or concentration, and taste disturbances, which are generally mild to moderate in severity. Uncommonly, topiramate causes visual adverse events including myopia, angle-closure glaucoma, and increased intraocular pressure, which require discontinuation of the medication. To minimize topiramate's adverse effects, a slow titration to the maximal dosage is recommended (i.e., over 6 to 8 weeks). Although the optimal topiramate dosage for alcohol treatment has not been determined, the reports by Miranda and colleagues (2008) and Kranzler and colleagues (2014) provide support for the utility of the 200-mg/day dose. Additional research is needed to test the validity of the genetic moderation of topiramate's efficacy in reducing heavy drinking (Kranzler et al., 2014), which has important implications both for the clinical utility of topiramate and for the potential insight that it provides into the mechanism of the medication's effect on heavy drinking.

STIMULANT DEPENDENCE

There are no medications currently approved for the treatment of cocaine or amphetamine/methamphetamine use disorder. However, there are several medications that have shown potential efficacy in controlled clinical trials for cocaine use disorder and a few that have shown potential efficacy for the treatment of methamphetamine use disorder. Medications for the treatment of cocaine use disorder and medications for the treatment of amphetamine/methamphetamine use disorder will be discussed separately (Table 24.6). Only medications that have potential efficacy demonstrated in controlled clinical trials will be presented. Medications for cocaine dependence will be grouped according to the neurotransmitter system they are thought to target. Medications found to be efficacious for cocaine use disorder only when used in conjunction with a novel psychosocial treatment called contingency management will be discussed next. Finally, medications for the treatment of amphetamine/methamphetamine use disorder will be discussed.

Dopamine Agonists for Cocaine Dependence

Agonist treatments have been used successfully to treat both opioid and nicotine use disorders. Ideally, in agonist treatment, the medication chosen should be one that binds to the same receptor as the abused drug, exerts similar effects, and has pharmacological properties that render it less abusable than the abused drug. Methadone, because of its slow onset of action, and buprenorphine, by virtue of its partial agonist activity at the opioid receptors, are effective agonist treatments for opioid use disorder. Likewise, the transdermal nicotine patch's slow absorption contributes

TABLE 24.6 Medications for Cocaine Dependence

Authors	*Class*	*N*	*Treatment Length*	*Follow-up Length*	*Results*	*Comments*
Direct Dopamine Agonists						
Levin at al. (2007)	1	106	14 weeks	—	Cocaine-dependent patients with comorbid attention-deficit/hyperactivity disorder (ADHD). Reduced cocaine use with methylphenidate. No difference in ADHD symptoms.	Methylphenidate was superior to placebo for reducing cocaine use.
Grabowski et al. (2001)	2	128	12 weeks	—	Long-acting dextroamphetamine was superior to placebo in promoting cocaine abstinence in cocaine-dependent patients	High dropout rate
Grabowksi et al. (2004)	2	94	26 weeks	—	Long-acting dextroamphetamine was superior to placebo in promoting cocaine abstinence in cocaine- and opiate-dependent patients maintained on methadone.	High dropout rate
Mooney et al. (2009)	2	82	8 weeks	—	Long-acting methamphetamine was superior to placebo and short-acting methamphetamine in promoting cocaine abstinence in cocaine-dependent patients.	High dropout rate
Mariani et al. (2012)	2	81	12 weeks	—	Mixed amphetamine salts combined with topiramate was superior to placebo in promoting 3 weeks of continuous abstinence from cocaine.	
Other Dopaminergic Medications						
Dackis et al. (2005)	2	62	8 weeks	—	Modafinil superior to placebo in reducing cocaine use	Patients included in this trial did not have comorbid alcohol dependence.
Anderson et al. (2009)	1	210	12 weeks	—	Among cocaine-dependent patients without comorbid alcohol dependence, modafinil was superior to placebo in reducing cocaine use.	Modafinil was not superior to placebo in the overall trial.
Dackis et al. (2012)	1	210	8 weeks	—	Modafinil was not superior to placebo in promoting cocaine abstinence.

Carroll et al. (1998)	3	122	12 weeks	—	Disulfiram-treated patients had longer sustained abstinence from cocaine compared to patients treated with psychotherapy alone.	Cocaine-dependent patients with comorbid alcohol dependence were included in this trial.
George et al. (2000)	2	20	12 weeks	—	Disulfiram-treated patients had longer periods of sustained abstinence from cocaine compared to placebo-treated patients.	This was a small pilot trial involving cocaine- and opioid-dependent patients treated with buprenorphine maintenance.
Carroll et al. (2004)	1	121	12 weeks	—	Disulfiram was superior to placebo in reducing the frequency of cocaine use.	Disulfiram was more effective in patients without comorbid alcohol dependence.
Pettinati et al. (2008)	1	208	11 weeks	—	The cocaine-dependent patients with comorbid alcohol dependence treated with the combination of naltrexone and disulfiram were more likely than placebo-treated patients to achieve 3 consecutive weeks of abstinence from both cocaine and alcohol.	Disulfiram, naltrexone, and the combination of the two medications were evaluated in cocaine-dependent patients with comorbid alcohol dependence.
Oliveto et al. (2011)	1	161	14 weeks	—	Disulfiram at 250 mg/day was not better than placebo in reducing cocaine use frequency. Lower doses of disulfiram (62 and 125 mg) were associated with more cocaine use.	Cocaine- and opioid-dependent patients maintained on methadone. Three doses of disulfiram were compared to placebo.
GABAergic/Glutamatergic Medications						
Kampman et al. (2004)	2	40	13 weeks	—	During the last 6 weeks of the trial topiramate-treated patients were significantly more likely to be abstinent from cocaine compared to placebo-treated patients.	Topiramate was tested in a relapse-prevention model in this small pilot trial. Patients had to have low cocaine withdrawal symptoms scores and had at least 3 days of self–reported abstinence before starting topiramate.
Kampman et al. (2013)	1	170	13 weeks	—	Significantly more topiramate-treated patients achieved 3 consecutive weeks of abstinence from cocaine during the last 3 weeks of the trial compared to placebo-treated patients.	Topiramate was tested in a relapse-prevention model. Patients had to achieve a period of abstinence from cocaine long enough to have a cocaine-metabolite-free urine drug screen on the day of randomization.

Johnson et al. (2013)	1	142	12 weeks	—	Topiramate was more efficacious than placebo at increasing the weekly proportion of cocaine nonuse days.	
LaRowe et al. (2013)	1	111	8 weeks	—	Three groups were included in this trial of N-acetylcysteine (NAC) for cocaine dependence: 1200 mg NAC daily, 2400 mg NAC daily, and placebo.	
Medications Combined with Contingency Management (CM)						
Kosten et al. (2003)	1	160	12 weeks	—	The combination of desipramine and CM was associated with more cocaine-metabolite-negative urine drug screens during the trial compared to patients treated with desipramine without CM, placebo with CM, and placebo without CM.	This trial was conducted in patients with comorbid cocaine and opioid dependence being treated with buprenorphine maintenance.
Poling et al. (2006)	1	106	25 weeks	—	Among the 4 groups included in this trial, patients treated with the combination of bupropion and CM had more consecutive weeks of cocaine abstinence compared to the other three groups.	This trial was conducted in patients with comorbid cocaine and opioid dependence being treated with buprenorphine maintenance. There were 4 groups bupropion plus CM, bupropion without CM, placebo with CM, and placebo without CM.
Moeller et al. (2007)	1	76	12 weeks	—	Patients treated with citalopram combined with CM had significantly fewer cocaine-metabolite-positive urine drug screens compared to patients treated with placebo combined with CM.	This was a two-group trial, citalopram and placebo, with both groups receiving CM.
Medications for Methamphetamine Dependence						
Elkashef et al. (2008)	2	151	12 weeks	—	In the group as a whole bupropion was not effective for the treatment of methamphetamine dependence. In a subgroup of light users (18 or less days of methamphetamine use in the 30 days prior to the trial) bupropion-treated patients had significantly more methamphetamine-abstinent weeks compared to placebo-treated patients.	One of two trials in which bupropion showed efficacy in light methamphetamine users

(*continued*)

TABLE 24.6 (continued)

Authors	*Class*	*N*	*Treatment Length*	*Follow-up Length*	*Results*	*Comments*
Shoptaw et al. (2008)	2	73	12 weeks	—	This was a 12-week trial of bupropion for methamphetamine dependence with a 2-week baseline. Urine drug screens were collected three times weekly. In a post hoc analysis, there was a statistically significant effect of bupropion treatment on methamphetamine use among participants with lighter (0–2 positive urine samples) but not heavier (3–6 positive urine samples) use during baseline.	The second trial in which bupropion showed efficacy in light methamphetamine users
Colfax et al. (2011)	2	60	12 weeks	—	This was a trial that involved methamphetamine dependent men who have sex with men. Patients treated with mirtazapine submitted significantly fewer methamphetamine positive urine drug screens during the trial.	This trial was a relatively small pilot. A replication trial has not yet been completed.
Elkashef et al. (2012)	2	140	13 weeks	—	In a small subgroup of patients ($n = 26$) who started the trial with a methamphetamine-negative urine drug screen, topiramate-treated patients had significantly more weeks of abstinence from methamphetamine compared to placebo-treated patients.	In the main trial topiramate was not effective for the treatment of methamphetamine dependence; however, a post hoc analysis showed a relapse-prevention effect for topiramate.

to its effectiveness in the treatment of tobacco use disorder. Cocaine has diverse effects in the brain and, unlike nicotine and opiates, there is not a single molecular target. Therefore, finding an effective agonist treatment for cocaine dependence has been more challenging.

Agonist treatments for cocaine dependence have thus far focused on the dopaminergic properties of cocaine. Early trials with methylphenidate were not positive (Grabowski et al., 1997). However, in at least one trial, Levin and colleagues found that among cocaine-dependent patients with comorbid attention-deficit/hyperactivity disorder, methylphenidate was associated with decreased cocaine use (Levin, Evans, Brooks, & Garawi, 2007).

More success has been achieved with amphetamine and methamphetamine for the treatment of cocaine dependence. In 2001 Grabowski and colleagues published results of the first pilot trial evaluating dextroamphetamine for the treatment of cocaine dependence (Grabowski et al., 2001). In this 12-week trial, 128 cocaine-dependent patients were randomly assigned to placebo, low-dose dextroamphetamine (30 mg/day), or high-dose dextroamphetamine (60 mg/day). Treatment retention was significantly better in the low-dose amphetamine group. Cocaine use was nonsignificantly lower in the high-dose amphetamine group. However, the dropout rate in this study was high. In a subsequent trial by the same group involving 120 cocaine- and opioid-dependent patients stabilized on methadone, significant reductions in cocaine use were seen in patients treated with 60 mg of dextroamphetamine compared to placebo or 30 mg. Again, treatment retention in this trial was poor, with less than 50% of subjects completing (Grabowski et al., 2004). In a trial of immediate- and sustained-release methamphetamine, the sustained-release methamphetamine group submitted significantly fewer cocaine-positive urine drug screens during the trial (29% sustained-release vs. 66% immediate-release vs. 60% placebo). However, this trial too suffered from excessive dropout, with only 32% of the patients completing the trial (Mooney et al., 2009). Although the results in these studies, in general, favored long-acting amphetamine and methamphetamine, the findings in all the trials were difficult to interpret due to high dropout rates.

Modafinil is a medication approved for the treatment of narcolepsy and shift work sleep disorder. It may be useful for the treatment of cocaine-dependent patients through several mechanisms of action, including reductions in cocaine withdrawal symptoms, cocaine craving, or cocaine-induced euphoria. As a mild stimulant, modafinil may be able to reduce cocaine withdrawal symptoms (Dackis & O'Brien, 2003). Modafinil has been shown to increase dopaminergic neurotransmission by blocking the dopamine transporter, and this may account for its ability to reduce cocaine withdrawal symptoms (Volkow et al., 2009). Modafinil also enhances glutamate neurotransmission (Touret et al., 1994). It may therefore be efficacious for cocaine dependence by ameliorating the glutamate depletion seen in chronic cocaine users (Dackis & O'Brien, 2003). Improved baseline glutamatergic tone in the nucleus accumbens prevents reinstatement of cocaine self-administration in an animal model of relapse (Baker et al., 2003).

Modafinil was found to block the euphoric effects of cocaine in three independent human laboratory studies (Dackis et al., 2003; Hart, Haney, Vosburg, Rubin, & Foltin, 2008; Malcolm et al., 2006). First, Dackis and colleagues conducted a double-blind, placebo-controlled cocaine/modafinil interaction trial. In this trial, cocaine-dependent patients were placed on modafinil 200 mg, 400 mg, or placebo and then challenged with 30 mg of intravenous cocaine. Pretreatment with modafinil significantly blunted cocaine-induced euphoria on one of the subjective measures (Dackis et al. 2003). In a separate, but very similar, human laboratory trial, Malcolm and colleagues found that modafinil at both 400 and 800 mg significantly reduced visual analogue scale ratings of "high," "any drug effect," and "worth in dollars" compared to cocaine alone (Malcolm et al., 2006). Finally, Hart and colleagues evaluated the effect of modafinil on the self-administration of cocaine in a human laboratory trial. In this trial, the effects of modafinil maintenance (0, 200, and 400 mg/day) on response to smoked cocaine (0, 12, 25, and 50 mg) were examined in non-treatment-seeking cocaine-dependent individuals (n = 8). Cocaine significantly increased self-administration, subjective-effect ratings, and cardiovascular measures; modafinil at both doses (200 and 400 mg/day) markedly attenuated these effects (Hart et al., 2008).

A double-blind, placebo-controlled pilot trial of modafinil involving 62 cocaine-dependent patients was completed in 2004. In this trial, modafinil-treated patients submitted significantly more

cocaine metabolite-free urine samples compared to placebo-treated patients (42% vs. 22%). Modafinil-treated patients were also rated as more improved compared to placebo-treated patients (Dackis, Kampman, Lynch, Pettinati, & O'Brien, 2005).

The results of the pilot trial were partly replicated in a larger multicenter trial involving 210 cocaine-dependent patients. In this 16-week trial, cocaine-dependent patients were treated with modafinil 200 mg daily, modafinil 400 mg daily, or placebo. In contrast to the pilot trial, in which none of the patients were both cocaine and alcohol dependent, in this trial 41% of the patients were both alcohol and cocaine dependent. In the group as a whole, modafinil was not superior to placebo in promoting abstinence from cocaine. However, among patients who were not also alcohol dependent, both doses of modafinil were superior to placebo for promoting abstinence from cocaine (Anderson et al., 2009). Modafinil may be efficacious only in cocaine-dependent patients without co-occurring alcohol dependence.

Enthusiasm for modafinil is somewhat dampened by results of a clinical trial recently completed by Dackis and colleagues (2012). In this trial, 210 cocaine-dependent patients (without comorbid alcohol dependence) who were actively using cocaine at baseline were randomized to 8 weeks of modafinil (0 mg/day, 200 mg/day, or 400 mg/day) or placebo combined with once-weekly CBT. The investigators found no effect of modafinil at either dose on cocaine use or cocaine craving. Currently there is one more clinical trial of modafinil yet to be completed. At this point, the usefulness of modafinil for the treatment of cocaine dependence has not been definitively established.

Disulfiram may be useful for the treatment of cocaine dependence by a unique mechanism of action. In addition to its effects on alcohol metabolism, disulfiram also blocks the enzymatic degradation of cocaine and dopamine, raising baseline levels of dopamine and causing extremely high cocaine and dopamine levels when cocaine is ingested (Karamanakos, Pappas, Stephanou, & Marselos, 2001; McCance-Katz, Kosten, & Jatlow, 1998). This may affect cocaine use by decreasing the reinforcing properties of cocaine by making cocaine use aversive (Hameedi et al., 1995; McCance-Katz et al., 1998).

In three out of four placebo-controlled clinical trials, disulfiram reduced cocaine use in cocaine-dependent patients (Carroll et al., 2004; Carroll, Nich, Ball, McCance, & Rounsaville, 1998; George et al., 2000; Petrakis et al., 2000). Petrakis and colleagues compared disulfiram to placebo in 67 cocaine- and opioid-dependent patients maintained on methadone. They found that disulfiram-treated patients self-reported significantly less cocaine use in a 12-week trial (Petrakis et al., 2000). In a smaller trial done with cocaine- and opioid-dependent patients maintained on buprenorphine, disulfiram was significantly better than placebo in reducing cocaine use measured by urine drug screens (George et al., 2000). In a trial of 130 cocaine-dependent patients not dependent on opioids, disulfiram was found to be associated with less cocaine use measured by urine drug screens. In this trial patients without a history of alcohol use responded better to disulfiram, confirming disulfiram's specific effect on cocaine use (Carroll et al., 2004). More recently, disulfiram at a dose of 250 mg daily was not found to be superior to placebo in reducing cocaine use in a trial involving 161 cocaine- and opioid-dependent patients maintained on methadone. Moreover, lower doses of disulfiram (62.5 or 125 mg/day) were found to be associated with significantly more cocaine use compared to placebo (Oliveto et al., 2011).

Although Carroll and colleagues (2004) found disulfiram to be more effective in cocaine users without comorbid alcohol dependence, Pettinati and colleagues (2008) found that the combination of disulfiram and naltrexone was better than placebo in promoting sustained abstinence from both cocaine and alcohol in patients with dual cocaine and alcohol dependence. Because of disulfiram's significant cocaine and alcohol interactions, the study of this medication for the treatment of cocaine dependence has largely been abandoned in favor of other dopamine beta-hydroxylase inhibitors without significant cocaine or alcohol interactions, such as nepicastat. Clinical trials with nepicastat have not yet been completed.

GABAergic and Glutamatergic Medications for Cocaine Dependence

Mesocortical dopaminergic neurons receive modulatory inputs from both GABAergic and glutamatergic neurons. GABA is primarily an inhibitory neurotransmitter in the central nervous system. Activation of

GABAergic neurons tends to decrease activation in the dopaminergic reward system. Preclinical trials of medications that foster GABAergic neurotransmission have suggested that these compounds reduce the dopamine response to both cocaine administration and to conditioned reminders of prior cocaine use (Dewey et al., 1992, 1997; Gerasimov et al., 1999). GABAergic medications also reduce the self-administration of cocaine in animal models (Kushner, Dewey, & Kornetsky, 1999; Roberts, Andrews, & Vickers, 1996). Therefore, GABAergic medications could prevent relapse by blocking cocaine-induced euphoria or by reducing craving caused by exposure to conditioned reminders of prior cocaine use. Animal studies of cocaine-induced neuroplasticity have demonstrated that increases in both dopamine and glutamate transmission in the nucleus accumbens are important for the development and expression of the neuroadaptations thought to underlie cocaine addiction (Cornish & Kalivas, 2000). Thus, medications that block glutamatergic input into the nucleus accumbens could reduce cocaine craving and prevent relapse to cocaine use in cocaine-dependent individuals (Kalivas & Volkow, 2011).

Topiramate may be an excellent medication for relapse prevention based on its effects on both GABA neurotransmission and glutamate neurotransmission. Topiramate increases cerebral levels of GABA and facilitates GABA neurotransmission (Kuzniecky et al., 1998; Petroff, Hyder, Mattson, & Rothman, 1999). Topiramate also inhibits glutamate neurotransmission through a blockade of AMPA/kainate receptors (Gibbs, Sombati, DeLorenzo, & Coulter, 2000). In animal models of cocaine relapse, blockade of AMPA receptors in the nucleus accumbens prevented reinstatement of cocaine self-administration (Cornish & Kalivas, 2000).

In a 13-week, double-blind, placebo-controlled pilot trial of topiramate for cocaine dependence involving 40 cocaine-dependent patients, topiramate-treated patients were significantly more likely to be abstinent during the last 5 weeks of the trial compared to placebo-treated patients (Kampman et al., 2004). In addition, among patients who returned for at least one visit after receiving medications, topiramate-treated patients were significantly more likely to achieve at least 3 weeks of continuous abstinence from cocaine compared to placebo-treated patients (59% vs. 26%), and topiramate-treated patients were significantly more likely than placebo-treated patients to be rated very much improved at their last visit (71% vs. 32%) (Kampman et al., 2004).

This pilot trial has now been replicated twice. First, in a 13-week trial that included 170 cocaine- and alcohol-dependent patients, topiramate-treated patients (300 mg/day) were significantly more likely to achieve 3 weeks of continuous abstinence from cocaine at the end of the trial. Twenty percent of the topiramate-treated patients were cocaine abstinent versus 6% of the placebo-treated patients (Kampman et al., 2013). More recently, Johnson and colleagues evaluated the efficacy of topiramate in 142 cocaine-dependent patients in a 12-week double-blind, placebo-controlled trial. In that trial, topiramate-treated patients had significantly more cocaine non-use days than placebo-treated patients during weeks 6 to 12 of the trial. Cocaine non-use days were determined by self-report verified by urine drug screens (Johnson et al., 2013). For the treatment of cocaine dependence topiramate has been found to be efficacious at both 200 mg/day (Kampman et al., 2004) and 300 mg/day (Johnson et al., 2013; Kampman et al., 2013).

Recently, researchers at Columbia conducted a trial of mixed amphetamine salts plus topiramate for the treatment of cocaine dependence. They randomly assigned 81 cocaine-dependent patients to 60 mg of extended-release mixed amphetamine salts plus 300 mg of topiramate daily or identical placebo capsules. They conducted a 12-week trial and found that patients treated with mixed amphetamine salts and topiramate were significantly more likely than placebo-treated patients to achieve 3 weeks of continuous abstinence during the trial (33% vs. 17%) (Mariani et al., 2012). Patients with more baseline cocaine use did the best on this combination. This trial at Columbia took advantage of preliminary findings demonstrating potential efficacy for both long-acting amphetamine and topiramate. The combination of the two medications was effective in this trial. However, whether this positive effect was due to amphetamine, topiramate, or the combination cannot be determined due to the design of this preliminary trial.

Another promising glutamatergic medication is *N*-acetylcysteine (NAC), an amino acid and a cysteine pro-drug. Preclinical and some early pilot clinical trials have suggested that it may be an effective medication for the treatment of addictive disorders. Preclinical studies have suggested that

levels of glutamate in the nucleus accumbens mediate reward-seeking behavior (Kalivas & Volkow, 2005; McFarland, Lapish, & Kalivas, 2003). Low levels of extracellular glutamate in the nucleus accumbens are associated with chronic cocaine exposure. Through stimulation of the cysteine-glutamate antiporters, NAC may increase extracellular glutamate levels. This in turn modulates the release of glutamate in response to drug taking via stimulation of metabotropic glutamate autoreceptors. This reduction in glutamate release may block drug-seeking behaviors and drug craving. In rats, NAC pretreatment blocked the reinstatement of drug-seeking behavior induced by cocaine or conditioned cues of cocaine (Baker et al., 2003). In a human laboratory trial, NAC reduced cocaine craving in non-treatment-seeking cocaine-dependent men and women (LaRowe et al., 2007). In an open-label trial, NAC was found to be safe and well tolerated in cocaine-dependent patients (LaRowe et al., 2006). Most recently, NAC was found to be superior to placebo in preventing relapse in cocaine-dependent patients. This trial involved 111 cocaine-dependent patients treated with NAC 1,200 mg, NAC 2,400 mg, or placebo for 8 weeks. Among patients who had achieved abstinence prior to starting NAC, those treated with 2,400 mg/day had a significantly longer time to relapse compared to placebo-treated patients (LaRowe et al., 2013).

Combining Contingency Management with Medications

Voucher-based reinforcement therapy (VBRT) is a behavioral treatment intervention for SUDs in which patients receive vouchers redeemable for goods and services in the community contingent upon achieving a predetermined therapeutic goal. VBRT targeting cocaine abstinence has been shown to be highly effective in promoting initial abstinence from cocaine among cocaine-dependent patients (Higgins et al., 1994). Researchers have begun to combine VBRT with medications to augment medication response in cocaine-dependent patients. In several trials, patients treated with the combination of VBRT targeting abstinence and medications have responded better than patients treated with either medications or VBRT alone. For example, Kosten and colleagues tested the efficacy of desipramine and VBRT in cocaine- and opiate-dependent patients maintained on buprenorphine. Desipramine had been studied for the treatment of cocaine dependence in the 1980s, but in association with standard psychosocial treatment it was not found to be consistently efficacious. In this trial, patients received desipramine or placebo with VBRT or a noncontingent voucher control. Cocaine-free and combined cocaine- and opiate-free urine samples increased more rapidly over time in those treated with desipramine or VBRT. Those receiving both VBRT and desipramine had significantly more drug-free urine samples than the other three groups (Kosten et al., 2003).

In a double-blind, placebo-controlled trial of bupropion and VBRT, the combination of bupropion and VBRT was found to be superior to bupropion alone, placebo bupropion, and VBRT alone in promoting abstinence from cocaine in cocaine-dependent patients (Poling et al., 2006). Similar results were found for the combination of the SRI citalopram and VBRT (Moeller et al., 2007). Several SRIs have been tested for the treatment of cocaine dependence but, like desipramine, SRIs have not been found to be consistently efficacious when used in association with standard psychosocial treatment. The use of VBRT targeting cocaine abstinence as a psychosocial treatment platform appears to be effective in increasing the efficacy of certain medications for the treatment of cocaine dependence.

Medications for Amphetamine Dependence

The effort to find medications for the treatment of amphetamine and methamphetamine use disorders started more recently than the search for a medication to treat cocaine dependence. Consequently, fewer medications have been tested. Similarities between the mechanisms of action of these drugs have suggested that medications effective for cocaine dependence may also be effective for amphetamine and methamphetamine dependence, and several medications being tested for cocaine dependence are currently undergoing or are about to undergo testing for methamphetamine dependence. So far only bupropion, topiramate, and mirtazapine have shown evidence of potential efficacy in controlled clinical trials.

Bupropion is an antidepressant medication that acts primarily as a reuptake inhibitor of dopamine and norepinephrine. It has also been shown to be

effective for the treatment of nicotine dependence. Bupropion may be effective for smoking and methamphetamine dependence by virtue of its effects on dopamine reuptake. Bupropion was thought to potentially alleviate stimulant withdrawal symptoms by facilitating dopamine neurotransmission. Bupropion was tested for cocaine dependence in the past and found to be ineffective (Margolin et al., 1995). For methamphetamine dependence, bupropion has been shown to be more promising.

Bupropion was tested for the treatment of methamphetamine dependence in 151 methamphetamine-dependent patients. In the group as a whole, there was a nonsignificant trend toward more weeks of abstinence from methamphetamine in the bupropion condition compared to placebo. In a subgroup of patients with less methamphetamine use at baseline, bupropion treatment was associated with significantly more weeks of abstinence from methamphetamine compared to placebo treatment (Elkashef et al., 2008). This finding was replicated in a subsequent trial involving 73 methamphetamine-dependent outpatients. Among light methamphetamine users (defined as zero to two out of six amphetamine-positive urine samples during a 2-week baseline), bupropion-treated patients compared to placebo-treated patients had significantly more methamphetamine-free weeks measured by negative urine drug screens (Shoptaw et al., 2008). Hence, for less severe amphetamine users, bupropion may be efficacious.

Preliminary evidence suggests possible efficacy for two more medications, topiramate and mirtazapine. Topiramate was tested for the treatment of methamphetamine dependence in a single study, a 13-week multicenter trial involving 140 methamphetamine-dependent patients who were randomly assigned to either topiramate 200 mg daily or identical placebo capsules. In the intent-to-treat analysis, topiramate did not increase abstinence from methamphetamine during the target weeks 6 to 12. However, topiramate reduced weekly median urine methamphetamine levels and observer-rated severity of dependence scores significantly. Subjects with negative urine screens before randomization had significantly greater abstinence if treated with topiramate versus placebo during study weeks 6 to 12 (Elkashef et al., 2012). Topiramate was safe and well tolerated in this trial.

The antidepressant mirtazapine is another medication with some positive preliminary data for the treatment of methamphetamine dependence. Mirtazapine blocks alpha 2-autoreceptors and alpha 2-heteroreceptors as well as 5-HT2 and 5-HT3 receptors. It is thought to raise synaptic levels of serotonin, norepinephrine and dopamine. Mirtazapine was evaluated in 60 methamphetamine-dependent men who have sex with men in a 12-week double-blind, placebo-controlled trial. Patients treated with mirtazapine submitted significantly fewer methamphetamine-positive urine drug samples during the trial (Colfax et al., 2011).

Conclusions

The goal of finding a medication FDA approved for the treatment of cocaine or amphetamine/methamphetamine dependence has not been achieved. Nevertheless, several medications for the treatment of cocaine dependence have shown promise in controlled trials and continue to be studied. Dopamine agonists and topiramate appear to be most promising at this point. For the treatment of amphetamine dependence, many more preliminary trials will need to be done because the process of medication development for this illness is not as far along. Preliminary results have shown a consistent response for bupropion for amphetamine-dependent patients with less severe disease and some early positive responses with topiramate and bupropion.

OPIOID DEPENDENCE

Although the history of opiate addiction in the United States goes back more than 100 years, most of the societal response has been legal rather than medical. Physicians are heavily restricted in their ability to deal with opiate addiction as a medical problem. Most treatment consists only of detoxification—that is, removal of the drug from the body by metabolism while withdrawal symptoms are being treated by another medication. In reality, detoxification is simply a first step in a long-term relapse-prevention program. Two medical approaches to aid in detoxification are available. One is the use of an opioid agonist in gradually decreasing doses over 5 to 10 days. This permits a smooth, comfortable detoxification for most patients. A long-acting medication such as methadone or buprenorphine is preferable because

it permits a smooth transition to the drug-free state. A second option is the use of a drug that blocks certain aspects of the withdrawal syndrome, such as clonidine or lofexidine.

Methadone

Some opioid addicts are able to detoxify and remain drug-free, but the majority relapse, even after intensive psychotherapy. More important, many heroin addicts will not even consider a drug-free treatment approach or entry into a therapeutic community. Maintenance treatment using methadone (Table 24.7), which was developed in the 1960s, consists of transferring the patient from heroin, a short-acting opiate that must be taken by injection two to four times daily, to methadone, a long-acting opioid that need be taken only once daily by mouth. The changes produced by transfer to a long-acting opioid are significant. The treatment requires relatively little effort on the part of the patient, giving it wide appeal. This appeal is important from a public health perspective because infections such as HIV and resistant tuberculosis threaten the general public as well as substance abusers.

Initially, most heroin addicts have poor motivation to change their lives. When first introduced to methadone treatment, they still want to get "high" and mix other drugs with prescribed medication. With appropriate counseling in a structured program, the patient can make the transition from thinking like a street addict to being a productive citizen. Methadone substitutes for heroin, reduces drug-seeking behavior, and blocks opiate withdrawal symptoms. It stabilizes physiological systems because of its long duration of action in contrast to the short action of heroin, which produces ups and downs (Kreek, 1992). Typically patients continue to use some heroin during the first few weeks or months on methadone. Methadone does not block the effects of heroin, but it produces cross-tolerance to heroin and all similar drugs. Thus, the effects of usual doses of heroin are diminished, and over time the typical patient decreases heroin use further and then stops.

Randomized studies have strongly supported the efficacy of methadone when used as a maintenance medication. A recent Cochrane Collaboration review (Mattick, Breen, Kimber, & Davoli, 2009) that included 11 studies compared methadone maintenance to no-opioid-replacement control groups (e.g., placebo medication, offer of drug-free treatment, detoxification, or waitlist control). The results indicated that methadone maintenance produced significantly longer retention in treatment (older studies RR = 3.05, 95% CI: 1.75–5.35; newer studies RR = 4.44, 95% CI: 3.26–6.04) and lower rates of opiate use as indicated by self-reported heroin use and biological measures (urine toxicology or hair analysis) (RR = 0.66, 95% CI: 0.56–0.78), compared to the control conditions. Methadone maintenance was also associated with less criminal activity (RR = 0.39, 95% CI: 0.12–1.25) and lower mortality rates (RR = 0.48, 95% CI: 0.10–2.39), although these findings were not statistically significant due to a smaller number of studies that considered these outcomes.

A comprehensive review of prior systematic reviews and more recent studies not included in these reviews also strongly supported the clinical effectiveness of methadone maintenance versus no drug therapy or placebo (Connock et al., 2007). This review indicated that methadone produced longer retention (pooled RR = 3.91, 95% CI: 1.17–13.2) and lower rates of opiate use (pooled effect size = 0.65, 95% CI: 0.41–0.89).

There is also some evidence that indicates the improvements shown by methadone patients are produced by a combination of medication (methadone) and psychosocial intervention (Connock et al., 2007). When methadone dose is held constant at a level adequate for most patients (60 mg), there is an orderly relationship between the "dose" of psychotherapy and the outcome of treatment (McLellan et al., 1993). Some improvement is seen with methadone alone, but with increments in psychosocial interventions, there is significantly greater improvement as measured by illicit drug use, psychiatric symptoms, family problems, and employment. Other studies have demonstrated that patients on methadone become healthier and have lower rates of exposure to infections, including HIV (Metzger et al., 1993).

The physiological stability produced by methadone is demonstrated in several ways. Patients report fewer sleep problems and less depression. Women report irregular menses while on heroin, but on methadone there is at first a suppression of menstruation and then, after about 6 to 12 months, a resumption of regular cycling. A similar stabilization is noted in the hypothalamic-pituitary-adrenal axis. Women can conceive while on methadone, and the babies are born physically dependent on the opioid. While on

methadone, expectant mothers can receive good prenatal care, and the withdrawal syndrome in newborns is readily treated. Although it would be preferable to have women drug-free during pregnancy, babies born to methadone-treated mothers are significantly healthier than babies born of mothers using street heroin.

Brief maintenance (extended detoxification) as defined by federal methadone regulations is up to 180 days of methadone treatment. This is enough time to give some patients a stable period during which they can organize their lives and become engaged in psychotherapy. Six months is too short for most patients, however, and the duration of methadone treatment should be determined by the patient's needs and not by an arbitrary time limit. Some patients require several years of stable methadone maintenance before they can be gradually detoxified by decreasing the dose of methadone. Many others require indefinite maintenance on this medication. For these patients, methadone should be considered as a kind of "hormone replacement therapy" analogous to thyroxine for patients with hypothyroidism or prednisone for patients with Addison's disease.

The endogenous opioid system is so complicated that a simple diagnostic test has not yet been devised that could demonstrate a primary or secondary deficiency state, if one existed. Some data measuring spinal fluid or plasma endogenous opioids from addicts do exist, but they are limited to individual peptides and do not give a clear picture of the overall system (O'Brien, 1993). There are also data from nonaddict populations showing that the system can

be congenitally hyperactive, resulting in babies born with stupor and respiratory depression that is reversed by opiate antagonists such as naloxone or naltrexone (Myer, Morris, Brase, Dewey, & Zimmerman, 1990). It is theoretically possible, therefore, that other individuals could be born with congenitally low endogenous opioids, possibly giving them a lower threshold for pain and making them more vulnerable to becoming opioid addicts. It is also possible, but not clearly demonstrated, that years of taking exogenous opiates, such as heroin, could suppress the production of endogenous opioids and create a need for lifetime methadone as "hormone replacement." This would explain why many former opioid addicts are unable to remain free of exogenous opioids despite apparently good motivation.

A hypothetical derangement of the endogenous opioid system would also be consistent with data demonstrating a protracted opioid withdrawal syndrome (Martin & Jasinski, 1969). Although the acute opioid withdrawal syndrome diminishes in a matter of 5 to 10 days whether or not treatment is received, a more subtle withdrawal syndrome lasting 6 months has been described under controlled inpatient conditions. Symptoms consist of sleep disturbance and dysphoria with accompanying disturbances in appetite, blood pressure, and cortisol rhythms. These symptoms would be expected to increase the probability of heroin use if the patient were in an environment where opiates were available.

Despite overwhelming evidence demonstrating efficacy (see Table 24.7), methadone remains a controversial treatment (Institute of Medicine, 1990). Methadone produces clear functional improvement, but not a cure. The patient remains physically dependent on a synthetic replacement medication and is capable of functioning normally. Tolerance develops to the sedating effects of opioids, and patients receiving methadone are quite alert (Zacny, 1995) and capable of operating motor vehicles and performing complex tasks such as teaching school or practicing law or medicine. Unfortunately, methadone programs are generally underfunded, and some programs do little more than dispense methadone. This can be of some benefit, but the full impact of methadone treatment requires a structured counseling/psychotherapy program. Eventually, frequent counseling sessions become unnecessary, and patients can be trusted to take methadone at home. Legal requirements permit only limited doses to be prescribed for use at home, even for patients who have demonstrated their trustworthiness.

Buprenorphine

Buprenorphine (Table 24.8) belongs to another class of medications called *partial agonists*. It was originally approved for the treatment of pain but has also shown good efficacy as a maintenance drug in clinical trials among heroin addicts. As a partial mu opiate agonist, buprenorphine activates opiate receptors, producing effects similar to those of heroin and methadone, but there is a "ceiling" such that higher doses produce no greater effect. In studies so far, overdose from buprenorphine alone has occurred rarely, if at all, but the drug can be lethal when mixed with benzodiazepines in high doses. If heroin or other opioids are taken, their effects are attenuated or blocked by the presence of buprenorphine. Buprenorphine

		620; 3	High		Opioid use—urinalysis	–1.23 (–0.95 to –0.51)	

was approved for treatment of opiate addiction in the United States in 2002. A unique aspect is that it can be prescribed in a doctor's office, thus eliminating the need to attend a strictly controlled methadone clinic.

Buprenorphine for the treatment of opioid dependence is available in two forms. The most commonly used form is buprenorphine combined with naloxone in a ratio of 4 to 1 (buprenorphine to naloxone). The combination product is intended to discourage intravenous abuse of buprenorphine. Naloxone has poor sublingual bioavailability. When the combination product is used sublingually, the effect is that of buprenorphine. If the product is diverted and used intravenously, the predominant effect is that of naloxone, which does not result in opioid high and may result in precipitated withdrawal in individuals physically dependent on opioids. The use of buprenorphine alone (without naloxone) should be reserved for pregnant women. The effects of naloxone on the developing fetus are unknown.

To legally prescribe buprenorphine, physicians must take a formal course on the drug to obtain a special license, and they are limited to 30 patients on this medication at any one time in their first year of practice, and 100 patients thereafter. The results of clinical trials are roughly similar to those involving methadone, although heroin addicts with a high degree of physical dependence may require the full agonist benefits of methadone (R. E. Johnson et al., 2000). The upper limit of buprenorphine effects is equivalent to about 40 mg of methadone. Based on experience from clinical trials, some heroin addicts prefer methadone, and others state that they feel the most stable and alert on buprenorphine. As with the treatment of other diseases, it is helpful for the clinician to have a selection of medications from which to choose.

A meta-analysis of studies that have compared buprenorphine maintenance to placebo was conducted recently by the Cochrane Collaborative (Mattick, Kimber, Breen, & Davoli, 2008). This review examined retention and opiate (urine toxicology), cocaine, and benzodiazepine use outcomes. The analyses broke studies down by the dose of buprenorphine that was provided. Low (RR = 1.50, 95% CI: 1.19–1.88), medium (RR = 1.74, 95% CI: 1.06–2.87), and high (RR = 1. 74, 95% CI: 1.02–2.87) doses of buprenorphine produced better retention rates than placebo. Medium (std. mean difference = –0.28, 95% CI: –0.47–0.10) and high doses (std. mean difference = –1.23, 95% CI: –0.95 to –0.51) of buprenorphine produced lower rates of heroin use than placebo, but low-dose buprenorphine did not differ from placebo (std. mean difference = 0.10, 95% CI: –0.80–1.01). Buprenorphine was generally not efficacious with regard to cocaine or benzodiazepine use.

Several other studies have investigated strategies to improve outcomes in buprenorphine treatment. One study tested whether increasing dosing in standard primary care medical management from one to three times per week and providing additional drug counseling in the sessions improved outcomes (Fiellin et al., 2006). Results indicated no advantage to more frequent dosing or additional drug counseling on drug use or retention. Combining naltrexone with buprenorphine produced better retention and drug use outcomes than buprenorphine only in another randomized study, as well as better scores on measures of irritability, depression, tiredness, and craving (Gerra, Fantoma, & Zaimovic, 2006). Kakko and colleagues (2007) found that a stepped-care protocol, in which patients began on buprenorphine and escalated to methadone if they did not do well on buprenorphine, produced retention and drug use outcomes that did not differ from a group randomized to initiate treatment on methadone. About half the participants (46%) in the stepped-care condition were able to remain on buprenorphine, which is a safer medication.

A two-phase adaptive trial by Weiss and colleagues (2011) with patients dependent on prescription opioids found that brief treatment (4 weeks) with buprenorphine–naloxone produced very poor outcomes (6.6% positive response rate), even when more intensive counseling was added. Providing nonresponders with 12 more weeks of buprenorphine–naloxone increased the positive response rate to 49.2%, but the rate dropped to 8.6% at 8 weeks after medication had been discontinued. Once again, there was no effect for more intensive counseling. In a second trial, investigators evaluated the efficacy of a brief stabilization with buprenorphine followed by oral naltrexone treatment. In this trial 50% of patients treated with a 4-week buprenorphine stabilization followed by 6 weeks of oral naltrexone therapy were abstinent from opioids at their last study visit (Sigmon et al., 2013). The results of these two trials suggest that buprenorphine can be effective for the treatment of prescription opioid dependence but brief treatments are likely to be ineffective.

Finally, Ling and colleagues (2010) tested the efficacy of buprenorphine implants, which address the problems with adherence and diversion that have been noted in clinical practice and research studies. Opioid-dependent patients randomized to buprenorphine implants had a higher percentage of opiate-negative urine samples over the 16-week trial than those who received a placebo implant (40.4% vs. 28.3%, $p = 0.04$). These results were obtained even though patients in both conditions could receive buprenorphine–naloxone tablets for emergent withdrawal or craving, and 91% of those in the placebo condition received these tablets, for an average of 19 days.

Methadone Versus Buprenorphine Maintenance

A meta-analysis of studies that have compared methadone maintenance and buprenorphine maintenance was conducted recently by the Cochrane Collaborative (Mattick, Kimber, Breen, & Davoli, 2008). This review examined retention, opiate use (biological assays and self-report), cocaine use, benzodiazepine use, and criminal activity. The analyses broke studies down by the dose of methadone and buprenorphine that were provided. Buprenorphine had lower retention rates than methadone in studies with flexible doses (RR = 0.85, 95% CI: 0.73–0.98) and those with low doses (RR = 0.67, 95% CI: 0.52–0.87), but not in studies with medium doses.

There was little evidence of any differences between methadone and buprenorphine maintenance on opioid urine toxicology or self-report outcomes, with the exception of opioid urine toxicology results favoring methadone when medium doses of both drugs were used (std. mean difference = 0.27, 95% CI: 0.05–0.50). There were no differences between the two medications on cocaine use, benzodiazepine use, or criminal activity. However, a second systematic review found that at equivalent doses methadone maintenance was more effective than buprenorphine maintenance on cocaine abstinence in patients with comorbid opioid and cocaine dependence (RR = 1.63, 95% CI 1.20–2.22, $p = 0.002$) (Castells, Kosten, Capella, Vidal, Colom, & Casas, 2009).

Opioid Antagonist Treatment

The discovery of specific opiate receptor antagonists in the early 1970s gave rise to hopes for the "perfect" medication for the treatment of heroin addiction. Naltrexone (Table 24.9) seemed to be the answer because it specifically blocks mu opiate receptors and, to a lesser extent, kappa receptors and delta receptors (Raynor et al., 1994), and it has little or no direct or agonist effects of its own. Naltrexone and its short-acting analogue naloxone have high affinity for opiate receptors and will displace drugs like morphine or methadone, resulting in the sudden onset of withdrawal symptoms when given to people who are opioid dependent. If the heroin addict is first detoxified so that opiate receptors are gradually evacuated, naltrexone will bind to the receptors and prevent subsequent injections of heroin from having an effect. Numerous clinical trials showed that naltrexone was effective in blocking opiate receptors and safe; thus, it was approved by the FDA in 1983 for maintenance treatment of heroin addiction.

Unfortunately, naltrexone is a much-underused medication in the treatment of heroin addiction. Unlike methadone, it has no positive psychoactive effects. Few street heroin addicts show any interest in this type of treatment, and few programs encourage patients to try it. Opioid antagonists are more complicated to prescribe than methadone, and most physicians have not been trained in their use. Opioid-dependent health care workers such as physicians, pharmacists, and nurses often do well on naltrexone because it enables them to return to work with no risk of relapse even though they work in areas with high drug availability. There is also evidence that naltrexone is helpful in preventing relapse in probationers who have a conditional release from prison after drug-related crimes (Brahen, Henderson, Copone, & Kordal, 1984; Cornish et al., 1997).

A recent multisite study done in Russia randomly assigned 250 opioid-dependent patients to placebo or an injectable form of naltrexone, both of which were administered by monthly injections for 6 months. All patients also were offered behavioral treatment, in the form of biweekly drug counseling sessions. Injectable naltrexone produced a higher percentage of urine-test-confirmed abstinent weeks (90.0% vs. 35.0%, $p = 0.0002$) and a higher percentage of patients with confirmed abstinence over the whole trial (45% vs. 28%, $p = 0.02$) than placebo.

Experience with naltrexone demonstrates that blocking opiate receptors does not impair normal function for most people. Studies in animals have implicated opiate receptors in a wide variety of functions

TABLE 24.9 Medications for Heroin Dependence: Naltrexone

Authors	*Study Class*	*N*	*Treatment Length*	*Follow-up Length*	*Results*	*Comments*
Lerner et al. (1992)	1	31	–	2 months	Craving reduced in naltrexone group; reports of euphoria blocked when opiates used, but no evidence of reduced drug use as compared with placebo	–
Shufman et al. (1994)	2	32	3 months	–	Fewer heroin-positive urine tests, more drug-free patients, more improvement in psychological parameters in naltrexone group	Small sample size.
Gerra et al. (1995)	1	152	3 months	6 months	Double-blind, placebo-controlled 3 months of daily medication: clonidine only, clonidine and naltrexone, clonidine and naloxone; placebos. Better results with longer duration of naltrexone treatment.	Consistent with prior studies showing high dropout rate, but good results for patients who remain longer
Cornish et al. (1997)	1	51	6 months	6 months	All participants were volunteers from federal probation. Those randomized to control group received equivalent counseling, but no placebo. 52% completion in naltrexone vs. 33% for controls. Opioid use 8% in naltrexone vs. 30% for controls. Only 26% of naltrexone groups were reincarcerated vs. 56% for controls.	Demonstrates potential usefulness of naltrexone in a parole population
Comer et al. (2006)	1	60	2 months	–	Depot naltrexone, Biotek version, placebo, 192 or 384 mg depot naltrexone per month; treatment retention, dose-related, 39%, 60%, 69% retention, positive urine samples varied according to dose	Minimal side effects.
Krupsky et al. (2011)	1	250	6 months	–	Opiate-dependent patients with 7 or more days of opiate abstinence were randomized to 380 mg extended-release naltrexone (XR-NTX) or placebo. Median proportion of weeks of confirmed abstinence was 90.0 in XR-NTX group, compared to 35.0 in the placebo group ($p = 0.0002$). Results with retention and secondary substance use outcomes also were significantly better in the XR-NTX condition.	XR-NTX is injectable, extended-release naltrexone. Injections provided every month

such as control of appetite, sexual behavior, and, of course, pain perception. Occasionally, normal volunteers given naltrexone report dysphoria or depression, but most former heroin addicts have few symptoms related to the antagonist. Some have remained on naltrexone for up to 20 years with no apparent change in appetite or pain perception and no impairment of ability to experience pleasure from sources such as sex or music. The recent approval of depot naltrexone should have an immediate positive effect on the treatment of heroin addiction. Although the cost of monthly injections will likely be an issue, it will be far less than the costs of drug-related crime and imprisonment.

CONCLUSIONS

The studies reviewed in this chapter indicate that, at this time, there are medications with at least some degree of efficacy in the treatment of nicotine, alcohol, and opiate use disorders. Several medications approved for other indications have shown efficacy for cocaine addiction. Methamphetamine addiction is the target of intense clinical research at present, and a medication that aids in the treatment of this difficult addiction will likely be discovered in the future. In addition, medications aimed at the treatment of drug craving are beginning to appear (O'Brien, 2005). Long-term psychosocial interventions should generally be used in conjunction with pharmacotherapy when treating SUDs to facilitate retention and compliance and to address the myriad of psychological and social problems that often accompany addiction (O'Brien, 1996). It is also important to treat comorbid psychiatric disorders, particularly when they are either preexisting or independent of the SUD. Additional studies are needed to examine issues such as the long-term efficacy and effectiveness of existing and new medications, matching subgroups of patients to particular medications, and potential dangers associated with severe relapse while on medications (Schuckit, 1996).

Treatments for Gambling Disorder and Impulse Control Disorders

Jon E. Grant
Brian L. Odlaug
Marc N. Potenza

Several controlled outcome studies (type 1 and type 2) suggest that specific behavioral (e.g., cognitive-behavioral therapy [CBT]) and pharmacological (e.g., naltrexone, nalmefene, lithium) treatments significantly reduce the symptoms of pathological gambling (now termed gambling disorder in *DSM-5*) in the short term compared with waitlist or placebo. Although long-term effects of manual-based CBT have been observed in several small studies, the long-term benefits of pharmacological treatment have not been adequately tested. Only one study combining behavioral and pharmacological therapies has been published to date. Thus, the potential benefit of combining behavioral and drug treatments for gambling disorder remains underresearched. Although several studies suggest that CBT is effective for trichotillomania, only two pharmacological treatment studies (both type 1) in adults (*N*-acetylcysteine [NAC], olanzapine) for this disorder have shown promise. Similarly, studies of group CBT (type 1) have demonstrated benefit for compulsive buying, but controlled pharmacological studies (type 1 and type 2) have shown mixed results. Although limited treatment studies exist for other impulse control disorders, one pharmacological study for kleptomania (type 1) and one for intermittent explosive disorder (IED type 1) have shown promise.

INTRODUCTION

Despite high prevalence rates in the general population (Kessler et al., 2005) and in psychiatric cohorts (Grant, Levine, Kim, & Potenza, 2005), impulse control disorders have been relatively understudied. Controlled treatment trials do not exist for many of the impulse control disorders. The disorder that has been arguably the most well researched (pathological gambling, which is now gambling disorder [GD] in *DSM-5*; we will use the term *GD* throughout the chapter to refer to pathological gambling or GD) has only recently been systematically investigated with respect to empirically supported behavioral and pharmacological treatments. Because rigorous research is particularly limited for several impulse control disorders (e.g., pyromania and Internet gaming disorder), this chapter reviews the available research on the treatment of gambling disorder, trichotillomania, compulsive buying, IED, and kleptomania.

Although this chapter reviews the pharmacological and psychological treatment of GD along with that of impulse control disorders, GD is now part of a new *DSM-5* section entitled "substance-related and addictive disorders." The similarities between GD and substance use disorders (e.g., phenomenology/clinical presentation, comorbidity, familiality, cognition, neuroanatomy/neurochemistry, and treatment) led to this

reclassification of GD together with substance use disorders in *DSM-5* (Grant & Chamberlain, 2013).

GAMBLING DISORDER

GD, characterized by persistent and recurrent maladaptive patterns of gambling behavior, is associated with impaired functioning, reduced quality of life, and high rates of bankruptcy, divorce, and incarceration (Hodgins, Stea, & Grant, 2011). GD usually begins in adolescence or early adulthood, with males tending to start at an earlier age (Ibanez, Blanco, Moreryra, & Saiz-Ruiz, 2003; Shaffer, Hall, & Vander Bilt, 1999). In epidemiological studies, women represent approximately 32% of individuals with GD in the United States (Volberg, 1994). Although prospective studies are largely lacking, GD appears to follow a similar trajectory as substance dependence, with high rates in adolescent and young adult groups, lower rates in older adults, and periods of abstinence and relapse (Grant & Potenza, 2004; Leeman & Potenza, 2012).

Males with GD appear more likely to report problems with strategic or "face-to-face" forms of gambling like blackjack or poker. Females with GD tend to report problems with nonstrategic, less interpersonally interactive forms of gambling like slot machines or bingo (Potenza et al., 2001). Both female and male gamblers report that advertisements are common triggers for their urges to gamble, although females are more likely to report that feeling bored or lonely may also trigger their urges to gamble (Afifi, Cox, Martens, Sareen, & Enns, 2010; Echeburúa, González-Ortega, de Corral, & Polo-López, 2011). Financial and marital problems are common (Grant & Kim, 2001). Many individuals with GD engage in illegal behavior, such as stealing, embezzlement, and writing bad checks, to fund their gambling (Potenza et al., 2000). GD frequently co-occurs with other psychiatric disorders, including mood, anxiety, and substance use disorders (Lorains, Cowlishaw, & Thomas, 2011; Petry, Stinson, & Grant, 2005) and is associated with poor overall health (Morasco, Vom Eigen, & Petry, 2006; Pietrzak, Morasco, Blanco, Grant, & Petry, 2007).

Pharmacological Treatment

Several medications have been investigated as treatments for GD (Table 25.1). These have included antidepressants (particularly serotonin reuptake inhibitors [SRIs]), lithium, glutamate agents, neuroleptics, and opioid antagonists. Multiple open-label studies using various medications (citalopram, escitalopram, carbamazepine, nefazodone, bupropion, valproate, naltrexone, tolcapone) for short periods of time (8 to 14 weeks) have demonstrated efficacy in approximately 70% to 75% of GD subjects. Seventeen double-blind, placebo-controlled pharmacotherapy studies have also been performed in GD, but the results of these studies have demonstrated mixed efficacy and tolerability.

Antidepressants

Hypotheses underlying the examination of antidepressant medications for GD are based on the neurobiology of GD and other impulse control disorders. Low levels of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA) and blunted serotonergic response within the ventromedial prefrontal cortex (vmPFC) have been associated with impulsive behaviors (Coccaro, 1996; Virkkunen, Goldman, & Nielsen, 1995). As compared with control comparison subjects, individuals with GD demonstrate diminished activation of the vmPFC when viewing gambling-related videotapes or during prepotent response inhibition when performing the Stroop color-word interference task (Potenza et al., 2003a, 2003b). Individuals with GD also show relatively diminished activation of the vmPFC during a simulated gambling task, and severity of gambling problem correlated inversely with signal intensity within this brain region (Reuter et al., 2005). In addition, levels of serotonin 1B receptor in the ventral striatum have been associated with problem gambling severity, suggesting that this receptor may in part contribute to differences in ventral striatal activity observed in GD (Potenza et al., 2013). Taken together, the findings suggest that drugs targeting serotonin neurotransmission may hold promise for the treatment of GD.

Of the 17 double-blind, placebo-controlled pharmacological studies in GD, 6 have examined SRIs. Clomipramine, an SRI that also inhibits norepinephrine reuptake, was the first SRI tested in a controlled fashion in GD. Hollander and colleagues (1992) reported a response to clomipramine in a single GD subject using a double-blind, placebo-controlled design. After receiving placebo for 10 weeks without

TABLE 25.1 Double-Blind, Placebo-Controlled Pharmacotherapy Trials for Gambling Disorder

Study	*Medication*	*Design/Duration*	*Subjects*	*Mean Daily Dose (± SD)*	*Outcome*
Hollander et al., 1992	Clomipramine	Parallel design 10 weeks	1 enrolled 1 completer	125 mg	90% improvement in gambling symptoms on medication
Saiz-Ruiz et al., 2005	Sertraline	Parallel design 6 months	60 enrolled 44 completers	95 mg	Similar improvement in both groups
Hollander et al., 2000	Fluvoxamine	Crossover 16-weeks with a 1-week placebo lead-in	15 enrolled 10 completers	195 mg (± 50)	Fluvoxamine superior to placebo
Blanco et al., 2002	Fluvoxamine	Parallel design 6 months	32 enrolled 13 completers	200 mg	Fluvoxamine not statistically significant from placebo
Kim et al., 2002	Paroxetine	Parallel design 8 weeks with 1-week placebo lead-in	53 enrolled 41completers	51.7 mg (± 13.1)	Paroxetine group significantly improved compared to placebo
Grant et al., 2003	Paroxetine	Parallel design 16 weeks	76 enrolled 45 completers	50 mg (± 8.3)	Paroxetine and placebo groups with comparable improvement
Grant & Potenza, 2006	Escitalopram	Open-label (12 weeks) with responders randomized to 8 weeks parallel design escitalopram or placebo	13 enrolled, all with co-occurring anxiety disorder and GD	25.4 mg (± 6.6)	Open-label reductions in anxiety and gambling and improvements appear to persist with active but not placebo drug
Black et al., 2007	Bupropion	Parallel design 12 weeks	39 enrolled 22 completers	324 mg	Bupropion and placebo groups demonstrated similar symptom improvement
Hollander et al., 2005	Lithium carbonate SR	Parallel design 10 weeks	40 Bipolar-spectrum patients enrolled 29 completers	1,170 mg (± 221)	Lithium group significantly improved compared with placebo
Kim et al., 2001b	Naltrexone	Parallel design 12 weeks with 1-week placebo lead-in	89 enrolled 45 completers	188 mg (± 96)	Naltrexone group significantly improved compared with placebo
Grant et al., 2008	Naltrexone	Parallel design 18 weeks with 1-week placebo lead-in (50 mg, 100 mg, 150 mg naltrexone vs. placebo)	77 enrolled 49 completers	Combined groups—no specific efficacious dose noted	Naltrexone group significantly improved compared with placebo on gambling and psychosocial function

(*continued*)

TABLE 25.1 (continued)

Study	*Medication*	*Design/Duration*	*Subjects*	*Mean Daily Dose (± SD)*	*Outcome*
Grant et al., 2006	Nalmefene	Parallel design 16 weeks	207 enrolled 73 completers	Fixed-dose study	Nalmefene 25 mg and 50 mg significantly improved compared to placebo
Grant et al., 2010	Nalmefene	Parallel design 16 weeks	233 enrolled 126 completers	Fixed dose study (20mg, 40mg, or placebo)	Initial analysis revealed no differences. Post-hoc analysis: 40 mg group significantly improved compared to placebo.
Grant et al., 2007	N-acetylcysteine (NAC)	Open-label with responders randomized to 6-weeks, parallel design NAC or placebo	27 enrolled 23 completers	1,476.9 mg (± 311.3)	NAC group had significant gambling symptom improvement in open-label phase; sustained in double-blind phase
Grant et al., 2014	NAC with imaginal desensitization	Parallel design 12 weeks	28 individuals with GD and nicotine dependence enrolled	1,200 mg to 3,000 mg	NAC + imaginal desensitization group significantly improved compared to placebo
Berlin et al., 2013	Topiramate	Parallel design 14 weeks	42 enrolled 27 completers	222.5 mg (± 108.5)	No differences between groups
McElroy et al., 2008	Olanzapine	Parallel design 12 weeks	42 enrolled 25 completers	8.9 mg (± 5.2)	Similar reductions in gambling symptoms in olanzapine and placebo groups
Fong et al., 2008	Olanzapine	Parallel design 7 weeks	23 enrolled 21 completers	2.5 mg to 10 mg	Similar reductions in gambling symptoms in olanzapine and placebo groups

response, the woman reported a 90% improvement in gambling symptoms after being treated with 125 mg/day of clomipramine. There have been no further controlled studies of clomipramine, however, to confirm the limited results of this initial study. In addition to its more common side effects (dry mouth, constipation, blurred vision, sexual dysfunction, weight gain, fine tremor, muscle twitching), clomipramine may also cause cardiac conduction problems and has significant drug–drug interactions.

In a double-blind, placebo-controlled study using sertraline, 60 subjects with GD were treated for 6 months (mean dose = 95 mg/day; Saiz-Ruiz et al., 2005). At the end of the study, 23 sertraline-treated subjects (74%) and 21 placebo-treated subjects (72%) were rated as responders based on the primary outcome measure (the outcome measure was the Criteria for Control of Pathological Gambling Questionnaire, a measure with good internal consistency and convergent validity), which assessed urges to gamble and gambling behavior. Sertraline did not demonstrate superiority to placebo. The authors presented only limited data on the psychometrics of their primary outcome measure. Sertraline was generally well tolerated, but, as with other antidepressants, it may cause sedation, constipation, weight gain, headache, sexual dysfunction, and dry mouth.

Only two SRIs have been examined in at least two randomized, placebo-controlled trials of GD. A double-blind, 16-week crossover study of fluvoxamine in 15 GD subjects demonstrated a statistically significant difference compared with placebo (Hollander et al., 2000). Interpretation of the study is complicated, however, by a phase-order treatment interaction (i.e., the medication did not separate from placebo during the first phase but did in the second phase). A 6-month double-blind, placebo-controlled trial of fluvoxamine in 32 gamblers failed to show statistical significance compared with placebo. The results of the latter study, however, are complicated by high rates of treatment discontinuation (only three subjects on medication completed the study) and a high placebo response rate (59%; Blanco, Petkova, Ibanez, & Saiz-Ruiz, 2002). Although differences in the results may be attributable to the temporal duration of each study, other design issues might also be important. For example, the study by Hollander and colleagues used the Pathological Gambling Modification of the Yale-Brown Obsessive Compulsive Scale (PG-YBOCS) as the primary outcome measure. The PG-YBOCS has demonstrated excellent validity and reliability in gambling treatment studies (Pallanti, DeCaria, Grant, Urpe, & Hollander, 2005). The study by Blanco and colleagues, however, used amount of money spent weekly as the primary outcome measure. These differences in outcome measures complicate the comparisons one can make between these two studies. Although fluvoxamine is generally well tolerated, it may result in gastrointestinal distress, sedation, mild anxiety, headache, increased urinary frequency, and sexual dysfunction. Fluvoxamine is a potent P450 1A2 inhibitor, and drug–drug interactions should be considered before it is prescribed.

As with fluvoxamine, studies have failed to demonstrate consistently the efficacy of paroxetine in treating GD. An initial double-blind, placebo-controlled study of paroxetine indicated its potential efficacy as a treatment for GD. Significant improvement was seen in subjects randomized to 8 weeks of treatment with paroxetine compared with those assigned to placebo (Kim, Grant, Adson, Shin, & Zaninelli, 2002). A larger multicenter, double-blind, placebo-controlled trial with patients with GD, however, failed to reproduce the results (Grant et al., 2003). In this second study, a high placebo response rate ("very much improved" or "much improved" based on the Clinical Global Improvement [CGI] scale) was observed: At study end, 48% of those assigned to placebo and 59% of those taking paroxetine were considered responders. Further study appears warranted to determine whether specific subgroups of individuals with GD (e.g., those with specific genetic characteristics) will respond preferentially to treatment with paroxetine or other SRIs. Consistent with this notion, preliminary data from an open-label escitalopram trial followed by double-blind randomization to active escitalopram or placebo phase suggest that individuals with GD and co-occurring anxiety disorders may benefit (on both measures of anxiety and gambling) from escitalopram (Grant & Potenza, 2006).

Although the randomized, placebo-controlled trials of antidepressants in GD have focused on medications with primarily serotonergic properties, one other antidepressant with a different mechanism of action has been tested. Bupropion (Black et al., 2007), a dopaminergic medication, was studied in 39 subjects during a 12-week period (mean dose = 324 mg/day). At the end of the study, both groups showed similar reductions in the PG-YBOCS, and five of

the bupropion-treated group (35.7%) and eight of the placebo-treated group (47.1%) were considered responders on the CGI scale. Bupropion was generally well tolerated but may cause headache, nervousness, stomach discomfort, and dry mouth.

Lithium

In one fluvoxamine study, two of three nonresponders worsened with active drug treatment and were observed to have symptoms of cyclothymia (Hollander et al., 1998). These findings suggested that an alternate medication, such as lithium, might be helpful for specific individuals with GD. In a double-blind, placebo-controlled study of 40 GD subjects with bipolar spectrum disorders (bipolar type II, bipolar not otherwise specified, or cyclothymia), sustained-release lithium carbonate (mean lithium level = 0.87 mEq/L) was shown to be superior to placebo in reducing GD symptoms during 10 weeks of treatment (Hollander, Pallanti, Allen, Sood, & Baldini Rossi, 2005). Although a majority (83%) of subjects in the treatment group displayed significant decreases in gambling urges, thoughts, and behaviors as measured by the PG-YBOCS, no differences were found in amount of money lost, episodes of gambling per week, or time spent per gambling episode. Active as compared with placebo drug was also superior in reducing symptoms of mania. Subjects in this study tolerated lithium without difficulty, but lithium may cause fine tremor, nausea, and diarrhea, and nephrotoxicity is possible when it is used chronically.

Opioid Antagonists

Opioid receptor antagonists inhibit dopamine release in the nucleus accumbens and ventral pallidum through the disinhibition of gamma-aminobutyric acid (GABA) input to the dopamine neurons in the ventral tegmental area (Broekkamp & Phillips, 1979; Phillips & LePiane, 1980; van Wolfswinkel & van Ree, 1985). As compared with control comparison subjects, individuals with GD show differences in nucleus accumbens activation during a simulated gambling task (Reuter et al., 2005). Although modulation of drive and subsequent behavioral output by dopamine, endorphin, and GABA have been investigated, the specific mechanisms underlying opioid receptor antagonism in specific patient groups such as those with GD remain incompletely understood.

A 12-week double-blind, placebo-controlled trial of naltrexone demonstrated superiority to placebo in 45 subjects with GD (Kim, Grant, Adson, & Shin, 2001b). Naltrexone (mean dose = 88 mg/day) was effective in reducing the frequency and intensity of gambling urges, as well as gambling behavior. A separate analysis of those subjects with at least moderate urges to gamble revealed that naltrexone was more effective in gamblers with more severe urges to gamble. The clinical use of naltrexone, however, is limited by significant side effects, as well as the occurrence of liver enzyme elevations, especially in patients taking nonsteroidal anti-inflammatory drugs (Kim, Grant, Adson, & Remmel, 2001a). More than 20% of subjects receiving active naltrexone developed abnormal liver function tests during a 12-week study (Kim, Grant, Adson, & Shin, 2001b). A second naltrexone study in 77 subjects randomized to either naltrexone or placebo over an 18-week period confirmed the findings of the initial study (Grant, Kim, & Hartman, 2008). Subjects assigned to naltrexone had significantly greater reductions in gambling urges and gambling behavior compared to subjects on placebo. Subjects assigned to naltrexone also had greater improvement in psychosocial functioning. By study endpoint, 39.7% of those on naltrexone were able to abstain from all gambling for at least 1 month, whereas only 10.5% on placebo attained complete abstinence for the same time period.

Two multicenter studies have further demonstrated the efficacy of opioid antagonists with the examination of nalmefene in the treatment of GD. In a large, multicenter trial using a double-blind, placebo-controlled, flexible-dose design, 207 subjects were assigned to receive 16 weeks of either nalmefene at varying doses (25, 50, or 100 mg/day) or placebo. At the end of the study, 59% of those assigned to nalmefene showed significant reductions in gambling urges, thoughts, and behavior compared to only 34% on placebo (Grant et al., 2006). The study, however, suffered from high rates of treatment discontinuation (63%). A second multicenter nalmefene study was performed with 233 participants using nalmefene (20 or 40 mg) or placebo (Grant, Odlaug, Potenza, Hollander, & Kim, 2010). In analyses performed using an intention-to-treat population, nalmefene failed to show statistically significant differences from placebo on primary and secondary outcomes. Post hoc

analyses of only participants who received a full titration of the medication for at least 1 week, however, demonstrated that nalmefene 40 mg/day resulted in significantly greater reductions on the primary outcome measure. These findings suggest that medication dosing may be an important consideration in achieving symptom control. One common side effect of opioid antagonists is nausea; these medications may also cause dizziness, insomnia, headaches, and loose stool. In addition, naltrexone, but not nalmefene, has been associated with a dose-dependent potential for hepatotoxicity.

Glutamate Agents

Because improving glutamatergic tone in the nucleus accumbens has been implicated in reducing the reward-seeking behavior in substance addictions (Kalivas, Peters, & Knackstedt, 2006), NAC, a glutamate-modulating agent, was administered to 27 GD subjects over an 8-week period, with responders randomized to receive an additional 6-week double-blind trial of NAC or placebo. Of those in the open-label phase, 59% experienced significant reductions in GD symptoms and were classified as responders. At the end of the double-blind phase, 83% of those assigned to receive NAC were still classified as responders compared to only 28.6% of those assigned to placebo (Grant, Kim, & Odlaug, 2007). A follow-up 12-week, double-blind, placebo-controlled study combining NAC with imaginal densensitization in 28 GD subjects who were also nicotine dependent found that NAC provided significant benefit compared to placebo on nicotine dependence symptoms during treatment and on gambling symptoms 3 months after formal treatment ended (Grant et al., 2014a).

Topiramate is a drug that is thought to influence mesolimbic dopamine transmission indirectly through GABAergic and glutamatergic mechanisms (Johnson, 2004). A 14-week, double-blind, placebo-controlled trial of topiramate in 42 subjects failed to show significant treatment effects for topiramate on the primary or secondary outcome measures (Berlin et al., 2013).

Atypical Neuroleptics

Two studies have examined the use of olanzapine in the treatment of GD. In a 12-week, double-blind, placebo-controlled trial of 42 subjects with GD, olanzapine (mean dose = 8.9 ± 5.2 mg) and placebo demonstrated similar reductions in gambling behavior and gambling urges (McElroy, Nelson, Welge, Kaehler, & Keck, 2008). Similarly, Fong and colleagues (2008) tested 23 GD subjects in a 7-week, double-blind, placebo-controlled trial and found similar reductions in cravings to gamble and gambling behavior in both the olanzapine and placebo groups.

Psychosocial Treatments

Current psychosocial treatment for GD involves multiple different options—brief interventions and individual and group CBT. All have demonstrated benefit in treating gambling disorders (Hodgins, Stea, & Grant, 2011). Although there is currently no agreed-upon standard-of-care for GD, the most widely studied psychological treatment for GD has been some form of CBT (Table 25.2). A meta-analysis identified 22 randomized trials published between 1968 and 2004 (Pallesen et al., 2005). This meta-analysis revealed that in general, psychological treatments were more effective than no treatment at both posttreatment (overall effect size = 2.01) and at follow-up averaging 17 months later (overall effect size = 1.59). A more recent meta-analysis that included 25 studies (Gooding & Tarrier, 2009) found that although there was considerable variability in the outcomes reported, posttreatment effects were generally positive for different types of therapy (e.g., behavioral, cognitive) and mode of therapy (e.g., individual, group, self-directed). To date, there are no randomized trials of inpatient treatment.

The majority of the psychosocial treatment literature for GD has focused on CBT techniques. The cognitive aspect includes psychoeducation, increased awareness of irrational cognitions, and cognitive restructuring. The behavioral techniques include identification of gambling triggers and the development of nongambling sources to compete with the reinforcers associated with gambling.

Cognitive Therapy

In a study of 40 subjects, individual cognitive therapy plus relapse prevention resulted in reduced gambling frequency and increased perceived self-control

TABLE 25.2 Controlled Psychological Treatment Trials for Gambling Disorder

Study	*Design/Duration*	*Subjects*	*Outcome*
Echeburúa et al., 1996	Stimulus control, in vivo exposure, relapse prevention vs. cognitive restructuring vs. combined treatment vs. waitlist/6 weeks with 12 month follow-up	64 enrolled 50 completers	At 12 months, 69% abstinence or much reduced in the first condition compared to 38% for cognitive restructuring or combined treatment
Milton et al., 2002	CBT vs. CBT + interventions, including positive reinforcement, barriers to change, problem-solving. Manualized. 8 weeks with 9 month follow-up.	40 enrolled 20 completers	No difference in outcome between treatments at 9-month follow-up, although both produced clinically significant change in the amount of money spent on gambling
Melville et al., 2004	1) Group CBT with/without mapping-enhanced treatment vs. waitlist control. 2) Mapping- enhancement treatment vs. waitlist control. Both 8 weeks.	1) 13 enrolled 2) 19 enrolled	CBT with mapping enhancement reported significant improvement; improvements sustained at 6-month follow-up
Marceaux et al., 2011	12-step procedures vs. CBT with mapping-enhancement vs. waitlist control	49 enrolled 44 completers	Both groups demonstrated significant improvement at the study end and 6-month study follow-up.
Wulfert et al., 2006	Cognitive–motivational–behavioral therapy (CMBT) vs. treatment as usual	21 enrolled 17 completers	CMBT group demonstrated significant improvements at a 12-month follow-up.
Sylvain et al., 1997	Cognitive therapy with relapse prevention vs. waitlist/30 sessions with 6-month follow-up	40 enrolled 14/22 in treatment group completed	36% improved on five variables compared to 6% on waitlist.
Ladouceur et al., 2001	Cognitive therapy + relapse prevention vs. waitlist/20 sessions with 12-month follow-up	88 enrolled 35/59 in treatment group completed	32% improved on four variables compared to 7% on waitlist.
Ladouceur et al., 2003	Group cognitive therapy + relapse prevention vs. waitlist/10 weeks with 2-year follow-up	71 enrolled 34/46 in treatment group completed	65% no longer met GD criteria compared to 20% for waitlist group.
Petry et al., 2005	Manualized CBT in individual counseling, vs. CBT workbook, vs. Gamblers Anonymous referral/ 8 sessions with 1-year follow-up	231 enrolled No data on completers	CBT was more effective than Gamblers Anonymous and individual counseling was more effective than workbook.
Dickerson et al., 1990	CBT workbook vs. workbook + a single in-depth interview	29 enrolled	Both groups showed improvement at 6 months.
Hodgins et al., 2001, 2004	CBT workbook vs. workbook + motivational enhancement intervention via telephone vs. waitlist	102 enrolled 85 available at 12 months	74% with motivational enhancement improved according to Clinical Global Impression compared to 61% with workbook and 44% on waitlist.
McConaghy et al., 1983	Aversion therapy vs. imaginal desensitization	20 enrolled 20 completers	Improvement in both groups over 12 months

McConaghy et al., 1988	Imaginal relaxation vs. imaginal desensitization	20 enrolled	Both groups improved after 1 week; however, treatment gains were not sustained at 12-month follow-up.
McConaghy et al., 1991	Aversion therapy vs. imaginal desensitization vs. in vivo desensitization vs. imaginal relaxation	120 enrolled 63 available 2 and 9 years later	Imaginal desensitization improved at 1 month and at 9 years
Grant et al., 2009a, 2011	Cue exposure with negative mood induction and imaginal desensitization with either individualized CBT or Gamblers Anonymous	68 enrolled 55 completed	64% of subjects receiving imaginal exposure + the negative mood induction vs. 17% of Gamblers Anonymous group were abstinent for 1 month. 77% of completers sustained improvements at 6-month follow-up.
Diskin & Hodgins, 2009	Single-session motivational interviewing (MI) + self-help workbook vs. workbook and talking to gambling interviewer for 30 minutes	81 enrolled 69 completers	The workbook + MI group reported less frequent gambling and with less money compared to the workbook-alone group at 1-year follow-up.
Oei et al., 2010	Individual vs. group CBT with 28 subjects assigned to waitlist control prior to intervention	102 enrolled	Individual CBT treatment resulted in better gambling symptom improvement; however, both treatments were effective in reducing gambling behavior compared to the waitlist control group.
Myrseth et al., 2009	Short-term group CBT (GCBT) vs. waitlist control	14 enrolled	85.7% of GCBT group had significant improvements in posttreatment gambling symptoms compared to 42.9% of a waitlist control.
Hodgins et al., 2007a	Detailed relapse prevention summary booklet mailed once or the same booklet with 7 additional informational booklets mailed over the next 12 months	169 enrolled	No group differences in gambling frequency or gambling losses at 12-month follow-up
Hodgins et al., 2009	Brief MI + mailed self-help workbook vs. workbook only vs. wait-list control	314 enrolled	MI + workbook and workbook-only groups reported significant decreases in gambling symptoms compared to the waitlist control.
Carlbring & Smits, 2008	Internet-based counseling vs. waitlist control	66 enrolled	Treatment group showed significant improvements in gambling symptoms as well as depression, anxiety, and overall quality of life.
Carlbring et al., 2012	Internet-based counseling vs. waitlist control	284 enrolled	Treatment group showed significant improvements in gambling symptoms as well as depression, anxiety, and overall quality of life. Maintained at 6-, 18- and 36 month follow-up.
Carlbring et al., 2010	MI vs. group CBT vs. waitlist	150 enrolled	MI and CBT groups reported significant improvement in gambling, depression, and anxiety symptoms.
Petry et al., 2009	10 minutes of brief advice, Motivational Enhancement Therapy (MET), MET + three sessions CBT, or no treatment (control group)	117 enrolled 113 completers	All treatments were equally effective in reducing gambling symptoms.

over gambling at 12 months when compared with a waitlist control group (Sylvain, Ladouceur, & Boisvert, 1997). Another study of cognitive therapy plus relapse prevention in 88 subjects also produced improvement in gambling symptoms compared with a waitlist group at 3 months that was maintained for 12 months (Ladouceur et al., 2001). Treatment discontinuation rates were high in both studies (37% and 47%, respectively), and the outcome analyses included only those subjects who completed the studies. Although the treatment was manualized, no measures of therapist competence and adherence were reported.

Group cognitive therapy has also been tested in 71 subjects with GD against a waitlist control condition (Ladouceur et al., 2003). Groups met for 2 hours weekly for 10 weeks. After ten sessions, 88% of those in group CBT no longer met GD criteria, compared with 20% in the waitlist condition. At the 24-month follow-up, 68% of the original group's cognitive therapy subjects still did not meet the criteria.

Although both individual and group cognitive therapies have shown promise in treating GD, rates of treatment discontinuation were high in these studies (up to 47%). In addition, the cognitive therapy studies have not yet determined the optimal number of sessions needed to reduce gambling symptoms and maintain improvement.

Cognitive-Behavioral Therapy

Although several trials have evaluated the efficacy of a purely cognitive approach, the largest number and the most rigorously designed trials have evaluated a combined CBT model. Although there is variability in the content and outcomes of CBT, positive effects have generally been found by different research groups.

A randomized study of CBT in GD compared four groups: (a) individual stimulus control and in vivo exposure with response prevention, (b) group cognitive restructuring, (c) a combination of (a) and (b), and (d) a waitlist control (Echeburúa, Baez, & Fernandez-Montalvo, 1996). At 12 months, rates of abstinence or minimal gambling were higher in the individual treatment group (69%) compared with group cognitive restructuring patients (38%) and the combined treatment group (38%). The same investigators further assessed individual and group relapse prevention for completers of a 6-week individual treatment program. At 12 months, 86% of those receiving individual relapse prevention and 78% of those receiving group relapse prevention had not relapsed, compared with 52% in the waitlist group.

One study compared CBT with CBT combined with interventions designed to improve treatment compliance (the interventions included positive reinforcement, identifying barriers to change, and applying problem-solving skills) in 40 subjects receiving eight sessions of manualized individual therapy. Only 35% of the CBT-alone group completed treatment compared with 65% of the CBT-plus-interventions group. At the 9-month follow-up, there was no difference in outcomes between treatments, although both produced clinically significant change (Milton, Crino, Hunt, & Prosser, 2002).

Melville and colleagues (2004) reported two studies that used a system targeting three topics (understanding randomness, problem solving, and relapse prevention) to improve outcome. In the first study, 13 subjects were assigned to 8 weeks of group CBT, group CBT with the topic-enhanced treatment, or a waitlist. In the second study, 19 subjects were assigned to a topic-enhanced group or a waitlist group for 8 weeks. For those subjects who were in the topic-targeting CBT group, significant improvement was maintained at both posttreatment and a 6-month follow-up (Melville, Davis, Matzenbacher, & Clayborne, 2004).

A large study described an eight-session manualized form of CBT where 231 subjects were randomized to weekly sessions with an individual counselor, the therapy in the form of a workbook, or referral to Gamblers Anonymous (Petry, 2005). Using an intent-to-treat analysis, the individual therapy and workbook reduced gambling behaviors to a greater degree than referral to Gamblers Anonymous.

In a study examining cognitive-motivational behavior therapy (CMBT), a method that combines gambling-specific CBT with motivational interviewing techniques to aid in resolving treatment ambivalence and improve retention rates, 9 subjects received manualized treatment and were compared with a control group of 12 subjects who received treatment as usual. All 9 subjects (100%) in the CMBT group completed treatment versus only 8 (66.7%) in the treatment-as-usual group. Significant improvements were observed at the 12-month follow-up in the CMBT group (Wulfert, Blanchard, & Freidenberg, 2006).

Cue Exposure

Cue exposure, based on classical conditioning, is a well-validated form of CBT used in the treatment of fear-based problems and has the goal of extinguishing the feared or learned response. The learned response is extinguished through repeated exposure to a conditioned stimulus in the absence of the feared consequence. The first randomized study compared imaginal desensitization (i.e., subjects were taught relaxation and then instructed to imagine experiencing and resisting triggers to gambling) with traditional aversion therapy (McConaghy, Armstrong, Blaszczynski, & Allcock, 1983). Both therapies had positive effects, but the imaginal desensitization was more successful in reducing gambling urges and behavior.

In a second study, 20 inpatient subjects were randomized to receive either imaginal desensitization or imaginal relaxation in 14 sessions over a 1-week period. Both groups improved at posttreatment, but the therapeutic gains were not maintained by either group at a 12-month follow-up (McConaghy, Armstrong, Blaszczynski, & Allcock, 1983).

In a larger study, 120 subjects were randomly assigned to aversion therapy, imaginal desensitization, in vivo desensitization, or imaginal relaxation. Subjects assigned to imaginal desensitization reported better outcomes at 1 month and up to 9 years later (McConaghy, Blaszczynski, & Frankova, 1991). This latter study, however, failed to follow up on approximately half of the subjects.

Using imaginal desensitization and combining cue exposure with negative mood induction, Grant and colleagues (2009a) examined 68 GD patients assigned to six sessions of treatment or Gamblers Anonymous. The negative mood induction involves focusing on the negative consequences of the problem behavior while the urge to engage in gambling is active. Individualized scripts were developed for each gambler, including gambling-related cues with the intention of activating each gamblers' urge via imagination (repeatedly listening to the script recorded). The scripts emphasized internal events, including thoughts and emotions experienced before, during, and after a gambling episode (e.g., euphoria before and during gambling and dysphoria and agitation after gambling). The pleasurable aspects of the script (i.e., anticipation of gambling and initial excitement) were then followed by the negative consequences of gambling unique to each gambler (negative mood induction). The study found that 64% of participants receiving imaginal exposure plus the negative mood induction as part of a six-session CBT program were able to maintain abstinence for 1 month, as opposed to only 17% of those randomly assigned to Gamblers Anonymous. For the CBT with imaginal exposure plus negative mood induction group, among those participants who responded to therapy after six sessions, 77% maintained their response for 6 months (Grant, Donahue, Odlaug, & Kim, 2011).

Brief Interventions

Brief treatments are not necessarily conceptualized as *treatment* by individuals who access them (Hodgins, Stea, & Grant, 2011) and therefore may be more appealing to gamblers who report significant ambivalence about stopping their behavior. Brief treatments may include single-session interventions, workbooks, or bibliotherapy.

In one study of brief interventions, Dickerson, Hinchy, and England (1990) randomly assigned 29 subjects either to workbook or to workbook plus a single in-depth interview. The workbook included cognitive-behavioral and motivational enhancement techniques. Both groups reported significant reductions in gambling at 6 months (Dickerson et al., 1990). Another study assigned gamblers to a CBT workbook, a workbook plus a telephone motivational enhancement intervention, or a waitlist. Rates of abstinence at 6 months did not differ among groups, although the frequency of gambling and money lost gambling were lower in the motivational intervention group (Hodgins, Currie, & el-Guebaly, 2001). Compared with the workbook alone, those gamblers assigned to the motivational intervention and workbook reduced gambling throughout a 2-year follow-up period (Hodgins, Currie, el-Guebaly, & Peden, 2004).

A study conducted by Diskin and Hodgins (2009) compared a single-session motivational interviewing module plus a self-help workbook with the workbook and speaking with an interviewer about gambling for 30 minutes. Half of the sample was randomized to each intervention. At the 12-month follow-up, those who received the motivational interviewing plus workbook gambled less and spent less money than the workbook-alone group (Diskin & Hodgins, 2009).

Motivational interviewing has been compared in individual versus group settings as well. Oei and colleagues (2010) randomized 102 gamblers to receive 6 weeks of individual or group CBT with motivational interviewing. At posttreatment and a 6-month follow-up, those completing the individual CBT program had better sustained outcomes in regard to gambling severity compared to the group CBT and waitlist control groups (although group CBT produced significant results vs. the waitlist control group as well) (Oei, Raylu, & Casey, 2010).

A study using a short-term group-CBT (GCBT) model for 14 subjects (78.6% male) found that 85.7% of the treatment group experienced significant improvements in posttreatment gambling symptoms compared to 42.9% of a waitlist control group (Myrseth, Litlerè, Støylen, & Pallesen, 2009). The other dependent variable, money spent gambling over the past week, however, failed to indicate any significant group differences, with 28.6% of both the GCBT and waitlist control groups experiencing improvement.

A study using a relapse-prevention bibliotherapy randomized 169 subjects who had recently quit gambling to receive either a summary booklet that detailed all available relapse-prevention information (single-mailing group) (n = 85) or to the same booklet plus seven additional informational booklets mailed over the next 12 months (repeated-mailing group) (n = 84) (Hodgins, Currie, el-Guebaly, & Diskin, 2007a). At the 12-month assessment, 24% of the repeated-mailing group reported using the strategies regularly to prevent relapse compared with 13% of the single-mailing group. Only 44% of the overall sample, however, reported not having gambled over the 3 months prior to the 12-month assessment.

Two self-directed motivational interventions were compared with a 6-week waitlist control and a workbook-only control in 314 GD patients (Hodgins, Currie, Currie, & Fick, 2009). Brief motivational treatment involved a telephone motivational interview and a mailed self-help workbook. Brief motivational booster treatment involved a telephone motivational interview, a workbook, and six booster telephone calls over a 9-month period. Both the brief and the brief booster treatment participants reported less gambling at 6 weeks than those assigned to the control groups. Participants in the brief booster treatment group, however, showed no greater improvement than brief treatment participants.

A similar combination of motivational interviewing and CBT was adapted to a Web-based format in which a therapist provides telephone support for individuals using online recovery materials (Carlbring & Smit, 2008). A waitlist control was compared with the 8-week Internet-based CBT program with minimal therapist contact via e-mail and weekly telephone calls of less than 15 minutes. The Internet-based intervention resulted in favorable changes in gambling, anxiety, depression, and quality of life. In a similar study, a larger sample of 284 GD subjects underwent an 8-week Internet-based CBT program with minimal therapist contact (average of 15 minutes per week and 4 hours throughout the entire program). The researchers found that gambling, depression, and anxiety symptoms decreased significantly following treatment and that treatment effects were maintained at 6-, 18- and 36-month follow-ups (Carlbring, Degerman, Jonsson, & Andersson, 2012).

A total of 150 primarily self-recruited patients with current gambling problems or GD were randomized to four individual sessions of motivational interviewing, eight sessions of CBT group therapy, or a no-treatment waitlist control. Treatment showed superiority in some areas over the no-treatment control in the short term, but no differences were found between motivational interviewing and group CBT at any point in time (Carlbring, Jonsson, Josephson, & Forsberg, 2010).

A randomized controlled study found that a 10-minute session of behavioral advice, one session of motivational enhancement therapy, or one session of motivational enhancement therapy plus three sessions of CBT were all equally effective in reducing gambling in a sample of 117 college students with either problem gambling or GD (Petry, Weinstock, Morasco, & Ledgerwood, 2009).

Family Therapy

A self-help workbook of the Community Reinforcement and Family Therapy (CRAFT) model, adapted for gambling, has been evaluated in two randomized controlled trials (Hodgins, Toneatto, Makarchuk, Skinner, & Vincent, 2007b; Makarchuk, Hodgins, & Peden, 2002). Family members are trained to use behavioral principles to reinforce nongambling behavior in individuals who are not addressing their gambling problem. Although positive effects

for family members and their gambling relatives were found in both trials, the studies found that behavioral principles were too complex for family members to implement without the support of a therapist.

A coping skills training program has also been evaluated for gambling. The program consists of 10 weekly individual sessions to teach more effective coping skills. A small (n = 23) randomized controlled trial comparing the coping skills program to a delayed treatment condition showed that partners of gamblers improved their ability to manage feelings of depression and anxiety. Partner gambling during that period decreased in both conditions but did not differ between them, nor did partner help seeking differ (Rychtarik & McGillicuddy, 2006).

Conclusions

Several conclusions can be drawn from the GD pharmacological and psychological treatment studies performed and published to date:

1. Although some pharmacotherapy and psychological treatment studies meet the criteria for a type 1 study, many GD studies have generally lacked a large enough sample for adequate statistical power. Exceptions to this would include the multicenter nalmefene studies (Grant et al., 2006, 2010) that were adequately powered at the time of enrollment and several of the CBT studies.
2. Although several different classes of medication have shown efficacy in treating GD in individual studies, only the opiate antagonists have had successful replication in randomized, placebo-controlled studies.
3. CBT has shown efficacy for GD, but no manualized CBT treatment has been examined in a confirmatory study by another independent investigator.
4. Different classes of medication seem equally effective in GD. No comparison studies of medications have been performed in a randomized, placebo-controlled design.
5. Both drug and behavioral treatments appear effective for GD. Few studies have systematically compared interventions or examined whether combinations of treatments are more beneficial. In addition, no study has examined whether certain individuals with GD would benefit differentially from specific pharmacotherapies or behavioral treatments.
6. Comparisons of treatment studies have generally been problematic due to the lack of consensus on appropriate outcome measure or measures.
7. With one exception, there have been no systematic dose-response studies for medication. The exception showed that nalmefene doses of 25 mg/day and 50 mg/day, but not 100 mg/day, were more effective than placebo (Grant et al., 2006).
8. CBT studies have shown that both brief interventions and longer-term therapy are potentially effective, but no study has yet examined the optimal duration of CBT.
9. The long-term effects of medication for GD remain largely untested. Only two studies have examined pharmacological effects for 6 months, but these studies experienced dropout rates of 59% (Blanco et al., 2002) and 44% (Saiz-Ruiz et al., 2005). No study has examined pharmacological treatment effects for longer than 6 months or whether the effects of acute treatment last beyond the 8 to 16 weeks.
10. There are limited data concerning the effectiveness of pharmacotherapy or CBT for GD subjects with co-occurring psychiatric conditions. Only scant preliminary data suggest that individuals with GD and bipolar symptoms respond to lithium (Hollander et al., 2005) and individuals with GD and nicotine dependence respond to NAC (Grant et al., 2014).

TRICHOTILLOMANIA

Trichotillomania has been defined as repetitive, intentionally performed pulling that causes hair loss and results in clinically significant distress or functional impairment. Trichotillomania appears relatively common, with an estimated prevalence between 0.6% and 3% (Christenson, Pyle, & Mitchell, 1991c; Duke, Keeley, Geffken, & Storch, 2010). The mean age of onset for trichotillomania is approximately 13 years (Mansueto & Rogers, 2012). Although prospective studies are lacking, the onset of trichotillomania has been associated with scalp disease and stressful life events (Mansueto & Rogers, 2012). Hair

pulling is subject to great fluctuations in severity, with worsening of symptoms often related to stress. Trichotillomania has traditionally been considered a disorder predominantly affecting females (Mansueto & Rogers, 2012) and is associated frequently with depression (39% to 65%), generalized anxiety disorder (27% to 32%), substance abuse (15% to 20%), and obsessive-compulsive disorder (13% to 23%; Christenson, Mackenzie, & Mitchell, 1991a).

Pharmacological Treatments

Several controlled pharmacological trials have been performed in trichotillomania (Table 25.3). Four of the eight double-blind pharmacological studies published to date have examined antidepressants, particularly SRIs. One study examined clomipramine compared with desipramine in a 10-week double-blind, crossover (5 weeks for each agent) design (following 2 weeks of single-blind placebo lead-in; Swedo et al., 1989). Twelve of 13 subjects had significant improvement on clomipramine.

Fluoxetine has been studied in three randomized trials with conflicting results. In one study, fluoxetine was compared with placebo in a 6-week double-blind crossover study (with a 5-week washout period between treatment arms; Christenson, Mackenzie, Mitchell, & Callies, 1991b). No significant differences were found between fluoxetine and placebo on measures of hair-pulling urges, frequency, or severity. In a study comparing fluoxetine with clomipramine, Pigott, L'Heueux, and Grady (1992) used a 2-week placebo lead-in followed by a double-blind, randomized 20-week crossover design (10 weeks on each agent). Both clomipramine and fluoxetine demonstrated a similar positive treatment effect (O'Sullivan, Christenson, & Stein, 1999). A third controlled study used a double-blind, placebo-controlled crossover design with 16 subjects treated with each agent for 12 weeks separated by a 5-week washout period (Streichenwein & Thornby, 1995). Fluoxetine failed to show significant improvement compared with placebo.

In one of the few studies to examine something other than an SRI, Christenson performed a placebo-controlled, 6-week, randomized, double-blind parallel-arm study of the opioid antagonist naltrexone (O'Sullivan et al., 1999). Of 17 subjects completing the study, 10 received placebo and 7 received 50 mg/day of naltrexone. Significant improvement was noted for the naltrexone group on one measure of trichotillomania symptoms (the NIMH Trichotillomania Symptom Severity Scale). However, although two other measures of symptom improvement (number of hair-pulling episodes and the NIMH Trichotillomania Impairment Scale) showed change in the anticipated direction for the naltrexone group, they failed to reach statistical significance.

A recent 8-week, double-blind study of naltrexone (dose titration from 50 mg to 150 mg/day) in 51 subjects using a standard outcome measure (the Massachusetts General Hospital Hair Pulling Scale) failed to find any difference on the outcome measure between naltrexone and placebo. Subjects taking naltrexone with a family history of addiction showed a greater numerical reduction in the urges to pull, although it was not statistically significant (Grant, Odlaug, Schreiber, & Kim, 2014b).

A study of NAC versus placebo was conducted in 50 adult subjects over a 12-week period. The study provided evidence that NAC is effective when compared with placebo; this finding was based on all primary outcome measures. The treatment effect was detected by 9 weeks (Grant, Odlaug, & Kim, 2009c). A similarly designed study in 39 children with trichotillomania, however, found no significant difference between NAC and placebo on any of the primary or secondary outcome measures (Bloch, Panza, Grant, Pittenger, & Leckman, 2013).

A double-blind, placebo-controlled study of olanzapine in 25 adults with trichotillomania found that 11 of 13 participants (85%) in the olanzapine group and 2 of 12 (17%) in the placebo group were considered responders according to the CGI but not on the more usually chosen outcome measure, the Massachusetts General Hospital Hair Pulling Scale. The mean dose of olanzapine at endpoint was 10.8 mg/day (Van Ameringen, Mancini, Patterson, Bennett, & Oakman, 2010).

Psychological Treatments

Behavioral interventions for trichotillomania have generally included three core elements: awareness training, stimulus control (which includes a variety of methods that serve to reduce the likelihood that pulling behavior begins), and competing response training (where patients are taught at the earliest sign of

TABLE 25.3 Double-Blind, Placebo-Controlled Pharmacotherapy Trials for Impulse Control Disorders

Impulse Control Disorder	*Medication*	*Design/Duration*	*Subjects*	*Mean Daily Dose (+SD)*	*Outcome*
Trichotillomania					
Bloch et al., 2013 (Children)	NAC	Parallel design 12 weeks	39 enrolled 35 completers	1,200 to 2,400 mg/day	No differences between groups
van Ameringen et al., 2010	Olanzapine	Parallel design 12 weeks	25 enrolled 23 completers	10.8 mg (± 5.7)	Olanzapine significant improvement over placebo on primary measure
Intermittent Explosive Disorder					
Coccaro et al., 2009	Fluoxetine	Parallel design 12 weeks	100 enrolled 55 completers	29.8 ± 12.6 for responders	Fluoxetine group had sustained reduction in symptoms.
Hollander et al., 2003	Divalproex	Parallel design 12 weeks	109 subjects No data on number of IED subjects who completed	1,567 mg	Similar improvement in IED and placebo
Kleptomania					
Grant et al., 2009b	Naltrexone	Parallel design 8 weeks	25 enrolled 23 completers	116.7 mg (± 44.4)	Naltrexone was significantly superior to placebo.

CMI = clomipramine; DMI = desipramine.

pulling, or of the urge to pull, to engage in a behavior that is physically incompatible with pulling for a brief period of time until the urge subsides). Few controlled psychological treatment studies for trichotillomania have been published to date (Table 25.4). Azrin and colleagues randomized 34 subjects to either habit reversal therapy or negative practice (where subjects were instructed to stand in front of a mirror and act out motions of hair pulling without actually pulling; Azrin, Nunn, & Frantz, 1980). Habit reversal reduced hair pulling by more than 90% for 4 months, compared with 52% to 68% reduction for negative practice at 3 months. No control group was included, and therefore time and therapist attention could not be adequately assessed.

One study examined 25 subjects randomized to 12 weeks (10 sessions) of either acceptance and commitment therapy/habit reversal or waitlist (Woods, Wetterneck, & Flessner, 2006). Subjects assigned to the therapy experienced significant reductions in hair-pulling severity and impairment compared with those assigned to the waitlist, and improvement was maintained at the 3-month follow-up.

A recent study examined behavioral therapy in children with trichotillomania compared to a minimal attention control condition in 24 children for a period

TABLE 25.4 Controlled Psychological Treatment Trials for Impulse Control Disorders

Impulse Control Disorder	*Design/Duration*	*Subjects*	*Outcome*
Trichotillomania			
Azrin et al., 1980	Habit reversal therapy vs. negative practice	34 enrolled 34 completers	Habit reversal reduced hair-pulling by more than 90% for 4 months, compared to 52%–68% reduction for negative practice at 3 months.
Woods et al., 2005	Acceptance and commitment therapy/ habit reversal vs. waitlist	28 enrolled 25 completers	Improvement for acceptance and commitment therapy/habit reversal maintained at 3 months
Franklin et al., 2011 (children)	Behavioral therapy vs. minimal attention control (MAC)	24 enrolled	Behavior therapy resulted in significant improvements compared to MAC.
Ninan et al., 2000b	CBT vs. clomipramine vs, placebo	23 enrolled 16 completers	CBT was significantly more effective in reducing the symptoms of trichotillomania than either clomipramine or placebo.
Van Minnen et al., 2003)	Behavior therapy vs. fluoxetine vs. waitlist	43 enrolled 40 completers	Behavior therapy resulted in statistically significant reductions in trichotillomania symptoms compared to either fluoxetine or waitlist.
Moritz & Rufer, 2011	Decoupling compared to muscle relaxation	42 enrolled 38 completed	Decoupling movement resulted in significantly greater reductions in trichotillomania symptoms compared to the muscle relaxation group.
Compulsive Buying			
Mitchell et al., 2006	Group CBT vs. waitlist control	28 enrolled	Group CBT reported significantly greater reductions in number of buying episodes and time spent buying. Maintained at 6-month follow-up.
Mueller et al., 2008	Group CBT vs. waitlist control	60 enrolled	Group CBT produced significantly greater reductions on all outcome variables compared to those assigned to waitlist. Improvement maintained at 6-month follow-up.
Muller et al., 2011	Group CBT vs. telephone-guided self-help vs. waitlist control	56 enrolled	Group CBT had significantly better reduction of compulsive buying symptoms at study endpoint and 6-month follow-up.

of 8 weeks. Behavioral therapy produced a superior outcome compared with a condition that controlled for participation, nonspecific therapist contact effects, repeated assessments, and the passage of time. Upon completion of acute treatment at week 8, the behavioral therapy group's gains were maintained through an 8-week maintenance treatment phase (Franklin, Edson, Ledley, & Cahill, 2011).

Another study used "decoupling" techniques, in which the patient learns to perform actions that unlink the behavioral components involved in hair pulling. The researchers randomized 42 adults with trichotillomania to either decoupling or muscle relaxation training for 4 weeks. Upon completion of the study, subjects undergoing decoupling reported significantly greater reductions in their pulling urges and behaviors compared to the muscle relaxation group (Moritz & Rufer, 2011).

Comparison Studies

Although the studies of either pharmacological or psychological treatment are too few to recommend specific treatment approaches, two studies have used controlled design to compare treatment interventions. Ninan and colleagues used a placebo-controlled, randomized, parallel-treatment design to compare CBT and clomipramine (Ninan, Rothbaum, Marsteller, Knight, & Eccard, 2000b). Twenty-three subjects entered the 9-week study. The CBT was a modified manualized treatment based on the habit reversal therapy tested in a controlled study by Azrin and colleagues (1980). CBT was significantly more effective in reducing the symptoms of trichotillomania than either clomipramine or placebo. Although clomipramine resulted in greater symptom reduction than placebo, the difference was not statistically significant.

In a second comparison study, behavioral therapy was compared with fluoxetine in a 12-week randomized trial using a waitlist control (van Minnen, Hoogduin, Keijsers, Hellenbrand, & Hendriks, 2003). Forty-three subjects were enrolled (14 in behavior therapy, 11 in the fluoxetine group, and 15 in the waitlist). Behavior therapy resulted in statistically significant reductions in trichotillomania symptoms compared with either fluoxetine or waitlist.

Conclusions

Although there are many case reports on effective treatments for trichotillomania, the data from controlled trials are sparse. The one treatment that has shown potential promise in treating trichotillomania is habit reversal therapy, or some modification thereof. No manualized treatment, however, has been published in a confirmatory study by an independent investigator. Although habit reversal appears promising in the short term, there are no controlled trials examining the long-term effects of this treatment. NAC and olanzapine may benefit adults with trichotillomania, but there are conflicting data supporting the use of selective SRIs.

COMPULSIVE BUYING

Although not specifically recognized in the *DSM*, the following diagnostic criteria have been proposed for compulsive buying: (a) maladaptive preoccupation with or engagement in buying (evidenced by frequent preoccupation with or irresistible impulses to buy; or frequent buying of items that are not needed or not affordable; or shopping for longer periods of time than intended); (b) preoccupations or the buying itself lead to significant distress or impairment; and (c) the buying does not occur exclusively during hypomanic or manic episodes (McElroy, Keck, Pope, Smith, & Strakowski, 1994).

The onset of compulsive buying typically occurs during late adolescence or early adulthood (Black, 1996). The disorder appears more common among females (Black, 1996; Christenson et al., 1994). Individuals with compulsive buying report repetitive, intrusive urges to shop that are often triggered by being in stores and worsen during times of stress, emotional difficulties, or boredom. Compulsive buying regularly results in substantial financial debt, marital or family disruption, and legal consequences (Christenson et al., 1994). Guilt, shame, and embarrassment typically follow the buying episodes. Most items are not used or even removed from the packaging (Christenson et al., 1994).

Pharmacological Treatments

The effectiveness of pharmacotherapy in treating compulsive buying has been examined in three

double-blind, randomized, placebo-controlled trials (see Table 25.3). In the first of two double-blind fluvoxamine studies, 37 subjects were treated for 13 weeks. Only 9 of 20 patients assigned to medication were responders (mean dose = 215 mg/day), and this rate did not differ significantly from that in the placebo group (8 of 17 were responders; Ninan et al., 2000a). In the second double-blind study, Black and colleagues treated 23 patients for 9 weeks following a 1-week placebo lead-in phase. Using a mean dose of 200 mg/day, no differences in response rates were observed between the groups treated with active drug or placebo (Black, Gabel, Hansen, & Schlosser, 2000).

The third controlled study was a 7-week open-label study of citalopram that randomized the responders to 9 weeks of double-blind medication or placebo (Koran, Chuong, Bullock, & Smith, 2003). Subjects taking citalopram demonstrated statistically significant decreases in the frequency of shopping and the intensity of thoughts and urges concerning shopping.

Psychological Treatments

There have been three randomized psychosocial treatment studies for compulsive buying (see Table 25.4). The first study assigned 28 subjects to either group CBT or a waitlist condition. After 10 weeks (which included 12 sessions of therapy), those assigned to the group CBT reported significantly greater reductions in the number of buying episodes and the time spent buying. The results were maintained for 6 months following treatment discontinuation (Mitchell, Burgard, Faber, Crosby, & de Zwaan, 2006).

A second study of group CBT using weekly sessions for 12 weeks found that those assigned to group CBT ($n = 31$) reported significantly greater reductions on all outcome variables compared to those assigned to a waitlist ($n = 29$). The improvement was noted both at the end of the study and again at the 6-month follow up (Mueller et al., 2008).

A third study compared group CBT to telephone guided self-help and to a third condition of waitlist in 56 subjects over a 10-week period. Those assigned to group CBT did significantly better in the reduction of compulsive buying symptoms compared to the other two groups at study endpoint and at the 6-month follow-up (Muller, Arikian, de Zwaan, & Mitchell, 2011).

Conclusions

There is scant evidence concerning effective pharmacological treatments for compulsive buying. Based on available data, citalopram may offer some benefit for this disorder, although the study suffers from several major limitations—small sample in the randomized phase ($n = 15$), a diagnostic instrument without sufficient psychometrics, and outcome measures that lack validity and reliability data.

Current data strongly support the use of group CBT for compulsive buying. The studies have replicated a group CBT approach, although not by independent investigators. The treatment effects have also been shown to persist after treatment is concluded.

INTERMITTENT EXPLOSIVE DISORDER

IED is defined by recurrent, significant outbursts of aggression, often leading to assaultive acts against people or property, which are disproportionate to outside stressors and not better explained by another psychiatric diagnosis. Recent research suggests IED may be common, with 6.3% of a community sample meeting criteria for lifetime IED (Coccaro et al., 2004).

IED symptoms tend to start in adolescence and appear to be chronic (Coccaro, Schmidt, Samuels, & Nestadt, 2004; McElroy, Soutullo, Beckman, Taylor, & Keck, 1998). Individuals with IED regard their behavior as distressing and problematic (McElroy et al., 1998). Outbursts are generally short-lived (usually less than 30 minutes in duration) and frequent (multiple times per month; McElroy et al., 1998). Legal and occupational difficulties are common (McElroy et al., 1998).

Pharmacological Treatments

Pharmacological treatment data for IED are limited (see Table 25.3). Although pharmacotherapies have been studied in the treatment of aggression, impulsivity, and violent behavior, there are only two controlled studies specific to IED.

A double-blind, randomized, placebo-controlled trial of fluoxetine in 100 individuals with IED found that fluoxetine treatment resulted in a sustained reduction in aggression and irritability as early as the second week of treatment. Full or partial remission of impulsive aggressive behaviors occurred in

46% of fluoxetine-treated subjects (Coccaro, Lee, & Kavoussi, 2009).

In a randomized, double-blind, placebo-controlled study, 96 subjects with Cluster B personality disorders, 116 subjects with IED, and 34 subjects with posttraumatic stress disorder were randomized to divalproex sodium or placebo for 12 weeks of treatment. Using an intent-to-treat analysis, the study found that divalproex had no significant influence on aggression in the subjects with IED (Hollander et al., 2003).

Psychological Treatments

Although case reports suggest that insight-oriented psychotherapy and behavioral therapy may be beneficial, there are no controlled psychological treatment studies in IED (McElroy et al., 1998).

Conclusions

Although there is a paucity of type 1 or 2 treatment studies for IED, the fluoxetine study suggests that fluoxetine may be an effective treatment for IED. There are only case reports of psychological treatments. IED is a disabling disorder with significant public health issues. Treatment studies for this disorder are needed.

KLEPTOMANIA

Kleptomania is characterized by repetitive, poorly controlled stealing of items not needed for personal use. Kleptomania begins most often in late adolescence or early adulthood (McElroy, Pope, Hudson, Keck, & White, 1991). The course of the illness is generally chronic, with waxing and waning of symptoms. Women appear twice as likely to suffer from kleptomania as men (Grant & Kim, 2002). Individuals with kleptomania frequently hoard, discard, or return stolen items (McElroy et al., 1991).

Most individuals with kleptomania try unsuccessfully to stop stealing. The difficulties with stopping the behavior often lead to feelings of shame and guilt (Grant & Kim, 2002). Many individuals with kleptomania (64% to 87%) have been apprehended at some time due to their stealing behavior (McElroy et al., 1991, with a smaller percentage (15% to 23%) having been jailed (Grant & Kim, 2002).

Pharmacological Treatments

There has been only one randomized, placebo-controlled study of medication in the treatment of kleptomania. An 8-week, double-blind, placebo-controlled trial was conducted to evaluate the safety and efficacy of oral naltrexone in 25 subjects with kleptomania (Grant, Kim, & Odlaug, 2009b). Naltrexone dosing ranged from 50 mg/day to 150 mg/day. Subjects assigned to naltrexone had significantly greater reductions in K-YBOCS total scores, stealing urges, and stealing behavior compared with subjects on placebo. The mean effective dose of naltrexone was 116.7 (± 44.4) mg/day. Naltrexone was well tolerated, with minimal nausea, and produced no elevated liver enzymes.

Psychological Treatments

No controlled studies of psychological treatments exist for kleptomania. Case reports suggest that cognitive and behavioral therapies may be effective in treating kleptomania. Undergoing seven sessions of covert sensitization combined with exposure and response prevention over a 4-month period, a young man was able to reduce his stealing frequency (Guidry, 1969). In another case of covert sensitization, a young woman underwent five weekly sessions wherein she was instructed to practice covert sensitization whenever she had urges to steal. She was able to then go 14 months with only a single lapse in behavior and with no reported urges to steal (Gauthier & Pellerin, 1982). Imaginal desensitization in 14 15-minute sessions over 5 days resulted in complete remission of symptoms for a 2-year period for two subjects (McConaghy & Blaszczynski, 1988).

Conclusions

There is one controlled study of naltrexone in kleptomania and it would suggest that naltrexone may be a beneficial treatment for this disorder. No controlled trials of psychosocial interventions have been reported. The current psychological research is based primarily on case reports.

The research on treatment outcome in kleptomania contrasts sharply with the quantity and quality of studies in GD. This state of affairs is probably attributable to the low prevalence of kleptomania and to

clinical difficulties in treating individuals involved in illegal activities. Nevertheless, there is a substantial need for systematic studies of the treatment of this disorder. Such studies may need to involve collaboration across multiple treatment centers in view of the disorder's low prevalence.

RECOMMENDATIONS BASED ON TREATMENT OUTCOME LITERATURE

In the areas of GD and impulse control disorders, the systematic study of treatment efficacy and tolerability is in its infancy. With few studies published yet that even approximate a type 1 study, it is not possible to make treatment recommendations with a substantial degree of confidence. No drugs are currently approved by the U.S. Food and Drug Administration for the treatment of any of the impulse control disorders. Nonetheless, specific drug and behavioral therapies offer promise for the effective treatment of GD. Treatment studies in GD are substantially limited. Most published studies have employed relatively small sample sizes, are of limited duration, and involve possibly nonrepresentative clinical groups (e.g., those without co-occurring psychiatric disorders). In addition, response measures have varied across studies, in part because the definition of "response" in GD treatment remains debated. Heterogeneity of treatment samples may also complicate identification of effective treatments. At present, issues such as which medication to use and for whom or the duration of pharmacotherapy or CBT cannot be sufficiently addressed with the available data. Two consistent findings across treatment studies, the high rates of placebo response and study discontinuation, and identification of factors related to placebo response and treatment discontinuation, would help inform future studies and advance treatment strategies for the disorder.

For the impulse control disorders, there are fewer available data to generate empirically supported treatment recommendations. For trichotillomania, habit reversal therapy, NAC, and olanzapine may be beneficial, but the evidence is based on only a few studies with small samples, each using a different variation of habit reversal therapy and, in the cases of two studies, lacking a control group. Although there is less evidence for effective treatments for compulsive buying, IED, or kleptomania, group CBT appears promising for compulsive buying, naltrexone may be beneficial for kleptomania, and fluoxetine may be beneficial for IED.

In conjunction with emerging epidemiological data supporting a relatively high prevalence of impulse control disorders, the small amount of empirical data in the area of effective treatments for impulse control disorders highlights the clinical need for additional research in this area.

Treatments for Neurocognitive Disorders

Pei Huey Nie
David L. Sultzer

Dementia, or neurocognitive disorders, refers to a number of clinical syndromes originating in brain pathology and characterized by cognitive deficits and functional impairment. Various definitions exist in an attempt to standardize the criteria. However, the diagnosis of dementia is ultimately a clinical one and includes a multidimensional perspective. As such, the treatment of dementia requires a comprehensive approach.

INTRODUCTION

Reports of dementia prevalence and incidence vary depending upon region and study methodology. Alzheimer's disease (AD) is widely considered the most common cause of dementia. AD accounts for about 60% to 80% of all dementia types in the United States, affecting approximately 5.4 million Americans ("Alzheimer's disease facts and figures," 2012). One in eight Americans age 65 or older and 45% of Americans over the age of 85 have AD. Consequently, it is the dementia type most studied and therefore the subject of a large portion of this chapter. Vascular dementia is the second most common type of dementia, followed by mixed-type dementia, also known as AD with cerebrovascular disease, dementia with Lewy bodies, and frontotemporal dementias (Table 26.1; Fratiglioni, De Ronchi, & Aguero-Torres, 1999; Schneider, Arvanitakis, Bang, & Bennett, 2007).

Dementia is distinct from other mental disorders because the neuropathological etiology is relatively better understood. Regardless of neurobiology, however, the behavioral manifestations, psychological impact, and consequent impact on lifestyle and interpersonal interactions can be similar to any primary psychiatric illness. Given the biopsychosocial model approach and need for ongoing care, mental health professionals are well suited to treat dementia and the associated symptoms.

Diagnostic Criteria

In 2013, the American Psychiatric Association released the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*-5), in which "dementia" is included within the newly named entity "neurocognitive disorders." Major and mild neurocognitive disorders are largely differentiated by two factors: (1) the severity of cognitive decline from a previous level of performance in one or more of the six defined cognitive domains and (2) whether cognitive deficits interfere with independence in daily activities. Features of major and mild neurocognitive disorders are shown in Table 26.2.

Etiologic specifiers are provided within each category of disorder. Specifiers are Alzheimer's disease, frontotemporal lobar degeneration, Lewy body disease, vascular disease, traumatic brain injury, substance/medication use, HIV infection, prion disease, Parkinson's disease, Huntington's disease, another medical condition, multiple etiologies, and unspecified. Criteria for clinical syndromes due to AD are shown in Table 26.3.

TABLE 26.1 Common Types of Dementia

Dementia Syndrome	*Key Clinical Features*
Alzheimer's dementia	• Insidious onset, gradual progression • Early deficits in recent memory, language, and visuoperceptive skills • Apathy and depression early in course • Psychosis and agitation later in course
Vascular dementia	• May be abrupt in onset with acute stroke • Small vessel cerebrovascular disease is more common, with gradual progression. • Variable deficits, depending on location of cerebrovascular disease • Forgetfulness, executive deficits, and poor concentration are common. • Often with depression, apathy, psychomotor slowing, motor/sensory signs, gait disturbance • Evidence of cerebrovascular disease by history, exam, or neuroimaging
Dementia with Lewy bodies	• Fluctuating cognition with varying attention, visuoperceptive deficit, visual hallucinations, and parkinsonism • Supportive features: falls, syncope, transient loss of consciousness, REM sleep changes, delusions
Mixed dementia	• Clinical features of both AD and another type of dementia
Parkinson's disease with dementia	• Tremor, rigidity, and bradykinesia precede cognitive deficits. • Cognitive slowing, forgetfulness, and executive deficits are common.
Frontotemporal dementia	• Early changes in personality and behavior: disinhibition, apathy, anxiety, lability, inflexibility, repetitive behaviors • Poor attention, distractible, executive deficits • Variable language impairment • Gradual progression of behavioral symptoms and cognitive deficits

In 2011, the National Institute of Aging and Alzheimer's Association introduced revised criteria for the diagnosis of all-cause dementia and for AD dementia. Further, they classified AD into three phases: preclinical phase, mild cognitive impairment due to AD, and dementia due to AD (Albert et al., 2011; McKhann et al., 2011; Sperling et al., 2011). Dementia due to AD is further divided into the categories of probable AD dementia, possible AD dementia, and probable or possible AD dementia with evidence of the AD pathophysiological process. The prodromal AD diagnostic criteria are based on clinical biomarkers and are intended to inform future classifications and treatments.

Summary of Chapter

The treatment of dementia is currently symptomatic in that the goal is to temporarily improve symptoms or slow the progression of cognitive, psychiatric, and behavioral symptoms. The understanding of dementia neuropathology is growing, and along with it, opportunities are increasing for psychopharmacological intervention. This chapter addresses treatments for two aspects of neurocognitive disorders. First, we review current pharmacological interventions that can temporarily slow the decline of cognitive deficits. Second, we include a review of the

TABLE 26.2 Major Versus Mild Neurocognitive Disorders (NCD)

	Major NCD	*Mild NCD*
1. Cognitive decline, as described by:		
a. Concern of cognitive decline by individual, informant, or clinician	Significant decline	Mild decline
b. Cognitive performance by standardized testing or other quantifiable assessment	Substantial impairment	Modest impairment
2. Interference with independence	Yes	No, but compensatory arrangements may be necessary

TABLE 26.3 Major Versus Mild Neurocognitive Disorder (NCD) Due to Alzheimer's Disease

	Major NCD due to AD	*Mild NCD due to AD*
A. Criteria met for:	Major NCD	Mild NCD
B. Insidious onset and gradual progression of impairment in:	At least two cognitive domains	One or more cognitive domains
C. Criteria met for probable AD or possible AD	*Major NCD due to probable AD* is diagnosed if there is:	*Mild NCD due to probable AD* is diagnosed if there is:
	1. Evidence of a causative AD genetic mutation from family history or genetic testing, OR	Evidence of a causative AD genetic mutation from family history or genetic testing
	2. All three present: a. Decline in memory and learning and at least one other domain, based on history or serial testing b. Steadily progressive, gradual decline in cognition, without extended plateaus c. No evidence of mixed etiology	
	Possible AD is diagnosed if neither of above 2 items is met.	*Possible AD* is diagnosed if there is no evidence of a causative AD genetic mutation from family history or genetic testing, AND All three present: 1. Decline in memory and learning 2. Steadily progressive, gradual decline in cognition, without extended plateaus 3. No evidence of mixed etiology
D. Not better otherwise explained by cerebrovascular disease, other neurodegenerative disease, substances, or other mental, neurological or systemic disorder.		

management of behavioral and psychological symptoms, also described as neuropsychiatric symptoms, that are associated with dementia syndromes. Lastly, we include a review of disease-modifying treatments in development that may beneficially alter the course of disease, or reduce or prevent symptom expression in those at risk.

TREATMENT OF ALZHEIMER'S DEMENTIA

The central pathological feature of AD is the presence of neuritic plaques, consisting primarily of β-amyloid peptide aggregates, and neurofibrillary tangles, composed of tau molecule aggregates (Querfurth & LaFerla, 2010). The focus of AD treatment has been to target the biochemical abnormalities that result from the subsequent nerve cell loss. For instance, cholinesterase inhibitors enhance cholinergic transmission by inhibiting the breakdown of acetylcholine, and memantine is thought to attenuate toxic effects of glutamate. These treatments are considered symptomatic.

While cholinesterase inhibitors and memantine are standard treatments for AD at this time, the referenced literature demonstrates only modest benefit and critics cite the variability in methodological quality of the trials (Kaduszkiewicz, Zimmermann, Beck-Bornholdt, & van den Bussche, 2005). Further, the AD2000 Collaborative Study concluded that donepezil, the most commonly prescribed cholinesterase inhibitor, provides little overall benefit and is not cost-effective. Small improvements in cognition and functional abilities were detected between groups receiving donepezil and placebo, as reflected in the 0.8-point increase in the Mini-Mental State Examination (MMSE) result and 1.0-point increase in the Bristol Activities of Daily Living Scale score. However, no improvement was detected on institutionalization rates or progression of disability

(Courtney et al., 2004). The United Kingdom's National Institute for Health and Clinical Excellence (*Dementia: A NICE-SCIE Guideline on Supporting People With Dementia and Their Carers in Health and Social Care*, 2007) also commented on the significant but relatively small evidence for dementia medication effectiveness. However, in 2011 they published guidance that increased the accessibility of dementia medications, compared to their earlier recommendation (National Institute for Health and Care Excellence, 2011).

The study designs for the more salient clinical trials are type 1, randomized, double-blinded, and placebo-controlled and usually 6 months in duration. Analyses discussed in this chapter are type 1 studies or type 4 systematic reviews or meta-analyses, unless otherwise specified. Rating scales are used in each study to measure primary and secondary outcomes. Dementia medication trials usually assess global function, cognitive performance, activities of daily living (ADLs)/functioning, behavioral disturbance, and tolerability. Rating scales most commonly used in trials include the following. For cognitive function:

- Alzheimer's Disease Assessment Scale, cognitive subscale (ADAS-cog): 70-point scale that measures cognitive performance, including common cognitive deficits in AD
- Severe Impairment Battery (SIB): 100-point scale designed to assess cognitive skills in those with more advanced AD
- MMSE: 30-point scale used to measure global cognitive deficits; the most widely used screening instrument in AD studies

For global assessment:

- Global Rating/Clinician's Interview-Based Impression of Change plus Caregiver Input (CIBIC-plus): uses the process of the Alzheimer's Disease Cooperative Study-Clinical Global Impression of Change (ADCS-CGIC). Measures global change based on a rater's evaluation of cognitive, functional, and behavioral symptoms through an independent semistructured clinical interview of the patient and the patient's caregiver.
- Global Deterioration Scale (GDS): measures overall illness severity and incorporates cognition, self-care, and ADLs

For ADLs:

- Alzheimer's Disease Cooperative Study-Activities of Daily Living (ADCS-ADL): designed to assess basic and complex tasks over a broad range of severity in patients with AD

For behavioral disturbance:

- Neuropsychiatric Inventory (NPI): a 10-item scale: delusions, hallucinations, agitation/aggression, depression, anxiety, elation/euphoria, apathy/indifference, disinhibition, irritability/liability, aberrant motor behavior

CHOLINESTERASE INHIBITORS

The cholinesterase inhibitors donepezil, rivastigmine, and galantamine are considered first-line pharmacological treatments for dementia and have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of mild to moderate AD. In 2006, donepezil received additional approval for severe AD. Typical adverse side effects of cholinesterase inhibitors are gastrointestinal and dose-related. The frequency of gastrointestinal adverse side effects ranges between 3% and 50% across clinical trials (Gauthier, 2001). The severity of adverse effects is usually mild, and their frequency declines after a few weeks. Less common but notable class-related adverse effects include bradycardia and syncope related to vagotonic cholinergic effects, aggression and sleep disturbance related to central nervous system involvement, and urinary incontinence from parasympathetic mechanisms. The dosage is titrated gradually to minimize the risk of adverse side effects (Inglis, 2002)

Donepezil

Pivotal Trials and Key Findings

The two pivotal trials in mild to moderate AD were conducted in the 1990s and lasted 12 to 24 weeks. Primary outcome measures included the ADAS-cog and CIBIC-plus. A small but statistically significant benefit was detected on both scales for donepezil-treated versus placebo-treated participants (Rogers, Doody, Mohs, & Friedhoff, 1998; Rogers,

Farlow, Doody, Mohs, & Friedhoff, 1998). A more recent clinical trial investigating the 23-mg dose used the SIB and CIBIC-plus as primary outcome measures. Compared to the group receiving 10 mg of donepezil, the higher dose was associated with improved cognition on the SIB. However, only in post hoc analyses and between severely advanced and less impaired patients was there a significant improvement on both SIB and CIBIC-plus scales. The 23-mg group reported 10% more adverse effects than the 10-mg group, primarily nausea, dizziness, and vomiting (Farlow et al., 2010)

In a 12-month study, both the donepezil and placebo groups declined on the global assessment scale by week 52, but the donepezil group exhibited less cognitive decline on the MMSE (by 2.2 points) compared to placebo (Winblad et al., 2001). The authors suggested that donepezil had delayed cognitive decline by almost 1 year. In a study of 531 patients with moderate dementia, a survival analysis found that donepezil prolonged the onset of clinically evident functional decline by 5 months compared to placebo (Mohs et al., 2001).

Meta-analyses and Recent Updates

A 2006 meta-analysis summarized findings from 15 clinical trials that included 4,406 total participants. Trials lasted 24 to 52 weeks and included patients with mild, moderate, and severe AD. Overall, there was benefit from donepezil treatment in the cognitive and global clinical domains. Improvement in ADLs and behavior domains was observed but was less substantial. Although efficacy was demonstrated, the recommendation for donepezil treatment is not unanimous given the relatively small treatment effects, cost-benefit ratios, and real-life clinical relevance (Birks & Harvey, 2006).

A systematic review of cholinesterase inhibitors for AD published in 2005 included 12 randomized controlled trials studying donepezil (Kaduszkiewicz et al., 2005). Improved cognition, measured with the ADAS, ranged between 1.5 and 3.9 points. (For reference, the FDA proposes that a 4-point minimum difference would indicate a clinically important effect based on expert opinion.) Differences on the CIBIC ranged between 0.26 and 0.54 points, which can be interpreted as modest at best.

Clinical Use

Donepezil is the first of the second-generation cholinesterase inhibitors used for dementia treatment (Table 26.4). It is also the most widely prescribed dementia medication. It appears to induce, on average, a small improvement in cognition and overall clinical symptoms. The treatment effect size and tangible effectiveness make the positive results less than resounding.

Rivastigmine

Pivotal Trials and Key Findings

The pivotal trials for rivastigmine capsules were also conducted in the 1990s and lasted 26 weeks. Primary efficacy measures were the ADAS-cog, CIBIC-plus, and Progressive Deterioration Scale. Both trials demonstrated a small but statistically significant benefit in cognition and global clinical ratings, but only one trial demonstrated significant improvement in ADLs (Corey-Bloom, Anand, & Veach, 1998; Rösler et al, 1999).

Transdermal rivastigmine has been studied in more recent trials. In a 6-month double-blind, placebo-controlled study of transdermal rivastigmine, 1,195 patients with mild to moderate AD were randomized to one of four treatment groups: placebo,

TABLE 26.4 Donepezil

Pharmacology	Noncompetitive, reversible cholinesterase inhibitor with greater selectivity for acetylcholinesterase than butyryl cholinesterase
Usual dosing	Donepezil 10 mg/day
Dosage forms available	Donepezil: 5-, 10-mg tablets; 5-, 10-mg oral disintegrating tablets. Aricept: 5-, 10-, 23-mg tablets; 5-, 10-mg oral disintegrating tablets
FDA-approved indications	Mild, moderate, and severe AD
Adverse effects	Nausea, vomiting, diarrhea, weight loss, vivid dreams

12 mg/day capsule rivastigmine, 10 cm^2 (9.5 mg/24 hours) transdermal rivastigmine, or 20 cm^2 (17.4 mg/24 hours) transdermal rivastigmine. Primary efficacy measures were the ADAS-cog and ADCS-CGIC. Both transdermal patch groups and the capsule group demonstrated improvement on the ADAS-cog compared to placebo. However, on the ADCS-CGIC, there were significant treatment differences between the 10-cm^2 patch and capsule compared to placebo but not between the 20-cm^2 patch and placebo. Rates of nausea and vomiting were significantly lower in groups receiving the 10-cm^2 transdermal patch compared to capsules. However, rates of these adverse effects were similar between groups receiving the capsules and 20-cm^2 patch, and they were higher in both compared to the 10-cm^2 patch (Winblad et al., 2007).

In 2013, the FDA expanded the transdermal rivastigmine indication to include severe AD based on the ACTION (ACTivities of Daily Living and CognitION) study. This double-blind, parallel-group, non–placebo-controlled trial randomized 716 patients with severe AD to receive either the 5-cm^2 (4.6 mg/24 hours) patch or the 15-cm^2 (13.3 mg/24 hours) patch. Primary efficacy measures included SIB and the ADCS-ADL-SIV, the severe impairment version. At week 24, the higher-dose group demonstrated greater improvement on both measures without a significant increase in adverse effects (Farlow, Grossberg, Sadowsky, Meng, & Somogyi, 2013).

The pivotal trial that examined rivastigmine in dementia associated with Parkinson's disease was a 24-week placebo-controlled trial involving 541 patients with mild to moderate dementia diagnosed 2 years or more after a Parkinson's disease diagnosis. Patients were randomized to receive placebo or a 3- to 12-mg/day dose of rivastigmine (mean dosage = 8.6 mg/day). Primary efficacy measures were ADAS-cog and ADCS-CGIC. Rivastigmine-treated groups demonstrated significant improvements on both measures compared to placebo but also exhibited more adverse effects, including tremor. Tremor was reported by 10.2% of patients in the rivastigmine group and 3.9% in the placebo group (Emre et al., 2004).

Meta-analyses and Recent Updates

A meta-analysis reviewed results of 13 randomized controlled trials studying rivastigmine in a total of 512 participants (Birks, Grimley Evans, Iakovidou, & Tsolaki, 2009). After 26 weeks of treatment with 6 to 12 mg/day of rivastigmine, cognitive ability, global assessment, and ADLs improved. At lower dosages of 1 to 4 mg/day, the effect was significant only for cognitive ability and global assessment. There are no double-blind placebo-controlled studies of rivastigmine beyond 26 weeks in duration.

Clinical Use

Gastrointestinal side effects appear to limit use of higher doses of rivastigmine by mouth. However, the transdermal formulation appears to be better tolerated among all cholinesterase inhibitors. A 9.5-mg rivastigmine transdermal formulation delivers 9.5 mg over 24 hours, and efficacy is equivalent to the 12-mg/day capsule. The transdermal patch is better tolerated, with 51% of patients reporting at least one adverse event compared to 63% in patients treated with capsules (Cummings, Farlow, Meng, Tekin, & Olin, 2010), suggesting greater clinical value of the transdermal formulation in those more vulnerable to gastrointestinal adverse effects. Further, the pharmacological profile may allow for a higher margin of safety with less potential for drug–drug interactions compared to other cholinesterase inhibitors (Inglis, 2002) (Table 26.5).

Galantamine

Pivotal Trials and Key Findings

Four pivotal trials were included in the FDA's assessment of galantamine in AD. Almost 2,000 patients with mild to moderate AD were enrolled in these randomized, double-blind, placebo-controlled studies (Raskind, Peskind, Wessel, & Yuan, 2000; Tariot et al., 2000; Wilcock, Lilienfeld, & Gaens, 2000; Wilkinson & Murray, 2001). Three trials used fixed galantamine doses and one trial had flexible dosing. Overall, doses ranged between 8 and 32 mg/day, and studies lasted 3 to 6 months. ADAS-cog and CIBIC-plus were primary efficacy measures for three of the trials; ADAS-cog was used in the flexible-dose study (Wilkinson & Murray, 2001).

A small but statistically significant improvement in cognitive function and global change was demonstrated for the groups receiving at least 16 mg/day,

TABLE 26.5 Rivastigmine

Pharmacology	Noncompetitive, slowly reversible cholinesterase inhibitor with inhibition of both acetylcholinesterase and butyryl cholinesterase. Metabolism bypasses the hepatic cytochrome P450 system, incurring a lower risk of drug–drug interactions.
Usual dosing	Rivastigmine 6–12 mg/day in twice-daily dosing
Dosage forms available	Rivastigmine: 1.5-, 3-, 4.5-, 6-mg capsule. Exelon: 1.5-, 3-, 4.5-, 6-mg capsule; 2-mg/mL solution. Rivastigmine transdermal/Exelon patch: 4.6, 9.5, 13.3 mg/24 hours.
FDA-approved indications	Capsule formulation: mild to moderate AD, and mild to moderate dementia associated with Parkinson's disease Transdermal formulation: mild, moderate, and severe AD, and mild to moderate Parkinson's disease dementia
Adverse effects	Nausea and vomiting were reported in the pivotal trials but were less common with slower titration and with food administration (Inglis, 2002). Transdermal formulation: application-site redness or rash, falls, insomnia, vomiting, diarrhea, weight loss, and nausea. These reactions occurred more frequently with the higher-dose Exelon patch (13.3 mg/24 hours) than with the lower-does one (4.6 mg/24 hours). More reports of tremor were noted in the rivastigmine-treated group in patients with Parkinson's disease dementia.

but not for the groups receiving less than 16 mg/day (Tariot et al., 2000). Greater effect was observed in those with an MMSE score of less than 18 (Wilcock et al., 2000). One trial included a 6-month open-label extension and suggested that cognitive improvement was maintained (Raskind et al., 2000). Rates of study withdrawal due to adverse effects were much higher in the 32-mg/day group, and the rapid dose titration over 1 to 2 weeks probably contributed to this (Wilkinson & Murray, 2001).

Meta-analyses and Recent Updates

The SERAD study (Safety and Efficacy of Galantamine in Severe Alzheimer's Disease) examined 407 nursing home residents in Europe with severe dementia over 6 months. Advantage over placebo was demonstrated in the domain of cognitive ability as detected on the SIB but not on ADLs (Burns et al., 2009).

The 2006 revised Cochrane review examined data from 10 clinical trials studying galantamine versus placebo in 6,805 patients with mild to moderate Alzheimer's dementia. Treatment with galantamine at doses of 16 to 36 mg/day, but not 8 mg/day, correlated with improved or unchanged global rating scale scores. At all dosing levels, there was a reduction in the ADAS-cog score and benefit was greater with 6 months of treatment compared to 3 months. The 16-mg/day dosage was best tolerated when titrated over 4 weeks, and efficacy was not statistically greater at dosages of more than 16 mg/day. Extended-release galantamine (16 to 24 mg/day) was found to have similar efficacy and adverse side effect profiles as the equivalent twice-daily regimen (Loy & Schneider, 2006).

Clinical Use

Galantamine was the first cholinesterase inhibitor to be available in generic form in the United States (Table 26.6). Efficacy of the once-daily dosing formulation appears comparable to the twice-daily formulation. The literature supports usual effective dosages of 16 to 24 mg/day. Galantamine's unique pharmacological mechanism—enhancing the response of nicotinic receptors to acetylcholine—while conceptually attractive has not translated into great clinical effectiveness than other cholinesterase inhibitors.

Memantine

Pivotal Trials and Key Findings

Two pivotal trials contributed to memantine's 2003 FDA approval for treatment of moderate to severe AD (Table 26.7). In the first trial, 252 patients with moderate to severe AD in the United States were randomized to receive either placebo or memantine 20 mg/day for 28 weeks. Primary efficacy variables were the CIBIC-plus and ADCS-ADL inventory modified for

TABLE 26.6 Galantamine

Pharmacology	Competitive, reversible inhibitor of acetylcholinesterase, with little butyryl cholinesterase activity, and nicotinic receptor agonism
Usual dosing/routes of administration	Galantamine 16–24 mg/day in twice-daily dosing. Galantamine's prolonged-release formulation is dosed once daily and has similar efficacy and tolerability at comparable doses to the immediate release.
Dosage forms available	Galantamine: 4-, 8-, 12-mg tablets; 8-, 16-, 24-mg extended-release capsules; 4 mg/mL solution. Razadyne: 4-, 8-, 12-mg tablets; 8-, 16-, 24-mg extended-release capsules; 4 mg/mL solution.
FDA-approved indications	Mild to moderate AD
Adverse effects	Nausea, vomiting, diarrhea, weight loss, decreased appetite, dizziness

severe dementia. The memantine group performed better than the placebo group on functional and global outcome measures. There was also improved cognition on the SIB, a secondary outcome measure. Most adverse events were mild to moderate in severity and were judged either not related to or unlikely to be related to memantine (Reisberg et al., 2003).

The second pivotal trial involved combination therapy with stable donepezil treatment. Four hundred four patients taking donepezil for moderate to severe AD received add-on memantine titrated up to 20 mg/day or placebo for 24 weeks. Primary outcome measures were the SIB and ADCS-ADL. Improvements in the memantine group were observed in the domains of cognition and functioning. Only as secondary outcomes were improvements detected in global and behavioral domains (Tariot et al., 2004).

Meta-analyses and Recent Updates

A Cochrane review summarized the findings of 12 randomized trials of memantine in people with AD, vascular, mixed, or unspecified dementia of all degrees of severity (McShane, Areosa Sastre, & Minakaran, 2006). A beneficial effect at 6 months was detected in the moderate to severe AD group treated with memantine in the domains of cognition (2.97 points on the 100-point SIB), activities of daily living (1.27 points on the 54-point ADCS-ADL), behavior (2.76 points on the 144-point NPI), and clinical impression of change (0.28 points on the 7-point CIBIC).

In the Donepezil and Memantine in Moderate to Severe Alzheimer's Disease (DOMINO) study, combination donepezil and memantine treatment was not significantly better than donepezil treatment alone (Howard et al., 2012). After at least 3 months of donepezil treatment, patients with moderate to severe AD were randomized to (a) continue donepezil alone, (b) discontinue donepezil and receive placebo memantine, (c) discontinue donepezil and initiate memantine, or (d) continue donepezil and initiate memantine. Donepezil and memantine individually performed better than placebo but did not differ significantly in the presence or absence of the other.

A prospective, randomized, double-blind, placebo-controlled study did not find any significant treatment benefit of memantine at the 24-week endpoint in moderate to severe AD. However, a significant effect was detected on cognitive and global outcome measures at intermediate time points, weeks 12 and 18 (van Dyck, Tariot, Meyers, & Resnick, 2007).

TABLE 26.7 Memantine

Pharmacology	N-methyl-D-aspartate (NMDA) receptor antagonist that reduces glutamate-induced excitotoxicity; renally cleared
Usual dosing	Memantine 20 mg/day in twice-daily dosing
Dosage forms available	Memantine: 5-, 10-mg tablets; 2 mg/mL solution. Namenda: 5-, 10-mg tablets; 2 mg/mL solution. Namenda extended-release, 28 mg once daily.
FDA-approved indications	Moderate to severe AD
Adverse effects	Headache, diarrhea, dizziness, confusion, hypertension

A meta-analysis reviewed three clinical trials of memantine for mild AD with an MMSE score between 10 and 23. None demonstrated efficacy of memantine for mild AD on primary outcome measures (Schneider, Dagerman, Higgins, & McShane, 2011).

Clinical Use

Memantine is the only medication without a mechanism involving cholinesterase inhibition that is FDA indicated for dementia treatment. Renal metabolism of memantine may confer an advantage when prescribing to patients taking multiple hepatic-metabolized medications. Memantine dose is reduced among those with significant renal insufficiency. As of yet, there are no trials comparing efficacy or tolerability between the conventional immediate-release and the extended-release formulation (Grossberg et al., 2013).

Comparisons Among Treatments

The only randomized double-blind study comparing two cholinesterase inhibitors, donepezil and rivastigmine (tablets by mouth), included 998 individuals with moderate dementia. There was no difference in cognitive or behavioral efficacy outcomes between treatment groups. The rivastigmine group performed better on ADLs than the donepezil group, although higher discontinuation rates may have confounded this analysis. After 16 weeks of treatment, the rivastigmine group had more gastrointestinal adverse events and more discontinuations compared to the donepezil group. However, discontinuation rates were the same for both groups during the 20-month maintenance period (Bullock et al., 2005).

A meta-analysis of 10 clinical trials involving cholinesterase inhibitors was conducted (Birks, 2006). These trials included 4,406 participants with mild, moderate, or severe dementia due to AD and lasted at least 6 months. Patients were treated with donepezil, rivastigmine, or galantamine at the usual recommended dose compared with placebo or another cholinesterase inhibitor. The groups showed benefit on global assessments, cognition, ADLs, and behavioral disturbance. Effect size were not large and even less so for severe AD. There was no difference among cholinesterase inhibitors on efficacy measures.

Treatment Combinations

Studies investigating the effectiveness of the combination of cholinesterase inhibitors and memantine have led to mixed conclusions. Modestly beneficial effects of the addition of memantine treatment to donepezil treatment in moderate to severe AD were described previously. In contrast, two randomized controlled trials found no advantage to combination therapy compared to monotherapy. In 2008, 433 patients with mild to moderate AD already receiving stable cholinesterase inhibitor medication received additional placebo or memantine. At 24 weeks, there was no significant differences in primary or secondary outcome measures, leading to the conclusion that the combination of memantine and donepezil did not show an advantage or any significant differences in tolerability and safety compared to donepezil alone (Porsteinsson, Grossberg, Mintzer, & Olin, 2008).

After discontinuing donepezil or galantamine due to ineffectiveness, 202 patients with moderate to severe AD received rivastigmine 3 to 12mg/day for 16 weeks in an open-label, multicenter study. Nonresponders at week 16 then received memantine as an add-on for 12 additional weeks. At week 28, 78% of patients receiving the combination of rivastigmine and memantine demonstrated improvement on the MMSE, with a mean change from baseline of 1.2 points (Dantoine et al., 2006).

Cholinesterase Inhibitors and Memantine for Dementia Syndromes Other than Alzheimer's Disease

Use of cholinesterase inhibitors in vascular dementia and Lewy body dementia is controversial, although there is supportive evidence. Patients diagnosed with either probable vascular dementia or AD combined with cerebrovascular disease were randomized in a double-blind 6-month trial to receive either galantamine or placebo. Greater efficacy on the primary outcomes, cognition and global function, was demonstrated in the galantamine group, but the study was not powered to compare among the subgroups with AD and cerebrovascular disease or vascular dementia (Erkinjuntti et al., 2002).

In a European trial, 120 patients with Lewy body dementia were randomized to receive either placebo or rivastigmine for 20 weeks. For this multicenter,

double-blind, placebo-controlled study, the NPI agitation subscale and a computerized cognitive assessment system were the primary efficacy measures. Significant improvements in the rivastigmine group were detected on both measures compared to placebo (McKeith et al., 2000). However, neither cholinesterase inhibitors nor memantine are approved in the United States for use in patients with vascular dementia or Lewy body dementia.

Studies that investigate the use of cholinesterase inhibitors in mild cognitive impairment, considered to be prodromal AD in some people, have not shown consistent benefit. Of the nine studies evaluated in a systematic review, only donepezil in one study demonstrated improvement in cognition as the primary outcome measure compared to placebo. The difference in ADAS-cog was small but significant, although other studies did not show benefit on primary outcomes (Cooper, Li, Lyketsos, & Livingston, 2013; Doody et al., 2009).

OTHER TREATMENTS FOR ALZHEIMER'S DISEASE

Natural products and supplements are increasingly popular among the aging population (Barnes, Bloom, Nahin, & Statistics, 2008). The more commonly mentioned include omega-3 fatty acids, s-adenosyl methionine, ginkgo biloba, huperzine A, and vitamin B. While some studies of omega-3 fatty acids and ginkgo biloba suggest neuroprotective properties with a delay in dementia onset, no study has consistently demonstrated treatment efficacy in those with a dementia syndrome (DeKosky et al., 2008; Issa et al., 2006; Lavretsky, 2009; Varteresian, Merrill, & Lavretsky, 2013).

TREATMENT OF NEUROPSYCHIATRIC SYMPTOMS ASSOCIATED WITH ALZHEIMER'S DISEASE AND OTHER DEMENTIAS

Neuropsychiatric symptoms include apathy, depression, irritability, agitation/aggression, and psychosis. These symptoms are now thought to be fundamental expressions of the neurodegenerative process and are considered core clinical features of AD. Over the entire course of AD, 80% to 100% of patients will develop such symptoms. At any given time, more than half of dementia patients will experience behavioral disturbances that can have a negative impact on the quality of life and the health of both patient and caregiver (Lyketsos et al., 2000).

A longitudinal study found that apathy, depression, and agitation were the most commonly reported neuropsychiatric symptoms in dementia and MCI (Lyketsos et al, 2002).The prevalence of overall neuropsychiatric symptoms increases and the symptom profile changes with disease progression. Apathy, depression, anxiety, and irritability are more common in mild AD, and agitation/aggression, delusions, hallucinations, and disinhibition are more common in more advanced stages. Management of neuropsychiatric symptoms is a major priority in dementia care. They are associated not only with impaired quality of life, but also with increased morbidity, caregiver burden, health economic costs, hospitalizations, and nursing home placement.

Improved understanding of the neurobiological etiology of neuropsychiatric symptoms will help guide future treatment developments. Researchers have identified dysfunction in three neurobiological models that may contribute to neuropsychiatric symptoms in AD: frontal-subcortical circuits, cortico-cortical networks, and the monoaminergic system (Geda et al., 2013). Moreover, individual symptoms are related to dysfunction in distinct neural systems (Sultzer et al., 2011, 2013). Further illumination of these models with neuroimaging, regional neuropathology, genetic, and other biomarker studies will inform treatment advances.

Rating scales commonly used to measure neuropsychiatric symptoms in research studies include the following:

- NPI: assesses the frequency and severity of 12 psychiatric and behavioral disturbances in dementia patients, including agitation, psychosis, and mood disturbance
- Neurobehavioral Rating Scale (NRS): a 28-item observer-rated scale with caregiver input. Includes domains of cognition, agitation/disinhibition, behavioral retardation, anxiety/depression, psychosis, and verbal output disturbance.
- Behavior Pathology in Alzheimer's Disease Rating Scale (BEHAVE-AD): a 25-item scale that includes seven groups of behavior: paranoid/delusional ideation, aggressiveness,

hallucinations, activity, diurnal rhythm, affective symptoms, anxiety, and phobias
- Brief Psychiatric Rating Scale (BPRS): an 18-item clinician-rated scale that measures psychiatric symptoms, including mood, psychosis, anxiety, and motor symptoms
- Cornell Scale for Depression in Dementia (CSDD): developed to assess depression in patients with dementia, based on semistructured interviews with the patient and caregiver
- Cohen-Mansfield Agitation Inventory (CMAI): a 29-item, informant-rated instrument. Categories of agitated behaviors include physical aggression, physical nonaggression (e.g., intense pacing, restlessness, repetitious behaviors), and verbal agitation.

Nonpharmacological Treatments

Behavioral disturbances should first be managed nonpharmacologically whenever possible. A thorough medication review and screen for substance use, including caffeine, can also identify inadvertent psychotropic agents that may exacerbate neuropsychiatric symptoms. Medical conditions such as pain, dehydration, urinary retention, and delirium can contribute to behavioral disturbance and warrant attention. Finally, environmental circumstances that foster neuropsychiatric symptoms or disruptive behaviors are also addressed.

Overall, nonpharmacological interventions are directed toward the patient, the caregivers, and the environment. Nonpharmacological interventions have been grouped into eight categories: sensory interventions, structural activities, social contact, medical/nursing interventions, environmental interventions, behavior therapy, staff training, and combination therapies (Cohen-Mansfield, 2013).

A comprehensive review of nonpharmacological interventions for behavioral symptoms of dementia included various forms of cognitive/emotion-oriented interventions, sensory stimulation interventions, and behavior management techniques (O'Neil et al., 2011). In most studies, there was insufficient evidence to recommend a standardized practice. Although some were randomized controlled trials, the majority of studies were small and methods were inconsistent across trials. The review suggested a beneficial role for sensory stimulations interventions (e.g., light therapy, aromatherapy, and massage/touch therapy) and behavior management techniques (including cognitive-behavioral therapy, token economies, habit training, communication training, and reinforcement strategies). The authors emphasized the need to tailor psychosocial therapies to the individual and to modify the intervention to best suit the caregivers and environment.

A systematic review evaluated 162 studies that used a psychological or psychosocial approach to treating neuropsychiatric symptoms of dementia (Livingston, Johnston, Katona, Paton, & Lyketsos, 2005). Three strategies were best supported by the reviewed literature. Behavioral management techniques tailored to a specific behavior were effective in reducing neuropsychiatric symptoms, and the benefit was sustained for several months. Individualized psychoeducation to change caregivers' interaction with the patient also had lasting effect. Finally, cognitive stimulation in the form of music and sensory enhancement was effective but not long-lasting. The authors noted that while some interventions may not have a substantial impact on neuropsychiatric symptoms, they can provide pleasure to the patient and/or caregiver and thus have value.

Few studies have assessed the effects of combined behavioral and medication treatment or have compared the effects of behavioral and pharmacological interventions. In one study, AD patients with agitated behaviors were treated with either haloperidol (mean dose = 1.8 mg/day), trazodone (mean dose = 200 mg/day), behavioral management techniques, or placebo. Interestingly, there was no significant difference among the groups on the primary outcome measure. Fewer adverse events were reported in the behavioral management group (Teri et al., 2000). These findings may highlight the challenge of matching an optimal treatment to an individual patient or symptom and are consistent with the relatively high placebo response rates seen across studies of the treatment of neuropsychiatric symptoms.

Pharmacological Treatments

To date, no pharmacological interventions are FDA approved for neuropsychiatric symptoms in the United States. In general, providers identify the target symptoms and match them to the relevant

medication class for treatment. However, there is little evidence to support this practice. Improved understanding of neurobiological and other factors that influence the expression of neuropsychiatric symptoms will help to identify the symptoms and the patients most likely to benefit from specific treatments and can provide targets for future treatment development. In many studies of dementia treatments, behavioral outcomes were secondary measures and trial participants had few behavioral symptoms at baseline (Rodda, Morgan, & Walker, 2009). The United Kingdom's Alzheimer's Society has provided clinicians with online practice guidelines (http://alzheimers.org.uk/bpsdguide). Below, we highlight studies that target the most common dementia-associated symptoms: apathy, depression, and agitation/psychosis.

Apathy

Apathy is one of the most frequent behavioral symptoms in AD (Aalten et al., 2007; Robert et al., 2005). The prevalence of apathy is between 55% and 80% in AD (van Reekum, Stuss, & Ostrander, 2005), up to 70% in mixed-type dementia (Mulin et al., 2011), and 56% in Parkinson's disease dementia (Dujardin et al., 2007). Standardized diagnostic criteria for apathy were proposed by Robert and colleagues (2009). Apathy is defined as a disorder of motivation that persists over time and meets the following requirements: (1) the core feature of apathy/diminished motivation must be present for at least 4 weeks; (2) two of the three dimensions of apathy (reduced goal-directed behavior, goal-directed cognitive activity, and emotional reactivity) must be present; (3) symptoms cause clinically significant functional impairment; and (4) symptoms are not due to other states that mimic apathy.

The Apathy in Dementia Methylphenidate Trial (ADMET) was a 6-week, randomized, double-blind, placebo-controlled study that included 60 patients with AD who were treated with either methylphenidate 20 mg/day or placebo. Primary outcome measures were scores on the Apathy Evaluation Scale and modified ADCS CGI-Change. Statistically significant improvement was detected on the ADCS CGI-Change and NPI apathy item score, the latter being a secondary measure. Improvement on the Apathy Evaluation Scale was not statistically significant. The methylphenidate group reported more adverse events of anxiety and weight loss (Rosenberg et al., 2013). Additional methylphenidate studies are in development.

Some studies of cholinesterase inhibitor medication have shown beneficial effects on apathy. In a subanalysis of a placebo-controlled trial of donepezil for moderate to severe AD, the change from baseline on the NPI apathy item was greater in the donepezil group than the placebo group. Moreover, among the 67% of participants with apathy at baseline, apathy scores improved with donepezil treatment, along with anxiety and irritability/lability scores (Gauthier et al., 2002).

Modafanil is a norepinephrine agonist that can increase dopamine and histamine levels in the brain and enhance motor activity. Small studies suggest that modafanil may reduce apathy in AD (Frakey, Salloway, Buelow, & Malloy, 2012). However, the available evidence is not robust enough to endorse routine use.

Depression

Depression in AD is likely different from mood disorders in young adults and in nondemented older adults. Amotivation and psychosis are more common in depression in AD, while guilt, suicidal thoughts, and low self-esteem are less common (Olin, Katz, Meyers, Schneider, & Lebowitz, 2002; Rosenberg et al., 2005). Diagnostic criteria for depression in AD have been developed (Olin et al., 2002). Depending on the population selected and the measure used to define depression, the prevalence of depression in AD ranges between 5% and 40%. Depression in AD is associated with poor quality of life, increased caregiver burden, higher rates of institutionalization, greater functional decline, greater likelihood of physical aggression, and higher rates of mortality (Lyketsos et al., 2003). As a distinct syndrome, depression in AD may respond to antidepressant treatment differently than in young adults or nondemented older adults.

The Depression in Alzheimer's Disease Study 2 (DIADS-2) was a randomized, double-blind, placebo-controlled study that examined the use of sertraline for the treatment of depression in patients with AD (Rosenberg et al., 2010). Participants met Rosenberg's 2005 criteria for depression in AD, which was an advantage over prior depression studies that did not include a dementia-relevant diagnosis. The

primary outcome measure was change in the mood domain on the modified ADCS-CGI-Severity at 12 weeks and secondary outcome measures were change in CSDD and remission. After 12 and 24 weeks of treatment, sertraline was not associated with significant improvement but was associated with a higher incidence of adverse effects. Notably, the majority of patients did demonstrate some improvement, which could have been due to the psychosocial intervention provided to both sertraline and placebo groups. Alternatively, improvement in both groups may have reflected spontaneous improvement of symptoms (Weintraub et al., 2010). A retrospective analysis of the DIADS-2 study found that sertraline was no more efficacious than placebo in subgroups that met diagnostic criteria for major depressive episode, minor depressive episode, or Alzheimer's-associated affective disorder (Drye et al., 2011).

A systematic review and meta-analysis examined antidepressant use for depression in dementia. Seven trials met selection criteria and included 330 patients. Depression measures, depression severity, and study design varied considerably across the trials. Two studies found antidepressants effective (clomipramine, sertraline) while the other five did not (Nelson & Devanand, 2011).

Agitation/Psychosis

Agitation occurs in 20% to 70% of patients with AD and is associated with poor quality of life, increased caregiver burden, and higher rates of institutionalization (Okura et al., 2010). Psychosis, in the form of delusions and hallucination, occurs in 30% to 50% of AD patients and is more prevalent in advanced AD (Craig, Mirakhur, Hart, McIlroy, & Passmore, 2005). Neuroimaging studies suggest that aggressive agitation in AD is associated with dysfunction in distinct fronto-temporal cortical systems (Sultzer et al., 2011). The term "agitation" can include a wide range of behaviors, and variability in the results of treatment studies is at least partly related to variability in the definitions and criteria used to define agitation. A standardized criterion for the syndrome of agitation in cognitive impairment is in development.

Historically, antipsychotic medications were used to treat psychosis, agitation/aggression, and some other neuropsychiatric symptoms in AD, although the evidence base supporting efficacy was thin. More recently concern about the safety and overuse of antipsychotics, particularly in nursing homes, has led to reduced numbers of prescriptions.

Cholinesterase Inhibitors

Compared to placebo, cholinesterase inhibitors may reduce the emergence of neuropsychiatric symptoms over 6-month treatment periods but do not clearly benefit those with active symptoms (Trinh, Hoblyn, Mohanty, & Yaffe, 2003). Studies that suggest that donepezil has efficacy for neuropsychiatric symptoms tend to include patients with no or mild symptoms, to address behavioral outcomes as secondary measures, or to demonstrate benefits that are more apparent for mood symptoms than for agitation or aggression.

In one study that enrolled only patients with clinically significant agitation, 272 AD patients with mean MMSE 8.2, mostly in residential care settings, were randomized to 12 weeks of treatment with either donepezil or placebo (CALM-AD). There was no significant difference in change of agitation symptoms or percent responders between the donepezil and placebo groups, as detected on the CMAI or NPI (Howard et al., 2007).

Improvement in agitation/aggression among patients treated with cholinesterase inhibitors was detected in a secondary analysis of data from a nursing home study. Two hundred eighty nursing home patients with AD were randomized to receive donepezil or placebo treatment. At baseline, agitation/aggression was the most common behavioral symptom among all patients. There was no significant difference between the treatment groups on either NPI-NH total or agitation item scores from baseline to endpoint. However, in a secondary analysis of categorical change, 67% of patients in the donepezil group exhibited significant improvement in agitation/aggression compared to 46% of patients in the placebo group (Tariot et al., 2001).

Memantine

Several studies have indicated that memantine treatment in moderate to severe AD may reduce the emergence of neuropsychiatric symptoms, but evidence supporting efficacy in those with active symptoms is limited. A study of donepezil and memantine suggested that the combination may decrease preexisting

behavioral disturbances and also delay the emergence of new behavioral disturbance in dementia (Cummings, Schneider, Tariot, & Graham, 2006). Significant differences were detected in the agitation, irritability, and appetite domains. However, at baseline the patients demonstrated only mild behavioral symptoms, and the findings emerged from a post hoc analysis of secondary outcomes.

In the DOMINO trial, patients with moderate to severe AD stable on donepezil treatment were randomized to continue donepezil, discontinue donepezil, discontinue donepezil and add memantine, or continue donepezil with memantine added for 52 weeks (Howard et al., 2012). A secondary analysis of total NPI scores (reflecting the sum of all neuropsychiatric symptoms) showed a small but significant benefit of memantine treatment over placebo, regardless of whether the memantine treatment was co-treatment with donepezil or stand-alone treatment. Presence of NPS was not a criterion for inclusion, and results for individual symptoms such as agitation were not reported.

A placebo-controlled trial of memantine in AD patients, specifically with agitated behaviors, showed contrasting results. Patients with AD and clinically significant agitation were randomized to receive either placebo or memantine treatment. No significant difference between groups was apparent on the primary outcome measure of agitated/aggressive behaviors, the CMAI. However, some benefit of memantine treatment was noted on the total NPI score, which was a secondary measure and more broadly encompasses aggregate neuropsychiatric symptoms (Fox et al., 2012).

Antipsychotic Medications

Off-label use of antipsychotic medications continues to be considered a reasonable pharmacological intervention for some patients with dementia and behavioral disturbance, when symptoms are severe and behavioral interventions are not effective (Alexopoulos, Streim, Carpenter, & Docherty, 2004). No medication is approved by the FDA for the treatment of neuropsychiatric symptoms in AD. Risperidone is approved by the European Medicines Agency for short-term treatment of persistent aggression in moderate to severe AD when there is risk of harm and unresponsiveness to nonpharmacological interventions.

The evidence from controlled trials of atypical antipsychotic medications reveals a statistically significant benefit of antipsychotic treatment for agitation/aggression in AD, although the magnitude of benefit is small on average. A large systematic review and meta-analysis assessed 18 placebo-controlled trials of antipsychotic medication for agitation or psychosis in dementia. Small but statistically significant benefits were observed for risperidone and aripiprazole (Schneider et al., 2006). Benefits were not seen in all treatment trials. In a more recent meta-analysis, 14 placebo-controlled trials were evaluated. Small but statistically significant effects were observed for risperidone, aripiprazole, and olanzapine for treatment of psychosis, agitation, and global behavioral symptoms in dementia (Maher et al., 2011). In these trials, the effect size for improvement in psychosis is smaller than for agitation, suggesting that psychosis in dementia is paradoxically a poor prognostic factor for antipsychotic treatment. Efficacy of low-dose quetiapine for agitation or psychosis in AD is not apparent in the controlled trials. Three trials compared effectiveness between risperidone and olanzapine, or risperidone and quetiapine. No significant differences were apparent in psychosis or global outcome (Maglione et al., 2011).

A black box warning was issued by the FDA in 2005 based on pooled results of controlled trials that showed increased mortality risk among dementia patients taking second-generation (atypical) antipsychotic medication. More recent studies support the elevated long-term risk of mortality (Ballard et al., 2009). The extent of risk varies across studies, and some analyses do not show increased mortality risk. Understanding true risk, however, is complicated when the frequency of events is low and the sample size is limited.

Most trials reported adverse effects such as somnolence, falls, injury, syncope, extrapyramidal effects, bruising, edema, and urinary tract infections. Although adverse metabolic changes are usually associated with younger patients, clinically significant weight gain and HDL reduction has been observed with second-generation antipsychotic treatment in dementia patients (Zheng et al., 2009). Further, simultaneous use of psychotropic medication with donepezil may negate the potential cognitive improvement afforded by dementia medication (Holmes et al., 2004; Vigen et al., 2011). When considering antipsychotic treatment in practice, clinicians must weigh the value

of modest benefit against the individual patient's risk for adverse effects and their consequences.

One study of antipsychotic treatment for agitation or psychosis in AD was designed to assess the effectiveness of treatment. The Clinical Antipsychotic Trials of Intervention Effectiveness-Alzheimer's Disease (CATIE-AD) study was a 42-site, double-blind, placebo-controlled trial that included 421 outpatients with AD and psychosis, aggression, or agitation. Each was initially randomly assigned to receive flexible dosing of olanzapine (mean dose = 5.5 mg/day), quetiapine (mean dose = 56.5 mg/day), risperidone (mean dose = 1.0 mg/day), or placebo, and patients were followed for up to 36 weeks. At any time after 2 weeks of treatment the initially assigned medication could be switched to an alternative treatment because of insufficient efficacy, adverse effects, or other reasons, based on the clinical impression of the blinded treating clinician. Time to discontinuation for any reason, the primary outcome, was no different between the antipsychotic and placebo treatment groups (Schneider et al., 2006). An analysis of clinical symptoms found that at the last observation on the initially assigned drug, those treated with olanzapine or risperidone had improved more than those treated with placebo on global NPS measures (Sultzer et al., 2008). The magnitude of improvement was greatest on the BPRS hostile suspiciousness factor, a measure of anger, aggression, and paranoia. On the BPRS psychosis factor, only risperidone showed benefit compared to placebo. Compared to placebo, antipsychotic treatment groups did not improve in daily functioning, care needs, or quality of life. These findings should be cautiously interpreted given the limitations of the study, including that the study design permitted clinicians to change medications. While this reflects real-world clinical care, the results at least partly reflect clinicians' expectations and behaviors along with medication effects.

One recent study assessed the consequences of discontinuing antipsychotic treatment among AD patients with psychosis or agitated/aggressive behavior who had clearly responded to the treatment. In this study, patients with AD with psychosis or agitation/aggression received open-label flexible-dose risperidone for 16 weeks. Those patients who responded to treatment were then randomized to receive either continued risperidone or placebo for an additional 16-week period, under blinded conditions. Among those switched to placebo treatment, the time to relapse was shorter and the rate of relapse was twice that of those continued on risperidone (60% vs. 33%) (Devanand et al., 2012).

Antidepressants

Sertraline, fluoxetine, citalopram, and trazodone have been evaluated in treatment studies for psychosis or agitation in dementia. Among five placebo-controlled randomized trials, only citalopram demonstrated efficacy for agitation and psychosis (Sink, Holden, & Yaffe, 2005). A recent systematic review identified 19 randomized controlled trials that used antidepressant medication for neuropsychiatric symptoms in dementia. Fifteen studied selective serotonin reuptake inhibitors, including sertraline, citalopram, paroxetine, fluoxetine, and fluoxamine, and the other four studied trazodone. Of these 19 studies, 11 demonstrated some therapeutic benefit for symptoms of irritability, depression, and agitation, although there was no consistent pattern of therapeutic response in any particular category. Not all studies were placebo-controlled and not all patients were diagnosed with Alzheimer's-type dementia (Henry, Williamson, & Tampi, 2011).

Effects of citalopram have been evaluated more recently. In the second phase of the CATIE-AD study, AD outpatients with psychosis or agitation/aggression were randomized to receive olanzapine, risperidone, quetiapine, or citalopram. There were modest improvements in symptoms that did not differ between antipsychotics and citalopram. There were more severe adverse effects with olanzapine and risperidone and more gastrointestinal adverse effects with citalopram (Schneider et al., 2009). Finally, a 9-week double-blind placebo-controlled study of citalopram up to 30 mg/day for agitation in patients with AD was recently completed. The Citalopram for Agitation in Alzheimer Disease Study (CitAD, Porsteinsson et al., 2014) randomized 186 patients with probable AD and clinically significant agitation to a psychosocial intervention plus either citalopram or placebo. The primary outcome measures were change in the scores on the NBRS agitation subscale and the modified ADCS-CGIC. Patients who received citalopram had significantly greater improvement on both agitation measures compared to those on placebo. However, patients in the citalopram group experienced worsening cognition and QT interval prolongation compared to the placebo group.

In a randomized, double-blind, parallel-group study, the effects of trazodone and haloperidol were

compared in AD patients with agitation using the CMAI (Sultzer, Gray, Gunay, Berisford, & Mahler, 1997). Overall, the efficacy of the two drugs was comparable, but adverse effects were more common in the haloperidol group. Patients with concomitant mild depressive symptoms exhibited better CMAI response to trazodone than haloperidol (Sultzer, Gray, Gunay, Wheatley, & Mahler, 2001). In contrast, patients with coexisting psychosis, as indicated on the BEHAVE-AD delusions and hallucinations subscores, did not respond better to haloperidol. The extent of improvement in agitated behaviors from trazodone or other serotonergic medications may be mediated by the presence of coexisting mood symptoms. In contrast, another randomized trial that compared trazodone, haloperidol, a behavioral management technique, and placebo for treatment of agitated behaviors in AD showed no difference in efficacy outcomes across the four groups (Teri et al., 2000).

Mood Stabilizers: Valproate and Carbamazepine

Five randomized controlled trials and one meta-analysis assessed the use of valproate for agitation in dementia, and most did not find improvement on global NPS scales (Herrmann, Lanctôt, Rothenburg, & Eryavec, 2006; Porsteinsson et al., 2001; Sival, Haffmans, Jansen, Duursma, & Eikelenboom, 2002; Tariot et al., 2001, 2005). Of the trials, two showed improvement on agitation subscales, although there were methodological limitations (Konovalov, Muralee, & Tampi, 2008). The first placebo-controlled study of valproate for agitation in dementia showed improvement on the BPRS Agitation subscale and the CGI, but the BPRS improvement did not reach statistical significance without second-order analysis, medications were handled by a nonblinded physician, the sample size was small, and the study duration was only 6 weeks (Porsteinsson et al., 2001). A Cochrane review of valproate for neuropsychiatric symptoms in dementia found that adverse effects were more commonly reported in the valproate-treated groups and were often clinically troubling. Those effects included sedation, falls, gastrointestinal upset, urinary tract infection, and thrombocytopenia (Lonergan & Luxenberg, 2009).

Three randomized controlled trials and one meta-analysis evaluated the use of carbamazepine for neuropsychiatric symptoms in dementia. In contrast to findings with valproate, most studies showed evidence of benefit from carbamazepine treatment for agitation in dementia. However, the potential drug–drug interactions from shared CYP450 metabolism and the black box warnings for potentially fatal skin reactions and hematological toxicity limit its use by clinicians. Common adverse effects included diarrhea, sedation, and dizziness, although these were generally mild (Tampi et al., 2011).

Adrenergic Antagonists: Prazosin

Prazosin is an alpha-1 receptor antagonist that may have anxiolytic properties. One study examined its use in patients with AD and agitation. In an 8-week, randomized, placebo-controlled parallel group study, 22 patients with agitation and aggression and probable or possible AD were randomized to receive placebo or prazosin, up to 6 mg/day. The patients treated with prazosin (mean dose = 5.7 mg/day) demonstrated improvement on all three primary outcome measures, the CGIC, NPI, and BPRS (Wang et al., 2009). More evidence would be useful, and a larger study of prazosin by the Alzheimer's Disease Cooperative Study is planned.

LIMITATIONS AND SUMMARY

A large majority of the dementia literature focuses on AD. Because of likely pathophysiological differences, the treatments for AD are not always generalizable to other forms of dementia. However, clinicians still prescribe AD medications for non-AD syndromes because there are relatively few studies available to guide clinicians otherwise. One exception is the understanding that cholinesterase inhibitors may exacerbate behaviors in frontotemporal dementia (Mendez, Shapira, McMurtray, & Licht, 2007).

Only three placebo-controlled trials have provided data beyond 6 months. As a result, there is little evidence guiding clinicians about when to discontinue medications for treatment of dementia or neuropsychiatric symptoms. Also, participants in clinical drug trials may not be representative of patients seen in primary care or specialty care settings. Strict inclusion and exclusion criteria may select for cohorts that favor one treatment domain over another, rendering study results difficult to interpret clinically. Current

treatment options for dementia and neuropsychiatric symptoms associated with dementia are limited, and the evidence to support their efficacy is modest.

TREATMENTS IN DEVELOPMENT FOR ALZHEIMER'S DISEASE

The lack of substantially efficacious treatments for AD and the increasing worldwide prevalence of the disorder have spurred efforts to develop new treatments for AD and, ideally, preventive strategies. Improved understanding of the neurodegenerative process at the molecular level has helped to guide recent treatment approaches.

There have been no new approved treatments for the symptoms of AD since 2004. New treatment efforts are focused on modifying the neurodegenerative process and thereby improving or arresting the course of disease progression. Specific steps in AD pathophysiology have been targeted, including amyloid production, amyloid aggregation, tau phosphorylation, neurofibrillary tangle formation, oxidation and lipid peroxidation, inflammation, and neuronal apoptosis. While such targeted therapies are more likely to be effective, many compounds have unfortunately not demonstrated efficacy in late-phase clinical trials over the past few years. In addition, while disease modification is a key treatment goal, clinical trials to measure treatment effects on disease progression are necessarily extended up to 18 months or beyond, and are thus lengthy and costly.

Several specific approaches have been tested and continue to be explored in clinical trials (Table 26.8). Anti-amyloid approaches include drugs that reduce beta-amyloid production by shifting amyloid precursor processing toward the production of less toxic peptides. Gamma-secretase inhibitors and modulators and beta-secretase inhibitors have advanced to phase 3 testing, but studies to date have not shown significant benefit or have suggested safety concerns. Active or passive anti-amyloid immunization can reduce toxic amyloid burden in the brain. Infusion of specific monoclonal antibodies has been shown to engage the amyloid target in some studies using brain, cerebrospinal fluid, or plasma biomarkers. However, 18-month phase 3 trials of bapineuzemab and solanezumab did not meet primary efficacy outcomes for cognitive improvement in mild to moderate AD, and bapineuzemab treatment was associated with amyloid-related neuroimaging abnormalities due to edema or effusion in approximately 10% of treated individuals (Sperling et al., 2013). A post hoc analysis of the solanezumab trial data revealed improved cognition in the subgroup of AD participants with mild cognitive deficits at baseline (Dean

TABLE 26.8 Targeted Mechanisms in Drug Development for Alzheimer's Disease or Prodromal Alzheimer's, and Examples of Drugs in Development

Mechanism or Treatment Target	*Examples of Drugs in Development*
Gamma- and beta-secretase inhibitors and modulators	Semagacestat Avagacestat LY2886721 MK8931
Immunotherapy, anti-amyloid and others	Bapineuzumab Solanezumab Crenezumab Human immunoglobulin
Amyloid aggregation	Tramiprosate
Tau aggregation	Methylene blue
Antioxidant	Vitamin E Resveratrol
Neuroprotection and other mechanisms	Dimebon (latrepirdine) PPAR agonists (e.g., pioglitazone) Intranasal insulin

Some of the drugs have not shown efficacy or revealed adverse effects in clinical trials and some are no longer in active development. Their underlying mechanisms may continue to be relevant. Other drugs are in ongoing human trials or other phases of development.

et al., 2013), consistent with the hypothesis that inhibiting beta-amyloid before more widespread neuropathology develops or clinical symptoms emerge is key to modifying the course of clinical symptoms. A follow-up study in patients with mild symptoms of AD who also have biomarker evidence of abnormal beta-amyloid is in progress. Trials of several other monoclonal antibodies are ongoing.

Other treatment approaches in development target toxic oxidative stress, inflammation, mitochondrial metabolism, neurotransmitter deficits, synaptic loss, or myelin abnormalities associated with the AD process, or provide homeostatic support via growth factors or stem cells. Some of these approaches are early in development.

Other treatments for AD symptoms that address neurotransmitter or neuroreceptor deficits, inflammation, or oxidative stress are farther along in development, although robust symptomatic improvement has not been demonstrated in most late-phase clinical trials. A recent longer-term study of vitamin E treatment showed modest benefit on measures of functional skills in mild to moderate AD (Dysken et al., 2014). These results, combined with evidence from trials of cholinesterase inhibitors and memantine, indicate that, while beneficial effects are modest on average, addressing neurotransmitter changes and oxidative stress related to AD pathology will continue to have a role in treating AD symptoms for many years, pending the availability of safe and effective disease-modifying treatments.

Two advances are contributing to treatment development for AD. First, animal models in mice and rats bred to express human beta-amyloid pathology can be used to evaluate the sequence of neurodegenerative events in AD disease progression, the relationships between neuropathologies and clinical symptoms, and the effects of interventions that target these pathologies. Second, biomarkers for AD-related biologies in humans can be measured in plasma and cerebrospinal fluid and noninvasively in the brain using neuroimaging techniques. These biomarkers for AD-related neuropathologies provide tools to evaluate drug–target engagement and also the longitudinal impact of treatment on the pathology represented. Biomarkers have been used in phase 3 trials to demonstrate treatment-related clearance of fibrillar amyloid from the brain, using amyloid ligand positron emission tomography (PET) neuroimaging. Such studies will help to refine understanding of key AD treatment mechanisms and can help to identify patients most likely to benefit.

Symptom prevention trials can take advantage of known genetic risk for AD or biomarker evidence of AD pathology before clinical symptoms are present. Three such multiyear treatment studies are in progress. Two trials (Dominantly Inherited Alzheimer Network trial; Alzheimer Prevention Initiative trial) include asymptomatic genetic risk carriers from kindreds with early-onset familial AD. Active treatments in these trials are either monoclonal anti-amyloid antibody or secretase inhibitor. The third trial (A4 trial, Alzheimer's Disease Cooperative Studies) includes older adults without cognitive deficits but with neuroimaging evidence of fibrillar amyloid deposits in the brain. Participants are being treated with anti-amyloid drug or placebo for 3 years and will be assessed longitudinally for the evolution of neurodegeneration markers and cognitive symptoms over time. These trials represent a first step toward the prevention of cognitive, functional, and behavioral symptoms in those at risk for AD.

There are also continued efforts to develop better treatments for neuropsychiatric symptoms such as apathy, depression, psychosis, and agitation/aggression in AD. Improved definitions of the clinical syndromes are in place. Behavioral interventions are being refined and optimal implementation strategies are under investigation. Pharmacological interventions have been broadened to include drugs that target alternative neurotransmitter/neuroreceptor systems, and drug development is increasingly guided by improved understanding of the neurobiological underpinnings of the clinical symptom clusters.

Psychological Treatments for Personality Disorders

Paul Crits-Christoph
Jacques P. Barber

A type 2 randomized controlled trial (RCT) found that 20 weeks of cognitive-behavioral therapy (CBT) led to greater improvement than either brief dynamic therapy or a waitlist control for *DSM-IV* avoidant personality disorder. Another type 2 RCT for avoidant personality disorder compared three group-administered behavioral interventions (graded exposure, standard social skills training, intimacy-focused social skills training) with a waitlist control; although all three treatments were more efficacious than the control condition, no differences among the treatments were identified either after the 10-week treatment or at follow-up. For the treatment of borderline personality disorder (BPD), a meta-analysis found statistically significant effects indicating a beneficial effect of dialectical behavior therapy (DBT) over treatment as usual for improvements in anger (two RCTs), parasuicidality (three RCTs), and mental health (two RCTs). All of these effects were moderate to large in size. However, DBT is not uniquely effective for BPD, with two type 1 RCTs finding equal effects for versions of psychodynamic therapy. Another type 1 study found that mentalization-based psychodynamic therapy was superior to structured clinical management in the treatment of BPD in terms of steeper declines in both self-reported and clinically significant problems, including suicide attempts and hospitalization. Single type 1 studies have also supported the efficacy, compared to treatment as usual, of cognitive therapy, schema therapy, and Systems Training for Emotional Predictability and Problem Solving (a therapy that combines cognitive-behavioral techniques and skills training with a systems component) as treatments for BPD. A meta-analysis of five RCTs concluded that there is insufficient trial evidence to justify using any psychological intervention for adults with antisocial personality disorder. No RCTs of psychological treatment for other personality disorders have been reported. Several review articles have found a consistent adverse impact of personality disorders on outcomes of treatment for a wide range of Axis I disorders.

DEFINITION, EPIDEMIOLOGY, AND ETIOLOGY OF PERSONALITY DISORDERS

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 2013a) defines personality disorders in terms of enduring patterns of thinking about oneself and others that significantly and adversely affect how an individual functions in various aspects of life. The *DSM-5* describes 10 specific personality disorder diagnoses. These are grouped into three clusters: (a) the "odd" cluster (paranoid, schizoid, and schizotypal), (b) the dramatic cluster (histrionic, narcissistic, antisocial, and borderline), and (c) the anxious cluster (avoidant, dependent, obsessive-compulsive). The criteria for diagnosing individual personality disorders

were unchanged between *DSM-IV* and *DSM-5*. Because *DSM-5* has moved to a single-axis system, personality disorders are no longer classified as "Axis II" disorders. An alternative trait-based model of personality disorders was proposed for *DSM-5*, but this alternative model was rejected as too complex for clinical practice (American Psychiatric Association, 2013b). However, a hybrid model that combines elements of the existing criteria for personality disorders with the trait-based approach was included in Section III of *DSM-5* to stimulate further study.

Although personality disorders are relatively common compared with many other psychiatric disorders, estimates of the prevalence of different personality disorders have been hampered by difficulty in reliably assessing these disorders. Strides have been made in the development of structured clinical interviews for assessing personality disorders, but to date these instruments have displayed modest and variable convergence (Clark, Livesley, & Morey, 1997; Perry, 1992; Widiger & Samuel, 2005) among themselves or with other measures. Poor convergent validity in assessing personality disorders suggests that one cannot necessarily treat similarly results from studies that use different instruments, thus limiting the validity of these measures (Perry, 1992). However, advances have been reported in the reliability of these measures. Maffei and colleagues (1997), for example, reported acceptable interrater reliability coefficients of 0.49 to 0.98 (kappas) for *DSM-IV* categorical diagnoses and excellent intraclass correlation coefficients from 0.90 to 0.98 for dimensional judgments. The Collaborative Longitudinal Personality Disorders Study (Zanarini et al., 2000), which focused on schizotypal, borderline, avoidant, and obsessive-compulsive personality disorders, also reported relatively good median interrater reliability kappa coefficients (0.40 to 0.75) for all personality disorders diagnosed five times or more, and excellent reliability for the diagnosis of antisocial personality disorder (kappa = 1.0). This study also found excellent interrater reliability (>0.75) when dimensional scores were used.

International community-based epidemiological studies have put the overall prevalence of *DSM-IV* personality disorders at about 6% for any personality disorder and 3.6%, 1.5%, and 2.7% for clusters A, B, and C, respectively (Huang et al., 2009). In the United States, the prevalence rate for any personality disorder has been estimated at 9.1% (Trull et al., 2010). For individual personality disorders, Trull and colleagues (2010) report the following prevalences: paranoid, 1.9%; schizoid, 0.6%; schizotypal, 0.6%; borderline, 2.7%; histrionic, 0.3%; narcissistic, 1.0%; antisocial, 4.1%; obsessive-compulsive, 1.9%; avoidant, 1.2%; and dependent, 0.3%. The presence/absence of a personality disorder has been found to be stable over 2 years among adolescents in a psychiatric setting (Chanen et al., 2004). However, a study examining stability of personality disorders in adults over a 4-year period found statistically significant variation in personality disorder features over time, suggesting that such features are not always enduring (Lenzenweger, Johnson, & Willet, 2004). The impairment in functioning that is commonly seen in those individuals with personality disorders does appear to be a relatively enduring aspect of these disorders (Skodol et al., 2005).

There is also an extensive amount of comorbidity among personality disorders—that is, having one disorder tends to be associated with having one or more additional personality disorder diagnoses. For example, Zimmerman, Rothschild, and Chelminski (2005) reported that, among psychiatric outpatients, 60.4% of those who had a personality disorder had more than one personality disorder, and 25.2% had two or more. In some disorders, such as BPD, the comorbidity rate ranges from 90% to 97% (Gunderson, Zanarini, & Kisiel, 1991).

Comorbidity of personality disorders with other psychiatric disorders is especially important for treatment planning. Data from the National Comorbidity Survey Replication, a large-scale U.S. epidemiological study, has provided the best evidence regarding such comorbidity. Results indicate that, with respect to antisocial personality disorder, 70.2% of patients with this personality disorder also meet criteria for at least one psychiatric disorder in the previous 12 months, with an average of 3.4 such disorders (Lenzenweger et al., 2007). For BPD, 84.5% of cases also have at least one other 12-month psychiatric disorder. For cluster A as a group, 41.1% have another psychiatric disorder; for cluster C, 49.7% have another disorder. Of those with a (non-personality disorder) psychiatric disorder, 25.2% also have at least one personality disorder (Lenzenweger et al., 2007).

Comorbidity of Axis II with substance use disorders has been studied extensively and has been found to be particularly high. Trull and colleagues (2010) report high comorbidity rates for lifetime alcohol dependence among those with antisocial (49.2%),

histrionic (49.8%), and borderline (47.4%) personality disorders. Comorbidity with lifetime drug dependence was high with histrionic (29.7%), dependent (27.3%), and antisocial (23.4%) personality disorders (Trull et al., 2010).

Little is known about the etiology of personality disorders. A number of studies have documented high rates of physical and sexual abuse or other trauma during childhood in patients later diagnosed as having BPD (Herman, Perry, & van der Kolk, 1989; Ogata, Silk, Goodrich, Lohr, Westen, & Hill, 1990; Westen, Lundolph, Misle, Ruffins, & Block, 1990). Most recently, Waxman and colleagues (2014) found that BPD and schizotypal personality disorder were most strongly predicted by sexual abuse, antisocial personality disorder by physical abuse, and avoidant and schizoid personality disorders by emotional neglect. However, a recent study implicated prenatal adversity (tobacco smoking, drug taking, maternal traumatic stress, medical complications) in the pathogenesis of BPD (Schwarze et al., 2012). Other studies have found evidence for familial transmission of BPD (Baron, Gruen, Asnis, Asnis, & Lord, 1985; Loranger, Oldham, & Tullis, 1982) and schizotypal personality disorder (Baron et al., 1985). Studies have supported a genetic component for schizotypal personality disorder (Torgersen, 1984) and BPD (Distel et al., 2008). Twin research, however, has suggested that the genetic risk factors for *DSM*-IV personality disorders do not reflect the cluster A, B, and C typology (Kendler et al., 2008). Instead, genes convey a broad vulnerability to personality disorder pathology and/or negative emotionality. There is also a rich literature on the childhood precursors (most important, the presence of conduct disorder in childhood and behavioral disinhibition) of antisocial personality disorder (Paris, 2000).

HISTORICAL PERSPECTIVE

Early psychoanalytic writings devoted a considerable amount of attention to the treatment of "characterological" problems (Alexander, 1930; Fenichel, 1945). Although some of this literature informs modern approaches, particularly modern psychodynamic approaches, it is difficult to see the relevance of these early writings to the current classification system for psychiatric disorders. For example, the distinction between obsessive-compulsive disorder and obsessive-compulsive personality disorder was not made in early writings on "obsessive-compulsive" character, and this distinction is likely to be important for treatment selection.

Within the psychodynamic literature, there has been voluminous writing on the nature and treatment of narcissistic and borderline personality types in particular (Kernberg, 1984; Kohut, 1984; see review by Aronson, 1989). Even in these more recent writings, however, there has remained a lack of use of a consensual definition of the target patient population. As a consequence of the varying definitions of "characterological" conditions, the research literature on the treatment of personality disorders begins with the advent of the *DSM-III* and *DSM-III-R* classification system for personality disorders.

This is not to say that the *DSM* definition of personality pathology is not without problems. A number of authors have described various problems with the *DSM* classification, including lack of discrimination of many of the *DSM* criteria (Svrakic & Divac-Jovanovic, 1994), problems in distinguishing normal from deviant personality (Livesly, Schroeder, Jackson, & Jang, 1994), and general lack of empirical support (Widiger, 1993). These problems with the *DSM* system generated the proposed trait-based alternative that is contained within the hybrid model in Section III in *DSM*-5. Further research will determine whether this hybrid model is incorporated into the next edition of the *DSM*.

REVIEW OF TREATMENT OUTCOME LITERATURE

Despite the relatively high prevalence of personality disorders, there have been relatively few outcome studies using patients with these disorders. Since the third edition of *Treatments That Work* (Nathan & Gorman, 2007), additional important research on the treatment of BPD has been published, but there continues to be little attention to other personality disorders.

The first meta-analysis on the effectiveness of psychotherapy for personality disorders in general was published by Perry, Banon, and Ianni (1999). These authors found 15 studies that attempted to systematically diagnose their patients and evaluate outcome. Since most of these studies were not randomized trials, the authors calculated the within-treatment

change effect size, which ranged between 1.1 and 1.3 depending on the measure. In addition, they compared results from four studies that reported the percentage of patients who no longer met Axis II criteria at follow-up with studies that examined the natural history of recovery of BPD patients. They showed that, in comparison to the natural history of the latter, personality disorder patients who received psychotherapy had a sevenfold faster rate of recovery. Unfortunately, only half of the patients in the four studies had a diagnosis of BPD, thus limiting the validity of the comparison.

Another meta-analysis compared psychodynamic therapy (n = 14 studies) and CBT (n = 11 studies) in the treatment of various personality disorders (Leichsenring & Leibing, 2003). Because many of the studies were uncontrolled, the authors relied on within-group effect sizes and concluded that there was evidence that both treatments are effective. However, many of the studies did not standardize treatment, and therefore it is difficult to know what interventions were actually provided. Because of this problem and the lack of controlled comparisons, these results cannot be used to provide empirical support for the use of specific treatment modalities with specific patient disorders or problems. A more recent meta-analysis focused on RCTs of at least moderate quality (eight studies) that investigated psychodynamic therapy for any type of personality disorder (Town, Abbass, & Hardy, 2011). The authors concluded that short-term psychodynamic therapy may be considered an efficacious empirically supported treatment option for a range of personality disorders, with significant and medium- to long-term improvements for a large percentage of patients.

A final recent meta-analysis examined the efficacy of psychodynamic therapy for personality disorders, relying solely on evidence from RCTs (Barber, Muran, McCarthy, & Keefe, 2013). They found that psychodynamic therapy for personality disorder was more effective than treatment as usual or waitlist controls (study n = 7, subject n = 452, g = 0.593, p = 0.001). Psychodynamic therapy also did not differ from alternative therapies for personality disorder (study n = 7, subject n = 528, g = –0.145, p = 0.150).

In the next sections, we summarize the existing literature on the treatment of personality disorders using the type 1 to type 6 classification of studies employed in this volume. Our emphasis is on type 1 and type 2 studies with patients who meet *DSM-III*, *DSM-III-R*, or *DSM-IV* criteria. Type 3 through type 6 studies, including any study using pre–*DSM-III* criteria, are mentioned only when no type 1 or 2 studies are available.

AVOIDANT PERSONALITY DISORDER

An RCT on *DSM-III* avoidant personality disorder compared graded exposure, standard social skills training, intimacy-focused social skills training, and a waitlist control (Alden, 1989). The behavioral treatments were all administered in group format. All of the active treatments were better than the waitlist, but no differences among the behavioral treatments were found at the end of the 10-week treatment period or at follow-up. Examination of the clinical significance of the outcomes revealed that although positive changes had occurred in the active treatment conditions, patients were not functioning at the level of normative comparison samples. This study, however, had minimal statistical power for detecting differences among the treatments (<20 patients per group) and therefore is a type 2 study.

One randomized trial (type 2) compared 20 weeks of brief dynamic therapy (n = 23), CBT (n = 21), and a waitlist control (n = 18) for *DSM-IV* avoidant personality disorder. The results indicated that patients who received CBT showed significantly greater improvement on a number of outcome measures in comparison to both the brief dynamic therapy and the waitlist groups. Results were maintained at follow-up.

One type 3 study (not controlled) has been reported on *DSM-III-R* avoidant personality disorder (Renneberg, Goldstein, Phillips, & Chambless, 1990). This study evaluated an intensive (4 full days) group behavioral treatment program with 17 patients. The treatment included group systematic desensitization, behavioral rehearsal, and self-image work. Outcome was evaluated at posttreatment and 1-year follow-up. The results evidenced positive changes, especially in terms of fear of negative evaluation. Gains were maintained over the follow-up period.

In a comparative study without a control group, Stravynski, Lesage, Marcouiller, and Elie (1989) compared social skills training with group discussion plus homework in a crossover design for patients with *DSM-III* avoidant personality disorder. Although significant improvements on most measures were found in general, no differences between the treatment

modalities were found, questioning the centrality of skills acquisition as the mechanism of action of social skills training. Treatment, however, may have been too brief (five sessions of each modality) to detect an effect. More recently, Stravynski, Belisle, Marcouiller, and Lavallee (1994) examined whether a combination of office-based and in vivo (real-life interactions with people in shopping malls, a cafeteria, and so forth) enhanced the outcome of office-based social skills training for 28 patients with *DSM-III* avoidant personality disorder. Outcomes were generally equal in the two conditions, although the in vivo condition had a greater attrition rate.

Because avoidant personality disorder appeared to be equally responsive to different kinds of behavioral treatments, Alden and Capreol (1993) examined the hypothesis that different kinds of interpersonal problems would moderate treatment response to various therapies. To test this hypothesis, data from the Alden (1989) project described above were used. Several findings emerged. Avoidant personality disorder patients who had greater problems related to distrustful and angry behavior benefited more from structured exercises that required them to approach and talk to others (graded exposure). Patients with problems resisting others' demands benefited from both graded exposure and social skills training but were particularly responsive to intimacy-focused social skills training. The results suggest that a comprehensive assessment of interpersonal problems may be important in planning what type of treatment intervention is most likely to be beneficial to patients with avoidant personality disorder.

In a quantitative case study, Coon (1994) has reported on the successful treatment of avoidant personality disorder using a schema-focused cognitive therapy. Positive outcomes were evidenced not only at termination but also at the 1-year follow-up. Similarly, a quantitative case study of a 5-year psychoanalysis for avoidant personality disorder showed clinically significant reductions in symptom severity and relational pathology at termination, with gains maintained at the 1-year follow-up (Porcerelli et al., 2007).

In an uncontrolled pilot (type 3) study of 52 weeks of supportive-expressive dynamic therapy, Barber, Morse, Krakauer, Chittams, and Crits-Christoph (1997) showed that, by the end of treatment (up to 52 sessions), 61% of carefully diagnosed avoidant personality disorder patients had lost their avoidant personality disorder diagnosis.

OBSESSIVE-COMPULSIVE PERSONALITY DISORDER

Barber and colleagues (1997) conducted an open trial of supportive-expressive dynamic therapy for obsessive-compulsive personality disorder (type 3 study). Obsessive-compulsive personality disorder patients lost their personality disorder diagnoses significantly faster than did avoidant personality disorder patients. By the end of treatment, 39% of avoidant personality disorder patients retained their diagnosis, whereas only 15% of obsessive-compulsive personality disorder patients (1 out of 13) did so. Most obsessive-compulsive personality disorder patients lost their diagnoses within the first 17 sessions of treatment. Both avoidant personality disorder and obsessive-compulsive personality disorder patients improved significantly across time on measures of personality disorders, depression, anxiety, general functioning, and interpersonal problems.

BORDERLINE PERSONALITY DISORDER

The most widely investigated treatment for any personality disorder has been DBT for BPD. DBT is actually a complex treatment modality that is more accurately described as eclectic rather than a traditional behavior therapy per se. The treatment consists of weekly group and individual sessions for a year. The group component includes psychoeducation, teaching interpersonal skills, distress tolerance/reality acceptance, and emotion regulation skills. The individual therapy sessions involve directive, problem-solving techniques, as well as supportive techniques such as empathy and acceptance. Behavioral goals serve as the focus of the individual sessions and are addressed in a sequential order, but previous goals are readdressed if the problem returns. These goals include decreasing suicidal behaviors, decreasing therapy-interfering behaviors, decreasing behaviors that interfere with quality of life, increasing behavioral skills, decreasing behaviors related to posttraumatic stress, increasing respect for self, and achieving individual goals. More details about DBT can be found in the published treatment manual (Linehan, 1993).

A recent Cochrane review (Stoffers et al., 2012) provides a systematic, meta-analytic overview of the literature on psychosocial treatments for BPD. This meta-analysis summarized all available

randomized studies involving samples of patients with BPD that compared a specific psychotherapeutic intervention against a control intervention or against a comparative specific psychotherapeutic intervention. Twenty-eight studies involving a total of 1,804 participants with BPD were included in the review. Calculation of effect sizes averaging over studies could only be done for comparison of DBT to treatment as usual. These included studies by Carter and colleagues (2010), Koons and colleagues (2001), Linehan, Hubert, Suarez, Douglas, and Heard (1991), Linehan and colleagues (2006), and Verheul and colleagues (2003). There were statistically significant effects indicating a beneficial effect of DBT over treatment as usual for improvements in anger (n = 46, two RCTs), parasuicidality (n = 110, three RCTs) and mental health (n = 74, two RCTs). All of these effects were moderate to large in size. However, there was no evidence of superiority of DBT over treatment as usual in terms of keeping participants in treatment (n = 252, five RCTs). All remaining findings reported in the review by Stoffers and colleagues (2012) were based solely on single studies; all of these single studies are reviewed in the following paragraphs.

Whether DBT is uniquely effective for BPD or for suicidal BPD has not been well established. Using opiate-dependent patients with comorbid BPD who were being treated with concurrent opiate agonist therapy, Linehan and colleagues (2002) compared DBT to another psychotherapy treatment (comprehensive validation therapy with 12-step) that consisted of the nonspecific elements of DBT (therapeutic warmth, responsiveness, and empathy) in combination with participation in 12-step programs. On most outcomes, there were no significant differences between the treatment groups, although the sample size was limited (type 2 study). In addition, results of a large RCT (type 1) indicate that, in the treatment of BPD, outcomes for DBT were no better than those for transference-focused psychotherapy or supportive psychotherapy (Clarkin et al., 2007). Another large RCT (type 1) found that DBT and general psychiatric management were not significantly different in the treatment of BPD (McMain et al., 2009). However, a small, randomized (but otherwise naturalistic) study (type 2) found that DBT (n = 12) was superior to client-centered therapy (n = 12) at 12 months on most outcome measures (Turner, 2000).

Nonrandomized (type 3) studies of DBT with special populations have also been reported. In an adaptation of DBT for suicidal adolescents with borderline personality features, DBT was found to yield better treatment retention and fewer hospitalizations than a nonrandomized treatment-as-usual control group (Rathus & Miller, 2002). In another nonrandomized comparison, Evershed and colleagues (2003) reported that DBT was superior to treatment as usual for male forensic patients with BPD in a high-security hospital, especially in reducing the seriousness of violence-related incidents and self-report of anger. Uncontrolled studies reporting favorable outcomes for DBT adapted for patients with eating disorders and BPD (Palmer et al., 2003) and posttraumatic stress disorder and BPD (Lanius & Tuhan, 2003) have also been published.

An intensive (3-week) version of DBT has also been evaluated as crisis intervention for outpatients with BPD. The intensive program appeared to retain patients well and reduced symptoms of depression and hopelessness (McQuillan et al., 2005).

Psychodynamic therapy in various forms has been evaluated in multiple RCTs as a treatment of BPD. In one early study (Stevenson & Meares, 1992; type 3 study), the treatment was, broadly speaking, based on self-psychology. Therapy had a maturational goal accomplished through helping the patient discover and elaborate his or her inner life, with empathy and attention to disruptions in empathy central aspects of the process of therapy (Meares, 1987). Thirty patients with *DSM-III* BPD were treated with twice-per-week therapy for 1 year. Outcome was assessed 1 year after termination of treatment. Substantial reductions in violent behavior, drug use, medical visits, episodes of self-harm, time away from work, and symptoms were found. Thirty percent of patients no longer met criteria for BPD. Improvement was maintained at 1- and 5-year follow-ups, with substantial saving in health care costs (Stevenson & Meares, 1999; Stevenson, Meares, & D'Angelo, 2005).

Munroe-Blum and Marziali (1995) compared open-ended individual psychodynamic therapy with a manualized interpersonal group therapy for 110 patients with BPD (type 1 study). The group treatment lasted 30 sessions. No differences between the groups at 1 year (termination) or 2 years were found, although patients in general benefited from both treatments.

Bateman and Fonagy (1999) reported on the treatment of BPD patients randomized to partial hospitalization (n = 19) or to standard care (n = 19; type 2 study). The partial hospitalization treatment included individual and group psychoanalytic psychotherapy (not standardized) for a maximum of 18 months. In this program, the therapies and informal patient–staff contact were guided by a psychoanalytic model of BPD as a disorder of attachment, separation tolerance, and mentalization (this refers to the capacity to think about oneself in relation to others and to understand others' state of mind). The standard care control condition consisted of regular psychiatric review with a senior psychiatrist and inpatient admission as appropriate with discharge to non-psychoanalytic psychiatric partial hospitalization focusing on problem solving, followed by outpatient and community follow-up (without formal psychotherapy). Results indicated that patients in the partial hospitalization group improved significantly more than controls in terms of decreased number of suicidal attempts, acts of self-harm, psychiatric symptoms, and inpatient days, and better social and interpersonal functioning at 6 months and 18 months (Bateman & Fonagy, 1999, 2001). In a subsequent trial (Bateman & Fonagy, 2009) (type 1), the mentalization treatment was manualized and delivered on an outpatient basis. Patients with BPD were randomized to the mentalization-based psychodynamic therapy (n = 71) or structured clinical management (n = 63) and treated for 18 months. The investigators found that patients assigned to mentalization-based psychodynamic therapy, compared to structured clinical management, showed a steeper decline of both self-reported and clinically significant problems, including suicide attempts and hospitalization.

A manualized form of dynamic therapy, transference-focused therapy (Kernberg, Selzer, Koenigsberg, Carr, & Appelbaum, 1989), has also been investigated as a treatment for BPD in several studies. An uncontrolled study of 23 female patients with BPD treated with a year of transference-focused psychotherapy demonstrated improvements in the severity of self-injurious behavior, fewer hospitalizations, and fewer suicide attempts in the year following treatment compared with the year prior to therapy (Clarkin et al., 2001). In another uncontrolled study of 19 patients with BPD evaluated after 48 sessions of transference-focused psychotherapy, positive changes in impulsivity and affective instability were observed (Lopez, Cuevas, Gómez, & Mendoza, 2004). As mentioned, results of a large, randomized (type 1) clinical trial indicate that, in the treatment of BPD, transference-focused therapy yielded improvements in symptoms and functioning equivalent to DBT and supportive psychotherapy (Clarkin et al., 2007). However, on psychodynamic measures of attachment patterns and reflective functioning, transference-focused therapy was superior to DBT and supportive therapy (Levy et al., 2006). In another RCT, Doering and colleagues (2010) found that transference-focused psychotherapy (n = 52) was superior to treatment by experienced community psychotherapists (n = 52) in the treatment of BPD (type 1).

The type 1 study by McMain and colleagues (2009), described in the previous section on DBT, also involved a psychodynamic therapy condition. Although this treatment condition was referred to in the article as general psychiatric management, it consisted of a psychodynamic therapy combined with symptom-targeted medication. There was no significant difference between the DBT and general psychiatric management conditions in the number of medications used per patient in the trial. As mentioned, the psychodynamic group achieved equal outcomes to DBT on all outcome measures.

In a small (n = 5) uncontrolled study, brief cognitive analytic therapy (an integration of cognitive theory and some facets of psychodynamic therapy) was found to result in improvements in the severity of BPD (Wildgoose, Clarke, & Waller, 2001). A larger RCT (type 1), however, found no difference at 24 months between 24 sessions of cognitive analytic therapy (n = 41) and manualized good clinical care (n = 37) in the treatment of adolescents who fulfilled two to nine of the *DSM-IV* criteria for BPD (Chanen et al., 2008). A final small, pilot/feasibility study (type 3) found that a manual-based psychodynamic therapy (n = 15) appeared promising (relative to treatment as usual, n = 15) as a treatment for patients with BPD and co-occurring alcohol use disorder (Gregory et al., 2008).

Cognitive therapy has also been adapted to the treatment of BPD (Layden, Newman, Freeman, & Byers Morse, 1993). Results from an open trial (single treatment group; type 3 study) investigating cognitive therapy for BPD (n = 32) (Brown, Newman, Charlesworth, Crits-Christoph, & Beck, 2004) indicated that clinically important decreases in

suicidal ideation, depressive symptoms, and number of borderline symptoms were evident at termination (1 year) and at the 18-month follow-up assessment. More compelling evidence has been reported in a randomized study (type 2) conducted in France that compared cognitive therapy (n = 33) to Rogerian supportive therapy (n = 32). One year of cognitive therapy was found to retain patients in therapy longer, to have earlier positive effects on hopelessness and impulsivity, and to demonstrate better long-term outcomes on global measures of improvement (Cottraux et al., 2009). However, another RCT (type 1) reported mixed results, with no difference over 2 years between cognitive therapy (n = 54) and treatment as usual (n = 52) in terms of a composite outcome that combined suicidal acts, inpatient hospitalizations, and accident/emergency contact (Davidson et al., 2006). A significant advantage for cognitive therapy was evident in regard to reductions in suicidal acts.

Young (1994) has developed a version of cognitive therapy ("schema therapy") that integrates a focus on maladaptive beliefs or schemas with experiential techniques. A case series of six patients showed that the approach has some promise in the treatment of BPD (Nordahl & Nysæter, 2005). In addition, a randomized (type 1) study of patients with BPD found that schema therapy (n = 44) was superior to transference-focused psychotherapy (n = 42) on measures of quality of life and retention in treatment (Giesen-Bloo et al., 2006), although questions about the adequacy of the implementation of the transference-focused therapy in this trial have been raised (the investigators had an allegiance with schema therapy), which may have led to a high attrition rate (Yeomans, 2007). An additional small study (type 2) found that schema-focused therapy (n = 16) was superior to treatment as usual (n = 16), with 94% of those who received schema-focused therapy, compared to 16% of those in treatment as usual, no longer meeting criteria for BPD at the end of treatment (Farrell, Shaw, & Webber, 2009).

A cognitive-behavioral–based treatment program (Systems Training for Emotional Predictability and Problem Solving [STEPPS]) that combines cognitive-behavioral techniques and skills training with a systems component has been described (Blum, Pfohl, St. John, Monahan, & Black, 2002). The systems component includes the involvement of other patients with BPD (in 20 weekly 2-hour group meetings), as well as other people in the patient's support system (e.g., family members, significant others, health care professionals). An uncontrolled study (type 3) found that this treatment program was effective at reducing negative behaviors and affect and BPD symptoms (Blum et al., 2002). A subsequent RCT (type 1) found that STEPPS plus treatment as usual (n = 93) was superior to treatment as usual alone (n = 72) in regard to reductions in borderline symptoms, impulsivity, negative affectivity, mood, and global functioning, but there were no differences between the groups on suicide attempts, self-harm acts, or hospitalizations (Blum et al., 2008). A modified version of STEPPS was tested for adolescents with BPD traits in an RCT (Schuppert et al., 2012) (type 2). This modified version (emotion regulation training) used the structure of STEPPS, combined with elements of DBT skills training and CBT, in a 17-week group format. No outcome differences between emotion regulation training plus treatment as usual (n = 54) in comparison to treatment as usual (n = 55) were found in this trial.

ANTISOCIAL PERSONALITY DISORDER

A recent Cochrane review (Gibbon et al., 2010) has summarized the available evidence for the efficacy of different psychosocial treatments for antisocial personality disorder based on five RCTs. The review concluded that there is insufficient trial evidence to justify using any psychological intervention for adults with antisocial personality disorder. For three of the studies in the meta-analysis, the participants with antisocial personality disorder were a subgroup of the total sample; for two studies, all participants met criteria for antisocial personality disorder. These two studies are described below.

Davidson and colleagues (2009) reported on the results of a study comparing CBT plus treatment as usual to treatment as usual alone for violent men with antisocial personality disorder. The results indicated that CBT did not improve outcomes more than treatment as usual. However, this was a small (n = 52) exploratory study (type 2).

The second study (type 1) recruited a sample of individuals with antisocial personality disorder and opioid dependence and compared a contingency management intervention to treatment as usual (methadone treatment) (Neufeld et al., 2008). The contingency management group (n = 51) had

significantly better attendance and reduced family/social problems compared to the treatment-as-usual group (n = 49), but no differences were found on other outcome measures.

OTHER PERSONALITY DISORDERS

No controlled treatment outcome studies have yet been performed for histrionic, dependent, schizotypal, schizoid, narcissistic, passive-aggressive, or paranoid personality disorder. A case study with quantitative outcome data has been published showing positive effects of cognitive therapy for a paranoid personality disorder patient (Williams, 1988). Another quantitative case study reported that functional analytic therapy produced positive outcomes in a patient with histrionic and narcissistic personality disorder diagnoses (Callaghan, Summers, & Weidman, 2003).

MIXED PERSONALITY DISORDER SAMPLES

There have been several controlled studies using a sample of mixed personality disorders. Winston and colleagues (1991, 1994) randomized 81 patients with personality disorders to two forms of brief dynamic therapy, one more cognitively oriented (brief adaptive therapy) and one more oriented toward confronting defenses and eliciting affect (modeled after Davanloo, 1980), and to a waitlist control condition. The sample consisted mostly of cluster B and C personality disorder types, as well as patients diagnosed with a personality disorder not otherwise specified (mostly with cluster C features). However, paranoid, schizoid, schizotypal, narcissistic, and borderline personality disorders were excluded. Treatment lasted on average 40 weeks, although the waitlist was on average only 15 weeks. Because of this confound of treatment condition with time, this study is classified as a type 2 study. The results showed that both forms of brief dynamic therapy produced substantial improvements across multiple outcome measures, including general psychiatric symptoms, social adjustment, and target complaints. At follow-up assessments, obtained at 1.5 years on average after the end of therapy, the gains in improvement were maintained on target complaints (the only outcome measured).

In another study by the same group, Hellerstein and colleagues (1998) described the results of a study involving mixed personality disorder patients who received 40 sessions of supportive therapy (n = 24) or short-term dynamic psychotherapy (n = 25). Thirty-five percent of the patients dropped out from treatment. There were no differences between the treatment modalities at midphase (week 20), termination, or the 6-month follow-up. However, within-group effect sizes (intake to termination) were large on all outcome measures.

An RCT (type 1) compared the efficacy of 40 sessions of supportive-expressive psychoanalytic psychotherapy (n = 80) with that of community-delivered psychodynamic therapy (n = 76) for patients diagnosed with any *DSM-IV* personality disorder (Vinnars et al., 2005). In both treatment conditions, the global level of functioning improved, and there were decreases in the prevalence of patients fulfilling criteria for a personality disorder diagnosis, personality disorder severity, and psychiatric symptoms. There were no outcome differences between the two treatments. During the 1-year follow-up, patients who received supportive-expressive psychotherapy made significantly fewer visits to the community mental health centers than the patients who received community-delivered psychodynamic therapy.

Hardy and colleagues (1995) reported on the 27 cluster C personality disorder patients out of the 114 depressed patients included in the Sheffield 2 study (Shapiro et al., 1994). Clusters A and B were not assessed in that study. In this type 2 study, white-collar, employed patients received either 8 or 16 sessions of either cognitive or psychodynamic psychotherapy. At the end of treatment, cluster C personality disorder patients continued to display significantly more severe symptoms than non–cluster C personality disorder patients if they had received dynamic therapy, but not if they had received cognitive therapy. Karterud and colleagues (1992) presented the results of the effectiveness of day hospital community treatment for decompensated personality disorder patients. In this type 3 study, 97 patients were prospectively followed; 74 had a personality disorder diagnosis (34 BPD, 13 schizotypal personality disorder, and 27 other personality disorder [two thirds of which were cluster C]). All but the schizotypal personality disorder patients improved significantly on the SCL-90 and Health Sickness Rating Scale at discharge (mean stay was 171 days [standard deviation of 109]).

Monsen, Odland, Faugli, Daae, and Eilertsen (1995) reported on the results of treating 25 patients

(23 of whom had a diagnosis of a personality disorder) with psychodynamic therapy based on object relations theory and self-psychology. Treatment lasted on average a little bit more than 2 years. Patients were assessed at termination and again 5 years after termination. At the end of treatment, substantial change was found on measures of symptoms, affect consciousness, and defenses. In addition, 75% of the patients who had an Axis I disorder at intake no longer qualified for an Axis I disorder at termination. Seventy-two percent of the patients with Axis II disorders no longer qualified for the disorder at termination. The gains were maintained at the 5-year follow-up.

Høglend (1993) compared 15 patients with personality disorders in comparison to 30 patients without personality disorders (type 2 study). The treatment was psychodynamic therapy of brief to moderate length (9 to 53 sessions) that was based on the approaches of Sifneos (1979) and Malan (1976). At termination, the personality disorder patients evidenced less change than the patients without personality disorder, but at the 4-year follow-up there was no difference. For the personality disorder patients, the number of treatment sessions was significantly related to the acquisition of insight and dynamic change at follow-up. Thus, length of treatment appeared to be a crucial factor in producing positive outcomes for the personality disorder patients (but not the patients without personality disorder).

In a nonrandomized (type 2) comparison using a mixed personality disorder sample, Chiesa and Fonagy (2000) compared the effectiveness of a residential treatment based on a combination of a sociotherapeutic intervention (e.g., daily unit meetings, community meetings, structured activities, co-responsibility planning of the running of the therapeutic community, dance therapy) and formal psychoanalytical psychotherapy (individual and in small groups) to a step-down program that consisted of a short-term residential stay followed by outpatient group psychoanalytic psychotherapy. At 1 year, and continuing through a 3-year follow-up, the stepped-care model was significantly more effective than the pure inpatient model (Chiesa & Fonagy, 2000). In another nonrandomized (type 2) study of mixed personality disorders, the step-down program was compared again with a long-term residential program and with general community psychiatric care (medications, supportive outpatient therapy, hospitalization as needed; Chiesa, Fonagy, Holmes, & Drahorad, 2004). The results again favored the stepped-down approach. Similarly, a program model of outpatient group psychodynamic therapy following a brief period of more intensive treatment (day treatment) was also supported by an uncontrolled (type 3) study in Norway (Wilberg et al., 2003). The treatment program in these studies, however, was not standardized, so the exact nature of the programs is unclear. Abbass, Sheldon, Gyra, and Kalpin (2008) conducted an RCT (type 2) comparing short-term dynamic therapy (Davanloo [1980] approach) ($n = 14$) to a minimal-contact, delayed treatment control group ($n = 13$) for *DSM-IV* personality disorders. Results indicated that patients treated with short-term dynamic therapy improved significantly more than controls on all primary outcome measures.

The most recent study (type 1) of mixed personality disorders compared 24 sessions of cognitive analytic therapy ($n = 38$) to treatment as usual ($n = 40$) (Clarke, Thomas, & James, 2013). The sample consisted of a range of cluster A, B, and C personality disorder diagnoses: 88% of the sample had two or more personality disorders, and 53% displayed diagnoses across two clusters and 28% across all three clusters. BPD was diagnosed in 68% of participants. However, patients who engaged in self-harming at least monthly were excluded from the trial. The results indicated that cognitive analytic therapy was more effective than treatment as usual: Participants receiving cognitive analytic therapy showed reduced symptoms and experienced substantial benefits compared with the treatment-as-usual controls, who showed signs of deterioration over the treatment period.

PERSONALITY DISORDERS AS MODERATORS OF TREATMENT OF OTHER PSYCHIATRIC DISORDERS

Reich (2003), Reich and Vasile (1993), and Reich and Green (1991) have reviewed studies of the relation of personality traits and personality disorders to the outcome of treatments (both psychosocial and psychopharmacological) for other psychiatric conditions. Examination of the studies in these reviews, plus some more recent studies that investigate specific personality disorders and specific psychosocial treatments, reveals the following findings:

- Antisocial personality disorder (without a co-occurring diagnosis of depression) predicted

poor outcome from cognitive therapy and psychodynamic therapy for opiate addiction (Woody, McLellan, Luborsky, & O'Brien, 1985).

- Avoidant personality disorder was associated with relatively poorer outcome for agoraphobia from exposure therapy (Chambless, Renneberg, Goldstein, & Gracely, 1992) or from exposure therapy and additional anxiety management and group and individual therapy (Chambless, Renneberg, Gracely, Goldstein, & Fydich, 2000).
- Schizotypal personality disorder was associated with poor outcome of behavior therapy for obsessive-compulsive disorder (Minichiello, Baer, & Jenike, 1987).
- Presence of a personality disorder predicted poor outcome of cognitive-behavioral group therapy for social anxiety (Turner, 1987) and panic disorders (Mennin & Heimberg, 2000).
- Patients with personality disorders show slower response to imipramine plus interpersonal psychotherapy for recurrent unipolar depression (Frank, Kupfer, Jacob, & Jarrett, 1987).
- Patients with a diagnosis in the anxious cluster of personality disorders evidenced much poorer outcome with imipramine plus interpersonal therapy for recurrent unipolar depression (Pilkonis & Frank, 1988).
- A comorbid personality disorder was associated with higher rates of recurrence of depressive episodes and shorter time to recurrence over 2 years of maintenance interpersonal psychotherapy for patients with recurrent depression who were initially treated to remission (Cyranowski et al., 2004).
- Patients with BPD have relatively poorer outcomes, and incur higher treatment costs, following brief cognitive therapy for recurrent self-harm, than those without this diagnosis (Tyrer et al., 2004).
- Combined medication plus psychotherapy (brief psychodynamic therapy) is more effective than medication alone for depressed patients with comorbid personality disorders, but not more effective for those without personality disorders (Kool, Dekker, Duijsens, de Jonghe, & Puite, 2003).
- The number of personality disorders rather than presence or absence of any personality disorder was predictive of the outcomes of brief interpretive and brief supportive psychotherapies (Ogrodniczuk et al., 2001).

In group therapy, the presence of a patient with BPD may be detrimental to treatment outcome for other patients. Cloitre and Koenen (2001) found that, in interpersonally oriented group therapy for women with posttraumatic stress disorder, groups that had at least one member with BPD showed less change than did groups that did not have any members with BPD.

Presence of a personality disorder, however, does not always lead to poor outcomes. Presence of a personality disorder did not predict outcome of behavioral treatment of panic disorder in one study (Ramnero & Ost, 2004), but it did predict relapse following behavioral treatment in another (Fava et al., 2001). Presence of a personality disorder also did not have an impact on outcome (prevalence of posttraumatic stress disorder) among women with chronic posttraumatic stress disorder who received prolonged exposure therapy (Hembree, Cahill, & Foa, 2004). In long-term group psychoanalytic therapy, presence of a personality disorder was not related to outcome (Lorentzen & Høglend, 2004). Kuyken, Kurzer, DeRubeis, Beck, and Brown (2001) reported that it was not personality disorder status per se but rather the presence of maladaptive and paranoid beliefs that predicted the outcome of cognitive therapy for depression.

In some studies, patients with selected personality disorders fared better in certain types of treatments. For example, Longabaugh and colleagues (1994) investigated the extent to which antisocial personality disorder moderated the treatment of alcohol abuse. Thirty-one alcohol-abusing patients with antisocial personality disorder were compared with 118 alcohol abusers without antisocial personality disorder randomly assigned either to a group extended cognitive-behavioral treatment (which included stimulus control, rearranging consequences, restructuring cognitions, assertion training, problem solving for alternatives to drinking, and dealing with slips/relapses) or to relationship-enhanced CBT (involving functional analysis, enhancing reinforcements in relationships with partners, using partners' relationship to reinforce abstinence, and educational/didactic sessions for partners). A significant interaction was found for antisocial personality disorder by treatment modality for the average number of drinks consumed on a drinking day, with patients with antisocial personality

disorder in the extended cognitive-behavioral treatment having the fewest drinks (about two on a drinking day) and patients with antisocial personality disorder in the relationship enhancement condition having the most (about eight). The patients without antisocial personality disorder had an intermediate level of drinking on a drinking day in both treatment conditions. This interaction, however, was not found for percent of days abstinent. At the 13- to 18-month follow-up, a main effect for antisocial personality disorder emerged, with antisocial personality disorder patients showing more days abstinent than those without antisocial personality disorder.

Rosenblum and colleagues (2005) also found an interaction of antisocial personality disorder and treatment type. In this study, substance-abusing patients with antisocial personality disorder had relatively better outcomes in group cognitive-behavioral therapy than in group motivational therapy. Similarly, Messina, Farabee, and Rawson (2003) found that cocaine-dependent patients with antisocial personality disorder were more likely to be abstinent following treatment, particularly contingency management, than those without antisocial personality disorder.

A moderating (interaction) effect of cluster C personality disorders was found by Milrod and colleagues (2007). In this study, patients with panic disorder and co-occurring cluster C personality disorder improved more in psychodynamic therapy compared to applied relaxation, while this between-group effect was less for those without a cluster C personality disorder diagnosis.

Barber and Muenz (1996) reported that features of two personality disorders, avoidant and obsessive-compulsive, interacted with type of psychotherapy in the treatment of depression. Using data from the Treatment of Depression Collaborative Study (Elkin et al., 1989), Barber and Muenz (1996) found that interpersonal psychotherapy produced better outcomes for depressed patients with features of obsessive-compulsive personality disorder, but cognitive therapy produced better outcomes for depressed patients with features of avoidant personality disorder (type 2 study).

In the treatment of public speaking anxiety among patients with social phobia, the presence of avoidant personality disorder did not predict outcome (i.e., treatment was equally successful in those with and without avoidant personality disorder) in one study (Hofmann, Newman, Becker, Taylor, & Roth, 1995). There may be ways in which standard treatment can be enhanced or improved to more effectively treat those with a (non-personality disorder) psychiatric disorder who have a comorbid personality disorder. For example, a case study by Walker, Freeman, and Christensen (1994) used restricted environmental stimulation to successfully enhance the exposure treatment of obsessive-compulsive disorder in a patient with schizotypal personality disorder. Although this treatment focused on the obsessive-compulsive disorder and not the schizotypal personality disorder per se, restricted environmental stimulation therapy was incorporated because of the attentional problems found with patients with schizotypal personality. Thus, this treatment may have other applications for schizotypal personality disorder as a means of increasing attentional focus.

SUMMARY OF RECOMMENDATIONS BASED ON TREATMENT OUTCOME LITERATURE

It is obvious that the systematic study of treatment efficacy with personality disorders remains in its infancy. With few type 1 studies published yet for all personality disorders with the exception of BPD, it is difficult to make recommendations with a high degree of confidence. Linehan's DBT is the most well-established treatment, with several RCTs documenting its efficacy. However, recent studies appear to question whether DBT is uniquely efficacious, in that other credible psychotherapies have yielded similar results. There is also evidence that psychodynamically oriented treatment is effective for BPD. Other promising treatments for BPD include adaptations of cognitive therapy and schema-focused therapy. Behavior therapy is promising in the treatment of avoidant personality disorder, but the specific form of behavior therapy may need to be tailored to patients' types of interpersonal problems, with graded exposure better when distrust is an issue and intimacy-focused social skills training preferable when resisting others' demands is the major interpersonal problem in patients with avoidant personality disorder. Psychodynamic therapy, particularly longer term and involving stepped-down care beginning with residential care and then moving to outpatient treatment, appears useful for the treatment of mixed personality disorders, as does cognitive analytic therapy. One clear recommendation can be made based on a consistent finding across many

studies: Standard brief treatments for psychiatric disorders other than personality disorders often fail when personality disorder pathology is also present, and therefore the clinician should be alert to the presence of a comorbid personality disorder and reevaluate the selection of treatment modality if progress is not made within the period of brief therapy. Consistent with this recommendation are the results of Kopta, Howard, Lowry, and Beutler (1994), who found that characterological symptoms that are typical of personality disorders improve slowly, with only 59% of outpatients achieving clinically significant change on such symptoms after 52 treatment sessions.

FUTURE DIRECTIONS IN THE TREATMENT OF PERSONALITY DISORDERS

The studies reviewed above begin to point to some promising developments in the treatment of personality disorders. First, we can predict that there will likely need to be modification of the existing treatments of common psychiatric disorders to take into account personality disorder pathology. These modifications should include the lengthening of brief treatments and greater attention to the longstanding rigid belief systems and maladaptive interpersonal patterns of personality disorder patients, rather than a focus only on symptoms or recent triggers. A second major direction will be the matching of patients to treatment modalities. This matching may occur at the level of the personality disorder syndrome, in view of Barber and Muenz's (1996) finding that depressed patients with features of avoidant personality disorder do better in cognitive therapy but depressed patients with features of obsessive-compulsive personality disorders fare better in interpersonal therapy. These authors have shown that using these two diagnostic categories (either dimensionally or categorically) could be helpful in matching patients to either cognitive or interpersonal psychotherapy. Alternatively, matching patients to treatment according to patient attributes that either underlie the distinctions between personality disorders or are other salient patient variables not captured in the current system may also take place. For example, Beutler, Mohr, Grawe, and Engle (1991) suggest that impulsivity/external coping style and resistance/reactance are two important dimensions for which there is preliminary evidence for the matching of patients to treatments. Thus, rather than using the diagnosis of antisocial personality disorder as a basis for recommending a more structured treatment modality, the underlying dimensions of impulsivity and low socialization that characterize but do not uniquely define antisocial personality disorder might be more salient for treatment selection. The hybrid dimensional system included in Section III of *DSM*-5 might be a useful starting point for such matching studies.

Another direction for the future is the movement toward psychotherapy integration. In fact, Linehan's DBT already integrates techniques from a wide variety of approaches. With personality disorders, such integration might be especially important because of the diverse set of problems that characterize these patients. Thus, a successful treatment might need elements of exposure therapy, understanding and modification of longstanding cognitive/interpersonal patterns, practice in new behaviors, and attention to disruptions in the therapeutic relationship (transference). Psychosocial and psychopharmacological interventions will also be examined in combination for personality disorders as a way of managing the symptoms while also treating the underlying psychological processes. Significant advances in the treatment of personality disorders can be expected to have important public health impacts, given the prevalence of these disorders and the impairment in social and occupational functioning associated with them.

Psychopharmacological Treatment of Personality Disorders

M. Mercedes Perez-Rodriguez
Larry J. Siever

Despite the lack of approval by the U.S. Food & Drug Administration (FDA), drugs are used widely to treat personality disorders, particularly borderline personality disorder (BPD), based on their effects known from clinical trials in other psychiatric disorders (off-label use). The role of medications in personality disorders is limited to moderate effects on some but not all of the symptom domains, and there are no medications available that improve global severity of any personality disorder as a whole. In BPD, evidence is strongest for second-generation antipsychotics (SGAs) and mood stabilizers, while dietary supplements such as omega-3 fatty acids hold some promise. However, medications have limited effectiveness and are still viewed as adjunctive to other forms of treatment, particularly psychotherapy.

INTRODUCTION

Medications are increasingly used to treat personality disorders as a result of the increasing number and quality of clinical trials available and the growing knowledge base about the biological correlates of the personality disorders. However, compared to other psychiatric disorders, research into the psychopharmacology of personality disorders is still in its infancy. There are a limited number of clinical trials, often with small sample sizes, and the evidence for symptom improvement is modest at best.

Personality disorders are commonly divided into three clusters: cluster A ("odd") disorders, cluster B ("dramatic") disorders, and cluster C ("anxious") disorders. The most extensive studies of the pharmacotherapy of personality disorders have examined the cluster B disorders, particularly BPD, and schizotypal personality disorder (SPD) in cluster A. Several case reports of the treatment of cluster C avoidant personality disorder have also been reported. However, the evidence for other personality disorders is very limited.

The pharmacotherapy of personality disorders represents a relatively new frontier of psychopharmacology. Traditionally, personality-disordered patients have been treated with psychotherapy and have been thought unresponsive to pharmacological intervention. However, advances in the field over the past three decades have challenged that perspective. A biological approach to the personality disorders has questioned the traditional separation of Axis I and Axis II diagnoses, resulting in the elimination of the axis system in the latest version of the *DSM*, *DSM-5* (American Psychiatric Association, 2013).

Research into the neurobiological basis of psychiatric disorders increasingly focuses on dimensions within domains of psychopathology that cut across diagnoses, and on their underlying neural circuits and molecular and genetic modulators. The Research Domain Criteria initiative (RDoC; Insel et al., 2010) is an example of this approach, which converges with recent efforts to examine the neurobiology of personality disorder traits. Thus, there is an

emerging neurobiology of personality disorders based in the brain circuit abnormalities underlying dimensions such as affective dysregulation, disinhibited aggression, anxiety/avoidance, cognitive/perceptual dysregulation, and social detachment/isolation. The following is a summary of the neurobiology and psychopharmacology of the personality disorders, including specific challenges.

The main challenges in the systematic investigation of biological etiologies and treatments for personality disorders are (1) the existence of significant clinical heterogeneity even within one personality disorder diagnostic category; (2) the overlap in symptomatology and comorbidity among the various personality disorder diagnoses; (3) the high symptom overlap and comorbidity with Axis I and II disorders; and (4) the limited reliability in the diagnostic assessment of the personality disorders.

Clinical Heterogeneity and Overlap of Axis II Disorders

The polythetic definition of personality disorders—each diagnosis requires meeting a certain number of criteria out of a larger set of criteria (e.g., five out of nine criteria for BPD)—means that it is possible for two people to meet the criteria for a given personality disorder and yet have very different personality traits. This heterogeneity is a major problem in assessing the effect of a medication. For example, it is possible to have a clinically heterogeneous group of patients in a study even though all the patients meet criteria for the same personality disorder. Moreover, different personality disorders share some of the criteria under the *DSM-IV* and *DSM-5* categorization, and often patients meet criteria for more than one type of personality disorder (Grant et al., 2008; Lenzenweger, Lane, Loranger, & Kessler, 2007; Skodol et al., 2005).

Reliability of Assessment Tools

Methodological problems in designing studies of patients with personality disorders include limited reliability assessment and limited longitudinal stability of the diagnoses. For example, BPD seems to be less stable across time points than expected for personality disorders, with high rates of remission in follow-up studies (Skodol et al., 2005; Zanarini, Frankenburg, Hennen, Reich, & Silk, 2006); in fact, there is an inverse relationship between age and prevalence of BPD in the general population (Grant et al., 2008).

Assessment instruments are of limited efficacy due to modest test–retest and intratest reliability (Gitlin, 1993). These difficulties in assessment may be related to our limited understanding of how to differentiate a personality disorder trait from the adaptive personality traits.

Developing standardized measures of change in personality disorder symptoms poses a challenge given that many of these symptoms are "persistently transient" (e.g., mood lability in BPD). Long follow-up periods are preferred to delineate the natural course of episodic personality traits such as mood lability. However, symptoms such as unstable interpersonal relationships or suspiciousness may interfere with the maintenance of the treatment alliance until completion of the research study, leading to high dropout rates.

Because most of the personality disorder symptoms are context dependent and reactive to the environment, it is critical to keep all nonpharmacological variables (such as milieu of the research setting and interactions with the research team) consistent across subjects and time points for each study.

The Need for Multiple Approaches to Defining and Treating Personality Disorders

Skepticism about the categorical nature of personality disorders (Eaton et al., 2011; Widiger, Livesley, & Clark, 2009) has been fueled by the high comorbidity and symptom overlap among personality disorders and between personality disorders and other psychiatric diagnoses (i.e., *DSM-IV* Axis I diagnoses). As a result, alternate dimensional models have been proposed. Some of these dimensional models are based on the Five Factor Model (Costa & Widiger, 2002). Another model classifies dimensions based on their prominence in particular personality disorders and their presumed underlying neurobiology, conceptualizing the core dimensions of personality as cognitive/perceptual distortions (cluster A, "odd"), affective lability and impulsivity/aggression (cluster B, "dramatic"), and anxiety (cluster C, "anxious").

Evidence for these dimensional approaches is derived from studies of biological correlates of personality traits and family and twin studies supporting the heritability of dimensions (Torgersen et al., 2000;

Trestman, deVegvar, & Siever, 1995). Large-scale twin studies also support a dimensional model for personality disorders, including four factors: internalizing, externalizing, anhedonic/introversion, and cognitive/relational disturbance (Kendler et al., 2011; Roysamb et al., 2011); this model also questioned the division between Axis I and II in *DSM-IV*. For example, antisocial personality disorder was most closely related to Axis I substance abuse disorders, and dysthymia was most closely linked to avoidant and dependent personality disorders.

The controversy about which approach (categorical vs. dimensional) is more valid led to the proposal of a hybrid system including both approaches for *DSM-5* (Rationale for the Proposed Changes to the Personality Disorders Classification in DSM-5: http://www.dsm5.org/ProposedRevision/Pages/proposedrevision.aspx?rid=17#). The final approved version of *DSM-5* maintains the categorical model and criteria for the 10 *DSM-IV* personality disorders and includes the newly proposed trait-specific classification system in a separate area of Section III.

One challenge in targeting a particular personality dimension is that the neural substrate for a specific dimension may include abnormalities in more than one neurotransmitter system (Gurvits, Koenigsberg, & Siever, 2000). Moreover, treating one core dimension does not address the complex clinical syndrome of the personality disorder as a whole. Finally, in defining a core dimension in personality disorders, a distinction must be made between traits and state symptoms. Despite these limitations, the dimensional approach avoids the problems of clinical heterogeneity and high comorbidity and provides a framework for inquiry into the interrelationships among types of behavior, their modulation by neurotransmitters, and pharmacological interventions.

In summary, categorical and dimensional approaches can be used for investigating psychopharmacological treatments for personality disorders. A categorical approach allows a more clinical conceptualization of the personality disorders but may not allow us to measure change in response to medication in a meaningful way, given the high symptom overlap and comorbidity with other disorders, and an incomplete distinction between state symptoms versus traits. A dimensional approach allows for more precise measuring of individual traits but may not fully capture the complex entity of each personality disorder. Although each approach has recognized limitations, each can also offer valuable frameworks within which these disorders can be further investigated.

We now turn to a review of the pharmacological treatments of personality disorders and the psychobiological findings that prompted the use of such treatments.

CLUSTER A DISORDERS ("ODD" CLUSTER)

Schizotypal personality disorder (SPD) has been the most carefully studied of the cluster A disorders. SPD, part of the schizophrenia spectrum, is characterized by attenuated symptoms similar to those present in chronic schizophrenia. The SPD population offers a unique opportunity to investigate the neurobiology and pathophysiology of schizophrenia without the confounds of medication and more severe functional impairment (Siever et al., 2002a). SPD is more common among the relatives of schizophrenic patients in comparison to control patients (Silverman et al., 1993), and having at least one parent with SPD increased the risk to develop both SPD and schizophrenia among siblings of probands with schizophrenia (Baron, Gruen, & Asnis, 1985).

Many of the abnormalities in brain structure and function (Kirrane & Siever, 2000; Koenigsberg et al., 2005; Siever et al., 2002a) and psychophysiological measures (e.g., smooth pursuit eye movements, backward masking tests, and continuous performance tasks) described in schizophrenia are also found in SPD (Siever, 1991). These findings support the concept of a spectrum of schizophrenia-like disorders. Psychobiological investigations into SPD, based on a dimensional model of symptoms, have also supported the relationship between SPD and schizophrenia and provide a logical starting point for psychopharmacological interventions for this personality disorder.

The neurobiology of SPD may be conceptualized in relation to its core traits, which broadly stem from disturbances within the cognitive/perceptual domain. These cognitive/perceptual disturbances result in impairments in attention to the environment, discrimination among stimuli, and information processing. Clinically, these impairments may translate into psychotic-like symptoms (such as magical thinking, ideas of reference, or perceptual distortion), deficit-like symptoms (such as poor interpersonal relatedness or social detachment), and cognitive disorganization (such as deficient performance on

cognitive, psychophysiological, and attentional testing) (Siever & Weinstein, 2009).

Psychotic-Like Symptoms in Schizotypal Personality Disorder

Psychotic-like symptoms are characteristic of SPD. Higher symptom severity along a dimension of psychotic-like perceptual distortions has been correlated with higher measures of dopaminergic activity. For example, cerebrospinal fluid homovanillic acid (HVA; the major dopamine metabolite) concentrations in SPD patients correlate significantly with psychotic-like symptoms and were significantly higher than in patients with other personality disorders and healthy controls (Siever et al., 1991). These findings support the use of dopamine antagonists in the treatment of SPD. Given the known efficacy of antipsychotic medications in schizophrenia, their effect on psychotic-like symptoms in SPD has also been investigated (Table 28.1). However, the majority of these studies primarily targeted subjects with BPD and described secondary findings for patients who also met criteria for SPD. The single study of first-generation antipsychotics including only SPD patients (Hymowitz et al., 1986), using a single-blind design, did not find any improvement in psychotic-like symptoms after treatment with haloperidol. The three double-blind, placebo-controlled studies of mixed populations of SPD and BPD patients (Cowdry & Gardner, 1988; Goldberg et al., 1986; Soloff et al., 1989) show an association between low-dose antipsychotic use and broad improvements in symptom scales of psychoticism, anxiety, depression, hostility, and rejection sensitivity. However, one of those studies (Cowdry & Gardner, 1988) included patients with severe affective instability, questioning the generalizability of these findings to the more typically emotionally constricted SPD subjects. Other non–placebo-controlled studies (Jensen & Andersen, 1989; Serban & Siegel, 1984) found moderate, global improvements in mixed BPD and SPD populations after treatment with antipsychotic medication.

The second-generation antipsychotic (atypical) medications (SGAs) are promising candidates for the treatment of SPD because of their potential for targeting negative symptoms (Javitt, 1999; Lane, Liu, & Chang, 1999). One open-label study of the SGA olanzapine in the treatment of dysthymic borderline patients—most of whom also met criteria for SPD (Schulz et al., 1999)—found robust improvement over the 8-week treatment period in global scores from five rating scales (see Table 28.1). Our group (Koenigsberg et al., 2003) completed a 9-week placebo-controlled, double-blind study of low-dose risperidone in the treatment of nondepressed SPD patients, only 20% of whom had comorbid BPD. We found statistically significant decreases in Positive and Negative Syndrome Scale (PANSS) negative and general symptom scores by week 3 and PANSS positive score by week 7 in the risperidone group compared with the placebo-treated group. Thus, it appears that schizotypal symptomatology in mixed SPD/BPD populations is modestly and broadly responsive to low-dose antipsychotic medication.

Given the state of dopamine antagonism induced by antipsychotic medications and the correlations between increased plasma and cerebrospinal fluid dopaminergic metabolites and psychotic-like symptoms in SPD, it is tempting to hypothesize that psychotic-like symptoms in SPD would be particularly responsive to antipsychotic medications. Future double-blind, placebo-controlled trials with primarily SPD subjects are needed to refine the role for these medications in SPD.

The attenuated nature of psychotic symptoms in SPD patients—compared to those found in schizophrenia—is believed to be due to better buffering of subcortical dopaminergic activity (Siever & Davis, 2004; Siever & Weinstein, 2009). This hypothesis is supported by the results of functional and structural imaging and neuroendocrine challenge studies. This better buffering may result in lower responsiveness to stress by subcortical dopaminergic systems, which may protect against overt psychosis (Mitropoulou et al., 2004; Siever & Davis, 2004; Siever & Weinstein, 2009).

Despite this better buffering, dopaminergic agonism might be expected to worsen the psychotic-like symptoms of SPD. Consistent with this theory and supporting the inclusion of SPD in the psychotic spectrum disorders, a study in a small sample of SPD/BPD and BPD patients with high affect lability showed that, after amphetamine administration, SPD subjects had significantly higher Brief Psychiatric Rating Scale (BPRS) scores of thought disturbance and self-rated psychoticism compared with BPD subjects (Schulz, Cornlius, Schulz, & Soloff, 1988).

TABLE 28.1 Antipsychotic Studies: Borderline Personality Disorder and Schizotypal Personality Disorder

Study	*Diagnosis*	*Study Design*	*Comment*
Goldberg et al. (1986)	N = 50 BPD and/or SPD patients (BPD with at least one prior psychotic episode)	Type 1 study: thiothixene (average 8.6 mg), 12 weeks, double-blind, placebo-controlled	Thiothixene led to improvement of psychotic-like/obsessive/phobic anxiety symptoms; no effect on depression.
Cowdry & Gardner (1988)	N = 16, female BPD outpatients; all characterized as "seriously ill with severe dysphoria in setting of rejection, and dyscontrol behavior such as assaultiveness, cutting, overdose"; of these, 6 patients also SPD	Type 1 study: tranylcypromine, trifluoperazine, carbamazepine, alprazolam; 6 weeks; double-blind, placebo-controlled	Tranylcypromine led to improved global and mood scores, improved impulsivity, but no effect on behavioral dyscontrol; trifluoperazine showed a trend toward broad symptomatic improvement; carbamazepine showed improvement of impulsivity and behavioral dyscontrol; alprazolam led to increases in suicidality and dyscontrol.
Soloff et al. (1989)	N = 90 inpatients with BPD, mixed SPD/BPD symptoms, and a small number of SPD patients	Type 2 study: amitriptyline (100– 175 mg) or haloperidol (4–16 mg); 5 weeks; placebo-controlled	Haloperidol led to global improvements, including hostile depression and impulsive ward behavior, especially if patient had severe schizotypal symptoms, hostility, or suspiciousness. Amitriptyline not as effective as haloperidol for anxiety and hostility; not effective on core depressive symptoms.
Serban & Siegel (1984)	N = 52 outpatients with SPD (14), BPD with prior psychotic episode (16), mixed SPD/BPD (16)	Type 2 study: haloperidol or thiothixene (4–12 mg), 6 weeks to 3 months, double-blind	Thiothixene > haloperidol led to moderate to marked improvements in all patients for general symptoms, paranoid ideation, anxiety, ideas of reference, and depression regardless of diagnosis.
Hymowitz et al. (1986)	N = 17 SPD outpatients	Type 2 study: haloperidol (up to 12 mg, average 3.6 mg); 6 weeks; single-blind, 2-week placebo washout	Drug led to mild to moderate improvement in ideas of reference, social isolation, odd communication, and thought disorder; also GAS scores increased.
Jensen & Andersen (1989)	N = 5 SPD, 5 BPD inpatients	Type 3 study: amoxapine (up to 300 mg); 3 weeks minimum; open label, no placebo; oxazepam prn agitation (36–42 mg qd)	SPD subjects showed broad improvement in BPRS (schizophrenia subscale) and HDRS scores. BPD subjects showed no improvement.
Chengappa et al. (1999)	N = 7 inpatients with BPD, 6 with Axis I psychotic disorders	Type 3 study: clozapine; chart audit with mirror image design; mean dose 421 mg/day.	Decrease in number of seclusion and restraint incidents, modest improvement in GAF.

(*continued*)

TABLE 28.1 (continued)

Study	*Diagnosis*	*Study Design*	*Comment*
Schulz et al. (1999)	N = 11 community-based referrals meeting criteria for BPD and dysthymia (7 of whom also met SPD criteria)	Type 3 study: olanzapine (up to 10 mg, average 7.7 mg); open label no placebo; 8-week study.	Olanzapine led to improvement in global scores on BPRS, BDHI, BIS11, GAF, SCL-90.
Koenigsberg et al (2003)	N = 25 community and clinic referrals meeting criteria for SPD (only 20% also meet BPD criteria)	Type 1 study: risperidone (up to 2 mg) 9-week double-blind, placebo-control; 2-week placebo wash-out	Risperidone led to significantly lower PANSS negative and general score by week 3 and PANSS positive score by week 7.
Rocca et al. (2002)	N = 15 outpatients meeting criteria for BPD (4 were comorbid for antisocial personality disorder)	Type 3 study: risperidone (mean dose 3.3 mg/day); 8-week open-label no placebo trial	Significant improvement in BPRS total, hostility/suspicion, and anergia scales; HDRS; GAF; AQ
Zanarini & Frankenburg (2001)	N = 28 females meeting criteria for BPD recruited by advertisement (1 comorbid for SPD)	Type 1 study: olanzapine (mean dose 5.3 mg/day). 6-month randomized placebo-controlled double-blind	Olanzapine significantly superior to placebo in SCL-90 anger/ hostility, anxiety, paranoia, interpersonal sensitivity. Few dropouts.
Zanarini et al.(2004)	N = 45 females meeting criteria for BPD recruited by advertisement	Type 2 study: randomized double-blind non-placebo-controlled 8-week parallel comparison of olanzapine (3.3 mg), fluoxetine (15 mg), and olanzapine/fluoxetine combination (3 mg/13 mg)	Olanzapine/fluoxetine combination is more effective than fluoxetine in treating impulsivity-aggression and dysthymia. Olanzapine is more effective than olanzapine/ fluoxetine combination in treating dysthymia and equally effective in impulsivity aggression. Few dropouts.
Soler et al. (2005)	N = 60 clinically referred BPD patients	Type 2 study: 12-week randomized double-blind, placebo-controlled trial of olanzapine (8.8 mg/day). Both groups received DBT.	Olanzapine + DBT superior to DBT alone in impulsive-aggressive behaviors, emergency department visits, depression, anxiety, and CGI score.
Villeneuve & Lemelin (2005)	N = 34 BPD patients with GAF < 55	Type 3 study: 12-week open-label trial of quetiapine (mean dose = 251 mg)	Significant improvement in impulsivity, hostility, anxiety depression, GAF score, and for patients with psychotic symptom at baseline, micropsychotic symptoms.
Mobascher et al. (2006)	N = 3 female patients with BPD and psychotic symptoms	Case series open-label study of aripiprazole up to 25 mg/day + cognitive-behavioral therapy	Decreased psychotic symptoms, self-damaging and aggressive behavior in 1 case, partial response in 1 case
Pascual et al. (2006)	N = 2 patients with BPD and agitation in the emergency department	Case series naturalistic open-label study of either olanzapine 10 mg IM or ziprasidone 20 mg IM.	Significant improvement in agitation up to 6 hrs after injection vs. baseline (pretreatment)

TABLE 28.1 (continued)

Study	*Diagnosis*	*Study Design*	*Comment*
Bellino et al. (2006)	N = 14 outpatients with BPD	12-week open-label quetiapine up to 400 mg/day	Symptom improvement in HAM-A, BPRS, CGI, SOFAS, BPDSI, and BIS11
McClure et al. (2007)	N = 29 patients with SPD	Randomized, double-blind, 4 weeks of guanfacine (up to 2 mg/day) vs. placebo, followed by 4 weeks of open-label guanfacine	After 4 weeks, greater improvements from baseline in neuropsychological measures of working memory (Modified AX-Continuous Performance Task) compared to placebo
Perrella et al. (2007)	N = 29 outpatients with BPD	12-week open-label quetiapine (up to 800 mg/day)	Symptom improvement in HAM-D, BPRS Hostility and Suspiciousness, CGI, GAF, AQ
Shoja-Shafti (2006)	N = 20 female patients with BPD	8-week open-label olanzapine (10 mg/day)	Symptom reduction with olanzapine (BPRS, BDHI, GAF)
Damsaet al. (2007)	N = 25 unmedicated patients with BPD and severe agitation in the emergency department	1 or 2 doses of open-label olanzapine (10 mg IM)	Significant reductions of agitation 2 hours after the first IM olanzapine
Nickel et al. (2006)	N = 52 patients with BPD	Randomized, double-blind study of 8 weeks of aripiprazole (15 mg/day) vs. placebo	Symptom improvement on SCL-90-R, HAM-D, HAM-A, and STAXI. Improvement on SCL-90-R, HAM-D, HAM-A, and STAXI was also observed at an 18-month follow-up (Nickel et al., 2007).
Friedel et al. (2008)	N = 18 patients with BPD	Open-label study of 8 weeks of risperidone (up to 2 mg/day)	Symptom improvement on all BDRS dimensions (affective dysregulation, cognitive impairment, impulsivity and disturbed relationships) and BSI scales
Van den Eynde et al. (2008)	N = 41 patients with BPD	Open-label study of 12 weeks of quetiapine (up to 800 mg/day)	Improvement of depressive, impulsive, aggressive, and affect lability symptoms
Roepke et al. (2008)	N = 15 inpatients with BPD, histrionic or narcissistic personality disorder	Open-label quetiapine (400 mg/day) for 8 weeks	Improvement of depressive symptoms but no effect on impulsivity
Bellino et al. (2008)	N = 21 outpatients with BPD who did not respond to sertraline (100–200 mg/day) for 12 weeks	Open-label adjunctive aripiprazole (10–15 mg/day) for 12 weeks	Symptom improvement at 12 weeks compared to baseline
Adityanjee et al. (2008)	N = 16 patients with BPD	Open-label case series of 8 weeks of quetiapine (average dose in completers = 286.1 mg/day)	Significant improvement in symptoms (measured by GAF, SCL-90, BIS)
Pascual, Soler et al. (2008)	N = 60 patients with BPD	Double-blind, randomized, 12 weeks of ziprasidone (up to 200 mg) vs. placebo	No statistically significant differences between ziprasidone and placebo in the CGI-BPD or other symptoms

(*continued*)

TABLE 28.1 (continued)

Study	*Diagnosis*	*Study Design*	*Comment*
Schulz et al. (2008)	N = 314 BPD outpatients	Randomized, double-blind study of 12 weeks of olanzapine (variable dose, up to 20 mg/day) vs. placebo	Symptom improvement not significantly greater than placebo
McClure et al. (2010)	N = 25 patients with SPD	Double-blind, randomized, 12 weeks of pergolide (up to 0.3 mg/day) vs. placebo	The pergolide group showed improvements in visual-spatial working memory, executive functioning, and verbal learning and memory.
Shafti & Shahveisi (2010)	N = 28 female inpatients with BPD	Randomized, double-blind study of 8 weeks of olanzapine vs. haloperidol	Symptom improvement on the BPRS between baseline and 8 weeks, no differences between olanzapine vs. haloperidol
Zanarini et al. (2011)	N = 451 BPD outpatients	Two randomized, double-blind studies of 12 weeks of olanzapine (up to 20 mg/day) vs. placebo	Treatment with olanzapine (5–10 mg/day) was associated with significantly greater decrease from baseline to endpoint in ZAN-BPD total score relative to placebo.
Carrasco et al. (2012)	N = 49 BPD patients refractory to oral medications	Open-label study of up to 50 mg IM of long-acting risperidone every 2 weeks for up to 6 months	Decreased symptom severity, aggression scores, and anxiety and increased psychosocial functioning at 6 months
Zanarini et al. (2012)	N = 444 BPD patients who had completed 12 weeks of double-blind olanzapine or placebo	Open-label study of up to 15 mg or 20 mg of olanzapine	Continued therapy with olanzapine may sustain and build upon improvements seen with acute olanzapine treatment of patients with BPD.
Koychev et al. (2012)	N = 248 HC scoring high (SPQ score >1 SD above the mean) or average on schizotypy (within +/- 0.5 SD of the mean)	Randomized, double-blind, single dose of risperidone (400 mg), amisulpride (2 mg), nicotine (7 mg transdermal), or placebo	Amisulpride improved working memory (on N-back) in the high schizotypy group but impaired it in those with average schizotypy. Risperidone improved only those with low baseline performance.
Rosell et al. (2015)	N=16 medication-free SPD patients who met criteria for cognitive impairment (i.e., scoring below the 25th percentile on tests of working memory)	Randomized, double-blind, placebo-controlled trial of the D1 agonist dihydrexidine (DAR-0100A) (15 mg/150 mL of normal saline administered intravenously over 30 minutes on 3 consecutive days)	DAR-0100A produced significant improvements in two measures of verbal working memory, particularly in the Paced Auditory Serial Addition Test (PASAT)

AQ = Aggression Questionnaire; BPD = borderline personality disorder; BDHI = Buss-Durkee Hostility Inventory; BDRS = Borderline Disorder Rating Scale; BIS11 = Baratt Impulsivity Scale version 11; BPDSI = Borderline Personality Disorder Severity Index; BPRS = Brief Psychiatric Rating Scale; BSI = Brief Symptom Inventory; CGI= Clinical Global Impression; CGI-BPD = Clinical Global Impression Scale for BPD; DBT = dialectical behavior therapy; GAS = Global Assessment Scale; GAF = Global Assessment of Function; HAM-A = Hamilton Anxiety Scale; HDRS, HAM-D = Hamilton Depression Rating Scale; HC = Healthy controls; PANSS = Positive and Negative Syndrome Scale; SCL-90 = Hopkins Symptom Check List 90; SCL-90-R = Symptom Checklist-90-Revised; OAS-M = Overt Aggression Scale-Modified; SOFAS = Social and Occupational Functioning Assessment Scale; SPD = schizotypal personality disorder; SPQ = Schizotypal Personality questionnaire; STAXI = State-Trait Anger Expression Inventory; ZAN-PBD = Zanarini Rating Scale for Borderline Personality Disorder.

In contrast, in another study nine patients selected only based on meeting SPD criteria showed no increase in psychotic-like symptoms with amphetamine administration (Siegel et al., 1996). This is consistent with a model of two distinct symptom profiles linked to relatively increased versus decreased dopaminergic activity respectively, depending on the predominance of psychosis-like (hypervigilance and stereotypic cognitions/behaviors) or deficit-like (deficits in working memory, cognitive processing, and hedonic tone) symptoms (Siever & Davis, 2004). Those SPD patients with hyperdopaminergic states may be more responsive to treatment with dopamine antagonists and respond negatively to dopamine agonists, whereas those with normal or reduced dopaminergic function may improve with dopamine agonists (see below).

Deficit-Like Symptoms and Cognitive Disorganization in Schizotypal Personality Disorder

Neurobiological studies of the deficit-like symptoms of SPD have investigated their relationship to psychophysiological and neuroanatomical measures and indices of neurotransmitter activity. Abnormalities in smooth pursuit eye movements, backward masking tests, and continuous performance tasks correlate with deficit symptoms of SPD (Siever, 1991). Cognitive disorganization, measured by performance on psychological testing, has also been found in SPD patients. Schizotypal patients make significantly more errors on the Wisconsin Card Sort Test compared to healthy control subjects and other patients with non–cluster A personality disorders (Trestman et al., 1995). These results suggest that abnormalities in the frontal and temporal cortices may be related to the deficit symptoms of SPD.

Correlations between neurotransmitter levels and deficit-like symptoms in SPD have been investigated. Whereas higher plasma HVA levels correlate with psychotic-like symptoms in patients with personality disorders, lower plasma HVA levels may be associated with deficit-like symptoms in relatives of patients with schizophrenia and with cognitive deficits in SPD patients (Siever, Kalus, & Keefe, 1993).

Investigations of cholinergic indices in patients with schizophrenia have yielded inconsistent results (Karson, Casanova, Kleinman, & Griffin, 1993; Tandon & Greden, 1989); however, data from our laboratory suggest that the cholinergic agent physostigmine may improve performance in visuospatial delayed-response attentional tasks in SPD patients (Kirrane et al., 2001).

The above findings suggest that dopaminergic agonists may be used to treat deficit symptoms and cognitive disorganization in SPD patients. One double-blind, placebo-controlled study of amphetamine in SPD/BPD patients found that in addition to worsening of psychotic-like symptoms in the SPD group, all subjects had increased activation scores on the BPRS (Schulz et al., 1988). This might suggest an improvement in deficit symptoms such as anergia and withdrawal. Further, a preliminary study of amphetamine administration in SPD patients showed improved performance on the Wisconsin Card Sort Test (Siegel et al., 1996). In a recent randomized, double-blind, placebo-controlled trial in our center, pergolide, a dopamine agonist targeting D1 and D2 receptors, significantly improved visual-spatial working memory, executive functioning, and verbal learning and memory in SPD patients (McClure et al., 2010) (see Table 28.2).

Furthermore, our group has carried out a randomized, double-blind, placebo-controlled pilot trial (Rosell et al., 2015) of the D_1 agonist dihydrexidine (DAR-0100A) in 16 unmedicated SPD patients who met criteria for cognitive impairment. DAR-0100A produced significant improvements in a number of cognitive domains, including verbal working memory and executive function. Specifically, two measures of verbal working memory that are known to implicate cognitive impairment in SPD patients were used: the Paced Auditory Serial Addition Test (PASAT) and the N-back test (ratio of 2-back:0-back scores). Subjects who received DAR-0100A showed significantly improved performance, particularly in the PASAT, relative to those who received placebo. Despite a modest sample size, the differences in verbal working memory improvement between DAR-0100A and placebo groups were associated with large effect sizes that reached statistical significance. While this pilot study successfully demonstrated the effectiveness of a selective, full D_1 receptor agonist in enhancing working memory in patients with schizophrenia-spectrum cognitive deficits, we are currently conducting a large, randomized, placebo-controlled, crossover trial of DAR-0100A in patients with SPD using a more comprehensive neuropsychological battery of

TABLE 28.2 Pharmacology of Borderline and Schizotypal Personality Disorder: Other Agents

Study	*Diagnosis*	*Study Design*	*Comment*
Bohus et al. (1999)	N = 13 BPD patients with prominent dissociative phenomena including flashbacks	Open-label naltrexone (25–100 mg qid) for at least 2 weeks	Improvement on a self-rated questionnaire measuring dissociation, analgesia, tonic immobility, and tension, and in dissociative phenomena, tonic immobility, analgesia and flashbacks
Zanarini & Frankenburg (2003)	N = 30 female BPD patients	8-week, placebo-controlled, double-blind study of ethyl-eicosapentaenoic acid (E-EPA) and omega-3 acid)	E-EPA was superior to placebo in decreasing aggression and depressive symptoms.
Philipsen et al. (2004)	N = 14 female BPD patients	Single dose of clonidine (75 mcg or 150 mcg) on 2 separate occasions in a single-blind, randomized crossover design	Significant decrease in self-reported aversive inner tension, the urge to commit self-injurious behavior, dissociative symptoms, and suicidal ideation at 30, 60, 90, and 120 minutes after administration
Miyaoka et al. (2008)	N = 20 female outpatients with BPD	Open-label 12 weeks of *yi-gan san* (a traditional Chinese herbal medicine)	Statistically significant reduction on self-rated and clinician-rated scales (BPRS, CGI, GAF, AQ)
Golubchik et al. (2008)	N = 14 adolescent females with BPD and ADHD	Open-label 12 weeks of methylphenidate	A significant improvement was detected in both ADHD and BPD severity.
Ziegenhorn et al. (2009)	N = 18 patients with BPD and a hyperarousal syndrome, +/- PTSD	Double-blind, randomized crossover study of clonidine vs. placebo (2 weeks each)	Hyperarousal improved regardless of PTSD comorbidity.
Schmahl et al. (2012)	N = 29 unmedicated patients with BPD	Double-blind crossover design, 3 weeks of up to 200 mg/day of naltrexone and 3 weeks of placebo in randomized order	Nonsignificant decreases in intensity and duration of dissociative symptoms with naltrexone vs. placebo
Bertsch et al. (2013)	N = 40 nonmedicated, adult female patients with BPD	Randomized double-blind, single-dose intranasal oxytocin (26 IU) vs. placebo	Decrease in hypersensitivity to social threat
Amminger et al. (2013)	N = 15 adolescents with BPD and ultra-high risk criteria for psychosis	Randomized double-blind trial; 12 weeks of 1.2 g/day long-chain omega-3 polyunsaturated fatty acids (PUFAs) or placebo	Improved global functioning (GAF) and reduced symptoms of depression (MADRS), and PANSS negative symptoms, suspiciousness, tension and poor impulse control

TABLE 28.2 (continued)

Study	*Diagnosis*	*Study Design*	*Comment*
Schmechtig et al. (2013)	*N* = 233 healthy participants with medium and high schizotypy based on their scores on the Schizotypal Personality Questionnaire	Randomized double-blind, single dose of nicotine (7 mg/24 hours, transdermal), risperidone (400 mg/day), or amisulpride (2 mg/day) vs. placebo	Nicotine improved performance in antisaccade tasks in medium and high schizotypes
Wingenfeld et al. (2013)	*N* = 71 women with BPD	Placebo-controlled, crossover study; 10 mg of hydrocortisone vs. placebo	Cortisol improved hippocampal-mediated memory processes in patients with BPD alone or BPD + PTSD (but not those with BPD + MDD).

ADHD = attention-deficit/hyperactivity disorder; AQ = Aggression Questionnaire; BPD = borderline personality disorder; BPRS = Brief Psychiatric Rating Scale; CGI = Clinical Global Impression Scale; GAF = Global Assessment of Functioning; MADRS = Montgomery-Asberg Depression Rating Scale; MDD = major depressive disorder; PANSS = Positive and Negative Syndrome Scale; PTSD = posttraumatic stress disorder.

working memory and verbal learning tasks to confirm initial findings.

Robust preclinical evidence (Franowicz & Arnsten, 2002) supports the role of noradrenergic agonists, particularly alpha-2 agonists, in enhancing working memory. Our group has carried out a trial of the alpha-2A agonist guanfacine and found that it improved neuropsychological measures of working memory in SPD patients (McClure et al., 2007).

The monoamine oxidase inhibitor (MAOI) tranylcypromine caused broad behavioral effects in one mixed SPD/BPD group (Cowdry & Gardner, 1988) (see Table 28.1), including an increased capacity for pleasure. Although this may reflect an improvement of deficit-like symptoms, it may also be due to the effect of tranylcypromine on comorbid mood disorders. Catecholaminergic agents need to be further investigated in SPD patients, with special focus on their effect on cognitive performance and on deficit-like symptoms.

Another approach to try to identify more efficient drugs for the treatment of cognitive symptoms in the schizophrenia spectrum involves the study of surrogate populations with high levels of schizotypy. Such studies showed that single, low-dose antipsychotics (amisulpride) and nicotine have positive effects on cognitive performance (e.g., working memory) and on disease biomarkers such as oculomotor deficits (Koychev et al., 2012; Schmechtig et al., 2013) (see Tables 28.1 and 28.2).

Growing evidence suggests that intranasal oxytocin, used as an adjunct in patients treated with antipsychotics, improves positive symptoms and social cognitive deficits in schizophrenia (Feifel, Macdonald, Cobb, & Minassian, 2012; Feifel et al., 2010; Goldman, Gomes, Carter, & Lee, 2011; Modabbernia et al., 2013; Pedersen et al., 2011). Whether a similar positive effect can be found in SPD remains untested.

Treatment of Comorbid Diagnoses in Schizotypal Personality Disorder

Antidepressant agents are often used in SPD based on the high rates of comorbidity between SPD and depressive disorders: 67% of individuals with SPD have at least one mood disorder, and over 70% have at least one anxiety disorder (Pulay et al., 2009). Thirty percent to 50% of SPD patients seen in clinical settings have a concurrent major depressive disorder, and 50% of patients have a history of major depressive disorder (Kaplan & Sadock, 1995). So far, however, trials with antidepressant agents in SPD have only been conducted in groups of mixed SPD/BPD patients (see Tables 28.1 and 28.3). The use of fluoxetine, up to 80 mg over a 12-week period, was investigated in a mixed group and was found to decrease obsessive symptoms, rejection sensitivity, depressive symptoms, anxiety, and psychoticism (Markovitz et al., 1991). These improvements occurred regardless of whether subjects had a concurrent diagnosis of major depressive disorder. Such findings are limited by the fact that the study was open-label and by the heterogeneity of the subjects.

TABLE 28.3 Pharmacology of Impulsive Aggression and Borderline Personality Disorder: Antidepressants

Study	*Diagnosis*	*Study Design*	*Comment*
Soloff et al. (1986)	N = 52, BPD inpatients	Type 2 study: amitriptyline; placebo-controlled	AMI nonresponders showed significantly more impulsive/assaultive behavior than placebo nonresponders; AMI responders showed improvement in impulsive behavior and depression scores.
Parsons et al. (1989)	All patients had symptoms of atypical depression; Group 1: *n* = 40 patients with >5 *DSM-III* BPD criteria, *n* = 61 patients with >4 criteria; Group 2: *n* = 19 patients, BPD to a considerable extent, *n* = 29, patients BPD to only some extent as measured by the Personality Assessment Form	Type 1 study: double-blind, placebo-controlled; random assignment to phenelzine 60 mg or imipramine 200 mg for 3–6 weeks each medication	BPD patients with symptoms of atypical depression had significant improvement in CGI scores due to phenelzine vs. imipramine and placebo; imipramine was felt to be minimally effective.
Norden (1989)	N = 12 BPD patients, all except 1 with histories of suicidality	Type 3 study: fluoxetine; open-label	Very much or much improved; irritability and suicidality among the most responsive symptoms
Cornelius et al. (1991)	N = 5, BPD inpatients who had failed to respond to phenelzine and at least one neuroleptic	Type 3 study: fluoxetine; open-label	Decreases in impulsivity and suicidality
Markovitz et al. (1991)	N = 22 outpatients: 8 BPD, 10 SPD/BPD with mixed symptoms, 4 SPD; 13 patients also with MDD	Type 3 study: fluoxetine; open-label; 20–80 mg over 12 weeks sensitivity, psychoticism, anxiety, and obsessive-compulsive symptoms regardless of comorbid diagnosis of MDD	Decrease in 50% of patients' self-mutilatory behavior; significant decrease in depression, rejection
Soloff et al. (1993)	N = 92, BPD and mixed BPD/SPD features	Type 1 study: comparison between haloperidol and phenelzine; double-blind, placebo-controlled	Phenelzine was less effective than haloperidol in decreasing impulsivity/hostile-belligerence; phenelzine did not improve atypical depressive symptoms but did decrease scores on Buss-Durkee Hostility Inventory.
Coccaro & Kavoussi (1995)	N = 40 personality disorder patients with histories of impulsive aggression	Type 1 study: fluoxetine 20–60 mg; double-blind, placebo-controlled; 12 weeks	Overt aggression scores were reduced at weeks 4, 10, 12, and endpoint; irritability scores were reduced at weeks 6–12 and endpoint.
Salzman et al. (1995)	N = 22 patients recruited from the community (13 met BPD criteria and 9 had BPD traits); mild to moderate severity	Type 1 study: fluoxetine 20–60 mg; double-blind, placebo-controlled; 13 weeks including 1-week placebo lead-in	Anger and depression significantly declined more in the fluoxetine group than in the placebo group. Measures included PDRS anger and depression, POMS anger and depression, OAS anger against objects, and HAM-D scales.

TABLE 28.3 (continued)

Study	*Diagnosis*	*Study Design*	*Comment*
Rinne et al. (2002)	*N* = 38 BPD patients; moderate to severe pathology from outpatient clinic and newspaper referral	Type 1 study: fluvoxamine (150–200 mg/day); randomized placebo-controlled double-blind for 6 weeks; followed by single-blind half-crossover for 6 weeks and open- label for next 12 weeks	Significant improvement in rapid-mood shift subscale of BPD-SI (independent of comorbid affective disorders or posttraumatic stress disorder). No significant medication effect upon BPD-SI anger or impulsivity.
Simpson et al. (2004)	*N* = 25 female BPD patients in treatment in a 5-day DBT-based partial hospital program, dissociation or GAF	Type 1 study: fluoxetine (40 mg/day); randomized double-blind 12-week comparison of DBT + fluoxetine to DBT + placebo	No added benefit of fluoxetine over placebo in aggression, self-injury, suicidality, depression
New et al. (2004)	*N* = 20 BPD patients recruited from advertisements and clinic referral	Type 3 study: fluoxetine (20 mg/day); randomized double-blind placebo-controlled. Only 3 placebo subjects completed.	Significant improvement from baseline to completion in OAS-M aggression and irritability scores but not suicidality or depression
Taner et al. (2006)	*N* = 43 outpatients with atypical depression (54% with comorbid personality disorder, 8.21% with BPD)	8-week, single-blind randomized study of reboxetine (up to 10 mg/day) vs. fluoxetine (up to 40 mg/day)	Both reboxetine and fluoxetine were effective in reducing symptoms of depression, but more patients taking reboxetine dropped out due to side effects.
Bellino et al. (2010)	*N* = 18 patients with BPD	Open-label duloxetine (60 mg/day) for 12 weeks	Symptom improvement, decreased aggression and impulsivity
Dunlop et al. (2011)	*N* = 90 patients with MDD	Double-blind open-label sertraline (50–200 mg/day) combined with tri-iodothyronine (T3, double-blind) or matching placebo	Sertraline reduced maladaptive traits of impulsivity and externalization measured with the Psychopathic Personality Inventory.

AMI = amitriptyline; BPD = borderline personality disorder; BPD-SI = Borderline Personality Disorder Severity Scale; CGI = Clinical Global Impression; DBT = dialectical behavior therapy; GAF = Global Assessment of Functioning; HAM-D = Hamilton Depression Rating Scale; MDD = major depressive disorder; OAS = McLean Hospital Overt Aggression Scale; PDRS = Personality Disorders Rating Scale; POMS = Profile of Mood States; SPD = schizotypal personality disorder.

There have been attempts to "pharmacologically distinguish" between affective and psychotic-like symptoms, primarily in BPD groups with some SPD patients included. In one large, mixed sample, amitriptyline led to a significant improvement in anxiety and hostility for the whole group, although less effectively than haloperidol (Soloff et al., 1989). Tranylcypromine was used in a primarily BPD group with a small subset of SPD patients and was found to decrease significantly a broad range of symptoms, including depressive scores, anxiety, rejection sensitivity, and impulsivity (Cowdry & Gardner, 1988). However, the generalized improvement failed to delineate a differential response of affective symptoms or psychotic-like symptoms to antidepressants in these patient populations. Thus, to determine the efficacy of antidepressants for SPD symptomatology, replication studies using double-blind, placebo-controlled methods in homogeneous groups of SPD patients are needed.

CLUSTER B DISORDERS ("DRAMATIC" CLUSTER)

The cluster B (dramatic) disorders are characterized by core dimensions of impulsivity/aggression and

affective lability. BPD and antisocial personality disorder are the prototype diagnoses involving these traits. Numerous studies have investigated the neurobiological substrates underlying each of these dimensions and the corresponding implications for pharmacological management of the disorders in this cluster.

Borderline Personality Disorder

The proposed traits that characterize BPD according to Section III of the *DSM-5* are based on the psychology literature and are derived from the Five Factor Model of personality (Costa & Widiger, 2002). The relation between Five Factor Model traits and *DSM-IV* personality disorders is supported by a growing body of data (Samuel & Widiger, 2008). The traits that characterize BPD according to *DSM-5* (negative affectivity, disinhibition, and antagonism) are closely linked to the core BPD traits of impulsive aggression and affective dysregulation, which have been consistently validated (Siever & Weinstein, 2009).

Affective Dysregulation and Impulsive Aggression Dimensions

Impulsive aggression and affective dysregulation have been associated with a number of determinants, including genetic factors, structural and functional brain abnormalities, and disturbances of neurotransmitter and neuropeptide systems.

Genetic Studies

Despite converging evidence from family, twin, and adoption studies supporting an underlying genetic vulnerability for BPD, the specific genetic underpinnings of BPD remain unexplored (Calati, Gressier, Balestri, & Serretti, 2013; Siever, Torgersen, Gunderson, Livesley, & Kendler, 2002b). There are only a few association studies, most of them in small samples, and their positive results remain largely unreplicated and have not been confirmed by meta-analyses (Calati et al., 2013).

BPD has heritability scores of 0.65 to 0.76 (Distel et al., 2008; New, Goodman, Triebwasser, & Siever, 2008; Torgersen et al., 2000) as estimated from twin studies. Moderate heritability has also been reported for dimensional BPD traits (Torgersen et al., 2008). Candidate genes for traits of impulsive aggression and emotional dysregulation include those that modulate the activity of neurotransmitters such as serotonin and catecholamines, as well as genes involved in neuropeptide systems (Siever, 2008; Siever & Weinstein, 2009).

Brain Abnormalities

Converging evidence supports a model of reduced prefrontal modulation of limbic structures (especially the amygdala and insula), which appear to be hyperreactive in patients with BPD, resulting in affective dysregulation and aggression (Bohus, Schmahl, & Lieb, 2004; Mauchnik & Schmahl, 2010).

Consistent with this model, structural brain imaging studies have reported abnormalities in the volumes and white matter integrity/connectivity of frontal and limbic regions. One of the most consistent structural findings in patients with BPD compared to healthy controls is a decrease in volume in the anterior cingulate gyrus (Hazlett et al., 2005; Minzenberg, Fan, New, Tang, & Siever, 2008; Soloff, Nutche, Goradia, & Diwadkar, 2008; Tebartz van Elst et al., 2003), especially in men (Soloff et al., 2008; Vollm et al., 2009). Other structural abnormalities in BPD include lower volumes in hippocampus (Brambilla et al., 2004; Irle, Lange, & Sachsse, 2005; Nunes et al., 2009; Ruocco, Amirthavasagam, & Zakzanis, 2012; Zetzsche et al., 2007), orbital frontal cortex (Tebartz van Elst et al., 2003), amygdala (Nunes et al., 2009; Ruocco et al., 2012; Tebartz van Elst et al., 2007), and surrounding areas of the temporal lobe (Goethals et al., 2005). Some but not all studies (de-Almeida et al., 2012; Ruocco et al., 2012) have raised the possibility that the smaller volumes in BPD may relate to comorbidity with posttraumatic stress disorder (PTSD) or a history of trauma for hippocampal volume (Nunes et al., 2009; Schmahl et al., 2009; Weniger, Lange, Sachsse, & Irle, 2009) and with major depressive disorder for amygdala volume (Zetzsche et al., 2006). Diffusion tensor imaging (DTI) studies also have found altered white matter tract integrity in the orbital frontal cortex (Grant et al., 2007) and diminished interhemispheric structural connectivity between both the left and right anterior cingulate gyrus in BPD (Rusch et al., 2010). This is consistent with the above model

of altered fronto-limbic circuitry in BPD, which has also been studied with functional neuroimaging methods as described below.

Many studies have consistently found decreased activation of prefrontal areas involved in emotion control in BPD. For example, early positron emission tomography (PET) imaging studies found lower activity of orbital frontal cortex and anterior cingulate gyrus in BPD compared to controls (Goyer et al., 1994; Leyton et al., 2001; New et al., 2002; Siever et al., 1999; Soloff, Meltzer, Greer, Constantine, & Kelly, 2000). More recently, a PET study of laboratory-induced aggression using the Point Subtraction Aggression Paradigm reported that BPD patients with high levels of impulsive aggression showed increased relative glucose metabolic rate in orbital frontal cortex and amygdala in response to provocation, but not in more dorsal brain regions involved in top-down control of aggression and of emotion (New et al., 2009). In contrast, healthy individuals did activate dorsal, cognitive control regions of prefrontal cortex during aggression provocation (New et al., 2009). Poor coupling between orbital frontal cortex and amygdala has also been reported in association with aggression (New et al., 2007).

Decreased prefrontal activation in BPD has also been shown by most functional magnetic resonance imaging (fMRI) studies using emotional stimuli, with some exceptions (Minzenberg, Fan, New, Tang, & Siever, 2007; Schmahl et al., 2006; Schnell, Dietrich, Schnitker, Daumann, & Herpertz, 2007). The majority of studies have shown less activation (or more deactivation) of orbital frontal cortex or anterior cingulate gyrus in BPD compared to healthy controls in response to emotional stimuli (Koenigsberg et al., 2009; Kraus et al., 2009; Schmahl et al., 2003; Schnell et al., 2007; Silbersweig et al., 2007; Wingenfeld et al., 2009) and to physical pain (Minzenberg et al., 2007; Schmahl et al., 2006; Schnell et al., 2007), although one study showed increased anterior cingulate gyrus activation to negative pictures in BPD (Minzenberg et al., 2007) and one to unresolved conflicts (Beblo et al., 2006).

Functional neuroimaging studies also suggest that amygdala and insula have abnormal activity (Ruocco, Amirthavasagam, Choi-Kain, & McMain, 2013) in BPD. Several studies, but not a recent meta-analysis (Ruocco et al., 2013), have shown increased amygdala activation to emotional stimuli (e.g., emotional pictures and faces) in BPD (Beblo et al., 2006; Donegan et al., 2003; Koenigsberg et al., 2009; Schulze et al., 2011). However, amygdala activity decreases in response to pain in BPD (Kraus et al., 2009; Niedtfeld et al., 2010; Schmahl et al., 2006).

In summary, in BPD patients, prefrontal brain regions that normally control emotional expression and aggression (e.g., orbital frontal cortex and anterior cingulate gyrus) may fail to activate during emotional provocation, while limbic regions (e.g., amygdala and insula) hyperreact to emotional probes. However, these findings potentially lack specificity, since many of the circuits implicated in BPD appear to be involved in other psychiatric disorders, including major depressive disorder (Davidson, Irwin, Anderle, & Kalin, 2003), bipolar disorder (Blumberg et al., 2003) and PTSD (Shin et al., 1999).

Neurotransmitter and Neuropeptide Systems

Studies probing the serotonergic system suggest that the model of decreased prefrontal regulatory control and increased limbic reactivity described above may relate to altered serotonergic facilitation of "top-down" control. Decreased serotonergic indices have been implicated in impulsive/aggressive behavior toward the self (i.e., suicide attempts) or others across diagnostic categories, supporting the conceptualization of impulsivity/aggression as a dimensional trait. For example, early cerebrospinal fluid studies found decreased levels of 5-hydroxyindolacetic acid—a serotonin metabolite—in subjects with a history of suicide attempts (Asberg & Traskman, 1981; Asberg, Traskman-Benz, & Thoren, 1976) or impulsive aggressive behavior (Coccaro, 1989). Since then, numerous studies employing a wide variety of methods have replicated the finding of decreased serotonergic function in BPD (Coccaro et al., 1989; Dougherty, Bjork, Huckabee, Moeller, & Swann, 1999; O'Keane et al., 1992), including neuroimaging studies using pharmacological probes of serotonin (Leyton et al., 2001; New et al., 2002, 2004; Siever et al., 1999; Soloff et al., 2000). Patients with personality disorders and impulsive aggression showed lower serotonin transporter availability compared with healthy controls, as measured by the PET ligand, [11C]McN 5652, in anterior cingulate gyrus (Frankle et al., 2005). Moreover, fluoxetine treatment enhances metabolic activity in orbital frontal cortex and anterior cingulate gyrus in impulsive aggressive individuals, which is associated

with symptomatic improvement (New et al., 2004). These studies provide strong neurobiological support for the use of selective serotonin reuptake inhibitors (SSRIs) to treat impulsivity/aggression in BPD.

Noradrenergic and cholinergic systems, which appear to play key roles in the genesis of mood disorders, have also been a logical area of study in the personality disorders. Initial investigations suggested that the transient dysphoria seen in BPD patients could be related to excessive cholinergic availability (Steinberg et al., 1997) and that hyperreactivity of the central adrenergic system may be involved in affective instability in BPD and other personality disorders (Southwick, Yehuda, Giller, & Perry, 1990).

Neuropeptides such as oxytocin are an area of growing interest in BPD. It has been suggested that deficits in the attachment and affiliative systems modulated by oxytocin may underlie the impulsive aggressive reactions to perceived rejection and loss that are common in BPD (Stanley & Siever, 2010). Because of its anxiolytic and prosocial effects (Macdonald & Macdonald, 2010; Meyer-Lindenberg, Domes, Kirsch, & Heinrichs, 2011; Zink & Meyer-Lindenberg, 2012), oxytocin has been suggested as a promising treatment for patients with disorders associated with severe deficits in social interactions, such as BPD (Meyer-Lindenberg et al., 2011). In BPD, preliminary data indicate similar stress-reducing effects of oxytocin (Simeon et al., 2011) and suggest that it modulates amygdala activity for optimal social cognitive functioning (Herpertz, Lischke, Berger, & Gamer, 2012)—that is, compensating for the hypersensitivity to social threat and amygdala hyperreactivity seen in BPD.

Given the high theoretical interest in the oxytocinergic system in BPD (Stanley & Siever, 2010), it is surprising that research examining the genetics of the oxytocinergic system in BPD populations is lacking. However, there is some evidence from genetic studies suggesting that the oxytocinergic system is involved in some of the core dimensions of BPD, such as interpersonal dysfunction and impulsive aggression. For example, oxytocin receptor gene (OXTR) polymorphisms have been linked to trait empathy (Wu, Li, & Su, 2012), aggressive behavior, the propensity to react to situations with elevated levels of anger (Johansson et al., 2012), and prosocial temperament (Tost et al., 2010). Oxytocin gene polymorphisms have been associated with aggressive-antisocial behaviors in children (Malik, Zai, Abu, Nowrouzi, & Beitchman, 2012) and with interindividual differences in dopaminergic responses to stress (Love et al., 2012). Moreover, OXT gene-knockout mice display exaggerated aggressive behavior (Ragnauth et al., 2005). However, there are no published genetic studies of oxytocinergic system genes in BPD. We have found a novel oxytocin haplotype, which is associated with aggression, attachment, and impulsivity, in a sample enriched for patients with personality disorders (Perez-Rodriguez et al., 2013).

Since opioids are also involved in social attachment, a deficit in endogenous opiates may underlie the interpersonal difficulties characteristic of BPD. One recent PET study (Prossin, Love, Koeppe, Zubieta, & Silk, 2010) measured mu-opioid receptor binding by using the mu-opiate ligand [^{11}C] carfentanil in patients with BPD during induction of neutral and sad sustained emotional states (Prossin et al., 2010). The study found greater baseline mu-opioid receptor availability in BPD, which may suggest a deficit in endogenous opioids. These results also suggest that BPD patients increase endogenous opiate availability more than controls during sad mood induction, which might reflect a compensatory response (Stanley et al., 2010; Stanley & Siever, 2010). In fact, one theory about self-cutting, a behavior common in BPD, is that it represents a method of releasing endogenous opioids to compensate for an intrinsic opioid deficit (New & Stanley, 2010; Stanley & Siever, 2010). We have found that polymorphisms of the mu-opioid receptor may be associated with affective instability and BPD (Siever et al., unpublished data). These associations seem to be potentiated by trauma, underscoring the interactive effects of genetics and environment.

Pharmacology of Borderline Personality Disorder

Antidepressants

Neurobiological evidence of blunted serotonergic systems in impulsivity/aggression and BPD would suggest that antidepressant medications enhancing serotonergic function may play an important role in the treatment of BPD. However, in the past decade of psychopharmacological research in BPD patients, there has been a shift from antidepressants to mood stabilizers and antipsychotics.

In fact, although SSRIs were traditionally considered the first-line treatment for BPD, several recent meta-analyses and reviews have concluded that antidepressants, including SSRIs and tricyclics, have the least effect on BPD symptoms, compared to mood stabilizers and antipsychotics (Abraham & Calabrese, 2008; Feurino & Silk, 2011; Ingenhoven, Lafay, Rinne, Passchier, & Duivenvoorden, 2010; Lieb, Vollm, Rucker, Timmer, & Stoffers, 2010; Mercer, Douglass, & Links, 2009; Stoffers et al., 2010). Antidepressants may have a role in reducing anxiety and impulsivity/aggression (Ingenhoven et al., 2010; Mercer et al., 2009) and in the presence of comorbid conditions such as major depression (Stoffers et al., 2010).

Studies of antidepressant agents in BPD are hampered by specific methodological challenges. First, there are very high rates of comorbidity between BPD and depressive disorders (Grant et al., 2008; Lenzenweger et al., 2007; Skodol et al., 2002, 2005). Moreover, the affective symptoms in BPD are closely related to those found in depressive disorders. A summary of antidepressant trials in the treatment of BPD can be found in Table 28.3.

Antipsychotics

Early studies of typical antipsychotic medication use for BPD (see Table 28.1) showed global but modest improvement in symptoms, including impulsivity, depression, suicidal ideation, rejection sensitivity, and psychotic-like symptoms, such as paranoid ideation, ideas of reference, and derealization (Soloff et al., 1989).

More recently, several studies have examined the effectiveness of SGAs. Olanzapine has now been studied in several open-label studies (Damsa et al., 2007; Shoja-Shafti, 2006; Zanarini et al., 2012) and randomized, double-blind trials (Schulz et al., 2008; Shafti & Shahveisi, 2010; Soler et al., 2005; Zanarini & Frankenburg, 2001; Zanarini et al., 2004, 2011). Most but not all (Schulz et al., 2008) of these studies find that olanzapine is effective in treating anger/aggression in BPD, and several studies report that olanzapine treats depression and anxiety as well. Olanzapine also appears to reduce interpersonal sensitivity and paranoia (Zanarini & Frankenburg, 2001). One study found that the combination of olanzapine and fluoxetine was less effective than olanzapine alone in treating the dysthymia characteristic of BPD (Zanarini et al., 2004). Injectable olanzapine has been used to reduce agitation in several open-label studies and case series in emergency room settings (Damsa et al., 2007; Pascual et al., 2006). All studies reported weight gain with olanzapine, and two recorded mean gains of greater than 6 lbs over a period of 12 weeks. These weight gains are likely to be troublesome to many borderline patients and may reduce their acceptance of the drug. Zanarini and colleagues (2004) reported less weight gain from combined treatment with olanzapine and fluoxetine than from olanzapine alone.

An open-label, uncontrolled trial of risperidone found it to be effective in reducing hostility, suspicion, and depression in BPD patients and did not report weight gain as a side effect (Rocca, Marchiaro, Cocuzza, & Bogetto, 2002). A more recent open-label study of 8 weeks of risperidone (up to 2 mg/day) found global symptom improvement across BPD-relevant domains, including affective dysregulation, cognitive impairment, impulsivity, and disturbed relationships, but a mean weight gain of 3.7 lbs was observed (Friedel et al., 2008). Depot formulations of risperidone have shown improvement in long-term symptom severity and functioning in an open-label study (Carrasco, Palomares, & Marsa, 2012).

A first open-label trial of quetiapine (with a high dropout rate of 33%) reported significant improvement from baseline levels in impulsivity, hostility, anxiety, depression, and social and global functioning, but not hopelessness, in a group of markedly to severely symptomatic BPD clinic outpatients (Villeneuve & Lemelin, 2005). More recent open-label trials of quetiapine observed symptom improvement across several domains, including global functioning, depressive symptoms, affect lability, global severity, impulsivity and anger/hostility, and anxiety (Adityanjee et al., 2008; Bellino, Paradiso, & Bogetto, 2006; Perrella, Carrus, Costa, & Schifano, 2007; Roepke et al., 2008; Van den Eynde et al., 2008).

A randomized, double-blind, placebo-controlled study reported an effect of aripiprazole in decreasing BPD symptoms, including depressive and anxiety symptoms, and anger. This improvement was sustained at an 18-month follow-up (Nickel, Loew, & Pedrosa Gil, 2007; Nickel et al., 2006).

Two open-label studies have examined the effect of the atypical antipsychotic medication clozapine. In a study of 12 BPD inpatients with severe psychotic-like

symptoms (Benedetti et al., 1990), low-dose clozapine treatment was associated with a decrease in psychotic-like symptoms, suicide attempts, physical fights, and depression. A retrospective mirror-image open-label chart review study (Chengappa, Ebeling, Kang, Levine, & Parepally, 1999) of the treatment of seven inpatients meeting criteria for BPD, six of whom also had psychotic disorder diagnoses, found a decrease in self-mutilation, seclusion, and use of antianxiety medications and an increase in Global Assessment of Functioning (GAF) score. It is not possible to determine whether the improvements were due to the effect of clozapine on BPD or on the comorbid disorder. Because of the risk of agranulocytosis, it is prudent to reserve trials of clozapine at present for the most severely symptomatic BPD patients who have psychotic symptoms and have not responded to other SGAs.

In summary, evidence from meta-analyses, double-blind, randomized clinical trials and open-label studies suggests that treatment with antipsychotics may be effective for treating core symptoms of BPD, including mood lability/affective dysregulation, anger and impulsive-behavioral dyscontrol, and cognitive-perceptual symptoms (Feurino & Silk, 2011; Ingenhoven & Duivenvoorden, 2011; Lieb et al., 2010; Mercer et al., 2009; Stoffers et al., 2010; Vita, De Peri, & Sacchetti, 2011).

Mood Stabilizers

The prominence of impulsive aggression and mood instability in BPD suggests that mood stabilizers may be valuable treatment options.

Lithium has been shown to decrease irritability, suicidality, and angry behavior, as rated by the treating therapist, in a cohort of borderline subjects (Links et al., 1990). Interestingly, there was a clear trend in this study for lithium to be more effective than desipramine (a noradrenergic agent) in decreasing anger and suicidality, as well as depression.

The use of carbamazepine for patients with behavioral dyscontrol/impulsivity or borderline patients has yielded mixed results in placebo-controlled trials. Carbamazepine has been found to decrease assaultiveness and depression significantly in patients with frontal lobe dysfunction (Foster, Hillbrand, & Chi, 1989) and was initially found to improve impulsivity and behavioral dyscontrol among BPD patients (Cowdry & Gardner, 1988). However, this finding was not replicated in a later study, which suggested that carbamazepine may have no effect on dyscontrol and may in fact be associated with an increase in impulsive, violent behavior in some BPD subjects (de la Fuente & Lotstra, 1994). In comparison to propranolol, use of carbamazepine may be associated with a decrease in aggression in patients with intermittent explosive disorder (Mattes, 1990), although both medications tend to lead to fewer aggressive outbursts. In this study, however, subjects also received antipsychotic agents, other anticonvulsants, and antidepressants, limiting the applicability of the findings. A 12-week open-label trial of oxcarbamazepine, a chemical analogue of carbamazepine that is less likely to cause blood dyscrasias, autoinduce its own metabolism, or interact with other drugs, found a statistically significant improvement in ratings of impulsivity, anger outbursts, affective instability, interpersonal sensitivity, anxiety, Brief Psychotic Rating Scale (BPRS) score, and Clinical Global Impression-Severity score (Bellino, Paradiso, & Bogetto, 2005; Table 28.4). However, 25% of patients dropped out by the fourth week for nonadherence.

The mood stabilizer most extensively studied in the BPD population is divalproex sodium. An early open-label 8-week trial (Stein, Simeon, Frenkel, Islam, & Hollander, 1995) of divalproex in 11 patients meeting *DSM-III-R* criteria for BPD showed an overall improvement in half of the sample, with modest beneficial effects on anger, impulsivity, irritability, and rejection sensitivity. A subsequent small, 10-week, double-blind, placebo-controlled study of divalproex sodium (Hollander et al., 2001) found a significant improvement in Clinical Global Impression (CGI) score and Global Assessment Scale (GAS) scores among the six patients who completed treatment. The study was limited by the premature dropout of all four placebo-treated patients and 50% of the divalproex-treated patients. Impulsiveness in this patient population contributed to the high dropout rate, rather than medication side effects, highlighting the challenge in conducting treatment studies of impulsive patients. A somewhat larger placebo-controlled, double-blind study of female BPD patients with comorbid bipolar disorder (Frankenburg & Zanarini, 2002) found divalproex sodium to be superior to placebo in reducing anger, hostility, aggression, and interpersonal sensitivity. Because these patients all met criteria for bipolar disorder, it remains unclear

TABLE 28.4 Pharmacology of Impulsive Aggression and Borderline Personality Disorder: Mood Stabilizers/Anticonvulsants

Study	*Diagnosis*	*Study Design*	*Comment*
Sheard et al. (1976)	N = 66, inmates characterized by extreme impulsivity, aggression, and hostility	Type 2 study: lithium vs. placebo	Decrease in number of major prison infractions
Links et al. (1990)	N = 15 BPD	Type 1 study: lithium vs. desipramine; double-blind, placebo-controlled	Lithium led to decrease in therapist's perception of patient irritability, anger, and suicidal symptoms; trend for desipramine to have no effect or to worsen symptoms of anger/suicide and to be less effective than lithium in decreasing depression scores.
Hollander et al. (2001)	N = 16 BPD patients referred clinically and from advertisements	Type 2 study: divalproex (mean blood level 64.6 micrograms/mL); 10-week randomized double-blind placebo-controlled trial	50% dropout rate in divalproex group, 100% in placebo group; among completers 5/6 were responders based on CGI.
Frankenburg & Zanarini (2002)	N = 20 female BPD patients who also met *DSM-IV* criteria for bipolar II disorder	Type 2 study: divalproex (mean dose 850 mg/day); 6-month randomized double-blind placebo-controlled trial	Divalproex superior to placebo for SCL-90 anger/hostility and interpersonal sensitivity and OAS-M aggression; 50% dropout in divalproex group by week 12
Hollander et al. (2003, 2005)	N = 96 cluster B personality disorder patients (including 52 with BPD); *n* = 34 PTSD and *n* = 116 IED patients	Type 1: divalproex (mean dose 1,404 mg, blood level 65.5 micrograms/mL); randomized multicenter 12-week double-blind placebo-controlled trial	For cluster B, divalproex superior to placebo in OAS-M aggression, verbal assault, assault against objects, assault against others, irritability scales, and CGI-S; no significant effect of diavalproex on aggression for the IED or PTSD patients
Nickel et al. (2004)	N = 29 female BPD patients recruited by advertisement who had subjective feelings of "constantly increasing anger"	Type 1: topiramate (dose titrated to 250 mg/day by week 6); 8-week randomized double-blind placebo-controlled trial	Topiramate superior to placebo on STAXI anger-out, anger-control, state anger, and trait anger, but not anger-in scales
Nickel et al. (2005)	N = 42 male BPD patients meeting criteria of Nickel et al. (2004), above	Type 1: topiramate same as Nickel et al. (2004), above	Topiramate superior to placebo on STAXI anger-out, anger-control, state anger, and trait anger, but not anger-in scales. Improvement was sustained after 18-month follow-up (Nickel & Loew, 2008).

(*continued*)

TABLE 28.4 (continued)

Study	*Diagnosis*	*Study Design*	*Comment*
Tritt et al. (2005)	N = 24 female BPD patients	Type 2: lamotrigine; 8-week double-blind placebo-controlled trial	Lamotrigine superior to placebo on STAXI anger-out, anger-control, state anger, and trait anger, but not anger-in scales. Improvement on aggression measures remained significant at an 18-month follow-up after study completion (Leiberich et al.. 2008).
Bellino et al. (2005)	N = 17 clinic outpatients meeting criteria for BPD	Type 3: oxcarbamazepine (mean dose 1,315 mg); 12-week open-label design	Significant improvement in impulsivity, affective instability, anger outbursts, interpersonal sensitivity, anxiety, CGI-S, but not depression or social-occupational functioning
Simeon et al. (2007)	N = 20 BPD outpatients	Open-label 12 weeks of divalproex extended-release	Significant improvement on the CGI-I, the Global Assessment Scale, the OAS-M irritability subscale, and the Aggression Questionnaire
Loew et al. (2006)	N = 56 females with BPD	Randomized, double-blind trial; 10 weeks of topiramate (up to 200 mg/day) vs. placebo	Improvement across symptom domains (Symptom-Checklist), health-related quality of life (SF-36 Health Survey), and interpersonal functioning (Inventory of Interpersonal Problems)
Reich et al. (2009)	N = 28 subjects with BPD	Randomized, double-blind trial; 12 weeks of lamotrigine (flexible dose; mean final dose = 106.7 mg/day) vs. placebo	Significantly greater symptom improvement (ALS affective lability scores and ZAN-BPD affective lability and impulsivity scores).
Moen et al. (2012)	N = 15 patients with BPD who had SCL-90 scores >150 after 4 weeks of "condensed DBT"	Randomized to 12 weeks of double-blind divalproex extended-release vs. placebo	No significant differences between the participants assigned to divalproex extended-release vs. placebo

ALS = Affect Lability Scale; BPD = borderline personality disorder; CGI-S = Clinical Global Impression-Severity; DBT = dialectical behavior therapy; IED = intermittent explosive disorder; OAS-M = Overt Aggression Scale Modified; PTSD = posttraumatic stress disorder; SCL-90 = Hopkins Symptom Check List 90; STAXI = State-Trait Anger Expression Inventory; ZAN-PBD = Zanarini Rating Scale for Borderline Personality Disorder.

whether the divalproex was treating the BPD or the bipolar disorder. A type 1 multisite, randomized, double-blind, placebo-controlled study of the efficacy of divalproex sodium in treating aggression in cluster B personality disorders (including BPD), intermittent explosive disorder, and PTSD represents the largest study of this medication in the treatment of BPD (Hollander et al., 2003). Although no effect of divalproex sodium in reducing aggression was reported for the sample taken as a whole, a post hoc analysis of the 96 cluster B personality disorder patients (52 of whom met criteria for BPD) showed that divalproex

sodium was superior to placebo in reducing aggression, verbal assault, assault against objects, and irritability and in improvement on the CGI severity scale. In this study, too, the dropout rate among the patients with cluster B personality disorders was close to 50% for both the placebo and divalproex groups. In a post hoc follow-on report, Hollander, Swann, Coccaro, Jiang, and Smith (2005) examined the response of the 52 individuals with BPD in more detail. They found that divalproex sodium was superior to placebo in reducing the Overt Aggression Scale aggression score when baseline aggression, impulsiveness, hypomania, and depression were entered as covariates. Moreover, baseline trait impulsivity and state aggression, but not trait aggression or hypomania, predicted treatment response to divalproex sodium. A recent double-blind, randomized, placebo-controlled trial in a small sample of patients who did not respond to dialectical behavioral therapy found no differences in the effects of divalproex extended-release compared to placebo (Moen et al., 2012), and another small open-label study found improvements in global severity and aggression (Simeon, Baker, Chaplin, Braun, & Hollander, 2007).

Three studies of the efficacy of topiramate in female and male BPD patients have been reported (Loew et al., 2006; Nickel et al., 2004, 2005). For both female and male patients, topiramate was associated with greater improvement across multiple symptom domains of the Symptom Checklist (SCL-90-R scale), including somatization, interpersonal sensitivity, anxiety, anger/hostility, phobic anxiety, and Global Severity Index. Patients also experienced significant improvements on all eight scales of health-related quality of life (measured with the SF-36 Health Survey) and in interpersonal functioning (Inventory of Interpersonal Problems). Topiramate is an attractive candidate for treating BPD because, unlike many of the other promising medications for BPD, which are associated with weight gain, topiramate was associated with modest weight loss (Loew et al., 2006). This should increase its acceptability in this population.

A case report series (Pinto & Akiskal, 1998) first described the open-label use of lamotrigine, the anticonvulsant and mood stabilizer, in eight severely disabled BPD patients who did not meet criteria for any concurrent major mood disorder. Three of the eight patients showed a dramatic improvement, with disappearance of suicidal, impulsive, sexual, and drug-taking behaviors, and no longer met BPD criteria at an average follow-up of 1 year. Two randomized, double-blind, placebo-controlled studies of lamotrigine in male and female BPD patients have been reported (Reich, Zanarini, & Bieri, 2009; Tritt et al., 2005). Lamotrigine was superior to placebo in reducing anger, affective lability, and impulsivity and did not cause clinically significant weight gain.

In a recent meta-analysis, mood stabilizers, with the exception of valproic acid, were found to have a large pooled effect size for treatment of anger symptoms. Valproic acid and carbamazepine also had a moderate effect on depression (Mercer et al., 2009). However, a more recent Cochrane systematic review on the use of antiepileptics for aggression and impulsivity concluded that there is not sufficient evidence to allow any firm conclusion to be drawn (Huband, Ferriter, Nathan, & Jones, 2010). Based on the results of individual studies, the authors found some evidence that valproic acid was superior to placebo for outpatient men with recurrent impulsive aggression and for impulsively aggressive adults with cluster B personality disorders; carbamazepine was superior to placebo in reducing acts of self-directed aggression in women with BPD; oxcarbazepine was superior to placebo for verbal aggression and aggression against objects in adult outpatients; and phenytoin was superior to placebo on the frequency of aggressive acts in male prisoners and in outpatient men with personality disorder (Huband et al., 2010).

Novel Agents

Despite evidence of increased noradrenergic activity in irritable or emotionally unstable patients with BPD, there are few BPD treatment studies of medications that directly target this system. Philipsen and colleagues (2004) examined for the first time the acute effect of clonidine, an alpha-2 agonist with peripheral and central activity that reduces norepinephrine release, in 14 female symptomatic BPD inpatients (Philipsen et al., 2004). Patients were instructed to notify staff at times of "strong aversive inner tension," at which point they would be administered clonidine 75 mcg or 150 mcg in a single-blind, randomized design. On the next occasion that they notified staff of high tension, they received whichever dose they had not received on the first occasion.

Self-report ratings of aversive inner tension, the urge to commit self-injurious behavior, dissociative symptoms, and suicidal ideation were obtained prior to drug administration and at 30-minute intervals for the next 2 hours. Repeated-measures ANOVAs showed a significant effect for time in all four measures. There was no main effect for dose (75 mcg vs. 150 mcg). Although this study is strongly limited by the lack of a placebo control or a blind to active treatment, it provided support for further investigation of alpha-2 agonists in the treatment of BPD. A more recent double-blind, randomized crossover study of clonidine versus placebo in patients with BPD and a hyperarousal syndrome, with or without comorbid PTSD, found that hyperarousal improved regardless of PTSD comorbidity (Ziegenhorn et al., 2009) (Table 28.2).

Following reports that omega-3 fatty acids may be effective adjunctive treatments for bipolar disorder or depression, Zanarini and Frankenburg (2003) administered 1 g of the omega-3 fatty acid ethyl-eicosapentaenoic acid (E-EPA) or placebo in an 8-week randomized, double-blind design to 30 female BPD subjects. E-EPA was superior to placebo at the 8-week point in improvement in scores on the Modified Overt Aggression Sale and the Montgomery-Asberg Depression Rating Scale. There were no clinically significant side effects, and 90% of the subjects in both groups completed the study. More recently, a randomized double-blind, placebo-controlled 12-week trial reported that a dosage of 1.2 g/day long-chain omega-3 polyunsaturated fatty acids (PUFAs) was superior to placebo in improving global functioning (GAF), symptoms of depression (Montgomery-Asberg Depression Rating Scale), and PANSS negative symptoms, suspiciousness, tension, and poor impulse control on the PANSS (Amminger et al., 2013).

Other drug classes that have been investigated in clinical trials and single-dose studies in BPD patients, but for which evidence is still very limited, include corticosteroids (Wingenfeld et al., 2013), intranasal oxytocin (Bartz et al., 2011; Bertsch et al., 2013; Brune et al., 2013; Ebert et al., 2013; Simeon et al., 2011), opioid modulators such as naltrexone (an opioid-receptor antagonist) (Bohus et al., 1999; Schmahl et al., 2012), the stimulant methylphenidate (Golubchik, Sever, Zalsman, & Weizman, 2008), and the traditional Chinese herbal medicine *yi-gan san* (Miyaoka et al., 2008).

Overview of the Pharmacotherapy of Borderline Personality Disorder

In the past decade there has been an advance in the number and quality of studies of the pharmacotherapy of BPD, with the publication of a growing number of type 1 randomized, placebo-controlled, double-blind studies of reliably defined and well-characterized patient populations, and several reviews and meta-analyses (Bellino, Rinaldi, Bozzatello, & Bogetto, 2011; Binks et al., 2006; Feurino & Silk, 2011; Grootens & Verkes, 2005; Herpertz et al., 2007; Ingenhoven & Duivenvoorden, 2011; Kapoor, 2009; Lieb et al., 2010; Mercer et al., 2009; Paris, 2009, 2011; Ripoll, 2012; Ripoll, Triebwasser, & Siever, 2011; Saunders & Silk, 2009; Stoffers et al., 2010; Vita et al., 2011). Placebo-controlled trials are particularly important in this area because of the high placebo response rate of BPD patients.

However, the latest Cochrane review and meta-analysis reported that pharmacotherapy in BPD is not yet based on robust evidence from trials, with "very sparse" RCT evidence and "only a few study results per comparison, with small numbers of included participants." They concluded that there is support for the use of SGAs, mood stabilizers, and omega-3 fatty acids, but these require replication since most effect estimates were based on single-study effects. They also pointed out that there is no evidence from RCTs that any drug decreases overall BPD severity, rather than specific symptom dimensions.

Specifically, evidence is emerging that supports the efficacy of the SGA aripiprazole in reducing interpersonal problems, impulsivity, anger, psychotic paranoid symptoms, depression, anxiety, and general psychiatric pathology (Stoffers et al., 2010). For olanzapine, while no significant effects were detected for any primary outcomes, secondary analyses showed significant decreases in affective instability, anger, psychotic paranoid symptoms, and anxiety. Unfortunately, weight gain with this medication may be problematic for some patients and may affect patient acceptability. Interestingly, tolerability (rate of noncompleters) did not differ between the drug and placebo arms for any of the drugs studied (Stoffers et al., 2010).

Anticonvulsant mood stabilizers also appear to be quite promising. Valproate had significant effects in improvement of interpersonal problems, depression, and anger. Lamotrigine was significantly superior to placebo in reducing impulsivity and anger.

Topiramate had significant effects on interpersonal problems, impulsivity, anger, anxiety, and general psychiatric pathology. Topiramate may have particularly high patient acceptability because it is not associated with weight gain, but rather with modest weight loss. Regarding antidepressants, there was only a significant effect for the tricyclic amitriptyline on depressive symptoms, but there were no significant effects for mianserin, the SSRIs fluoxetine and fluvoxamine, or the MAOI phenelzine sulfate. Omega-3 fatty acids were found to have a significant effect on suicidality and depressive symptoms (Stoffers et al., 2010).

Based on their Cochrane review findings, Stoffers and colleagues (2010) make the following recommendations:

1. Pharmacological treatment of BPD should be targeted at defined symptoms.
2. Treatment with a given drug should last a sufficient period of time (according to the pharmacokinetic and dynamic properties of the drug) to judge if there are any benefits, but should be stopped or changed if there are none.
3. Polypharmacy is not supported by the RCT evidence and should be avoided whenever possible.
4. Special attention should be paid to toxic effects in case of overdosing (e.g., tricyclic antidepressants) and the potential for misuse or substance dependence (e.g., hypnotics and sedatives).
5. In the presence of a comorbid eating disorder, weight-related side effects (especially weight gain with olanzapine treatment and weight loss with topiramate treatment) should be taken into account (Stoffers et al., 2010).

CLUSTER C ("ANXIOUS" CLUSTER)

The psychobiology of anxiety (cluster C) has been investigated in greater depth. The guiding principle for much of the research is the assumption that the biological factors regulating anxiety provide a common basis for the anxiety spectrum disorders, superseding Axis I and Axis II distinctions.

There have been no pharmacotherapy trials involving the anxious cluster disorders. A limited number of controlled studies have looked at avoidant personality traits in patients with social phobia (see Herpertz et al., 2007, and Ripoll et al., 2011, for a review), whereas the use of medications for avoidant personality disorder alone has been documented only in case reports. Several medications have been tested and shown to be effective for social phobia, including MAOIs, the benzodiazepine clonazepam, and antidepressants. Among the latter, paroxetine, sertraline, and extended-release venlafaxine are approved by the FDA for the treatment of social phobia.

Case reports have described the usefulness of the MAOIs phenelzine and tranylcypromine for subjects with avoidant personality disorder: After 4 to 6 weeks of treatment, patients experienced marked improvements in their abilities to socialize. These gains were maintained at a 1-year follow-up when the patients continued to take the medications (Deltito & Stamm, 1989). Two case reports document the efficacy of fluoxetine for avoidant personality disorder (Deltito & Stamm, 1989; Goldman & Grinspoon, 1990). Within several weeks of initiating treatment, subjects reported decreases in social sensitivity and improvements in socialization, self-confidence, and assertiveness. Further controlled studies with well-defined groups of avoidant personality disorder and other anxious-cluster subjects are needed to establish the clinical indications for pharmacotherapy in this group of patients.

CONCLUSION

Despite significant advances over the past decade, research into the psychopharmacology and neurobiology of personality disorders is still in its infancy compared to other psychiatric disorders. The number of clinical trials is limited, and many have small sample sizes. Taken together, the evidence for symptom improvement is modest across personality disorders. However, despite the lack of FDA approval, drugs are used widely to treat personality disorders, particularly BPD. Therefore, it is critical to develop novel, more effective treatments grounded in better understanding of the neurobiology of the personality disorders.

Future research should be aimed toward fractionating the personality disorders into objectively measurable dimensions of psychopathology, such as affective lability or impulsive aggression, and examining their underlying neurobiology through the integration of multimodal levels of analysis, such as structural and functional neuroimaging, psychophysiology, and genetics, to name a few. These integrated multimodal measures should serve as outcome

measures for further controlled clinical trials to test the efficacy of new medications.
